Abstract Five of the most common macrophytes from an aquaculture facility with high densities of the herbivorous Asian grass carp (*Ctenopharyngodon idella*) were commonly unpalatable to three generalist consumers—grass carp and the native North American crayfishes *Procambarus spiculifer* and *P. acutus*. The rooted vascular plant *Micranthemum umbrosum* comprised 89% of the total aboveground plant biomass and was unpalatable to all three consumers as fresh tissues, as homogenized pellets, and as crude extracts. Bioassay-guided fractionation of the crude extract from *M. umbrosum* led to four previously known compounds that each deterred feeding by at least one consumer: 3,4,5-trimethoxyallylbenzene (**1**) and three lignoids: β -apocropodophyllin (**2**); (–)-(3*S*,4*R*,6*S*)-3-(3',4'-methylenedioxy- α -hydroxybenzyl)-4-(3'',4''-dimethoxybenzyl)butyrolactone (**3**); and (–)-hibalactone (**4**). None of the remaining four macrophytes produced a chemically deterrent extract. A 16-mo manipulative experiment showed that the aboveground biomass of *M. umbrosum* was unchanged when consumers were absent, but the biomass of *Ludwigia repens*, a plant that grass carp preferentially consumed over *M. umbrosum*, increased over 300-fold. Thus, selective feeding by grass carp effectively eliminates most palatable plants from this community and promotes the persistence of the chemically defended *M. umbrosum*, suggesting that plant defenses play critical yet understudied roles in the structure of freshwater plant communities.

Introduction

Herbivores were historically thought to have little impact on the ecology and evolution of freshwater plant communities (e.g., Shelford, 1918; Hutchinson, 1975). However, quantitative reviews show that herbivore impacts in freshwater systems rival those of marine and terrestrial systems, and aquatic herbivores often reduce the standing stock and alter the species composition of freshwater plant communities (Lodge, 1991; Newman, 1991; Cyr and Pace, 1993; Lodge et al., 1998). Additionally, aquatic herbivores exhibit selective avoidance of chemically or structurally defended plants (Newman et al., 1996; Bolser et al., 1998; Cronin, 1998; Cronin et al., 2002); yet there is surprisingly little direct evidence linking consumer feeding preferences to particular plant traits, or ultimately to shifts in plant community structure. For example, the introduced crayfish *Orconectes virilis* selectively consumes the filamentous green alga *Cladophora* over the blue-green alga *Gleotrichia*, and instigates a shift from green to blue-green algae in experimental ponds (Dorn and Wojdak, 2004), but the mechanisms conferring resistance to herbivores in *Gleotrichia* were not investigated.

A number of studies show that freshwater macrophytes are frequently unpalatable and contain a variety of secondary metabolites that could function as herbivore deterrents (Ostrowsky and Zettler, 1986; Cronin et al., 2002). More than one half of the crude extracts from 21 species of aquatic macrophytes that Prusak et al. (2005) surveyed, for example, deterred feeding by an omnivorous crayfish, although they did not identify the metabolites responsible for feeding deterrence. In fact, we know of only three freshwater plants with identified compounds that deter herbivores—watercress, *Rorippa nasturtium-aquaticum* (L.) Hayek (Newman et al., 1996), the waterspider bog orchid, *Habenaria repens* Nutt. (Bolser et al., 1998; Wilson et al., 1999), and lizard's tail, *Saururus cernuus* L. (Kubanek et al., 2000, 2001)—with a total of nine described secondary metabolites that influence herbivore feeding. In contrast, hundreds to thousands of secondary metabolites that deter consumers have been described from marine and terrestrial primary producers (Seigler, 1998; Faulkner, 2002 and references therein). These molecules can have strong cascading impacts on the ecology and evolution of plant–herbivore interactions in these systems (Hay and Fenical, 1988, 1996; Hay, 1996), suggesting that plant chemical defenses may play similar, but relatively uninvestigated, roles in freshwater systems.

Here, we examined the feeding preferences of three generalist consumers among five species of macrophytes collected from an aquaculture facility stocked with high densities of the herbivorous Asian grass carp *Ctenopharyngodon idella*. To determine the traits promoting macrophyte persistence under intense herbivory, we assessed the palatability of (1) whole plants, (2) plant tissues ground and imbedded in a gel-like matrix to retain most of the chemical and nutritional traits but with normal morphological traits removed, (3) plant crude extracts, and (4) specific metabolites isolated using bioassay-guided fractionation. We also conducted

a manipulative field experiment excluding herbivorous fishes. We then assessed the changes in the littoral plant community after 16 mo to determine whether well-defended species were disadvantaged in the absence of herbivores.

Methods and Materials

Study Organisms

We collected macrophytes from two 91 × 61 m wide, 1.3 m deep earthen ponds at the Owens and Williams fish hatchery in Hawkinsville, GA, USA. Each pond was stocked with >100,000 juvenile, triploid Asian grass carp, *C. idella*, an exotic herbivorous fish introduced throughout the United States to reduce aquatic plant abundance (USGS, 2005). On one occasion, we observed one turtle (pond slider—*Trachemys scripta* Wied) and evidence of crayfish (i.e., a single crayfish moult) in one of the ponds; these omnivores also consume macrophytes and, if common, could have further enhanced herbivore impact (Lodge et al., 1998). However, their effects were likely small relative to the large numbers of grass carp in each pond. The rooted, vascular plant *Micranthemum umbrosum* appeared to be the predominant plant species in one pond, while the floating green alga *Spirogyra* sp. appeared to be the predominant plant species in the other. The hatchery owner informed us that grass carp would frequently bite *M. umbrosum* but then forcibly reject it, and that *Spirogyra* sp. often persisted until all other macrophyte species had been consumed (P. Williams, personal communication). Based on these observations, the high density of herbivores in these ponds, and the acrid taste of *M. umbrosum* (J.P., personal observation), we hypothesized that these macrophytes possessed defensive traits promoting their persistence under intense herbivory.

On April 26, 2004, we determined the abundance of macrophytes in each pond by randomly locating five 0.25-m² quadrats on the littoral fringe (<1 m depth) of one side of each pond and determining the identity of macrophytes located beneath 36 points in each quadrat (we did not sample the remaining sides because they were disturbed by seine netting to capture fish). The five most common macrophytes (the green alga *Spirogyra* sp., and the vascular plants *M. umbrosum*, *Ludwigia repens*, *Juncus repens* Michx., and *J. effusus* L.)—were collected, transported to the laboratory in a chilled cooler, and fed to three consumer species within 24 hr of collection. We fed macrophytes to juvenile grass carp and to the native North American crayfishes *Procambarus spiculifer* and *P. acutus*. Both crayfishes have ranges across the southeastern United States (Hobbs, 1981). We used crayfish as a bioassay organism because they can have strong impacts on aquatic macrophyte communities (Lodge and Lorman, 1987; Creed, 1994; Lodge et al., 1994; Dorn and Wojdak, 2004), they are diverse and abundant foragers in aquatic habitats throughout North America (Lodge et al., 2000), they feed well in the laboratory (Bolser et al., 1998; Parker and Hay, 2005), and we observed evidence of crayfish in one of the ponds.

P. spiculifer were collected from the Chattahoochee River, Atlanta, GA (33°54'N, 84°27'W); *P. acutus* were collected from an adjacent wetland. We housed each crayfish in a separate 12 × 12 × 10 cm cubicle with perforated walls that received recirculating, filtered water. All animals were fed a maintenance diet of Bio-Blend Herbivore food (Marineland Labs) 3–4 times wk. Grass carp would not

feed when kept individually, so we housed them in small groups of 3–6 animals in 3.5-l buckets with recirculating water.

Feeding Assays

We determined the relative palatability of all five macrophyte species by offering 12–15 individuals of each consumer species a bite-sized portion of each macrophyte and recording whether each portion was eaten or rejected. If rejected, we fed consumers a piece of palatable aquatic macrophyte (*Egeria densa* Planch.) to ensure that they were not satiated. If the palatable macrophyte was rejected, that replicate animal was not included in the assay because it appeared satiated. Because grass carp were kept in small groups, we report results from the first fish that fed in each bucket as a replicate ($N = 12$ –15 separate buckets). Order of macrophyte presentation was randomized separately for each replicate consumer. We then analyzed (using a Fisher's exact test) the proportion of animals that were willing to feed on each individual macrophyte species relative to the palatable control.

Low palatability of fresh macrophyte tissues could result from structural, morphological, nutritional, chemical, or other characteristics. To determine whether macrophyte morphology could account for feeding preferences, we destroyed morphological traits by incorporating freeze-dried and finely ground macrophyte tissues into gel-based foods constructed with 30% sodium alginate by dry mass (Hay et al., 1998). We added enough macrophyte powder to the paste to approximate the same dry mass per volume of macrophyte found in tissues from each species of macrophyte being assayed (see [Macrophyte Traits](#)). The gel was then coated onto the interior wall of a glass Petri dish and immersed in a hardening solution of 0.25 M calcium chloride. After approximately 1 min, the gel was removed, rinsed in water, and cut into bite-sized portions. This method resulted in reconstituted macrophytes with similar morphologies and a soft, fleshy texture not unlike cooked pasta. Nutritional values and chemical defenses should have remained similar to those of intact macrophytes (however, freeze-drying can alter the structure and the activity of some metabolites; Cronin et al., 1995). These artificially softened macrophytes were then assayed against a palatable control food—a 1:1 mixture of freeze-dried and powdered broccoli and lettuce (“broc-let”) that herbivores readily accept as food (Bolser et al., 1998). Broc-let content matched the dry mass per volume of each macrophyte being assayed. Feeding on pellets was recorded as the frequency of acceptance or rejection of treatment or control pellets, with these pellets being offered alternately. We analyzed (via Fisher's exact test) the proportion of animals feeding on each individual reconstituted macrophyte species relative to the palatable control.

If gel-based treatments were unpalatable, this suggested a chemical basis for feeding rejection. We tested for chemical defenses by conducting feeding assays with crude extracts from each macrophyte incorporated into broc-let based sodium-alginate pellets as above (see above and Hay et al., 1998 for a general review). Extracts were acquired by macerating fresh macrophyte tissues in a 1:1 mixture of water and methanol overnight, then successively extracting the macrophyte material for at least 2 hr in 1:1 and 1:2 methanol/dichloromethane. The extracts were combined, and solvents were removed under vacuum to yield a crude extract. For food preparation, each crude extract was dissolved in acetone, incorporated into broc-let powder and sodium alginate, and the solvent was evaporated by vigorous stirring in a fume hood. Control foods were treated identically (including addition of

acetone) but without the addition of crude extracts. The dry mass content of treatment and control pellets matched the dry mass per volume content of each macrophyte being assayed. Pellets were fed to animals and the results were statistically analyzed as described above.

Macrophyte Traits

We measured macrophyte traits that are thought to be indicative of macrophyte nutritional quality or availability as a food, including: toughness, dry mass/volume, ash-free dry mass/volume, soluble protein/volume, and soluble protein/dry mass. Dry mass/volume was determined by drying 3–8 replicate samples of known volume at 60°C for at least 2 d; ash-free dry mass/volume was determined by combusting these same samples at 450°C for at least 6 hr. Toughness was estimated by using a penetrometer (see Duffy and Hay, 1991) to determine the mass required to pierce a leaf with a needle. Two of the five macrophytes could not be adequately tested with this approach. The rush *J. effusus* was too tough to pierce with our penetrometer; the strands of the green alga *Spirogyra* were too thin to accept the needle.

Soluble protein content was estimated with the Bradford (1976) method. Triplicate composite samples of ground macrophyte material from each species (~5 mg) were digested in 1 ml sodium hydroxide (1 mol/l) for 24 hr at 2.5°C, centrifuged, and 100- μ l aliquots of the supernatant were added to 5-ml samples of Bradford reagent. After 10–15 min, absorbance of each sample at 595 nm was measured using a Spectronic 21D spectrophotometer against bovine serum albumin (BSA) standards.

Results were analyzed with ANOVA followed by Tukey multiple comparison tests, with transformations ($\log + 1$) to correct heteroscedastic variances when necessary. Protein analyses were conducted on pooled samples of tissues from many individual plants. These data were not statistically analyzed because variances associated with the means were methodological rather than associated with differences among individual, replicate plants.

Bioassay-Guided Fractionation

M. umbrosum was the only macrophyte species with consistent evidence for a strong chemical defense. To separate and identify the defensive compounds, we used bioassay-guided fractionation of the total crude extract by assessing the feeding response of the crayfish *P. spiculifer*. We used crayfish rather than grass carp for these assays because grass carp had not yet acclimated to feeding in the laboratory when we began this fractionation. We did, however, use all three consumer species to test the deterrence of each isolated metabolite and also of the remaining crude extract minus these compounds. Extracts were initially tested at twice their extracted concentrations (by volume) to offset loss due to inefficient extractions and/or compound decomposition. Chromatographic fractions and pure compounds were tested by offering crayfish broc-let based pellets incorporated with fractions or compounds vs. control foods; results were statistically analyzed with Fisher's exact tests.

Fresh tissues of *M. umbrosum* were extracted successively with dichloromethane, acetone, and methanol, and these extracts were combined to produce a crude extract. The deterrent crude extract was fractionated by using silica gel flash chromatography (40–63 μ m Aldrich silica gel eluting with increasing concentration

of ethyl acetate in petroleum ether). The resulting 36 fractions were grouped by similar thin layer chromatography (TLC) properties into seven fractions, of which two were deterrent. The deterrent component within the less polar deterrent fraction was purified by repeated flash chromatography, as described above, followed by silica gel high-performance liquid chromatography (HPLC) with hexane/ethyl acetate as the mobile phase. The more polar deterrent fraction yielded two deterrent pure compounds via: (1) repeated silica gel flash chromatography eluting with toluene/ethyl acetate or toluene/petroleum ether/ethyl acetate; (2) recrystallization from hexanes/methanol/toluene (3:2:1); and (3) silica gel HPLC eluted with hexane/ethyl acetate, using a Zorbax RX-SIL HPLC column (9.4 × 250 mm; 5 μm) attached to a Waters Breeze HPLC system consisting of Waters 515 pump and Waters 2487 UV detector recording at 210 and 254 nm. A third fraction from the initial flash column separation did not initially deter crayfish feeding, but unusual ^1H NMR signals motivated the purification of a fourth compound by flash column chromatography and HPLC as described above.

Pure compounds from each fraction were identified on the basis of ^1H , ^{13}C , and 2D NMR spectroscopy, and comparisons of NMR, IR, and mass spectral data with literature data. Optical rotations were obtained using a Jasco P-1010 polarimeter. IR data were acquired on a Nicolet 520 FTIR spectrophotometer with thin films on NaCl plates. ^1H , ^{13}C , and 2D NMR spectral data were obtained on a Bruker Avance DRX 500 MHz spectrometer using CDCl_3 referenced to residual CHCl_3 (δ 7.28).

Quantification of Isolated Compounds

To determine whether our isolated yields were comparable to the natural concentrations in plant tissues, we quantified the concentrations of each of the four compounds from five separate individuals of *M. umbrosum* collected at the same time and under the same conditions as the bulk material used in this study. Frozen plants were individually extracted with a 1:1 mixture of water and methanol, then successively for at least 2 hr in 1:1 and 1:2 methanol/dichloromethane.

Quantification of natural products was achieved by LC-MS/MS using a Micromass Quattro triple quadrupole mass spectrometer in conjunction with an Agilent 1100 HPLC. A reversed-phase Zorbax eclipse XDB-C8 column (1.0 × 150 mm, 3.5 μm) was used to separate the natural products with a gradient system of water/acetonitrile (0.1% formic acid) 95:5 (v:v) to 5:95 (v:v) over 31 min. Three or four standard solutions (0.0001–0.10 mg/ml) of each of the four pure compounds were used to measure sample concentration by integration of the peaks areas for monitored transitions arising from dissociation of $[\text{M} + \text{H}]^+$ precursor ions to a structure-specific fragment ion for each compound. These data were used to establish standard curves ($R^2 > 0.99$ for each compound) for the quantification of compounds in crude extracts of the five macrophyte samples. Once natural concentrations were known, we tested the effects of each compound at its natural concentration and at its isolated yield with each of our three consumers species.

Experimental Exclusion of Herbivores and Tests of Herbivore Preference among Plants

To determine whether the chemically defended *M. umbrosum* was disadvantaged relative to less-defended plants in the absence of herbivory, we excluded grass carp

and other potential consumers from caged areas of the pond for 16 mo and measured the abundance of plants in caged vs. control areas. On April 26, 2004, we established five blocks in the pond with three treatments in each block: (1) an uncaged treatment allowing full herbivore access, (2) a three-sided cage control allowing herbivore access but controlling for cage artifacts, and (3) 2 four-sided cages excluding herbivores. Each block had 2 four-sided cages because we had originally intended to establish another treatment in one of the cages. We never imposed this treatment, thus, both cages were considered replicates in the same block to calculate the cage effect. Each treatment area was $0.9 \times 0.9 \times 0.9$ m, with the cage control and cage areas marked by 1.0-m-tall steel rebar posts. Cages were constructed of 3.0-mm plastic mesh affixed to the rebar posts with cable ties. A 10- to 15-cm skirt was anchored around each cage to prevent consumers from burrowing under the mesh walls. On only one occasion did we encounter grass carp in the cages; both fishes were removed and were likely too small (<2 cm in length) to have begun feeding on macrophytes given that grass carp typically do not become herbivorous on macrophytes until they reach approximately 3 cm in length (Hickling, 1966). Treatment blocks were established in linear arrays separated from each other by at least 4.0 m along the shoreline that was not used to seine fish. Treatments were randomly assigned to each position in the block, with the restriction that the open treatment was on either end of the block. Watermarks on the cage walls suggested that the average treatment depth was approximately 15 cm, but we observed that cages were occasionally dry or up to 30 cm deep, consistent with the variability of water depth that we observed in natural ponds in the area. Poor water clarity, however, prevented monitoring of plant cover when water depth exceeded approximately 10 cm.

We estimated initial plant cover in the treatments by determining the identity of macrophytes located beneath 36 points in a 0.25-m^2 quadrat placed directly in the center of each cage or open treatment. We analyzed the initial total plant cover and the initial cover of the two species (*M. umbrosum* and *L. repens*) that were most abundant at the end of the experiment with a blocked one-way ANOVA, transforming ($\log + 1$) to correct heteroscedastic variances (determined via Cochran's tests) when necessary.

On August 29, 2005, we harvested all of the aboveground plant material from each cage and weighed it to the nearest gram. We analyzed the total aboveground biomass and the biomass of the two most common plant species in our treatments with a blocked one-way ANOVA, transforming ($\log + 1$) to correct heteroscedastic variances (determined via Cochran's tests) when necessary. Significant ANOVA results were followed by multiple comparisons (Tukey tests) among treatment means.

Although our earlier laboratory feeding assays allowed us to determine which plant species were unpalatable, they were unsuitable for determining preference hierarchies among plant species. Thus, we conducted choice-feeding assays comparing grass carp preference for *M. umbrosum*, the plant that dominated cover in one of the grass carp ponds, with *L. repens*, a formerly rare plant that heavily recruited into our exclusion cage treatments (see Results). We also compared grass carp preference for *M. umbrosum* vs. *Najas guadalupensis*, and *L. repens* vs. *N. guadalupensis*; we chose *N. guadalupensis* because it dominated (>80% cover, $N = 20$ quadrats) the cover of a nearby (~300 m distant) pond of natural origin that did not have grass carp. We hypothesized that the dominant plants from the grass

carp pond (*M. umbrosum* and *L. repens*) would be of lower preference than the dominant plant (*N. guadalupensis*) from a habitat that lacked grass carp, and that *M. umbrosum* would be of lower preference than a plant that recruited only to cages where we excluded grass carp.

Each replicate assay consisted of placing a binder clip with a 2.0-cm portion of each of two plant species into 18 buckets containing 2–5 grass carp. Each replicate was periodically checked to determine which plant had been eaten first, with all treatments harvested the following morning. We did not retain the replicates where both plants had been eaten, as we could not determine which plant had been eaten first. We analyzed the number of occasions in which each species was eaten first with Fisher's exact tests.

Results

Macrophyte Abundance

In late April 2004, the littoral fringe of both grass carp ponds was largely unvegetated (mean ± 1 SE of bare space; Pond 1 = $76.7 \pm 10.6\%$, Pond 2 = $80.6 \pm 10.3\%$, both $N = 5$), but macrophyte cover in each of the ponds was dominated by a single species (Pond 1: *M. umbrosum* = $86.5 \pm 6.8\%$ of total plant cover; Pond 2: *Spirogyra* = $94.4 \pm 5.6\%$ of total plant cover). Of the remaining four macrophyte species, *J. effusus* represented $9.8 \pm 5.3\%$ of total plant cover in Pond 1 and $2.8 \pm 2.8\%$ in Pond 2, *J. repens* comprised $2.8 \pm 2.8\%$ in Pond 2, and there were trace amounts of *L. repens* in Pond 1. A single individual of the sedge *Carex* sp. occurred in Pond 1; because this was only one individual, we did not include this species in our feeding assays. No other aquatic macrophytes were observed in the ponds.

Feeding Assays

When offered as fresh macrophyte tissues, each of the five macrophyte species assayed was unpalatable relative to a control food to at least two of the three consumer species tested (Fig. 1A). Of the two most common macrophytes, *M. umbrosum* was significantly less palatable than control food (*E. densa*) to all three consumers, whereas *Spirogyra* was significantly less palatable to *Procambarus acutus* and *C. idella*, but not to *P. spiculifer*. Although relatively uncommon in the ponds, *L. repens* also was significantly less palatable to all three consumers than was the control food. After we destroyed plant morphological traits, palatability increased for some macrophytes, but feeding on *M. umbrosum*, *Spirogyra*, and the rush *J. repens* remained similar to that on intact plants (Fig. 1B). When the crude extracts from macrophytes were incorporated into a palatable control food, only *M. umbrosum* remained unpalatable—suggesting a strong chemical deterrent to feeding by all three consumers (Fig. 1C).

Macrophyte Traits

Table 1 shows toughness, dry mass, ash-free dry mass, and protein content of the macrophytes examined. *M. umbrosum* was the softest macrophyte that we tested with the penetrometer, was of intermediate rank in dry mass and in soluble protein

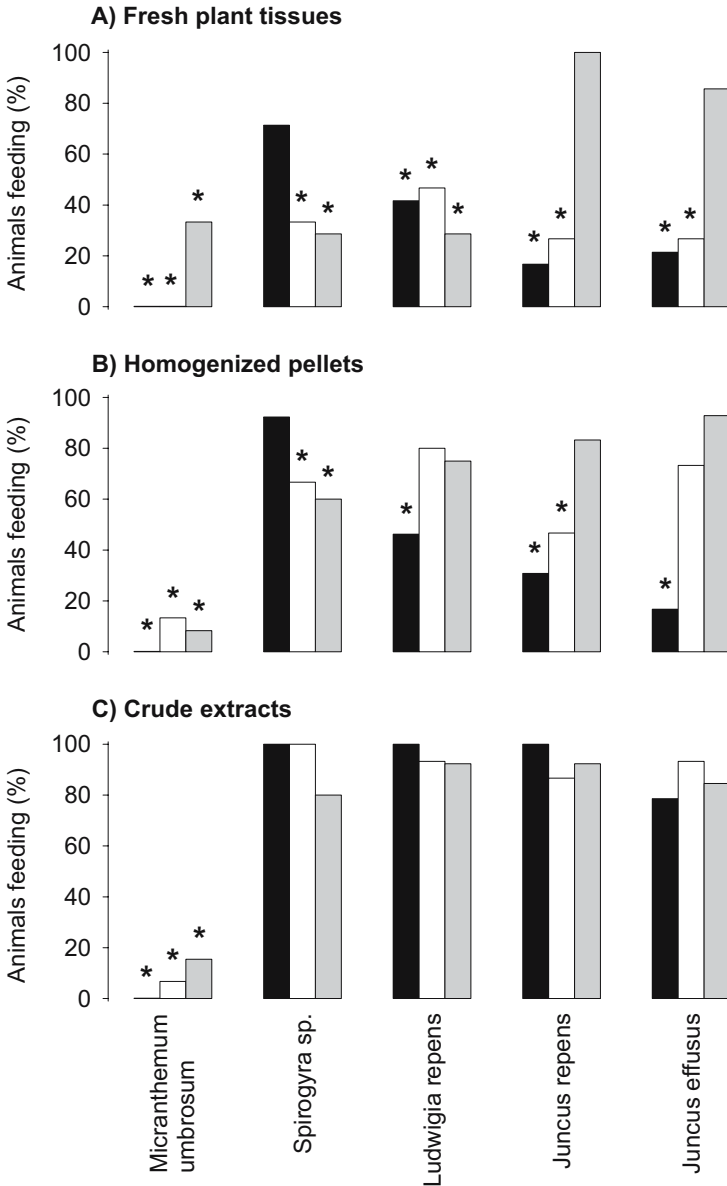

Fig. 1 Percentage of 12–15 individual *Procamburus spiculifer* (filled bars), *P. acutus* (open bars), and *Ctenopharyngodon idella* (gray bars) feeding on (A) fresh macrophyte tissues, (B) homogenized macrophyte pellets at natural dry mass content, and (C) crude extracts from five aquatic macrophyte species. Asterisks denote statistically significant ($P < 0.05$) reductions in feeding relative to a palatable control (*Egeria densa*) for each consumer species (Fisher’s exact tests)

Table 1 Mean (\pm SE) and sample sizes (in parentheses) for each analysis of selected macrophyte traits*

per volume of plant, but had the highest ash-free dry mass per volume of macrophyte. *Spirogyra* could not be tested with the penetrometer because of its filamentous morphology, but it has no obvious structural barriers to grazing. *Spirogyra* was generally nutritionally poor relative to the other plants; it ranked lowest in dry mass, ash-free dry mass, and protein content per volume of plant (Table 1). *L. repens* was relatively soft and of intermediate to low rankings in mass and protein content. The prostrate rush *J. repens* was the toughest macrophyte that we could test, and it had the highest dry mass, second highest ash-free dry mass, and protein content when measured volumetrically, but the lowest protein content when expressed as a % of dry mass. The emergent rush *J. effusus* was too tough to test with the penetrometer, and had intermediate dry mass per volume, relatively low ash-free dry mass per volume, and moderately low protein content. Our palatable control food, a 1:1 mixture of powdered broccoli and lettuce (broc-let), had relatively low dry mass, ash-free dry mass, and protein content per volume of plant, but it had the highest protein content of all the foods when expressed as a % of dry mass (Table 1).

Bioassay-Guided Fractionation

The crude extract of *M. umbrosum* strongly deterred feeding by *P. spiculifer* (Fig. 2). Two of the initial seven fractions from this extract strongly reduced crayfish feeding (fractions B and E, Fig. 2). Purification of the active component in fraction B via three silica gel chromatographic columns revealed 3,4,5-trimethoxyallylbenzene (elemicin) (**1**) as the bioactive metabolite (Fig. 2). Similar bioassay-guided separation of fraction E, followed by HPLC purification, led to identification of the deterrent compounds β -apocipopodophyllin (**2**) and (-)-(3*S*,4*R*,6*S*)-3-(3',4'-meth-

Fig. 2 Bioassay-guided fractionation of crude extracts from *Micranthemum umbrosum*. Each graph shows the percentage of 12–15 individual *P. spiculifer* feeding on a solvent-only control food (open bar) vs. control food containing macrophyte extracts. Shaded graph panels denote statistically significant ($P < 0.05$) feeding reductions relative to the palatable control (Fisher's exact tests). See [Methods and Materials](#) for mobile phases and chromatographic details

ylenedioxy- α -hydroxybenzyl)-4-(3'',4''-dimethoxybenzyl)butyrolactone (**3**) (Fig. 2). Although fraction C did not initially deter crayfish feeding (Fig. 2), unusual ^1H NMR signals motivated the purification of (–)-hibalactone (**4**), also known as (–)-savinin, from this fraction (Fig. 3).

Quantification of Compounds 1–4

We initially tested the deterrent fractions at twice their yield (by volume) to make up for assumed losses during purification, but compound quantification by LC-MS/MS showed that even doubling the presumed natural concentration did not approach the actual concentration occurring in the crude extract for each of the four compounds assayed (Table 2). The isolated yields of compounds **1** and **2** were 19% and 16% of their natural concentrations, respectively, while compounds **3** and **4** were isolated at only 1% and 8% of their natural concentrations, respectively.

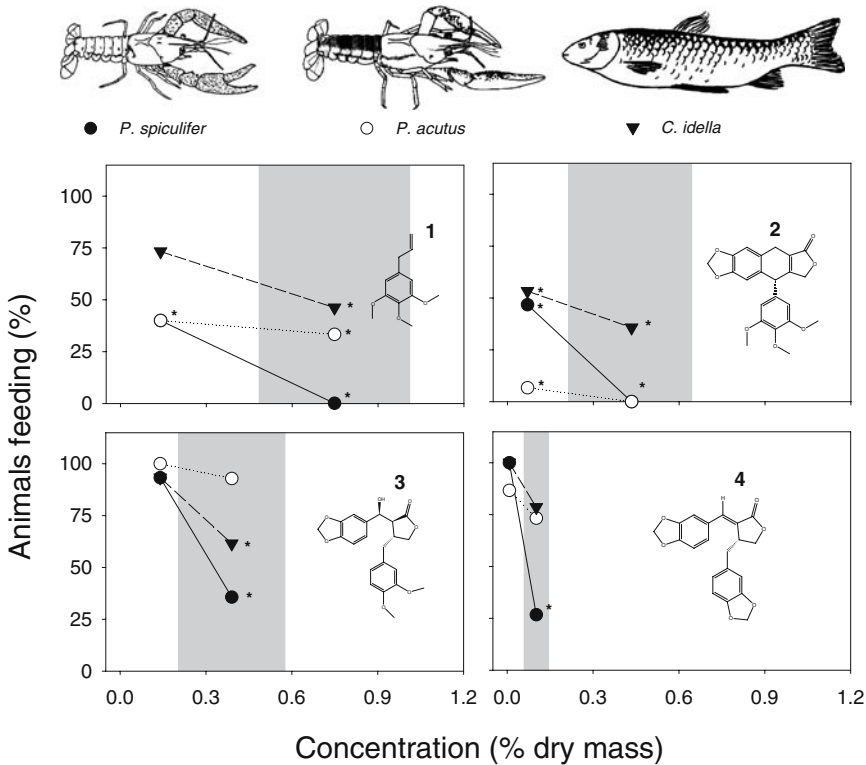

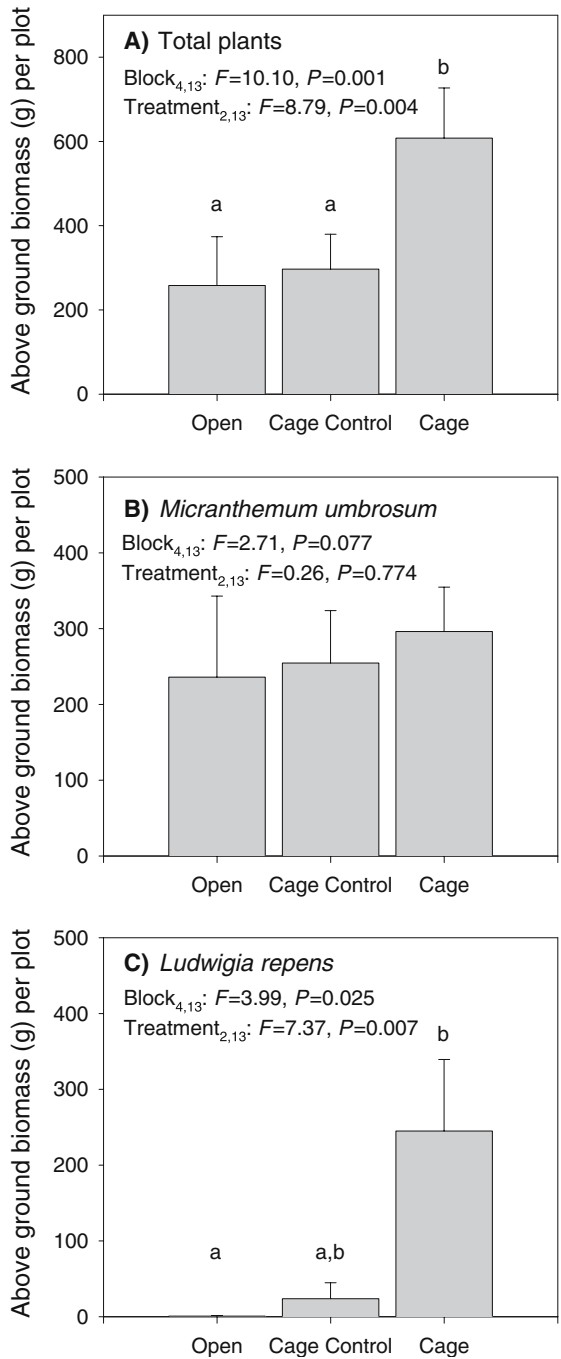

Fig. 3 Percentage of 12–15 individual *P. spiculifer* (filled circles), *P. acutus* (open circles), and *Ctenopharyngodon idella* (filled triangles) feeding on pellets containing (A) 3,4,5-trimethoxyallylbenzene (**1**); (B) β -apopropodophyllin (**2**); (C) (–)-(3*S*,4*R*,6*S*)-3-(3',4'-methylenedioxy- α -hydroxybenzyl)-4-(3',4'-dimethoxybenzyl)butyrolactone (**3**); and (D) (–)-hibalactone (**4**). Asterisks denote statistically significant reductions in feeding relative to a palatable control for each consumer species ($P < 0.05$; Fisher's exact tests). The shaded area is the quantified natural concentration (by dry mass) ± 1 standard deviation (see Table 2); feeding assays to the left of this shaded area were conducted at the isolated yield of each metabolite

When elevated to their natural concentrations, compounds **1** and **2** were both deterrent to all three consumers (Fig. 3). In contrast, when we elevated compounds **3** and **4** to their natural concentrations, compound **3** was deterrent to *P. spiculifer* and to grass carp, but not to *P. acutus*, whereas compound **4** was deterrent to *P. spiculifer* but not to the other consumers (Fig. 3). For three of the four

Table 2 Isolated yield and quantitatively determined dry mass concentrations (% of dry mass \pm SD) of four deterrent compounds isolated from the crude extract of *Micranthemum umbrosum*

Quantification method	Concentration of compound (% of macrophyte dry mass)			
	1	2	3	4
Isolated yield ($N = 1$)	0.14	0.070	0.0045	0.0078
LC-MS/MS ($N = 5$) quantification	0.75 ± 0.26	0.43 ± 0.22	0.39 ± 0.19	0.10 ± 0.04

Fig. 4 Final aboveground biomass per plot of (A) all plants, (B) *M. umbrosum*, and (C) *Ludwigia repens* in open, cage control, and cage treatments after 16 months. Statistical results are from one-way blocked ANOVAs. Bars that share the same letter were not statistically different ($P < 0.05$) from one another in Tukey's tests

compounds tested, the magnitude of feeding depression appeared stronger for *P. spiculifer* than for the other consumers (Fig. 3).

We also tested whether we had isolated all of the strongly deterrent compounds by assaying the crude extract minus the fractions containing the four isolated compounds (i.e., we used TLC to group fractions from the first silica gel column that lacked compounds 1–4). None of our three test consumers were significantly deterred by this “crude minus deterrent fractions” extract ($N = 13$ – 15 for each consumer species, % acceptance $\geq 86.7\%$, $P \geq 0.50$). However, given the significant compound degradation and/or inefficient yields that we observed (Table 2), it is possible that unknown, but potentially deterrent, compounds within this crude extract were tested at concentrations significantly lower than their natural levels.

Experimental Exclusion of Herbivores

At the initiation of the experiment, there was no difference in total plant cover ($P = 0.833$), the cover of *M. umbrosum* ($P = 0.089$), or the cover of *L. repens* ($P = 0.641$) among the open, cage control, and cage treatments (data not shown). After 16 mo of excluding grass carp and other potential herbivores (e.g., crayfish, turtles), there was 2.4-fold more total plant biomass ($P = 0.004$, Fig. 4A) and over 300-fold more *L. repens* ($P = 0.007$, Fig. 4C) in the cage vs. open treatments. Biomass of the unpalatable macrophyte *M. umbrosum* was unaffected ($P = 0.774$, Fig. 4B). Thus, herbivore exclusion allowed other species to increase in abundance but did not alter the abundance of the chemically defended *M. umbrosum*.

When offered a choice between two plant species, grass carp preferred *L. repens* over *M. umbrosum* by 14 to zero ($P < 0.001$), *N. guadalupensis* over *M. umbrosum* by 11 to zero ($P < 0.001$), and *N. guadalupensis* over *L. repens* by 14 to zero ($P < 0.001$). The striking differences in preference for all contrasts clearly establishes a preference hierarchy of *N. guadalupensis* > *L. repens* > *M. umbrosum*.

Discussion

It is a common pattern in marine and terrestrial habitats for selective feeding by herbivores to shift plant species composition toward chemically or structurally defended plants (Hay and Fenical, 1988; Rosenthal and Berenbaum, 1992; Hay, 1997). In contrast, although aquatic herbivores commonly reduce plant standing stock and alter species composition (Lodge, 1991; Newman, 1991; Cyr and Pace, 1993; Lodge et al., 1998), experimental investigations linking herbivore feeding preferences to particular plant traits and ultimately to shifts in plant community structure are rare. Here, we show that five of the most common macrophytes collected from an aquaculture facility for herbivorous Asian grass carp, *C. idella*, were commonly unpalatable to three generalist consumers—nonnative grass carp and the native North American crayfishes *P. spiculifer* and *P. acutus*. The most common macrophytes—*M. umbrosum* and *Spirogyra* sp.—comprised 87% and 94%, respectively, of the total macrophyte cover in two grass carp ponds, and both were unpalatable to grass carp (Fig. 1). *Spirogyra* appeared nutritionally inadequate to these consumers, and *M. umbrosum* was chemically defended by at least four secondary metabolites (Figs. 2 and 3). When we excluded grass carp and other potential herbivores from experimental portions of one of the ponds, a plant that

was preferred over *M. umbrosum*—*L. repens*—increased over 300-fold in the herbivore exclusion treatment. A nearby natural pond that lacked grass carp was dominated by *N. guadalupensis*, a plant that grass carp preferentially consumed over both *M. umbrosum* and *L. repens*. Thus, selective feeding by grass carp effectively eliminates most palatable plants from this community and promotes the persistence of less palatable, chemically defended or nutritionally inadequate plants.

Grass carp and most crayfish species are generalist consumers that will eat a variety of plants (Parker and Hay, 2005) but still selectively feed among species based on their structural, nutritional, and chemical traits (Cronin et al., 2002). However, knowledge of traits alone may not be predictive of feeding preferences among different consumer species (e.g., Hay et al., 1987; Hay and Fenical, 1996). For example, both the grass carp and crayfish *Procambarus acutus* rejected the filamentous green alga *Spirogyra* (Fig. 1). The crayfish *P. spiculifer*, however, readily consumed *Spirogyra* (Fig. 1), and in another study the crayfish *Pacifastacus leniusculus* preferred it over other aquatic plants (Warner and Green, 1995). Among the five plant species that we tested, *Spirogyra* had the lowest protein content per volume of plant (Table 1), suggesting that nutritional inadequacy may explain its low palatability to *P. acutus* and to grass carp, but the variation among consumers (Fig. 1; Warner and Green, 1995) suggests that palatability depends on the palate of the consumer, or on considerable intraspecific variance in the defensive traits of the plants studied (e.g., Taylor et al., 2003). Moreover, *Spirogyra* and other filamentous algae reportedly persist in these and other ponds only until submersed macrophytes have been selectively removed by grass carp (P. Williams, personal communication; Van Dyke et al., 1984). This suggests that plants can delay or reduce herbivory by being nutritionally poor, but they may be unlikely to escape consumption once higher preference plants have been removed.

It is uncertain why *L. repens* was rejected in the fresh tissue assays (Fig. 1). It was readily eaten over *M. umbrosum* in choice assays with fresh tissue, was readily eaten by all but one consumer as homogenized pellets (Fig. 1B), and was eaten by all consumers when extracts were incorporated into a palatable control food (Fig. 1C). It could be that our methodology of offering bite-sized pieces rather than whole plants altered the acceptability of this or other plant species. The prostrate rush *J. repens* and the emergent rush *J. effusus* were both tough plants that may have been structurally defended from consumption by crayfishes (Table 1, Fig. 1). However, at least one crayfish species rejected the softened, homogenized pellets of each species (Fig. 1B), although no consumers rejected the chemical extracts (Fig. 1C). Thus, it appears that both rushes could be structurally defended, but we cannot exclude the possibility that deterrent compounds in the softened foods were lost during the extraction process. Alternatively, the higher protein content of broc-let powder (Table 1) may have provided extra feeding incentives that counterbalanced deterrent chemistry. Other investigations have shown that consumers are more likely to feed on chemically defended foods if they are nutritionally rich (Duffy and Paul, 1992; Cruz-Rivera and Hay, 2003).

Despite these ambiguities for some consumer and macrophyte species, *M. umbrosum* was clearly chemically distasteful to all three consumers (Fig. 1), and we isolated four natural products that serve as chemical defenses against herbivory (Figs. 2 and 3). Each of the four compounds has previously been described, but this is the first study to report on their ecological function as defenses against herbivory. Compound **1** is an essential oil commonly found in aromatic plants including nutmeg

and parsley (De Vincenzi et al., 2004). It has been implicated as an antimicrobial compound (Marston et al., 1995), a growth inhibitor of green algae (Della-Greca et al., 1992), and as an insecticide (Miyazawa et al., 1992). β -Apopicropodophyllin (**2**) has previously been isolated from the Mexican medicinal plant *Hyptis verticillata* “bushmint,” and is from a class of lignoids active against several cancer cell lines (e.g., Novelo et al., 1993). Compound **3** has been synthesized but was not previously known as a natural product (Pelter et al., 1988). Lignan **4** occurs in juniper and several woody plant species (e.g., Hartwell et al., 1953); it inhibits prostaglandin E₂ production (Ban et al., 2002), tumor necrosis factor- α production and T-cell proliferation (Cho et al., 2001), and is a synergist for insecticides (Matsubara, 1972). We lost from 81% to 99% of the natural concentrations of these four molecules during isolation procedures (Table 2). Given this poor yield, it is possible that additional deterrents were present but recovered at concentrations too low to be biologically active.

Prior to this study, there were only three freshwater plants with described herbivore feeding deterrents—watercress, *R. nasturtium-aquaticum* (L.) Hayek (Newman et al., 1990, 1996); the waterspider bog orchid, *H. repens* Nutt. (Bolser et al., 1998; Wilson et al., 1999); and lizard’s tail, *S. cernuus* L. (Kubanek et al., 2000, 2001)—with a total of nine described secondary metabolites demonstrated to influence herbivore feeding. Our study brings the new total of described herbivore antifeedants in freshwater plants to 13. Of these 13, 10 are lignoids, including three in this study and seven compounds isolated from *S. cernuus* (Kubanek et al., 2001). This general, though still preliminary, pattern suggests that lignoids—of which several thousand have been described from numerous plant taxa (Seigler, 1998; Ward, 1999)—are common, but often overlooked, defensive compounds warranting additional study.

Plant defense theory predicts that chemically defended plants have fewer resources for growth and will be competitively displaced by less defended plants when herbivore pressure is lessened (Herms and Mattson, 1992). To test this, we excluded grass carp for 16 mo and documented a 300-fold increase in the abundance of *L. repens* (Fig. 4), a plant that was preferred over *M. umbrosum* in a choice feeding assay. However, we did not observe a decrease in the abundance of *M. umbrosum* in the cage treatments (Fig. 4). Thus, although chemical defenses in *M. umbrosum* appear to promote its persistence in the face of intense herbivory, we saw little evidence to suggest competitive displacement of *M. umbrosum* by *L. repens* in the absence of herbivores. There are several potential explanations. Our experiments ran through two growing seasons, but the long history (>20 yr) of grass carp herbivory in this habitat may have consistently excluded other species and reduced the potential pool of new colonists exhibiting high-growth, low-defense strategies. In support of this hypothesis, *M. umbrosum* typically takes at least 4 yr to recruit into new ponds in this system, after which it persists indefinitely (P. Williams, personal communication). Additionally, the only species that showed a large increase in abundance—*L. repens*—is also relatively unpalatable (Fig. 1), and may not be a much better competitor than *M. umbrosum*. Moreover, despite the long-standing view that constructing and storing defensive compounds is physiologically costly and detracts from growth and reproduction, empirical evidence is conflicting (Koricheva, 2002), suggesting that investment in chemical defense need not necessarily restrain growth and competitive ability (Cronin, 2001). Finally, grass carp will repeatedly sample foods even if they do not ingest the plants (P. Williams,

personal communication); this chronic sampling may have depressed *M. umbrosum* abundance in the open and cage control treatments and obscured competitive effects in the cage treatments. Nevertheless, on a percentage basis, excluding herbivores led to dramatic increases in *L. repens* that reduced the relative abundance of *M. umbrosum* from 89% to 54% of the total plant community, indicative of chemical defenses promoting the relative dominance of *M. umbrosum* in this community.

Herbivory in freshwater systems is more important than previously thought (Lodge and Lorman, 1987; Newman, 1991; Cyr and Pace, 1993; Lodge et al., 1994, 1998; McKnight and Hepp, 1995), and freshwater plants are frequently chemically or structurally defended from consumers (Newman et al., 1996; Bolser et al., 1998; Cronin, 1998; Kubanek et al., 2001; Cronin et al., 2002; Prusak et al., 2005). Rarely, however, have the mechanisms of deterrence (e.g., structural or chemical defenses) been linked to the broader context of community structure. Here, we show that selective herbivory by grass carp shifts the species composition of freshwater plant communities toward plants that are distasteful, structurally defended, or nutritionally inadequate (Figs. 1 and 4), suggesting that plant defenses can play critical yet understudied roles in the structure of freshwater plant communities.

Acknowledgments We thank Paul Williams of the Owen and Williams Fish Hatchery for supplying grass carp, macrophytes, and the observations about fish feeding. L. Stefaniak trained the grass carp for feeding assays; D. Burkepile and W. Morrison assisted with the caging experiment. Abstract Information on natural concentrations or variability of secondary metabolites in marine organisms may be important both to ecological/evolutionary and applied approaches. A gas chromatographic procedure with an electron capture detector (GC-ECD) was developed to quantify the sesquiterpenoid elatol at the surface and within-thalli of 70 specimens of the red seaweed *Laurencia obtusa*. The concentration of elatol was highest within-thalli [9.89 mg g^{-1} of *L. obtusa*, dry weight (d.w.)], compared to lower values found at the surface [0.006 mg g^{-1} of *L. obtusa* (d.w.), or $0.5\text{--}10.0 \text{ ng cm}^{-2}$]. This method provides a rapid and inexpensive quantification of small quantities of elatol, and probably may also be used to quantify other halogenated compounds usually found in red seaweeds.

Introduction

Marine secondary metabolites are undoubtedly important in mediating interactions at the surface of many host marine organisms. Knowledge of both the amount and variation of secondary metabolites of marine organisms is an essential element for assessing studies in chemical ecology, and more significant if put into an ecological

and evolutionary background (Schmitt et al., 1995; De Nys et al., 1995, 1998; Hay et al., 1998). However, one of the major problems faced by researchers in marine chemical ecology is determining natural secondary metabolite concentrations and, consequently, the reproduction of realistic concentrations that can be applied in bioassays. In general, measurements have been made for entire plants, with few results being related to variability in parts thereof. For instance, variations between surface and within-thallus concentrations of seaweed metabolites are rarely studied (e.g., De Nys et al., 1998).

Determination of near or at the surface antifouling metabolites of host organisms is essential because an antifouling function cannot be inferred without demonstrating the secondary metabolites concentrations *in situ* (De Nys et al., 1998). Only investigations that quantify the amounts of compounds released from organisms, or use known concentration of metabolites that are ecologically realistic should be used in assays (Hay et al., 1998).

Until the 1970s, the scarcity of reports was largely determined by technological limitations (Schmitt et al., 1995), i.e., difficulty in identifying, quantifying, and testing chemical cues for colonization *in situ* (Steinberg and De Nys, 2002). Current analyses have been carried out with modern technologies such as high-performance liquid chromatography (HPLC) (e.g., Gerwick et al., 1985; Paul and Fenical, 1986; Hay et al., 1987; Paul and Van Alstyne, 1992; Schmitt et al., 1995; Cronin and Hay, 1996) or gas chromatography coupled to mass spectrometry (GC-MS) (e.g., Mynderse and Faulkner, 1978; De Nys et al., 1998). However, few reports explain the method applied (see Phillips and Towers, 1982; De Nys et al., 1996a, 1998; Taylor et al., 2003, for exceptions). Therefore, when marine chemical ecology studies are evaluated, it often remains unclear if concentrations, methods, and organisms applied in marine bioassays constitute ecologically realistic conditions. This study quantified a marine halogenated secondary metabolite based on a gas chromatographic technique coupled to electron-capture detection (GC-ECD).

Methods and Materials

GC-ECD was used to quantify elatol in specimens of the seaweed *Laurencia obtusa* (Ceramiales, Rhodophyta) from Cabo Frio Island, in the state of Rio de Janeiro, Brazil. Elatol, the major secondary metabolite in Brazilian specimens of *L. obtusa* from Cabo Frio Island, is known as an effective chemical defense against herbivores and fouling organisms (Da Gama et al., 2003; Pereira et al., 2003). Specimens ($N = 70$) were collected and maintained in individual plastic bags and transported to the laboratory. Under these conditions, there is no stress that might lead to release of elatol (Sudatti et al., unpublished data). At the laboratory, fronds were weighed wet (mg), their surface area (cm^2) was estimated, and they were submitted to extraction procedures. All weights were obtained from wet seaweed, from which excess water was removed by using a “salad spinner.”

To determine the surface concentration of elatol, surface areas of pieces of *L. obtusa* were calculated by using a wet weight (mg) to surface area (cm^2) conversion factor as proposed by De Nys et al. (1998). Additionally, the levels of within-thallus elatol were estimated by dry weight for each individual specimen (mg g^{-1}). Superficial area/weight was measured via two methods. In the first

approach, 13 branches of the *L. obtusa* frond were separated. Each was weighed to a precision of 0.01 mg, and the area of a cylinder, defined by the mean diameter (taken at three heights) and the height of the frond, were calculated. The mean value of all measurements was determined. In the second method, a total of 21 subunits of the branches were weighed, and the areas of the cylinders, defined by their diameter and height, were calculated. The mean value of all measurements was determined. Difference among the values obtained by these methods was considered significant when $P < 0.05$ ($\alpha = 5\%$), evaluated by *t* test.

Extraction Procedure for Surface Metabolites

Each specimen of *L. obtusa* was held in hexane according to the protocol proposed by De Nys et al. (1998). These authors dipped the algae in different solvents and for different time periods for extraction. After each period, a piece of alga was directly observed and quantitatively assessed for the presence of lysed cells by using epifluorescence microscopy. Of the five solvents tested, all except hexane caused lysis of surface cells for *L. obtusa* at all tested times. There was a significant increase in the concentration of total metabolites between extraction times of 50 and 60 sec, corresponding to an increase in the mean number of cells lysed. More stringent extraction procedures with other solvents, or with longer extraction times in hexane (>50 sec) caused significant quantifiable cell damage. In addition, dipping thalli for 30 sec also caused no cell lysis in eight other seaweeds, including brown and green species. Thus: 1) this method may be used for quantitative extraction of nonpolar natural products from the surface of seaweeds without disrupting cells; 2) the time period for extraction is about 40 sec. Based on this study, our procedure for extraction of surface metabolites consisted in dipping the frond into a solvent (hexane, 85%) for 40 sec. Each of the 70 fronds was individually immersed in 100 ml solvent, then air-dried at room temperature, and transferred, with hexane, to 2-ml vials through consecutive washes. These fronds of *L. obtusa* were individually reserved for further extraction of within-thallus metabolites.

Extraction Procedure for Within-Thallus Metabolites

Extractions of total secondary metabolites were obtained by exhaustive extraction of each specimen in hexane, following standard procedures for marine natural products. The crude extract was transferred, with hexane, to 2-ml vials through consecutive washes.

Both extraction procedures sought to verify surface and within-thallus metabolites. Although extractions promote total secondary metabolites removal, only the major compound elatol was quantified. Both extracts obtained (from the surface and within-thalli) were weighed and dissolved in hexane for quantification.

Extraction of Blank

In order to evaluate any solvent interference in the above extraction processes, 100 ml of hexane were processed and dried at room temperature, then transferred, with hexane, to 2-ml vials through consecutive washes.

Fig. 1 Elatol, the major secondary metabolite from Brazilian specimens of *Laurencia obtusa*

Elatol Standard

Additional fronds of *L. obtusa* were submitted to exhaustive extraction in hexane or dichloromethane. The resulting extract containing elatol was identified by using thin layer chromatography (TLC) (Merck Al TLC 20 × 20 cm silica gel 60F₂₅₄) and ¹H NMR and by matching the results found in the literature (Konig and Wright, 1997). Elatol isolation was carried out on precoated TLC plates, and quantification was performed by using a GC-ECD by the external standardization method.

GC-ECD Analysis

Chromatographic analyses were performed with a Varian CP-3800 and processed by Star Chromatography Workstation 6.0 version software. The GC was fitted with a WCOT CP sil 8 CB capillary column (30.0 m × 0.25 mm, 5% phenyl, 95% dimethylpolysiloxane; Chrompack). The oven temperature program was as follows: 80°C (1 min), 10°C min⁻¹ to 250°C (16 min) then 15°C min⁻¹ to 80°C. Nitrogen (N₂) 99.999% (Aga or White Martins) was used as carrier (28 cm sec⁻¹), makeup (35 m sec⁻¹), and purge (15 ml sec⁻¹) gas. Detector temperature was 320°C and injection pressure was 120 kPa. Splitless cold injections were carried out (0.5–1 μl).

Purified elatol was used as an external standard, and quantifications were made through analytical curves calculated from four to six different concentrations

Fig. 2 Chromatograms: (a) standard, (b) surface sample

through standard solutions in hexane. New analytical curves were constructed whenever the values obtained for the standards exceeded the previous series by more than 15%. Detection and quantification limits were determined according to U.S. EPA provisions; an analytical curve in a concentration range almost 5 times the noise of the baseline was obtained. Then, the concentration of seven replicates of a standard was determined from this curve, and its standard deviation(s) was calculated. The limits of detection and quantification were defined as 3 and 7 times the standard deviation, respectively.

Results

The halogenated sesquiterpene elatol (Fig. 1) is a transparent and viscous purple oil easily recognizable via TLC ($r_f = 0.45$) and ^1H NMR analyses. Pure elatol was

Fig. 3 Amount of elatol found within-thallus (a) and on the surface (b) of *L. obtusa*. Values are expressed in percentage (elatol weight/dry weight of the frond)

obtained by removing and filtering the silica band corresponding to its rf region. The pure compound was used as a standard. After chromatographic conditions were optimized, it was eluted at 250°C, and the average retention time was 32.5 min. Detection and quantification limits were established at 0.048 and 0.112 mg elatol l⁻¹ solution, corresponding to 48 and 112 pg, respectively, in 1.0 µl injected. Elatol was detected on the surface and within-thalli of *L. obtusa* specimens. Figure 2 shows the chromatograms of the standard (Fig. 2a) and the surface sample (Fig. 2b).

Artifacts or contaminants derived from the solvent or the extraction method had no interference in the analyses: the chromatograms of pure hexane and the method blank showed no peak at 32.5 min. Two analytical curves with different concentration ranges were established due to the widely different levels observed on the surface (4 standards from 0.06 to 1 ppm, $R^2 = 0.999$) and within-thallus samples (6 standards, from 1 to 20 ppm, $R^2 = 0.991$) of *L. obtusa*.

The effectiveness of this method allowed the quantification of low levels of elatol, especially those found at the surface of *L. obtusa*. Among the 140 quantitative analyses performed, corresponding to 70 specimens collected (70 surface samples and 70 within-thallus samples), only two were under the detection limit, and another three were under the quantification limit. The mean within-thallus elatol concentration was 9.89 mg g⁻¹, d.w., varying from 0.1 to 2.2% d.w. (Fig. 3a). Conversely, the mean surface elatol contents reached much lower values (0.006 mg g⁻¹ d.w.) varying from 5×10^{-6} to 5×10^{-3} % d.w. (Fig. 3b). The ratios between surface area and wet weight of the fronds, obtained by the two methods described, were 71.69 and 65.01, respectively. Since there was no significant difference between these two values ($P > 0.05$, *t* test), the amount of elatol per surface area of *L. obtusa* was estimated to vary from 0.5 to 10 ng cm⁻² for 52% of the analyzed specimens.

Discussion

To our knowledge, the application of a GC-ECD method to quantify a seaweed secondary metabolite is a new initiative. Research on seaweed secondary metabolite quantification is usually carried out via colorimetric techniques (e.g., Ragan and Glombitza, 1986; Tugwell and Branch, 1989; Denton et al., 1990; Pereira and Yoneshigue-Valentin, 1999), HPLC (e.g., Phillips and Towers, 1982; Gerwick et al., 1985; De Nys et al., 1996b), or GC-MS (e.g., Mynderse and Faulkner, 1978; De Nys et al., 1996a, 1998; Dworjanyn et al., 1999). The literature on quantification of marine secondary metabolites usually lacks details, making the possible application or necessary comparisons between methods difficult.

Colorimetric techniques do not allow for the identification of compounds, limiting use to that of assessing specific classes of compounds such as polyphenols from brown seaweeds (Ragan and Glombitza, 1986; Denton et al., 1990). Some studies have applied this kind of polyphenolic quantitative analyses to evaluate chemical defenses against herbivores in a marine environment (see Targett and Arnold, 1998).

HPLC is widely applied to quantify marine secondary metabolites (De Nys et al., 1995, 1996b); however, there are sensitivity limitations. It is usually applied to measure total levels (e.g., Phillips and Towers, 1982; Taylor et al., 2003). Once the molecular weight of a molecular structure is known, the GC-MS technique has high

sensitivity, and the GC-ECD technique can be superior for halogenated compounds (Weinberg et al., 2002).

Ordinarily, such methods allow one to quantify metabolites localized in parts of thalli or in the whole seaweed. In both cases, detectable levels may vary from 0.1 to 5.0% d.w., particularly for aldehydes, acetogenins, terpenoids, or other more complex molecules (Paul and Fenical, 1986), and from 5.0 to 20.0% d.w. for polyphenols found in brown seaweeds (Tugwell and Branch, 1989; Denton et al., 1990).

Quantification of surface metabolites from seaweeds has only been described twice (De Nys et al., 1998; Wright et al., 2000) by GC-MS. Unlike other techniques, the GC-ECD method applied here was successfully used in measuring very low levels, revealing detection and quantification limits of 28 and 60 pg of elatol, respectively. Of the 140 analyses performed, only two were under the detection limit and three were under quantification limits. The lower levels of elatol varied from 5×10^{-6} to 5×10^{-3} % d.w. Similar very low levels of surface metabolites were described by De Nys et al. (1998): the mean total surface concentration of natural products from *L. obtusa* was $<1 \text{ ng cm}^{-2}$, while much higher values ($7 \text{ } \mu\text{g mg}^{-1}$) were found for the whole plant. Low concentrations of secondary metabolites on surface of seaweeds, compared to those of whole plants, were also found via a method in which surface material was sampled with a cotton wool swab (Schmitt et al., 1995).

Natural concentrations of elatol, similar to those found within-thalli, exhibit some biological or ecological activities. For example, this sesquiterpenoid inhibited the establishment of the mussel *Perna perna* (Da Gama et al., 2003), and its consumption by the sea urchin *Lytechinus variegatus* (Pereira et al., 2003), the crab *Pachygrapsus transversus* (Pereira et al., 2003), and certain fish (Hay et al., 1988). In addition, it had an effect against larval settlement of the barnacle *Balanus amphitrite* and the bryozoan *Bugula neritina* at concentrations ranging from 0.01 to $10.0 \text{ } \mu\text{g cm}^2$ (De Nys et al., 1996b). On the other hand, it had less or no effect on bacterial growth or on the germination and settlement of the green alga *Ulva lactuca*. Recent work has verified that low concentrations of elatol on the surface of *L. obtusa* have no inhibitory effects on feeding by sea urchin, or against the establishment of mussel and barnacle larvae (the authors, unpublished). The indirect evidence that low concentrations of compounds at the surface of *L. obtusa* inhibit fouling settlement in concentrations that are 2 to 3 orders of magnitude greater than those naturally found at the surface of this seaweed from Australia (Steinberg et al., 1998) also supports our argument. Differing or conflicting results reveal the importance of realistic assays that pay careful attention to concentration scales and target organisms, because a simple compound can vary in its concentration, its effects at different levels, or its action in a species-specific way.

Besides the sesquiterpene elatol, many *Laurencia* species and other red seaweed species produce halogenated metabolites (Hay and Fenical, 1988). Since the GC-ECD technique is sensitive to halogens, especially to bromine, the methodology developed in this study could be applied to other typical halogenated compounds from red seaweeds.

Abstract Plants release volatile chemicals into their surrounding air space that can affect the physiology of neighboring plants and influence the behavior of insects. In studying these interactions, it is desirable to collect volatiles from plants that have not been excised and are growing under as natural conditions as possible. We compared a vessel of borosilicate glass and Nylon-6 or polyester [poly(ethylene terephthalate) or PET] cooking bags for enclosing plants during collection of volatiles. A push–pull airflow system was used, and volatiles were trapped on Tenax TA and analyzed by gas chromatography after thermal desorption. Low levels of impurities were found for the glass vessel and polyester bags. Nylon bags contained higher levels and more impurities. Recoveries of standards of 10 plant volatiles were measured in static and dynamic systems. In a static air system, there was good recovery only from the glass vessel. In a dynamic system, there was generally good recovery from both the glass vessel and polyester bags. Recoveries of α -pinene and (*Z*)-jasmone were poor throughout. The former was shown to have a very low breakthrough volume on the Tenax TA adsorbent, and the latter may be strongly adsorbed on glass. All three materials were essentially transparent in the IR and visible (photosynthetic) range but with significantly different absorptions in the UV range. In a simulated dynamic entrainment in full sunlight, internal vessel temperatures were higher than ambient by up to 9.5°C in the glass vessel and 7.5°C in the polyester bag. Lower increases in temperature relative to ambient (<1°C) were recorded when entrainments were conducted in the shade. In a field trial, the profiles of volatiles collected from an apple tree infested with rosy apple aphid using a glass vessel and a polyester bag were similar. Polyester bags are recommended as more convenient than glass vessels for the enclosure of plants during the collection of volatiles.

Introduction

Plants release chemicals into their surrounding air space that can affect the physiology of neighboring plants as well as influencing the behavior of insects. In recent years, there has been considerable interest in identifying such volatiles and understanding their effects in plant–plant systems (Bruin and Dicke, 2001; Pickett and Poppy, 2001; Engelberth et al., 2004), plant–herbivore systems (Visser, 1986; Bernasconi et al., 1998; Blackmer et al., 2004), and tritrophic systems (De Moraes et al., 1998; Powell et al., 1998; Smid et al., 2002; Birkett et al., 2003).

A diverse range of sampling methods has been employed for the collection of plant volatiles, including microwave-assisted extraction, sampling from warmed leaves using a gas syringe, or entraining over macerated plant, chopped foliage, whole leaves cut from the plant, whole branches/stems including leaves, uprooted plants in water, and whole plants including pot and soil (respective examples: Töllsten and Bergström, 1988; Smith et al., 1996; Geervliet et al., 1997; Landon et al., 1997; Du et al., 1998; Rojas, 1999; Choh et al., 2004; De Boer et al., 2004). Whereas these approaches have increased our understanding of plant semiochemicals, there are drawbacks to physically wounding the plant. Workers try to limit sample contamination from the wound by placing cut parts in vials of water, or wrapping them in wet cotton, Parafilm, or Teflon (respective examples: Mumm et al., 2003; Choh et al., 2004; Russell et al., 2004; Van Den Boom et al., 2004). However, wounding a plant not only causes the localized release of volatiles, but it also generates electrical, hydraulic, and/or chemical signals that act systemically. These signals stimulate the release of new volatiles far from the site of damage and also cause quantitative and qualitative changes in the volatiles relative to those from undetached parts (Galliard, 1978; Davies, 1987; Mookherjee et al., 1990; Rhodes et al., 1999; Backman et al., 2001; de Bruxelles and Roberts, 2001; Schmelz et al., 2001). Furthermore, detection by the plant of C_6 volatiles associated with physical damage can again trigger rapid systemic responses in which volatiles are released (Farang and Paré, 2002).

To minimize damage to a plant during sampling of volatiles, a common approach has been the use of a guillotine-style enclosure vessel. This isolates part of or a whole plant, and clean air is blown into the enclosing vessel at a rate greater than that at which headspace is sampled through a trapping adsorbent (see Heath and Manukian, 1994). Typically, the main body of such vessels is made of glass and the guillotine of Teflon or aluminum (Heath and Manukian, 1994; Röse et al., 1996; Paré and Tumlinson, 1997; Agelopoulos et al., 2000; Mattiacci et al., 2001; Rodriguez-Saona et al., 2003). However, these heavy, bulky glass vessels require considerable support and are inconvenient for sampling plants growing naturally.

Translucent plastic oven bags offer an easily transportable and disposable alternative to glass vessels, that would also facilitate replicated sampling from plants in the field. Reports in which different types of bags have been used are listed in Table 1. Although studies have compared the effects of gas syringe sampling, solid-phase microextraction (SPME), different trapping adsorbents, elution solvents,

solvent desorption vs. thermal desorption, and pump flow rates in the collection and analysis of plant volatiles (Agelopoulos and Pickett, 1998; Raguso and Pellmyr, 1998), there has been no study that critically assesses the merits and limitations of glass vs. plastic bag enclosure methods.

Two principal considerations for any enclosure material are chemical contamination and chemical adsorption. The effects of enclosing on the plant itself are often overlooked. Enclosure will qualitatively and quantitatively affect light wavelengths reaching the plant and may also affect both temperature and humidity. In this paper, we compare a glass chamber, Nylon-6 oven bags, and polyester (PET) oven bags. Using 10 functionally and structurally diverse chemicals produced by a wide range of plants, we assessed recoveries of headspace injected into static air sealed in the vessels for 30 min and recoveries when headspace was added to air drawn through the different vessels. We also investigated light absorption properties of the materials by spectrophotometry and measured the internal temperatures of the vessels vs. ambient temperatures. Finally, the glass chamber and the polyester bag were tested in the field by sampling volatiles from aphid-infested leaves from an apple tree growing in a commercial orchard.

Methods and Materials

Headspace Mixtures

Standards of (*E*)-2-hexenal, α -pinene, 6-methyl-5-hepten-2-one, (*Z*)-3-hexenyl acetate, limonene, linalool, citronellal, methyl salicylate, (*Z*)-jasmone, and (*E*)-caryophyllene were obtained from commercial suppliers (Sigma-Aldrich Company Ltd., Gillingham, Dorset, UK; Fluka, Buchs, Switzerland; Avocado, Heysham, Lancashire, UK). All chemicals were of $\geq 98\%$ purity except for citronellal, (*Z*)-jasmone, and (*E*)-caryophyllene that were of 87.5, 93.7, and 86.8% purity, respectively. Headspace mixtures were prepared in glass vessels (2 l) fitted with Teflon-backed silicone septa. To one vessel, (*E*)-2-hexenal, α -pinene, 6-methyl-5-hepten-2-one, (*Z*)-3-hexenyl acetate, and limonene (5 μ l of each) were added before sealing. Linalool, citronellal, methyl salicylate, (*E*)-caryophyllene (5 μ l of each), and (*Z*)-jasmone (100 μ l) were added to the other vessel before sealing, and these are referred to as mixture 1 and mixture 2. Both vessels containing headspace mixtures were kept in a dark incubator (20°C, Sanyo MIR 152, Watford, Hertfordshire, UK), and the vessels were equilibrated for 24 hr before any samples were taken.

Vessels Used as Enclosures

A cylindrical borosilicate glass jar (30.8 cm \times 11.1 cm \times 3.5 mm thick) with a ground glass flange at one end was selected as an aeration chamber. The jar had threaded fittings on the top end (outlet) and on the side near the flange (inlet). The base was sealed using an aluminum plate bound tight using PTFE tape and clamped onto the flange. The inlet near the flange was sealed using a Teflon-backed silicone septum, and the outlet on the top of the vessel was sealed using two bands of PTFE tape onto which a prebored (5 mm), Teflon-backed silicone septum was tightened.

Unless specified, plants are intact and have not been excised; table ordered according to bag description.

Two different plastic bags were used: Turkey Roasting Bags (Nylon-6, volume 10 liters, ~20- μ m thickness, max. 200°C, Baco Consumer Products Ltd., Amersham, UK) and Multi-Purpose Cooking Bags [poly(ethyleneterephthalate) or PET, volume 3.2 liters, ~12.5- μ m thickness, max. 200°C, Sainsbury’s Supermarkets Ltd., London, UK]. Bags were fitted with threaded glass tube inserts (5 cm long, 8 mm i.d.) fixed using UNEX tubing clips (Fisher Scientific UK Ltd., Loughborough, Leicestershire, UK). The inlet was fitted to the middle of the open end of the bag, and the outlet was fitted to a corner of the bag after cutting off with scissors. Inlet and outlet inserts were closed with Teflon-backed septa as above.

The glass jar, aluminum plate, and threaded glass inserts were cleaned using detergent, acetone, and distilled water before baking overnight in an oven (200°C). Soon after purchase, bags were always removed from packaging and nylon tags discarded (included in both bag types). Bags were then stored in the laboratory until

required. To clean, the nylon bags were opened and baked in an oven (120°C, 4 hr) before fitting the glass inserts and stored overnight in an incubator (50°C; Sanyo MIR 152) while inflated and with activated charcoal filtered air flowing through (1 l/min). The polyester bags were relatively clean and were opened and baked in an oven (120°C) for 2 hr. Before experiments, both bags were inflated with clean air and then deflated three times to remove any residual contamination.

Headspace Recovery

All headspace samples were trapped on Tenax TA (50 mg, mesh 60–80, Supelco, Bellefonte, PA, USA) held in injector liners (81 mm long, o.d. 5 mm, i.d. 3.2 mm) by plugs of silanized glass wool. Before use, filled liners were washed with redistilled diethyl ether (5 ml) and thermally desorbed under a slow flow of purified nitrogen (225°C, 2 hr). Recoveries of chemicals from the glass vessel or plastic bags were always paired to a control sample from the headspace source that was taken and analyzed about an hour previous to that replicate. A closed loop system was used, consisting of a diaphragm pump (12 V, KNF Neuberger, Germany), flow meter, activated charcoal filter, and glass tube, connected together with Teflon tubing (i.d. 1.5 mm). The glass tube was fitted with an inlet, an outlet with screw adapter holding a Tenax-filled liner, and sidearm with Teflon-backed septum allowing injection of materials onto the neck of the liner. For controls, headspace samples of mixture 1 (100 µl) and mixture 2 (1 ml) were injected onto the liner with gas-tight syringes such that the mixtures were immediately pulled onto the Tenax (1 l/min), and airflow was maintained for 30 sec.

For static headspace sampling, the glass jar or bags were first flushed (three times vessel volume) and inflated with clean air by means of a Pasteur pipette pushed through the intact septum fitted on the vessel inlet and connected by Teflon tubing to the pump and activated charcoal filter. The Pasteur pipette was then removed, and headspace samples of mixtures 1 and 2 were injected through the same septum (100 µl and 1 ml, respectively). After 30 min, a Tenax-filled liner was pushed through the cored septum at the outlet and connected to the pump. The Pasteur pipette was then pushed through the inlet septum, thus completing the closed system. The pump was turned on (1 l/min), and the vessel was flushed through 10 times for the glass jar (30 min) or 5 times for the bags (10-l nylon, 50 min; 3-l polyester, 15 min). The bags were also collapsed by removing the Pasteur pipette, thus pulling the remaining air volume in the bag onto the Tenax.

For dynamic sampling, the glass jar or bag was incorporated in a closed loop system with pump, flowmeter, and charcoal filter. A three-way glass tube, as used for the preparation of control samples, was also connected to the inlet of the vessel. Thus, headspace samples could be added to the air entering the vessel by injecting through the septum in the sidearm of the inlet tube. A Tenax-filled liner was fitted to the outlet of the vessel and connected to the pump (circulating airflow of 1 l/min). After injection of headspace samples of mixtures 1 and 2 (100 µl and 1 ml, respectively) into the inflowing air, the experiment was run such that each vessel was flushed through five times (glass jar, 15 min; nylon bag, 50 min; polyester bag, 15 min).

Following observation of low recoveries of α -pinene, a breakthrough test was performed with two Tenax-filled liners held in series. Headspace mixtures were injected onto the neck of the first liner as above, and in different trials, airflow was thereafter maintained for 0.5, 2.5, 5, 10, or 20 min before analysis of the trapped volatiles.

Spectrophotometric Analyses

A sample of borosilicate glass was cut from the same source that was used to make the glass vessel. Samples were also taken from the nylon and polyester bags (after the cleaning process). Absorption (200–800 nm) was quantified on a spectrophotometer (U-2000, Hitachi, Maidenhead, Berkshire, UK) at 2-nm intervals.

Measurement of Vessel Internal Temperature

Glass and polyester vessels only were compared in this experiment because these were to be used in the field trial. Two experiments were performed: one in an exposed location and the other in the shadow of a large bush. The glass vessel was held horizontally, and aluminum base plates with a hole through the middle were clipped on as used in field experiments. Similarly, the polyester bag was inflated and held horizontally. A thermometer was inserted horizontally into each such that the thermometer bulbs were in the center of the vessels, and a third thermometer was held horizontally by a tripod to measure ambient air temperature. For both experiments, the temperatures of air, glass, and polyester vessels were recorded at the start of the experiment and every 10 min for 3 hr. Notes of weather conditions in the preceding 10 min were also taken. To reproduce the conditions of a real collection of volatiles from a plant, clean air was blown into the vessels (1.2 l/min) and drawn out onto a Tenax-filled liner (1 l/min), and this airflow was maintained throughout the experiments. For the experiment performed in the shadow of a large bush, at the end of the experiment, the vessels were brought into full sun, and their internal temperatures were recorded after 10 min to confirm that differences observed were not a day artifact.

Field Collections

Field entrainments were conducted in orchards belonging to the Leckford Fruit Farm, Leckford Estate, Hampshire, UK. Apples were Cox's Orange Pippins on MM106 rootstocks, and the tree entrained was infested by rosy apple aphids *Dysaphis plantaginea* (Passerini) (Homoptera: Aphididae). Entrainments were performed to compare the polyester and glass vessels only. A branch with aphid-infested leaves on the shaded side of the tree was selected and enclosed in a vessel. Air cleaned by activated charcoal was blown into the vessel (1.2 l/min), and headspace was drawn out through Tenax-filled liners at the outlet (1 l/min). The pumps were driven by using a car battery (12 V). Control sample was taken from an empty conainer before sampling from the branch to check for system/filter contamination (2 hr), and then the branch was sampled by using the polyester bag and then the glass vessel (2 hr each). For the polyester bag, the inlet was a glass tube (6 mm) that ran parallel to the branch and was held in place by a gardening twist-tie that also closed the bag around the plant. The outlet was a Tenax-filled glass liner fitted into a corner of the bag. The glass vessel was held in place by a tripod and was enclosed around the plant with two semicircular aluminum plates with a hole in the middle that allowed the branch to pass through (similar to Agelopoulos et al., 2000).

Analysis by Gas Chromatography

Entrainment samples were desorbed using an Optic 2 programmable injector (Anatune, Cambridge, UK) fitted to an Agilent 6890N gas chromatograph (GC) with a flame ionization detector. Injector conditions were equilibrated (1 min) then ramped from 30 to 220°C at 16°C/sec while operated in splitless mode. An HP-1 column (50 m × 0.32 mm i.d., 0.32- μ m film) was used. The carrier gas was helium (constant flow 30 cm/sec), and the oven temperature program was 30°C/2 min, 5°C/min to 150°C, then 10°C/min to 250°C and held for 6 min; detector temperature was 300°C. Data were processed by using ChemStation Plus software (Rev. A09.03). Compounds from the field entrainment were tentatively identified with Kovats indices and by thermal desorption on an Optic 2 injector fitted to a Hewlett-Packard 5890 series II GC linked to an HP 5972 mass selective detector using similar conditions to those described above.

Data Analyses

For the two recovery experiments, five replicates were carried out, and chemical recoveries were tested against respective controls by one-sample *t* tests. A two-way analysis of variance was used to determine whether differences and interactions existed between bags and headspace chemicals, and the Fisher least significant difference test was used to identify where such differences existed. UVC, B, A, visible, and infrared absorption chroma (% absorption within band) of spectrophotometric data were characterized, and absorption cutoff points (upper points of inflection) were calculated. Differences in spectrophotometric properties of the material were tested using a Freidman test. Internal temperature experiments were also analyzed by using a Freidman test. All data were analyzed on Minitab 13.1 (Minitab Inc., State College, PA, USA), and differences were considered significant if the probability of their occurrence by chance was less than 5%.

Results

Contamination

After cleaning, the glass chamber gave a low background, but it was difficult to completely eliminate minor contaminant peaks. When a polyester bag was taken directly from its cardboard packaging and sampled (15 min), significant background contamination was detected. The main contaminant was tentatively identified as isopropyl dodecanoate, and low levels of *n*-alkanes (C14–18) were identified, as were traces of some branched alkanes. Bags that had been baked (120°C, 2 hr) and inflated/deflated three times before sampling (1 hr at 1 l/min) were almost contamination free (at most, 2 ng when compared to detector responses for *n*-alkanes). No dimethyl terephthalate or ethylene glycol was detected in polyester bags. Greater contamination problems were associated with the Nylon-6 bags. Before baking, significant quantities of caprolactam (hexahydro-2*H*-azepin-2-one) could be collected, and this gave a broad fronting peak just after methyl salicylate. After baking and cleaning as above (see [Methods and Materials](#)), caprolactam was much reduced and occasionally absent. Other unidentified peaks (including two

Fig. 1 Recoveries of headspace injected into a glass vessel, inflated Nylon-6, and inflated polyester (PET) bags after allowing 30 min for chemicals to interact with the internal surfaces ($N = 5$)

phthalates) associated with bag contamination were observed, but their presence and abundance were quite variable.

Headspace Recoveries

In recoveries from static headspace, vessel material, headspace chemical, and interactive effects were all significant factors contributing toward the variation in

Fig. 2 Recoveries of headspace chemicals when injected into the air flowing through a glass vessel, inflated Nylon-6 bag, and an inflated polyester (PET) bag ($N = 5$)

Table 2 Summary of spectrophotometric data for vessel materials

Material	Absorption chroma bands (% total absorption in band)					Absorption cutoff ^a (nm)
	UVC, 10–280 nm	UVB, 280–320 nm	UVA, 320–400 nm	Visible, 400–700 nm	Infrared, 700–800 nm	
Glass	97.8	39.1	3.2	1.3	1.3	276
Nylon	50.7	10.0	6.9	2.2	2.2	228
Polyester	99.3	76.0	4.2	2.1	2.1	306

^a Midway between points of inflection.

recoveries in comparison to controls (Fig. 1; $P \leq 0.001$ for all), with less material recovered from the polyester bag than from the glass vessel or nylon bag ($P \leq 0.001$). For glass, by comparison to the controls, there were losses in recovery of α -pinene, limonene, and (*Z*)-jasmone ($P \leq 0.001$, $P = 0.02$, and $P \leq 0.001$, respectively). From nylon bags, there were losses of (*E*)-2-hexenal, α -pinene, (*Z*)-3-hexenyl acetate, limonene, linalool, methyl salicylate, and (*Z*)-jasmone when compared to the controls ($P = 0.016$, $P \leq 0.001$, $P = 0.009$, $P = 0.002$, $P = 0.049$, $P = 0.01$, and $P = 0.003$, respectively). For polyester bags, there were losses in recovery for all compounds when compared to the controls (all $P < 0.05$).

Fisher least significant difference tests were performed to see how material affected the ratios of headspace chemicals recovered. For glass, all chemicals were recovered equally except for α -pinene and (*Z*)-jasmone, for which recoveries were lower but no different from each other ($P \leq 0.001$). For nylon, all chemicals were recovered equally except for α -pinene that was lower than others and (*E*)-caryo-

Fig. 3 Percentage absorption of different wavelengths by the glass, Nylon-6, and polyester (PET) materials when tested over the 200- to 800-nm range. UVC (10–280 nm), B (280–320 nm), A (320–400 nm), visible (400–700 nm), and infrared (700–800 nm)

phyllene that was higher ($P \leq 0.001$). The latter observation was probably caused by an unidentified minor contaminant found in collections from empty nylon bags that coeluted with (*E*)-caryophyllene. For polyester bags, all chemicals were recovered equally except for α -pinene that was lower than all others ($P = 0.002$). Recoveries of (*Z*)-jasmone from all materials were different ($P \leq 0.001$), with recovery from nylon bags the highest, polyester intermediate, and glass the lowest.

As with recoveries from static air, for headspace recoveries from flowing air, vessel material, headspace chemical, and interactive effects were all factors contributing to variation (Fig. 2; $P \leq 0.001$ for all). α -Pinene and (*Z*)-jasmone were lost in the glass and polyester vessels (glass: both $P \leq 0.001$; polyester: $P = 0.002$ and $P = 0.008$, respectively), but for all other chemicals tested in these vessels, there were no changes in recovery in comparison to the controls. In the nylon vessel, there were losses of (*E*)-2-hexenal, α -pinene, limonene, citronellal ($P = 0.036$, $P \leq 0.001$, $P = 0.009$, $P = 0.04$, and $P \leq 0.001$, respectively), and an increase in linalool peak area ($P = 0.038$) when compared to the controls. The slight increase in linalool peak area was caused by an unidentified coeluting minor contaminant from the nylon bag. Fisher least significant difference tests for the glass vessel and polyester bag confirmed that all chemicals were recovered equally with the exception of α -pinene

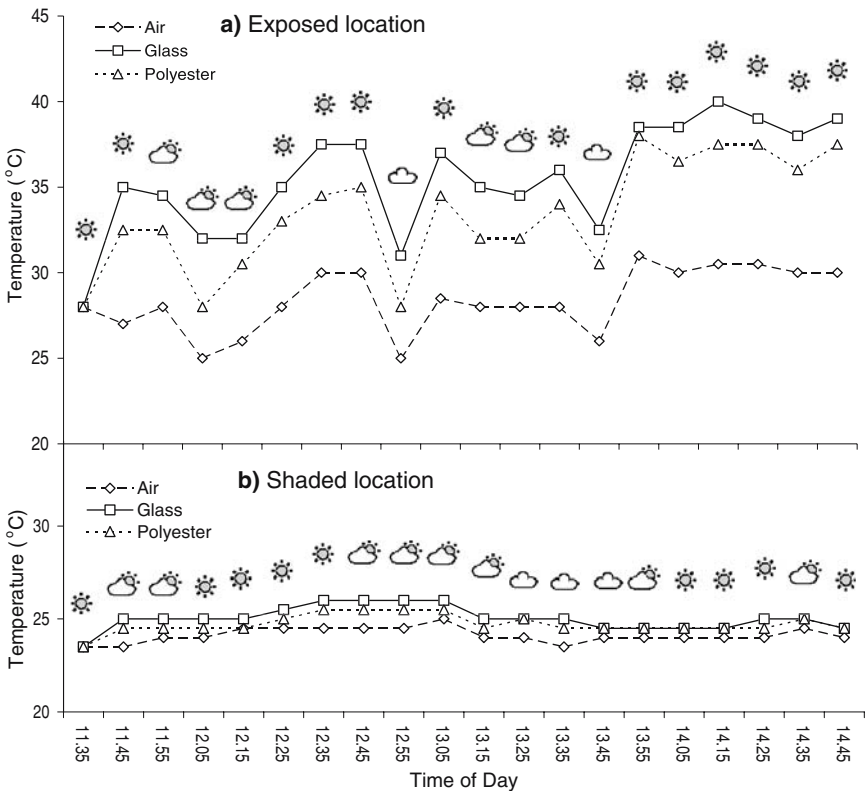

Fig. 4 Ambient temperature and internal temperatures of the glass vessel and polyester (PET) bag in a replicated dynamic entrainment conducted in (a) an exposed location and (b) the shadow of a large bush. Symbols indicate weather conditions in the 10 min preceding the temperature reading

and (*Z*)-jasmone, and hence ratios were preserved. For glass, recoveries of α -pinene and (*Z*)-jasmone were not significantly different, but for polyester, recovery of (*Z*)-jasmone was significantly higher than that of α -pinene.

Breakthrough

The breakthrough test showed that low recoveries of α -pinene in the above experiments were a result of breakthrough on the adsorbent. Within 30 sec, traces of α -pinene (<1 ng) were detected on the second liner held in series, and after 5 min, there was more α -pinene on the second liner than on the first. No breakthrough was detected for any of the other chemicals tested in the headspace mix.

Spectrophotometric Analyses

Although all the materials tested were essentially transparent to the human eye, there were differences in the light absorption properties of all these materials ($P \leq 0.001$), particularly in the UV range (Table 2; Fig. 3). Both glass and polyester had similar transmission properties in the IR, visible, and UVA ranges, allowing over 95% of the light through. Nylon absorbed slightly more light of these wavelengths, but the difference was small. The main differences in transmission were in the UVB

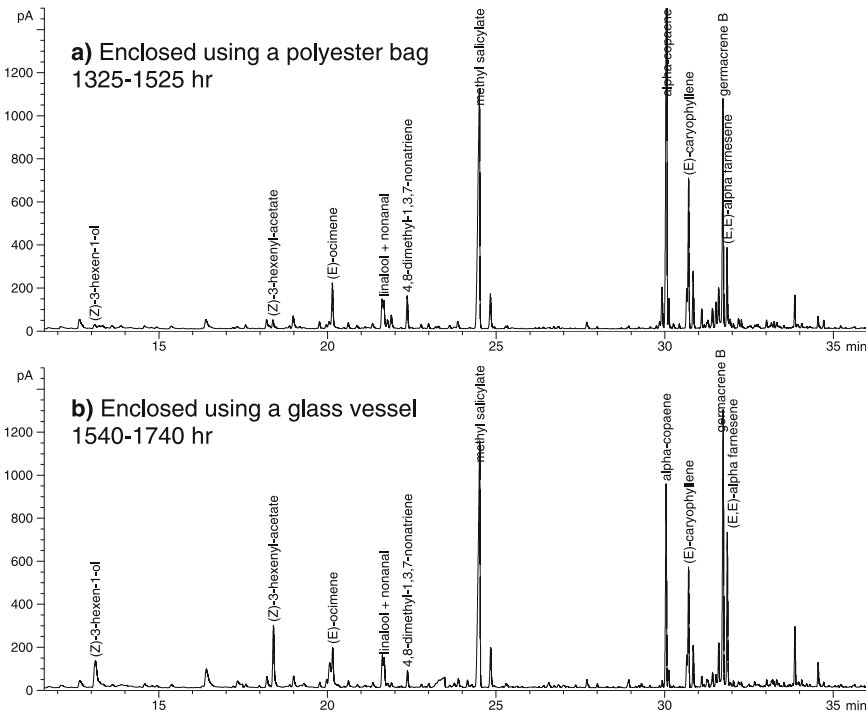

Fig. 5 Example of field entrainments from an apple tree infested with rosy apple aphids. Samples were captured on Tenax TA in a dynamic entrainment system, and plant parts were enclosed using (a) a polyester (PET) bag and (b) a glass vessel. Time of day during which samples were collected are indicated for both

range. Polyester absorbed most light in the UVB range (76%), glass about 40%, and nylon 10%. Both glass and polyester blocked all UVC, and nylon allowed about 50% transmission.

Measurement of Vessel Internal Temperature

In simulated dynamic entrainments conducted in full sun, the internal temperatures of both the glass and polyester vessels were higher than the ambient air ($P \leq 0.001$; Fig. 4a). On average, the glass vessel was 7.5°C hotter and the polyester 5.2°C hotter. Maximum differences relative to ambient were 9.5 and 7.5°C, respectively. When simulated dynamic entrainments were conducted in the shade, the glass vessel was, on average, only 0.9°C hotter, and the polyester 0.6°C hotter than ambient, but these differences were significant ($P \leq 0.001$; Fig. 4b). Although vessels were always marginally hotter than ambient when shaded, the presence/absence of cloud did not cause rapid fluctuations in temperature as observed for exposed vessels (Fig. 4a). At the end of the shaded experiment, when the vessels were taken from the shade and placed in full sun, after 10 min, ambient air, glass, and polyester temperatures were recorded as 26.0, 33.5, and 29.5°C, respectively.

Field Entrainments

The glass vessel and polyester bags performed similarly when tested in field entrainments (Fig. 5). No significant contamination was detected from the bag, and the small differences seen between the enclosures might be attributable to time-of-day effects.

Discussion

Chemical ecologists trying to identify plant volatile blends accurately and/or understand their roles in plant–plant or plant–insect systems need to be able to sample from unexcised plants, ideally both in the laboratory and in the natural environment. Indeed, for rare plants or tree species, sampling in the natural environment might be the only option.

Previous reports and the work described here show that enclosing a plant in a glass vessel with guillotine-type seal and push–pull airflow gives good results in terms of low levels of contamination and good recovery for most volatile compounds. However, much of this equipment is not readily available and is expensive to make. As a result, sample replication in the field is difficult because collections are limited by the number of vessels available and the need for these to be cleaned between collections. Furthermore, the bulk and fragility of glass apparatus makes it inconvenient for carrying to the field and, once in the field, requires substantial devices to hold it in position. The inflexibility of the chamber can also lead to damage of the enclosed plant or plant part. Enclosure of plants in disposable plastic bags can avoid many of these difficulties. When used with the push–pull airflow system, the bag will remain inflated and, to some degree, self-supported. In the field, additional support can be easily improvised to avoid plant injury. From a survey of the literature, bags made of polyester seem to be most commonly used for collection of plant/leaf volatiles, whereas bags made from poly(vinyl acetate) seem to be the most common

material used in floral collections (see Table 1). There is no obvious reason for this, and some have questioned whether bag materials are optimal or simply used because of lack of evidence to the contrary (Raguso and Pellmyr, 1998). One source of confusion we encountered was in the bag terminology (see Table 1). More precise and standardized descriptions are desirable, such as common name, chemical name, supplier, and dimensions. Similarly, descriptions of the actual entrainment systems were generally vague. Better descriptions of experimental methodology would help other workers with their collection methods, and also support meaningful comparative work, e.g., across taxa.

Contamination

Clean gas sampling bags made from Tedlar or Teflon are available (e.g., Alltech UK Ltd., Stamford, Lincolnshire, UK), and these come with centrally positioned molded fittings to attach inlet and outlet sources. Although these bags could be cut open and used for field entrainments, a bag of similar size to the polyester bags used in experiments costs about 200 times more. As a result, cost makes these bags unsuitable for repeated field sampling.

Chemical contamination was a particular problem with the Nylon-6 oven bags, and we tentatively identified the principal contaminant as caprolactam, the starting monomer that is used to manufacture Nylon-6 by ring opening polymerization. Numerous other contaminants were observed, and the amounts of these were variable. Another problem we found with the Nylon-6 bags was that they could contaminate glassware in the oven if baked together, so we developed our two-stage cleaning method. This solution was not really practical nor was it consistently satisfactory. Other cleaning methods, such as baking in a vacuum oven, might further reduce the level of impurities and make such bags usable. In contrast, it was easy to purge contaminants from polyester oven bags. High-temperature baking, however, was detrimental to these bags because seams became brittle and cracked, causing leakage. Nevertheless, other workers have tailor-made bags from polyester tubing by heat-sealing an end (Kalberer et al., 2001). Reports from the food industry indicate that polyester heated up to 270°C (melting) does not release artifacts or other volatiles (Freire et al., 1999), and such tailor making of bags to fit particular plant shapes offers great versatility. Unlike Nylon-6 bags, we did not detect the monomers used in the manufacture of polyester, dimethyl terephthalate, or ethylene glycol. Contamination that was detected might have come from the printed packaging or the machinery used during manufacture. Despite low levels of contamination in polyester bags and glass vessels, it is always good practice to take control blank entrainments before use in experiments.

Recovery of Volatiles

In our experiments, there were consistently low recoveries of two chemicals, α -pinene and (*Z*)-jasnone. For α -pinene, this was caused by breakthrough on the Tenax TA adsorbent. Because control samples were prepared by pulling headspace onto the Tenax TA for 30 sec, breakthrough would not have affected their preparation. Although we have not conclusively explained the behavior of (*Z*)-jasnone, our experiments provide circumstantial evidence for strong absorption onto glass. We

checked that loss was not to the aluminum base plate by running trials in which a sheet of glass replaced the aluminum and still obtained poor recoveries of (*Z*)-jasmane (data not shown). In preparation of the headspace mixtures in glass vessels, 100 μl of (*Z*)-jasmane headspace were required to give a headspace concentration comparable to those of the other compounds for which only 5 μl were required. Furthermore, in both recovery experiments, loss of (*Z*)-jasmane was greatest in the glass vessel. We also recorded similar behavior for methyl jasmonate with glass (data not shown). Adsorption of other volatiles onto glass because of interactions between hydroxyl groups or the π electrons of a double bond has been reported, and double-bond interactions were strongest when bonds were in the (*Z*)-configuration (Shani and Clearwater, 1997). Glass surfaces should, therefore, be deactivated, but, with few exceptions (e.g., Zini et al., 2003), this is rarely carried out.

The static headspace experiments were designed to test the different materials rigorously for chemical porosity and absorbence. Apart from α -pinene and (*Z*)-jasmane, there were good headspace recoveries from the glass vessel, and the ratios between compounds were well preserved. There were greater losses of some chemicals in the nylon bag, suggesting that some had absorbed or diffused out, and a slight distortion of ratios. Interestingly, (*Z*)-jasmane was recovered well in the headspace from this material, reinforcing ideas of selective absorption onto glass. Recoveries were poor for all compounds when sealed in the polyester bag for 30 min. The data suggest that this bag material, which was very thin (about 12.5- μm thickness), might be chemically porous, and that significant outward diffusion takes place relatively quickly. Although there was significant quantitative loss, the polyester was qualitatively better than the nylon. The polyester bags that we used are, therefore, not effective for the sampling of headspace in sealed systems, e.g., by SPME. Nylon bags would be better, although there would be some loss/distortion, and our experiment only sealed headspace for 30 min. Nylon bags have been used for the creation of enriched floral headspace (15 min) and subsequent SPME sampling (15 min; Raguso et al., 2003). Overall, we found the glass vessel to be most suitable for the sealing of headspace and later sampling.

The dynamic headspace experiments were designed to test the suitability of the different materials for continuous headspace sampling. By adding chemicals to the air blowing/being-pulled through the vessel, we tried to replicate the way chemicals might be pulled away from plants as they are released. With the exception of α -pinene and (*Z*)-jasmane, there were excellent recoveries and preservation of ratios for both the glass and polyester materials, indicating that both would be suitable for dynamic headspace entrainments. As used in our experiments, we would recommend relatively high flow rates to vessel volume (e.g. 1:3). The moderate loss of (*Z*)-jasmane in the polyester system was puzzling and may have occurred because a glass insert was used at both the inlet and outlet ends of the bag. The inclusion of the insert was necessary at the inlet for both static and dynamic recovery experiments but would have only been necessary at the outlet for the static recoveries experiment. However, for experimental consistency, we also included the glass insert at the outlet for the second laboratory experiment as well as for the field entrainment. In future field entrainments, it would be better not to include a glass insert and to fix the liner into the cut corner of the bag using several twists of wire. Nylon performed badly in the dynamic headspace experiment, and significant distortion of relative ratios occurred. This may have been caused by the relatively

voluminous nature of the bag as well as by the presence of a number of low-level background contaminants.

Spectrophotometric Properties

Photosynthetic available radiation roughly corresponds to what humans describe as visible light (400–700 nm), so if a material is transparent, it should not interfere with photosynthetic processes within a plant. The spectrophotometric study confirmed that little visible light was absorbed, and also showed that IR and UVA absorption was slight for all materials. UVA is not absorbed by the ozone layer and reaches the earth's surface, so translucence in this bandwidth by all materials was important. UVB is only partially absorbed by the ozone layer, and so would also reach plants growing naturally *in situ*. Glass (5-mm thickness) did absorb some UVB (39%), whereas the polyester bag (~12.5 µm thick) was an effective UVB screen (76%) due to the benzene rings in the polymer. However, such reduction of UVB is unlikely to unnaturally stress the plants because they grow well in greenhouses (reduced UVB) and are exposed to natural daily variations in UVB (e.g., clouds). UVC does not penetrate the atmosphere and does not reach the surface of the earth; therefore, strong absorption in this band range by all the materials is irrelevant. Overall, the polyester was optically more similar to the glass than was the nylon.

Temperature Effects

It was expected that enclosure would raise internal vessel temperatures by a “greenhouse effect.” When tested in an exposed area, internal temperatures of both the glass and polyester vessels increased, even when there was cloud cover. For glass and polyester, average increases of 7.5 and 5.2°C were calculated, and maximum differences above ambient were 9.5 and 7.5°C. From a temperature perspective, this smaller increase makes polyester marginally better than glass. The temperature effect was almost immediate such that within 10 min, the temperatures were elevated to levels that were typical for within the enclosure. These recorded internal temperatures, however, may have been lower than would occur during an actual headspace collection from plants because the vessels did not include the dark foliage of plants or water vapor resulting from evapotranspiration. Both these factors might further contribute to a warming effect. Indeed, under natural light in a greenhouse, workers have reported a glass vessel internal temperature to reach 38°C (Paré and Tumlinson, 1997). In contrast, under artificial lighting using bags, only 1°C increases have been reported (Zhang et al., 1999). This small increase in temperature was similar to the increases we recorded from outdoor entrainments in the shade (average increase of 0.9 and 0.6°C for glass and polyester, respectively). Whereas elevated temperatures might be advantageous in the short term due to increased release rates of volatiles from the plant, extended periods at elevated temperatures during entrainment might also initiate the release of stress-related compounds. Monoterpene emission rates have been reported to increase exponentially with temperature from a number of tree species (Dement et al., 1975; Kamiyama et al., 1978; Guenther et al., 1991; Tingey et al., 1991). However, others have reported a plateauing effect for all volatiles with little increase in emissions above 24–32°C, possibly caused by the closing of stomata (Zhang et al., 1999), and even a decrease in induced emissions beyond 27°C (Gouinguene and Turlings, 2002). Although field

entrainments are desirable, conducting them in full sun clearly creates problems. Higher flow rates relative to vessel volume may help, but we suggest shading with netting or an umbrella. Although artificial, this should avoid excessive heating of a plant. Such overheating problems should not affect entrainments conducted under forest canopy or in shadow.

Field Sampling

When volatiles were collected from aphid-infested leaves on an apple tree in the field, samples collected using polyester were not significantly different from those collected using the glass vessel. Although use of cut plants in the laboratory is a convenient way to isolate electrophysiologically/behaviorally active chemicals, it is important to confirm that such compounds are also released from unexcised plants growing in their natural habitat. Indeed, some authors have voiced concern over the commonplace extrapolation from controlled laboratory experiments, often on seedling crop plants, into wider ecological generalizations occurring in the field (van der Meijden and Klinkhamer, 2000). Furthermore, it is known that for a number of species, there is a great genotypic variation in the release of tritrophic defense volatiles (Loughrin et al., 1994; Turlings et al., 1998b), and some “silent” genotypes that do not release such volatiles have been identified (Halitschke et al., 2000). Examples reiterate the importance of field sampling, where the role of plant volatiles can be properly assessed in fitness terms and in the appropriate ecological/habitat context. Both qualitative and quantitative assessments under field conditions are required to determine whether, at these realistic levels, volatiles have significant plant fitness effects. Quantitation is particularly important because plants in the field may be stressed by a multitude of abiotic and biotic factors that may draw antagonistically on the same resource pool.

In summary, of the materials tested, both in the laboratory and in the field, we found polyester bags to perform well in dynamic headspace entrainments. Under dynamic entrainment conditions in the laboratory, polyester bags actually performed better than the borosilicate glass because of problems of adsorption onto the glass. Furthermore, polyester is optically similar to glass, but might be better than glass in the field because it created less of a greenhouse effect. The bags are cheap, easy to set up and use, and well suited for use in push–pull entrainment systems. We hope our results will encourage more widespread use of polyester bags for enclosing intact plants or plant parts during headspace sampling in the field. Such replicated *de vivo* and *in situ* sampling will contribute to the task of increasing our understanding of plant volatile chemistry and ecological function.

Acknowledgments This work was supported by funds from the Department for the Environment, Food and Rural Affairs. The Leckford Estate kindly granted permission to use their apple orchards, and project collaborators at East Malling Research and Rothamsted Research provided useful discussion.

Abstract Gas chromatography–electroantennographic detection analysis of sex pheromone gland extracts of the common forest looper *Pseudocoremia suavis* (Lepidoptera: Geometridae), a polyphagous defoliator of introduced Pinaceae and many New Zealand trees, revealed four compounds that elicited antennal responses. The two major active compounds (6Z)-*cis*-9,10-epoxynonadec-6-ene and (3Z,6Z)-*cis*-9,10-epoxynonadeca-3,6-diene were identified by comparison with known standards. Of the two minor active compounds, one was tentatively identified as (3Z,6Z)-*cis*-9,10-epoxyhenicosa-3,6-diene, whereas the other could not be identified because of insufficient amounts in extracts. (6Z)-*cis*-9,10-Epoxynonadec-6-ene, (3Z,6Z)-*cis*-9,10-epoxynonadeca-3,6-diene, and (3Z,6Z)-*cis*-9,10-epoxyhenicosa-3,6-diene were present in *P. suavis* gland extracts from Eyrewell Forest, a *Pinus radiata* plantation in the South Island of New Zealand, in a ratio of 35:65:5, respectively. Trapping trials in Eyrewell Forest established that (6Z)-*cis*-9,10-epoxynonadec-6-ene attracted male *P. suavis*. However, addition of (3Z,6Z)-*cis*-9,10-epoxyhenicosa-3,6-diene to the lure at <10% of (6Z)-*cis*-9,10-epoxynonadec-6-

ene reduced capture of male moths, suggesting that one of its enantiomers was acting as a behavioral antagonist. During January–March of 2005, a blend trial involving single, binary, and ternary mixtures of the three components at Eyrewell Forest and at three other sites (two in the South Island and one in the North Island) revealed the existence of a second taxon of *P. suavis* at the three additional sites that was attracted to lures containing (3Z,6Z)-*cis*-9,10-epoxynonadeca-3,6-diene, either singly or in binary and ternary mixtures with (6Z)-*cis*-9,10-epoxynonadec-6-ene and (3Z,6Z)-*cis*-9,10-epoxyhenicosa-3,6-diene. This second taxon was not attracted to lures loaded solely with (6Z)-*cis*-9,10-epoxynonadec-6-ene.

Introduction

The common forest looper *Pseudocoremia suavis* (Butler) (Lepidoptera: Geometridae) is a polyphagous moth endemic to New Zealand, the larvae of which eat the leaves of a wide variety of native and exotic trees and shrubs, including southern beech (*Nothofagus* spp., Nothofagaceae), Podocarpaceae, and introduced Pinaceae (Dugdale, 1958; Stephens, 2001). In the 1950s and 1960s, *P. suavis* was responsible for major defoliation in *Pinus radiata* (D. Don) plantations at Eyrewell Forest (North Canterbury, South Island, NZ; White, 1974), and in the 1970s, it also caused considerable damage in Douglas fir [*Pseudotsuga menziesii* (Mirb.) Franco] stands in Kaingaroa Forest (Bay of Plenty, North Island, NZ; Alma, 1977).

There are over 30 species of *Pseudocoremia* in New Zealand (Stephens, 2001). The genus is endemic to New Zealand and Norfolk Island, but has close affinities to geometrids from the Western Pacific (Dugdale, 1989). Both males and females of *P. suavis* are known to demonstrate developmental polymorphism, and the species appears not to have clearly synchronized generations (Berndt et al., 2004).

Our objective was to identify the sex pheromone of *P. suavis* as a tool for further study of its ecology and phenology, and for detection and delimitation surveys. A sex pheromone may also be useful for controlling future outbreaks by using mating disruption, lure and kill, or mass trapping technologies (e.g., Suckling and Karg, 2000).

To date, sex pheromones or attractants have been identified for more than 120 geometrids but none from the genus *Pseudocoremia* (El-Sayed, 2006). Typically, geometrids have sex pheromones consisting of single or multicomponent blends of unsaturated hydrocarbons and/or epoxides, with enantiomeric specificity often serving as a species-isolating mechanism (Mori, 1998; Millar, 2000; Ando et al., 2004). These types of compounds have also been identified from the pheromone glands of lymantriids, arctiids, noctuids, pyralids, and crambids (Ando et al., 2004; El-Sayed, 2006).

In this study, we describe the identification of two compounds in pheromone gland extracts of *P. suavis* from Eyrewell Forest, by gas chromatography–electro-

antennographic detection (GC-EAD) and gas chromatography–mass spectrometry (GC-MS) analysis, and confirm their biological activity with field bioassays. We also establish that *P. suavis* is likely to be a species complex with two distinct pheromone taxa that so far are only distinguishable by differential attraction to pheromone components and by geographic location. This is also the first identification of a sex pheromone of a New Zealand geometrid.

Methods and Materials

Insects

A colony of *P. suavis* was established at Forest Research (now Ensis), Christchurch, with material gathered from Eyrewell Forest, a pine plantation in North Canterbury (43.4170°S, 172.4235°E; see Berndt et al., 2004). Pupae were placed individually in plastic containers (Lily[®] 35-ml portion cups with lids, Huhtamaki Henderson Ltd., Auckland, NZ) at HortResearch, Lincoln, under a 12-hr light/12-hr dark reverse photophase lighting regime, at 22°C and 50% RH. Newly emerged female *P. suavis* were transferred to a humidified, 350-mm³ clear polycarbonate plastic box and provided with 10% sugar solution.

Pheromone Gland Extracts

The pheromone glands of 24- to 48-hr-old female moths were excised and placed into 20–30 µl of *n*-hexane (BDH Laboratory Supplies, Poole, UK), contained within a liquid-nitrogen-cooled 0.5-ml conical vial (Wheaton, Millville, NJ, USA). Gland extracts were taken from females 2–3 hr into the scotophase, when moths were actively calling. After all glands had been excised, the vial and its contents were brought to room temperature, and the liquid phase was transferred to a 1.1-ml conical glass vial (Alltech, Deerfield, IL, USA). The volume of extract was then reduced to 10 µl by using a stream of argon and was then stored at –18°C.

Gas Chromatography–Electroantennographic Detection

Pheromone gland extracts of *P. suavis* females were analyzed by GC-EAD with a Varian 3800 GC equipped with two columns of differing polarity, coupled to an EAD Recording Unit (Syntech, Hilversum, The Netherlands). Extracts were run on DB-5 (30 m × 0.25 mm ID × 0.5 µm film; Agilent Technologies, Palo Alto, CA, USA) and DB-Wax columns (30 m × 0.25 mm ID × 0.5 µm film; Agilent) with 1:1 split outlets. Helium was used as carrier gas (1 ml/min), and injections were in splitless mode. Injector and detector temperatures were 220 and 300°C, respectively, and the GC oven was programmed from 80°C/min to 240°C at 10°C/min, hold 35 min. An excised male *P. suavis* antenna was positioned between two glass electrodes containing BE Ringer's solution with 10% polyvinylpyrrolidone (molecular weight 360,000; Sigma Chemical Co., North Parramatta, NSW, Australia). Each glass electrode held a length of 1-mm silver wire to connect the preparation to the recording unit. The EAD exit port temperature was maintained at 200°C, and the antennal preparation was placed in a charcoal-filtered and humidified airstream (400 ml/min). Kováts retention indexes (KIs; Kováts, 1965; Marques et al., 2000) were

calculated for the compounds that elicited strong antennal responses to compare relative retention times.

Gas Chromatography–Mass Spectrometry

The retention times and mass spectra of the active compounds in a *P. suavis* pheromone gland extract [1 μ l = 5.8 FE (female equivalents/aliquot)] were compared with those of known standards on BPX-70 (30 m \times 0.25 mm ID \times 0.25 μ m film; SGE, Victoria, Australia) and VF-5ms (30 m \times 0.25 mm ID \times 0.25 μ m film; Varian Inc., Walnut Creek, CA, USA) columns, by using a Varian 3800 GC in splitless mode, coupled to a Varian 2200 MS. Helium was used as carrier gas (1 ml/min) with the transfer line at 250°C and the ion trap temperature at 200°C. The GC injector temperature was set at 220°C, and the oven was programmed from 80°C/min to 140°C at 10°C/min, hold 5 min, then to 200°C at 5°C/min, hold 25 min (BPX-70 column), or 80°C/min to 240°C at 10°C/min, hold 35 min (VF-5ms column).

Chemicals

(6*Z*)-*cis*-9,10-Epoxynonadec-6-ene (6*Z*-*cis*-9,10-epo-19Hy) and (3*Z*,6*Z*)-*cis*-9,10-epoxynonadeca-3,6-diene (3*Z*,6*Z*-*cis*-9,10-epo-19Hy) were synthesized at HortResearch, Palmerston North (see below). Samples of (3*Z*,6*Z*)-*cis*-9,10-epoxyhenicosa-3,6-diene (3*Z*,6*Z*-*cis*-9,10-epo-21Hy), (3*Z*,6*Z*)-9*S*,10*R*-epoxyhenicosa-3,6-diene, and (3*Z*,6*Z*)-9*R*,10*S*-epoxyhenicosa-3,6-diene were supplied by T. Ando, Tokyo University of Agriculture and Technology. (6*Z*)-9*S*,10*R*-Epoxyhenicos-6-ene (6*Z*-9*S*,10*R*-epo-21Hy) was available from previous work (El-Sayed et al., 2005).

Synthesis of Mono- and Diunsaturated Racemic Epoxides

6Z-cis-9,10-Epo-19Hy. 6*Z*-*cis*-9,10-Epo-19Hy was synthesized by the methods of Zhang et al. (1999) and Soulie and Lallemand (1995). The final step (reduction of the triple bond with Lindlar's catalyst) was carried out at 0°C, and the final product contained less than 2% of the *E* isomer. A small quantity of *E*-isomer-enriched (25%) final product was also produced for GC analysis by carrying out the same reaction at room temperature. 6*Z*-*cis*-9,10-epo-19Hy: ¹H NMR (CDCl₃, 400 MHz): δ (ppm) 5.50 (1H, m), 5.38 (1H, m), 2.90 (2H, m), 2.35 (1H, dt, *J* = 13.4 Hz, 6.4 Hz), 2.15 (1H, dt, *J* = 13.4 Hz, 6.7 Hz), 2.01 (2H, q, *J* = 6.9 Hz), 1.50 (4H, m), 1.24 (18H, m), 0.86 (3H, t, *J* = 6.9 Hz), 0.85 (3H, t, *J* = 6.9 Hz). ¹³C NMR (CDCl₃, 100 MHz): δ (ppm) 132.71, 123.81, 57.24, 56.58, 31.90, 31.50, 29.58, 29.58, 29.53, 29.31, 29.25, 27.79, 27.42, 26.61, 26.22, 22.68, 22.57, 14.21, 14.06.

3*Z*,6*Z*-*cis*-9,10-Epo-19Hy

3*Z*,6*Z*-*cis*-9,10-Epo-19Hy and its regioisomers (3*Z*,9*Z*)-*cis*-6,7-epoxynonadeca-3,9-diene (3*Z*,9*Z*-*cis*-6,7-epo-19Hy) and (6*Z*,9*Z*)-*cis*-3,4-epoxynonadeca-6,9-diene (6*Z*,9*Z*-*cis*-3,4-epo-19Hy) were synthesized by the method of Ando et al. (1993). 3*Z*,6*Z*-*cis*-9,10-epo-19Hy: ¹H NMR (CDCl₃, 400 MHz): 5.43 (3H, m), 5.27 (1H, m), 2.91 (2H, m), 2.77 (2H, t, *J* = 7.0 Hz), 2.37 (1H, m), 2.19 (1H, m), 2.04 (2H, pent, *J* = 7.3 Hz), 1.5 (4H, m), 1.24 (12H, m), 0.94 (3H, t, *J* = 7.5 Hz), 0.85 (3H, t, *J* = 6.7 Hz).

^{13}C NMR (CDCl_3 , 100 MHz): 132.65, 131.18, 127.08, 124.63, 57.65, 56.86, 32.30, 29.98, 29.98, 29.94, 29.72, 28.19, 27.02, 26.65, 26.13, 23.10, 20.99, 14.67, 14.54.

Field Bioassays—Eyrewell Forest Trials 1–5

An initial series of bioassays (Trials 1–5) were carried out in mature stands of *P. radiata* in Eyrewell Forest, during December 2004 and January 2005. In all trials, either green delta traps (Clare et al., 2000) or green Unitrap (International Pheromone Systems Ltd., Cheshire, UK) bucket traps were suspended from rope strung between two pine trees at a height of 2 m, with >20-m spacing between treatments and >100-m spacing between replicates. Trap positions within each replicate were rerandomized, and sticky inserts were replaced at each check for capture of male *P. suavis*. Test compounds were loaded onto red rubber septa (Thomas Scientific Inc., Philadelphia, PA, USA).

- Trial 1. Trial 1 (December 7–14, 2004) investigated the attraction of *P. suavis* males to various combinations of the three candidate racemic epoxides, based on ratios established from analysis of *P. suavis* gland extracts by GC. Delta traps were checked four times at intervals of 1–2 d. Treatments were (1) blank control, (2) 100:0:0, (3) 0:100:0, (4) 35:65:0, and (5) 35:65:5 μg loadings of 6Z-*cis*-9,10-epo-19Hy, 3Z,6Z-*cis*-9,10-epo-19Hy, and 3Z,6Z-*cis*-9,10-epo-21Hy ($N = 5$).
- Trial 2. A dose response trial based on treatment 2 (6Z-*cis*-9,10-epo-19Hy) from trial 1 was set up from December 14 to 20, 2004. Delta traps were checked four times at intervals of 1–3 d. Treatments were (1) blank control, (2) 10, (3) 100, and (4) 1000 μg doses of 6Z-*cis*-9,10-epo-19Hy ($N = 4$).
- Trial 3. A third trial was undertaken from January 26 to February 14, 2005 to investigate whether the addition of 3Z,6Z-*cis*-9,10-epo-19Hy to lures inhibited capture of male *P. suavis*. Delta traps were checked six times at intervals of 3–4 d. Treatments were (1) blank control, (2) 100:0, (3) 99.35:0.65, (4) 93.5:6.5, (5) 35:65, and (6) 35:0 μg loadings of 6Z-*cis*-9,10-epo-19Hy and 3Z,6Z-*cis*-9,10-epo-19Hy ($N = 5$).
- Trial 4. During trials 2 and 3, on several occasions, traps captured >20 male moths in a 3- to 4-d period. Because of the relatively large size of *P. suavis* (wingspan of c. 30 mm), trap saturation was likely to be a problem. Therefore, in trial 4, we investigated nonsaturating bucket traps for capture of *P. suavis* males. We were also interested in establishing an alternative to the use of dichlorvos strips (Agrisense-BCS Ltd., Pontypridd, UK) as the insecticide “knockdown” component of this system because of availability and toxicity concerns. We compared trap catch of *P. suavis* males in delta traps with trap catch in bucket traps containing either (1) dichlorvos strips, (2) diazinon strips [20-mm strips of dog flea collar (Vitapet Corp. Ltd., Gracefield, NZ) with 15% diazinon as the active ingredient], or (3) 200 ml of water plus 5 ml of 200 Fluid 350 cs paraffin oil (Ajax Chemicals, Auckland, NZ).

Trial 4 ran from December 20 to 24, 2004 with traps checked daily between 0800 and 1000 hr ($N = 5$). Septa were loaded with 100 μg of 6Z-

cis-9,10-epo-19Hy. Bucket traps were opened inside a polyethylene bag to avoid the loss of live males. Numbers of live and dead moths in each bucket trap treatment and the delta trap treatment were recorded.

Trial 5. Trial 5 (December 24, 2004 to January 19, 2005) compared trap catch in delta traps and the bucket trap oil-and-water-system over a 4-wk period using lures loaded with 100 µg of 6*Z*-*cis*-9,10-epo-19Hy. Traps were checked every 7–10 d, rotating the positions of each trap type at each count date.

P. suavis Taxa Trial

To discover how widespread *P. suavis* was in exotic forestry blocks in the Canterbury region, we placed a replicate of trial 1 in a small south-facing, hillside forestry block at Cass Bay in Lyttelton Harbor, Banks Peninsula (43.5984°S, 172.6902°E), from December 26, 2004 to January 6, 2005.

A last trapping trial was set up in early 2005 (same treatments as trial 1) to investigate the possibility of *P. suavis* comprising more than one taxon, e.g., cryptic species. It was undertaken at three sites on the South Island in Canterbury: Eyrewell Forest (February 15–March 9, $N = 5$, traps checked five times at intervals of 3–5 d); Burnham Plantation, Kerrs Road, Burnham (43.5793°S, 172.3399°E; February 8–March 8, $N = 5$, traps checked five times at intervals of 3–4 d, except for the last occasion when traps were left for 15 d because of low catches during that period); Cass Bay (January 21–March 7, $N = 3$, traps checked six times at intervals of 5–7 d, except for the last occasion when traps were left for 12 d), and one site in the North Island [Forest Research/Ensis campus, Rotorua (38.1615°S, 176.2669°E); February 17–March 7, $N = 3$, traps checked five times at intervals of 3–4 d]. These trials were run concurrently to avoid temporal differences in response by *P. suavis* males to the candidate pheromone components (e.g., Steck et al., 1982; Szöcs et al., 1993). Green delta traps were used at all sites.

Statistical Analyses

Only treatments that trapped moths were included in the statistical analyses. For each trial, the sum of moths captured per trap was analyzed for treatment effects using analysis of variance (ANOVA; SAS Institute Inc., 1998). Residual plots were used to check the validity of the ANOVA assumptions, and $\log_{10}(x + 1)$ transformations of the summed captures were undertaken when necessary to remove variance heterogeneity. Means were compared by Fisher's protected least significant differences test ($P = 0.05$; SAS Institute Inc., 1998).

Results

Identification of Gland Components Eliciting Antennal Responses

Antennal responses were elicited by four compounds in gland extracts of *P. suavis* from Eyrewell Forest, only two of which (peaks 1 and 2, Fig. 1) gave peaks detectable by GC (KIs of 2052 and 2058, respectively, on the DB-5 column and 2341 and 2405, respectively, on the DB-Wax column). Male antennae were also screened

Fig. 1 Coupled gas chromatogram–electroantennogram of a *P. suavis* male antenna responding to compounds (**1**=6*Z*-*cis*-9,10-epo-19Hy, **2**=3*Z*,6*Z*-*cis*-9,10-epo-19Hy, **3**=unknown, and **4**=tentatively identified as 3*Z*,6*Z*-*cis*-9,10-epo-21Hy) in pheromone gland extracts, eluting from a DB-Wax column

with a range of synthetic standards of unsaturated hydrocarbons, epoxides, and ketones using GC-EAD analysis. From the standards tested, the diene monoepoxide 3*Z*,6*Z*-*cis*-9,10-epo-21Hy had retention times indistinguishable from those of compound **4** on both columns.

A search of the literature indicated that C19 trienes and the corresponding diunsaturated monoepoxides occur most frequently as sex attractants in the family Geometridae (El-Sayed, 2006), and comparison of the KIs for peaks **1** and **2** suggested that they might have differing degrees of unsaturation because their retention indices were relatively closer on the DB-5 column than the DB-Wax column. In addition, the relative retention times of compounds **2**, **3**, and **4** (Fig. 1) suggested that they could be a homologous series. Therefore, we hypothesized that compounds **1**–**4** were C19, C20, or C21 diene or triene alkenes, or the corresponding mono- and diunsaturated monoepoxides.

GC-MS analysis of 5.8 FE of *P. suavis* gland extract on the VF-5ms column revealed two closely eluting peaks, the mass spectra of which were consistent with those of a mono- and a diunsaturated monoepoxide, respectively (Ando et al., 1993, 1995; Millar, 2000). The spectrum of compound **1** had a base peak of m/z 67 [C_5H_7]⁺ with diagnostic ions at m/z (relative intensity) 71 (18) [C_5H_{11}]⁺, 81 (80) [C_6H_9]⁺, 97 (31) [C_7H_{13}]⁺, 110 (12) [C_8H_{14}]⁺, 124 (5) [C_9H_{16}]⁺, 153 (7) [$C_{10}H_{17}O$]⁺, 155 (5) [$M-C_9H_{17}$]⁺, 169 (2) [$M-C_8H_{15}$]⁺, 209 (7) [$M-C_5H_{11}$]⁺, 262 (1) [$M-H_2O$]⁺, and 280 (1) [M]⁺, and matched the spectrum of a 6*Z*-*cis*-9,10-epo-19Hy standard. The retention times of **1** and the 6*Z*-*cis*-9,10-epo-19Hy standard were the same on the VF-5ms and BPX-70 columns (KIs of 2054 and 2413, respectively), and 6*Z*-*cis*-9,10-epo-19Hy and 6*E*-*cis*-9,10-epo-19Hy were easily separated on the VF-5ms column (KIs of 2054 and 2067, respectively), confirming compound **1** as 6*Z*-*cis*-9,10-epo-19Hy.

Fig. 2 Attraction of *P. suavis* males to lures consisting of (A) the three GC-EAD active components in *P. suavis* pheromone gland extracts, (B) various doses of 6Z-*cis*-9,10-epo-19Hy, and (C) addition of 3Z,6Z-*cis*-9,10-epo-19Hy to a lure containing 6Z-*cis*-9,10-epo-19Hy. All trials were undertaken at Eyrewell Forest, between December 2004 and January 2005. Amounts on the x-axis are micrograms per lure. Treatments labeled with the same letter are not significantly different ($P > 0.05$)

The spectrum of compound **2** had a base peak of m/z 79 $[C_6H_7]^+$ with diagnostic ions at m/z 108 (21) $[C_8H_{12}]^+$, 122 (9) $[C_9H_{14}]^+$, 209 (2) $[M-C_5H_9]^+$, 249 (4) $[M-C_2H_5]^+$, 260 (3) $[M-H_2O]^+$, and 278 (4) $[M]^+$, and matched the spectrum of authentic 3Z,6Z-*cis*-9,10-epo-19Hy. The retention times of compound **2** and the 3Z,6Z-*cis*-9,10-epo-19Hy standard were the same on the VF-5ms and BPX-70 columns (KIs of 2059 and 2486, respectively). 3Z,6Z-*cis*-9,10-epo-19Hy eluted later than its two regioisomers, 3Z,9Z-*cis*-6,7-epo-19Hy (KI 2050) and 6Z,9Z-*cis*-3,4-epo-19Hy (KI 2056) on the VF-5ms column, confirming compound **2** as 3Z,6Z-*cis*-9,10-epo-19Hy.

Whereas it was not possible to identify minor compound **3** from gland extracts because of the small amount present, we were able to tentatively identify compound **4** as 3Z,6Z-*cis*-9,10-epo-21Hy. The spectrum and retention time (KI 2261) of compound **4** were the same as those of 3Z,6Z-*cis*-9,10-epo-21Hy on the VF-5ms column, with a base peak of m/z 79 $[C_6H_7]^+$, and diagnostic ions at m/z 108 (45) $[C_8H_{12}]^+$, 122 (8) $[C_9H_{14}]^+$, 237 (5) $[M-C_5H_9]^+$, 277 (2) $[M-C_2H_5]^+$, 288 (1) $[M-H_2O]^+$, and 306 (1) $[M]^+$. In addition, 6Z-9S,10R-epo-21Hy eluted well before this peak (KI 2255). However, we were not able to categorically confirm the structure of compound **4** by GC-MS analysis because it coeluted with another compound in gland extracts on the BPX-70 column.

Field Bioassays

A total of 127 male *P. suavis* were captured in trial 1 at Eyrewell Forest over seven nights, and all of these moths, with the exception of 1 in treatment 4, were attracted by the single-component lure loaded with 100 μ g of 6Z-*cis*-9,10-epo-19Hy (Fig. 2A).

In a dose response trial (Fig. 2B), more male *P. suavis* moths were attracted to lures loaded with 1000 μ g of 6Z-*cis*-9,10-epo-19Hy ($P < 0.05$) than to those loaded

Fig. 3 Mean catches (\pm SEM) of *P. suavis* males in a trapping trial to test an alternative trapping system to delta traps for capturing male *P. suavis*. All treatments used a 100- μ g lure, loaded with 6Z-*cis*-9,10-epo-19Hy. The trial was carried out at Eyrewell Forest in December 2004. Treatments labeled with the same letter are not significantly different ($P > 0.05$)

with either 100 or 10 µg. One hundred sixty-two moths were captured over six nights, with a strong positive correlation between dose and number of moths captured ($r^2 = 0.84$, $df = 14$, $P < 0.001$).

In the third trial (Fig. 2C), we tested the effect of the addition of 3Z,6Z-*cis*-9,10-epo-19Hy to a lure containing 6Z-*cis*-9,10-epo-19Hy. A total of 297 moths were trapped during the 19 nights, and the results indicated that 3Z,6Z-*cis*-9,10-epo-19Hy was inhibitory. Addition of <10% of 3Z,6Z-*cis*-9,10-epo-19Hy significantly reduced trap capture of male moths ($P < 0.05$).

In the fourth and fifth trials at Eyrewell Forest, we tested an alternative trapping system for capturing male *P. suavis* because of the likelihood of saturation of delta traps. Forty-eight moths were captured during the four nights of trial 4, and the results (Fig. 3) indicated that bucket traps, with either a diazinon strip or with water and oil, were as effective as the delta trap ($P > 0.05$). Bucket traps with a dichlorvos pesticide strip trapped fewer male moths ($P < 0.05$) than did the delta traps, suggesting a repellent effect from the dichlorvos strip.

In the bucket-trap diazinon strip trapping system, all moths were alive (13 moths trapped in total) when the traps were cleared the following morning, whereas only 1 moth was alive in the bucket-trap dichlorvos strip system (6 moths trapped), indicative of the relative vapor pressures of these two insecticides (1.4×10^{-4} and 1.2×10^{-2} mm Hg at 20°C, respectively; Windholz, 1983). In the bucket-trap water–oil system, 12 moths were trapped, and all of these were immobilized in the water–oil solution. In trial 5, we trapped 193 moths over a 4-wk period, and there was no difference ($P > 0.05$, data not shown) in mean catches of *P. suavis* males, using either delta traps or the bucket trap water–oil system.

P. suavis Taxa Trial

Trap catches indicated the presence of *P. suavis* in a forestry block in Cass Bay during late December 2004 and early January 2005. However, male moths were not attracted to treatment 2 (100 µg of 6Z-*cis*-9,10-epo-19Hy), but instead to treatments 3–5 (a total of 12 moths trapped over 11 nights). A repeat of trial 1 at four forestry sites (Fig. 4) confirmed the existence of two distinct taxa of *P. suavis*, based on attraction of male moths to the racemates of the two major pheromone components identified from gland extracts of female moths from Eyrewell Forest. A preliminary morphological investigation of the male genitalia of *P. suavis* has revealed no consistent differences between moths from Eyrewell Forest and moths from Rotorua, Burnham, or Cass Bay (Stephens, personal communication).

At the Eyrewell site, only 2 of the moths captured (115 moths trapped in total) were attracted to lures other than 6Z-*cis*-9,10-epo-19Hy (treatment 2), consistent with trial 1. However, at Rotorua (85 moths trapped), Burnham (170 moths trapped), and Cass Bay (66 moths trapped), the majority of *P. suavis* males were attracted to treatments 3–5, with only 3 being attracted to other treatments (1 moth in treatment 2 at Burnham and Cass Bay, and 1 moth in the blank control at Burnham).

Fig. 4 Mean catches (\pm SEM) of *P. suavis* males in a blend trial of the three components in *P. suavis* pheromone gland extracts that elicited EAD responses, at four locations in New Zealand. Trials were undertaken between January 2005 and March 2005. Amounts on the x-axis are micrograms per lure, and treatments labeled with the same letter are not significantly different ($P > 0.05$)

At the Burnham site, the three-component lure of 6*Z*-*cis*-9,10-epo-19Hy, 3*Z*,6*Z*-*cis*-9,10-epo-19Hy, and 3*Z*,6*Z*-*cis*-9,10-epo-21Hy trapped more moths ($P < 0.05$) than the single component 3*Z*,6*Z*-*cis*-9,10-epo-19Hy lure, suggesting that 3*Z*,6*Z*-*cis*-9,10-epo-21Hy might be a component of the sex pheromone of this population of *P. suavis*. However, in an earlier trial at Eyrewell Forest in March of 2003, 100- μ g doses of 3*Z*,6*Z*-*cis*-9,10-epo-21Hy or its enantiomers in single-component lures failed to attract any moths (Brockerhoff, unpublished data), indicating that this diunsaturated monoepoxide is not active as a single component.

We also attracted small numbers of two other closely related *Pseudocoremia* spp. (Stephens, 2001) to 6*Z*-*cis*-9,10-epo-19Hy lures over the course of the trial at the Rotorua site [16 *Pseudocoremia fenerata* (Felder and Rogenhofer) males during February and March], the Burnham site [1 *Pseudocoremia leucelaea* (Meyrick) male in March], and at Cass Bay (3 *P. leucelaea* males in February). Similarly, a trap baited with 6*Z*-*cis*-9,10-epo-19Hy in a *P. radiata* block at Whataroa (43.1167°S, 170.3085°E), South-Westland, in early January 2005 captured 2 *P. leucelaea* males but no *P. suavis*. At Cass Bay, *P. productata* (Walker) adults were observed in the *P. radiata* plantation on numerous occasions during January and February 2005, but no males of this species were ever captured in baited traps.

Discussion

We have identified 6*Z*-*cis*-9,10-epo-19Hy and 3*Z*,6*Z*-*cis*-9,10-epo-19Hy from pheromone gland extracts of the common forest looper *P. suavis*. We have also tentatively identified the homologous diene monoepoxide 3*Z*,6*Z*-*cis*-9,10-epo-21Hy in gland extracts. All of these compounds have previously been found as either sex pheromone components or attractants in other geometrids of the subfamily Ennominae (El-Sayed, 2006).

At Eyrewell Forest, male *P. suavis* moths were attracted to 6*Z*-*cis*-9,10-epo-19Hy as a single component. Because we used the racemate in our trapping trials, the active attractant may be one of the enantiomers or some mixture of the two enantiomers. For example, Millar et al. (1991) found that racemic 6*Z*-*cis*-9,10-epo-19Hy was attractive to the geometrid *Euchlaena madusaria*, and the individual enantiomers failed to attract moths of this species, whereas *Xanthotype sospeta* (a sympatric species) was selectively attracted by 6*Z*-9*S*,10*R*-epo-19Hy and 6*Z*-9*R*,10*S*-epo-19Hy antagonized attraction. Therefore, removal of one of the enantiomers from the blend may enhance, reduce, or eliminate attraction of male *P. suavis* at the Eyrewell site.

Addition of 3*Z*,6*Z*-*cis*-9,10-epo-19Hy to the lure inhibited capture of moths at Eyrewell Forest. Because 3*Z*,6*Z*-*cis*-9,10-epo-19Hy was identified in gland extracts from female moths from Eyrewell Forest, this observed inhibitory effect was possibly due either to one of the enantiomers in the racemic mix or to an incorrect blend of the two enantiomers. Thus, determination of the natural enantiomer of 3*Z*,6*Z*-*cis*-9,10-epo-19Hy or blend from gland extracts may aid in developing a better lure for *P. suavis* males at Eyrewell Forest.

Both 6*Z*-*cis*-9,10-epo-19Hy and 3*Z*,6*Z*-*cis*-9,10-epo-19Hy attracted male moths but not at the same location. Therefore, *P. suavis* is likely to be a species complex comprising two distinct pheromone taxa. This finding will be verified by further trapping trials using the enantiomers of the monoepoxides identified in gland ex-

tracts of *P. suavis* from Eyrewell Forest. In addition, an investigation to determine subtle differences in morphology of genitalia for this species complex and DNA analysis of *P. suavis* from the various locations is underway. There are other examples in the New Zealand Lepidoptera where identification of sex pheromone components has enabled cryptic species to be recognized. For example, Foster et al. (1991) investigated the sex pheromones of distinct geographic populations of various tortricid species in the genera *Planotortrix* and *Ctenopseustis*, and Frérot and Foster (1991) elucidated two distinct pheromone taxa within the noctuid *Graphania mutans*.

A cladistic analysis by Stephens (2001) indicated that *P. suavis* belongs to the clade containing *P. leucelaea*, *P. fenerata*, and *P. monacha*. Our study of the sex pheromone of *P. suavis* supports this finding. We captured both *P. fenerata* and *P. leucelaea* in our field trials, in addition to *P. suavis*. Both *P. suavis* and *P. fenerata* have been recorded as exotic forestry pests (Alma, 1977; Nuttall, 1983), and *P. leucelaea* also feeds on exotic pines (Dugdale, personal communication). Whereas *P. monacha*, like its host genus *Phyllocladus* spp., is restricted in its distribution, being characteristic of upland or montane forest sites (Dugdale, personal communication), the other three species are widespread throughout New Zealand.

At the Rotorua site, *P. fenerata* males were attracted to 6Z-*cis*-9,10-epo-19Hy, and whereas *P. leucelaea* is also present (Alma, unpublished data), we did not trap any of this species during our trial. However, *P. leucelaea* were attracted in low numbers to 6Z-*cis*-9,10-epo-19Hy at three sites in the South Island. Further trapping trials, using enantiomers of the two major pheromone components identified from *P. suavis* gland extracts, could be useful in establishing species-isolating mechanisms among these three sympatric species.

Of the trapping systems tested for capture of *P. suavis*, bucket traps with water and oil were most appropriate for long-term studies. However, it may be possible to further refine the trapping system because *P. suavis* males were caught in reasonable numbers in bucket traps with neither an insecticidal strip nor water and oil (Gibb, unpublished data). Such traps would be useful for collection of live specimens, for example, for GC-EAD or DNA analyses.

Acknowledgments We thank John Allen (HortResearch, Palmerston North) and Diane Stewart and Robert Franich (Forest Research, Rotorua) for mass spectrometry, and Carter Holt Harvey, Selwyn Plantation Board, and John and Jenny Taylor for access to trapping sites. Tetsu Ando, Tokyo University of Agriculture and Technology, Japan, provided samples of 3Z,6Z-*cis*-9,10-epo-21Hy, (3Z,6Z)-9S,10R-epoxyhenicosa-3,6-diene, and (3Z,6Z)-9R,10S-epoxyhenicosa-3,6-diene. Technical assistance in the field was provided by Paula Thompson (HortResearch, Lincoln) and Belinda Gresham (Ensis, Rotorua). Thanks are also due to Barry Donovan for placement and checking of a trap at Whataroa and to John Dugdale, Andréa Stephens, and David Logan for commenting on earlier versions of the manuscript. Funding was provided by the New Zealand Foundation for Research, Science, and Technology (under C04X0302 to Forest Research) and the New Zealand Forest Health Collaborative.

Individual, Sexual, Seasonal, and Temporal Variation in the Amount of Sagebrush Lizard Scent Marks

Abstract Although many animals deposit scent marks, previous studies have focused almost entirely on rodents or on the chemical structure of the signal. Here, we study the quantity and temporal pattern of chemical deposition by the territorial sagebrush lizard *Sceloporus graciosus*, measuring both femoral pore and fecal deposits. Specifically, we tested whether variation in deposition is a good cue of individual and sexual identity and/or whether it is more closely associated with body size and reproductive state, indicators of physiological condition. The results support the latter hypothesis. We found that although the amount of fluid deposited on a single perch (rarely quantified in mammals) carries little information on individual or sexual identity, it reflects the physiological condition and reproductive state of individual lizards and is replenished on a roughly weekly cycle, potentially providing additional information on the producer's activity level. The amount of deposition may thus provide important information to chemical receivers making mate choice and territorial defense decisions. The results further suggest that seasonal increases in gland production allow lizards to mark more sites rather than to influence the quality of the signal on a single perch.

Introduction

In many animals, the behavior of scent marking, including spatial and temporal patterns of deposition, can supplement a chemical signal with information about the producer's activity, physiology, or motivational state. Many animals leave chemical signatures passively wherever they go, offering a receiver information about their general activity (see review by Wyatt, 2003). Others modify the quantity and quality of chemical signals by changing their position with respect to the wind, by wing fanning, or by urinating, defecating, or rubbing against a substrate. For example, voles scent-mark in response to chemical signals left by other animals (Wolff et al., 2002; Mech et al., 2003). In rodents, there are considerable individual and seasonal differences in the frequency of scent marking (Nevison et al., 2003; Ferkin et al., 2004), such that the deposition of chemical signals also contains information on the producer's individual identity and reproductive state. Despite major recent advances in determining the structural composition and functional use of chemical signals, little is known about the quantity and temporal pattern of chemical deposits in nonrodent taxa (Wyatt, 2003). In this study, we document patterns of sexual, seasonal, and individual variation in chemical deposition by *Sceloporus graciosus*, the sagebrush lizard, and test hypotheses to determine whether the quantity of deposits carries information on the individual and sexual identity of resident animals, or whether it better reflects physiological condition.

The chemical structures of lizard secretions convey information on the individual, sex, population, and species identity of producing animals (Alberts et al., 1993; Escobar et al., 2001). As reviewed by Mason (1992) and Halpern (1992), most lizards produce chemical secretions in skin or specialized glands and have highly developed chemical discrimination abilities. Many species can use olfaction to distinguish the sex (Labra and Niemeyer, 1999; López and Martín, 2001), social status (Alberts et al., 1994; Molina-Borja et al., 1998), and body size (Aragón et al., 2000) of conspecifics. They also can use chemical cues to identify preferred prey (Cooper and Habegger, 2000) and to avoid predation (Downes, 2002). An impressive diversity of lizard species can distinguish familiar from unfamiliar conspecifics on the basis of chemical cues (Aragón et al., 2001, 2003; Labra et al., 2001; Bull and Lindle, 2002).

The quantity of chemical produced by individual lizards also exhibits intraspecific variation and may be used to transfer information on physiological or reproductive condition as well as identity. As reviewed by Mason (1992), chemical-secreting glands are usually larger and more active in breeding males than in females or juvenile animals. For example, male green iguanas, *Iguana iguana*, maximize production of femoral pore secretions during breeding months, and pore size is associated with plasma levels of testosterone and visual display behavior (Alberts et al., 1992). Testosterone implants cause female whiptail lizards (*Cnemidophorus uniparens*) to exhibit the large, active femoral pores typical of males (Wennstrom and Crews, 1998; Crews et al., 2004), and juvenile tree lizards (*Urosaurus ornatus*) treated with testosterone develop larger femoral pores (Hews et al., 1994).

In contrast, the deposition of lizard chemical signals has received minimal study, making it difficult to determine whether the frequency of scent marking is an

important element of the chemical signal that may also evolve via natural and sexual selection. Here, we monitored lizard scent marks on a primary perch for 35 consecutive days before and 21 d after a hibernation period. We then used these data to determine whether the amount of secretion is better explained by individual and sexual differences, and/or whether they are better explained by general physiological (as reflected by body size and time in captivity) and reproductive condition (as reflected by season). Because these hypotheses are not mutually exclusive, we used multiple regression analyses to compare the relative importance of each factor. We further tested for the importance of individual as opposed to physiological differences by comparing the amount of secretion produced by the same lizards in different seasons. Finally, we examined the time series of chemical deposition to determine how often scent marks were replenished. Although we focused on femoral pore secretion deposits, we also measured fecal spots, which may also carry chemical information (see Mason, 1992).

Methods and Materials

Animals and Housing

Sagebrush lizards are small, insectivorous lizards found throughout the western US. In the field, both males and females are active from mid-March to September. Males are especially territorial in May and June (during the mating season), whereas both sexes defend territories aggressively from July through September (Martins, 1991, 1993). We used 82 males and 49 females that were captured near Wrightwood in southern California (34°23'30"N, 117°42'W) in two separate collections (May 2002 and 2003) and established in separate rooms of our laboratory colony at Indiana University. We used only adult animals. Males were slightly larger than females in both snout-to-vent-length [SVL; male = 5.8 ± 0.04 cm (mean \pm SE); female = 5.7 ± 0.04 cm] and weight (male = 8.8 ± 0.17 g; female = 8.1 ± 0.14 g).

Lizards were kept under standard housing, lighting, feeding, and hibernation conditions. For most of the year, individuals were housed in 5-gal aquaria, visually isolated from their immediate neighbors by opaque cardboard barriers, but able to see animals on other cage racks across the room (2–3 m away). Each aquarium was equipped with sand substrate, a water dish, and a split-level brick perch (5.5 cm wide \times 21.5 cm long \times 6.5/11 cm tall). Each row of cages was illuminated on a 12-hr light cycle by two fluorescent light bulbs stretched across the row and by a single 40-W incandescent bulb hung directly over the highest level of the brick perch on one side of each cage. Although air temperature outside the cages was held at a constant 28°C, the brick perch warmed to as much as 4°C higher than other parts of the cage and was used frequently by active animals. Lizards were watered and misted daily and were fed three times each week with *ad lib* mealworms and vitamin-enriched crickets. Once every 2 wk, large fecal material was removed. From June to September, animals were placed in groups of two to eight animals in 3 \times 3 m outdoor enclosures (prior to experiments). In November–January, animals were allowed to hibernate in individual cloth bags at 11°C (during the experimental period; see next section).

One room housed animals (35 males and 24 females) that had been in captivity for more than 1 yr, having been captured in May 2002 and undergoing one period in the outdoor enclosures and one hibernation period before entering the experiment in

2003. The second room housed animals that were brought into the lab in May 2003 but did not spend time in the outdoor enclosures or undergo hibernation before beginning the experiment. Lizards increase in SVL continuously as adults, such that body size and weight are reasonable indicators of physiological condition. Lizards grew quickly in the outdoor enclosures, such that animals that had been in captivity for longer were also slightly larger (SVL = 5.8 ± 0.04 cm compared to SVL = 5.7 ± 0.04 cm).

Chemical Sampling

Although lizards move and potentially deposit secretions throughout their cages, we measured only secretions deposited on the split-level brick, a preferred basking perch. In the field, *Sceloporus* lizards defend several preferred basking perches, leaving the intervening space undefended such that there is considerable home range overlap between individuals (Sheldahl and Martins, 2000). We limited the current study to deposits on a single preferred perch to ensure that our efforts addressed territorial use of chemical deposits rather than general activity. We used white marking tape to attach white paper towels to the top surface of the single brick in each cage. We changed the paper towels daily so that spots could be counted and measured. Used towels were placed under a black light, which makes the femoral pore secretion spots (FPSs; which are UV-reflective, Alberts, 1993) visible to a human observer. Fecal spots are not UV-reflective, and hence were easily distinguished from femoral pore spots. We counted and measured the diameter (to the nearest 0.5 mm) of each femoral pore and fecal spot, using the radii (r) to estimate total area of spots for each lizard on each day (area = $\sum \pi r^2$, where the sum is across all femoral pore or fecal spots produced by one lizard in 1 d).

Data were collected daily from 13 October to 16 November 2003 (35-d prehibernation sequence) and then again from 26 January to 15 February 2004 (21-d posthibernation sequence). During the intervening period, animals were measured, weighed, and allowed to hibernate. Data were not collected 1 wk before and 1 wk after hibernation. In captivity, sagebrush lizards will remain active for 10 or more months of the year, with females readily laying two successive clutches of eggs. The prehibernation period of our study corresponds with a period of territorial aggression in which animals of both sexes actively exclude conspecifics of both sexes from their preferred feeding and basking sites. In contrast, the posthibernation period corresponds to the early mating season when both males and females were at peak activity. During the mating season, males extend their territories into larger areas, each of which encompasses the smaller home ranges of several females, whereas females reduce aggressive territorial behavior. Territorial aggression is stronger in males than in females, and this sexual difference is more pronounced during the mating season than afterwards (Martins, 1993). Thus, if femoral pore or fecal spots are used in territorial defense, we also might expect them to be larger or more abundant in males than in females, especially during the mating season.

Statistical Analyses

We began by using generalized linear mixed models [GLMMs, implemented using the GLIMMIX procedure of SAS (2005)] to estimate the relative importance of identity (individual and sex) and condition (season, body size, and time in captivity) in explaining variation in femoral pore spot deposition. GLMMs are regression-type

models that rely on a family of exponential distributions instead of the usual normal distribution to describe the response variable (in our case, spot number or size). The SAS GLMMIX procedure chooses from among discrete (e.g., Poisson, negative binomial) and continuous (e.g., normal, gamma) exponential distributions using likelihood statistics to find the best fit to the data.

We fitted two GLMMs (one model for spot number and a second model for spot area) to describe the effects of various factors on variation in femoral pore spot deposition. The factors included individual identity (codes for 128 animals), sex (male or female), body size (SVL and weight in grams, as measured just before hibernation), and time in captivity (0 or 1 to distinguish the two collection periods corresponding to 5 or 17 mo in captivity) as potentially relevant predictors. We also included a factor for fecal deposition (fecal spot number and area) for comparison. We report results from analyses using type III sums of squares, which estimate effects for each factor while taking all other variables into account. Residual analyses confirmed that we did not violate the homoscedasticity assumptions of these models.

As a second test of the same hypothesis, we estimated Pearson product moment correlations between daily averages of spot number and area, calculated for each lizard before and after hibernation. Strong correlations indicate the importance of individual identity in determining deposition quantity. Although the counts and areas were not normally distributed, average spot number for a single lizard across several days was close to normal. For comparison, we did the same calculations for both femoral pore and fecal spots and estimated also correlations between femoral pore and fecal spots.

Finally, we examined the temporal pattern of spot deposition. First, we assumed that lizards were temporally synchronized, averaging spot number across all lizards on each day of our sample. This is a reasonable expectation because all animals were kept on identical environmental, husbandry, and feeding regimes for at least 5 mo prior to and during data collection. Again, although the counts are not normally distributed, the averages across all of our lizards on a single day were well simulated by a normal distribution. We used these averages to fit time series models, forecasting across a single series of 56 d (35 d before hibernation + 21 d afterwards) to maximize our predictive ability.

Results

Although all lizards produced FPS on at least 1 d in the 35-d sequence before hibernation, 10 of 82 males and 5 of 49 females did not contribute to the 21-d posthibernation data set. The number of FPS deposited onto the paper towels ranged between 0 and 11 per day (Fig. 1A). Most lizards deposited spots on the brick perch on fewer than 30% of the days in our study. Femoral pore spots varied considerably in size, with most spots being less than 3 mm² in area, but a few ranging as high as 18 mm² (Fig. 1B). Distributions of fecal spot numbers were similar, but less dispersed, with fewer lizards exhibiting the rare large numbers of spots observed for femoral pore secretions (Fig. 1A). Fecal spots were sometimes larger, ranging up to 40 mm² in area (Fig. 1B).

The number and area of femoral pore spots were explained better by physiological condition than by individual identity or sex. Counts of femoral pore

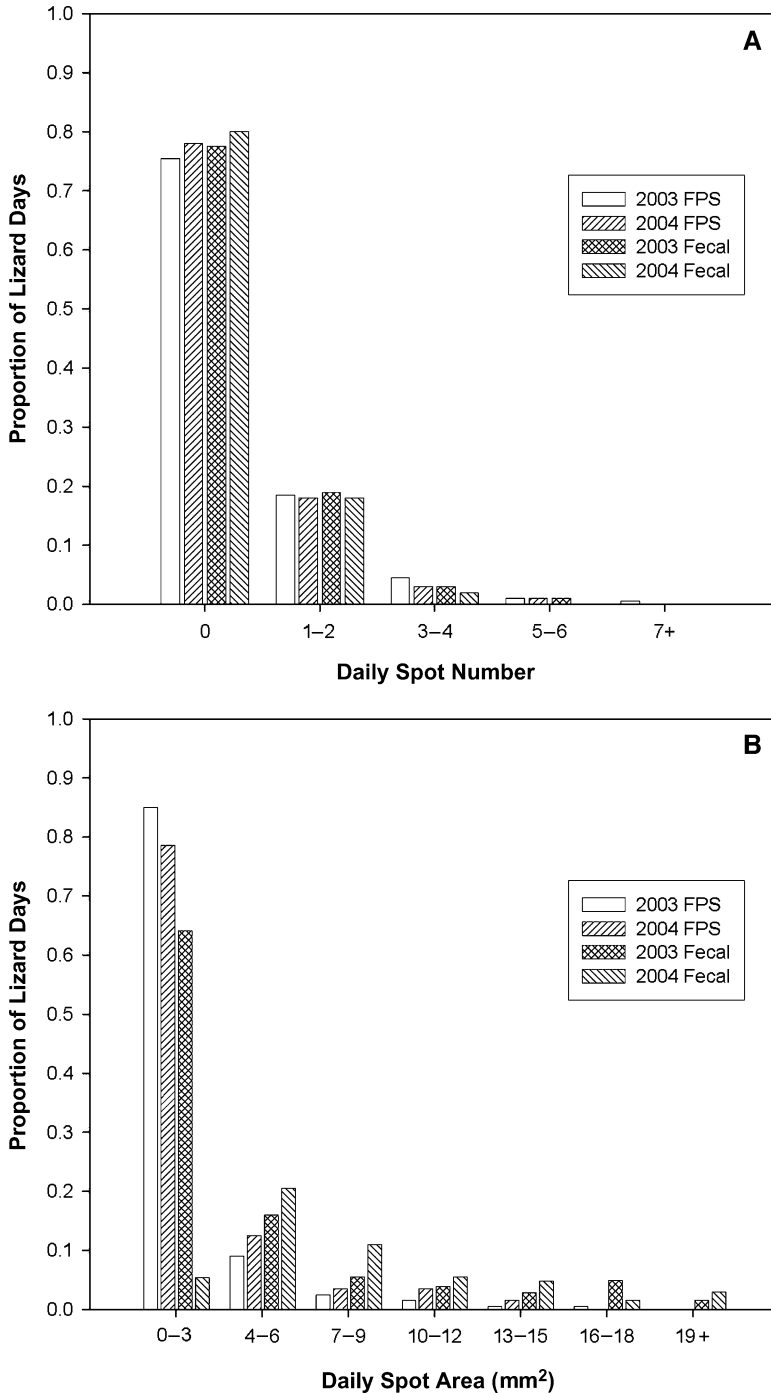

Fig. 1 Distribution of the number (A) and size (B, area in mm²) of spots produced each day, combining data from both sexes and across the full 56 d of our experiment. 2003: Prehibernation, territorial season. 2004: Posthibernation, mating season

Table 1 *F* Values and predicted effect size estimated by general linear mixed models of femoral pore secretion spot (FPS) number and size (area in mm²)

Factor	Number ^a	Predicted effect (%)	FPS size ^b	Predicted effect
Season ^c	16.18*	−20	16.24*	0.16
Sex ^c	0.43	−2	2.00	0.08
Captivity ^c	10.41*	−23	111.15*	0.54
Length (mm)	7.19*	−33	0.40	−0.15
Weight (g)	2.37	7	0.52	0.03
Fecal spot no.	15.75*	14	1.91	0.04
Fecal spot area	5.89	1	0.06	0.00

spots were too widely dispersed to be described well by normal or Poisson distributions, but a GLMM with a negative binomial distribution and a log-link function provided a good fit to spot counts. Femoral pore spot area was described better by a lognormal distribution. There was a seasonal effect on both FPS number and area (Table 1). Lizards deposited about 20% fewer FPS during the mating season than during the prehibernation territorial season and increased FPS area by about 0.16 mm². Moreover, lizards with longer snout-vent lengths produced fewer, but not smaller, spots (Table 1). Although weight was not a good predictor of either response variable, time in captivity appeared as a related and highly significant predictor, with animals that had spent more than a year in captivity producing fewer but larger FPS than did animals that had been in captivity for only 5 mo. Lizards that had been in captivity for more than 1 yr were also slightly larger (*F* = 4.1, *df* = 1,121, *P* < 0.05 for SVL, including sex also in the model) and considerably heavier (*F* = 13.6, *df* = 1,121, *P* < 0.001) than animals that had been in the lab for a shorter

Table 2 Pearson product-moment correlations between number and size (mm²) of spots in the same (repeatability) and different years

period. In using type III SS to estimate GLMM parameters (Table 2), we confirmed that time in captivity was an important factor even after differences in body size had been taken into account. Surprisingly, sexual differences were small and did not contribute to variation in FPS number or area, despite visibly larger femoral pores in males, especially during the mating season. Animals that produced more fecal spots also produced more FPS, but size of fecal spots was not related to FPS number or size.

In our second test, individual lizards that produced more or larger spots during the territorial season did not tend to be the same animals that produced more or

Fig. 2 (A) Relationship between number of femoral pore secretion spots (FPS) in territorial and mating seasons ($r = 0.08$, $P > 0.05$). Size of FPS and number of fecal spots give very similar patterns (Table 2). (B) Relationship between size of fecal spots in the two seasons is statistically significant ($r = 0.4$, $P < 0.05$), but probably because of a single influential outlier (Table 2)

larger spots during the mating season (Table 2, Fig. 2A). Only the area of fecal spots showed a positive relationship between seasons, and this relationship seems to be driven by outliers (Fig. 2B). For the most part, measures of femoral pore and fecal spot deposition were positively associated with each other within but not across seasons (Table 2). The number of FPS was only loosely associated with fecal spots during the

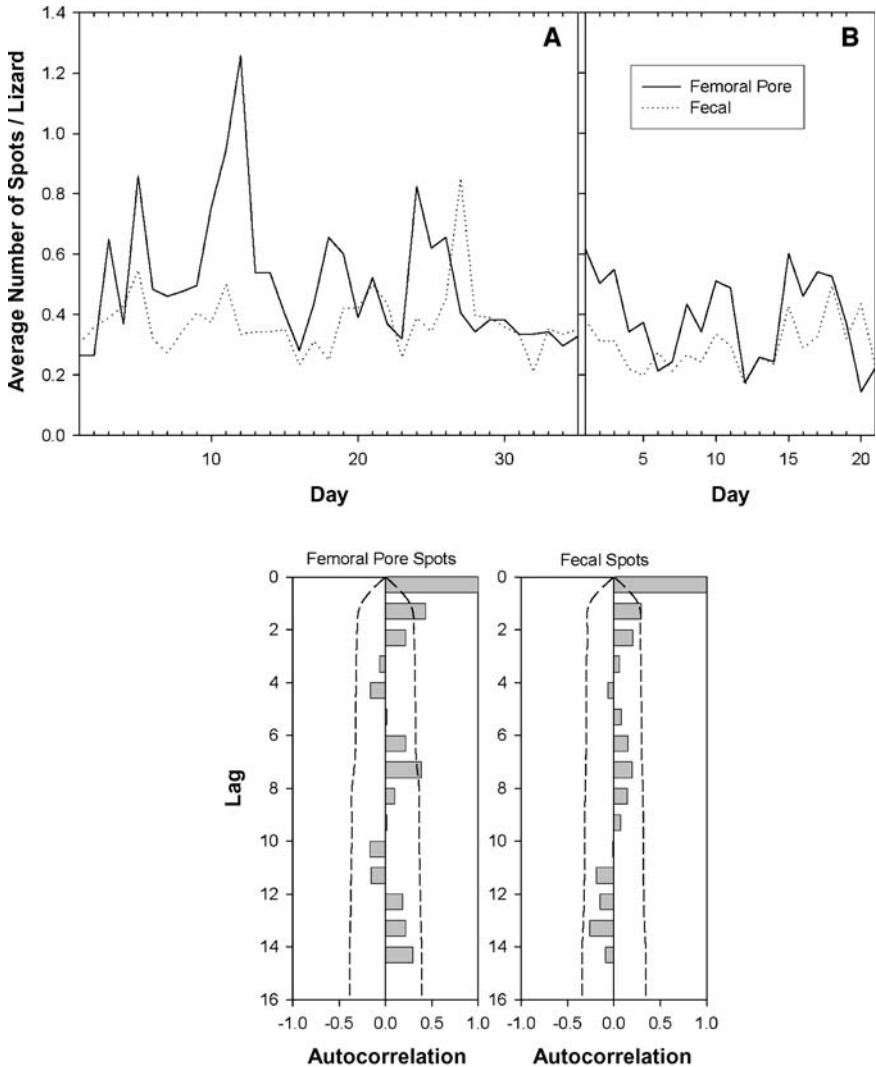

Fig. 3 Mean number of spots produced by lizards on each day of our study, averaging data for all male and female lizards. The first time sequence (A) was in October–November 2003, long after the mating season had ended. The second time sequence (B) was in January and February 2004, after animals emerged from hibernation and were beginning to show signs of reproductive activity. (C) Autocorrelation function (ACF) plots for the two time series describing relationships between the number of spots produced on different days. Bars show the magnitude of correlation coefficients calculated between the graphed data and the same time series shifted by a specified lag (up to 16 d). Dashed lines show 95% confidence intervals around a correlation of zero

territorial season (2003), but was strongly correlated with fecal spots during the subsequent mating season (2004).

Finally, assuming that lizards were synchronized with each other, time series analyses identified a cyclical pattern to the number of spots deposited, with lizards decreasing and then increasing the number of femoral pore and fecal spots produced each day (Fig. 3). This cyclical variation could be seen in the autocorrelation plots for the number of femoral pore spots, with significant positive autocorrelations at lags 1 and 7 ($r = 0.4$), with an intervening dip into negative autocorrelations at an intermediate lag 4 ($r = -0.2$). The pattern for fecal spots was similar, though weaker (autocorrelation $r = 0.2$ and 0.3 at lags 1 and 7, $r = -0.1$ at lag 4). With a series of relatively short duration (56 d), a first-order autoregressive model offered a sufficient fit to both femoral pore and fecal spot data, yielding the lowest BIC scores despite retaining much of the autocorrelation in the data.

Synchronization seems to have been stronger after hibernation than before. On days in which lizards produced more FPS, lizards also tended to produce larger spots, but this relationship was stronger during the mating season ($r = 0.7$, $P < 0.001$) than during the territorial season ($r = 0.4$, $P < 0.02$). Although there was no relationship between fecal spot number and size during the territorial season ($r < 0.1$, $P > 0.05$), the relationship was stronger but still not significant ($r = 0.35$, $P < 0.2$) during the mating season. The number of pore spots and the number of fecal spots produced by individual lizards on each day of the study were temporally linked during the mating season ($r = 0.5$, $P < 0.02$), but not before ($r = 0.2$, $P > 0.05$). There were no significant relationships between areas of femoral pore and fecal spots in either season.

Discussion

The results suggest that the amount of secretion deposited by lizards on a single perch may be an important component of the overall chemical signal, offering information on resident activity and physiological condition. The quantity of chemical deposits differed among animals of different body sizes and among animals in different part of their reproductive cycles. Deposits also varied on a weekly cycle, such that their degradation may convey information about resident lizard activity. Interestingly, a lizard could potentially gather this information from a distance, seeing as well as smelling the FPSs (Alberts, 1993). We found little difference between the sexes in the amount of chemical deposits, and no relationship between the amount of deposit produced by the same animal on different days or in different seasons of the year, suggesting that scent-marking behavior is not a good indicator of individual or sexual identity.

We found a discrepancy between gland production and chemical deposition on a single perch. Reproductively active males deposited fewer secretions than did females or territorially aggressive males, despite the known positive influence of androgens on gland productivity (Wade et al., 1993; Lindzey and Crews, 1993). This apparent contradiction can be resolved by recognizing that male sagebrush lizards are considerably more active than females, especially during the mating season, when most males defend several basking perches (Martins, 1991, 1993). Reproductively active rodents scent-mark more locations than do animals in other contexts (Wolff et al., 2002; Ferkin et al., 2004). Similarly, in a natural context, the extra

chemical secretions produced by sagebrush lizards during the mating season may be used to mark more locations rather than to mark any single location more heavily.

In mammals, seasonal increases in scent marking have been interpreted as support for the hypothesis that scent marks are used to advertise individual identity, especially at times in the seasonal cycle (i.e., mating season) when such information may be particularly important (Wolff et al., 2002; Ferkin et al., 2004). Our results extend the advertisement hypothesis by suggesting that the amount of deposition may convey information about physiological condition that supplements the information conveyed by the chemical structure of the signal. Thus, the amount of deposition may be an important element of the chemical signal, providing information about physiological condition and influencing the outcome of mate choice and aggressive interactions. We know that experimental manipulation of chemical cues on a lizard's skin alters its recognition by conspecifics (López and Martín, 2002), and the addition of femoral pore secretions to a robotic lizard model changes the behavioral response in playback experiments (Thompson, 2002). Playback studies are now also needed to determine whether receivers (lizard or mammal) can interpret effectively the information on physiological condition contained in deposit quantity.

The weekly cycle of scent-mark deposition also supports the hypothesis that femoral pore secretions function as territorial markers. Unlike in rodents, however, deposits were remarkably infrequent, with some lizards allowing several weeks to pass before depositing again, despite our daily removal of chemical secretions. Although it seems likely that the weekly cycle is required for replenishing a constant signal, further research is needed to determine whether, and how quickly, the signal is degraded and the extent this degradation may relate to the weekly cycle of deposition. Although experimental blocking of olfaction did not affect home ranges of sleepy lizards (Zuri and Bull, 2000), further studies of this sort with other lizard species may reach different conclusions. Most lizards maintain relatively exclusive territories despite considerable overlap in home ranges (Sheldahl and Martins, 2000) and behave differently when placed in an enclosure that has been previously occupied by other lizards (Labra et al., 2001). There also appears to be a relationship between the use of chemical secretions and the territorial headbob displays (Hews and Benard, 2001). Thus, experimental manipulation of olfaction with more targeted measures of changes in territory defense may yield further insights.

Finally, we found little evidence that lizards can determine individual identity, sex, or species of other animals from the quantity of chemical deposits. It seems more likely that differences in chemical composition of secretions among individuals, sexes, populations, and species (Alberts et al., 1993; Escobar et al., 2001) are used by lizards to distinguish sex, social status, and individual identity of conspecifics (Labra et al., 2001; López and Martín, 2001; Bull and Lindle, 2002; Aragón et al., 2003). We did not observe consistent individual differences in chemical deposition, as would be expected if secretion quantity were an indicator of individual identity. Moreover, an individual lizard's deposition during the prehibernation territorial season was not a good predictor of deposition during the posthibernation mating season. Further studies varying the amount and chemical composition of secretions or determining the amount of secretions produced in response to particular types of conspecifics are needed to confirm their use as territorial markers and communicative signals.

Acknowledgments We thank Yoni Brandt, Heather Bleakley, and Erin Kelso for help in collecting lizards in the field, Erin French and Heather Bleakley for methodological development, Sarah Davenport and Erin Kelso for lizard care, and Barbara Clucas, Jessica Stapley, and two anonymous reviewers for comments on a previous version of the manuscript. Abstract Barnyard grass is a problematic weed worldwide. It competes with crops and causes reduction in crop yields. In this study, barnyard grass suppressed rice emergence, and the degree of rice inhibition was proportional to the density of barnyard grass. Root exudates of barnyard grass reduced germination and growth of lettuce, rice, and monochoria. Fifteen compounds potentially involved in the phytotoxic activities of barnyard grass were isolated and identified, including phenolics, long-chain fatty acids, lactones, diethyl phthalate, acenaphthene, and derivatives of phthalic acids, benzoic acid, and decane. Quantities of diethyl phthalate, decanoic acid, myristic acid, stearic acid, 7,8-dihydro-5,6-dehydrokavain, and 7,8-dihydrokavain were 2.7, 11.1, 19.6, 35.5, 10.3, and 15.5 $\mu\text{g/ml}$ of barnyard grass root exudates, respectively. The two lactones exhibited the greatest inhibition, followed by the phenolics and the derivatives of phthalic acids. Fatty acids had stronger suppression than diethyl phthalate and ethyl ester-4-ethoxy-benzoic acid. The acenaphthene and decane derivatives were the least phytotoxic. The phytotoxins released by barnyard grass roots showed strong inhibition on growth of broadleaf indicator plants and paddy weeds, but were less effective on barnyard grass itself and rice. Our study revealed that in addition to competition, barnyard grass also interferes with rice and other plants in its surroundings by chemical means.

Introduction

Barnyard grass [*Echinochloa crusgalli* (L.) Beauv.], an annual grass, has been reported to cause problems in at least 61 countries and in at least 36 different crops (Holm et al., 1991). It is a major weed in paddy fields as it competes with rice (*Oryza sativa* L.) and causes reduction in rice yield. Competition from 25 barnyard grass plants/m² can cause 50% reduction in rice yield (Chin, 2001). Some weeds exude allelochemicals that suppress crop growth as well as other weed species in fields (Tang and Young, 1982; Qasem and Foy, 2001). However, differentiating between allelopathic effects and resource competition in the field is not easily achieved (Yamamoto et al., 1999). Therefore, the identification of allelochemicals exuding from roots in laboratory experiments, where the competitive factors can be eliminated, is useful to understand the phytotoxic activities of such weeds. Yamamoto et al. (1999) reported that during germination and early growth, barnyard grass inhibited the growth of cockscomb (*Celosia cristata* L. var. *kunze*), timothy (*Phleumpratense* L.), cress (*Lepidium sativum* L.), amaranth (*Amaranthus viridis* L.), rice, lettuce (*Lactuca sativa* L.), and barnyard grass. *p*-Hydroxymandelic acid, an allelochemical exuding from young barnyard grass roots, strongly inhibited the growth of rice at 59.5–178.6 μ M (Yamamoto et al., 1999). Most of the studies on rice–weed interactions focus on the weed-suppressing potential of rice, many of which concentrate on using rice allelopathy to control barnyard grass (Rimando et al., 2001; Chung et al., 2003). Major allelochemicals in rice capable of suppressing barnyard grass have been detected including phenolics, indoles, momilactones, and terpenoides (Khanh et al., 2005). Chung et al. (2003) and Jung et al. (2004) noted that barnyard grass was the least susceptible to rice allelopathy among the paddy weeds. Barnyard grass is in the same family as rice (Graminae), which may be one of the reasons for its superior ability to compete against rice. On the other hand, this noxious weed may also release growth inhibitors that inhibit emergence of rice and other paddy weeds. However, except for *p*-Hydroxymandelic acid, the composition of its root exudates, which may be responsible for such allelopathic activities, has not been investigated. Therefore, we conducted this research to isolate and identify allelochemicals in root exudates of barnyard grass and to examine their bioactivities against several important plant species.

Methods and Materials

Plants

Alfalfa (*Medicago sativa* L.), lettuce, sesame (*Sesamum indicum* L.), and rice (cv. Koshihikari) seeds from commercial sources (Wakaba company, Japan) were used. Seeds of barnyard grass, monochoria (*Monochoria vaginalis* Presl var. *plantaginea* Solms-Laub.), and Indian jointvetch (*Aeschynomene indica* L.) were collected from Miyazaki fields, Japan, in 2003. Empty and undeveloped seeds were discarded by floating in tap water. The remaining seeds were air-dried and stored hermetically at -20°C . These were sterilized with 1% sodium hypochlorite for 30 min and rinsed many times with distilled water before use. The germination percentage was randomly checked, and all were greater than 90%.

Effects of Barnyardgrass on Rice Growth

Ten healthy rice seeds were sown evenly in a Petri dish (9 cm diam) lined with filter paper and moistened with 10 ml distilled water. To the Petri dish, 10, 50, and 100 seeds of barnyard grass were added evenly between the rice seeds. Five replicates of all treatments were placed in an incubator (25°C, 4000 lx, with an 8-hr day/16-hr night cycle, humidity: 75%) using a completely random design. After 7 d, the number of germinated rice seeds was counted, and the length of shoots and roots was measured.

Barnyardgrass Exudates

Ten grams of healthy barnyard grass seeds was put in a glass pot with 100 ml of distilled water for 7 d in a growth chamber (25°C, 4000 lx, with an 8-hr day/16-hr night cycle, humidity: 75%). The distilled water was changed every 2 d. The resulting root exudates were filtered and set as the original dose, and a one-half strength solution was also prepared. Effects on emergence of rice, lettuce, and monochoria were examined by using methods similar to those described above against 20 seeds of each indicator plant. In another trial, 100 ml of the barnyard grass exudates was extracted with 70% MeOH in a shaking bath at 40°C for 24 hr. The solution was filtered, evaporated to dryness, dissolved in MeOH, and analyzed by thin-layer chromatography (TLC).

TLC Experiment

Many TLC solvent systems were tested. The combination of chloroform/ethyl acetate/acetic acid (10:3:1) gave the best separation and was selected. TLC plates were coated with 500- μ m layer of silica gel (Merck). The prepared barnyard grass root exudates were applied to the TLC plate (16 \times 20 cm). R_f values of the colored spots detected under the UV light were recorded, and the plate area was scraped and eluted with methanol. After evaporation to dryness, the residue was dissolved in distilled water, adjusted to 50 ppm, and tested for its effects on germination and growth of barnyard grass. Spots that inhibited lettuce emergence were collected, dissolved in acetone, and used for gas chromatography–mass spectrometry (GC-MS) analysis.

GC-MS Analysis

An aliquot of 2 μ l was injected (splitless) into the GC-MS (QP-2010, Shimadzu Co., Japan). The data were obtained on an ID-BPX5 column (30 m \times 0.25 mm ID, 0.25- μ m film thickness, SGE, Australia). The carrier gas was helium, and the GC oven temperature program was as follows: 50°C hold for 5 min, rate of 5°C/min to 280°C, and hold for 5 min. The injector and detector temperatures were set at 220 and 280°C, respectively. The mass range was scanned from 15 to 900 amu. The control of the GC-MS system and the data peak processing were carried out by means of the Shimadzu's GC-MS solution software, version 2.1.

Quantification of Allelochemicals in Exudates of Barnyardgrass

Phytotoxic compounds identified in the exudates were quantified. Pure reference standards were purchased from Wako (Japan). Two lactones were purified in our

laboratory. All compounds were dissolved in acetone and by using similar GC conditions to those described above to quantify the constituents of the barnyard grass root exudates by comparing the retention time and areas between the standard chemicals and the samples. However, some of the identified constituents could not be quantified as they could neither be purchased nor purified in our laboratory.

Effects of Isolated Compounds on Plant Growth

Dilution of pure reference chemicals detected in exudates of barnyard grass at 100 ppm was prepared and examined for their influence on emergence of alfalfa, monochoria, lettuce, Indian jointvetch, sesame, and rice (var. Koshihikari) using the reported bioassay method.

Statistical Analysis

All treatments were arranged in a completely randomized design with at least three replications. Bioassays were replicated five times. Data were analyzed with SAS version 6.12 (SAS Institute, 1997) using analysis of variance and least significant difference at the 0.05 probability level.

Results

Effects of Barnyardgrass on Rice Growth

Barnyard grass was sown at different densities to examine its effects on rice growth. Germination was not influenced by the presence of barnyard grass, but elongation of rice roots and shoots was suppressed when density of barnyard grass was increased (Table 1). At the rate of 10 seeds per Petri dish, no impact on root length was observed, but shoot length was significantly reduced, relative to the control. When the density of barnyard grass increased to 50 and 100 seeds per Petri dish, inhibition of rice roots was increased by 30–40%. However, shoot length was not significantly affected by the increase in barnyard grass density. This experiment found that barnyard grass had a chemical effect on rice emergence. Barnyard grass density was positively correlated with rice root and shoot length ($r = 0.94$ and 0.81 , respectively; Table 1). The inhibitory effect on rice growth was proportional to the density of barnyard grass.

Table 1 Inhibitory effects of barnyard grass on rice growth

Barnyard grass density (seeds)	Inhibition (% of control)		
	Germination	Root length	Shoot length
10	0.0a	3.0a	26.2b
50	0.0a	30.0b	31.6b
100	0.0a	39.4c	31.3b

Correlation coefficients of barnyard grass density against rice root and shoot length: $r = 0.94$ and 0.81 , respectively. Means with the same letter in a column are not significantly different at $P = 0.05$.

Table 2 Effects of barnyard grass exudates on emergence of lettuce, rice, and monochoria

Concentration	Inhibition (% of control)		
	Germination	Root length	Shoot length
Lettuce			
1/2	15.8a	44.1a	13.7a
1.0	30.6b	94.5b	88.2b
Rice			
1/2	0.0a	33.2a	26.2ab
1.0	5.0a	48.1b	27.5b
Monochoria			
1/2	7.4a	28.6a	28.7a
1.0	25.9b	65.0b	28.6a

Means with the same letter in a column are not significantly different at $P = 0.05$.

Effects of Barnyardgrass Exudates on Lettuce, Rice, and Monochoria

Barnyard grass root exudates were selected to determine potential phytotoxicity toward plants that are commonly found nearby such as rice and monochoria. The root exudates exhibited strong inhibitory effects on emergence of lettuce, rice, and monochoria (Table 2). Germination of lettuce and monochoria was reduced at the two applied doses in comparison with the controls, whereas no effect on rice germination was found. The roots of these indicator plants were more affected than their shoots. At one-half dose, the roots of monochoria and rice were suppressed by a similar level (about 30%), whereas lettuce roots were reduced by about 45% (Table 1). However, shoot length of lettuce was less affected than rice and monochoria at this concentration. At the original full dose, lettuce emergence was suppressed by about 90%. On the other hand, emergence of rice and monochoria was not significantly reduced as compared to the one-half dose, with the exception of monochoria root, which was inhibited by 65%. This experiment reveals that barnyard grass releases toxic compounds during germination that strongly reduce the growth of lettuce, rice, and monochoria.

TLC Experiment

Several spots were observed on TLC plates under UV light and examined for their activities on lettuce germination and growth at 50 ppm. Of these, only five spots suppressed lettuce emergence, with Rf values of 0.24, 0.29, 0.35, 0.42, and 0.72

Table 3 Effects of spots isolated from TLC on emergence of lettuce at 50 ppm

Spots	Rf values	Inhibition (% of control)		
		Germination	Root length	Shoot length
1st	0.24	44.4c	57.5c	33.5b
2nd	0.29	11.1ab	28.6ab	20.0b
3rd	0.35	5.6a	14.6a	2.6a
4th	0.42	22.2b	37.9b	18.0b
5th	0.72	60.6d	77.7d	54.2c

Means with the same letter in a column are not significantly different at $P = 0.05$.

(Table 3). These were selected for analysis. At 50 ppm, the compounds contained in each spot significantly reduced germination and growth of lettuce, as compared to the control, with the exception of the third spot that had no significant effect on lettuce germination. The constituents of the fifth spot exerted the greatest influence on lettuce emergence followed by the first spot (Table 3), whereas the third spot was the least inhibitory.

GC-MS Analysis

Fifteen compounds were detected in the five spots collected by TLC as shown in Table 4. Their chemical structures are described in Fig. 1. The first spot consisted of two phenolics [2-ethyl-phenol and 2,4-bis (1,1-dimethyl)-phenol] and three derivatives of phthalic acids (dimethyl ester-phthalic acid, butyl 8-methylnonyl ester-phthalic acid, and diisooctyl ester-phthalic acid). The second spot contained diethyl phthalate and a derivative of benzoic acid (ethyl ester-4-ethoxy-benzoic acid). Derivatives of decane (2,3,7-trimethyl-decane and 2-methyl-dodecane) and acenaphthene were detected in the third spot. Three long-chain fatty acids were observed in the fourth spot, including decanoic acid, myristic acid, and stearic acid. In the fifth spot, two lactones were identified [7,8-dihydro-5,6-dehydrokavain (DDK) and 7,8-dihydrokavain (DHK)]. All of these 15 constituents have been identified in barnyard grass root exudates for the first time.

Table 4 Substances identified from spots that showed inhibition on emergence of lettuce and their quantities in barnyard grass exudate

Compounds	Retention time (min)	Molecular weight	Amount in exudates of barnyard grass ($\mu\text{g/ml}$)
Spot 1			
2-Ethyl-phenol	19.4	122	–
Dimethyl ester-phthalic acid	27.8	194	–
2,4-bis (1,1-Dimethyl)-phenol	29.4	206	–
Butyl 8-methylnonyl ester-phthalic acid	39.9	223	–
Diisooctyl ester-phthalic acid	50.1	279	–
Spot 2			
Ethyl ester-4-ethoxy-benzoic acid	29.9	194	–
Diethyl phthalate	31.5	222	2.7 ± 0.01
Spot 3			
2,3,7-Trimethyl-decane	22.5	141	–
2-Methyl-dodecane	24.1	169	–
Acenaphthene	26.1	153	–
Spot 4			
Decanoic acid	30.7	200	11.1 ± 0.03
Myristic acid	35.5	228	19.6 ± 0.02
Stearic acid	43.9	284	35.5 ± 0.06
Spot 5			
7,8-Dihydro-5,6-dehydrokavain	33.4	230	10.3 ± 0.05
7,8-Dihydrokavain	43.2	232	15.5 ± 0.03

–: Measurement was not conducted.

\pm : Standard errors ($N = 5$).

Only 6 of the 15 detected compounds were quantified, as the remaining chemicals were uncommon and could neither be purchased nor successfully purified. Diethyl phthalate accounted for 2.7 $\mu\text{g/ml}$ of the root exudates (Table 4). The quantities of decanoic acid, myristic acid, and stearic acid were 11.1, 19.6, and 35.5 $\mu\text{g/ml}$, respectively. The amounts of lactones were 10.3 and 15.5 $\mu\text{g/ml}$ for DDK and DHK, respectively.

PHYTOTOXINS FROM ROOT EXUDATES OF BARNYARDGRASS

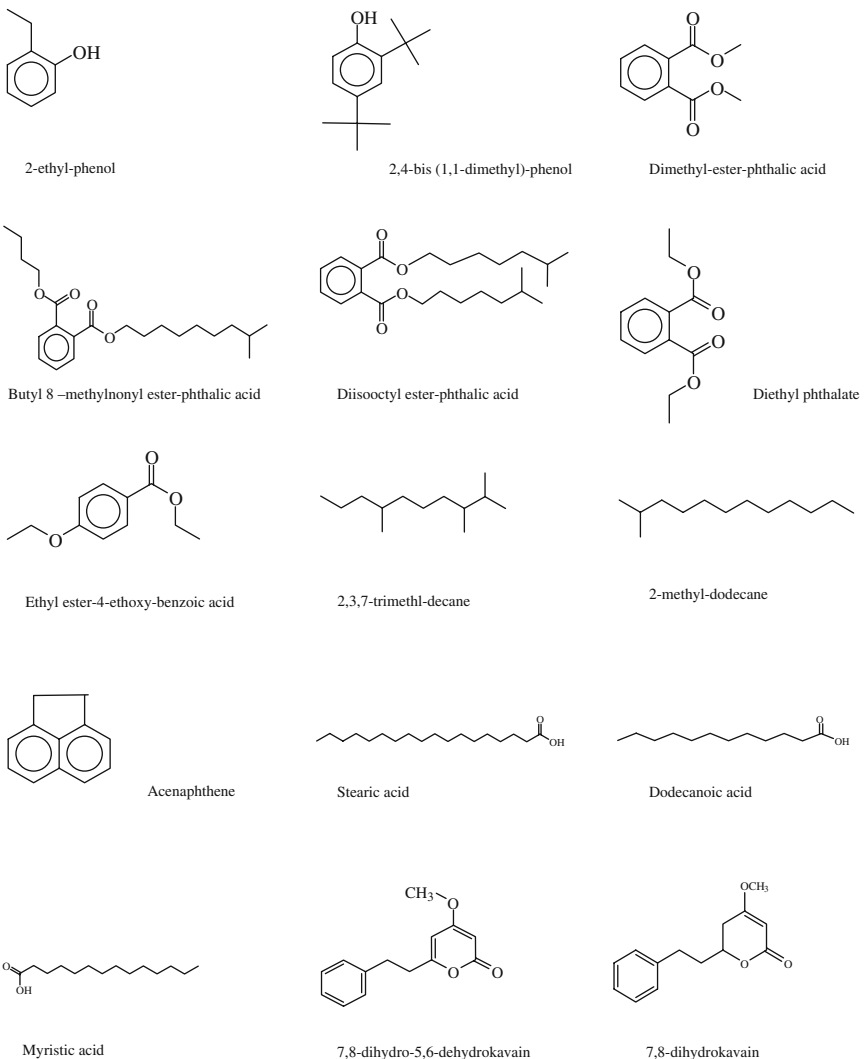

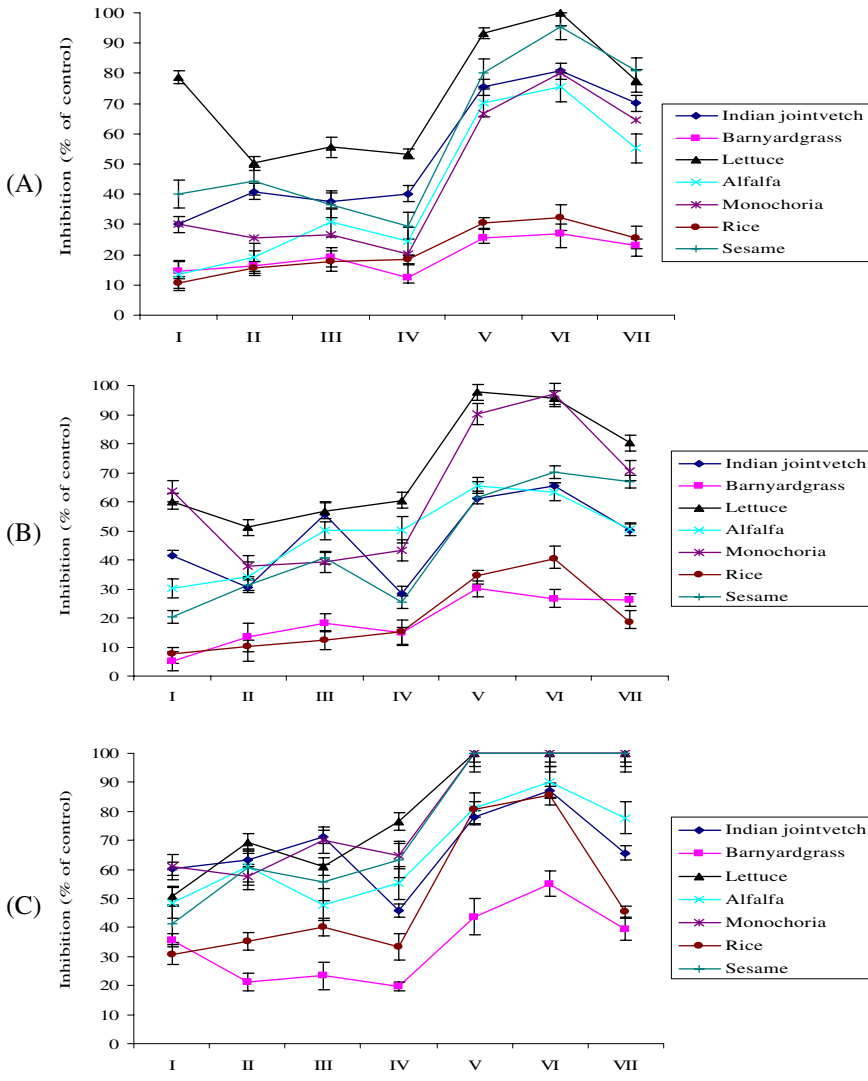

Fig. 1 Chemical structure of chemicals involved in inhibitory activities of barnyard grass root exudates

Effects of Chemicals in Root Exudates of Barnyardgrass on Plant Emergence

The effects of the two lactones on lettuce were the most detrimental, followed by the two phenolics and derivatives of phthalic acids (Tables 3 and 4). Fatty acids gave greater suppression than the derivative of benzoic acid (ethyl ester-4-ethoxy-benzoic acid; Tables 3 and 4). Acenaphthene and derivatives of decane exhibited the least effects among identified substances (Tables 3 and 4).

I: Diethyl phthalate II: Decanoic acid III: Myristic acid IV: Stearic acid
 V: 7,8-dihydro-5,6-dehydrokavain VI: 7,8-dihydrokavain VII: Mixture

Fig. 2 Effects of six individual compounds isolated from barnyard grass root exudates on emergence of seven plants [(A) germination, (B) shoot length, and (C) root length] at 100 ppm. Vertical bars represent standard errors

The six quantified compounds were tested individually for their influence on germination and growth of alfalfa, barnyard grass, Indian jointvetch, lettuce, monochoria, rice, and sesame at 100 ppm [405.5, 500.0, 438.5, 352.1, 434.8, and 431.0 μM for diethyl phthalate, decanoic acid, myristic acid, stearic acid, DDK, and DHK, respectively] (Fig. 2). In general, diethyl phthalate showed greater inhibition on growth of indicator plants than the fatty acids. The two lactones, however, inhibited indicator plant growth far more than the other compounds. The growth of all tested plants, except for barnyard grass and rice, was strongly inhibited by the quantified compounds.

The phytotoxins released by barnyard grass root exudates were least effective against rice and barnyard grass itself as compared to other broadleaf species (Fig. 2). Germination and shoot growth of barnyard grass and rice were not much affected; however, the growth of rice root was significantly suppressed by DDK and DHK and the mixture (60–70% of inhibition). The inhibitory effect of the two lactones on root elongation of barnyard grass was markedly lower than the effect on rice.

Discussion

Certain weeds are known to release allelochemicals into the environment and suppress both crops and other weeds in their vicinity (Bais et al., 2003). Therefore, the invasiveness of certain weeds may also be dependent on their allelopathic activities including the influence of exuded phytotoxins against neighboring plants. Numerous allelochemicals from weeds have been identified and reported to exhibit strong phytotoxic activity. However, most of them are from upland weeds (Qasem and Foy, 2001). Allelochemicals detected in upland weeds belong to several chemical classes, including phenolics, sesquiterpenes, flavonoids, terpenes, alkaloids, and their derivatives (Qasem and Foy, 2001). Little information on allelochemicals from weeds in rice paddies has been documented, although weeds cause serious interferences in agricultural production. Much of current research is concentrating on the biological control of rice paddy weeds in attempts to minimize the use of synthetic herbicides.

Major research efforts have focused on evaluating the ability of certain crop species to suppress barnyard grass infestation and on enhancing the allelopathic potential of these crop species, especially in rice (Chung et al., 2003). The incorporation of phytotoxic plant material into soil to suppress paddy weeds such as barnyard grass has also been investigated (Xuan et al., 2004), as well as the search for allelochemicals to control barnyard grass (Jung et al., 2004). In contrast, the allelopathic potential of this harmful weed species has not received much interest. Xuan et al. (2001, 2002, 2003, 2004) selected plants with strong weed-suppressing ability and applied them to soil 2 d after transplanting at 1–2 tons/ha. Weed biomass was controlled up to 80%, and rice yield increased by 20%. However, barnyard grass appeared to be the most difficult of the paddy weeds to control. The cause of this phenomenon is not known, although it is possible that chemical interference may have a role.

Yamamoto et al. (1999) reported that barnyard grass exhibited allelopathic potential. Root exudates of young barnyard grass suppressed root elongation of the seven plant species tested (cockscumb, timothy, cress, amaranth, rice, lettuce, and barnyard grass). A phenolic acid (*p*-Hydroxymandelic acid) was isolated and

identified in the root exudates that inhibited rice growth at concentrations of 59.5–178.6 μM . This compound has been shown to be involved in the phytotoxic activity of barnyard grass against rice (Yamamoto et al., 1999). However, to date, no further information about allelochemicals released by barnyard grass has been reported.

In this study, barnyard grass suppressed rice emergence, and the degree of rice inhibition was proportional to the density of barnyard grass. Root exudates of recently germinated barnyard grass exerted strong inhibition on germination and growth of lettuce, rice, and monochoria. Monochoria is also a noxious weed and is distributed widely in paddy fields and wet areas in the subtropics and tropics (Holm et al., 1991). Therefore, investigation of the chemical interactions among barnyard grass, rice, and monochoria, in addition to other weeds, is needed. As crop–weed interactions are better understood, the biological elimination of noxious paddy weeds may be more feasible. Lettuce is a common indicator plant used in bioassays related to allelopathy because of its high sensitivity to chemicals at low concentration (Xuan et al., 2004). Diethyl phthalate and phthalic acid derivatives are commercially important chemicals used predominantly as plasticizers in high-molecular-weight polymers, which are toxic to humans, animals, microorganisms, algae, aquatic invertebrates, and fish (Staples et al., 1997; Jonsson and Baun, 2003; Sung et al., 2003; Chen and Sung, 2005; Hu et al., 2005), as well as plants (Herring and Bering, 1988; Saarma et al., 2003). We, at first, thought the presence of diethyl phthalate and derivatives of phthalic acid might be caused by contaminants from either the sample preparation or analytical instruments. Therefore, the existence of these compounds in the root exudates of barnyard grass was examined carefully. Control experiments and samples of root exudates were repeated several times and were analyzed on two different GC-MS. Results from these experiments unequivocally confirmed that these compounds are not derived from contamination because of plasticizers used during extraction and sample preparation or due of solvent impurities. Recent reports show that diethyl phthalate is either bacterium or plant derived. Keire et al. (2001) reported that *Helicobacter pylori* secreted diethyl phthalate as a chemotactic factor. It was the first example of a phthalate ester that is produced by a bacterium. Elzaawely et al. (2006) reported that *Rumex janonicus* Houtt., a perennial herb widely distributed in the subtropics, produces diethyl phthalate. We suggest that diethyl phthalate and derivatives of phthalic acid may be derived from plants and act as a new class of plant phytotoxins. However, this needs confirming in other plant species, and the mechanism of producing these compounds by plants should be examined before concluding that these substances are natural products.

In this research, the most common phenolics found in many reported allelopathic plants were not detected in root exudates of barnyard grass. Three phenolics [2-ethyl-phenol, 2,4-bis (1,1-dimethyl)-phenol, and ethyl ester-4-ethoxy-benzoic acid] and derivatives of phthalic acids did show strong inhibition when isolated from TLC as a mixture. The amounts of these phenolics have not been quantified, but in gas chromatograms, they appeared to have lower peak areas than other identified substances (data not shown). Effects of these phenolics on plant growth need to be determined individually and compared to those of other common phenolic acids.

The two lactones were the most phytotoxic against the growth of seven plants at 431 and 434.8 μM for DDK and DHK, respectively. It is likely that lactones released by barnyard grass roots may play a major role in the allelopathic activities of the

weed. A mixture of these compounds was more inhibitory than diethyl phthalate and fatty acids, but it was lower than the effects of the two lactones individually. In this study, however, all detected phytotoxins in barnyard grass root exudates were present in low concentrations (Table 4), suggesting perhaps that in field conditions, they might not accumulate to the phytotoxic levels needed to affect rice and other weeds (Fig. 2). It is possible that phytotoxins other than those identified here may exist, and they may have allelopathic activity that accounts for the invasiveness of this harmful weed. They might be released by barnyard grass roots at stages other than the early growth stage.

This paper reveals that barnyard grass has allelopathic potential. It releases numerous phytotoxins into the environment during germination and early growth. These compounds could suppress the growth of rice and other plants, depending on the density of the grass in paddy fields. It appears that the phytotoxins that inhibit the growth of rice and other weeds have less influence on barnyard grass growth (Fig. 2). It is possible that phytotoxins released by monocots inhibit the growth of dicots more than the growth of monocots themselves and vice versa. The exudation of these phytotoxins into the environment may contribute to the success of barnyard grass as an invasive species. Both the release of these toxic compounds by barnyard grass at different growing stages and their interactions under natural conditions against crops and other weed species should be further studied.

Tracing Pollinator Footprints on Natural Flowers

Thomas Eltz

Received: 14 December 2005 / Revised: 22 January 2006 /

Abstract Many insects are known to leave lipid footprints while walking on smooth surfaces. Presumably, the deposited substances improve tarsal adhesion. In bumblebees, footprint hydrocarbons also function as scent marks that allow detection and avoidance of recently depleted flowers. I used GC-MS to detect hydrocarbons deposited by bumblebee (*Bombus pascuorum*) on flowers of *Lamium maculatum*. In addition to the plants' own cuticular lipids, extracts of corollas that had been visited by bumblebees contained odd-numbered alkenes. The amount of pentacosenes ($C_{25}H_{50}$) on corollas was linearly related to the number of bumblebee visits, with workers depositing approximately 16 ng per visit (extrapolated to a total of 65 ng of bumblebee cuticular hydrocarbons). Pentacosenes were retained on visited flowers without loss for 2 hr, and probably longer. This and results from flight cage experiments suggest that flower epicuticles retain a chemical record of pollinator visitation, including information on visiting bee species. Continuous footprint accumulation necessitates new explanations concerning the reversibility of “repellent scent marks” of bumblebees.

Keywords Footprints · Cuticular hydrocarbons · Hydrocarbon signature · Scent marks · *Bombus* · *Lamium*

Introduction

Insect cuticular lipids serve a range of functions, including reducing evaporative water loss over the body surface as well as improving adhesion for movement on smooth surfaces (Lockey, 1988; Jiao et al., 2000). Additionally, the same lipids may constitute chemical signals for conspecifics, e.g., by mediating mate recognition or relating information on reproductive status (Blomquist et al., 1998). In foraging

e-mail: eltz@uni-duesseldorf.de

bees, especially bumblebees (*Bombus* sp.), cuticular lipids are thought to function as scent marks that allow foragers to detect and avoid flowers that have been previously visited and depleted (Goulson et al., 1998, 2000, 2001; Stout et al., 1998; Williams, 1998; Gilbert et al., 2001; Gawleta et al., 2005). When approaching an inflorescence, bumblebee workers briefly hover in front of a depleted flower, but then reject it without actually probing for the concealed nectar reward. Behavioral experiments (Stout et al., 1998; Goulson et al., 2000) have indicated that the remote assessment of flowers is not based on a direct perception of nectar, but rather indirectly on the perception of hydrocarbon marks deposited by previous visitors. Flowers treated with hexane extracts of bumblebee tarsi elicited a repellent effect similar to that of a natural bumblebee visit, with nectar levels remaining unaltered. Similar results were obtained when researchers applied several pure synthetic hydrocarbons (*n*-alkanes, alkenes), the main contents of cuticular lipids of bumblebees (Schmitt, 1990; Oldham et al., 1994; Goulson et al., 2000), to flowers (Goulson et al., 2000). It is unclear whether the deposition of repellent substances is an active process that merits the term “scent marking” or whether the deposits are unavoidable “footprints” (Thomson and Chittka, 2001; Gawleta et al., 2005). A further corollary is that the repellent effect is only temporary. In most cases, repellency of visited flowers is lost after 20–60 min, which has been attributed to a progressive evaporation of the deposited substances (Stout et al., 1998; Stout and Goulson, 2002).

So far, no attempts have been made to directly measure bumblebee chemical traces on natural flowers. Schmitt et al. (1991) analyzed filter paper attached to artificial feeders of *B. terrestris* laboratory colonies and found cuticular hydrocarbon profiles that were similar to those of extracts of *B. terrestris* tarsi. The same substances might be detectable on real flower petals after natural visits of bumblebees. In this case, hydrocarbon signatures of bees would have to be discernable within the hydrocarbon profile of the plant (e.g., Griffiths et al., 1999). In the present study, I compared the cuticular hydrocarbons of the common Deadnettle *Lamium maculatum* (Lamiaceae) with those of its bumblebee visitors. I asked whether bumblebee hydrocarbons are detectable on visited flowers, and explored the temporal dynamics of footprint accumulation.

Methods and Materials

The study was conducted in patches of *L. maculatum* growing in the University of Düsseldorf Botanical Gardens. At the time of the study (August 10 to September 3, 2004), the flowers were mostly visited by workers of *Bombus pascuorum*. A 1 × 1 m area of the patch was covered by a mosquito mesh tent to prevent bees from accessing these flowers.

Hydrocarbon Contrast between Bees and Flowers

The following samples were collected for GC-MS: (1) individual sets of tarsi of worker *B. pascuorum* (cut at the distal end of the tibia, combining all six legs per individual sample; $N = 6$), (2) corollas of screened unvisited inflorescences ($N = 8$), and (3) corollas of screened inflorescences that were immediately presented to for-

aging bumblebees, allowing exactly one visit per corolla ($N = 7$). For items (2) and (3), five corollas from the same inflorescence were combined in one sample. Corollas were removed by tearing them from the receptacle with clean forceps; anthers were removed at the base with scissors. Every sample was extracted for 30 sec in 1 ml *n*-hexane (p.a., Merck) containing 10 μg 2-undecanone as internal standard. In the laboratory, the solvent was reduced to 0.15 ml at room temperature.

Footprint Accumulation on Visited Flowers

Unvisited inflorescences were cut, placed individually in water-filled vials, reduced to five open flowers, and presented to bumblebees in the field. Within 15 min, 0, 5, 10, 15, 20, 25, or 30 bee visits were allowed per inflorescence, corresponding to 0 to 6 visits per flower. Larger numbers of visits were increasingly difficult to induce, because the bees strongly rejected these inflorescences. Two series were done synchronously. In one of the series, the corollas were extracted in hexane immediately after the 15-min visitation time window. In the other, the inflorescences were placed in an insectary (not accessible to foraging bees) for 2 hr and then extracted. The same procedure was replicated three times, resulting in $7 \times 2 \times 3 = 42$ samples. For a given sample, all five flowers of the inflorescence were combined and extracted for 30 sec.

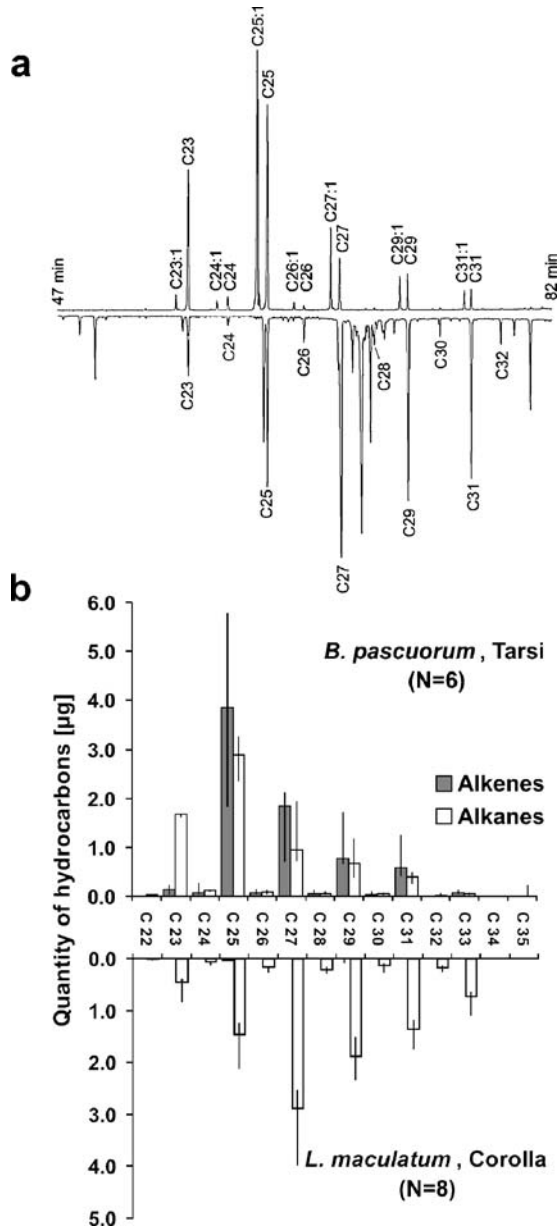

Bee-specific Hydrocarbon Signatures

Worker bumblebees were introduced into a mosquito mesh tent covering approximately 150 unvisited open *Lamium* flowers. Five bees were introduced between 08:30 and 09:30 in the morning and allowed to forage during the day. At 16:00 hr, bees were removed, and three replicate samples of five corollas each were extracted (as above). The experiment was done three times on consecutive occasions, once with *B. pascuorum*, once with *B. hortorum*, and once with *B. terrestris* workers. After an experiment with a given species was completed, all open corollas were removed from stalks with forceps and the next experiment started 2 or 3 d later when new (unvisited) flowers had opened in the tent. Tarsal extracts were taken from individuals of each of the bumblebee species ($N = 3$ per species; tarsi of all six legs pooled per sample). Effects of the (visiting) bee species on alkene composition of tarsal and corolla extracts were analyzed by using nonparametric ANOSIM permutation tests (Clarke, 1999; Clarke and Gorley, 2001). A similarity matrix based on the Bray–Curtis index (Legendre and Legendre, 1998) was calculated based on standardized data. I tested whether the factor (*visiting*) *bee species* had an effect on the rank order of between-sample similarities, separately for tarsal and corolla extracts. I also tested whether *sample type* (bee tarsi, corolla) had an effect.

Chemical Analysis

Gas chromatography-mass spectrometry (GC-MS) was performed with an HP 5890 II GC fitted with a 30-m nonpolar DB-5 column and an HP5972 mass selective detector. Injection was splitless, the oven programmed from 60 to 300°C at 3°C/min with automatic pressure programming. Characterization of hydrocarbons was done by comparison with authentic standards. Quantifications of hydrocarbon contents were based on internal (2-undecanone) and external (pentacosane) standards.

Fig. 1 (a) Total ion chromatograms of hexane extracts of *B. pascuorum* tarsi (on top) and unvisited *L. maculatum* corollas (bottom). *n*-Alkanes and alkenes are labeled and numbered with reference to the number of carbon atoms and double bonds. Unlabelled peaks in *Lamium* extracts are lipids that were not characterized. (b) Amount of hydrocarbons (median and quartile range) in tarsal and corolla extracts. Quantifications are given per individual set of tarsi ($N = 6$) and per corolla ($N = 8$), respectively. On average ($N = 6$), tarsal extract contained $8.02 \pm 2.49 \mu\text{g}$ alkanes and $8.47 \pm 3.51 \mu\text{g}$ alkenes. *n*-Pentacosane (C25) and pentacosenes (C25:1) were consistently the most abundant components, representing 19.4% and 24.0% of total individual hydrocarbons, respectively. Corolla extracts contained on average ($N = 8$) $12.27 \pm 6.44 \mu\text{g}$ alkanes (C:22 to C:33)

Results

Hydrocarbon Contrast between Bees and Flowers

Tarsal extracts of *B. pascuorum* were characterized by a series of *n*-alkanes and corresponding alkenes between C22 and C31, with odd-numbered homologs prevailing, confirming the results of an earlier investigation (Goulson et al., 2000)

(Fig. 1a, b). Corolla extracts of unvisited *L. maculatum* also contained large quantities of *n*-alkanes, but no or only traces of the respective unsaturated alkenes ($0.12 \pm 0.17 \mu\text{g}$; Fig. 1b). They also contained a range of additional lipids that were not further characterized (Fig. 1a). Four odd-numbered alkenes (C25:1 to C31:1) were well-defined markers for bumblebees. In comparison to unvisited controls, these alkenes were more abundant in samples of flowers that had received one visit per flower (Mann–Whitney *U* test: $P < 0.001$ for C25:1 and C31:1, $P < 0.01$ for C27:1, and $P < 0.05$ for C29:1; $N = 15$). As in *B. pascuorum* tarsal extracts, pentacosenes (C25:1) were the dominant alkenes on visited flowers.

Footprint Accumulation on Visited Flowers

There were significant positive effects of the number of visits on the amount of pentacosenes extracted from corollas, both when extraction was immediate or delayed (Fig. 2). Although samples with delayed extraction contained slightly lower amounts of pentacosenes, this effect was not significant (one-way ANOVA: $N = 42$; $F = 1.40$; $P = 0.24$). Inclusion of the number of visits as a covariate did not change this result ($N = 42$; $F = 2.84$; $P = 0.10$). Judging from the slopes of the linear regressions in Fig. 2, individual bumblebees deposited on average 16 ng pentacosenes per flower visit.

Bee-specific Hydrocarbon Signatures

Extracted tarsal alkenes differed qualitatively and quantitatively between different species of bumblebees (ANOSIM: $N = 9$; $R = 1$, $P < 0.01$), as did alkenes extracted from corollas visited by the different species of bumblebees ($N = 9$; $R = 1$, $P < 0.01$). There was no overall difference of alkene composition between tarsal extracts and visited corolla extracts ($N = 18$; $R = 0.043$; $P = 0.58$), with alkene profiles extracted from corollas closely corresponding to those of the visiting species of bumblebee (Fig. 3). The chain length of the dominant alkene in deposited footprints increased

Fig. 2 Relationship between the number of bumblebee visits per flower and the amount of pentacosenes extracted from corolla samples per flower. Black diamonds represent corolla samples that were extracted immediately after bumblebee visitation (linear regression: $N = 21$; $R^2 = 0.50$; $t = 4.39$, $P < 0.001$). Circles are corolla samples that were extracted after a delay of 2 hr ($N = 21$; $R^2 = 0.53$; $t = 4.66$, $P < 0.001$)

Fig. 3 (a) Alkene profiles of tarsal extracts of three species of bumblebees ($N = 3$ per species) and (b) of corolla extracts of *Lamium maculatum* visited by the three bumblebee species ($N = 3$ per visiting bee species). The mean and standard deviation are given

from tricosenes in *B. hortorum*, to pentacosenes in *B. pascuorum* and nonacosenes in *B. terrestris*.

Discussion

This is the first study to trace bumblebee “footprints” on natural flowers. Detection in corolla extracts was possible because several straight-chain alkenes served as chemical “bumblebee markers,” as they occurred abundantly on bee tarsi but not on unvisited *Lamium* flowers. Extrapolating from these markers to the entire set of tarsal hydrocarbons (see Fig. 1, assuming that deposition occurs in equal proportions), individual workers deposited approximately 65 ng of hydrocarbons per visited flower.

The origin of the deposited substances is as yet unknown. Schmitt et al. (1991) as well as the present study found that deposited substances were similar in composition to those in tarsal extracts, suggesting that tarsal glands situated in the fifth tarsomer are the secretory source (Schmitt, 1990; Schmitt et al., 1991). However, the tarsal gland reservoir has no opening to the outside in any of the several investigated bee species, which has cast doubt on their involvement in scent marking (Jarau et al., 2005). Furthermore, the hydrocarbons found on bumblebee tarsi can

also be found in similar composition on the cuticle of other body parts (Oldham et al., 1994; Goulson et al., 2000), suggesting that they are part of the hydrocarbon layer covering the entire body surface (Oldham et al., 1994). While probing *Lamium* flowers, bumblebees touch the corolla not only with their feet but also with the head, thorax, and abdomen, thus exposing the plant to a broad surface area of cuticle from which hydrocarbons may be acquired. This may be responsible for the rather large amounts of bumblebee hydrocarbons found on *Lamium* corollas in the present study.

The linear relationship between the amount of deposited pentacosenes and the cumulative number of visits per flower suggests that deposition is not reward-dependent and, therefore, probably passive (see Thomson and Chittka, 2001). Nonetheless, the depositions may be used as cues by foragers that enable them to detect recently depleted flowers (cues rather than signals; see Schmidt et al., 2005 for an example with an attractive effect). An unresolved problem exists concerning the temporal dynamics of the repellent response. In field studies with bumblebees, depleted flowers regain their original attractiveness after relatively short periods of time, in most cases between 20 and 60 min following a visit, depending on plant species and situation (Stout et al., 1998; Williams, 1998; Stout and Goulson, 2002; personal observation). It has been hypothesized that loss of repellency is observed because scent marks evaporate. In conflict with this idea, the amount of pentacosenes on visited flowers was not reduced by a 2-hr time delay before extraction, although longer delays might produce such effects. Generally, long-chain hydrocarbons such as those on bumblebee tarsi are of low volatility. This point is well illustrated by a study of Ginzel and Hanks (2002) that used combinations of synthetic alkanes (C24 to C31) to mark elytra of milkweed beetles. The profiles remained unchanged in quality and quantity over weeks, despite exposure to direct sunshine (Ginzel and Hanks, 2002). Thus, it seems unlikely that evaporation or molecular break down leads to a rapid vanishing of bumblebee footprints from flower corollas.

Why then is repellency reversed? Two alternative explanations seem plausible. First, bumblebee hydrocarbons accumulate, but are only slowly incorporated into the semiliquid layer of plant epicuticular lipids (see Jetter et al., 2000), rendering them increasingly imperceptible to foraging bees. Alternatively, bumblebee footprints may contain small quantities of low-molecular-weight volatiles that have not been detected in hexane extracts. Perception of such compounds could modify the behavioral response elicited by the hydrocarbons alone. Future studies will have to address this issue.

The present investigation shows that detection and quantification of bumblebee footprints is relatively simple and straightforward by using solvent extraction of flowers and GC. Probably the approach is also applicable to other plant–bumblebee systems. Cuticular hydrocarbons of bumblebees typically contain odd-numbered alkenes, with species-specific differences in chain length distribution (Goulson et al., 2000; this study). On the other hand, corolla extracts of bee pollinated plants lacked these alkenes (Griffiths et al., 1999, 2000; Goodwin et al., 2003; Eltz, unpublished data for *Symphytum officinale* and *Linaria vulgaris*), thus providing an unobscured background for extractive footprint detection. The finding that footprint hydrocarbons accumulate on petals without loss suggests that flowers carry a complete chemical record of bumblebee visitation, including information on visitation frequency and composition of the pollinator community. Reading this record by means of chemical analysis may constitute a powerful tool for pollination ecologists, re-

ducing time and manpower necessary for multireplicate field studies. Pilot studies will have to evaluate the feasibility and scientific potential of such an approach.

Acknowledgments I thank Reinhard Jetter, Klaus Lunau, Sebastian Witjes, and the participants of the Sensory Ecology Seminar for discussions and comments on the manuscript. The staff of the botanical garden in Düsseldorf is acknowledged for logistic support as well as continued tolerance of insect screens on their Deadnettle populations. Fragrance of Canada Thistle (*Cirsium arvense*) Attracts Both Floral Herbivores and Pollinators

Nina Theis

Abstract The evolution of floral scent as a plant reproductive signal is assumed to be driven by pollinator behavior, with little attention paid to other potential selective forces such as herbivores. I tested 10 out of the 13 compounds emitted by dioecious *Cirsium arvense*, Canada thistle, including 2-phenylethanol, methyl salicylate, *p*-anisaldehyde, benzaldehyde, benzyl alcohol, phenylacetaldehyde, linalool, furanoid linalool oxides (*E* and *Z*), and dimethyl salicylate. Single compounds (and one isomer) set out in scent-baited water-bowl traps trapped over 10 species of pollinators and 16 species of floral herbivores. The two dominant components of the fragrance blend of *C. arvense*, benzaldehyde and phenylacetaldehyde, trapped both pollinators and florivores. Other compounds attracted either pollinators or florivores. Florivores of *C. arvense* appear to use floral scent compounds as kairomones; by advertising to pollinators, *C. arvense* also attracts its own enemies.

Keywords *Cirsium arvense* · Trapping · Florivores · Pollinators · Scent · Herbivores · Phenylacetaldehyde · Benzaldehyde · Fragrance · Volatiles

Introduction

Insects navigate complicated odor landscapes, identifying the scent of a host plant while filtering out irrelevant chemical signals (Metcalfe, 1987; Masson and Mustaparta, 1990). Since the diversification of the angiosperms and many of their pollinators during the Cretaceous period, selection by beneficial insects has been acting on floral scent. Most research on floral volatile evolution has considered pollinators as the primary biotic selective agent (Dobson, 1994; Raguso, 2001). However, it has been proposed that the original role of plant volatiles was as deterrents against herbivores

(Pellmyr and Thien, 1986). Mounting evidence suggests that floral herbivores, which include both florivores and predispersal seed predators, are an important factor in selection on fragrance and other floral characters. Florivores can affect fitness directly (through tissue destruction) and indirectly (by deterring pollinators) (Strauss, 1997; Krupnick and Weis, 1999; Mothershead and Marquis, 2000; Adler et al., 2001). Ultimately, these losses can affect seedling recruitment (Louda and Potvin, 1995; Kelly and Dyer, 2002). Studies have demonstrated the role of florivores in the evolution of floral morphology (Brody, 1997; Kudoh and Whigham, 1998; Campbell et al., 2002; Ehrlèn, 2002), flowering phenology (Eriksson, 1995; Pilsen, 2000; Mahoro, 2002), flower number (Ohashi and Yahara, 2000), and floral scent (Galen, 1983; Baldwin et al., 1997). If detrimental insects use floral scent to locate their hosts, then they too will contribute selective pressures that affect the evolution of floral scent. Similar scent compounds that attract both pollinators and detrimental insects may be subject to opposing selection pressures: pressure to be both apparent to pollinators and inconspicuous to florivores.

Of the studies that have investigated the attraction of herbivores to floral volatiles, many have focused on agricultural pests (Dobson, 1994). Studies have been carried out both on insects that feed on floral tissue and on those that oviposit into a flower head where their larvae feed (Cantelo and Jacobson, 1979; Wiesenborn and Baker, 1990; Haynes et al., 1991; Roseland et al., 1992; Tingle and Mitchell, 1992; Smart and Blight, 1997; Metcalf et al., 1998; Smart and Blight, 2000). Canada thistle, *Cirsium arvense* (Asteraceae), is an invasive species in the eastern United States, and native to Europe, Western Asia, and North Africa; it was probably introduced into Canada in the early 17th century (Moore, 1975). I chose to study an exotic invasive species because of its potential to demonstrate both coadapted interactions with introduced insects, as well as novel, interactions with native herbivores.

Cirsium is pollinated by a wide range of generalists, including insects from several different orders (Proctor et al., 1996). In this population, I found the most abundant pollinator on *C. arvense* to be the nonnative (but coadapted, as it is native to Europe) honeybee (*Apis mellifera*), with high visitation rates by other bees, especially *Halictus* and *Lasioglossum* ssp. (Halictidae; Theis, 2003). Other pollinators included hover flies (Diptera: Syrphidae) and common diurnal Lepidoptera, including *Vanessa atalanta* and *Pieris rapae*. A field experiment determined that nocturnal pollination is not relevant in the study population (Theis, 2003). Florivorous insects from several orders feed on *C. arvense* flower heads, including beetles (Mordellidae, Phalacridae, Meloidae, Cantharidae) and grasshoppers (Acrididae, Tettigoniidae) (Theis, 2003). Many species of *Cirsium* and other closely related groups are considered noxious weeds in the United States, and a number of biocontrol agents have been introduced to control *C. arvense*, including root, leaf, and flower feeders (McEvoy and Coombs, 1999). *Dasineura gibsoni*, an introduced cecidomyiid fly, and two introduced weevils were found on *C. arvense*; one weevil, *Larinus planus*, was quite common, whereas *Rhinocyllus conicus* was rare. With a generalist pollination system and a large number of both introduced and native florivores, it is an ideal choice for studies on potential balancing or diversifying selection on floral scent.

I quantified the chemical composition of both staminate and pistillate *C. arvense* plants and used scent-emitting traps to determine the olfactory preferences of both pollinators and florivores to *C. arvense* fragrance components. If beneficial and

detrimental insects use different fragrance components, then directional selection should minimize the compounds attractive to the detrimental insects.

Methods and Materials

Taxa and Field Sites

Cirsium arvense (L.) Scopoli, Canada thistle, (Asteraceae), is an erect perennial whose height at reproduction ranges from 0.3 to 2.0 m. Unique among thistles, *C. arvense* has dioecious flower heads of pink-purple disk flowers, which bloom from July through September (Nuzzo, 1997). I conducted this study at the U.S. Fish and Wildlife Service Wallkill River National Wildlife Refuge. Located on the border of Sussex, NJ, and Warwick, NY, USA (74°31'W, 41°17'N), the site is a former sod farm. It is dominated by mixed communities of native and exotic invasive plants in open fields, including *Asclepias syriaca*, *Ambrosia artemisiifolia*, *Solidago* sp., *Lythrum salicaria*, and *Carduus nutans*.

Emission Rates

Volatiles were collected from *C. arvense* by using dynamic headspace sampling in the field. Intact flower heads were enclosed within a nylon resin oven bag (Reynolds Consumer Products, Richmond, VA, USA). Ambient air flowed into the bag across the flower head and into Porapak® Q (80–100 mesh) packed cartridges at a flow rate of ca. 200 ml/min, via either an Air Check 52 or Air Check 2000 diaphragm pump (SKC Inc., Eighty Four, PA, USA). Cartridges were eluted with 3 ml hexane, and an internal standard of 3 µl of 0.01% anisole in hexane was added. Samples were concentrated to 75 µl with N₂. To ascertain the fragrance production of cut flower heads (*N* = 2 staminate, 3 pistillate), scent was collected for 4 hr before cutting and 4 hr immediately after cutting. Emission rates from the traps were measured for 10 min by using the same protocol described above, but in a growth chamber with controlled light and temperature (24°C) to mimic average field conditions (*N* = 3).

Fragrance Analysis

Combined capillary gas chromatography-mass spectrometry (GC-MS), with a Shimadzu GC-17A equipped with a Shimadzu QP5000 quadrupole electron impact MS as a detector (Shimadzu Scientific Instruments, Inc., Columbia, MD, USA), was used to analyze the fragrance. A 1-µl aliquot was injected splitless onto a polar column (EC WAX) (30 m × 0.25 mm; Alltech Associates, Deerfield, IL, USA) at an initial temperature of 60°C for 3 min, which was increased by 10°C/min until 260°C, where it was held for 7 min (Theis and Raguso, 2005). Compounds were identified by using retention time (from previously injected standards) and mass spectral libraries [Wiley (1995) and NIST (1998)], with greater than 120,000 mass spectra. Quantification was achieved by relating the mass ion of each scent compound to the mass ion of the internal standard with serial dilution curves of the scent compounds run as external standards.

Scent-Baited Traps

I used scent-emitting insect traps, during July and August 2002, to attract both pollinators and florivores by using 10 of the 13 floral compounds identified from the scent blend of *C. arvensis* (Andersson et al., 2002; Theis and Raguso, 2005). Each trap consisted of a clear bowl (8-in. plastic bowls; Hummert International, Topeka, KS, USA) fixed to a tier of a tomato cage at a similar height level with that of the blooming plants. A second bowl filled with soapy water (Alconox liquid detergent 1 ml/5 l; Alconox, White Plains, NY, USA) was set inside the fixed bowl. Suspended above the soapy water by a wire was a microcentrifuge tube filled with either scent or an unbaited control tube. A hole was cut into the microcentrifuge tube, and a wick of single-stranded embroidery floss was submerged in the chemical and projected 7 mm above the top of the tube, in order to emit scent. All wicks were renewed (cut and pulled another 7 mm) once a day. Scents were refilled at least once a week. As a visual display, a cut staminate or pistillate *C. arvensis* flower head (set into a water-pik) was suspended above water bowls. Flower heads also were renewed daily.

Two field experiments were run simultaneously for 4 wk, spanning the peak of *C. arvensis*'s flowering season. One experiment had six treatments, including three pure compounds (phenylacetaldehyde, methyl salicylate, 2-phenylethanol), racemic linalool, one blend of two linalool oxide furanoid isomers, and a dry control tube. The second experiment consisted of seven treatments: two pure compounds (dimethyl salicylate, benzyl alcohol), two compounds diluted by 1/2 with mineral oil (*p*-anisaldehyde, benzaldehyde), one control tube containing mineral oil, and two cut flower heads (one staminate, the other pistillate). The cut flower heads were not used until the second week of the experiment. I did not test the pyranoid linalool oxide isomers or benzyl benzoate in the traps. The treatments were arranged in a circular array surrounding a patch of *C. arvensis*. Each circle contained two replicates of each treatment, and the arrangement of compounds was randomized once a week. Traps were placed 3 m apart and a replicate circle was set up at least 10 m away, for a total of four replicate traps. Trapped insects were identified daily and collected every 2 d.

Chemicals

The synthetic compounds were obtained from Sigma-Aldrich (St. Louis, MO, USA; 2-phenylethanol 100%, methyl salicylate 99%, *p*-anisaldehyde 99%, benzaldehyde 99%, benzyl alcohol 99%, phenylacetaldehyde >90%, (±)-linalool 97%, furanoid linalool oxide mixture of isomers >97%) and from Quest International (Ashford Kent, UK; dimethyl salicylate).

Statistical Analyses

Trap catch was not normally distributed for any insect species. For groups with more than 24 trapped individuals, I used Systat 10.0 to test for differences in trap catch between each treatment and the control within each circle (replicates were lumped) by using the Wilcoxon's signed-ranks test for paired comparisons (Sokal and Rohlf, 1995).

Results

Trapped Species

In two field experiments, I tested the attraction of pollinators and florivores to 10 components of the *C. arvensis* blend (eight compounds and one isomeric mixture). Emission rates from the traps ranged from 343 to 769 $\mu\text{g/hr}$ (Table 1). For comparison, the average total emission rate from *C. arvensis* is 19 $\mu\text{g/hr}$ for staminate flower heads and 4 $\mu\text{g/hr}$ for pistillate. I captured a total of 15 species of florivores and nine species of pollinators, seven of which were bees, including three genera of Halictidae (Table 2). Butterflies pollinate *C. arvensis*, although infrequently in this population, but were not captured within water bowl traps.

Pollinator Attractants

A pollinator assemblage, summed for all species of pollinators with greater than 10 representative individuals, was tested for fragrance preference. Three compounds were more attractive to pollinators than the control: benzaldehyde, phenylacetaldehyde, and *p*-anisaldehyde (Wilcoxon's signed-ranks test, $P < 0.05$; Table 2, Fig. 1). Of these, *p*-anisaldehyde and phenylacetaldehyde were by far the most attractive compounds, trapping on average 48% and 37% of all pollinators within each of the respective experimental arrays. Only honeybees and *Lasioglossum* were caught in sufficient numbers to be able to detect significant differences in trap preference for individual pollinator genera; both were trapped by *p*-anisaldehyde. Phenylacetaldehyde and linalool were also attractive to honeybees.

Florivore Attractants

Florivores were attracted to floral scent compounds from *C. arvensis*. I summed the data for all florivores (that had greater than 10 individuals trapped) and determined that 26% of all florivores were trapped by benzaldehyde (Wilcoxon's signed-ranks test, $P < 0.05$; Table 2, Fig. 1). In contrast, more florivores were trapped by the control than by linalool. Specific florivores also demonstrated significant prefer-

^a "Pollinators" and "florivores" represent summed data, excluding groups with ten or fewer individuals.

^b Wilcoxon's signed-ranks test for paired comparisons between treatments and control, * $P < 0.05$, significance not tested for any group with fewer than 24 individuals.

Fig. 1 The average number of trapped pollinators and florivores in each scent trap contrasted with the abundance of each of these compounds in the floral blend of staminate *Cirsium arvense*, in parentheses next to compound name. Trap catch was normalized by total trap catch and control trap catch. Significance tested by Wilcoxon’s signed-ranks test paired comparisons between treatments and control * $P < 0.05$

ences, both positive and negative. Ants (Formicidae) were attracted to phenylacetaldehyde, and mordellids were attracted to benzyl alcohol and to the furanoid linalool oxide isomers. In the first 2 wk of the experiment, mordellids were frequently trapped by dimethyl salicylate, but this preference was not consistent throughout the experiment, and it is not significant. The tettigoniid grasshoppers (predominantly nymphs) were never trapped by linalool or 2-phenylethanol.

Visual Display

Cut flower heads also trapped both pollinators and florivores. Cut flower heads emitted less than half the total emission of intact flower heads (approximately 44% for staminate flower heads and 35% for pistillate flower heads). In spite of fragrance reduction, staminate and pistillate cut flower heads were attractive to pollinators (Wilcoxon’s signed-ranks test, $P < 0.05$; Table 2). Summed data for all pollinators was strongly influenced by *Lasioglossum*, which were more frequently trapped by cut pistillate flower heads, and by honeybees, which were more frequently trapped by cut pistillate flower heads, although these preferences were not significant. Florivores and particularly the tettigoniids were attracted to cut staminate flower heads.

Discussion

Floral Scent Traps Both Pollinators and Florivores

The fragrance emitted by *C. arvensis* attracts both pollinators and florivores (Table 2, Fig. 1). Some compounds significantly attracted only pollinators (i.e., *p*-anisaldehyde), while others significantly attracted only particular species of florivores (i.e., benzyl alcohol). Some compounds were attractive to both pollinators and florivores (benzaldehyde and phenylacetaldehyde). Attractive compounds were not necessarily the most abundant components of the *C. arvensis* fragrance blend (Fig. 1). For example, *p*-anisaldehyde is 0.5% of the total blend, but a highly attractive compound for pollinators. Although trapping experiments using blends would convey a more complete picture of selection on the fragrance phenotype, pure compounds, nonetheless, should be informative. From studies on the neurophysiology of honeybees, Galizia and Menzel (2001) have demonstrated that a mix of two compounds results in a signal in the insect brain that is not novel, but rather additive of the component parts with some degree of deviation, both positive and negative (inhibition). There could be synergistic effects of compounds in the blend that result in an increase in attraction, reducing our ability to identify the intensity of selection on any one of these compounds, but not changing the direction of selection. Overall, these results demonstrate that the fragrance emitted from *C. arvensis* is perceived and utilized not just by beneficial insects, but by detrimental insects as well. As a result, components of the fragrance blend should be shaped by opposing selection pressures.

Diversity of Pollinators in Odor Traps

The dominant pollinators of *C. arvensis* were caught in the traps, including species from five families in two insect orders (Table 2). The largest numbers of individuals were caught from the family Halictidae, a sample dominated by *Lasioglossum* (*Dialictus*) bees. Also trapped were honeybees, the dominant pollinators of *C. arvensis* at this study site, as indicated in a census (Theis, 2003). Lepidopteran pollinators were excluded from analysis for two reasons: the water bowl traps did not attract butterflies, and nocturnal pollination does not occur in this population (Theis, 2003). Therefore, the moths that were trapped in these experiments, while indicative of the general attraction to aromatic floral compounds (see Cantelo and Jacobson, 1979; Plepys et al., 2002), are omitted from further discussion.

Diversity of Florivores in Odor Traps

A large diversity of dominant florivores were caught in the traps, including species from 14 families in five insect orders. All of the insects defined as florivores were seen feeding on *C. arvensis*, and many are recognized as highly detrimental, including the Japanese beetle (*Popilla japonica*), the tarnished plant bug (*Lygus lineolaris*), and blister beetles (*Epicauta* sp.) (Borror et al., 1992). Two of the florivore groups in this system have been implicated as selective forces driving the evolution of floral scent in other plant species: Negro bugs (*Corimelaena* sp.) on *Nicotiana* (Baldwin et al., 1997) and ants (Formicidae) on *Polemonium* (Galen,

1983). Nevertheless, the classification of these insects as detrimental is only putative. This applies particularly for the Cantharidae, which may be predatory on other florivores, resulting in a net positive effect. Many of the florivores that are attracted to *C. arvensis* floral odors are specialists on Asteraceae (Borrer et al., 1992). Some insects, such as *L. planus*, were frequently found on *C. arvensis*, but were infrequently captured in the traps, including control traps. It is possible that these insects are attracted by scent, but the trapping apparatus does not efficiently trap them. With such a high diversity of florivores on *C. arvensis*, none of which is completely specialized or devastating, selection pressure from this group is likely to be somewhat diffuse.

Repellent Compounds

Only florivores were significantly less attracted to some components of the floral scent blend (e.g., linalool) than to the unbaited control. A trap with the full blend minus the putative repellent could establish repellence for individual components. Repellent compounds have infrequently been reported in the literature (Dobson, 1994; Theis and Raguso, 2005), perhaps because florivores may adapt to perceive a compound as attractive if there is a reward associated with the cue.

Selection on Floral Scent Biosynthesis

Selection acting on quantitative variation in the emission of specific components of the floral scent blend may result in selection on the biochemical pathways from which those compounds are produced. The 13 compounds emitted by the flowers of *C. arvensis* are products of two biosynthetic pathways. Phenylacetaldehyde, benzaldehyde, and *p*-anisaldehyde are all products of the shikimate pathway (Dey and Harborne, 1997). In the shikimate pathway, phenylalanine ammonia lyase (PAL) is the “branch-point” enzyme between primary and secondary metabolism (Dixon and Paiva, 1995). The monoterpenoids, linalool and the linalool oxides, are produced in the DOXP/MEP pathway localized to plastids (Lichtenthaler et al., 1997; Raguso and Pichersky, 1999). Multiple enzymes may be at work in producing the diversity of volatiles, but single terpene synthase enzymes are sometimes responsible for the synthesis of several major and minor volatile products (Bohlmann et al., 1998). If selection acting on one compound affects the production of a different compound in the blend, a number of outcomes could arise. For example, honeybees are attracted by linalool, whereas florivores may be repelled. With this simple model, I would expect that linalool should increase in the blend. However, the mordellid beetles are attracted by the furanoid linalool oxide isomers (Table 2), and it is possible that positive selection acting on linalool could be constrained by negative selection on the linalool oxides, which are produced from linalool (Raguso and Pichersky, 1999). If the pollinator attractant increases, perhaps its associated oxides would also increase, resulting in the attraction of florivores. Only a few of the enzymes involved in the production of floral scent compounds have as yet been identified (Dudareva et al., 2003). However, understanding the selection pressures on the components of the floral scent blend will require knowledge of enzymatic pathways in order to obtain a full picture of selection pressure on the blend.

Acknowledgments I thank Robert Raguso and Manuel Lerdau for discussion and comments; Laurel Reid, Eileen Rios, and Sarah Brice for help with data collection; Karen Goodell for help with bee identification; Robin Clery from Quest International for samples of dimethyl salicylate; and two anonymous reviewers for helpful comments. Abstract The volatiles emitted by fresh whole flowers and isolated flower organs of male, female, and hermaphrodite carob trees (*Ceratonia siliqua* L.; Leguminosae) were analyzed by headspace solid-phase microextraction followed by capillary gas chromatography and mass spectrometry. The headspace of carob flowers is mainly constituted of high amounts of monoterpenes and sesquiterpenes, and more than 25 compounds were identified. The gender and cultivar affected both the qualitative profile and the relative abundances of the volatiles of whole flowers and isolated floral organs. Linalool and its derivatives (*cis*-linalool furan oxide, 2,2,6-trimethyl-3-keto-6-vinylnorbornene, *cis*-linalool pyran oxide, and *trans*-linalool furan oxide), α -pinene, and α -farnesene were the dominant volatiles. Female flowers had a higher diversity of volatile compounds than males and hermaphrodites, but a lower abundance of the major ones. Similarly, the floral scent of female flowers of cv. Mulata had a higher content of volatiles but a lower abundance of the major ones, when compared to cv. Galhosa. In each of the three gender types of flowers, the nectary disks seemed to be the major source of volatiles.

Introduction

Animal-pollinated plants advertise their flowers to attract pollinators, and this can take the form of visual (color and shape) and olfactory (scents) cues (Dobson, 1994). Floral scents may function as long-distance and/or short-distance attractants (reviewed by Dobson, 1994) not only to insect pollinators (Ômura et al., 1999; Wright et al., 2002) but also to key insect pests (Nojima et al., 2003; Tasin et al., 2005).

In flowering plants, inbreeding avoidance and resource reallocation favor the evolution of gender dimorphism (i.e., females and males or hermaphrodites; reviewed in Charlesworth, 1999). However, females, which produce no functional male organs, often suffer inadequate visitation and pollen limitation (Ashman, 2000; Williams et al., 2000; Ashman and Diefenderfer, 2001). The reduction in visual floral cues (petal size and flower number) or rewards (pollen and nectar) are usually referred to as the factor responsible for the lower attractiveness to pollinators as displayed by females rather than males or hermaphrodites (Ashman et al., 2000). However, Ashman et al. (2000) evaluated the characters responsible for sex-differential visitation in *Fragaria virginiana* and found that visual cues or reward status could not fully explain the male bias in pollinator service.

Given the differences in total floral investment (reviewed in Eckhart, 1999) and in allocation to floral organs (Ashman, 1994; Jones and Burd, 2001), sex morphs of gender dimorphic plants are expected to exhibit differences in floral scent because the emission of volatiles can be biomass-dependent, and the compounds emitted can vary among the floral organs (Dobson and Bergström, 2000). In spite of the high degree of similarity usually observed in the type of compounds present in the scent profile between sexual types, differences in the abundances of the main constituents are common, namely, in some species of Salicaceae (Tollsten and Knudsen, 1992), Arecaeae (Ervik et al., 1999), and in *Geonoma macrostachys* (Knudsen et al., 1999) and *Ficus carica* (Grison-Pige et al., 2001). However, it is not yet known if this variation has functional implications since information about the source of sex differences is scarce (Dobson and Bergström, 2000), and there are no reports on whether or not they cause differential pollinator attraction.

The solid-phase microextraction (SPME) process is a fast and a powerful solventless technique, allowing the establishment of the equilibrium between the analytes from the headspace of the sample matrix and the stationary phase coating of a fused silica fiber, followed by thermal desorption of the concentrated analytes into the gas chromatograph (GC) inlet (Flamini et al., 2003; Pellati et al., 2005). Furthermore, this technique is sensitive enough to identify plant odors from specific tissues (Barták et al., 2003), such as flower organs, pollen (Flamini et al., 2003), and nectar (Raguso, 2004). The use of headspace techniques to sample volatiles in the air surrounding a plant has revealed that olfactory stimuli differ not only among species, but also among different organs within a single flower (Flamini et al., 2003; Dötterl and Jürgens, 2005). These spatial fragrance patterns within the flowers can guide insects to both nectar and pollen (Dobson, 1994; Dötterl and Jürgens, 2005). Studies of floral scents and of their patterns within a single flower are important to

better understand the chemical bases of plant–animal relationships and pollination ecology (Flamini et al., 2003) because quantitative and qualitative differences in the volatiles emitted from flower parts may be important in effecting pollinator attraction (Dobson et al., 1990). Some papers have ascribed this to distinct volatile compounds or blends emitted by different flower parts (Dobson et al., 1990, 1996; Knudsen and Tollsten, 1991; Pichersky et al., 1994; Bergström et al., 1995; MacTavish and Menary, 1997; Flamini et al., 2003; Azuma et al., 2004; Ashman et al., 2005).

Floral scent can be crucial in ensuring fertilization and in determining fruit or seed set, thus having a substantial impact on the yield of agronomically important crops (Dudareva et al., 2000), such as the carob tree (*Ceratonia siliqua* L.; Leguminosae), where the economical value relies on the fruit production and seed yield. The economic importance of this species is a result of the locust bean gum (LBG) extracted from the seeds and used in the food industry as a viscosifier, stabilizer, and gelling agent in products such as juices, dietetic beverages, desserts, baby foods, and pet foods (Batlle and Tous, 1997).

The carob tree is a polygamo-dioecious or monoecious species (Tucker, 1992). Individual trees may be male (with inflorescences carrying only staminate flowers), female (with inflorescences carrying only pistillate flowers), and hermaphrodite (with some inflorescences carrying staminate and others pistillate flowers, or with inflorescences carrying hermaphroditic flowers).

The carob is the only Mediterranean tree that has its main flowering season in autumn (September–November) with a peak in October (Martins-Loução and Brito de Carvalho, 1989; Retana et al., 1994; Batlle and Tous, 1997), when only few species are in flower (Arroyo, 1988). Moreover, carob flowers offer high amounts of nectar and pollen (Ortiz et al., 1996). Both the lack of alternative flowering species and the presence of abundant rewards mean that carob flowers are highly visited. It has been observed that the male flowers receive a higher number of floral visitors than the female ones, although the latter produce significantly higher amounts of nectar (Ortiz et al., 1996). However, the carob displays a low percentage of fruiting per raceme in both wild (Ortiz et al., 1999) and cultivated populations (Bosch et al., 1996), and it has been pointed out that the fruit production per raceme is limited by both the availability of resources and by deficient pollination (Arista et al., 1999). This evidence posed the question of whether there are differences in the scent emitted by flowers of the different genders of carob tree, which could lead to different patterns of floral visitations. To answer this, in a previous report, Custódio et al. (2004) analyzed the volatile composition of the scent emitted *in vivo* by the flowers of each of the three gender types in carob, and by flowers at different developmental stages, by using headspace SPME followed by capillary gas chromatography coupled with mass spectrometry (HS-SPME-GC/MS). More than 25 compounds were identified, and both gender and developmental stages affected the volatile composition. In male and hermaphrodite flowers, the total volatile compounds were more abundant in stage III (when the mature flowers show nectar secretion and pollen has not been shed), and in female flowers, in stage IV (when nectar and stigmatic fluids are secreted; the color of the stigma turns from greenish-yellow to yellow and brownish-yellow; brownish spots appear until the whole stigma turns brown and black). The most abundant volatile compounds reported in the headspace of carob flowers were linalool and *trans*-linalool oxide and were present in higher abundance in male flowers.

In this work, we expanded upon this earlier study by analyzing the main volatiles in the scent emitted *in vivo* by whole flowers and isolated flower organs of male, hermaphrodite, and by the two most economically important female carob cultivars (Mulata and Galhosa) to evaluate the contribution of the volatiles emitted by the different floral organs to the scent of whole flowers and to assess if the differences in the scent are linked to specific emissions of certain compounds by different organs. Additionally, the influence of the mean weight of whole flowers, nectary disks, stigmas, and stamens on the emission of volatiles was studied.

Methods and Materials

Plant Material

Inflorescences were collected from 14-year-old male, female, and hermaphrodite carob trees, growing in a nonirrigated and nonfertilized orchard, located in the south of Portugal (37°07'N; 7°39'W). Male trees were seminal, whereas female and hermaphrodite ones were grafted. Two female cultivars were studied: the Galhosa and the Mulata. The climate of the region is typically Mediterranean (Mitrakos, 1981), and the annual rainfall (400–500 mm) is mainly distributed throughout winter and early spring.

Floral Analysis

For each gender, 3 trees were selected and 25 individual flowers were randomly collected per tree from all canopy orientations. The average weight of whole flowers and of the stamens (including filaments and anthers), nectary disks (including pedicel), and stigmas was determined.

For the headspace analysis, 500 mg of each floral sample type was used. The floral material was collected at mid-day, at stages found by Custódio et al. (2004) to emit the most volatiles (Fig. 1): (1) male whole flowers at stage III, (2) hermaphrodite whole flowers at stage III, (3) female whole flowers at stage IV, and (4) separate floral organs (stamens, nectary disks, and stigmas) from male (stage III), hermaphrodite (stage III), and female flowers (stage IV).

Flowers from each sample were collected and introduced into a 30-ml amber glass vial with screw caps (Supelco). The SPME device (Supelco Inc., Bellefonte,

(C) Female flower with a calyx tube (ct), sepals (s), and a pistil (pi) formed by a short stipe (st), an abbreviated style (sty), and a peltate stigma (stg; bar = 13.88 mm)

Table 1 Weight (mg) of whole flowers and isolated flower organs of the three genders of carob

	Hermaphrodite	Male	Female
Whole flower	100 ± 10Aa	30 ± 1Ba	30 ± 2Ba
Stamens	40 ± 1Ab	20 ± 1Bb	–
Nectary disks	30 ± 1Abc	10 ± 0Bd	10 ± 2Bb
Stigmas	20 ± 0c	–	20 ± 2c

In each column, statistical comparisons were made between different floral parts of the same sexual type and are shown in lower case letters. In each row, statistical comparisons were made between genders, for the same flower organ, and are shown in capital letters. Values represent means ± SE of three replicates with 25 flowers each. Values followed by different letters are significantly different at $P < 0.05$ (one-way ANOVA, Duncan's new multiple range test). Absence of letters indicates no significant differences at $P \geq 0.05$.

PA, USA), coated with polydimethylsiloxane fiber (100 μm), was first activated by inserting it into the GC injector port at 250°C for 1 hr. For sampling, the fiber was inserted into the headspace for 15 min at room temperature (20°C). Following sampling, the SPME device was introduced into the injector port for chromatographic analysis, where it remained in the inlet during the run, thus preparing it for the next collection of volatiles. The analyses were performed in triplicate, and blank assays using empty vials were conducted as controls.

Capillary GC/MS analyses were performed on an Agilent 6890 series gas chromatograph interfaced to an Agilent 5973 *N* mass selective detector (Agilent Technologies, Little Falls, DE, USA). A vaporization injector was used in the splitless mode (2 min) at 250°C, with a fused silica capillary column, 30 m \times 0.32 mm ID \times 0.25 μm d_f (HP-5MS; 5% diphenyl, 95% dimethyl polydimethylsiloxane, Agilent Technologies). The oven temperature program was 40°C for 2 min and then increased at 5°C min^{-1} to 180°C, followed by 15°C min^{-1} to 240°C, and held isothermally for 15 min. Helium was used as carrier gas at 30 cm sec^{-1} .

Electron ionization mass spectra in the range 40–400 Da were recorded at 70 eV. The quadrupole, source, and transfer line temperatures were maintained at 150, 230, and 280°C, respectively, and a turbo molecular pump (10^{-5} torr) was used. All data were recorded with an MS ChemStation (G1701CA; Rev C.00.00; Agilent Technologies).

The identity of each compound was determined by comparison of its retention index relative to C_6 – C_{24} n-alkanes (Adams, 2001), as well as of its spectral data with the Wiley's library spectral data bank (G1035B; Rev D.02.00; Agilent Technologies) or homemade libraries (Flavour2.1). For semiquantification purposes, the normal-

Results

Weight of Whole Flowers and Floral Organs

The gender significantly affected the weight of whole flowers and isolated flower organs ($P < 0.05$), except for stigmas. Male and female flowers had similar mean weights, and the hermaphrodites were heavier (Table 1). In the hermaphrodites, the stamens were heavier than the stigmas, and in males and females, the heavier flower organs were the stamens and the stigmas, respectively (Table 1).

In the male flowers, the stamens and nectary disk comprised 64.6 and 33.7% of the total flower weight, whereas in the females, 58% of the total floral weight corresponded to the stigma and 33.1% to the nectary disk (Fig. 2). In the hermaphrodite flowers, the contribution of stamens, nectary disk, and stigma to the total flower weight was 38.4, 32.6, and 20.4%, respectively (Fig. 2).

Headspace Emission from Whole Flowers

More than 25 compounds were identified, representing 54.2–97.0% of the total volatile constituents (Table 2). The scent of the carob flowers is richer in monoterpenes than in sesquiterpenes, and linalool and its derivatives are the most abundant compounds. Differences in volatile composition were observed between the genders and the two female cultivars (Table 2).

The headspace of whole flowers of hermaphrodites, males, and female Galhosa were mainly constituted of oxygenated monoterpenes, accounting for 56.2, 73.1, and

43.8% of the total volatile emission, respectively (Table 2). The sesquiterpene compounds were present in higher abundances in the scent of whole flowers of hermaphrodites (6.9%) and females (Mulata: 5.7% and Galhosa: 15.0%; Table 2). The major components of the scent from the hermaphrodite and male flowers were *cis*-linalool furan oxide (26.4 and 32.9%, respectively), *trans*-linalool furan oxide (5.5 and 7.8%), *trans*-linalool pyran oxide (6.3 and 7.3%), linalool (6.7 and 9.9%), α -pinene (16.3 and 3.2%), α -farnesene (5.9 and 3.1%), and 2,2,6-trimethyl-3-keto-6-vinyltetrahydropyran (9.1 and 13.5%; Table 2 and Fig. 3).

In the two female cultivars, differences in the number and abundance of the compounds emitted by whole flowers were observed (Table 2 and Fig. 3). The Galhosa cultivar had a lower content of volatiles than the Mulata cultivar, dominated by *cis*-linalool furan oxide (23.5%), limonene (12.6%), α -farnesene (12.2%), and α -pinene (9.8%; Table 2 and Fig. 3). In the Mulata, 23 compounds were identified, and more than half of the fragrance of whole flowers consisted of α -pinene (59.4%), a highly volatile compound; other important constituents were *cis*-linalool furan oxide (10.3%) and β -pinene (5.1%; Table 2 and Fig. 3).

Headspace Emission from Flower Organs

There were differences in the composition of the volatiles emitted by the different floral organs (Table 2 and Fig. 3). Moreover, differences were observed between the female cultivars, in the spatial fragrance patterns within the flowers (Table 2 and Fig. 3). Cultivar Mulata emitted a higher number of volatiles compared to Galhosa, but a lower abundance of the principal compounds (Table 2 and Fig. 3). Similar to the patterns observed in hermaphrodites, the male and both female cultivars had nectary disks that showed a richer blend of compounds compared to the sexual organs (Table 2).

Nectary Disks

These structures were the major source of volatiles, and the relative abundances of the major ones were higher in the males, followed by the hermaphrodites, Galhosa and Mulata (Fig. 3). In the hermaphrodites, the main compounds in the scent of nectary disks were *cis*-linalool furan oxide (21.8%), linalool (15.4%), *trans*-linalool furan oxide (7.6%), α -pinene (7.5%), and *trans*-linalool pyran oxide (6.3%). In the cultivar Galhosa, the volatiles profile of whole flowers and nectary disks were similar, except for γ -terpinene and β -guaiene, which are only present in nectary disks in very low amounts (0.3 and 0.2%, respectively; Table 2).

Stamens

In the hermaphrodite flowers, the fragrance of the stamens consisted almost exclusively of monoterpenes, and only one sesquiterpene (α -farnesene) was detected (Table 2). Almost half of the fragrance consisted of *cis*-linalool furan oxide (44.4%; Table 2 and Fig. 2). Other important compounds were *trans*-linalool pyran oxide (15.6%) and α -pinene (13.4%; Table 2 and Fig. 3). In hermaphrodite and male flowers, only one component of the monoterpene hydrocarbon fraction (α -pinene) was emitted by the stamens (Table 2). In the males, the stamens did not produce sesquiterpenes (Table 2).

Fig. 3 Average abundance of α -pinene, linalool, and linalool derivatives, and α -farnesene, found in the volatiles of whole flowers (WF) and isolated flower organs (ND: nectarial disk; Sta: stamens; Sti: stigmas) from field grown male, hermaphrodite, and female carobs by HS-SPME-GC/MS

It is worth noting that, in the male flowers, only six monoterpene compounds were positively identified in the headspace of the stamens compared to those in the hermaphrodites. The three main volatiles, representing 45.4% of the total constituents, were α -pinene (20.7%), *cis*-linalool furan oxide (14.9%), and *trans*-linalool pyran oxide (9.8%; Table 2 and Fig. 3).

Stigmas

In the hermaphrodite, α -pinene dominated the headspace of the stigma (38.8%), together with *trans*- β -ocimene (8.9%) and *cis*-linalool furan oxide (17.5%; Table 2 and Fig. 3).

In female Mulata, the emission of its major volatile compound (α -pinene) depended largely on the emission by the stigma (20.8%). In female Galhosa, only one monoterpene hydrocarbon is present in the headspace of the stigma (Table 2).

Discussion

The scent of carob flowers is mainly attributed to a high abundance of monoterpenes and to a less content of sesquiterpenes, and linalool and its derivatives were the most abundant compounds, as previously reported in this (Custódio et al., 2004) and in other species (Azuma et al., 2001). Both the gender and the cultivar affected the number and abundance of the compounds in the headspace of whole flowers.

Contrary to previous observations (Custódio et al., 2004), female flowers had a higher diversity of volatile than males and hermaphrodites. The flower volatile composition differed from that obtained in earlier findings: linalool was in much lower abundance, while amounts of *trans*-linalool oxide were comparatively higher. Furthermore, besides linalool and *trans*-linalool pyran oxide, other derivatives of that acyclic monoterpene alcohol were identified, namely, *cis*-linalool pyran oxide, 2,2,6-trimethyl-3-keto-6-vinyltetrahydropyran, *cis*-linalool furan oxide, and *trans*-linalool furan oxide. Both studies were based on samplings taken in the field. Therefore, environmental conditions, such as temperature, humidity, light, and time of the day, may have affected the total amount and chemical composition of the floral scents (Azuma et al., 2001). Furthermore, those differences could be ascribed to the different germplasm tested, sampling period, or physiological status of the trees (Siani et al., 2002).

In spite of the fact that the female Mulata emitted a higher number of volatiles compared to female Galhosa, the abundance of the principal volatiles was lower, and there were remarkable differences between the female cultivars in spatial fragrance patterns within flowers. In the Mulata, emission of its major volatile compound (α -pinene) depended largely on emission by the stigma. In the Galhosa, the volatiles profile of whole flowers and nectary disks were similar, which may indicate that the scent of the nectary disks resembled more the fragrance of the whole flowers rather than the gynoecium. Genetic variation within a species may modify the amount and type of compounds in an odor profile (Wright et al., 2002), which may explain the differences in the volatile composition between the two female cultivars. Intraspecific variation in floral scent chemistry has been reported in other species, namely, in *Platanthera bifolia* and *P. chlorantha* (Tollsten and Bergström, 1993), *Clarkia brewerii* (Nam et al., 1999), *Antirrhinum majus* (Dudareva et al., 2000), and *Tanacetum vulgare* (Keskitalo et al., 2001). There are many reasons for intraspecific chemical variation, namely, adaptation to different pollinator species, introgression effects involved in hybridization events, random genetic drift, adaptations to disruptive learning processes in pollinators among deceptive (nonrewarding) flowers, etc. (Tollsten and Bergström, 1993; Barkman et al., 1997). In the carob tree, there are few studies about floral visitors and pollination (Ortiz et al., 1996; Arista et al., 1999), and only one (Ortiz et al., 1996) reports differences between males and females. Nothing is known about pollinator assemblages of different female cultivars, although this information is crucial for the ecological investigation of reproductive traits (Johnson and Steiner, 2000).

The female Portuguese cultivars Galhosa and Mulata are economical and ecologically interesting (Martins-Loução and Brito de Carvalho, 1989; Batlle and Tous, 1997), and the Mulata, in particular, is considered a very productive cultivar (Batlle and Tous, 1997). Pollination is a critical step for the successful production of fruits and seeds, and thus, the absence of efficient pollination can lead to low crop yields. Different scent compounds or chemical compositions may attract different pollinator species, which could cause reproductive success to vary among scent types, and the types will encounter different selective pressures from pollinators (Azuma et al., 2001). The higher amounts of volatiles identified in flowers from cultivar Mulata could be related to a more successful mechanism of reproduction leading to more efficient pollination and thus to higher production. This hypothesis needs further research through field observations of natural pollinators and

bioassays using scent compounds. It is also necessary to assess the different scent compounds and chemical profiles found in the genders and female cultivars of carob to determine if they are equally effective in attracting pollinators.

In this work, the dominant volatiles (linalool, linalool derivatives, and α -pinene) were found in all floral organs, except in the stigma of the female Galhosa, which did not include α -pinene in its scent. Usually all floral organs contain volatiles typical of that species (MacTavish and Menary, 1997). However, quantitative differences between attractive, nonfood structures (perianth) and attractive food sources, such as the androecium and gynoecium, are common (Dobson et al., 1990). Generally, the scent composition emitted by female organs is markedly different from stamens (Pichersky et al., 1994). Spatial scent patterns within a flower may function like visual patterns. Thus, differences in the strength and/or quality of emitted volatiles between floral organs may serve as guides to insects, assisting them in finding food rewards or leading them to position themselves suitably on a flower for effective pollination (Bergström et al., 1995). Furthermore, the existence of organ-specific synthesis of certain compounds was observed, which can be related to the fact that the pathway(s) for synthesis and pattern of accumulation of terpenes differs considerably between the floral organs (Dudareva and Pichersky, 2000).

Despite the fact that sexual organs accounted for higher percentages of the total flower weight compared to the nectary disks, these structures were the major source of volatile emission. This observation, together with previous findings (Custódio et al., 2004), suggests the presence of scented nectar in carob tree flowers.

Nectar is a multicomponent aqueous solution and contains aromatic compounds and other substances (Tóth et al., 2003). Among these, the most important are sucrose, glucose, and fructose (Thornburg et al., 2003). The various types of nectars can be ordered into three groups, according to sugar content: sucrose prevalent, glucose and fructose prevalent, and almost equal amounts of sucrose, glucose, and fructose (Roshchina and Roshchina, 1993). In the carob, glucose is the major nectar sugar, regardless of the tree genders, and it is present in higher concentration in male flowers, followed by the female Galhosa, the female Mulata, and the hermaphroditic ones (Custódio, 2005).

Scented nectar was found on four out of seven tested angiosperms (Raguso, 2004) and would provide an honest signal to nectar-feeding pollinators (Raguso, 2004; Dötterl and Jürgens, 2005), or serve a defensive function, such as protecting the plant crops from harmful visitors (Galen, 1999; Raguso, 2004). Additionally, scented nectar may also have an indirect impact on plant fitness, through antimicrobial activity, pleiotropic interactions with plant defense, and communication with predators and parasitoids (Pichersky and Gershenzon, 2002; Raguso, 2004).

In summary, the HS-SPME-GC/MS method allowed the collection and the analysis of volatiles emitted from whole fresh flowers and from different flower organs of three genders and two female cultivars of the carob. The reason for the chemical variation observed in floral scent between the genders and female cultivars of the carob is unknown. The results raise some pertinent questions, namely, the nature of the pollinators of the different genders and female cultivars and their reproductive success. It is also still necessary to assess if the different scent compounds and chemical profiles found in the genders and female cultivars of carob are equally effective in attracting pollinators.

Abstract Egg-laying females of the pine weevil, *Hylobius abietis* (L.), regularly deposit feces adjacent to each egg. Egg cavities are gnawed in the bark of roots of recently dead conifer trees. After egg deposition, the cavity is sealed by feces and a plug of bark fragments. Root bark containing egg cavities with feces is avoided as food by pine weevils, which indicates the presence of natural antifeedants. Here we present the first results of the isolation and chemical analyses of antifeedant compounds in the feces of *H. abietis*. In feeding bioassays, methanol extracts of the feces revealed strong antifeedant properties. Methanol extracts were fractionated by medium-pressure liquid chromatography and the antifeedant effects were mainly found in the fractions of highest polarity. Volatile compounds in the active fractions were identified by gas chromatography–mass spectrometry (GC–MS) and the nonvolatile compounds were characterized by pyrolysis–GC–MS. Based on mass spectra, a number of compounds with various chemical structures were selected to be tested for their antifeedant properties. Antifeedant effects were found among compounds apparently originating from lignin: e.g., a methylanisol, guaiacol, veratrol, dihydroxybenzenes, and dihydroconiferyl alcohol. A weak effect by fatty acid derivatives was found. The types of naturally occurring antifeedant compounds identified in this study may become useful for the protection of planted conifer seedlings against damage by *H. abietis*.

Introduction

Adult pine weevils, *Hylobius abietis* (L.) (Coleoptera: Curculionidae), feed on tender bark of a wide range of conifer trees, with Scots pine (*Pinus sylvestris* L.) as the preferred host (Day et al., 2004). Bark of living as well as of recently dead trees is utilized, and weevils feed both below and above ground, although a sheltered feeding position is preferred (Nordlander et al., 2005). Planted conifer seedlings are frequently girdled and killed by weevil feeding, which makes *H. abietis* a severe pest of reforestation in large parts of Europe and Asia (Långström and Day, 2004).

Pine weevil larvae develop under the bark of recently dead conifer roots, in managed forests usually the roots of fresh stumps (Day et al., 2004). Large numbers of flying weevils of both sexes arrive during spring migration in areas with fresh stumps for reproduction (Örlander et al., 2000), attracted by the degradation product ethanol together with α -pinene and other host monoterpenes (Nordlander et al., 1986; Schlyter, 2004). Females lay their eggs either in the soil near roots or in specific egg cavities gnawed into the root bark (Nordlander et al., 1997).

The habit of inserting eggs into host plant tissues with the aid of the snout is an ancestral trait of the weevil family (Marvaldi et al., 2002). To construct the egg cavity, female *H. abietis* chew through the outer bark and continue into the phloem tissue along the xylem, about as far as reached by her snout (Fuchs, 1912). She then turns around and deposits an egg together with feces in the cavity, after which she turns once again and pushes the egg and feces deeper into the cavity with her snout (Nordlander et al., 2000). The opening of the cavity is finally sealed with a plug made of fragments nibbled from the outer bark (*H. Nordenhem*, personal observation). Similar egg-laying behavior has been observed in other *Hylobius* species (Wen et al., 2004), as well as in species of the weevil genus *Pissodes*, ovipositing in bark of aboveground parts of conifer trees (Wallace and Sullivan, 1985; Langor and Williams, 1998; Zhang et al., 2004), and in the boll weevil, which oviposits in flower buds (Stansly and Cate, 1984).

It is not known why female *H. abietis* place her feces close to or on top of her eggs. A likely function of the feces is that it contains oviposition deterrents (Anderson, 2002), as suggested for *Pissodes terminalis* (MacLaughlan and Borden, 1995). Feces might also contain substances that give protection to the egg against predation (Blum and Hilker, 2002) or the destruction by feeding pine weevils (Nordlander et al., 1997). Indeed, it has been reported that most feeding is done on the opposite side of pine bolts from where the majority of eggs were laid (Bylund et al., 2004). If feces in the oviposition cavity have a feeding-deterrent effect on *H. abietis*, this may be either a mechanism to avoid feeding that destroys eggs in the bark or a mechanism to avoid making oviposition cavities adjacent to existing ones, which may later cause competition for the newly hatched offspring.

A primary aim of our research was to find the chemical cues that deter pine weevils from feeding at oviposition sites. In this study, we investigated whether constituents in the feces from *H. abietis* could inhibit or stop the initiation of feeding by other individuals of this species. The antifeedant activity in feces extracts and

fractions thereof was measured in a laboratory feeding bioassay by using twigs of Scots pine as food.

Methods and Materials

Collection and Maintenance of Weevils

Pine weevils of both sexes were collected during spring migration at a sawmill in southern Sweden, where they landed in large numbers as a response to a massive emission of attractive conifer volatiles. After collection, weevils were stored in darkness at 10°C and provided with fresh Scots pine branches or stems with tender bark as food. These storage conditions interrupted their reproductive development, so that no oviposition started until about a week after the weevils had been transferred into experimental conditions, i.e., 22°C and 18:6 (L/D) regime. This transfer of weevils was made about 10 d before their use in a bioassay or for the production of feces.

Feeding Bioassay

Various extracts, fractions, and single compounds were tested for antifeedant effects on the *H. abietis* by using a two-choice laboratory bioassay described by Bratt et al. (2001). Fresh pieces of Scots pine twigs (50 mm long, 15 mm diam) were split, and each half (= test twig) was wrapped in aluminum foil. On each test twig, two sharp-edged metal rings (5 mm diam) were placed at 25 mm distance and punched through the foil into the bark. The rings and the pieces of aluminum foil inside them were then removed. The thin outer layer of cork bark inside two circular areas was carefully removed with a scalpel. Thereafter, new rings were fitted into the bark around the two bark areas exposed and 100 µl of the extract/compound to be tested were applied to the bark in one of the two rings. In the other ring, the same amount of the solvent was applied as control. When the solvent had evaporated, the metal rings were removed. Each test twig was placed onto moistened filter paper in a 142-mm-diam Petri dish and one weevil was placed into each dish. Forty replicates were used, 20 with females and 20 with males. The weevils were all in the reproductive phase of their life cycle and were starved for 24 hr in the Petri dishes prior to the test period. Each weevil was used only once. The bioassays were conducted at room temperature (ca. 22°C).

The amount of feeding on treatment and control areas of each test twig was recorded after 6 and 24 hr. The proportion of available bark area that had been penetrated by the test weevil was estimated under a stereomicroscope and with the aid of a transparent millimeter grid. In most of the tests, there was no significant difference in response between the sexes, and most of the data presented were, therefore, pooled. Effects of the various treatments were described by two variants of the antifeedant index (AFI; Blaney et al., 1984): $(C - T) \times 100 / (C + T)$. (1) In AFI area (AFIa), C represents the mean area of control surfaces consumed and T the mean consumed area of treated surfaces. (2) In AFI number (AFIn), C is the number of control surfaces with feeding scars and T the number of treated surfaces with feeding scars.

Hence, AFIn indicates to what extent feeding is completely inhibited on the treated area during 24 hr, whereas AFIA also includes the reduction in feeding where it has been initiated. The two indices are fairly well correlated, but AFIA tends to be higher than AFIn because the antifeedant substances generally affect both the initiation of feeding and the amount consumed, if feeding has started. For both indices, an antifeedant effect gives positive values up to a maximum of 100. Statistical differences in feeding/no feeding between treatment and control were tested with Fisher's exact test of a 2×2 table: * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$.

Collection and Extraction of Feces

Feces were collected by placing weevils of either sex into clean glass Petri dishes for 24 hr. No food was provided in the Petri dishes but the weevils had been feeding on fresh Scots pine bark until just before the feces collection started. After the 24 hr period, the weevils were removed and the feces were scraped off the glass surfaces with a razor blade. The collecting procedure was repeated during several days and the feces were stored in a sealed vial at 5°C for up to a week before the entire material from each sex was subjected to extraction. Feces were divided into two equal parts: one was extracted with methanol (pa Merck) and the other with n-hexane (pa Merck). The methanol extract was first washed with hexane and then subjected to chromatography. Extracts were tested in the feeding bioassay at a concentration corresponding to the amount of feces produced by three individuals during 24 hr. This was a high concentration, more than what the female deposits on an egg, but used to compensate for the anticipated loss of activity due to absorption effects during the solvent extraction.

Isolation and Fractionation

The hexane-washed methanol extracts from 1.5 to 1.8 g of feces were evaporated under reduced pressure at ambient temperature. The gummy residue obtained was dissolved in a minute amount of methanol, mixed with silica gel (Merck 60, 230–400 mesh ASTM), and the solvent was evaporated to dryness. Medium-pressure liquid chromatography (MPLC) of the extracts was carried out on silica gel, using a laboratory pump and preparatory chromatography columns (Baeckstrom Separo AB, Stockholm, Sweden). A representative fractionation by MPLC started with pure hexane, followed by a gradient of hexane/ethyl acetate, to obtain fractions containing compounds with increasing polarity. Subsequent changing of the gradient to ethyl acetate/methanol and finally elution of the column with pure methanol gave fractions with increasing polarity. In all, more than 80 chromatography fractions were collected. These were pooled into 10 major fractions, guided by thin-layer chromatography (TLC), and selected by obvious chemical resemblance. An attempt to fractionate the most polar fraction resulted in partial solvolysis during the chromatography procedure, and a new medium polar fraction was thereby obtained. The most polar compounds had an R_f value of 0–0.05 on TLC (using 40% ethyl acetate in hexane as eluent). The hydrolyzed medium polar fraction had a broad R_f value of 0.4–0.7. TLC was visualized by spraying with a solution of 3% vanilla (by weight) in 1% conc. sulfuric acid (by volume) dissolved in ethanol. Hexane and methanol extracts, and the MPLC fractions dissolved in methanol were tested for their antifeedant properties.

Chemical Identification of Volatile Constituents

Separation and identification of components in the various extracts and fractions were made by gas chromatography–mass spectrometry (GC–MS) using a Varian 3400 GC connected to a Finnigan SSQ 7000 quadrupole mass spectrometer. The GC was equipped with a split/splitless injector (splitless mode, 30 sec; injector temperature, 220°C; carrier gas, He). A DB-5 or a DB-wax capillary column (30 m, 0.25 mm i.d., and 25 μ m film thickness) was used with a temperature program: 40°C (1 min)–5°C/min–230°C (in 20 min). The MS ion source temperature was 150°C; mass spectra were obtained at 70 eV with a mass range of 30–400 *m/z*. Mass spectra of unknown compounds were compared to the Finnigan NIST MS library, and available authentic standards by comparing GC retention times and by co-injections.

Chemical Identification of Nonvolatile Constituents

The gummy mixture obtained from the most polar MPLC fraction was dissolved in methanol and analyzed by a pyrolysis–GC–MS both with and without the alkylating reagent tetramethylammonium hydroxide (Hardell and Nilvebrandt, 1996). The injector temperature was kept either at 400°C or at 600°C. A DB-5 fused silica capillary GC column (30 m, 0.25 mm i.d., and 0.25 μ m film thickness) was used with the temperature program 50°C (5 min)–10°C/min–310°C.

Reference Compounds

Synthesis of dihydroconiferyl alcohol, 3-(4-hydroxy-3-methoxyphenyl)propan-1-ol: Methyl 3-(4-hydroxy-3-methoxyphenyl)propanoate (1.57 g, 7.48 mmol, obtained from previous work by Drs. H. Erdtman and T. Norin at the Department of Chemistry, Organic Chemistry, KTH, Stockholm, Sweden) was reduced by lithium aluminum hydride (570 mg, 15 mmol) in tetrahydrofuran (THF, 20 ml). The reaction mixture was neutralized with diluted sulfuric acid and partitioned between *t*-butyl methyl ether and water. The organic phase was separated and dried with MgSO₄, filtered and then mixed with silica gel, after which the solvent was evaporated. Dihydroconiferyl alcohol (1.089 g, 5.98 mmol) was obtained after chromatography. The yield was 80%. ¹H NMR δ : 6.83 (1H, d, *J* = 7.6 Hz), 6.70 (1H, s), 6.68 (1H, d, *J* = 7.5 Hz), 3.86 (3H, s), 3.67 (2H, t, *J* = 6.4 Hz), 2.64 (2H, t, *J* = 7.6 Hz), 1.86 (2H, m).

Synthesis of 1-(4-hydroxy-3-methoxyphenyl)-3-methoxypropane and 1-(3,4-dimethoxyphenyl)-3-methoxypropane: Sodium hydride in oil (91 mg, 2.28 mmol) was rinsed with hexane and then a mixture of 3-(4-hydroxy-3-methoxyphenyl)propan-1-ol (215 mg, 1.18 mmol) in 1.5 ml THF, was added. After the evolution of hydrogen had ceased, methyl iodide (170 mg, 1.20 mmol) diluted with 1.5 ml THF was added. The reaction mixture was heated at 38°C for 4 hr. Toluene (1 ml), ammonium chloride (125 mg, 2.38 mmol), and silica gel (1.2 g, Merck 60 type) were added; the reaction mixture was impregnated to dryness and the impregnated silica gel was put on top of a silica gel column. Two methylated products (109 mg) and some unreacted starting material were obtained after chromatography. The mono-methylated product was separated from the dimethylated product in a subsequent chromatography: 1-(4-hydroxy-3-methoxyphenyl)-3-methoxypropane (major product): ¹H NMR δ : 6.83 (1H, d, *J* = 7.9 Hz), 6.70 (1H, s), 6.68 (1H, d, *J* = 7.8 Hz), 5.50

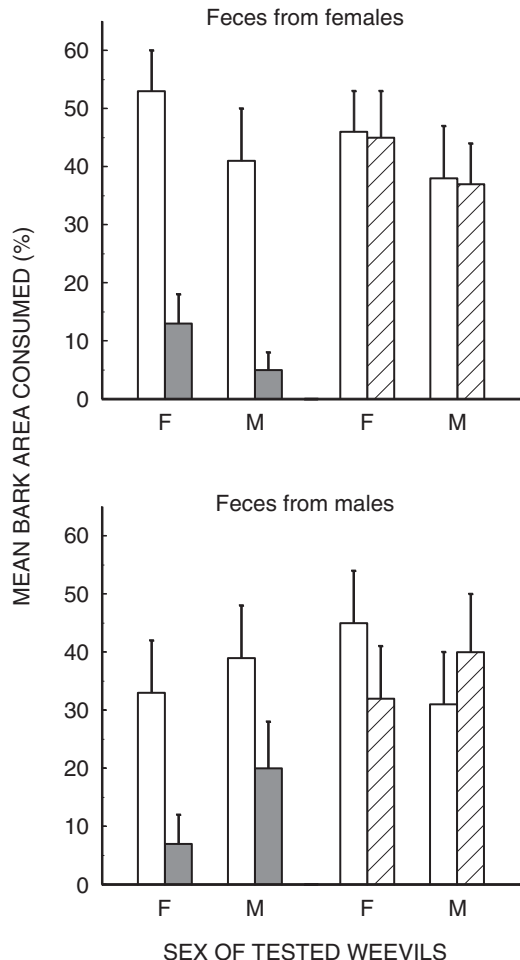

(1H, s), 3.86 (3H, s), 3.38 (2H, t), 3.35 (3H, s), 2.61 (2H, t, $J = 7.5$ Hz), 1.86 (2H, m). 1-(3,4-Dimethoxyphenyl)-3-methoxypropane (minor product): $^1\text{H NMR } \delta$: 6.81–6.71 (3H, m), 3.87 (3H, s), 3.86 (3H, s), 3.39 (2H, t, $J = 6.2$ Hz), 3.35 (3H, s), 2.63 (2H, t), 1.87 (2H, m).

All reference compounds were purchased from commercial suppliers (i.e., Lancaster or Sigma-Aldrich) except the two substances for which we have described the synthesis.

Results

Pine weevils of both sexes avoided feeding on pine twigs treated with a methanolic extract of pine weevil feces (Fig. 1). Feces from both sexes had this antifeedant effect, although males tended to be less deterred from feeding by feces from males than by feces from females. In the crude methanol extract of female feces (Fig. 2), a complex mixture of aromatic compounds (Table 1) and saturated and unsaturated

fatty acids with a length of 14–18 carbon atoms were identified by means of GC–MS (Table 2). In addition, oxygenated terpenes and resin acids were present in trace amounts. Among the structurally related aromatic compounds, the main constituent was identified as dihydroconiferyl alcohol (Fig. 3). Hexane extracts of both male and female feces contained large numbers of monoterpenes and sesquiterpenes. These extracts had no effect on feeding by any of the sexes (Fig. 1). Therefore, no further fractionations of the hexane extracts were made.

MPLC Fractions

The crude methanol extract was fractionated by MPLC and the 10 fractions were all tested for antifeedant activity (Fig. 2). The most polar fraction (fraction 10) showed significant and relatively strong antifeedant effect after testing periods of 6 and 24 hr. Fraction 2 had a significant, but weak, antifeedant effect after the first 6 hr, whereas fractions 6 and 8 showed weak antifeedant effects after 24 hr. No significant feeding differences were observed between the sexes.

The most polar fraction (10, Fig. 2) was characterized by the use of pyrolysis–GC–MS. A large number of possibly lignin-related aromatic compounds were present, e.g., phenol, dihydroxybenzene, methylanisols, guaiacol, veratrol, hydroxyl- and methoxy-substituted benzoic acids, a phenylacetate ester, and some phenyl-

Fig. 3 Total ion chromatogram of fraction 10:2 obtained by GC–MS. The main compound is dihydroconiferyl alcohol

propanoids (Table 1). One of the main constituents was a compound with a mass spectrum similar to that of dihydroconiferyl alcohol.

This active MPLC fraction (10) was rechromatographed to give five fractions (10:1–10:5, Fig. 2). The strongest activity was still shown by the most polar fraction (10:5), apparently containing the major part of the lignin-related compounds already identified in fraction 10. In addition, weak antifeedant activities were found in fractions 10:2 and 10:4. Fraction 10:2 consisted of compounds that increased in concentration or formed during the collection and chromatography of fraction 10. These compounds appeared as a streaking blue spot with vanilla reagent in TLC (R_f value 0.4–0.7). The fraction contained more than 80% of one aromatic compound that was also present in the crude methanol extract (Fig. 3, peak at R_T 26.69). The following ^1H NMR data were found for this main constituent: ^1H NMR δ ; 6.83 (1H, d, $J = 7.9$ Hz), 6.70 (1H, s), 6.69 (1H, d, $J = 8.2$ Hz), 3.88 (3H, s), 3.68 (2H, t, $J = 6.4$ Hz), 2.64 (2H, t, $J = 7.5$ Hz), 1.87 (2H, m). These data and the mass spectrum suggest that the compound is dihydroconiferyl alcohol. However, the mass spectrum is also similar to that of homovanillic acid, commonly present in lignin fractions. Dihydroconiferyl alcohol was synthesized (see Reference Compounds), and by comparing MS data it was confirmed that the main constituent in the blue spot in fact was dihydroconiferyl alcohol (Table 1).

Test Results of Separate Constituents in the Active Fractions

Based on the GC–MS analyses of the crude extract and the active fractions, some identified compounds and some additional structurally related ones were selected for further testing of antifeedant properties (Table 1). The main component in the female extract was dihydroconiferyl alcohol [3-(4-hydroxy-3-methoxyphenyl)propan-

1-ol] (Fig. 3), but this compound showed only a weak antifeedant effect during the first 6 hr (AFIn = 27). The methyl ether of dihydroconiferyl alcohol [1-(4-hydroxy-3-methoxyphenyl)-3-methoxypropane], a slightly more hydrophobic compound, showed a strong antifeedant effect (AFIn = 93 after 6 hr and AFIn = 76 after 24 hr). Strong but short-lasting antifeedant effects were obtained with anethol (AFIn = 94, 6 hr), found in the methanol extract, and eugenol (AFIn = 88, 6 hr), present in the pyrolysis extract of the most polar MPLC fraction.

Monoaromatic molecules with one or two oxygen atoms showed a strong antifeedant effect during the first 6 hr of the test period. However, 1,4-dihydroxybenzene still had a significant antifeedant effect after 24 hr (AFIn = 42), as did the 1,4-dimethoxybenzene (AFIn = 31). The more volatile 1,2- and 1,4-anisoles (methoxymethylbenzenes) had a high effect, lasting for 6 hr, whereas 1,3-anisole remained active as antifeedant after 24 hr (AFIn = 23).

The fatty acids showed no significant antifeedant effect; hence, they seemed to be less active than the corresponding methyl ester, methyl linoleate (AFIn = 31, 6 hr).

Discussion

In this study, we demonstrate the antifeedant properties of fractions from pine weevil feces and chemical cues (semiochemicals) that deter adult pine weevils from feeding. Guided by a bioassay developed for testing antifeedant effects on the pine weevil (Bratt et al., 2001; Legrand et al., 2004), we first investigated the activity of total extracts of male and female feces, respectively. We found that both sexes were strongly deterred from feeding by the methanol extracts but not by the hexane extracts. Females tended to be more deterred than males by the methanol extract of female feces. By further bioassay-guided fractionation of the methanol extracts of female feces, several compounds with antifeedant effects were identified. As the most polar fraction was the most active one, we used both GC–MS and pyrolysis–GC–MS to identify antifeedant components in the extracts. The results of the pyrolysis–GC–MS enabled us to verify that molecular fragments related to lignin were present in the extract. The brown gummy mixture obtained from the methanol extracts and from the most polar MPLC fraction largely consisted of fragments that looked like catabolized lignin, e.g., *o*-cresol, resinol, guaiacol, veratrol, dihydroxybenzenes, anethole, and eugenol. However, no trace of coniferyl alcohol was found, which has been reported previously to be a common lignin constituent (Hardell and Nilvebrandt, 1996, and references therein). Instead, we identified dihydroconiferyl alcohol, which was also present in the active fractions identified by GC–MS with standard injector temperature. Dihydroconiferyl alcohol is possibly formed during degradation of lignin in the pine weevil gut, as it has not been found in methanol extracts of fresh Scots pine phloem (A.-K. Borg-Karlson, unpublished data). Thus, enzymes capable of cleaving carbon–carbon bonds or of hydrogenation of double bonds might be present in the gut of *H. abietis*.

The results obtained by the GC–MS and the pyrolysis–GC–MS techniques provided us with a number of candidates to be used for antifeedant tests. Also, the highly polar compounds ferulic acid and *p*-hydroxycinnamic acid were identified by silylation of the methanol extract and subsequent GC–MS analyses (Borg-Karlson et al., unpublished data), which revealed additional aromatic structures with possible antifeedant activities. The major components and chemically related compounds

were selected for tests of their antifeedant activity. The strongest antifeedant effects were obtained with compounds having one aromatic ring, preferably with hydroxyl, methyl, and/or methoxy groups. Lignans and related compounds with a methylenedioxyphenyl structure have a feeding-deterrent effect on storage pests such as *Tribolium* species (Harmatha and Nawrot, 2002). In the present study, simple metabolites of lignin (KEGG: Kyoto Encyclopedia of Genes and Genomes, 2005) as several aromatic compounds, e.g., *o*-cresol and 1,4-dihydroxybenzene, showed long-lasting antifeedant effects. The structurally related 1,4-dimethoxybenzene had a similar antifeedant effect. The main compound in the volatile part of the female feces, dihydroconiferyl alcohol, showed a weak antifeedant effect, which initiated further investigations on the effects of other substituents on the aromatic ring (Unelius et al., submitted).

Early studies with direct stimulation, using a single-cell recording technique (Mustaparta, 1975), revealed that *H. abietis* can sense over 130 compounds belonging to various compound classes, such as oxygenated aliphatic compounds, terpenoids, and aromatic compounds. Recordings from single neurones in the antenna combined with gas chromatography (GC–SC) have shown that the receptors are selectively tuned to each of the main constituents in conifer volatiles, especially to (+)- and (–)- α -pinene and (+)- and (–)-limonene (Wibe et al., 1998). These monoterpenes are also known to be important for the orientation toward the host (Nordlander, 1990, 1991). Ground traps baited with α -pinene attract large numbers of pine weevils, but when limonene is added, this attraction is almost completely inhibited (Nordlander, 1990). Monoterpenes, mainly α -pinene and β -pinene, were present in the hexane extract in this study. This extract did not negatively affect pine weevil feeding on the pine bark, although it in itself contained high amounts of feeding stimulant compounds.

The chemical perception of an insect is restricted by the molecular receptive ranges of its odor and taste receptors. The antennal receptors serve as detectors for the volatile constituents of the hosts. We expect that taste receptors on the palpi and the mouth parts are involved in the reception of the low volatility and highly polar compounds, but specific sensillae on the antennae are also known to contain taste receptors (Mustaparta, 1975; A. Wibe, personal communication). We have limited knowledge of the molecular receptive range of these receptors. Only a few compounds, such as glucose, certain amino acids, and methyl salicylate, are known to activate the taste receptors in *H. abietis* (A. Wibe, personal communication). Aromatic compounds as those we have identified in the feces, i.e., anethole, eugenol, guaiacol, *p*-cresol, and anisaldehyde, all elicited high responses using antennal single-cell recordings by direct stimulation (Mustaparta, 1975). Recent investigations using the GC–electroantennogram technique have confirmed the strong antennal activity of anethole and also of 2-, 3-, and 4-methylanisol (Wibe et al., 2001). These receptor responses can now be tentatively linked to a behavioral response, as our feeding tests with 2-methylanisol show a clear antifeedant effect during the first 6 hr.

The fatty acid derivatives we tested showed no antifeedant effect. In the earlier study by Mustaparta (1975), a 9,12,15-octadecatrienoic acid and its corresponding methyl ester elicited strong responses in single-cell recordings by direct stimulation of receptor cells in *sencilla basiconica*. In our antifeedant tests, methyl linolenate showed only short-term effects. The acids present in the methanol extract, with carbon atom chain lengths of 14 and 16, showed the same patterns with minute antifeedant effects. Fatty acids and their corresponding methyl esters were present

in large amounts in the active methanol extract (ca. 40%), and in a silanized methanol extract of pine weevil feces (A.-K. Borg-Karlson, unpublished data). These acids did not seem to elicit any persistent antifeedant effect, although they may be active in combination with other constituents identified in the extracts. Månsson et al. (2005) have shown that aliphatic acids with shorter chain lengths, i.e., octanoic, nonanoic, and decanoic acid, have an antifeedant effect on *H. abietis*, whereas acids with longer carbon chains, in accordance with our results, have low or no effect. Nonanoic acid and acids with similar chain lengths are frequently present in solvent extracts of plant tissues and can be formed during degradation of unsaturated fatty acids (Borg-Karlson, 1990).

The compounds identified in this study are not unique to our pine weevil–conifer system. Most of the compounds have been identified previously in other plants and show a variety of functions as pollinator attractants or bacteriostatics (e.g., Anderson et al. 1993; Hilker and Meiners, 2002). Fungal fruiting bodies emit aromatic compounds related to the ones we have identified, e.g., anisole, benzaldehyde, methyl-anisate, and methyl 4-methoxyphenylacetate (Rösecke et al., 2000; Rösecke and König, 2000). These constituents may indicate that the host is infested with fungi and, thus, unsuitable for egg laying, similar in function to that of pine weevil feces. The odor might be a negative signal for the female. Similarly, it has been suggested that the oxygenated monoterpene verbenone, which is frequently present in volatiles of old sawdust (Wibe et al., 1997), serves as a chemical cue to the pine weevil indicating an old and unsuitable host (Lindgren et al., 1996).

We searched for chemicals in the feces of *H. abietis*, which might act as cues deterring pine weevils from feeding at oviposition sites. A large number of aromatic compounds were present in the most active extracts and fractions. The most active compounds were structurally related to the building blocks of lignin and most probably the results of lignin degradations in the gut, either by bacteria (Dillon and Dillon, 2004) or by fungal symbionts. Feces constituents formed by bacterial symbionts have recently been shown to affect the behavior of *Blatta germanica* (Schal et al., 2002). The compounds we have identified are biologically relevant for the pine weevil because they are present in the feces of this species and because feces are deposited at the oviposition sites. Promising antifeedant candidates for future studies can be selected among the aromatic compounds, e.g., ethers of dihydroconiferyl alcohol, methyl-, hydroxy-, or methoxybenzene, or benzoic acid derivatives. The compounds we have tested, showing high antifeedant effect, will be key compounds in the search for even more active substances and may prove to be useful in finding a sustainable method for protecting planted conifer seedlings against damage by the pine weevils.

Acknowledgments This study was supported by Formas (The Swedish Research Council for Environment, Agricultural Sciences and Spatial Planning; G.N., R.U., A.K.B.K.), the Carl Trygger Foundation (A.K.B.K. and R.U.), the Swedish *Hylobius* Research Program (G.N.), and the University of Kalmar (R.U.). We also thank Björn Bohman for laboratory assistance and Claes Hellqvist for data processing and statistical calculations.

Abstract Gossypol is a sesquiterpene that occurs naturally in seed and other parts of the cotton plant. Because of restricted rotation around the binaphthyl bond, it occurs naturally as enantiomeric mixtures with (+)-gossypol to (–)-gossypol ratios that vary between 97:3 and 31:69. Commercial cotton varieties (*Gossypium hirsutum*) normally exhibit an approximate 3:2 ratio. (+)-Gossypol is significantly less toxic than (–)-gossypol to nonruminant animals; thus, cottonseed containing high levels of (+)-gossypol might be safely fed to nonruminants. Gossypol, however, is an important component in the cotton plant's defense against insect herbivores, but it is not known how cotton plants that exhibit high levels of (+)-gossypol in the foliage might be affected by insect herbivory. To address this question, 1-d-old *Helicoverpa zea* larvae were fed diets with 0.16, 0.20, and 0.24% racemic, (+)-, and (–)-gossypol. Larval pupal weights, days-to-pupation, and survival were adversely affected by all gossypol diets compared with the control diet. Statistical differences were determined by comparing the compounds among themselves at the three levels and between the three compounds at the same level. When the compounds were compared among themselves, no large differences were observed in pupal weights or in days-to-pupation among any of the diets. Among the three compounds, at the 0.16% level, the diet containing racemic gossypol was the most effective at reducing survival. At the 0.20 and 0.24% levels of racemic (+)- and (–)-gossypol, survival was not statistically different. The overall results indicate that (+)-gossypol is as inhibitory to *H. zea* larvae as racemic or (–)-gossypol, and thus, cotton plants containing predominantly the (+)-enantiomer in foliage may maintain significant defense against insect herbivory.

(-)-Gossypol · Host defense · *Helicoverpa zea* · Cotton

Introduction

World cottonseed production for 2004/2005 is estimated to be 42.9 million metric tons. Cottonseed is a highly nutritious source of protein; however, it is considered a by-product of fiber production because it contains gossypol (Fig. 1), a naturally occurring toxin. Complete elimination of gossypol from the plant is not practical because plants lacking gossypol are highly susceptible to a host of insect herbivores (Jenkins et al., 1966; Lukefahr et al., 1966; Oliver et al., 1971; Meisner et al., 1977; Zur et al., 1979). Moreover, high levels of gossypol in the foliage are associated with resistance to insects.

Gossypol exhibits optical activity because of restricted rotation around the binaphthyl bond (Jaroszewski et al., 1992a). Of the two possible enantiomers, (-)-gossypol is significantly more toxic to nonruminant animals. In commercial *Gossypium hirsutum* cottonseed, the ratio of (+)- to (-)-gossypol is usually about 3:2. However, in some cultivars such as Texas Marker 1, the ratio is approximately 1:1 (actual 53:47). In contrast, some moco cotton varieties that are native to Brazil have (+)- to (-)-gossypol ratios as high as 96:4. Feeding experiments have demonstrated that (+)-gossypol had little effect on mean cumulative weight gain and feed conversion ratios of chickens (Bailey et al., 2000; Stipanovic et al., 2001; Lordelo et al., 2005). This implies that increasing the (+)- to (-)-gossypol ratio in commercial cottonseeds could overcome the impediment to utilizing this high-quality protein as a nonruminant feed source.

Through a traditional backcross breeding program that used these native varieties, the percent (+)-gossypol in the commercial seed was increased to over 90% (Bell et al., 2000). However, little is known concerning how high levels of (+)-gossypol in the foliage might affect resistance to herbivorous insects. It is known that the total concentration of gossypol varies significantly in different plant tissues depending on environmental conditions (Stipanovic et al., 1988). For example, the mean concentration of gossypol in various plant tissues for 14 *G. hirsutum* varieties grown at five locations from south Texas to north Texas (~1000 km) varied as follows: leaves, 0.04–0.10%; flower buds, 0.8–1.0%; seed 0.9–1.1%. Yang et al. (1999) reported that *Helicoverpa armigera* larvae raised on artificial diets containing (+)-gossypol matured more slowly, and the percentage of larvae surviving to the adult stage was lower as compared to those raised on (-)-gossypol. Herein, we report the results on racemic gossypol [a 1:1 mixture of (+)- and (-)-gossypol, designated as (±)-] and (+)- and (-)-gossypol in artificial diet feeding studies on the

Fig. 1 Structure of gossypol

generalist herbivore *Helicoverpa zea* (Boddie). Because the (+)- to (–)-gossypol ratio varies between approximately 3:2 and 2:3 in commercial cotton cultivars (Cass et al., 1991; Jaroszewski et al., 1992b; Percy et al., 1996), we included (±)-gossypol as a check to approximate commercial cottons.

Methods and Materials

Preparation of (+)-, (–)-, and (±)-Gossypol

A crystallization process to separate the gossypol enantiomers as gossypol–acetone (1:3) followed by storage of the products under vacuum for 3 d to remove essentially all of the acetone was used to obtain chemically pure chiral gossypol (Dowd, 2003). Purified racemic gossypol acetic acid (1:1) was obtained by repeated recrystallization of gossypol from acetone and acetic acid. The gossypol samples were analyzed by high-performance liquid chromatography as previously described (Puckhaber et al., 2002) to confirm enantiomeric content. The racemic gossypol was 49.9% (–)-gossypol and 50.1% (+)-gossypol, whereas the enantiomer samples were >99.5% optically pure.

Preparation of Diets

Five diet sets were prepared. Four contained Alphacel (ICN Nutritional Biochemicals), which is a nonnutritive polysaccharide that was used as a carrier, and one control diet set contained no Alphacel. Each gossypol sample was dissolved in 35 ml of ethyl acetate and was quantitatively added to 15 g of Alphacel. The suspensions were evaporated to dryness. Hexane (~50 ml) was added to the dry samples and evaporated to remove traces of ethyl acetate. The samples were left under vacuum for 36 hr. Six gossypol/Alphacel preparations were made with 800, 1000, or 1200 mg of either (+)- or (–)-gossypol; 893, 1116, and 1339 mg of (±)-gossypol–acetic acid (1:1), which is 89.62% gossypol by weight, was used to make the three (±)-gossypol/Alphacel preparations. To account for the acetic acid in the (±)-gossypol/Alphacel preparations, an equivalent amount of acetic acid was added to the Alphacel/chiral gossypol and Alphacel control (i.e., Alphacel with no gossypol) preparations.

Diets were prepared from a dry soy bean–wheat germ premix (Instant Soybean–Wheat Germ Insect Diet; Stonefly Industries, Inc., Bryan, TX, USA) with a slight modification of the manufacturer's instructions. Specifically, a dilute vinegar solution was prepared from water (75%) and 5% vinegar (Albertson's, white vinegar; 25%). This dilute vinegar solution (390 ml) was added to 15 g of Alphacel with or without gossypol and 100 g of the diet premix. This provided 505 g of finished diet. One additional control diet was prepared according to the manufacturer's instructions (i.e., 100-g dry diet, 284 ml water, and 16 ml 5% vinegar) with no Alphacel. The final levels of gossypol were 0.16, 0.20, or 0.24%.

Larvae

Larvae were reared from *H. zea* (Boddie) moths collected from the wild and raised in rearing chambers at College Station, TX. Newly hatched larvae were allowed to feed on the artificial diet with neither Alphacel nor gossypol for 1 d before transfer

to the test diets. This delay assured their fitness and more closely mimics their behavior in nature. That is, other researchers have noted that newly hatched *Heliothis virescens* larvae carefully avoid consumption of cotton glands (Hedin et al., 1992).

Feeding Trials

Larvae were raised on the 11 diets [i.e., soybean–wheat germ diet, soybean–wheat germ diet plus Alphacel, and the latter diet with 0.16, 0.20, or 0.24% of (+)-gossypol, (-)-gossypol, or racemic gossypol]. A single 1-d-old *H. zea* (Boddie) larva was placed in a 22-ml plastic cup that contained 4–5 g of a specific diet. Each treatment consisted of 40 larvae, which were raised in incubators at 27°C on a 12-hr light/12-hr dark regime. The following parameters were measured: number of survivors, days-to-pupation, and pupal weight. After 10 d, cups were inspected daily to check for larval survival and pupation. Pupae were allowed to harden for 1 d and then weighed.

Statistical Analyses

Logistic regression and frequency analysis (Proc Logistic and Proc Freq, respectively) were performed to determine the comparative probability of survival on different diets. Results of logistic regression are the ratio of survival odds for larvae consuming two different diets. For example, the odds of survival [$p/(1 - p)$] on the 0.16% (-)-gossypol diet is $[0.70/(1 - 0.70)]$ (see Table 1), whereas the odds of survival in the 0.20% (-)-gossypol diet is $[0.40/(1 - 0.40)]$. To compare the survival on these diets, the ratio of these two odds was calculated (Hosmer and Lemeshow, 2000; Agresti, 2002). This provides a measure of the likelihood of survival between these two groups. Thus, the odds ratio of larval survival on the 0.16% (-)-gossypol diet compared to the 0.20% (-)-gossypol diet shown in Table 1 is calculated as follows:

$$\left(\frac{0.7}{1 - 0.7}\right) / \left(\frac{0.4}{1 - 0.4}\right) = \left(\frac{0.7}{0.3}\right) / \left(\frac{0.4}{0.6}\right) = 3.5$$

Table 1 Odds ratios of survival and probability of significance for survival of *Helicoverpa zea* larvae fed with racemic, (+)-, or (-)-gossypol at different concentrations

Gossypol form	Odds ratio comparison between gossypol concentrations		
	0.16/0.20	0.16/0.24	0.20/0.24
(±) ^a	nsd ^b (0.470) ^c	nsd (0.352)	4.8 (0.036)
(-)	3.5 (0.008)	16.3 (<0.001)	nsd (0.742)
(+)	10.5 (<0.001)	22.7 (<0.001)	2.2 (0.075)

^a (±)- denotes gossypol racemate.

^b nsd denotes not statistically different (logistic regression analysis with a 95% Wald confidence level).

^c Value in parentheses is the probability that the difference within the survival comparison is statistically significant.

Statistical differences between days-to-pupation on different diets and least-square mean weights of pupae on different diets were determined using Proc Mixed in SAS version 9.1 (SAS Institute, Cary, NC, USA, 2003) software computations. Survival odds and differences in days-to-pupation and least-square mean pupae weights were made between the control diet with no Alphacel and the control diet with Alphacel, but no gossypol. Similarly, all gossypol diets were compared to the two control diets. In addition, in designing the experiment, an *a priori* decision was made to evaluate the gossypol diet data by dividing the study into 18 groups. Nine groups considered how a concentration of each enantiomer or the racemate affected the larvae compared to other concentrations of the same enantiomer or racemate. The other nine groups considered how each enantiomer or racemate at a specific concentration affected the larvae compared to the other enantiomer or racemate at the same concentration. These were the only pairwise comparisons evaluated among the gossypol diets.

Results

We found a clear dose response to gossypol for survival and, to a lesser extent, pupal weight. Furthermore, overall survival, days-to-pupation, and pupal weights were not different when the larvae were fed with racemic, (+)-, and (-)-gossypol at the same concentration. Specific analyses of the data are given below.

Survival

The survival results of the feeding experiment are shown in Fig. 2. Contingency table analysis indicated no significant difference in survival between the diet and the diet with Alphacel. The same analysis showed that larval survival on all of the 0.20% and 0.24% gossypol diets was lower than the diet with Alphacel without gossypol. For the 0.16% diet, this was only true for the (\pm)-gossypol diet.

Fig. 2 Percentage survival of *Helicoverpa zea* larvae raised on artificial diet containing Alphacel with various amounts of racemic, (+)-, and (-)-gossypol

The odds ratio of survival at different levels of racemic, (+)-, or (–)-gossypol is given in Table 1. When the effect of feeding racemic gossypol at different levels was compared, the only statistically significant difference in survival was between the larvae fed with the 0.20 and 0.24% diets (Table 1). That is, larvae fed with the diet containing 0.20% racemic gossypol were 4.8 times more likely to survive as compared with larvae fed with the diet containing 0.24% racemic gossypol. Among the (–)-gossypol diets, larvae fed with the 0.16% diet were 3.5 times more likely to survive than larvae fed with the 0.20% diet and 16.3 times more likely to survive than larvae fed with the 0.24% diet. The (+)-gossypol diets showed a similar trend with larvae fed with the 0.16% diet being 10.5 times more likely to survive than larvae fed with the 0.20% diet and 22.7 times more likely to survive than larvae fed with the 0.24% diet, whereas larvae fed with the 0.20% diet were 2.2 times more likely to survive than those on the 0.24% diet. All other comparisons of survival with concentration differences were not statistically different. When survival was compared between the two enantiomers and racemic gossypol treatments at equivalent concentrations, the only significant differences were at the 0.16% level (Table 2). Specifically, larvae fed with the (–)-gossypol diet at the 0.16% level were 6.2 times more likely to survive compared with larvae fed with the racemic diet at this level, and larvae fed with the (+)-gossypol diet at the 0.16% level were 14.9 times more likely to survive than larvae fed with the racemic diet at this level. This same set of comparisons at the 0.20 and 0.24% diets showed no statistical differences in survival. Odds ratios of survival of the (+)-gossypol diets compared to the (–)-gossypol diets at the same levels were not statistically different.

Days-to-Pupation

There was no statistical difference in the time needed to reach pupation between the diets with and without Alphacel (data not shown). However, there were differences between the Alphacel diet without gossypol and the Alphacel diets that contained gossypol (Fig. 3). In all of the latter, the days-to-pupation increased. Among the various gossypol diets, moderately significant different delays in pupation were noted between (–)-gossypol at the 0.16 and 0.24% levels ($P = 0.03$) and between the 0.20 and 0.24% levels ($P = 0.02$). The only other pupation delay was noted for the (+)-gossypol diets between the 0.16 and 0.24% levels ($P = 0.06$), and this difference

Table 2 Odds ratios of survival and probability of significance for survival of *H. zea* larvae fed with racemic, (+)-, or (–)-gossypol at equivalent concentrations

Percent gossypol in diet	Odds ratio comparison between gossypol forms		
	(–)- ^a /(±)-	(+)-/(±)-	(–)-/(+)-
0.16	6.2 (<0.001) ^b	14.9 (<0.001)	nsd (0.298)
0.20	nsd ^c (0.664)	nsd (0.792)	nsd (0.592)
0.24	nsd (0.724)	nsd (0.385)	nsd (0.791)

^a (±)- denotes gossypol racemate.

^b Value in parentheses is the probability that the difference within the survival comparison is statically significant.

^c nsd denotes not statistically different (logistic regression analysis with a 95% Wald confidence level).

Fig. 3 Average days-to-pupation of *H. zea* larvae raised on artificial diet containing Alphacel with various amounts of racemic, (+)-, and (-)-gossypol

was also moderate. No significant delays to pupation were noted among the three racemate levels. Furthermore, there were no significant differences in days-to-pupation between the racemate and the (+)-gossypol or (-)-gossypol diets or between the (+)-gossypol and (-)-gossypol diets at the same levels of gossypol.

Pupal Weights

There was no large statistical difference in pupal weights between the diet alone and the diet plus Alphacel (data not shown). Pupae from larvae raised on all diets

Fig. 4 Average pupal weights (mg) of *H. zea* larvae raised on artificial diet containing Alphacel with various amounts of racemic, (+)-, and (-)-gossypol

containing gossypol were smaller than those raised on the diet plus Alphacel (Fig. 4). Statistical differences in pupal weights were observed when comparing (\pm)- or (+)- or ($-$)-gossypol under our *a priori* criteria. For the (\pm)-gossypol diets, pupae from larvae raised on the 0.24% diet weighed less than those raised on the 0.16% diet ($P = 0.1$); no difference was found when the other racemate diets were compared. Pupae weighed less for larvae raised on the 0.24% ($-$)-gossypol diet vs. the 0.20 and 0.16% ($-$)-gossypol diets ($P < 0.001$). Pupae from larvae raised on the (+)-gossypol diets were different at all three concentrations ($P < 0.1$). There were no significant differences in pupal weights between the racemate and the (+)-gossypol or ($-$)-gossypol diets at the same levels of gossypol except at the 0.16% level where pupae weights were less for the racemate vs. (+)- or ($-$)-gossypol ($P = 0.06$ and $P = 0.09$, respectively). Additionally, there were no significant differences between the (+)-gossypol and ($-$)-gossypol diets at the same levels.

Discussion

These results show that racemic, (+)-, and ($-$)-gossypol were comparable at reducing survival, days-to-pupation, and pupal weight. One exception was in the survival study where the 0.16% racemic gossypol diet reduced larval survival more effectively than did either of the individual enantiomers at that level. In addition, ($-$)-gossypol was more effective in extending the days needed to reach pupation at the 0.24% level than either (+)-gossypol or the racemate. No large significant differences in pupal weights were observed when racemic, (+)-, or ($-$)-gossypol were compared at the same levels.

These results are somewhat different from those reported by Yang et al. (1999) for *H. armigera*, who, in their artificial diet study, found that larvae matured more slowly, and the percent survival was lower when (+)-gossypol was incorporated into the diet as compared with ($-$)-gossypol. Yang et al. did not include (\pm)-gossypol in their study.

Others have reported enhanced biological activity of ($-$)-gossypol in a variety of enzyme, cell, and whole animal studies (Matlin et al., 1985; Lindberg et al., 1987; Benz et al., 1990; Sang et al., 1991; Gonzalez-Garza et al., 1993; Li and He, 1993; Lin et al., 1993; Blackstaffe et al., 1997; Shelley et al., 1999). Therefore, one might anticipate that the ($-$)-enantiomer would be a more potent inhibitor of insect herbivory. However, we did not find meaningful differences between the enantiomers or between the enantiomers and the racemate in this study. Thus, these results are consistent with the theory that cotton plants with high levels of either (+)- or ($-$)-gossypol in the foliage will not be substantially more susceptible to generalist insect herbivores than cotton plants with ratios of (+)- to ($-$)-gossypol that vary between 3:2 and 2:3. However, these results are based on the generalist herbivore *H. zea*, and an additional study on at least one other species that utilizes cotton as a host will be conducted. Ultimately, validation of this hypothesis awaits field studies.

Acknowledgments This research was supported by the Cotton Foundation. We thank Michael O'Neil and Brittany Fuchs for excellent technical assistance.

Abstract To elucidate the role of the plant lipoxygenase (LOX)/lyase pathway for host search behavior of two parasitic wasps attacking herbivorous larvae, an *Arabidopsis* mutant (*all84*) was isolated with a mutation somewhere in the LOX/lyase pathway. Detached leaves of the mutant were shown to release less (*Z*)-3-hexenal, a first green leaf volatile (GLV) product of the LOX/lyase pathway. The braconid larval parasitoids studied, *Cotesia glomerata* and *Cotesia plutella*, differ in their ability to discriminate among plant volatiles induced by feeding of lepidopteran hosts and nonhosts: *C. plutella* only responds to plant volatiles induced by hosts (*Plutella* larvae), whereas the response by the more generalist *C. glomerata* is not host specific. The *Arabidopsis* mutant *all84* infested by *Pieris* larvae was less attractive to *C. glomerata* than *Arabidopsis* wild type (wt) infested by the host larvae. *C. glomerata* was attracted by two of the GLV biosynthesized through the LOX/lyase pathway, (*E*)-2-hexenal and (*Z*)-3-hexenyl acetate. However, attraction of *C. plutellae* to volatiles from *Plutella*-infested *all84* plants did not differ from attraction to host-infested wt *Arabidopsis*. Both wasp species were arrested to the respective host-infested edge of the wt leaf by showing characteristic antennal searching behavior on the edge. In *C. glomerata*, the duration of this searching behavior at the infested leaf edge was significantly shorter on *all84* plants than on wt plants. By contrast, the duration of the searching behavior of *C. plutellae* on the host-infested leaf edge of *all84* was not significantly different from that on the wt

leaf. These data suggest that the LOX/lyase pathway is directly involved in the production of attractants and arrestants important for host search behavior of the more generalist *C. glomerata*, but not for the specialist *C. plutellae*.

Introduction

Plants show induced responses to herbivory. Induced responses that benefit plants are called induced defenses (Karban and Baldwin, 1997). Induced defenses can be divided into two categories: induced direct defenses (e.g., induced production of toxic compounds, digestibility reducers, repellents, trichomes, etc.) and induced indirect defenses (i.e., enhancing the effectiveness of carnivorous natural enemies of herbivores). An example of an induced indirect defense of a plant is the attraction of carnivorous natural enemies to herbivores by the production of herbivore-induced volatiles. Induced indirect defense responses by plants have attracted much attention from ecologists (for reviews, see Takabayashi and Dicke, 1996; Dicke and Vet, 1999; Dicke and van Loon, 2000; Kessler and Baldwin, 2002).

Studies on the mechanisms involved in the production of herbivore-induced volatiles in plants (e.g., Hopke et al., 1994; Dicke et al., 1999; Ozawa et al., 2000; Horiuchi et al., 2001; Van Poecke and Dicke, 2002; Schmelz et al., 2003) are important in understanding ecological aspects of induced indirect defense responses by plants (Kessler and Baldwin, 2002). *Arabidopsis thaliana* is a model plant for molecular biology and genetic engineering, and mutants related to induced-defense responses are available. Therefore, *Arabidopsis* is also a model plant species for the study of the molecular mechanisms involved in the production of herbivore-induced volatiles by plants. By using *Arabidopsis* mutants, Van Poecke and Dicke (2002) reported that the octadecanoid and the salicylic acid pathways of host-infested plants were involved in attracting the parasitic wasp *Cotesia rubecula*, one of the most important parasitoids of cabbage white butterfly larvae, *Pieris rapae* (Lepidoptera: Pieridae), in Eurasia.

The so-called “green leaf volatile compounds” (GLV) are produced by green plants in response to mechanical wounding by herbivores, and some GLVs are known to be involved in interactions between plants and parasitic wasps (e.g., Takabayashi et al., 1991; Whitman and Eller, 1992; Birkett et al., 2003; Gouinguéné et al., 2005). GLV are produced through the lipoxygenase (LOX)/lyase pathway from linolenic and linoleic acid in green plants (Matsui et al., 2000). Here, our first objective was to investigate the role of the LOX/lyase pathway in the production of herbivore-induced plant volatiles that attract parasitic wasps. We isolated an *Arabidopsis* mutant (*all84*) with a mutation somewhere in the LOX/lyase pathway that results in changes of the amount of (*Z*)-3-hexenal, the first biosynthesized GLV of the LOX/lyase pathway. (*Z*)-3-Hexenal is further converted into other GLV such as (*E*)-2-hexenal (leaf aldehyde), (*Z*)-3-hexenol (leaf alcohol), and (*Z*)-3-hexenyl acetate, all of which are in the LOX/lyase pathway (Hatanaka, 1993; Matsui et al., 2000). After identifying the mutant, we studied whether the mutation would affect the interaction between host-infested plants and their parasitoids mediated by

herbivore-induced plant volatiles by focusing on the following two tritrophic systems: (1) *Arabidopsis*, cabbage white butterfly larvae (*P. rapae*) and its parasitoid *Cotesia glomerata* and (2) *Arabidopsis*, diamondback moth larvae (*Plutella xylostella*) and its parasitoid *Cotesia plutellae*. We have previously reported that both of these parasitoid species are attracted to volatiles emitted from cruciferous plants infested by their respective host larvae (Takabayashi et al., 1998; Shiojiri et al., 2000a). Interestingly, the response of *C. glomerata* is not host specific: The wasps preferred plants infested with either the cabbage white (hosts) or diamondback moth larvae (nonhosts) to intact plants (Shiojiri et al., 2000a). In contrast, the response of *C. plutellae* was highly host specific: the wasps were attracted only to host-infested plant volatiles (Shiojiri et al., 2000a).

After finding a host-infested plant through attraction to herbivore-induced plant volatiles, *C. glomerata* and *C. plutellae* search for their hosts on the infested plants. Both wasps were chemically arrested to the host-infested edge of the leaf by showing characteristic antennal searching behavior (Sato, 1979; Horikoshi et al., 1997; Shiojiri et al., 2000b). This behavior is host specific: Neither wasp species showed the behavior on artificially damaged edges or on edges damaged by nonhost larvae (Shiojiri et al., 2000b). This behavior enhances the wasps' chance of finding their hosts (Sato, 1979; Shiojiri et al., 2000b). Neither leaf juice nor host regurgitant alone applied on a piece of filter paper elicited the same behavior in the wasps. However, immediately after leaf juice and host regurgitant were applied together on the same piece of filter paper, the wasps showed the same antennal searching behavior (Sato, 1979; Horikoshi et al., 1997; Shiojiri et al., 2000b), indicating that chemicals (arrestants) that are formed immediately after mixing leaf juice and regurgitant are an important host-specific cue in host searching by *C. glomerata* and *C. plutellae*. However, mechanisms involved in the formation of these host-specific arrestants along the host-infested edge are unknown. Thus, the second objective of this paper was to use the *Arabidopsis* mutant to elucidate whether the LOX/lyase pathway is involved in the production of *C. glomerata* and *C. plutellae* arrestants.

Methods and Materials

Insects and Plants

Adult females of *P. rapae* were collected from a field in Kyoto City, Japan, in order to obtain eggs during the experimental period. Hatched larvae, which were reared on cabbage leaves in a climate-controlled room (25 + 2°C; 50–70% relative humidity (r.h.); 16L:8D), were used for the experiments. *P. xylostella* larvae were collected from crucifer crops in the same field in Kyoto City and reared in a climate-controlled room (25 ± 2°C, 50–70% r.h., and 16 hr photophase), with cabbage leaves as food to obtain adults. We then kept the adults in the climate-controlled room to obtain eggs. The hatched larvae, which were reared in the climate-controlled room, were used for all experiments.

C. glomerata and *C. plutellae* were obtained from parasitized host larvae collected in a field in Kyoto, Japan. Adults of each parasitoid species were separately maintained in plastic cages (130 × 200 × 300 mm) with honey as food in a climate-controlled room (18 ± 2°C, 50–70% r.h., and 16 hr photophase) for 3 d to ensure

mating. Females were then individually transferred to a glass tube (20 mm diam., 130 mm long) containing honey as food, and kept in a climate-controlled room ($18 \pm 2^\circ\text{C}$, 50–70% r.h., 24 hr darkness) until used. Females were never kept for more than 10 d. At least 1 hr before the start of each experiment, oviposition-inexperienced female wasps were transferred to another climate-controlled room ($25 \pm 2^\circ\text{C}$, 50–70% r.h.) where they were kept under constant light conditions.

Arabidopsis (ecotype Landsberg) plants were grown in plastic pots (five plants per pot) in a climate-controlled room ($22 \pm 2^\circ\text{C}$, 16 hr photophase, 5000 lx) for 4–5 wk. Fully developed but nonflowering plants were used for all experiments.

Isolation of an *Arabidopsis* Mutant

In this study we isolated *Arabidopsis* plants (ecotype Landsberg), with a mutation somewhere in the LOX/lyase pathway, by characterizing the amount of (*Z*)-3-hexenal, the first biosynthesized GLV in plants. Rosette leaves of M2 plants of 3- to 4-wk-old EMS-treated *Arabidopsis* were collected. They were put individually into glass vials with 50 nmol of *n*-heptanal as an internal standard and frozen at -80°C for at least 1 hr. For each vial, a small glass column packed with 2,4-dinitrophenylhydrazine-coated silica gel (140 mg) was connected, and then the vial was heated at 100°C for 20 min. As (*Z*)-3-hexenal in the leaves vaporized and passed through the column, it was converted to the corresponding hydrazone derivatives on the surface of the silica gel. After elution of the hydrazones with hexane, (*Z*)-3-hexenal was quantitatively analyzed with HPLC as described by Matsui et al. (2000). Approximately 1000 lines were screened, and a mutant deficient in GLV formation was isolated [designated as *all* (aldehyde-less)]. In this study, the mutant used was backcrossed three times with wt plants. Details of the biochemical nature of the mutant and its volatile profiles will be reported in our forthcoming paper (Matsui et al., unpublished).

Flight Response of *C. glomerata* and *C. plutellae* to *Arabidopsis* Infested by Host Larvae

The flight response of female *C. glomerata* and *C. plutellae* were observed with respect to two groups of 4 *Arabidopsis* plants, each group in a different pot and receiving a different treatment. Two pots were positioned ca. 25 cm apart in a cage ($25 \times 35 \times 30$ cm) with three windows covered by nylon gauze and one door for introducing plants and wasps. The cage was placed in a climate-controlled room ($25 \pm 2^\circ\text{C}$, 50–70% r.h.; Shiojiri et al., 2000a). Five to ten wasps at a time were released halfway between the two pots. The first landing by each wasp on a plant in either of the 2 pots was recorded as its choice. Once the wasp landed on a plant, it was immediately removed from the cage with an insect aspirator. If the wasp did not land on any of the two pots within 30 min, it was evaluated as a no-choice result. The trial was repeated four to five times, and the pots were replaced for each trial. Four second instar *P. rapae* or ten third instar *P. xylostella* were placed on *Arabidopsis* plants in a pot. After 24 hr, they were used as infested plants. The artificially damaged plants were prepared by punching holes in leaves three times at 12-hr intervals to mimic damage found in infested plants.

Significant preferences in dual-choice tests were analyzed by using a binomial probability function under the null hypothesis that wasps had a 1:1 distribution over

the two groups of plants. The wasps that did not make a choice were ignored for further statistical analysis. In earlier experiments, we found that releasing five to ten wasps at the same time did not significantly affect the choice of the individual wasps (Shiojiri, unpublished data).

Response of *C. glomerata* to Three Synthetic GLV

To determine if the volatiles biosynthesized through the LOX/lyase pathway attract *C. glomerata* to host-infested *Arabidopsis*, we chose three GLV: (*E*)-2-hexenal (leaf aldehyde), (*Z*)-3-hexanol (leaf alcohol), and (*Z*)-3-hexenyl acetate. These components were found in the headspace of wt *Arabidopsis* infested by *P. rapae* larvae (Ozawa, unpublished data). Tested compounds (97–98% purity) purchased from Wako Chemical Industries Co. Ltd. were individually dissolved in hexane (0.01 mg/ml solution). Ten microliters of the solution (0.1 µg compound) were applied on a piece of sponge cellulose (5 × 25 × 25 mm). To facilitate a low volatilization rate, the sponge was placed in a sealed polyethylene film bag (50 × 70 mm), and the bag was then placed in another sealed bag after evaporation of the solvent for 3 min. The amount (ion intensity) of each compound vaporized from the sealed bag per unit time (1 hr) was ca 1.9×10^7 [(*E*)-2-hexenal], 4.4×10^6 [(*Z*)-3-hexanol], and 6.4×10^6 [(*Z*)-3-hexenyl acetate], which was similar to that emitted from infested wt: 1.2×10^7 [(*E*)-2-hexenal], 9.5×10^6 [(*Z*)-3-hexanol], and 3.0×10^7 [(*Z*)-3-hexenyl acetate] (Tenax trapping, flow rate; 100 ml/min, 2 l grass bottle). As a control, 10 µl of pure hexane were impregnated in a piece of sponge cellulose. The bag containing a sample or a control piece of sponge was placed on the soil in a pot with three intact wt plants. Flight preference of the wasps for plants with the sample compared with control plants was observed. Samples were renewed every 30 min. Every hour, plants were replaced by new plants to avoid the possibility that the tested volatiles induce any response in *Arabidopsis* plants themselves (Bate and Rothstein, 1998; Kishimoto et al., 2005). When *C. glomerata* showed no preference for the test compound or the control, sample solutions of different concentrations (0.1 and 0.001 mg/ml) were applied to the sponge cellulose following the same procedure as described above.

Antennal Response of *C. glomerata* and *C. plutellae* to Host-Infested Edges of *Arabidopsis* Leaves

The antennal searching behavior of *C. glomerata* and *C. plutellae* to host-infested leaf edges was observed in a test tube (20 mm diam., 130 mm long). Four second instar *P. rapae* larvae or ten third instar *P. xylostella* were placed on *Arabidopsis* plants in a pot. After 24 hr, larvae and their associated products such as silks and feces were removed from the leaves with a small fine brush. After washing the leaves with water, we cut out a piece (50 mm²) with a herbivore-infested edge ca. 8 mm long. We also prepared pieces of artificially damaged leaves. The artificially damaged plants were prepared by punching holes in leaves. The damaged area was the same as in herbivore infested plants. We then cut out a piece (50 mm²) with an artificially damaged edge ca. 8 mm long. The piece of leaf was placed in a tube into which one wasp had been introduced. When the wasp showed strong antennal contact with the piece of leaf, it was judged as showing searching behavior, and the duration of the searching behavior (searching time) was recorded. When the wasp

left the piece of leaf for more than 10 sec or started antennal cleaning on it, searching behavior was judged to be finished. When the wasp did not show searching behavior within 5 min, it was judged to have shown no response. Twenty females were used for each bioassay.

Results

Isolation of *Arabidopsis* Mutants

One mutant (*all84*) that produced significantly less (*Z*)-3-hexenal (57.7 ± 8.5 nmol/g fresh weight, $n = 11$) than wt plants (300.2 ± 108.7 nmol/g fresh weight; $n = 6$) (*t* test, $P = 1.7 \times 10^{-6}$) was isolated. Under the growing conditions used, no apparent difference in phenotype could be observed between *all84* and wt.

Flight Response of *C. glomerata* to *Arabidopsis* Infested by *P. rapae* Larvae

When comparing intact wt plants and intact *all84* plants, most *C. glomerata* showed no choice. However, wasps showed a significant preference for host-infested *all84* plants over intact *all84* plants. In addition, wasps preferred infested wt plants to infested *all84* plants, and artificially damaged wt plants to artificially damaged *all84* plants (Fig. 1).

Flight Response of *C. plutellae* to *Arabidopsis* Infested by *P. xylostella* Larvae

C. plutellae showed equal preference when comparing intact wt plants with intact *all84* plants, and infested wt plants with infested *all84* plants. However, wasps showed significantly greater preference for infested *all84* plants than for intact *all84* plants (Fig. 2).

Fig. 1 Flight response of *C. glomerata* to an *Arabidopsis* wt and a GLV-deficient mutant plant (*all84*) in different treatments. NS, not significantly different; * $0.05 > P > 0.01$, ** $0.01 > P > 0.001$, *** $0.001 > P$ (binomial test)

Fig. 2 Flight response of *C. plutellae* to an *Arabidopsis* wt and a GLV-deficient mutant plant (*all84*) in different treatments. NS: not significantly different; **0.01 > P > 0.001 (binomial test)

Response of *C. glomerata* to Three Synthetic GLV

Significantly more *C. glomerata* females were attracted to intact wt plants with (*E*)-2-hexenal (0.01 mg/ml concentration) than to the wt control plants. Wt plants treated with (*Z*)-3-hexenyl acetate of the same concentration were also preferred to wt control plants. However, at the same concentration, the wasp showed equal preference for wt plants treated with (*Z*)-3-hexenol and for wt control plants (Fig. 3). At higher (0.1 mg/ml) and lower (0.001 mg/ml) concentration of (*Z*)-3-hexenol, the wasps were not attracted to the compound (data not shown).

Antennal Response of *C. glomerata* and *C. plutellae* to the Edge Damaged by the Hosts of *Arabidopsis* Leaves

The searching time of *C. glomerata* on artificially damaged wt leaves and on artificially damaged *all84* leaves did not differ significantly (*t* test, P = 0.08). However, the searching time of the wasp on *P. rapae* (host)-damaged *all84* leaves was reduced compared to host-damaged wt leaves (*t* test, P = 0.005) (Fig. 4, left). No differences

Fig. 3 Flight response of *C. glomerata* to three synthetic GLV (0.1 µg compound in a piece of sponge cellulose in a sealed polyethylene film bag) placed on intact *Arabidopsis*. NS, not significantly different; *0.05 > P > 0.01 (binomial test)

in searching times were found for *C. plutellae* having contact with artificially damaged wt leaves vs. artificially damaged *all84* leaves (*t* test, $P = 0.38$) or with *P. xylostella* (host)-damaged leaves vs. host-damaged *all84* leaves (*t* test, $P = 0.41$; Fig. 4, right).

Discussion

C. glomerata is attracted to host-infested cruciferous plants over uninfested cruciferous plants (Takabayashi et al., 1998; Dicke and van Loon, 2000; Shiojiri et al., 2000a). *C. glomerata* are also attracted to artificially damaged cruciferous plants, and cruciferous plants infested by nonhost larvae (*P. xylostella*) over uninfested plants (Takabayashi et al., 1998; Shiojiri et al., 2000a). Thus, not only are *C. glomerata* attracted to compounds that are produced in response to injury by their hosts, but also to injury caused by other lepidopteran larvae. As green plants emit GLVs through the LOX/lyase pathway when damaged mechanically (Matsui et al., 2000), we hypothesized that some GLV from the LOX/lyase pathway are involved in the attraction of *C. glomerata* by infested cruciferous plants. Here, we showed that the attractiveness of host-infested *all84* plants to *C. glomerata* was weaker than that of host-infested wt plants. This was also observed when comparing artificially damaged *all84* and wt plants. In addition, we also showed that the addition of the GLV (*E*)-2-hexenal or (*Z*)-3-hexenyl acetate to intact wt plants increased their attractiveness to *C. glomerata*. These results indicate the importance of GLV of the LOX/lyase pathway in the attraction of *C. glomerata* to herbivore-infested cruciferous plants.

Artificially damaged and host-infested *all84* plants were more attractive than intact *all84* plants to *C. glomerata*. This could be because the production of (*Z*)-3-hexenal was not completely suppressed in *all84* plants. (*Z*)-3-Hexenal is converted into other GLV such as (*E*)-2-hexenal (leaf aldehyde), (*Z*)-3-hexenol (leaf alcohol), and (*Z*)-3-hexenyl acetate in the LOX/lyase pathway (Hatanaka, 1993; Matsui et al.,

2000). Thus, artificially damaged and host-infested *all84* would still have produced relatively larger amounts of not only (*Z*)-3-hexenal, but also of other GLV when compared with intact *all84*. The slight increase of the wasp-attractive GLV in infested *all84* plants would in part explain the preference of *C. glomerata* to infested *all84* plants over intact *all84* plants. Furthermore, wasps might also use volatile chemicals biosynthesized in pathways other than the LOX/lyase pathway emitted from infested *all84* plants.

C. plutellae preferred host-infested cruciferous plants over uninfested cruciferous plants, artificially damaged plants, and plants infested by nonhost (*P. rapae*) larvae (Shiojiri et al., 2000a). These results indicate that *C. plutellae* responds to compounds that are produced only in response to injury by their hosts. Thus, it is unlikely that they respond only to GLV. In this paper, we showed that infested *all84 Arabidopsis* plants were more attractive to *C. plutellae* than intact *all84* plants, and there were no differences in attractiveness between infested *all84* and infested wt plants. These data indicate that the mutation in the LOX/lyase pathway in *all84* does not negatively affect *C. plutellae* attraction.

C. glomerata and *C. plutellae* show antennal host searching behavior to filter paper impregnated with a mixture of host-food plant juice and host regurgitant, but do not respond to either substance on its own (Sato, 1979; Shiojiri et al., 2000b). Thus, the plant factors as well as the host factors are involved in the production of arrestants that elicit the antennal searching behavior. Interestingly, the duration of antennal searching of *C. glomerata* on the host-infested edge of *all84* leaves was significantly shorter than that on wt leaves, suggesting the LOX/lyase pathway could also be involved in the production of arrestants for *C. glomerata*. By contrast, the duration of antennal searching by *C. plutellae* on host-infested edges of *all84* leaves did not differ significantly from that on infested wt leaves. The data indicate that the mutation in the LOX/lyase pathway in *all84* does not negatively affect the production of the *C. plutellae* arrestants.

Although the site of the mutation in *all84* is not yet clarified, our data show that the LOX/lyase pathway plays an important role in the interaction between host-infested *Arabidopsis* and *C. glomerata* mediated by attractants and arrestants. In contrast, the mutation in the LOX/lyase pathway in *all84* did not affect the chemical interaction between *Arabidopsis* and *C. plutellae*. This, however, does not necessarily mean that the LOX/lyase pathway is not involved in the production of *C. plutellae* attractants and arrestants. Identification of the mutation in *all84* is extremely important and is now under way. Van Poecke and Dicke (2002) reported that the jasmonic acid signaling pathway and the salicylic acid signaling pathway were both involved in the production of attractants for *C. rubecula*, a parasitoid of *P. rapae* larvae, by host-infested *Arabidopsis* plants. Whether these signaling pathways are also involved in the interaction between *Arabidopsis* and the two parasitic wasps in this study needs to be determined. Further detailed studies on the molecular mechanisms involved in the production of attractants and arrestants for both parasitic wasps would contribute to the understanding of the ecology and evolution of these tritrophic systems, and to the attempt to increase the effectiveness of natural enemies by using attractants and/or arrestants of plant origin in integrated pest management systems.

Abstract There has been an ardent interest in herbivore saliva due to its roles in inducing plant defenses and its impact on herbivore fitness. Two techniques are described that inhibit the secretion of labial saliva from the caterpillar, *Helicoverpa zea*, during feeding. The methods rely on cauterizing the caterpillar's spinneret, the principal secretory structure of the labial glands, or surgically removing the labial salivary gland. Both methods successfully inhibit secretion of saliva and the principal salivary enzyme glucose oxidase. Caterpillars with inhibited saliva production feed at similar rates as the untreated caterpillars, pupate, and emerge as adults. Glucose oxidase has been suggested to increase the caterpillar's survival through the suppression of inducible anti-herbivore defenses in plants. Tobacco (*Nicotiana tabacum*) leaves fed on by caterpillars with ablated salivary glands had significantly higher levels of nicotine, an inducible anti-herbivore defense compound of tobacco, than leaves fed upon by caterpillars with intact labial salivary glands. Tomato (*Lycopersicon esculentum*) leaves fed upon by caterpillars with suppressed salivary secretions showed greatly reduced evidence of hydrogen peroxide formation compared to leaves fed upon by intact caterpillars. These two methods are useful techniques for determining the role that saliva plays in manipulating plant anti-herbivore defenses.

Introduction

Insect saliva contributes to a wide range of functions, such as digestion, water balance, circumventing animal–host defenses, maintenance of mouth parts, pheromone production, pathogen transmission, and antipredator defenses, and is suspected to have antimicrobial properties (Ribeiro, 1995; Felton and Eichenseer, 1999; Liu et al., 2004; Musser et al., 2005). Emerging data indicate that insect feeding induces plant responses that are qualitatively and quantitatively different than mechanical wounding (Felton et al., 1994; Stout et al., 1994, 1998; Alborn et al., 1997; McCloud and Baldwin, 1997; De Moraes et al., 1998; Felton and Korth, 2000; Kahl et al., 2000; Reymond et al., 2000; Musser et al., 2002a,b). A principal factor in determining the unique and specific plant responses to herbivory may be oral secretions released by the herbivore during feeding. Studies demonstrate that the application of insect regurgitant (or head extracts) to an artificial wound on plants can elicit defenses that are not associated with artificial wounding alone (Mattiacci et al., 1995; Alborn et al., 1997; McCloud and Baldwin, 1997; Felton and Korth, 2000; Kahl et al., 2000; Reymond et al., 2000; Musser et al., 2002b; but see Mithofer et al., 2005). β -Glucosidase and fatty acid–amino acid conjugates (e.g., volicitin) are elicitors of plant defenses and components of caterpillar regurgitant (Mattiacci et al., 1995; Alborn et al., 1997, 2000; Halitschke et al., 2001).

There are two principal limitations to the use of oral secretions as utilized in the studies cited above. First, the origin of the oral secretions is undefined. Regurgitant and head extracts include chemicals that may not be typically associated with caterpillar feeding (Ribeiro, 1995; Felton and Eichenseer, 1999). Regurgitant includes not only saliva from the labial and mandibular glands, but also gut enzymes, partially digested plant material, and gut microbes (Ribeiro, 1995; Felton and Eichenseer, 1999). Indeed, it has been suggested that elicitors could be of microbial origin (Spiteller et al., 2000). Caterpillar saliva originates from the labial and mandibular salivary glands (Felton and Eichenseer, 1999). For caterpillars, the spinneret functions as the secretory structure for labial saliva (Felton and Eichenseer, 1999). Second, there is a critical lack of dose response in these studies because it is not known if the amount of oral secretions applied to plant tissues is consistent with what is produced by caterpillars during feeding (see Peiffer and Felton, 2005).

Glucose oxidase (GOX), a salivary enzyme present in many lepidopteran and some herbivorous hymenopteran larvae, catalyzes D-glucose in the presence of oxygen to D-gluconic acid and hydrogen peroxide (H₂O₂) (Eichenseer et al., 1999; Felton and Eichenseer, 1999; unpublished data). GOX occurs in especially high levels in larval *Helicoverpa zea* and has been suggested to increase the caterpillar's survival through the suppression of inducible herbivore defenses in plants (Eichenseer et al., 1999; Felton and Eichenseer, 1999; Musser et al., 2002a). A wounded tobacco leaf treated with GOX had significantly less induction of nicotine, an inducible anti-herbivore defense, compared to tobacco plants that were wounded and treated with inactive GOX (Musser et al., 2002a).

In this paper we demonstrate two techniques that can be used to suppress herbivore saliva production *in situ*. These methods were then used to determine how saliva modulates induced defenses.

Methods and Materials

Plant and insect rearing

In a rearing facility with a 15-hr photoperiod, neonates of *H. zea* were fed a wheat germ and soy-protein-based artificial diet at 28°C until the sixth instar (Chippendale, 1970; Broadway and Duffey, 1986). Tobacco seeds were sown in 4-l plastic pots filled with a Redi Earth Peat-Lite soil mixture (Scott-Sierra Horticulture Products Company, Marysville, OH, USA) in a greenhouse at the University of Arkansas in Fayetteville, Arkansas. The greenhouse was maintained on a 14-hr photoperiod, with high-pressure sodium lights (1000 W) and day and night temperatures of approximately 33°C and 20°C, respectively. Plants were watered every 2 d and fertilized (N:P:K = 15:30:15, American Plant Food Co. Creve Coeur, MO, USA) once a week. When the tobacco plants exceeded a height of 0.33 m, they were used in the bioassays described below. Tomato plants (cv. Better Boy) were grown at 25°C in a greenhouse. Plants with four nodes were used for all experiments. *Pieris rapae* were reared on cabbage in a greenhouse at the University of Lausanne, Switzerland, in a manner described by Reymond et al. (2000).

Caterpillar spinneret cauterization

Spinnerets of actively feeding sixth instar *H. zea* caterpillars were cauterized in order to inhibit secretions from the labial salivary. Caterpillars were anesthetized with ice, held still with soft forceps, and viewed under a dissecting microscope while a red-hot metal probe touched the spinneret until the spinneret was cauterized sufficiently to remove the cone appendage. The probe was heated with a Bunsen burner. The spinnerets for mock-treated caterpillars had their cuticles cauterized near the spinneret and away from notable sensory structures so that the spinneret remained functional.

A 3,3'-diaminobenzidine tetrahydrochloride (DAB) assay was used to determine if the cauterization of the spinneret was successful. The caterpillars were starved for 1 hr, and then fed on glass fiber disks soaked with a mixture of 50 mg/ml sucrose and 50 mg/ml glucose solution. After feeding, damage of approximately 20% was apparent on the glass microfiber filters (Whatman International Ltd., Maidstone, UK), the fiber disk was treated with 75 μ l of DAB at a concentration of 0.5 mg/ml (dissolved in distilled water and HCL for a pH 5.0) (Sigma Chemical Co., St. Louis, MO, USA) and a solution of 75 μ l of 0.5 mg/ml of horseradish peroxidase (Sigma Chemical CO., St Louis, MO, USA). These two solutions turned the damaged disks brown if H₂O₂ was present due to catalysis of glucose. Similar cauterization was performed on an alternative species, fifth instar *P. rapae*; however, no screening method was used because we found that *P. rapae* contained no detectable GOX activity as determined by the methods described by Eichenseer et al. (1999), and their feeding activity was disrupted due to the cauterization.

Scanning electron microscopy

Samples for scanning electron microscopy were prepared as described by Hayat (1989). Briefly, the larvae's heads were removed and fixed overnight in 2.5% glutaraldehyde (Electron Microscopy Sciences, Fort Washington, PA, USA) in 0.1 M phosphate buffer, pH 7.4. Larvae were rinsed in 0.1 M phosphate buffer and treated with 2% aqueous osmium tetroxide (EMS) for 2 hr. Following water rinses, the larvae were dehydrated in graded ethanols (70 to 100%), then dried in a Baltec SCD030 (Techno Trade, Manchester, NH, USA) critical point dryer. Dried samples were mounted and coated with gold/palladium to increase conductivity (Baltec SCD050, Techno Trade). Samples were imaged at 20 KV in a JSM 5400 scanning electron microscope (JEOL, Peabody, MA, USA), and images were captured by using IMIX-PC v.10 software (Princeton Gamma Tech, Princeton, NJ, USA).

Caterpillar labial gland ablation

The labial salivary glands were removed from living sixth instar *H. zea* caterpillars. Caterpillars were chilled at 4°C, submerged in antibacterial soap at 10 mg/l for 1 min, and then submerged in 0.5% solution of H₂O₂ for 1 min. The washed caterpillar was immediately placed onto a parafilm wax-coated dissection dish filled with water and then held dorsal end down by two pinned strips of parafilm. One strip was placed over the hindgut portion of the caterpillar, and the other strip was placed over the head and foregut. While the larva was submerged, the cuticle of the second abdominal segment between the true legs and prolegs was lifted slightly with forceps. A small incision was made in the cuticle that provided access to the pair of labial salivary glands. Using forceps, the labial salivary glands were completely extracted from the body cavity. The cuticle was pinched back together with the caudal portion overlapped by the anterior section of cuticle. The caterpillar was rinsed with distilled water to remove residual soap and peroxide, removed from the straps, and blotted dry with a tissue paper. The caterpillar remained lying dorsally on the tissue until the cuticle appeared sealed and the caterpillar became active (approximately 30 min). Mock-treated caterpillars had a wounded abdomen as described above, but the labial salivary glands were not removed from the cavity of the caterpillar. The caterpillars fed on glass fiber disks, and the disks were assayed with DAB as described above. *P. rapae* (fifth instar) caterpillars were ablated in a manner described above, except that the caterpillars were not washed in soap or H₂O₂.

To quantify the levels of GOX secreted by caterpillars with intact labial salivary glands vs. caterpillars without intact labial salivary glands, approximately 140 sixth instar *H. zea* caterpillars were selected; half had a surgery that removed their labial salivary glands, and the other half had a mock surgery where the glands remained intact as described directly above. After the caterpillars healed, they were individually placed into a medicine cup containing a 25-mm-diam glass fiber disk (Whatman Inc., Florham Park, NJ, USA) containing 50 mg/ml solution of sucrose, and placed into a 33°C incubator. We monitored the caterpillars for 10 hr, so that whenever approximately 30% of the glass fiber disk was eaten, the disk was stored in one of six 50-ml Corning™ polypropylene centrifuge tubes (Corning, New York, NY, USA) on ice. We evenly sorted the fed-on disks so that there were three

samples/centrifuge tubes containing disks fed on by caterpillars with intact salivary glands and three samples/centrifuge tubes containing disks fed on by caterpillars without labial salivary glands. In addition, after the above disks were eaten, the caterpillars received additional glass fiber disks that could have been added to the tubes above. Also, the caterpillar frass was removed from the disk as soon as possible to reduce the addition of gut enzymes or salivary GOX swallowed by the caterpillar before the surgery. We have determined that the frass still can have GOX activity and that may have slightly altered our quantified results. Caterpillars that appeared dead or did not feed due to the surgery were removed from the experiment.

After 10 hr, the partially eaten disks were washed by putting 5 ml of deionized water into the centrifuge tubes and vigorously shaken. The centrifuge tubes were spun in a centrifuge for 10 min at 5,000 rpm. The liquid supernatant was concentrated by cellulose 30,000 molecular weight cutoff Micron® centrifugal filter devices (Millipore Corp., Bedford, MA, USA) to approximately 1 ml per centrifuge tube. The concentrated retentate was assayed for the presence of GOX. Glucose oxidase activity was measured by the change of absorbance of the reaction mixture at 460 nm, read with a TU-1901 Double Beam Spectrophotometer (GenTech Scientific, Inc., Arcade, NY, USA) for a 1-min kinetic assay as described by Eichenseer et al. (1999).

(C) Dark stain on glass fiber disks fed upon by *H. zea* caterpillars with intact spinnerets indicates that salivary GOX catalyzed the formation of H_2O_2 . (D) Glass fiber disks fed upon by caterpillars with cauterized spinnerets stained light compared to glass fiber disks fed upon by caterpillars with intact spinnerets indicating lower levels of secretion of the salivary enzyme, GOX

Effect of saliva on nicotine levels in situ

One *H. zea* caterpillar with either intact or ablated labial salivary glands was placed into a 9.5-mm-diam plastic Petri dish clip cage. This caged larva was attached on the second uppermost fully expanded tobacco leaf for 24 hr. Three days after the 24-hr feeding treatment, approximately 150 mg of the remaining leaf that was fed upon by the caterpillar were prepared for high-performance liquid chromatography (HPLC) analysis with C:18 column and MeOH/H₂O gradient to quantify nicotine (Saunders and Blume, 1981). A mean comparison of nicotine levels was analyzed with a Tukey–Kramer HSD test in a one-way analysis of variance with JMP (Sall and Lehman, 1996). The experiment was replicated six times.

Effect of saliva on H₂O₂ formation in tomato leaves

A DAB assay was also used for H₂O₂ production in tomato foliage fed upon by *H. zea* larvae with cauterized or intact spinnerets. The assay was slightly modified from Orozco-Cardenas and Ryan (1999). Tomato plant leaves were removed with a scalpel, and the cut end was placed in 1 mg/ml DAB (free base) for 3 hr. Sham-operated or cauterized larvae were allowed to feed on the leaves until they had eaten approximately 1 cm². Leaves remained in the DAB for an additional 2.5 hr, and were then cleared by boiling in 96% ethanol. Leaves were stored in 100% ethanol.

Results

Caterpillar spinneret cauterization and labial salivary gland ablation

H. zea caterpillars with cauterized spinnerets (Figures 1 and 2) or without labial salivary glands (Fig. 3) had drastically less labial salivary secretions than the mock-treated caterpillars as determined by glass fiber disk staining for H_2O_2 (Figures 1 and 4). In addition, when the glass fiber disks fed on by the caterpillars with intact labial glands were washed, we performed an enzyme assay on the retentate and determined that the collected salivary secretions showed drastically higher levels of the major labial salivary protein, glucose oxidase [2395.76 ± 1064.8 (mean \pm SE) $\mu\text{m mg}^{-1} \text{min}^{-1}$] compared to glass fiber disks fed on by caterpillars without labial glands (126.90 ± 52.2 $\mu\text{m mg}^{-1} \text{min}^{-1}$). So, although the caterpillars without labial salivary glands secreted negligible amounts of these enzymes in comparison to caterpillars with intact labial salivary glands, the feeding level for caterpillars with the suppressed salivary secretion was similar to the feeding level of their mock counterparts according to the percentage of glass fiber disk eaten per hour or the amount of artificial diet eaten ($P > 0.05$; data not shown). Both groups of caterpillars could still pupate and eclose to adults. We noted that if fifth instars had a cauterized spinneret, the sixth instar would lack a labium and the ability to secrete saliva.

Fig. 3 Labial salivary gland removal from living *H. zea* caterpillars. (A) Incision of cuticle of sixth instar *H. zea* on second abdominal segment with pair of salivary glands pulled from cavity. (B) Healed cuticle from sixth instar *H. zea* with ablated salivary glands

A. *H. zea* Labial Salivary Gland Extraction

B. *H. zea* Cuticle After Salivary Gland Extraction

Fig. 4 Glass fiber disk fed upon by *H. zea* caterpillars with ablated salivary glands or intact salivary glands. (A) Glass fiber disks fed upon by caterpillars with ablated salivary glands were light brown and white, which indicated low levels of H_2O_2 production compared to glass fiber disks fed upon by caterpillars with intact salivary glands (B) that were dark brown, which indicated high levels of H_2O_2 production

Other methods of salivary ablation were attempted with mixed results. Super glue[®] (Pacer Technology, Rancho Cucamonga, CA, USA) dabbed on the spinneret did not provide adequate inhibition of labial salivary secretions. Another approach involved the ablation of the labium and spinneret with dissecting scissors in the fifth instar. This resulted in adequate inhibition of labial saliva in the sixth instar because the labium and spinneret was absent after the molt. However, this dissection was more time-consuming than the procedures described above and resulted in higher levels of mortality (H. Eichenseer, personal communication).

P. rapae with cauterized spinnerets showed minimal signs of feeding and shortly died. However, labial salivary gland ablation was successful, and these caterpillars would feed at a similar rate as the mock-wounded caterpillars as determined by the number of *Arabidopsis* leaves fed on per hour per caterpillar. These caterpillars could also pupate and eclose to adults. In addition, mandibular salivary glands could

Fig. 5 Nicotine levels in tobacco leaves fed on by *H. zea* caterpillars. Nicotine content was analyzed by HPLC and expressed in milligrams per gram leaf wet weight. Different letters represent statistically significant differences between treatments at $P < 0.05$. Bars indicate mean \pm SE

be ablated in *P. rapae*, and these caterpillars could feed at a sufficient rate for experimentation. These results with *P. rapae* will allow further testing of the role of salivary secretions in eliciting plant responses.

Effect of Saliva on Nicotine Levels in Tobacco in situ

Tobacco leaves fed upon by *H. zea* caterpillars with intact salivary glands had significantly lower levels of nicotine compared to leaves fed upon by caterpillars with ablated salivary glands (Figure 5; $0.01 < P < 0.05$). These results are consistent with what was previously reported for the cauterization technique (Musser et al., 2002a).

Fig. 6 Effect of saliva on H_2O_2 formation in tomato leaves. Leaves were fed on by *H. zea* larvae with intact spinnerets or cauterized spinnerets. Dark deposits of DAB indicate the formation of H_2O_2

Effect of saliva on H₂O₂ formation in tomato leaves

The cauterization of spinnerets substantially reduced the oxidative burst in leaves fed upon by insects (Figure 6). H₂O₂ formation was visible by the brown deposits of oxidized DAB. Caterpillars with intact salivation elicited systemic peroxide formation, whereas caterpillars with compromised salivation elicited limited peroxide formation, primarily confined to the feeding sites and the vascular tissues. Tomato plants were chosen for this experiment because they showed a consistently stronger oxidative burst in response to larval feeding.

Discussion

Herbivores may elicit specific plant responses that are qualitatively and/or quantitatively unique compared to mechanical wounding (Felton et al., 1994; Stout et al., 1994, 1998). The oral secretions of herbivores are considered key components contributing to these unique and specific plant responses (e.g., Mattiacci et al., 1995; Alborn et al., 1997; Felton and Korth, 2000; Kahl et al., 2000; Reymond et al., 2000; Musser et al., 2002a,b). Techniques have not been available to determine the role of oral secretions or saliva *in situ*; to date, researchers have relied on collecting regurgitant and applying it to artificial wounds to mimic oral secretions during feeding. More recently, Mithofer et al. (2005) have developed a “mechanical” worm to simulate caterpillar feeding, and have demonstrated that volatile profiles emitted from lima bean leaves by using this device were qualitatively similar to caterpillar feeding. Here, we show that two methods could be successfully employed to suppress the production of saliva of caterpillars during feeding. By using these techniques, we show that plant defensive responses to caterpillar feeding are qualitatively different when caterpillars are able to secrete saliva compared to their treated counterparts in which salivary secretions are eliminated.

The ability to nearly eliminate the secretion of saliva *in situ* is a powerful tool that can be applied to investigate the physiology of caterpillar saliva. We have used this technique to study the role of saliva in modulating the induced responses of host plants (e.g., Musser et al., 2002a). *H. zea* caterpillars with cauterized spinnerets or ablated salivary glands had a dramatic reduction of H₂O₂ staining on the glass fiber disk in comparison to mock-treated caterpillars. This provided solid evidence that labial saliva in general and the labial salivary enzyme GOX specifically was suppressed.

Cauterization of the spinnerets prevented much of the oxidative burst in tomato foliage that follows rapidly after feeding. Mechanical damage in tomato triggers a rapid and systemic production of many signaling compounds such as jasmonic acid (Schilmiller and Howe, 2005). H₂O₂ has been shown to act as a secondary messenger for the induction of plant defense genes encoding proteinase inhibitors and polyphenol oxidases (Orozco-Cardenas and Ryan, 1999). The more extensive release of H₂O₂ in foliage fed upon by caterpillars with intact salivary secretion is likely due to the release of GOX during feeding. H₂O₂ is highly permeable across membranes and could easily diffuse from the initial feeding site as the insect enzyme oxidizes glucose in the plant tissues. Alternatively, GOX or other component(s) of saliva could mediate reiterative, systemic oxidative bursts by plant cells (Alvarez et al., 1998).

In most examples where the spinneret cauterization procedure was used, we concluded that saliva plays a role in suppressing plant defenses. *H. zea* with intact salivary glands that fed upon tobacco plants counteracted the stimulation of nicotine and proteinase inhibitors in comparison to feeding by caterpillars with ablated labial salivary glands (Musser et al., 2002a; unpublished data). Glucose oxidase was determined to be the principal salivary enzyme responsible for suppressing the induction of nicotine in wounded tobacco plants (Musser et al., 2002a). In addition to suppressing nicotine in tobacco, spinneret cauterization in *Spodoptera exigua* indicated that saliva and the enzyme GOX could decrease transcript levels of *Medicago truncatula* genes encoding terpenoid biosynthesis (Bede et al., 2006). The response of plants to herbivore feeding not only involves the induction of scores of defense-related genes, but also involves the repression of comparable numbers of genes (Arimura et al., 2000; Reymond et al., 2000). Saliva no doubt plays an important role in both the induction and repression of plant responses to herbivory.

Acknowledgments Support from the United States Department of Agriculture and the National Science Foundation is greatly appreciated. Insights and experiences of Herb Eichenseer were especially helpful during the formulation of this project. We also thank C. James White for technical support.

UV-Induced Mortality in Encapsulated Intertidal Embryos: Are Mycosporine-Like Amino Acids an Effective Sunscreen?

Abstract Mycosporine-like amino acids (MAAs) are believed to protect a variety of marine organisms against the negative effects of ultraviolet radiation (UVR). However, their role in protecting developing intertidal encapsulated embryos remains untested. In the present study, we focused on the UV protective role of natural concentrations of MAAs for two intertidal gastropod species, *Bembicium nanum* and *Siphonaria denticulata*, which lay egg masses in habitats exposed to direct sunlight. We predicted that in both species, a higher concentration of MAAs within the egg mass would increase the likelihood of embryonic survivorship in the presence of UVR. Egg masses from both species were collected along the rocky shores of southeastern New South Wales, and a portion from each was subjected to one of three separate spectral treatments: full spectrum, UV-B block, and UV block. Proportions of surviving embryos were recorded following 72 hr exposure to spectral treatment. In addition, MAAs in each egg mass were quantified. Levels of variation in MAA concentration were striking, with *S. denticulata* egg masses showing more intraspecific variation than those of *B. nanum*. Surprisingly, survivorship under all spectral treatments was extremely high for both species, irrespective of MAA concentration. Under full spectrum treatments, *B. nanum* survivorship and total MAA concentration were significantly and positively correlated; however, MAA accounted for just 23.6% ($R = 0.486$) of the variation in survivorship. In contrast, survivorship in *S. denticulata* was not correlated with MAA concentration under full spectrum light. We conclude that the dependence on MAAs as photoprotection may be species-specific; however, it is likely that both species possess alternative mechanisms that minimize the negative effects of UVR.

Introduction

Increasing levels of potentially harmful UVR are reaching the earth's surface due to the thinning of the ozone layer (Bjorn, 1999). Tropical areas have some of the highest levels of UVR because of the relative thinness of the ozone layer near the equator and the low zenith angle of the sun (Baker et al., 1980). However, organisms living at high latitudes have no less risk to UVR exposure, as seasonal ozone depletion has been detected above the midlatitudes (Platt, 2000). The harmful effects of solar ultraviolet radiation (UVR) are well documented in both terrestrial and marine environments, and they include DNA and protein damage, deleterious effects on behavior, reproduction, and overall ecosystem function (reviewed by Haeder et al., 1998; Paul and Gwynn-Jones, 2003). Indeed, increased exposure may already be a factor in global declines and range reductions in some aquatic populations (Belden and Blaustein, 2002).

In assessing the effects of UVR on marine organisms, particular attention has been placed on organisms inhabiting shallow waters. Potentially harmful UV-B wavelengths (280–320 nm) can penetrate to depths of up to 20 m (Booth and Morrow, 1997). Intertidal organisms are at the greatest risk of exposure and potentially experience some of the highest UVR intensities (Karentz, 2001). Even more vulnerable are the developing embryos within egg masses deposited in habitats exposed to sunlight. UVR can stunt development, produce deformities, and cause the death of encapsulated embryos of some intertidal gastropods (Biermann et al., 1992; Rawlings, 1996; Przeslawski et al., 2004); however, egg masses of species that routinely spawn in full-sun habitats are generally more resistant to the negative effects of UVR than egg masses from those species that spawn only in shaded habitats (Przeslawski et al., 2004). The reasons for these observations remain unknown, but it may be that embryos of these species are biochemically protected against UV-induced damage.

Mycosporine-like amino acids (MAAs) are known to serve many marine organisms as biochemical sunscreens (reviewed by Shick and Dunlap, 2002). They are clear, water-soluble compounds that absorb UVR maximally within the potentially harmful wavelengths 310–360 nm. MAAs encompass 19 known compounds; but some of these, such as mycosporine–taurine, are restricted to only a few taxa (Karentz, 2001). Overall, mycosporine–glycine, porphyra-334, shinorine, and palythine are the most common MAAs in marine organisms (Karentz, 2001). Plants, algae, and cyanobacteria are able to synthesize MAAs *de novo* through the shikimate pathway (Bentley, 1990). In contrast, animals lack this pathway and, therefore, likely acquire MAAs through symbioses or diet (reviewed by Karentz, 2001; Shick and Dunlap, 2002).

The biological importance of MAAs as natural sunscreens has been inferred, in part, by their widespread occurrence in algal and invertebrate species that inhabit shallow water throughout the world's oceans and lakes (Karentz et al., 1991; Shick et al., 1992; Jeffrey et al., 1999; Sommaruga and Garcia-Pichel, 1999). Three pieces of evidence underscore the important photoprotective role of MAAs. First, MAA concentrations are positively correlated with levels of UV-B radiation exposure in organisms that are able to synthesize MAAs *de novo* (Franklin et al., 1999; Shick et al., 1999). Second, MAAs accumulate in potentially vulnerable tissues such as the skin, ovaries, and eggs of marine invertebrates, likely providing UV screening protection (Shick et al., 1992; Gleason and Wellington, 1995; Adams et al., 2001).

Finally, experiments confirm that developmental abnormalities in planktonic larvae after exposure to UVR is inversely correlated to MAA concentration (Gleason and Wellington, 1995; Adams and Shick, 1996, 2001).

MAAs are prevalent in intertidal egg masses (Przeslawski et al., 2005a), although their photoprotective role in this stage of development remains untested. The present study is the first to examine the relationship between MAAs and mortality in encapsulated embryos; moreover, it represents the first study to examine this relationship in more than one intertidal organism, thus allowing interspecific comparison of photoprotective mechanisms. *Siphonaria denticulata* and *Bembicium nanum* were chosen because their egg masses are found abundantly year-round along the rocky shores of southeastern Australia (authors' unpublished data), and both species incorporate MAAs in their egg masses (Przeslawski et al., 2005a). Furthermore, *S. denticulata* and *B. nanum* spawn exclusively in habitats exposed to full sunlight (Benkendorff and Davis, 2004). In the present study, we sought to determine how natural variation in MAA concentration affects subsequent survivorship following exposure to UVR. We predicted that embryonic survivorship in both species would be positively correlated with the concentration of MAAs following exposure to full spectrum light.

Methods and Materials

Egg Mass Collection

Undeveloped (retrochophore) egg masses of *S. denticulata* and *B. nanum* ($N = 26$) were collected from three intertidal locations along the Illawarra coast, NSW, Australia during March–April 2004. *S. denticulata* deposits cylindrical gelatinous ribbon egg masses, and *B. nanum* deposits discrete connected gelatinous capsule egg masses (see Przeslawski et al., 2005b). We collected both species from rocky intertidal locations at Bass Point (34°35'S, 150°53'E), Bellambi (34°37'S, 150°92'E), and North Wollongong (34°25'S, 150°55'E). Previous research revealed no spatial or temporal differences in MAA complements within egg masses from these sites (Przeslawski et al., 2005a). All egg masses were examined under a dissecting microscope (40× magnification) to confirm the retrochophore stage of development.

Spectral Treatments

Egg masses were cut in half, and one half was further divided into three pieces. Previous research has confirmed that cutting gelatinous egg masses does not have any negative effects on embryonic mortality (Rose, 1986; Przeslawski et al., 2005b). Each piece was placed in small plastic containers (height 2.5 cm, diam 6 cm) in an outdoor 300-l recirculating aquarium. Natural sunlight and cutoff filters were used to obtain three spectral treatments: (1) full spectrum (no filter), (2) UV-B block (mylar film), and (3) UV block (polyethylene film with UV absorption) (refer to Przeslawski et al., 2004 for spectral transmission properties). Containers were randomly repositioned daily within the aquarium. Salinity was maintained at 35 ppt with the addition of distilled water. A submerged refrigeration unit maintained temperature at $19.7 \pm 0.2^\circ\text{C}$ (mean \pm SEM). This was confirmed for the duration of

the experiment with records taken at 15-min intervals with a thermal microchip (Thermochron I-Button).

After 72 hr in experimental treatments, all egg mass pieces were removed and examined with a dissecting microscope (40× magnification). Peripheral embryos were examined as they were most directly exposed to spectral treatments. Also, only peripheral embryos could be examined without destroying the integrity of the egg mass (see Przeslawski et al., 2004). Survivorship of embryos was estimated for each replicate by scoring a random sample of 100 embryos on both sides of the egg mass as alive or dead. Embryos were considered dead if they were degenerating (Przeslawski, 2004).

MAA Analysis

The other half of each egg mass was cleaned by agitation in filtered seawater for 30 sec followed by gentle blotting to remove excess water. The egg masses were lyophilized and stored at -80°C for up to 4 wk until extractions were performed. Previous research has shown that such a storage time does not affect MAA concentration (Dunlap and Chalker, 1986; Karsten et al., 1998).

Three serial extractions were performed on 20 mg dry weight of each egg mass in 0.5 ml of 80% HPLC-grade methanol for 1 hr at room temperature. Extraction efficiency was tested and was over 95% after three extractions for both species. The supernatant was pooled, and MAAs were separated by reverse-phase high performance liquid chromatography (RP-HPLC) on a Phenosphere C8 5 μm (4.6 i.d. \times 250 mm) column with guard (Phenomenex) at a flow rate of 0.8 ml min^{-1} . The aqueous mobile phase was 39.9:0.1:60 (water/acetic acid/methanol.) MAAs were identified using maximum wavelength absorption and cochromatography with prepared standards from the Australian Institute of Marine Science.

Statistical Analysis

To determine potential inter- and intraspecific differences in MAA complements, nonmetric multidimensional scaling and one-way ANOSIMs were performed by using PRIMER (v.5). Potential effects of species and spectral treatment on embryonic mortality were analyzed with a nested ANOVA with the REML technique in JMP (v.4). To satisfy assumptions of ANOVA, survivorship was transformed by using $\arcsin\sqrt{x}$ due to its binomial distribution (Zar, 1998). Potential relationships between embryonic survivorship and total MAA concentration were resolved by using correlation analyses for each species under each spectral treatment using JMP (v.4). $\alpha = 0.05$ for all statistical tests.

Results

MAA Concentrations

Mycosporine-like amino acids were found in all egg masses. Seven distinct MAAs were detected (Table 1), and the chromatograms revealed no unidentified MAAs. We recorded the presence of seven MAAs in egg masses of *S. denticulata* and four in *B. nanum* egg masses (Table 1). Egg masses from *B. nanum* had the lowest total

Table 1 Mean concentrations of mycosporine-like amino acids (nmol mg⁻¹ dry weight) in *Siphonaria denticulata* and *Bembicium nanum* egg masses (*N* = 26)

	<i>Siphonaria denticulata</i>	<i>Bembicium nanum</i>
Mycosporine-glycine	3.41 ± 0.38	6.30 ± 0.41
Shinorine	0.88 ± 0.40	0.69 ± 0.16
Porphyra-334	3.76 ± 0.68	1.30 ± 0.18
Mycosporine-2-glycine	0.01 ± 0.01	0.04 ± 0.04
Palythene	1.56 ± 0.32	NP
Palythine	0.52 ± 0.09	NP
Asterina-330	3.04 ± 0.60	NP
Total	13.17 ± 1.31	8.33 ± 0.45

NP indicates a compound was not present. Error is standard error of mean.

concentrations of MAAs (8.33 nmol mg⁻¹ ± 0.45 SE), while total concentrations of MAAs in egg masses of *S. denticulata* averaged 13.17 nmol mg⁻¹ (± 1.31 SE). The highest individual total MAA concentration recorded was 23.20 nmol mg⁻¹ in an egg mass of *S. denticulata*.

An n-MDS plot revealed that MAA complements differed among species (Fig. 1), and an ANOSIM confirmed that these differences were significant (*R* = 0.598, *P* = 0.001). Intraspecific variation of MAAs was relatively high in egg masses of *S. denticulata* as revealed by the relatively large spread of data points in the n-MDS plot (Fig. 1). In contrast, egg masses of *B. nanum* showed much lower levels of intraspecific variation in MAA complements (Fig. 1).

Fig. 1 A nonmetric multidimensional scaling of MAA complements in egg masses from two species of intertidal mollusk (*N* = 26). Points that are relatively close denote similarities in their MAA complements. Stress = 0.12

Fig. 2 Mean embryonic survivorship following exposure of each mollusk species to spectral treatments ($N = 26$). Error bars are standard error of the mean

Embryonic Survival

On average, *S. denticulata* had the highest proportion of surviving embryos in all spectral treatments with at least 98% survivorship across all treatments (Fig. 2). Furthermore, embryonic survivorship of this species showed little variation as evidenced by the relatively small error bars (Fig. 2). On average, *B. nanum* had lower embryonic survivorship (Fig. 2). An ANOVA confirmed that embryonic survivorship significantly varied between species ($F = 11.149$, $P < 0.002$) (Table 2). In contrast, spectral treatment did not significantly affect embryonic survival ($F = 1.581$, $P = 0.211$) (Fig. 2, Table 2).

MAA Concentration and Embryonic Survival

Data plots revealed several outliers that disproportionately affected correlations (Fig. 3, Table 3). Accordingly, these outliers were omitted from remaining analyses following the criteria outlined in Chatterjee and Price (1977). Embryonic survival of *B. nanum* was significantly positively correlated with total MAA concentration only

Table 2 Effects of species and spectral treatment on embryonic survivorship as determined by ANOVA

Effect	df	MS	F	P
Egg mass (species)	50	0.085	2.527	<0.001
Species	1	0.373	11.149	0.002
Spectral	2	0.053	1.581	0.211
Species \times Spectral	2	0.018	0.541	0.584
Residual	100	0.034		

An arcsin transformation was used on data. Italics denote a random factor.

under the full spectrum treatment ($R = 0.486$, $P = 0.016$) (Fig. 3a) (Table 3). Embryonic survival of *S. denticulata* was not correlated with MAA concentration in any treatment (Fig. 3, Table 3).

Discussion

We documented high survivorship for embryos of both species across all spectral treatments (Fig. 2), irrespective of MAA concentration. Contrary to our prediction, MAAs do not seem to be an effective sunscreen in embryos of either *Bembicium nanum* or *Siphonaria denticulata*. Rather, our results suggest that MAAs play only a minor photoprotective role for the embryos of *B. nanum* and provide no detectable photoprotection for embryos of *S. denticulata*. It therefore, seems likely that *B. nanum* and *S. denticulata* embryos use protective measures other than MAAs to minimize the deleterious effects of UV radiation.

The photoprotective role of MAAs in developing intertidal embryos varies across species as indicated by differences in the relationships between embryonic survivorship and MAA concentration under full spectrum treatments for *B. nanum* and *S. denticulata* (Fig. 3a). Moreover, a relatively large intraspecific variation in *S. denticulata* MAA complements (Fig. 1) suggests that MAAs are not of uniform importance to all encapsulated embryos of this species, despite all egg masses being laid in habitats exposed to direct sunlight. Factors such as diet and viability can affect MAA complements (Przeslawski et al., 2005a). These results highlight the importance of examining the interspecific variation in the photoprotective role of MAAs and emphasize the need to be cautious in drawing general conclusions regarding the role of MAAs in marine organisms from other studies that examine single species (Gleason and Wellington, 1995; Adams and Shick, 1996; Franklin et al., 1999).

The distinct MAA complements provide a possible explanation for the difference in photoprotective dependence between *B. nanum* and *S. denticulata*. In this study, the only MAA detected that absorbs maximally in the UV-B range is mycosporine-glycine ($\lambda_{\max} = 310$ nm). Mycosporine-glycine is also a moderate antioxidant and so may provide additional protection against damaging reactive oxygen species produced by UVR exposure (Dunlap and Yamamoto, 1995). Therefore, mycosporine-glycine may provide more protection to developing embryos against UV-B-induced damage than the other MAAs.

In addition, the distinct MAA complements within egg masses of both species could potentially be used as a taxonomic character. This result supports findings by Shick and co-workers (2002), who found that the MAA complements of four North American sea anemone species *Anthopleura* showed distinct phylogenetic differences. Phylogenetic factors were recently shown to affect MAA complements in intertidal egg masses (Przeslawski et al., 2005a).

Bembicium nanum embryonic survivorship was not significantly correlated to MAA concentration when UV-B was blocked (Fig. 3b), suggesting that it was primarily the damage associated with UV-B that was minimized. UV-B is absorbed by nucleic acids and proteins and can thus negatively affect the rapidly dividing cells of marine larvae. For example, UV-B can cause developmental retardation and abnormalities in planktonic urchin and coral larvae (Gleason and Wellington, 1995; Adams and Shick, 2001). Egg masses of *B. nanum* had the highest concentrations of

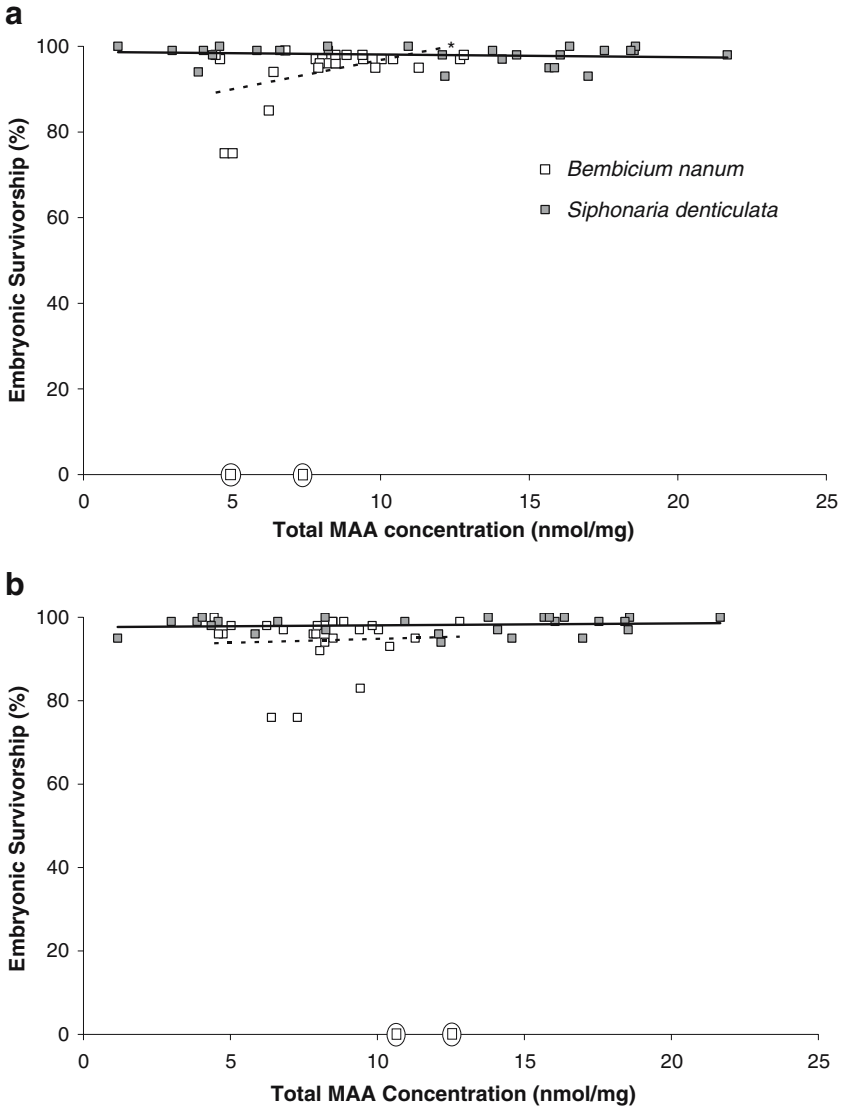

Fig. 3 Correlation between total concentration of mycosporine-like amino acids and embryonic survivorship for two species of mollusk under different spectral treatments: (a) full spectrum, (b) UV-B blocked, and (c) UV-blocked. See Table 3 for *N* values excluding outliers. Solid lines indicate best-fit lines for *Siphonaria Denticulata*, and dashed lines indicate best-fit lines for *Bembicium Nanum*. Outliers are circled and excluded from best fit lines. (*Significance at $A = 0.05$)

mycosporine–glycine (Table 1), and MAAs in egg masses of this species showed the clearest photoprotective function (Fig. 3a, Table 3).

High embryonic survivorship observed in this study across all spectral treatments, irrespective of MAA levels, suggests that neither species relies heavily on MAA's photoprotective qualities (Fig. 3a,b). *B. nanum* and *S. denticulata* may incorporate other photoprotective measures including UV-absorbing compounds such as

Fig. 3 (continued)

melanin (Cockell and Knowland, 1999; Karentz, 2001), which has been found in other mollusks (Prota, 1988), as natural photoprotection. Alternatively, these species may contain high levels of DNA repair enzymes to combat the potential negative effects of UV exposure. Photolyase, an inducible DNA repair enzyme, has been found in several adult mollusks (Carlini and Regan, 1995), but its presence and protective capabilities in molluskan embryos remains unknown. DNA repair enzymes are more effective at warmer temperatures (Macfadyen et al., 2004), and recent research has revealed that embryos of *S. denticulata* show reduced UV-induced mortality at warmer temperatures, a finding consistent with the presence of such enzymes (Przeslawski et al., 2005b). Moreover, embryos of *S. denticulata* show some evidence of UV-A inducible repair functions (Przeslawski, 2005). The consistently high survivorship of embryos of both species following UVR exposure, regardless of their MAA concentration, is striking and merits further investigation into other potential protective mechanisms.

Despite the unexpectedly low dependence for MAA photoprotection in embryos of both species, the presence and abundance of MAAs in all egg masses examined indicates that they may nonetheless be important to encapsulated embryos. This study only focused on UV-induced mortality, and it is possible that MAAs reduce

the rates of abnormalities and other sublethal effects not detected in this study. Furthermore, MAAs have been considered as reproductive and osmotic regulators, although the case remains to be proven for marine invertebrates (reviewed by Shick and Dunlap, 2002). Therefore, MAAs may have such regulatory functions in encapsulated development for the intertidal species examined here.

It has been widely assumed that MAAs have a photoprotective role in marine organisms (Garcia-Pichel and Castenholz, 1993; Teai et al., 1997; Helbling et al., 2002); however, it is difficult to assign such a role unambiguously given the potential for other photoprotective mechanisms or physiological functions associated with MAAs (Cockell and Knowland, 1999). Previous research has shown that the accumulation of MAAs lowers the rates of UV-induced mortality and abnormalities in coral planulae and urchin embryos (Gleason and Wellington, 1995; Adams and Shick, 2001); however, these studies focused on single taxa. Our work shows that the photoprotective role of MAAs is species-specific in encapsulated intertidal embryos. Further research examining interspecific variation in planktonic or subtidal larvae may reveal similar species-specific effectiveness. Alternatively, the trend may be confined to intertidal encapsulated embryos. They are potentially exposed to more synchronous abiotic stressors than planktonic embryos and larvae (Przeslawski, 2004). These abiotic stressors can act synergistically with UVR to increase risk to embryos (Przeslawski et al., 2005b). Species that spawn in the intertidal zone, particularly those like *S. denticulata* and *B. nanum*, which spawn in habitats exposed to full sun, may have evolved multiple protective mechanisms to protect against damage from environmental stress, including UVR. Based on the results of this study, we conclude that MAAs do not represent the primary photoprotective strategy used by either species.

Acknowledgments The authors acknowledge Todd Minchinton and other anonymous reviewers for comments on this manuscript and previous drafts. W. Dunlap at the Australian Institute of Marine Science generously provided guidance and facilities to R.P. for MAA standard synthesis. This work was supported in part by a grant to R.P. from the Conchologists of America. This paper represents contribution #265 from the Ecology and Genetics group at the University of Wollongong.

Abstract The genetic nature of pheromone variation within species has rarely been studied, and never for male-produced long-range pheromones. Males from western North American populations of *Ips pini* produce predominantly (*R*)-(-)-ipsdienol, whereas those from eastern North American populations produce higher proportions of (*S*)-(+)-ipsdienol. From a population in the hybrid zone, we divergently selected lines for the opposing pheromonal types and then created F1, F2, and backcross lines. We formed additional F1, F2, and backcross lines, first by using populations with low (+)-ipsdienol enantiomeric ratios near to and distant from the hybrid zone, and then by using populations with high (+)-ipsdienol enantiomeric ratios near to and distant from the hybrid zone. Three types of analysis were employed: (1) line means analysis; (2) Mendelian analysis of assigned high and low (+)-ipsdienol enantiomeric ratio phenotypes when applicable; and (3) Castle–Wright estimation of the number of effective factors. Dominance at one autosomal locus explains much of the variation in ipsdienol blend between the divergently selected lines. Thus, as in all previously studied female long-range pheromone systems, a major genetic element is implicated. The populations with low (+)-ipsdienol enantiomeric ratios near and distant to the hybrid zone differ negligibly for this trait. We confirmed previous studies showing slightly higher ratios of (+)-ipsdienol at the hybrid zone than in a distant eastern population and reveal a genetic basis for this difference.

Introduction

An important consideration for the speciation theory is the number of genes required for reproductive isolation. Traditional population genetic theory suggests that evolution progresses by the accumulation of small genetic changes (Fisher, 1930; Dobzhansky, 1937). In the past two decades, this assumption has been challenged on theoretical and experimental grounds (Kimura, 1983; Orr and Coyne, 1992), and the list of cases where major genes are involved in premating isolation has grown (Coyne and Orr, 1998; Ritchie and Phillips, 1998).

While pheromones are involved in reproductive isolation across a wide range of taxa (Costa et al., 1997; Kotani et al., 2001; Miyanoshita and Tatsuki, 2001; Lemaster and Mason, 2003), inquiry into the genetic nature of such isolation has generally been limited to a few well-studied systems. Variation in *Drosophila* cuticular hydrocarbon profiles both between- (Coyne et al., 1994; Coyne, 1996) and within-species (Takahashi et al., 2001) has been shown to be controlled by relatively few loci, as are corresponding response preferences (McMahon et al., 2002). Major gene control of female-produced, long-range pheromones is also a well-established phenomenon in Lepidoptera (Löfstedt, 1990). Underscoring the degree to which major genetic shifts can occur in moth systems, the activation of long-dormant pseudogenes was recently implicated in differences between pheromone components of Asian vs. European corn borers (Roelofs et al., 2002). Major gene control of pheromone blend production and response have also been shown between pheromone races of moth species such as the European corn borer, *Ostrinia nubilalis* (Klun and Maini, 1979; Hansson et al., 1987; Roelofs et al., 1987), and the turnip moth, *Agrotis segetum* (LaForest et al., 1997).

Males of most species are more likely to experience strong sexual selection because females are usually the resource-limiting sex (Bateman, 1948; Williams 1966; Trivers, 1972; Clutton-Brock, 1988). Phelan (1992) argued that signaling systems involving pheromone production by females allow relatively high variation in pheromone production, but they place more stringent selection upon male response. This pattern, applicable to most of the well-studied lepidopteran systems, leads to the possibility of sudden large pheromone shifts by females that will inevitably be tracked by responding males. Conversely, Phelan (1992) proposed that changes in male signaling systems will more often involve runaway sexual selection (Fisher, 1930), leading to a building of linkage disequilibrium between signal and response.

The implications of such strong sexual selection in male signaling systems upon the genetics of pheromone blend variation remain largely unexplored. Indeed, variation in orthopteran male auditory signals, which perform a similar behavioral role, is usually controlled by multiple loci (Shaw, 1996, 2000). Alternatively, biochemical constraints may make major genetic changes likely for all pheromone systems, including those where males signal. Major gene control has been implicated in variation of male *Drosophila melanogaster* hydrocarbons (Ferveur and Jallon, 1996), but it is unclear if such hydrocarbons are actually used in mate discrimination (Scott, 1994; Cobb and Ferveur, 1996). Males of many bark beetle species (Coleoptera:

Scolytidae) produce aggregation pheromones that may be relevant to reproductive isolation. In scolytids, pheromone blend usage across multiple species is not affected by phylogenetic proximity (Symonds and Elgar, 2004a), or overlap in geographic range or host utilization (Symonds and Elgar, 2004b). Symonds and Elgar argue that these patterns suggest frequent saltational shifts in pheromone blends.

The pine engraver, *Ips pini* (Say), provides an ideal candidate for investigating some of the above-stated theoretical predictions on a microevolutionary scale. Eastern and western populations of this species are distinguished by morphological characteristics (Hopping, 1964) and pheromones, including ipsdienol (2-methyl-6-methylene-2,7-octadien-4-ol) (Birch et al., 1980; Lanier et al., 1980), and lanierone (4,4,6-trimethyl-2-hydroxy-2,5-cyclohexadiene-1-one) (Teale et al., 1991). Populations from California to southern British Columbia are predominantly characterized by greater production of and preference for high ratios of the (*R*)-(-)-enantiomer of ipsdienol (Birch et al., 1980; Miller et al., 1989; Seybold et al., 1995a) (Fig. 1). We generally refer to these populations as “western.” Conversely, populations from the eastern United States to western Canada produce and respond to blends of ipsdienol that are racemic or have a higher ratio of the (*S*)-(+)-enantiomer (Lanier et al.,

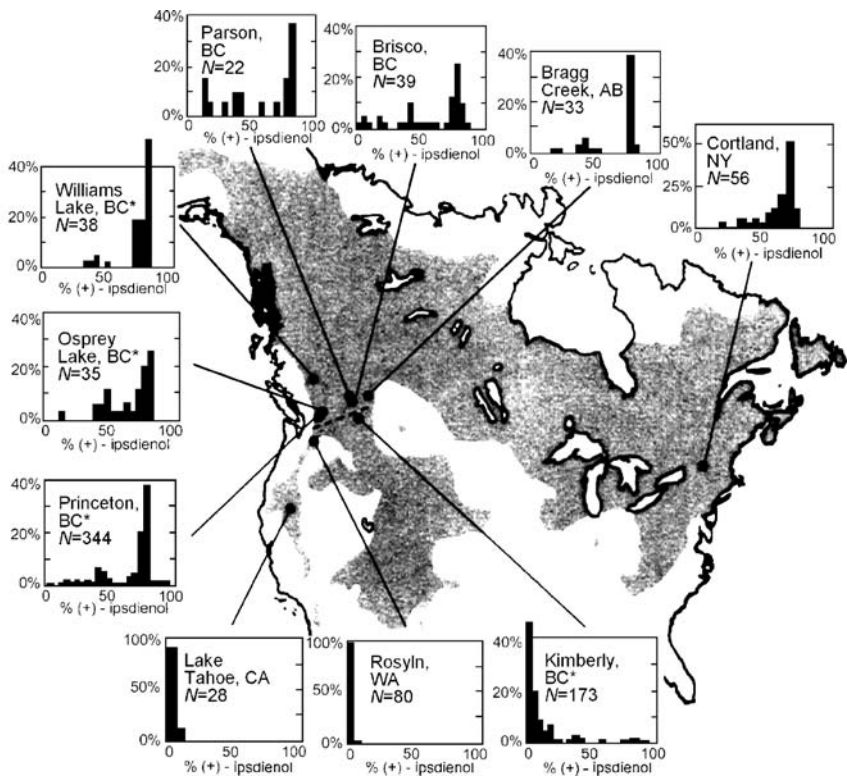

Fig. 1 Distribution of *Ips pini* pheromone types in North America based on the profiles of the enantiomeric composition of ipsdienol from individual males. Shaded area indicates range of *I. pini* (Lanier, 1972). A hybrid zone is depicted in southern British Columbia by a dashed line. Histograms indicated with an asterisk (*) have been reproduced from Miller et al. (1996), with the permission of the authors and publisher

1980; Miller et al., 1989; Seybold et al., 1995a). We refer to such contiguous populations as “eastern.”

This pattern of geographic variation also suggests that there is a hybrid zone in southern British Columbia (Fig. 1), lying on a north–south gradient (Miller et al., 1989, 1996; Seybold et al., 1995a). Additionally, British Columbia populations have many individual males that produce approximately 80% (+)-ipsdienol (Miller et al., 1989, 1996), while no more than 70% (+)-ipsdienol has been observed in individuals further east (Miller et al., 1989) (Fig. 1). Assortative mating based on ipsdienol enantiomeric blend has been demonstrated within a New York population (Teale et al., 1994).

Lanierone is strongly synergistic with ipsdienol in eastern populations of *I. pini* (Teale et al., 1991; Miller et al., 1997), but is rarely produced and weakly synergistic with ipsdienol in California (Seybold et al., 1992; Miller et al., 1997). Lanierone has been shown to increase trap captures in eastern Oregon (Zhou et al., 2001).

To investigate the genetic control of geographic variation in ipsdienol enantiomeric blend in *I. pini*, we performed three crossbreeding experiments. First, we obtained breeding lines that exhibit the extreme pheromone phenotypes from one population in the putative hybrid zone, and performed crosses between these lines. We also performed mirroring crosses between populations near to and distant from the hybrid zone, on the two opposing sides.

Methods and Materials

Field Populations

Ips pini was collected from two sites near the hybrid zone in British Columbia. The first site, near Brisco, British Columbia, Canada (hereafter referred to as BC) (Fig. 1), was approximately 30 km from Radium where Miller et al. (1996) observed high population diversity in pheromone enantiomeric composition. The Brisco site was characterized by a cluster of blown down trees of lodgepole pine, *Pinus contorta latifolia*, which had been colonized by *I. pini* within 5 d of our collection. All of the adult specimens that we collected had recently colonized the logs, and the females were in the early stages of egg gallery construction. Forty frass samples and the corresponding males were collected from the bark surface and phloem for pheromone analysis. These frass samples represented boring dust contributed by both males and females. An additional 30 males and 70 females were collected and stored at 5°C in fresh phloem. Twenty-one of these males were each paired with two females in logs of red pine, *Pinus resinosa*, to establish a laboratory colony in Syracuse, NY, USA. From a second site in Parson, BC, 40 males were excavated from infested logs of *P. contorta latifolia* and later sampled for pheromone production on *P. resinosa* in Syracuse.

From Roslyn, Washington, USA (hereafter referred to as WA), 10 males and 14 mated females were collected from logs of *P. contorta latifolia* and taken live to Syracuse. Females were provided with individual slabs of *P. resinosa* in separate containers to oviposit and progenies were allowed to emerge. Ipsdienol enantiomeric blend was measured (see below) on frass samples from all first- and second-generation males that had developed in *P. resinosa*. This population is proximate to

previously described populations with low (+)-ipsdienol enantiomeric ratios south of the hybrid zone (Seybold et al., 1995a).

From three sites near Lake Tahoe, California, USA (hereafter referred to as CA), 51 males and 47 females were collected from ponderosa pine, *P. ponderosa*, singleleaf pinyon pine, *P. monophylla*, or Sierra lodgepole pine, *P. contortamurrayana* and taken live to Syracuse to establish another colony of *I. pini* in a manner identical to that described above.

From Bragg Creek, Alberta, Canada (hereafter referred to as AB), eight males and 30 females were collected from *P. contorta latifolia*, taken live to Syracuse, and handled similarly to the WA and CA populations.

From two sites near Cortland, New York (hereafter referred to as NY), *P. resinosa* logs colonized by *I. pini* were collected and placed in 25-l emergence containers. Approximately 200 emerging beetles were collected and used to initiate a laboratory colony. Ipsdienol enantiomeric composition was not analyzed from males for three to four generations. At that time, males were randomly selected for analyses before line crosses were initiated.

Measurement of Pheromone Component Ratios

With the exception of the field-collected samples of frass from BC, pheromone samples were obtained by extraction of frass from single males by using the gelatin-pill-capsule technique (Borden, 1967). Laboratory-collected samples were obtained from males that had been secured for 48 h under gelatin capsules (Bioquip, Gardena, CA, USA) that covered holes drilled in the bark of *P. resinosa* logs. The accumulated frass was transferred to 500- μ l glass inserts in 1.5-ml autosampler vials with 200 μ l HPLC-grade pentane (Sigma-Aldrich). We stored pheromone extracts at -30°C for up to 6 mo before analysis.

Gas chromatography (GC) was used for analytical resolution of the enantiomers of ipsdienol (Seybold, 1992). A 1- μ l aliquot of each sample was injected into a Hewlett Packard gas chromatograph/mass spectrometer (GC-MS) (model 5890 series II/model 5971), equipped with a GC column with a chiral stationary phase [0.25 mm (internal diameter) \times 50 m] (Cydex-B; SGE Inc., Austin, TX, USA). A Hewlett Packard Automatic Liquid Sampler (model 7673) was used to increase the throughput of the GC-MS. Synthetic standards of racemic ipsdienol (10 ng/ μ l) were analyzed approximately every 50 samples.

The mass spectrometer was set to selective ion-monitoring mode to minimize signal from host volatiles and maximize signal from pheromones ($m/z = 85$ for ipsdienol, and $m/z = 109, 124, 137, 152$ for lanierone). Although we screened the samples for lanierone, we did not include it in our phenotypic analyses. A number of practical considerations precluded us from analyzing the quantities of ipsdienol and lanierone, and the presence or absence of lanierone. The large number of crude frass extracts injected into the GC-MS for the analyses resulted in the steady degradation of the injector and column in the analytical system. Ensuring reliable and low detection limits for ipsdienol and lanierone would have required an impractical allocation of effort for maintaining our analytical equipment. Thus, we focused our analysis on the measurement of ipsdienol enantiomeric blend ratio, which is highly reproducible in *I. pini* (Teale et al., 1994). If sample traces showed no ipsdienol, the corresponding beetles were not considered in further statistical analyses.

Initiating Crosses

Potential female mates were tested for virginity by securing them for 5–7 d under metal wire screens in holes drilled in the bark of *P. resinosa* and observing whether they oviposited. To initiate crosses, males were secured in holes drilled in the bark of separate *P. resinosa* slabs (~15 × ~25 cm). Gel capsules were used to secure the males if pheromone was to be collected; otherwise, wire screen was used. Females were introduced 48 h later into the male galleries and the gallery entrance holes were again covered with screen. Cylindrical metal containers [60 cm (length) × 25 cm (diameter)] with detachable glass vials were used to house each log and to collect offspring.

Divergent Selection of BC Population

For the BC population, we divergently selected lines for extreme ratios of (+)- to (–)-ipsdienol. From 189 first-generation males, those producing greater than 75% (+)-ipsdienol or less than 30% (+)-ipsdienol were randomly mated. In succeeding generations, males matching these criteria were mated to females, both of which originated from broods where at least half of the males met the appropriate criteria. Five generations were used to obtain lines for crossbreeding. Eight related lines of beetles with high (+)-ipsdienol enantiomeric ratios bred true for three successive generations, matching the selection target in all male progeny. Beetles from these lines will be referred to as P^+ . Males of two unrelated lines, P^{-a} and P^{-b} , were used for the opposite parental type. These lines did not yield broods with uniformly low (+)-ipsdienol enantiomeric ratios over multiple generations. We proceeded with the line crosses at this time because we feared that inbreeding depression might cause extinction of the P^{-a} and P^{-b} lines.

Line Crosses

Line crosses were performed on beetles derived from five locations with an emphasis on the divergent lines from BC (Table 1). Biases in the numbers of crosses performed were typically attributable to shortages of beetles of a particular sex or line. For example, there were no virgin P^{-b} females available for crossing to P^+ males. Additionally, crosses were performed within parental lines concurrent to the F1 generation. Twelve crosses were performed within and between the P^+ broods. Because the F1^{-b} results suggested that the P^{-b} line was heterozygous, only two crosses within the P^{-a} line were used for further breeding.

For the CA × WA line crosses, the parental lines are represented as P^- and P^+ , respectively (Table 1). Because these crosses were derived from large colonies, we were able to maintain a more balanced design. We performed 11 crosses of both of the F1 subtypes and five of each of the F2 and backcross subtypes.

We also created crosses between the AB and NY populations. In AB, we hoped to obtain a population that uniformly produced high ratios of (+)-ipsdienol. However, this population possessed similar variation in ipsdienol enantiomeric composition as that observed in eastern British Columbia (Fig. 1). We did not wish to select for this high (+)-ipsdienol ratio phenotype as we did in the divergent line crosses by using BC material. Such a practice may inadvertently remove epistatic

Table 1 Number of crosses of the pine engraver, *Ips pini*, in line cross experiment among populations from Alberta, British Columbia, California, New York, and Washington

^aThe subscript r indicates that X-chromosome inheritance is different despite similar autosomal inheritance.

^bPopulations: BC (P⁺, P⁻) is Brisco, British Columbia; CA (P⁻) is Lake Tahoe, California; WA (P⁺) is Roslyn, Washington; AB (P⁺) is Bragg Creek, Alberta; and NY (P⁻) is Cortland, New York. For BC, the crosses derived from the independently selected low (+)-ipsdienol enantiomeric ratio lines are noted separately as a and b.

^cFor pheromone analyses and subsequent line crosses, beetles were taken directly from colony populations, where parentage was unknown from amongst more than 30 males and females.

genetic variation that might influence the ipsdienol blend, which was not desired in this case.

To avoid this difficulty, we used only AB males that produced >80% (+)-ipsdienol and performed our F1 crosses in only one direction, between AB males (P⁺) and NY females (P⁻) (Table 1). These F1 offspring were used to create F2 crosses and backcrosses to the parental types with the exception that we did not perform backcrosses to AB females. Furthermore, all AB males used in backcrosses also produced greater than 80% (+)-ipsdienol (B⁺). Finally, we performed additional crosses between the B⁺ females and NY males. Crosses of this type help to increase our power in detecting X-linked genetic effects, being most similar to the reciprocal F1 that could not be performed.

Means Analysis

A genetic model based on the mean ipsdienol enantiomeric ratios of the line crosses was used to evaluate composite additive [d], dominance [h], and X-linked [d_X]

effects, and all possible digenic epistatic effects. The model was derived from groupings of the parental, F1, F2, and backcrosses that shared the same possible autosomal and X-linked genetic effects (Table 1), and included up to nine lines. We considered additive by additive [i], additive by dominance [j], dominance by dominance [l], additive by X-linked [$d-d_x$], and dominance by X-linked [$h-d_x$] as epistatic factors. The mean effect [m] was included in all models. The notation follows Mather and Jinks (1982).

The line cross data from each experiment did not generally meet the assumption of normality, due—in many cases—to pronounced bimodality in the phenotypic distribution of ipsdienol blend. Therefore, a resampling procedure was performed to estimate the mean pheromone enantiomeric ratio of each line. For 1000 replicates, data from each line were sampled with replacement N_i times. Here, N_i is the number of observations for the i th line (Simon, 1969).

The average resampled line means were used to estimate the parameters for each genetic effect contained in vector $\hat{\mathbf{y}}$, and their variances $\hat{\mathbf{S}}$ (Mather and Jinks, 1982; Lynch and Walsh, 1998):

$$\hat{\mathbf{y}} = (\mathbf{C}^T \mathbf{V}^{-1} \mathbf{C})^{-1} \mathbf{C}^T \mathbf{V}^{-1} \mathbf{x},$$

and

$$\hat{\mathbf{S}} = (\mathbf{C}^T \mathbf{V}^{-1} \mathbf{C})^{-1},$$

where \mathbf{C} is the coefficient matrix of genetic effects specific to each cross type, \mathbf{V} is a diagonal matrix of the variances of the resampled line means, and \mathbf{x} is the vector of the average resampled line means. Models were evaluated by a χ^2 test for goodness of fit (Hayman, 1958).

We used a stepwise procedure to decide which genetic effects to include in our model. We began with a null model by using the mean effect [m]. At each successive step, we tested all models that added a single appropriate genetic effect to the existing model. Additive [d] and X-linked [d_x] effects were added first. Dominance [h] was not tested until an additive effect was established in the model, nor were any interactions tested until multiple effects had been included in the model. We continued with this process until we arrived at a model that showed no significant improvement in the χ^2 statistic (Lynch and Walsh, 1998). This procedure, called joint-scaling, evaluates the difference between χ^2 values in successive models as a χ^2 distribution with 1 *df*. The significance levels of individual parameters (genetic effects) were determined by using the 1000 resampled estimates to construct two-tailed 95% confidence intervals.

The data also allowed us to expand the analyses to consider maternal and paternal effects as long as we further divided the lines to accommodate such effects. This division can be observed by noting that the four entries of F2 have different combinations of paternal grandfathers and maternal grandmothers (Table 1). We performed such analyses for the BC and the CA \times WA experiments. Because maternal and paternal effects were never included in these models, we do not provide details of these analyses or further consider the issue. Such an analysis was not possible for the AB \times NY crosses, because all these line crosses had AB paternal and NY maternal effects.

Mendelian Analysis

Pronounced bimodality appeared in the outcomes of many of the BC crosses. Furthermore, examination of the pooled distribution of phenotypes from all parental hybrid and backcross lines revealed a bimodal distribution with a sharp trough at 70% (+)-ipsdienol (Fig. 2). This observation led us to group all males in this experiment into categories of high or low (+)-ipsdienol enantiomeric ratio. We tested the categorical data for deviations from patterns predicted by Mendelian inheritance by using χ^2 analysis. This analysis was not performed for the other experiments because segregation was not clear (Fig. 2).

Number of Effective Factors

For all three line cross experiments, we calculated the Castle–Wright estimator (Castle, 1921; Wright, 1968) for the number of effective genetic factors, n_e , that cause differences in ipsdienol enantiomeric composition. We used two different methods for estimating one model component, the segregation variance, $\hat{\sigma}_s^2$. The first estimate employed a least-squares approach to minimize the residual variance in a model that simultaneously examines additive and segregation variance in all lines (Hayman, 1960; Lynch and Walsh, 1998). We also calculated segregation variance by using twice the variance in F2, minus the variance in each backcross. The latter estimate is more robust against biases caused by dominance (Lynch and Walsh, 1998).

Results

Enantiomeric Composition of Ipsdienol from Source Populations

Male *I. pini* from BC showed a highly variable distribution in the enantiomeric composition of ipsdienol (Fig. 1). Of the frass samples collected from *P. contorta latifolia* in the field from Brisco, 21 clustered between 71% and 84% (+)-ipsdienol.

Fig. 2 Frequency histograms of the enantiomeric composition of ipsdienol from male *Ips pini* based on pooled parental hybrid and back cross data from the Brisco, British Columbia (A) and Bragg Creek, Alberta \times Cortland, NY (B) line-cross experiments. The mean (\pm SD) enantiomeric compositions of ipsdienol of the two parental lines are indicated as horizontal bars above the histograms. In (B), the horizontal line at the lower percentage of (+)-ipsdienol represents the NY parental population; the horizontal line at the higher percentage represents the AB parental population. In (A), a vertical dotted line indicates the criterion for separating phenotypes for Mendelian analysis

The remaining 18 samples were distributed widely between 2.4% and 62% (+)-ipsdienol (39 of 40 samples were successfully analyzed). Of the frass samples collected from Brisco males in *P. resinosa* in the laboratory, 14 of 21 contained sufficient ipsdienol for enantiomeric determination. Half of the 14 samples contained 74–84% (+)-ipsdienol. The enantiomeric compositions in the remaining samples varied between 18% and 41% (+)-ipsdienol. Of the frass samples collected from Parson males in *P. resinosa* in the laboratory, 22 of 40 males contained sufficient ipsdienol for enantiomeric determination. In this case, 11 of the males produced greater than 70% (+)-ipsdienol (Fig. 1).

Male *I. pini* from WA and CA produced very low enantiomeric ratios of (+)-ipsdienol in *P. resinosa* logs in the laboratory. Of 51 WA males tested in the first laboratory generation, 49 produced less than 5% (+)-ipsdienol, and two produced between 5% and 10% (+)-ipsdienol (Fig. 1). Of 28 CA males tested in the first laboratory generation, 25 produced less than 5% (+)-ipsdienol, and three produced between 5% and 10% (+)-ipsdienol (Fig. 1).

Male *I. pini* from AB, similar to the BC populations, had a highly variable distribution of ipsdienol enantiomeric compositions (Fig. 1). In the first laboratory generation, 24 of 33 tested males produced greater than 75% (+)-ipsdienol. The enantiomeric composition of the remaining nine samples varied from 20% to 50% (+)-ipsdienol.

Divergent Selection of the BC Population

Twenty-two lines for the high (+)-ipsdienol trait (P^+) were established by using BC material that bred true for all male offspring for at least two generations. In our crosses, we conservatively used 14 males from eight of the lines that bred true for all male offspring for three generations. The phenotypic distribution of ipsdienol enantiomeric ratio in these lines was quite narrow (Fig. 3A). In generations 3–5, P^+ males produced 80.2–84.1% (+)-ipsdienol; P^{-a} males produced 9.6–53.4% (+)-ipsdienol; and P^{-b} males produced 14.1–43.1% (+)-ipsdienol (Table 2).

We did not obtain a line for very low (+)-ipsdienol enantiomeric ratio production that reached the selection target for all offspring for multiple generations. In earlier generations, broods with uniformly low (+)-ipsdienol blends were found, but were unsuccessfully propagated. Between the third and fifth generations, two such broods (P^{-a} and P^{-b}) showed a progressive decline in both (+)-ipsdienol enantiomeric ratio and variability in enantiomeric composition (Table 2). The phenotypic distributions of ipsdienol enantiomeric ratio were relatively broad in the fifth generations of P^{-a} and P^{-b} (Fig. 3B and C, respectively).

Divergent Line Crosses

The phenotypic distributions of (+)-ipsdienol produced by males in all line crosses resulted in a variety of patterns (Fig. 3). The $F1^a$ and $F1_r^a$ crosses generally show a range of phenotypes between 0% and 50% (+)-ipsdienol (Fig. 3D, E). The $F1^a$ distribution is more skewed to intermediate phenotypes than $F1_r^a$. The $F1^b$ hybrids showed a much different distribution, with approximately half of the individuals segregating to the P^+ parental type (Fig. 3F). The B^+ and B_r^+ backcrosses showed distinct bimodal distributions, with roughly half of offspring very similar to P^+ and the other half varying between 0% and 50% (+)-ipsdienol (Fig. 3G, H). The dis-

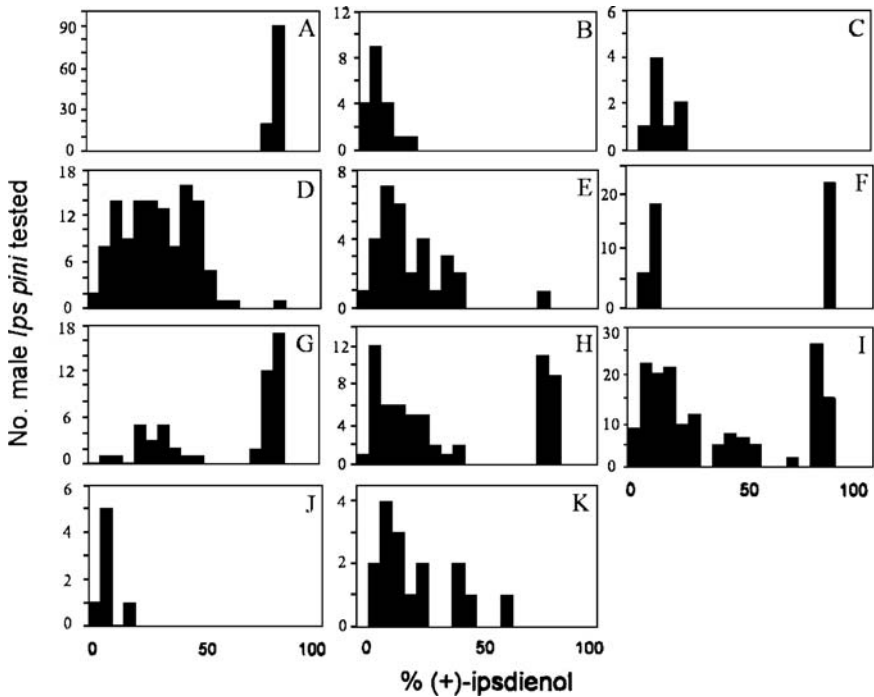

Fig. 3 Frequency histograms of the enantiomeric composition of ipsdienol from all experimental crosses with the Brisco, British Columbia population. Data include parental populations (A, B, and C = P⁺, P^{-a}, and P^{-b}, respectively); F1 generation (D, E, and F = F1^a, F1^a, and F1^{-b}, respectively); backcrosses of F1 to P⁺ (G, H = B⁺, B⁺); F2 generation (I = F2), and backcrosses of F1 to P^{-a} (J, K = B⁻, B⁻) for all male progeny from a given group

tribution of the B_r⁺ line was more skewed to the P⁻ phenotype. The F2 generation showed three peaks in distribution (Fig. 3I), one of which was very narrow at 80% (+)-ipsdienol and the others wider at 0–30% and 35–55% (+)-ipsdienol. The number of samples for B⁻ and B_r⁻ was small, but both distributions centered at low ratios of (+)-ipsdienol (Fig. 3J, K).

We omitted P^{-b} and F1^b from the BC means analysis, because of the high degree of segregation in F1^b, which suggests that P^{-b} was not homozygous. Six genetic effects [*m*], [*d*], [*h*], [*d_x*], [*j*], and [*h.d_x*] were included in the model that provided the

Table 2 Proportion of (+)-ipsdienol in the P⁺, P^{-a}, and P^{-b} lines of the pine engraver, *Ips pini*, for the three generations prior to crossing in the BC divergent selection experiment (mean ± sd, *n*)^a

<i>d_X</i>	-35.853	-0.235	-1.655
<i>j</i>	-35.470		
<i>h:d_X</i>	31.081		

^a For all effects, 95% confidence intervals (not shown) do not overlap zero.

^b Effects include mean (*m*), additive (*d*), dominance (*h*), X-linked (*d_X*), additive by dominance (*j*), and dominance by X-linked (*h:d_X*).

best fit to the line means (Table 3). Dominance [*h*], X-linked [*d_X*], and additive by dominance [*j*] effects were negative. All factors, including the interactions, [*j*] and [*h:d_X*], were relatively large in magnitude and capable of strongly affecting ipsdienol enantiomeric blend. The expected line mean values calculated by the model do not differ significantly from the resampled line means ($\chi^2 = 2.667$, $df = 3$, $P = 0.446$; Table 4). Joint-scaling tests were significant at $\alpha = 0.05$ for the addition of each factor up to the accepted model. No factor could be added to this model that significantly improved the fit as evaluated by joint-scaling. Because of the strong dominance and interaction factors, we repeated the analysis by using a square root transformation, which did not affect the results (details not shown).

CA × WA Crosses

All of the lines in the CA × WA experiment were represented by 26 or more samples of males, with the exception of the B_r⁺ line, which expired before sampling. Nearly all males produced <5% (+)-ipsdienol in every line (Fig. 4). However, with

Table 4 Averaged resampled line means, model-predicted means, and sample sizes for line cross experiments among populations of *Ips pini* from British Columbia, California, Washington, Alberta, and New York

Joint scaling ^a	<i>P</i> = 0.446			<i>P</i> = 0.132			<i>P</i> = 0.139		

^a Test is based on χ^2 test for goodness of fit, where acceptable model is assumed when $P > 0.05$.

the exception of F1_r and B⁻ (Fig. 3D, F), all the lines had a few individuals that produced slightly higher ratios of (+)-ipsdienol. The resampled line means from these crosses were similar and ranged from 1.730 to 3.374 (Table 4). Line means analysis for the CA × WA crosses resulted in the addition of small, but significant, additive and X-linked effects to the model (Table 3). The expected line means derived from this model do not differ significantly from the resampled line means ($\chi^2 = 8.480, df = 5, P = 0.132$) (Tables 3 and 4). Joint-scaling tests were significant at $\alpha = 0.05$ for the addition of both factors. No factor could be added to this model that significantly improved the fit.

AB × NY Crosses

All of the planned lines in the AB × NY experiment had more than 30 samples each (Fig. 5). The AB (P⁺) line consisted of 77 males from the first two generations of laboratory breeding that all produced >75% (+)-ipsdienol (Fig. 5A). These samples were among the top 65% in (+)-ipsdienol enantiomeric ratio and were separated from those producing a lower ratio of (+)-ipsdienol by at least 20%. Seventy-nine males from the NY (P⁻) colony generally showed a range of phenotypes between 50% and 70% (+)-ipsdienol (Fig. 5B). This distribution was skewed toward a large peak near 70% (+)-ipsdienol. All the line crosses derived from the AB and NY lines had mean enantiomeric compositions ranging from 68.5% to 74% (+)-ipsdienol (Table 4). The frequency histograms of each generation showed phenotypes between approximately 50% and 85% (+)-ipsdienol, with varying degrees of skewness to higher percentages of (+)-ipsdienol (Fig. 5C–H).

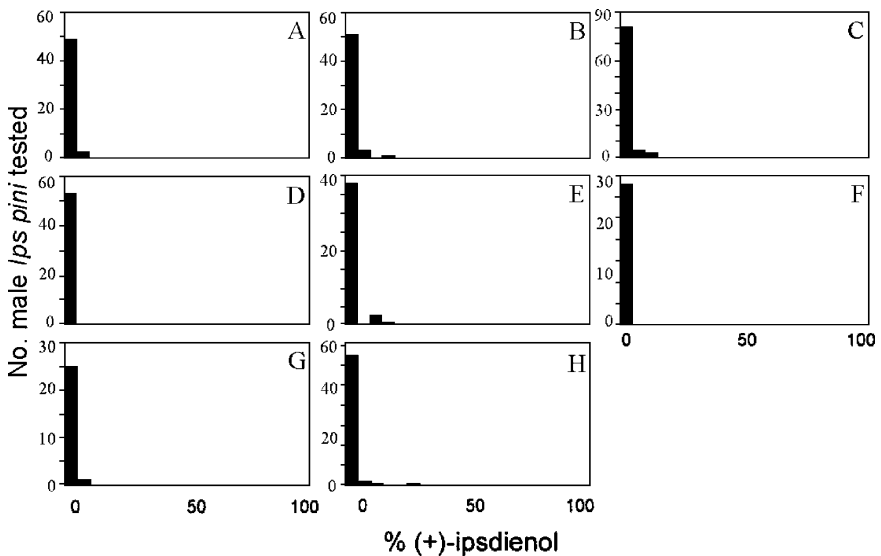

Fig. 4 Frequency histograms of the enantiomeric composition of ipsdienol from male *Ips pini* from all experimental crosses with the Lake Tahoe, CA and Roslyn, WA populations. Data include parental populations (A, B = WA:P⁺, CA:P⁻); F1 generation (C, D = F1, F1_r); backcross to WA (E = B⁺), backcrosses to CA (F, G = B⁻, B_r⁻), and F2 generation (H) for all male progeny from a given group

Fig. 5 Frequency histograms of the enantiomeric composition of ipsdienol from male *Ips pini* from all experimental crosses with the Bragg Creek, Alberta (AB) and Cortland, NY populations. Data include parental populations (A, B = AB:P⁺, NY:P⁻), F1 generation (C), backcross of F1 to AB (D = B_r⁺), backcrosses to NY (E, F = B⁻, B_r⁻), F2 generation (G), and B⁺ crossed to NY (H) for all male progeny from a given group

The line means analysis for the AB × NY crosses resulted in the addition of additive, X-linked, and dominance effects to the model (Table 3). While the additive effect [*d*] was positive, the other effects were negative and smaller in magnitude. The expected line means derived from this model do not differ significantly from the resampled line means ($\chi^2 = 6.938$, $df = 4$, $P = 0.140$) (Tables 3 and 4). Joint-scaling tests were significant at $\alpha = 0.05$ for the addition of all the factors.

Adding the dominance by X-linked effect [*h.d*_X] significantly improved the model ($P = 0.014$). However, we chose not to include this factor. With this interaction, the confidence interval for the dominance factor overlapped zero and the model became more difficult to interpret. Furthermore, the simpler model did not show a significant difference between the predicted and observed line means (Table 4).

Mendelian Analysis of Divergent Line Crosses

For the Mendelian analysis, we assumed a simple autosomal model and combined reciprocal lines (e.g., B⁺ = B⁺ and B_r⁺). From F1^a, 149 of 151 males produced <70%

Table 5 Comparisons of the observed to predicted Mendelian ratios of high/low (+)-ipsdienol phenotypes of *Ips pini* from British Columbia crosses

Cross	Ratio	3:1	1:1	1:3
F1 ^a	2:150	440.1 ^b	144.1 ^b	45.47 ^b
F2	41:116	200.1 ^b	35.83 ^b	0.1040
B ⁺	52:58	45.10 ^b	0.3273	29.10 ^b
B ⁻	0:23	69.00 ^b	23.00 ^b	7.667 ^a
F1 ^b	22:24	18.12 ^b	0.0870	12.78 ^b

^a $P < 0.01$ (χ^2 test).

^b $P < 0.005$ (χ^2 test).

Table 6 Castle–Wright estimators of number of effective segregating loci for the BC, CA × WA, and AB × NY line cross experiments

V(S) estimate	BC crosses	CA × WA crosses	AB × NY crosses
Least squares	0.662 ± 0.072	−0.002 ± 0.040	0.340 ± 0.071
2F2–B ⁺ –B [−]	1.383 ± 0.565	−0.004 ± 0.064	0.228 ± 0.086

(+)-ipsdienol. This low (+)-ipsdienol ratio differed significantly from a 3:1, 1:1, or 1:3 ratio (Table 5). The F1^b line yielded a bimodal distribution with 22 of 46 male offspring producing >70% (+)-ipsdienol, and this ratio did not differ significantly from a 1:1 phenotypic ratio (Table 5).

In the F2 generation, there were 41 high (+)-ipsdienol ratio males to 116 low (+)-ipsdienol ratio males. This ratio did not differ significantly from a 1:3 phenotypic ratio. The ratio was significantly different from 3:1 or 1:1 (Table 5). The backcrosses to the P⁺ lines (B⁺) exhibited a 52:58 high/low ratio, which was not significantly different from a 1:1 phenotypic ratio, but was significantly different from 3:1 and 1:3 phenotypic ratios (Table 5). All 23 offspring of backcrosses to P^{−a} (B[−]) were assigned the low (+)-ipsdienol ratio phenotype, which differed significantly from 3:1, 1:1, and 1:3 phenotypic ratios. An X-linked single gene model shows significant difference from expected ratios in each generation (comparisons not shown).

Number of Effective Factors

Significance of the estimates for number of effective factors cannot be estimated because of nonnormality and nonadditive effects. The estimates were low for each of the three experiments (Table 6). Both the least-squares and 2F2–B⁺–B[−] estimates for the segregation variance in the BC line crosses yielded estimates of n_e close to 1. The Castle–Wright estimator for the CA × WA crosses was near 0 for both segregation variance assumptions. The AB × NY crosses led to estimates of n_e that were less than 1.

Discussion

This study represents the first instance where the genetic control of a long-range pheromone signal is investigated at a natural hybrid zone. Our analyses of the BC experiment implicate a recessive allele that controls most of the variation in ipsdienol enantiomeric ratio at the hybrid zone. For the Mendelian model, only the F1^b line differed from such a pattern, because half of the beetles show the phenotype associated with P⁺. This result can easily be explained if all the P^{−b} parents of this line were heterozygous carriers of the recessive allele. The strong dominance effect in the line means analysis is also consistent with the action of this major gene. The Castle–Wright estimator is close to 1, which also supports our general conclusion that few genetic factors control the differences in pheromone blend at the hybrid zone. However, nonnormal data and inequality of genetic effects may bias this estimate.

Miller et al. (1989) speculated that there was quantitative variation in ipsdienol blend production because of the variety of phenotypes found in his samples. Despite

the major gene effect on pheromone production, there may be quantitative effects at other levels of genetic control. Additional loci for ipsdienol enantiomeric blend are implied in our means analysis by the interactions [j] and [$h.d_X$], and the X-linked factor [d_X]. Zhu et al. (1996a) similarly showed that there are two levels of control in pheromone production between variants of the European corn borer, but were unsure if the second level of control involves additional loci. Thus, despite the different ecological roles between *Ips* aggregation pheromones and lepidopteran sex pheromones, we do see a convergence.

Our experimental design and analyses assume that there are no postmating isolation mechanisms relevant to this system. Lanier (1972) found high egg hatchability in hybrid crosses between Ontario and California populations of *I. pini* in both directions. Throughout the five generations of our divergent selection experiment, we observed many broods with high phenotypic variation, suggesting that hybrids can produce viable offspring for several generations. Furthermore, by divergently selecting from one population in that experiment, we decreased the likelihood of encountering a factor such as *Wolbachia* infection, which has been reported in this family (Vega et al., 2002).

Although the knowledge of the biochemical mechanisms of insect pheromone production is increasing (Tillman et al., 1999), we do not have a full mechanistic understanding for how changes in isomer-specific pheromone blends occur. *I. pini* produces ipsdienol *de novo* in the midgut by using the mevalonate pathway (Seybold et al., 1995b; Tillman et al., 1998; Hall et al., 2002), but may also convert the host-produced compound myrcene to ipsdienol (Vanderwel, 1991). Seven mevalonate pathway genes have been identified from *I. pini* that are active in the midgut (Eigenheer et al., 2003), with two male-specific genes (Keeling et al., 2004), indicating involvement in pheromone production. Because enantiomers of ipsdienol are interconvertible in the California fivespined ips, *Ips paraconfusus* (Fish et al., 1979, 1984), the control of ipsdienol enantiomeric blend may occur relatively late in this pathway. Lepidopteran pheromones generally arise from fatty acid synthetic pathways, with important roles of desaturation and chain-shortening enzymes (Roelofs, 1995). In European corn borers, the reductase complex has been implicated in the production of the specific ratios of the pheromone isomers (Zhu et al., 1996b). However, the enzymes actually determining the isomer-specific pathway also remain unknown for European corn borers. Further knowledge in the biochemical pathways of pheromone production may reveal how the putative major genes operate. Adding a quantitative trait loci (QTL) approach to line crosses may be necessary to fully describe how genetic control of isomer blends is achieved, particularly if modifiers of normal biochemical pathways are involved.

Our experiment involving crosses between beetles from California and Washington indicates little difference in the genetic control of enantiomeric blend. In these parent populations, and all their line cross derivatives, most beetles produced close to 0% (+)-ipsdienol. However, we did uncover very small significant additive and X-linked effects that were likely due to rare alleles for slightly higher ratios of (+)-ipsdienol. Because the high (+)-ipsdienol ratio phenotypes appeared so rarely in our lines, we cannot argue that our model results accurately indicate any real population differences between the two geographic areas.

On the other side of the hybrid zone, we confirm that many *I. pini* males in British Columbia and Alberta produce proportions of (+)-ipsdienol that are higher than ever measured in eastern populations like New York (Miller et al., 1989, 1996).

The use of the same host material and rearing facility ensures that these differences are not attributable to environmental conditions, an explanation previously considered (Miller et al., 1989; Seybold et al., 1995a). Our study also provides a limited insight into the genetic nature of this difference. Our failure to observe transgressive segregation in the AB \times NY crosses (Table 5, Fig. 5) suggests that the NY population may possess a gene similar to that which distinguishes the P⁺ and P⁻ lines of the BC experiment. Moreover, there were no complicated genetic interactions in the AB \times NY crosses that suggest radically different genetic control of pheromone blend. However, without a full mechanistic understanding of the genes involved, our results cannot completely rule out such radically different genetic architectures for the high (+)-ipsdienol ratios observed in these populations. Additionally, our comparison only involves two populations from a large geographic continuum (Lanier, 1972). The enantiomeric composition of ipsdienol across this range has been estimated from groups of 20–230 males (Seybold et al., 1995a), but profiles from individual males do not exist for many populations over this range. Thus, additional genetic modes of enantiomeric blend production may exist.

The separation of eastern and western forests during Pleistocene glaciation has been cited as the likely cause for the divergence in pheromone biology between the corresponding populations of *I. pini* (Seybold et al., 1992, 1995a). However, a more complete evolutionary model for the system must also explain the variation in pheromone profiles within what is considered the “eastern type” population, which is consistent with character displacement at the hybrid zone. A review of the literature on *I. pini* suggests three possible causes for this current geographic pattern of ipsdienol enantiomeric ratios: (1) reinforcement, (2) strong natural selection, and (3) multiple allopatric separations.

Serious consideration of the reinforcement model would require much deeper knowledge on the geographic pattern of ipsdienol variation, strength of assortative mating at the hybrid zone, and amount of introgression between populations. While assortative mating based on ipsdienol enantiomeric blend has been described in New York (Teale et al., 1994), the matter has not been investigated at or near the hybrid zone. As a further caution, Miller et al. (1996) found that profiles of male pheromone production do not always match that of female response to lures in British Columbia.

Nevertheless, aspects of the genetic architecture of ipsdienol enantiomeric blend production uncovered here may be consistent with a process such as reinforcement. For multilocus reinforcement models, assortative mating will be difficult to maintain in the face of any gene flow. Single-locus reinforcement models are also problematic because narrow clines will limit the power of selection for further reproductive isolating methods (Butlin, 1989). A two-level genetic model of canalization of pheromone blend (Zhu et al., 1996a) could avoid these theoretical difficulties via the reinforcement hypothesis. Pheromone production and response may change in allopatry by minor incremental changes at multiple loci due to sexual selection (Fisher, 1930; Lande, 1981) and/or natural selection. A single locus encoding a major shift in the trait may arise, but remains rare until selected after secondary contact. Our characterization of two levels of control of pheromone blends in British Columbia supports the plausibility of this process. However, our lack of a complete mechanistic understanding of how such genetic factors operate, coupled with the unknown role of female preference, suggests caution.

Much research on North American *Ips* spp. has focused upon the intense interspecific competition and predation mediated by semiochemicals. Among competitors, resource partitioning might influence blends used. For example, *I. paraconfusus*, a species that occurs in California and Oregon, is interrupted by (–)-ipsdienol (Light and Birch, 1979). Conversely, this species produces (+)-ipsdienol and (–)-ipsenol, which interrupt aggregation by *I. pini* (Birch et al., 1977, 1980). However, the selective pressures from such competitors are often more complicated because competitors may also be synergistically attracted to semiochemical blends, where the components are derived from multiple species (Hedden et al., 1976; Ayres et al., 2001).

Predators can be a stronger selective factor than competitors in some populations of *I. pini* (Erbilgin et al., 2002). Furthermore, predators often exhibit preferences for certain pheromone phenotypes of *I. pini*, potentially resulting in selective feeding upon beetles (Raffa and Klepzig, 1989; Herms et al., 1991; Raffa, 1991; Raffa and Dahlsten, 1995). The pheromone lanierone tends to increase trap captures of predator species in western populations where it is not used by *I. pini* (Seybold et al., 1992; Miller et al., 1997; Dahlsten et al., 2003). Conversely, in Wisconsin, some predators are attracted most strongly to low (+)-ipsdienol enantiomeric blends with no lanierone (Aukema et al., 2000). Thus trapping both predators and competitors over a range of blend ratios at the hybrid zone might reveal if a selective advantage to the specific “80% (+)-ipsdienol phenotype” exists.

Finally, the differences in pheromone biology between the California, New York, and Alberta/British Columbia populations may reflect at least three recent allopatric separations. Both lodgepole pine and jack pine, *Pinus banksiana*, the two primary hosts of *I. pini* in Canada and Alaska, may have had multiple refugia at the last glacial maximum (Critchfield, 1985). Furthermore, Cognato et al. (1999) found three mitochondrial lineages of *I. pini*. The distributions of these lineages coincide roughly with the eastern (NY), Rocky Mountain (AB/BC), and southwestern (CA) populations of *I. pini*. Given such a model, the slight differences between the AB/BC and NY pheromone phenotypes may have evolved in allopatry due to genetic drift or convergent evolution.

In summary, our results help to define at least three distinct geographic populations with respect to the genetics of ipsdienol enantiomeric ratio. Additionally, a major gene controls most variation in crosses between the opposing pheromone types at the presumed hybrid zone. Although AB/BC and NY populations are genetically distinct with respect to ipsdienol enantiomeric ratio, crosses between these populations do not provide evidence that the major gene architecture is unique to the hybrid zone. A more complete understanding of the evolutionary system requires further inquiry into the biochemical details of enantiomeric blend production and the strength of assortative mating and natural selection in various populations. In a broader perspective, we provide the first description of the genetic architecture of intraspecific variation in a male long-range pheromone component. A major genetic change occurs, just as it has been often reported for female-produced sex pheromones (Löfstedt, 1990), and as predicted for scolytids by Symonds and Elgar (2004a).

Acknowledgments We thank E. Begin of the Invermere Forest District and M.L. Reid of the University of Calgary for assistance in locating field sites in British Columbia and Alberta. A.I. Cognato provided beetles from California and Washington. We thank M.J. Bohne for assistance with aspects of the lab work.

Abstract Nestmate recognition plays a key role in kin selection to maintain colony integrity in social insects. Previous studies have demonstrated that nestmate recognition is dependent on detection of cuticular hydrocarbons. However, the absence of intraspecific aggression between some colonies of Isoptera and social Hymenoptera questions whether kin recognition must occur in social insects. The purpose of this study was to determine if cuticular hydrocarbon similarity and high genetic relatedness could explain the lack of intraspecific aggression among and within colonies of the introduced subterranean termite *Reticulitermes santonensis*. We performed both GC analysis of cuticular hydrocarbons and genotyping by using 10 DNA microsatellite loci on the same 10 workers from each of 14 Parisian colonies. Multivariate analyses demonstrated correspondence between cuticular hydrocarbon patterns and genetic variation. By using a redundancy analysis combining chemical and genetic data, we found that a few hydrocarbons (mainly short vs. long chains; saturated vs. unsaturated alkanes) were associated with most genetic variation. We also found a strong positive correlation between chemical and genetic distances between colonies, thus providing evidence of a genetic basis for cuticular hydrocarbon variation. However, genetic distance did not account for all chemical variation, thus suggesting that some hydrocarbon variation was environmentally derived. Investigation at the intracolony level indicated that cuticular hydrocarbons did not depend on colony social structure. Based on our findings, we speculate that the absence of intraspecific aggression in *R. santonensis* may result

Introduction

In social insects, the ability to distinguish among individuals from different colonies of the same or different species is essential to prevent competition, predation, and parasitism (Wilson, 1971). Nestmate recognition is also required for kin selection that is essential for maintenance of eusocial behavior (Hamilton, 1964). In most cases, discrimination of unrelated individuals triggers aggressive behavior, but this may not always be the case. Aggressive behavior is not observed between colonies of arboreal nesting termite species (Leponce et al., 1996), dampwood *Zootermopsis* species (Haverty and Thorne, 1989), and subterranean species such as *Coptotermes formosanus* (Su and Haverty, 1991; Husseneder and Grace, 2001) and *Reticulitermes flavipes* (Grace, 1996; Bulmer and Traniello, 2002).

In France, colonies of the subterranean termite *R. santonensis* never display intraspecific aggression regardless of the geographic distances among populations (Clément, 1986; Clément and Bagnères, 1998; Vieau, 2001). Many studies support that *R. santonensis* descended from one or more populations of *R. flavipes* imported from North America (see Dronnet et al., 2004, 2005a; Austin et al., 2005). Based on this assumption, the nonaggressive behavior of *R. santonensis* is comparable to that of other imported species such as the Argentine ant, *Linepithema humile* (Hymenoptera: Formicidae), which forms competitively dominant supercolonies without territorial boundaries (Tsutsui et al., 2000; Giraud et al., 2002) and the tramp ant, *Wasmannia auropunctata* (Le Breton et al., 2004). Therefore, the understanding of mechanisms that explain the lack of intraspecific aggression can be tackled, at least partially, by investigating the compounds involved in recognition systems.

Cuticular hydrocarbons, i.e., epicuticle lipids that prevent desiccation, are reported to serve as chemical cues in the recognition process during interindividual interactions (Howard and Blomquist, 2005; Ozaki et al., 2005). Recognition processes based on genetically derived compounds are also essential for determining the degree of relatedness for kin selection (reviewed in Breed and Bennett, 1987). Hydrocarbon composition is often colony-specific (e.g., ants, Vander Meer and Morel, 1998; termites, Clément and Bagnères, 1998; bumblebees, Dronnet et al., 2005b). Although they can be influenced by the physical and social environment (e.g., Husseneder et al., 1997), cuticular hydrocarbons are thought to have a genetic basis that played a major role in the evolution of social behavior (Carlin and Hölldobler, 1986).

Study of chemical cues provides a powerful system for understanding the absence of intraspecific aggression. Since the hydrocarbon composition of related colonies can be expected to be similar, it should be possible to establish genetic relationships

among colonies by evaluating the potential for recognition on the basis of putative heritable compounds, as is the case in *Schedorhinotermes lamanianus* (Husseneder et al., 1998) and *Macrotermes subhyalinus* (Kaib et al., 2004). Within colonies, since the breeding system is fundamentally linked with colony genetic structure, it is essential to understand how it could influence cuticular hydrocarbon variation. In *Reticulitermes* species, the number and type of reproductives may vary from one single outbred primary pair to multiple inbred secondary reproductives (offspring of the primary reproductives) or to multiple unrelated reproductives (Thorne et al., 1999). Colonies with a number of unrelated reproductives may present a greater variety of derived compounds than highly inbred colonies. In this regard, it should be underlined that *R. santonensis* colonies consist mainly of families headed by inbred secondary reproductives (neotronics) (Dronnet et al., 2005a).

The aim of this study was to determine if the cuticular hydrocarbon composition of the nonaggressive introduced termite *R. santonensis* reflects the genetic relationships inferred from microsatellite molecular markers among and within colonies. We asked the following four questions. Can the apparent lack of conspecific recognition be explained by similarities in cuticular hydrocarbon composition between colonies? Is there sufficient genetic variation to distinguish colonies? Is there a correlation between the cuticular hydrocarbon composition and genetic distance among colonies? Are differences in cuticular hydrocarbon composition among nestmates within the same colony affected by colony social structure?

Methods and Materials

Termites

In 2003, 14 colonies of the subterranean termite *R. santonensis* were collected for gas chromatographic (GC) analysis of cuticular hydrocarbons and for genotyping analysis using microsatellite DNA. The sampling sites were selected within and around Paris, France (Fig. 1). Ten workers per colony ($N = 140$) were randomly taken either from mud tubes on tree bark or from inside buildings. Each termite was isolated into different conical glass vials (Wheaton, 0.3 ml) to avoid mixing of cuticular hydrocarbons, immediately killed by freezing, and stored at -20°C until the time of analyses.

Gas Chromatographic Analysis of Cuticular Hydrocarbons

Cuticular hydrocarbons were extracted by rinsing individuals in 500 μl pentane for 2 min. Following extraction, termites were retrieved with a fine wire (previously washed in pentane) and placed in 95% ethanol for later genetic analyses. After evaporation of pentane, the extracted hydrocarbons were redissolved in 50 μl pentane containing 0.1 $\mu\text{g}/\mu\text{l}$ *n*-eicosane as an internal standard. Samples were analyzed with a Perkin-Elmer Autosystem XL GC (Perkin-Elmer, Wellesley, MA, USA) equipped with a flame ionization detector (FID) and interfaced with Turbochrom workstation software. Analyses were carried out in splitless mode using a 25 m \times 0.32 mm \times 0.5 μm BP1 nonpolar capillary column (SGE, Austin, TX, USA) programmed at 150°C for 2 min, followed by $5^{\circ}\text{C}/\text{min}$ up to 300°C for 5 min.

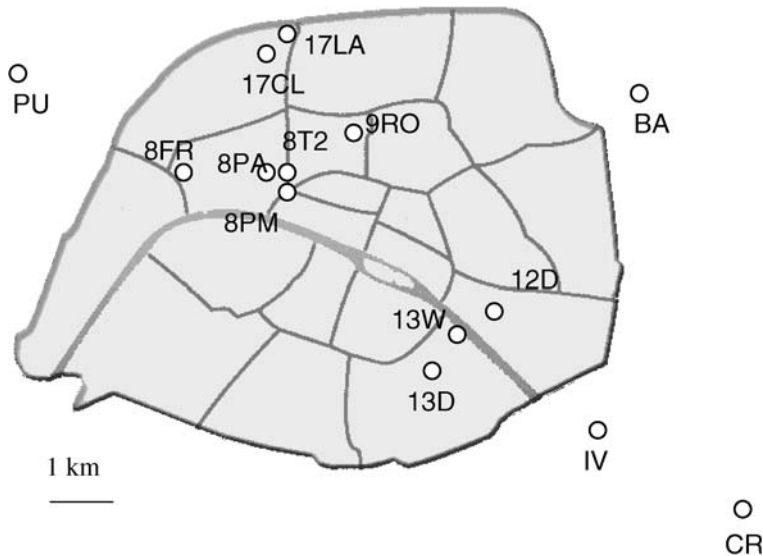

Fig. 1 Map of the city of Paris (France) showing the locations of the 14 *Reticulitermes santonensis* colonies. Ten colonies were collected within Paris: 8T2 [8th Arrondissement (=Ardt), Tronchet street], 8PA (8th Ardt, Pasquier street), 8PM (8th Ardt, Madeleine Place), 8FR (8th Ardt, Friedland avenue), 9RO (9th Ardt, Rochechouart street), 12D (12th Ardt, Daumesnil avenue), 13D (13th Ardt, Dunois street), 13W (13th Ardt, Louise Weiss street), 17CL (17th Ardt, Clichy avenue), 17LA (17th Ardt, Lantiez street). Four colonies came from cities around Paris: PU (Puteaux), BA (Bagnole), IV (Ivry-sur-Seine), and CR (Créteil)

The carrier gas was helium at 1 ml/min. Extracts from different colonies were injected alternatively to avoid the possible biasing effect of injecting extracts from the same colonies one after another. Compound identification was based on previous analyses of the cuticular hydrocarbons of *R. santonensis* by coupled GC-MS (Bagnères et al., 1990).

Chemical Analyses

To allow analysis of the 140 individual hydrocarbon profiles, areas of peaks were readjusted by using an FID correction coefficient (Bagnères et al., 1990). We selected cuticular hydrocarbons that represented >0.3% relative peak area and were present in all individuals. Cuticular hydrocarbons were coded following the notation used by Bagnères et al., 1990 (see also footnote “b” in Table 1): 9-C23:1 (*e1*), *x*-C23:1 (*e2*), *n*-C23 (*a3*), 11-MeC23 (*m4*), 4/2-MeC23 (*m5*), (*Z*)-9-C24:1 (*e6*), 3-MeC23 (*m7*), *n*-C24 (*a8*), 11+12-MeC24 (*m9*), 4/2-MeC24 (*m11*), (*Z*)-9-C25:1 (*e12*), *n*-C25 (*a14*), 11+13-MeC25 (*m16*), 7,9-C25:2 (*n17*), 4/2-MeC25 (*m18*), 3-MeC25 (*m19*). The relative areas of some cuticular hydrocarbon pairs were summed [9-C23:1 + *x*-C23:1 (i.e., *e1* + *e2*); (*Z*)-9-C24:1 + 3-MeC23 (i.e., *e6* + *m7*)], because they were most frequently combined (integrated together) by the GC software. To visualize patterns of chemical similarity among individuals from the same and different colonies, the relative areas of the 14 selected peaks were subjected to principal component analysis (PCA) using the XLSTAT 7.1 software

(Addinsoft, NY, USA). The 95% confidence ellipses around workers from the same colony were obtained using STATGRAPHICS v.4.0 (StatPoint, Inc., Herndon, VA, USA) and UNIWIN PLUS v.3.0 (SIGMA PLUS, Levallois-Perret, France).

Microsatellite Genotyping

Microsatellite genotyping was performed on all 140 individuals that underwent chemical extraction. Genomic DNA extraction and PCR amplification were performed as described by Dronnet et al. (2004). The amplified products were separated by electrophoresis on 6% polyacrylamide gels with a Li-Cor 4000L sequencer. Genotyping was performed at 10 loci. These included four loci originally isolated from *R. flavipes* (*Rf1-3*, *Rf6-1*, *Rf11-1*, and *Rf15-2*; Vargo, 2000) and six loci characterized from *R. santonensis* (*RS10*, *RS15*, *RS68*, *RS76*, *RS78*, and *RS81*; Dronnet et al., 2004). For the description of statistical analyses, these loci will be numbered 1 through 10 in the order listed in the previous sentence. Alleles were scored using the computer program GENE PROFILER 4.03 (Scanalytics, Inc., Rockville, MD, USA).

Genetic Analyses

Patterns of genetic differentiation were initially ordinated by factorial correspondence analysis (FCA) to maximize the correspondence between allele and individual scores. The GENETIX 4.05.2 software used for FCA also codes the alleles by the presence/absence of each feature including homozygous state (Belkhir et al., 1996–2001). As a secondary approach to assess an unrooted network of the genetic distances between the 140 individuals, the proportion of shared allele distance, defined as one minus half the mean number of shared alleles per locus, was computed with the SHAREDST program (J. Brzustowski; available at <http://www2.biology.ualberta.ca/jbrzusto/sharedst.php>). A Fitch & Margoliash tree (Fitch and Margoliash, 1967) was constructed from the two distance matrixes by using the FITCH program in the PHYLIP package v.3.06 (Felsenstein, 1993). Conventional population genetic analyses were used to support the previous analyses. Genotypic frequencies between colonies were compared by means of a log-likelihood (*G*)-based test of differentiation using GENEPOP ON THE WEB (Raymond and Rousset, 1995). The overall significance was determined by using Fisher's combined probability test with Bonferroni's method for multiple comparisons.

Correlation Between Genetic and Chemical Data among Colonies

Redundancy Analysis

The relationship between cuticular hydrocarbon and microsatellite DNA data was tested via direct canonical ordination by using a redundancy analysis (RDA; Ter Braak, 1987) performed with Biplot and Singular Value Decomposition Macros for Excel (Lipkovich and Smith, 2002). The major difference between RDA and PCA is that RDA minimizes error by basing linear regression directly on *x* variables (environmental variables), thus forcing ordination vectors to be maximally related to combinations of the *x* variables (see Legendre and Legendre, 1998). In this way,

results can be expected to express only the part of variation that is significantly linked to the y variables (response variables). RDA was originally used for ecological applications, such as the analysis of community gradients to obtain constrained ordinations of species abundance frequency data in the function of environmental variables. In the present study, the table of y variables corresponded to the allele frequency data in each colony, and x variables corresponded to the mean relative area of each cuticular hydrocarbon peak calculated from the relative areas of the 10 individuals per colony. In addition, PCA was performed again on chemical data at the colony level. Spearman's rank correlation coefficients (r_s) between the colony scores were calculated from RDA and PCA to explore the cuticular hydrocarbon variables affecting colony ordination in multivariate analysis.

Matrix Correlations

Differences in hydrocarbon composition among colonies were quantified by modifying the standard genetic distance of Nei (1987) using the following formula, $D = -\ln \sum^n x_i y_i / \sqrt{(\sum^n x_i^2 \sum^n y_i^2)}$, where n is the number of selected cuticular hydrocarbons, x_i is the relative area of hydrocarbon i for colony x , and y_i is the relative area of hydrocarbon i for colony y . The dissimilarity matrix including all possible colony pairs was constructed from the previously calculated mean relative areas of cuticular hydrocarbons. Independent matrices coding genetic distances between colonies were then calculated from allele frequency data. Nei's standard genetic distance (D_S ; Nei, 1987) among colonies was calculated by using the GENDIST program in the PHYLIP package v.3.06. To test the robustness of our results, we used the Cavalli-Sforza and Edwards (1967) chord distance that makes no biological assumptions except that gene frequency changes can be attributed to genetic drift alone. For matrix correlations, we used XLSTAT 7.1 software to perform Mantel tests with a permutation test strategy (10,000 permutations), because the pairwise distance values among colonies were not independent of each other.

We investigated whether there was isolation by distance by plotting geographic distances vs. chemical and genetic distances, respectively. For genetic distance, F_{ST} among colonies was computed using FSTAT 2.9.3.2 (Goudet, 1995), and significance of the correlation between $F_{ST}/(1 - F_{ST})$ and the logarithm of geographical distances were tested. Mantel tests were computed using XLSTAT 7.1.

Correlation between Chemical Distance and Genetic Relatedness within Colonies

The breeding system was studied with hierarchical F -statistics using FSTAT, following the notation of Thorne et al. (1999), as explained in detail in Dronnet et al. (2005a). The 95% confidence intervals were obtained by bootstrapping over loci 15,000 times. It was assumed that the colony inbreeding coefficient, F_{IC} , was strongly negative in simple family colonies; approached zero as the number of neotenic reproductives increased; and became positive with assortative mating among multiple unrelated reproductives (Thorne et al., 1999).

Variation in chemical composition within colonies was investigated as a function of intracolony genetic relatedness. Genetic relationship between nestmate workers was assessed by measuring intracolony relatedness using RELATEDNESS v. 5.00

(Queller and Goodnight, 1989). Colonies were weighted equally. Mean Nei chemical distance within colonies was calculated from all possible pairs of individuals. Standard error of relatedness within single colonies was determined by jackknifing over loci. Spearman's rank correlation (r_s) was applied to test the relationship between these chemical and genetic variables within colonies.

Results

Chemical Analyses

Quantitatively, the major cuticular hydrocarbons were 11+13-MeC25, *n*-C25, 4/2-MeC24, (*Z*)-9-C25:1, and *n*-C23 (Table 1). The mean percentages of these cuticular hydrocarbons and others were used for statistical analyses *between* colonies (RDA, PCA among colonies, Nei's distance for matrix correlations). Principal component analysis of the quantitative variation in individual hydrocarbon data revealed that the first two principal components, PC-I and PC-II, accounted for 60.2% of total chemical variation (Fig. 2A). Nestmates were regrouped in their respective colonies, but variation also occurred among colonies ranging from low individual variability within some colonies (e.g., *I3W*) to more dispersed patterns (e.g., *I2D*). In the multivariate space, the distinction between colonies was relatively pronounced for *CR*, *IV*, *PU*, *I3W*, *I7CL*, and *I2D*. There was some overlap among the eight other colonies. Differences in colony profiles can be attributed to the effects of the cuticular hydrocarbons that contributed to the principal components. On the biplot (not shown), major contributions to PC-I (in brackets with the hydrocarbons) included two positive compounds, 4/2-MeC24 (*m11*, 14.2%) and 4/2-MeC25 (*m18*, 13.6%), and three negative compounds, (*Z*)-9-C25:1 (*e12*, -14%), (*Z*)-9-C24:1 + 3-MeC23 (*e6+m7*, -11.8%) and 11-MeC23 (*m4*, -10.9%). Major contributions to PC-II included one positive compound, 11+13-MeC25 (*m16*, 27.6%), and one negative, *n*-C23 (*a3*, -25.2%). Colonies *8PA* and *8T2* were more separate from the other colonies when PCA was performed by using PC-III that accounted for 11.4% of the variance (data not shown). Major contributions to PC-III included one positive compound, *n*-C24 (*a8*, 27.6%), and one negative compound, *n*-C25 (*a14*, -15.6%).

Genetic Analyses

Factorial correspondence analysis revealed that most colonies were distinct and plotted into three areas of the multivariate space (Fig. 2B). The two first factorial components (FC-I and FC-II) accounted for 25% of the total genetic variation. Three colonies (*CR*, *IV*, and *I3W*; group one) were completely separated from all the other colonies on the negative part of FC-I, whereas two other groups were distinct on FC-II. On FC-II, spatial distributions of the individual genotypes from four colonies (*9RO*, *I2D*, *I7CL*, *I7LA*) overlapped (group two), while individuals from the other colonies were mixed (group three) on the negative part of FC-II. Colony *PU* was clearly separated from all other colonies on FC-III (data not shown).

The unrooted tree based on allele-sharing distances among individuals provided some support to the results of FCA (Fig. 3). Individuals from colony *IV* clustered and formed a distinct subgroup from the mixed *I3W* and *CR* subgroups. Other

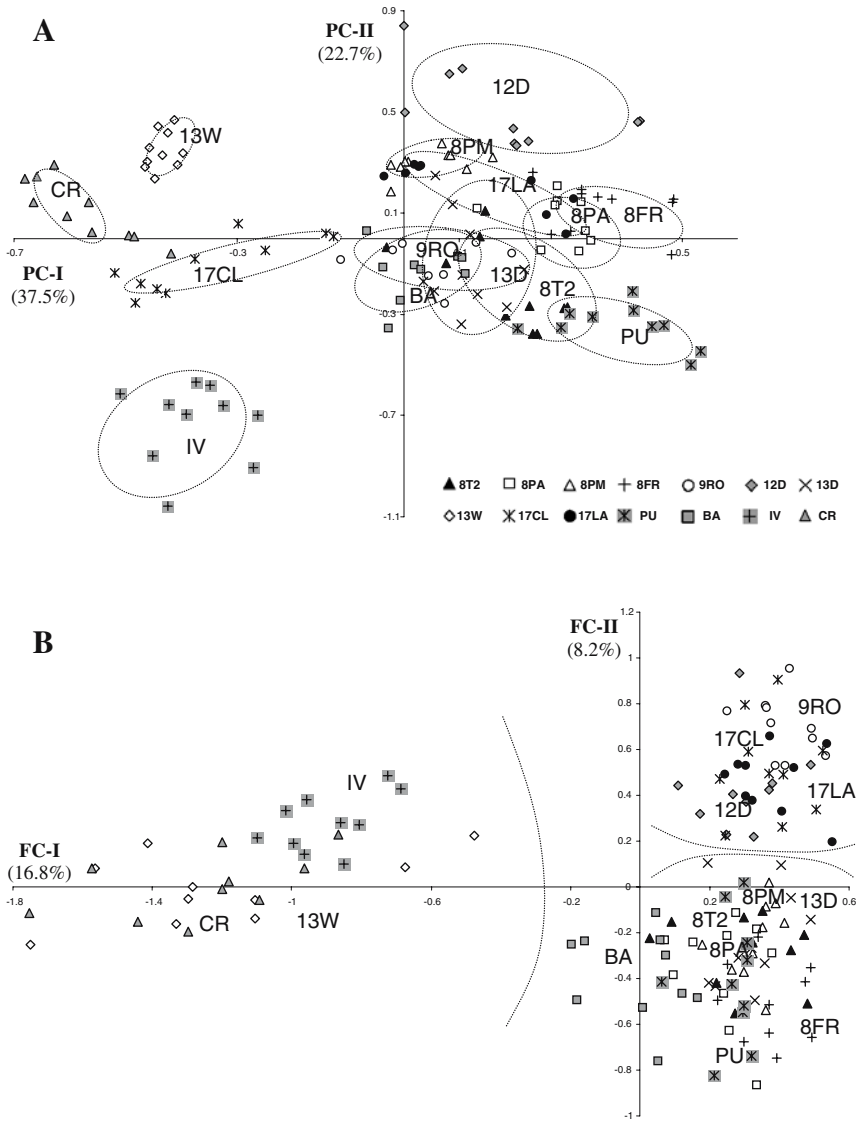

Fig. 2 Multivariate analyses showing the chemical and genetic relationships among the same 140 workers from *Reticulitermes santonensis* colonies. (A) Principal component analysis (PCA) of the cuticular hydrocarbon profiles. The 95% confidence ellipses are dotted. (B) Factorial correspondence analysis (FCA) of the microsatellite multilocus genotypes. The curves (dotted) were drawn by hand to delimit the distributions of the individuals belonging to the three distinct groups (see text). For both analyses, symbols of the same shape represent individuals from the same colony (see legend and Fig. 1)

distinct subgroups appeared including one formed by *8FR* and *PU*, and another by *17CL*, *17LA*, and *12D*.

Significant differentiation was observed among most of the colonies (*G* test: $P < 0.01$), except among colonies in the three groups defined by FCA.

Correlation between Chemical and Genetic Data among Colonies

Redundancy Analysis

Redundancy analysis performed on allele frequency data for all 14 hydrocarbon variables revealed an ordination pattern of colonies (Fig. 4) that closely resembled the ordination pattern produced by FCA plotting of the individual genotypes (Fig. 2B). The first two axes (RD-I and RD-II) accounted for 57.6% of the total variation. The scores of the 14 colonies on RD-I were positively correlated (Spearman's rank test: $r_s = 0.54$, $P = 0.02$) with the scores on the first axis of a PCA performed on cuticular hydrocarbons among colonies (plot not shown), suggesting that these variables adequately explained the variation in the allele frequency data along this axis. Most of the variation on RD-I was explained by a combination of cuticular hydrocarbons strongly correlated with this axis (Fig. 4, long arrows). This correlation was positive mainly for long-chain methylbranched hydrocarbons [3-MeC25 (*m19*), 4/2-MeC25 (*m18*), 4/2-MeC24 (*m11*)] and negative mainly for short-chain hydrocarbons [mainly monoenes (*Z*)-9-C25:1 (*e12*), 9-C23:1 + *x*-C23:1 (*e1* + *e2*), (*Z*)-9-C24:1 (*e6*); shorter methylbranched hydrocarbons 11-MeC23 (*m4*), 3-MeC23 (*m7*)]. Again, CR, 13W, and IV appeared to be different

Fig. 4 Redundancy analysis (RDA) ordination triplot of the 14 *Reticulitermes santonensis* colonies (capitalized letters) with the microsatellite alleles from 10 loci (roman) indicated by dashed lines and the cuticular hydrocarbons (italic) indicated by arrows (environmental variables). Note that for clarity, only microsatellite alleles related to colony ordination are indicated. [For abbreviations of loci, see [Methods and Materials](#); the letters represent the alleles at each locus (not detailed in text)]

from the other colonies with regard to both allele frequency data and cuticular hydrocarbons. When colony *17CL*, whose position was relatively inconsistent with the results of the PCA, was removed from the datasets, the correlation coefficient slightly increased ($r_s = 0.63, P = 0.01$).

The scores of the 14 colonies on RD-II were not significantly correlated ($r_s = 0.25, P = 0.20$) with the scores on the second axis of PCA performed on colony hydrocarbons (without *17CL*, $r_s = 0.27, P = 0.19$). Therefore, cuticular hydrocarbons did not have an influence on the ordination among the colonies along the RD-II axis, as also revealed by the small size of the nearest arrows to this axis [11+13-MeC25 (*m16*), *n*-C23 (*a3*)]. These results suggested that ordination of the colonies along the RD-II axis was attributable mainly to genetic data, which would explain the congruence between the RDA and FCA plots. The main alleles involved in the variation in allele frequency data along the RD-II axis were from loci *RS76* (alleles 8a and 8d), *RS15* (6d), *Rf11-1* (3c), and *Rf6-1* (2d and 2h) (Fig. 4).

Matrix Correlations

Hydrocarbon distances among the 14 colonies were strongly and positively correlated with microsatellite genetic distances; Nei distance (Mantel test, $r_s = 0.40, P = 0.005$); and Cavalli-Sforza and Edward’s chord distance (Mantel test, $r_s = 0.42, P = 0.004$). Colonies showing more similar hydrocarbon profiles were genetically closer.

There was a positive correlation between geographic distance and genetic differentiation between colonies (Mantel test: $r = 0.49, P = 0.005$), but not between geographic and chemical distances (Mantel test: $r = 0.25, P = 0.072$).

Fig. 5 Mean (+SD) chemical distances among nestmates within the 14 *Reticulitermes santonensis* colonies (histogram bars) and intracolony genetic relatedness (data points). Standard errors for genetic relatedness obtained by jackknifing over loci are in bold. The codes for the colonies are indicated on the horizontal axis

Correlation between Chemical Distances and Genetic Relatedness within Colonies

Based on examination of genotype arrays, all the studied colonies appeared to have more than one primary reproductive pair since all had more than four genotypes at one or more loci. Interestingly, the F_{IC} estimate was close to and not significantly different from zero; $F_{IC} = -0.037$ (-0.107 to 0.049).

Mean intracolony chemical distance was variable among colonies with large standard deviations (Fig. 5). Intracolony genetic relatedness ranged from 0.19 to 0.63 (mean \pm SE = 0.44 ± 0.05). We arbitrarily ordered colonies according to increasing values of relatedness (Fig. 5). The correlation between intracolony chemical distance and relatedness was not significant (Spearman's rank test, $r_s = -0.20$, $P = 0.24$).

Discussion

Our cuticular hydrocarbon data indicated that there were chemical differences among most colonies. The PCA performed on individuals showed strong differences in five colonies, more specifically along the first axis, i.e., the axis that accounts for most of the variation. The other colonies had overlapping 95% confidence ellipses, and so could not be clearly distinguished from each other. These findings were unexpected considering the lack of intraspecific aggressive behavior in *R. santonensis*, but would not have been surprising in the other *Reticulitermes* species distributed in Europe. Indeed, intraspecific aggression recorded in *R. grassei* and *R. banyulensis* has provided evidence that these species are able to perform nestmate recognition, most likely on the basis of cuticular hydrocarbons (Clément and Bagnères, 1998). Results

similar to ours have been reported on imported populations of *C. formosanus* from Florida and Hawaii insofar as their cuticular hydrocarbon patterns were not correlated with agonistic responses (Su and Haverty, 1991). Aggressive behavior was demonstrated to be low or absent among Hawaiian colonies (Husseneder and Grace, 2001). However, it must be emphasized that absence of overt aggression does not necessarily mean that no nestmate recognition takes place. Signs of recognition can be observed by examining subtle differences in behavioral interactions and by various ethological tests (Cornelius and Osbrink, 2003; Bagnères and collaborators, unpublished data).

Our genetic data demonstrated almost the same ordination pattern as the cuticular hydrocarbon data. Three colonies were strongly separated along one FCA axis, whereas the other 11 colonies were distributed in two genetically distinct groups. Since the method of factorial analysis used maximized the correspondence between allele and individual scores, it can be assumed that individuals within each group shared common alleles. The unrooted tree based on allele-sharing distance not only confirmed this assumption, but also yielded better resolution among a few colonies within groups. There was sufficient variation to measure genetic distances among most colonies.

Our findings showing general variation in both cuticular hydrocarbon and microsatellite compositions suggest a genetic basis for cuticular hydrocarbons. The multivariate approach that uses a redundancy analysis of chemical and genetic data simultaneously allowed us to isolate the cuticular hydrocarbons that specifically explained the observed variation. The combination of six major cuticular hydrocarbons highly correlated with the first canonical axis appeared to account for genetic variation among colonies. Interestingly, long- vs. short-chain hydrocarbons and saturated vs. unsaturated alkanes were found to correlate positively and negatively, respectively, with the axis. Mantel tests provided a strong positive correlation between chemical and genetic distances among colonies. Other studies in ants and termites have demonstrated a correlation between the level of intercolonial aggression during recognition processes and genetic distances between colonies (Beye et al., 1998; Husseneder et al., 1998). In the mound-building termite, *M. subhyalinus*, direct analyses showed that intercolonial differences in cuticular hydrocarbons were also negatively correlated with genetic similarity among colonies (Kaib et al., 2004).

However, several findings indicated that some chemical compounds may not be genetically derived. Some colonies, e.g., *I7CL*, were genetically similar and yet showed different ordination based on hydrocarbon profiles. Observation of significant isolation by distance among colonies indicated that genetic differentiation increases with geographic distance but, as previously shown in *M. subhyalinus* (Kaib et al., 2004), hydrocarbon differences did not correspond to the geographic population structure (geographic distance). Cue origin could account for the differences between chemical data in the genetic or geographical datasets. Cuticular hydrocarbons may also depend on environmental factors. Previous studies in other social insects such as the wood ant, *Formica pratensis*, have shown that environmental compounds not only are important for nestmate recognition, but they can also override genetically based cues (Pirk et al., 2001).

The presumed imported origin of *R. santonensis* could explain the lack of intra-specific aggression in *R. santonensis* despite the chemical differences observed be-

tween colonies. Although *R. santonensis* does not display the extraordinary supercolony structure of the imported populations of the Argentine ant, *L. humile*, it may have undergone changes in its breeding system. Unlike *R. flavipes* colonies, which are mainly headed by primary reproductive pairs (Vargo, 2003), *R. santonensis* colonies tend to be large with high numbers of neotenic reproductives (Dronnet et al., 2005a). Introduction to Europe may have been accompanied by a loss of genetic diversity at neutral markers in *R. santonensis* resulting in fewer alleles and a lower level of heterozygosity in comparison with *R. flavipes* (Dronnet et al., 2004). One of the hypotheses used to explain the absence of intraspecific aggression in *L. humile* may also explain how introduction events affected the mechanisms underlying the recognition process in *R. santonensis* (Tsutsui et al., 2000; Giraud et al., 2002). A founder event accompanying initial introduction into Europe may have reduced genomic diversity, including both microsatellite loci and genes controlling hydrocarbon expression. The resulting fixation of most recognition alleles could have caused a breakdown of intraspecific recognition ability. However, it should be emphasized that colonies of *R. santonensis* have maintained the ability to discriminate among allospecifics since they sometimes behave aggressively against other species.

Investigation at the intracolony level allowed us to study the influence of the social structure inferred from worker genotypes on hydrocarbon composition. This was especially important insofar as many colonies were headed by many breeders (neotenic reproductives) in each colony, which was revealed by the low F_{IC} value close to zero. These results were consistent with our previous data on other *R. santonensis* populations (Dronnet et al., 2005a) as mating among multiple neotenic resulted in significant inbreeding in each colony. Although extensive variation in intracolony relatedness (from low to high) could have influenced the diversity in cuticular hydrocarbons within colonies, no significant correlation was found between intracolony chemical distance and relatedness. This suggests that cuticular hydrocarbon composition did not depend on social structure. The supposed loss of genetic diversity during introduction may also have affected the recognition process within colonies. However, other factors such as intestinal flora (*R. speratus*; Matsuura, 2001) or diet-derived chemicals (*C. formosanus*, Florane et al., 2004) may influence recognition among individuals within colonies.

Based on our findings, we conclude that genetic relationships among colonies are well reflected by cuticular hydrocarbon variation. This conclusion supports a genetic component to these chemical compounds. Because this species does not show intraspecific aggression, i.e., a common trait for invasive species, it is possible that the supposed loss of genetic diversity also affected the ability to discriminate among more or less related individuals. Further studies focusing on other *Reticulitermes* species showing various degrees of intraspecific aggression will be needed to investigate the influence of cuticular hydrocarbons on recognition.

Acknowledgments We are grateful to the “Section de Lutte contre les termites” (SMASH, Paris) and the pest control operators (HIE Piguy, Hygiène Office, Techmohygiène & APBM Bruant) for kindly providing some samples. We thank P. Legendre (Université de Montréal) for advice on the published material on redundancy analysis, and K. A. Copren, C. Husseneder, M. Kaib, N. D. Tsutsui, and E. L. Vargo for comments on this manuscript, and we thank A. Corsini for help in improving the English of the manuscript. This study was supported by a contract between the Centre de la Recherche Scientifique (CNRS) and the City of Paris (Direction des Parcs, Jardins et Espaces verts).

Abstract The mandibular gland secretions of *Apis mellifera capensis* virgin queens were analyzed by gas chromatography–mass spectroscopy. Changes in the patterns of the mandibular gland volatiles of *A. m. capensis* virgin queens were followed from emergence until 14-d-old. Ontogenetic changes in the mandibular gland secretions were largely quantitative in nature, delineating the age categories (global $R = 0.612$, $P = 0.001$), except for 7- and 14-d-old queens, which cannot be separated on their mandibular gland profiles ($P = 0.2$). (*E*)-9-Oxodec-2-enoic acid (9ODA) contributes most and most consistently to the dissimilarity between groups as well as the similarity within groups. Worker reactions to introduced virgin queens of various ages were recorded. Workers showed a significant increase in hostile reactions as queens aged ($r = 0.615$, $N = 20$, $P < 0.05$). Consequently, worker reactions and relative 9ODA production exhibit a positive queen age-dependent response.

Introduction

Age-related changes in the development of honeybees are well documented. The study of signal variation over time was first investigated in the 1960s and focused on the variation of (*E*)-9-oxodec-2-enoic acid (9ODA) in queens and (*E*)-10-hydroxydec-2-enoic acid (10HDA) in workers (Barbier and Pain, 1960; Pain et al., 1960, 1967). Boch and Shearer (1982) were the first to investigate whether the relative composition or the total quality of the mandibular gland secretion varied with the age of a worker bee. They found an increase in the amount of acids with age, which reached a plateau at 17 d. Subsequent studies have further documented the changes in the chemical composition of the extracts of exocrine glands during ontogenetic development (Allsopp, 1988; Whiffler et al., 1988; Crewe and Moritz, 1989; Slessor et al., 1990; Engels et al., 1997). The ultrastructure of the mandibular glands of queens has been found to develop in conjunction with pheromonal activity during queen aging (De Hazan et al., 1989b). Similar age-related changes in the fine structure and secretory activity of the mandibular glands have also been demonstrated for honeybee drones (Lensky et al., 1985). In addition, ontogenetic changes in the composition and quantity of the defense pheromones produced by workers in their sting and mandibular glands have also been shown (Whiffler et al., 1988).

The attractiveness of queens to workers and drones increases as the queens develop and are mated, with the mandibular gland secretion being primarily responsible for queen attractiveness (Butler, 1960; Gary, 1961). The components and blends in virgin queens' signals change with age and become dominated by 9ODA and (*E*)-9-hydroxydec-2-enoic acid (9HDA; Crewe, 1982; De Grandi-Hoffman and Martin, 1993; Plettner et al., 1995; Pankiw et al., 1996). Butler and Paton (1962) found that the quantity of 9ODA in queen heads increased considerably (7.2–132.5 µg) as queens aged from 1–2 d to 5–10 d. Mating induces additional changes to the signal with increases in aromatic compounds and the appearance of 4-hydroxy-3-methoxyphenylethanol (HVA; Slessor et al., 1990; Pankiw et al., 1996). The progressive change in mandibular gland secretions with age is evident in *Apis mellifera scutellata*, *A. m. mellifera*, and *A. m. intermissa* virgin queens (Pain et al., 1960, 1967; Pain and Roger, 1976) but not *A. m. capensis* queens (Crewe, 1988; Crewe and Moritz, 1989), which have been suggested to produce large amounts of 9ODA at emergence as a necessity in establishing queen–worker relationships (Crewe, 1982, 1988).

Detailed analyses of the mandibular gland extracts of honeybee queens have revealed that ontogenetic changes in the chemical composition of these glands are more complex than a simple increase in quantity. Most of the variation in secretions hinges on a quantitative difference in the relative proportions making up the mixture. The relative proportions of certain compounds, such as 10HDA, decrease in the mandibular gland signal, whereas those of the queen mandibular pheromones (QMP), 9ODA and 9HDA, increase as the queens age and are mated (Crewe and Velthuis, 1980; Crewe, 1982). Of the compounds comprising the QMP complex as defined by Slessor et al. (1988), 1-d-old *A. m. intermissa* queen head extracts are dominated by 9HDA with a significant contribution of 9ODA. In 4-d-old queens, the contribution of these two dominant components is reversed, with 9ODA dominating the signal (Crewe and Moritz, 1989; Slessor et al., 1990). Of those compounds not comprising the QMP complex, oleic acid has been shown to be the main component of recently emerged queens. It has been suggested that the

persistent levels of this acid in young queens, which decreases only with egg-laying activity, could label gynes (Engels et al., 1997).

This change in pheromone composition with queen age is an important factor for beekeepers to consider when replacing old queens with young vigorous virgin queens. The introduction of a new queen into an established colony often results in the workers behaving aggressively toward such queens by balling them (Yadava and Smith, 1971a,b). This worker aggression is related to the pheromonal attractiveness of a particular virgin queen (Yadava and Smith, 1971c). It is well documented that the response of workers to a queen changes during her maturation and subsequent aging, especially as related to changes in the mandibular gland pheromones (Gary, 1961). Besides the mandibular glands, several other sources of pheromonal secretions have been implicated in initiating worker aggression toward introduced queens (Boch and Morse, 1974; Ambrose, 1975; Lensky et al., 1991; Pettis et al., 1998).

The first objective of this study was to investigate ontogenetic patterns in the mandibular gland secretion profiles of *A. m. capensis* virgin queens. The second was to relate these profiles to the reactions of *A. m. capensis* workers exposed to virgin queens of different ages.

Methods and Materials

Samples and Sample Preparation

Queens were reared from established *A. m. capensis* colonies in Stellenbosch, South Africa (33°56'S, 18°52'E). Upon emergence, the virgin queens were placed alone in 40-ml bottles in an incubator at 30–32°C. Queens were supplied with honey-water and water *ad libitum*. They were aged and removed at 1, 3, 7, and 14 d old for mandibular secretion analyses and behavioral observations.

Behavioral Bioassay

Behavioral observations were conducted in the Department of Zoology and Entomology, Rhodes University, Grahamstown, South Africa. Three-frame free-flight queen-right observation hives ($N = 3$) were used to monitor colony behavior toward introduced virgin queens of different ages. Queens were introduced and removed through portals in the walls situated on either side of each frame. The colonies were established in the observation hives for a minimum of 2 wk prior to testing.

Five virgin queens from each age category were introduced to the top frame as far removed from the resident queen as possible, on the side of the frame opposite to that on which the mated queen was observed. A voice-activated tape recorder was used by the observer to record behavioral interactions. During continuous observations, the reactions of the workers to the introduced queens were analyzed in terms of those reactions during the initial 15 min after introduction. All interactions occurring between the introduced queens and the workers were noted. Specific reactions, such as licking and palpating, were considered nonhostile or investigative behaviors. Mounting, biting, pulling, and stinging were considered aggressive or hostile behaviors (Pettis et al., 1998).

A Spearman's correlation was carried out to determine whether virgin queen age affected the reactions of workers to introduced queens. The number of nonhostile

and hostile reactions observed during the 15-min observation periods was calculated as a percentage of the total number of reactions observed during that time period.

Chemical Analysis

The mandibular glands were removed from individual queens ($N = 10$ virgin queens per age category and four mated queens) and stored individually in 100 μl dichloromethane for spectroscopy (Merck, Uvasol). The extracts were evaporated just to dryness under a stream of N_2 , and the acids in the extracts were derivatized with bis-(trimethylsilyl)-trifluoroacetamide (Merck) and quantified according to the method of Gehrke and Leimer (1971). Extracts were analyzed on a Hewlett-Packard 5890 gas chromatograph (GC) fitted with a split-splitless injector, a flame ionization detector, and an HP-1 column (25 m \times 0.32 mm \times 0.52 μm film), temperature programmed from 60°C (1 min), 50°C/min to 100°C, and 3°C/min to 220°C (10 min). The injection port was set at 230°C, and the detector temperature was 280°C. Compounds were identified by comparing their electron impact mass spectra with those in the Wiley MS database and verified using previously published reports (see Table 1 for details) or by comparison with authentic standards (Sigma; Wessler and Crewe, 1999).

The 10 major compounds with possible biological activity were used in the analysis. The exact quantities and percentage compositions of the major biologically active compounds were calculated for queens of various ages. Multivariate analyses were performed by using PRIMER (Plymouth Routines in Multivariate Ecological Research, version 5.2.9, 2004; Plymouth Marine Laboratory, UK). The composite signal, as well as the percentage composition of the major compounds, was transformed by using double square root transformation to give an equal weighting to compounds with high or low representation in the profiles. The similarity matrix was calculated with Bray–Curtis coefficients (Bray and Curtis, 1957). Multidimensional scaling (MDS) was used to provide a visual representation of the pattern of proximities (i.e., similarities or distances) among the mandibular gland secretions of queens in various age classes (Kruskal and Wish, 1978). The MDS was rerun 10 times to ensure that the stress value was at the global minimum (Clarke and Warwick, 2001). Analysis of similarity (ANOSIM) was used to test for differences in queen mandibular gland secretion profiles between the various age classes (Clarke and Green, 1988). PRIMER'S SIMPER (similarity percentage) procedure was used to determine the percentage contribution of those compounds in the mandibular gland secretions responsible for the differences between each pair of test groups (Clarke, 1993). This method also computes the consistency of each of the compounds to the similarity within a test group, as well as to the differences between test groups. This is calculated as the ratio of the mean contribution to the standard deviation of the contribution; thus, a high ratio implies that the compound contributes consistently to the similarity/differences within and between groups.

Results

Chemical Analysis

The major component of the mandibular gland secretions was 9ODA for all test groups except 1-d-old virgin queens, in which the minor aliphatic acids dominated,

^a Abbreviations for the compounds are as follows: 7HOA = 7-Hydroxyoctanoic acid; 8HOA = 8-hydroxyoctanoic acid; 9ODA = (*E*)-9-oxodec-2-enoic acid; 9HDA = 9-hydroxydecanoic acid; 9HDA = (*E*)-9-hydroxydec-2-enoic acid; 10HDA = 10-hydroxydecanoic acid; 10HDA = (*E*)-10-hydroxydec-2-enoic acid; HOB = methyl-*p*-hydroxybenzoate; 4HBA = 4-hydroxybenzoic acid; HVA = 4-hydroxy-3-methoxyphenylethanol. The percentage composition ($\geq 1\%$) of compounds relative to the other 12 compounds is given in parenthesis. Compounds in very low concentrations are denoted by a “t”.

particularly oleic acid (Table 1). The observed increase in 9ODA corresponded with an increase in 8HOA (end-point by-product of 9ODA biosynthesis) and a decrease in palmitic and stearic acids (precursors to 9ODA biosynthesis; Table 1; see Plettner et al., 1995). Increased levels of 9ODA, HVA, and 9HDA, the components of the QMP complex, were found in virgin queens aged 7- and 14-d (Table 1).

The percentage composition of those compounds generally considered as biologically active in the honeybee mandibular gland signal, the major aliphatic acids, and the phenols, are presented in Table 2. The profile of the overall signal changed as the queens aged, with significant quantitative differences found in the mandibular gland secretions of virgin queens from all different age categories (global $R = 0.61$, $P = 0.001$, permutations = 999, random sample from total possible number of permutations; Fig. 1 and Table 3), except for 7- and 14-d-old virgin *A. m. capensis* queens, which cannot be separated on their mandibular gland profiles (Table 3). These results are consistent for absolute amounts of compounds found in the signal as well as for the ratios of those compounds considered to be the major constituents of mandibular gland signals (global $R = 0.47$, $P = 0.001$, permutations = 999, random sample from total possible number of permutations). However, on pairwise comparisons (using the Bonferroni sequential correction; Rice, 1989), queens aged 3-, 7-, and 14-d-old cannot be delineated accurately from each other when ratios (qualitative variation) and not absolute amounts (quantitative variation) are considered. A multivariate approach of a more composite mandibular profile incorporated additional mandibular gland compounds in the analyses [compounds listed in Table 1, as well as other identified compounds in the secretion, namely, propanoic acid, 2-propenoic acid, 3-phenyl-2-propenoic acid, dodecanoic acid, decanoic acid, (*Z*)-9-hexadecenoic acid, (*E*)-9-hexadecenoic acid, 10-undecenoic acid, benzoic acid, and 4-hydroxy-3-methoxybenzoic acid], revealed the same results (global $R = 0.63$, $P = 0.001$, permutations = 999, random sample from total possible number of permutations), and similarly, 7- and 14-d-old queens could not be delineated on their mandibular profiles.

The PRIMER'S SIMPER procedure (Clarke, 1993) indicated which compounds contribute most, and most consistently, to the average dissimilarity between the

Fig. 1 Multidimensional scaling ordination for the mandibular gland secretion profiles of the 10 major compounds known to be biologically active for *A. m. capensis* queens of different ages. Queens of different ages, except 7- and 14-d-old queens, can be delineated on their mandibular gland profiles. The age groups are as follows: 1-d-old = ○; 3-d-old = ▲; 7-d-old = ■; 14-d-old = ◇; mated queen = +. See Clarke and Warwick (2001) for MDS methods

various test groups, in relation to absolute amounts. In all age classes of queen, 9ODA contributes most to the dissimilarity, followed by 9HDA (Table 4). Mated queens were different from the other test groups, not only because of 9ODA, but also because of the presence of methyl-*p*-hydroxybenzoate (HOB). Besides 9ODA being responsible for the dissimilarity between groups, it also made the greatest contribution within a group and was the compound most responsible for the similarity of the mandibular gland profiles within each of the groups (Table 4). 9HDA also made a major contribution to the mandibular profiles and contributed

Table 3 Comparisons of the probabilities similarity (ANOSIM) of the major aliphatic acids and phenols (µg) present in the mandibular gland secretions of the various test groups^a

consistently to the similarity within the test groups, except for 3- and 7-d-old virgin queens, where 9HDAA had a low average contribution to the similarity within the groups; however, it contributed consistently to that similarity. The compounds contributing most to the similarity within the mated queen group were 9ODA, 9HDA, HOB, and 10HDA; of these, only 9ODA and 9HDA made consistent contributions, together with 8HOA (Table 4).

Behavioral Bioassay

The response of workers toward introduced virgin queens showed a significant increase in hostile reactions as queens aged ($r = 0.62$, $N = 20$, $P < 0.05$; Fig. 2). This consistent increase in aggression corresponded with the relative increase in 9ODA as queens aged (Table 2), suggesting a positive relationship between the level of aggression and the relative proportion of 9ODA. With regard to the major aliphatic acids and phenols, the mandibular gland secretions of 1-d-old virgin queens possessed 72% 9ODA (Table 2), and they received $55.8 \pm 6.5\%$ hostile reactions from workers, whereas queens 3 d and older possessed 87% 9ODA and elicit $88.6 \pm 7.9\%$ hostile responses from workers. Upon introduction into the observation hives, virgin queens attracted the immediate attention of workers. Workers generally reacted to 1-d-old virgin queens with a combination of investigative behaviors, including licking and palpating (44.2% investigative reactions), followed by hostile reactions prior to balling. Virgin queens, 3 d and older, elicited substantially more hostile reactions from workers than 1-d-old queens ($P < 0.05$; Kruskal–Wallis one-way analysis of variance by ranks), with few investigative reactions being detected prior to balling.

Fig. 2 Graphic representation of the percentage aggressive reactions by workers to virgin queens of various ages. The size of the circles indicates sample overlap for a given level of aggression

Discussion

It is well documented that the amount and composition of the compounds produced in queen mandibular glands change with age, with young virgin queens producing smaller quantities compared to older and mated queens (Crewe, 1982; Crewe and Moritz, 1989; De Hazan et al., 1989a; Slessor et al., 1990; Pankiw et al., 1996; Engels et al., 1997), as well as the proportions of these components differing from mated queens (Pankiw et al., 1996). This age-dependent change in the quantities and blends of chemicals produced in the mandibular glands is also evident for *A. m. capensis* virgin queens (Tables 1 and 2), with virgin queens of the different age classes being readily distinguishable on the basis of their mandibular signal. The only age classes that cannot be separated on the basis of signal (Table 3) are 7- and 14-d-old virgin queens, suggesting that “fully mature virgin queen” status has been reached when queens are ≥ 7 -d-old. This is to be expected because Cape virgin queens typically have mated by 5–6 d (Allsopp, unpublished data). It further suggests 7-d-old as an appropriate age class for fully developed Cape virgin queens for any subsequent studies.

The major factors in the maturity of the mandibular gland signals of *A. m. capensis* virgin queens are the increasing prominence of 9ODA and 9HDA as the queens age (Table 4). The observed increase in 9ODA production as *A. m. capensis* queens age corresponds with an increase in 8HOA and a decrease in palmitic and stearic acids (Table 1). These results concur with the biosynthetic pathways proposed by Plettner et al. (1998) for the synthesis of 9ODA in queens. Palmitic and stearic acids are precursors of the pathway, whereas 8HOA is considered a by-product in the synthesis of 9ODA (Plettner et al., 1995). Plettner et al. (1998) suggested that the stearic acid required for the biosynthesis of 9ODA is produced in the mandibular gland. The data presented here provide quantitative evidence to support this suggestion. The elevated levels of the precursors and their associated isomers found in 1-d-old queens (which decreased as 9ODA production increased as the queens aged) indicated that these compounds are produced in the mandibular gland and are utilized in 9ODA synthesis, resulting in the decreased levels observed in older queens producing increased levels of 9ODA.

The 1-d-old Cape queens analyzed in this study had a signal in which all of the identified volatiles, albeit in small or trace quantities, were present. Subsequent to our analyses, a further active compound, coniferyl alcohol, was reported in the mandibular glands of mated but not virgin *A. m. ligustica* queens (Keeling et al., 2003). Qualitative changes as described for other species of *Apis* (Plettner et al., 1997) and other races of *A. mellifera* (Crewe, 1982; Pankiw et al., 1996) were not as pronounced. Although *A. m. capensis* appears to produce a mandibular gland signal in young virgin queens that is unique to the race, recently emerged queens have a signal dominated by oleic acid, consistent with the findings of Engels et al. (1997). Oleic acid concentrations decrease with age in *A. m. capensis* virgin queens and again upon mating (Table 1); however in *A. m. carnica* virgin queens, oleic acid remains constant during the 2-wk postemergence and decreases only slightly after mating (Engels et al., 1997). With respect to the QMP compounds, 9HDA is the only compound in young Californian queens (<24 hr old; Slessor et al., 1990). The ontogenetic composition of the QMP compounds of *A. m. capensis* is more complex, with detectable quantities of 9ODA, 9HDA, and HVA found in all 1-d-old queens analyzed in this study. HOB was also detected in trace quantities in the queens

analyzed. Whereas the signal of *A. m. capensis* virgin queens more closely resembles that of the other southern African honeybee, *A. m. scutellata*, than it does that of Africanized and European queens, significant differences in the percentage composition of the major compounds, as identified by Crewe (1982), are apparent. Young (1–2-d-old) *A. m. scutellata* queen signals are dominated by 10HDA with a significant contribution by 9ODA (Crewe, 1982). In comparison, when considering the percentage of the major compounds of the mandibular gland secretions (Table 2), the 1-d-old queens analyzed had a signal in which 9ODA predominated (72%), with 10HDA making only a small contribution (3.56%) to the signal. It has been suggested that the significance of the uniqueness of the signal of young *A. m. capensis* queens is necessary for the establishment of appropriate queen–worker relationships in a race where workers readily produce queen-like signals (Crewe, 1988).

Comparisons of the relative proportions of 9ODA in the mandibular gland signals of virgin queens having reached mating age of the different races are difficult because many of the studies only provide data for the four compounds comprising the QMP complex (Slessor et al., 1990; Pankiw et al., 1996; Engels et al., 1997). These studies all found that 9ODA predominated in the QMP complex of receptive Africanized and European virgin queens. Data provided by Crewe (1982) and Plettner et al. (1997) suggest that the data of these other studies are not a true reflection of the signal of receptive queens. Their data indicate that when the “worker substance” 10HDA is incorporated into relative calculations of the contribution of the major compounds in mandibular gland extracts, a different pattern emerges. They found that receptive virgins of *A. mellifera* (Plettner et al., 1997) and *A. m. mellifera* (Crewe, 1982) had a signal dominated by 10HDA with a significant contribution of 9ODA. This is not the case in *A. m. capensis* virgin queens in which 10HDA contributes minimally to the mandibular signal.

Mating induces additional changes to the signal bouquet with increases in the aromatic compounds and the appearance of HVA in European queens (Slessor et al., 1990; Pankiw et al., 1996). Interestingly, *A. m. capensis* virgin queens produce detectable quantities of HVA at emergence and, by 14 d, are producing approximately 5.5 µg (Table 1), considerably higher than even mated queens of European origin, which produce between 1.5 and 4.2 µg (Slessor et al., 1990; Engels et al., 1997; Plettner et al., 1997). In contrast, HOB is found in lower concentrations in virgin *A. m. capensis* queens compared to virgin queens of European origin (trace quantities compared to 0.4 µg; Slessor et al., 1990), but queens of both origins produce a significant increase on mating. The change in mandibular gland secretions with mating is less pronounced in *A. m. capensis* queens than in *A. m. scutellata* queens and queens of European origin (Crewe, 1988; Slessor et al., 1990; Plettner et al., 1997).

Worker aggression toward *A. m. capensis* virgin queens increased with age (Fig. 2), with workers balling the introduced queens. Whereas the quantities of all the major compounds of the mandibular gland extract increased with age, the relative proportion of the queen substance 9ODA exhibited a positive age-dependent aggressive response by workers, as previously reported by Yadava and Smith (1971c). One-day-old virgin queens produced proportionally less 9ODA and elicited less aggressive behavior from workers than queens 3 d and older. Pettis et al. (1998) suggested that the lower levels of QMP in virgin queens might facilitate their acceptance by a colony. They illustrated that the acid component, and not the aromatic components, of the QMP elicits aggressive behavior by workers. We tested

the absolute amounts of compounds present in the mandibular gland secretions, and our results support the notion that the acid components, particularly 9ODA, correlate to aggressiveness. These findings partially support the suggestion that the reaction of workers to foreign queens is dependent on pheromone cues and qualitative as well as quantitative differences in mandibular gland volatiles (Engels et al., 1997; Pettis et al., 1998).

This study has not only shown ontogenetic changes in absolute amounts of various mandibular gland components but also that the pattern of the signal changes with age. These age-dependent changes in mandibular gland secretions are positively correlated to worker responses with respect to their levels of aggression.

Acknowledgments We thank the National Research Foundation for funding this project. Thanks are also due to Dr. Arnaud Grégoire for his statistical contribution.

Abstract Mate location responses of male and female solitary-reared locusts that had either experienced no crowding or that had been crowded for varying periods were studied in a flatbed wind tunnel. Two hypotheses were explored: that both sexes of this phase of the locust participate in locating the other by using a combination of chemical and visual signals, and that individuals that experience some crowding (i.e., undergo varying levels of phase shift) can compete effectively with their solitary counterparts in mate location and mating. Our results confirm that both male and female solitarius locusts actively participate in mate location, although the former is the more aggressive partner. The responses of the insects are stronger when a visual cue is provided with the olfactory signal. Crowding of solitary-reared adults enhances their responsiveness to the other sex in the absence and presence of the visual cue. This phenomenon may constitute one of several mechanisms that are involved in recruiting solitary individuals into gregarizing groups and facilitating the spread of gregarious characters across a reproductively active solitarius population.

Introduction

Acridids are known to use acoustic, visual, tactile, and chemical signals, singly or in combination, in mate location and recognition (Whitman, 1990). Although pheromone communication has been recognized to play a role in the mating behavior of many orthopteroid groups, to date, the mediation of sex pheromones in acridids has been demonstrated in only a few species. In *Hieroglyphus nigrorepletus*, males are attracted to a pheromone of medium volatility associated with female excreta (Siddiqui and Khan, 1981). In *Taeniopoda eques*, a contact pheromone of low volatility present on the cuticle of female locusts and in their defensive exudates elicits copulatory attempts by males (Whitman, 1982). Behavioral observations have also implicated the mediation of sex pheromones in the neotropical grasshoppers *Elaeochlora trilineata* and *Chromacris speciosa* (Riede, 1987). None of these pheromones has been characterized.

In locusts, two extreme situations occur. High population densities ($>1.5 \times 10^4 \text{ ha}^{-1}$) in the gregarious phase (El Bashir et al., 1993) reduce mate finding to close-range recognition, probably mediated by visual cues and short-range or contact chemical signals (Inayatullah et al., 1994; Hassanali et al., 2005). In high-density populations, males move toward females, but females do not appear to display similar behavior (Inayatullah et al., 1994). On the other hand, solitarious-phase locusts occur in low densities ($<5 \text{ ha}^{-1}$) and may use both long- and short-range recognition cues. Moreover, both sexes appear to be active in the mate location process (Uvarov, 1977; Byer, 1991). In a detailed study of the responses of solitary-reared *Schistocerca gregaria* (Forskål) males in a wind tunnel to solitary-reared females, solitary-reared females with glued wings (to restrict their vibration and any acoustic signal), and female decoys, the responses of males to females with glued wings were not significantly different from those toward normal solitary-reared females, thus ruling out the possibility of involvement of an acoustic cue from the female (Inayatullah et al., 1994). Solitarious males oriented to live solitary-reared females upwind but not to female decoys, suggesting the mediation of a chemical signal. On the other hand, blinded males did not move upwind toward virgin females, suggesting that vision may be essential for predisposing individuals to sexual activities (Inayatullah et al., 1994).

In the solitarious population at the onset of phase shift, solitarious and gregarious locusts also encounter one another (Roffey and Popov, 1968). The present study attempts to understand the relationship between mating patterns and phase dynamics at the early stages of gregarization, to determine how phase shifts influence mating, and to clarify the relative importance of chemical and visual signals from the two sexes of solitarious individuals in mate location. We tested two hypotheses: (1) Solitarious individuals of both sexes use olfactory and visual cues for mate location and (2) insects that experience some crowding (and, therefore, are shifting to the gregarious phase) may compete effectively with solitary individuals in mate location and mating.

Methods and Materials

Insects

Locusts were from the ICIPE colony, propagated from a stock that originated from the Desert Locust Control Organization for Eastern Africa (DLCO-EA) in Addis Ababa, Ethiopia, in 1989, with repeated inclusion of collections from the field. Gregarious insects of mixed sexes were reared under crowded conditions (300–400) in aluminum cages (50 × 50 × 50 cm) in a well-aerated room (4.5 × 4.5 m) with a duct system (10–15 air changes/hr) that maintained a negative pressure (Ochieng-Odero et al., 1994). Solitary males and females were reared separately, each in an aluminum compartment cage (10 × 10 × 24 cm), arranged side by side in banks of eight with no visual contact between them (Ochieng-Odero et al., 1994). The top was made of wire screen for ventilation and the front of Plexiglas for visibility. Solitary rearing rooms (1.5 × 4.5 m) were maintained at 30 ± 4°C, 40–50% relative humidity, and 12:12 L/D photoperiod. Fresh wheat seedlings and bran were provided daily.

Treatment of Test Insects

Crowd-reared mature males (24-d-old) and females (23- to 26-d-old) were used from the appropriate colony without further treatment. Unmated (virgin) solitary-reared

mature locusts (24-d-old males, 23- to 26-d-old females) were used after varying periods of pretreatment as follows (Table 1): (i) crowded for the last 8 d (days 17 to 24) in mixed sex groups (1:1) of 8 per cage ($20 \times 20 \times 20$ cm), (ii) crowded for the last 16 d (days 9 to 24) as in (i), (iii) crowded for the whole period (fledgling to d 24) as in (i), and (iv) left uncrowded for the whole period. During these treatments, wheat seedling and bran were also provided daily.

Wind Tunnel

Experiments were performed in a Plexiglas flatbed tunnel, 180 cm long \times 45 cm wide \times 30 cm high (Fig. 1), similar to that described by Inayatullah et al. (1994). An exhaust fan sucked air through a Plexiglas charcoal filter container ($45 \times 5 \times 5$ cm, with inlet and outlet sides made of wire mesh). Air from the tunnel was vented outside the room through a chimney. The downwind end of the tunnel had a small wire mesh chamber ($14 \times 7 \times 7$ cm) for prerelease holding of the test insect. In the upwind side, 150 cm apart, was placed a small wire mesh cage ($20 \times 20 \times 5$ cm) that could be covered with black muslin to hide a locust placed therein. Air passed through activated granular charcoal filter (4–14 mesh; Sigma Chemical Co., St Louis, MO, USA) previously cleaned with dichloromethane and activated under nitrogen for 2 hr. The airspeed inside the tunnel was about 20 cm/sec. Smoke was initially used to confirm laminar airflow and to reveal the path of the odor plume through the tunnel. The floor of the working area of the tunnel was covered with thick gray manila paper marked with six stripes (30 cm apart) to facilitate the monitoring of the test insect's movement. Five bulbs (60 W each) were placed 70 cm above the tunnel equally spaced

along its length for uniform lighting. The temperature inside the tunnel during the experiments was $25 \pm 1^\circ\text{C}$.

Long-range Behavioral Observations

We studied the responses of virgin individual insects to one of the following sets of signals derived also from virgin individuals: (i) olfactory signals alone (wire mesh cage covered), (ii) combination of olfactory and visual signals, and (iii) control (empty cage upwind) (Table 1). For treatments (i) and (ii), one adult insect was placed in the upwind cage. Insects were initially observed in photo- and scotophase, but as there were no significant differences, all subsequent observations were made in the photophase. Each observation cycle in the wind tunnel was undertaken for 30 min. The Observer 3.0 software (Noldus, Wageningen, the Netherlands) was used to record (i) the number of scans (movement of the front part of body, $4\text{--}6^\circ$, to either side (Wallace, 1959); (ii) time spent walking/running vs. resting (no movement, abdomen touching the floor); (iii) number of jumps, flights, or abortive flights (in the limited wind tunnel space, abortive flights could not be distinguished from jumping); (iv) distance to signal source traversed in 30 min; and (v) number of individuals that crossed 100 cm and/or arrived at signal source.

Close-range Behavioral Observations

The close-range behaviors of solitary-reared males (24-d-old) and females (23- to 26-d-old) in response to the solitary-reared opposite sex were compared by moving the release cage within 30 cm of the upwind cage. The number of males and females that moved to the target in the presence and absence of olfactory and visual cues from the opposite sex over 30-min observation periods were noted.

Statistical Analyses

Mean distance traversed by test insects, as well as behavioral frequencies recorded during observations, were transformed to $\log_{10}(x + 10)$ to stabilize the variance and analyzed using analysis of variance (ANOVA) followed by least significant difference (LSD) test at $P < 0.05$ (The SAS System 8.02, SAS Institute, Inc., Cary, NC, USA). The percentage of test insects that reached the source of signal(s) in different treatments was compared by Student *t* test.

Results

Responses of Males to Female Olfactory Cues

Figure 2 summarizes the average behavioral responses of individual males in different physiological states to a putative olfactory cue from solitary-reared individual females upwind. Although solitary-reared males appeared more responsive in the presence of the olfactory signal than in its absence, none of

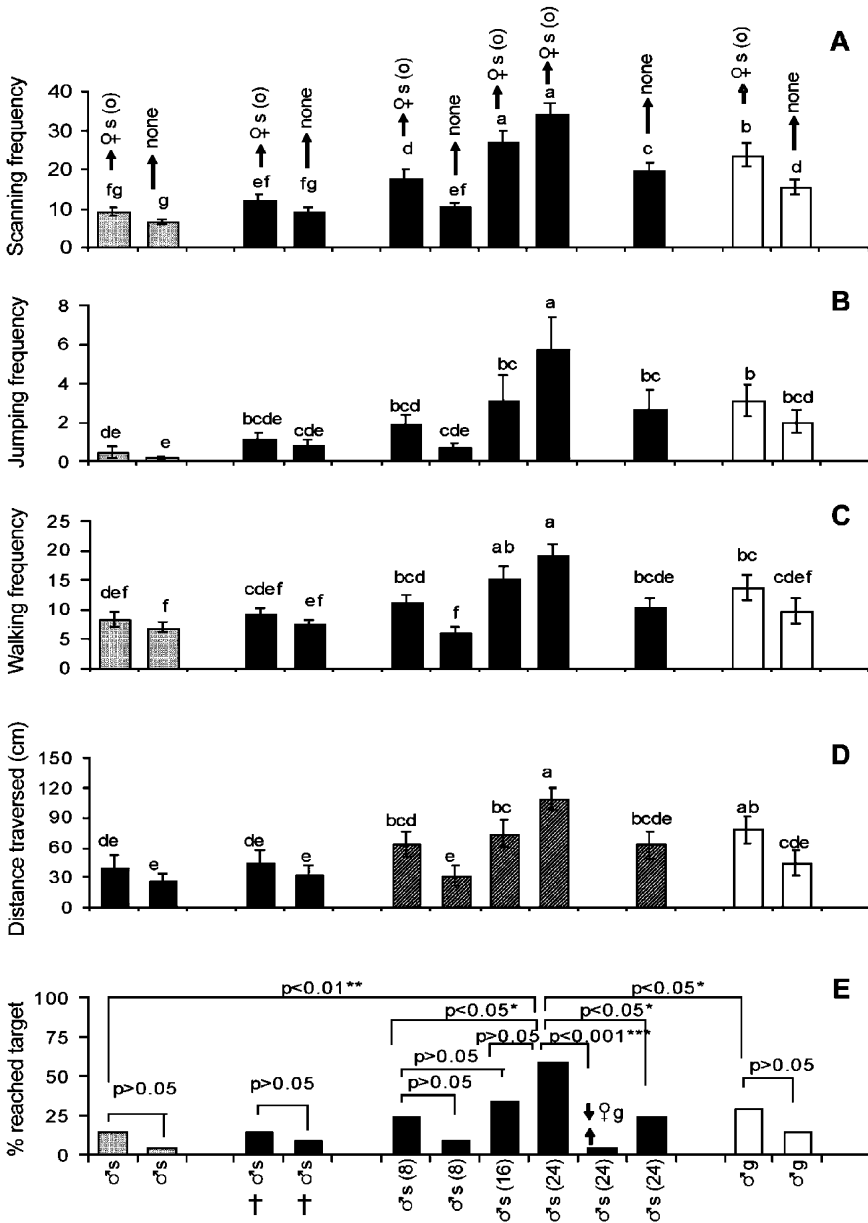

Fig. 2 Responses of mature solitary-reared males, uncrowded and crowded for varying periods, and crowd-reared (gregarious) males to hidden solitary-reared females (except where indicated). Status of males released downwind is indicated on the x axis of E: ♂s, solitary male; †, experiment in scotophase; ♂s (8), solitary male crowded for 8 d; ♂s (16), solitary male crowded for 16 d; ♂s (24), solitary male crowded for 24 d; ♂g, gregarious male. Signal sources are indicated in A: ♀s, solitary female; ♀g, gregarious female; (O), olfactory signal. Columns with the same letter are not significantly different at $P < 0.05$ (ANOVA, LSD test)

the behavioral elements quantified was statistically significant. There were no differences between insects in their photophase or scotophase. Males that were crowded for 8 d were significantly more active in the presence of the putative olfactory cue from uncrowded solitary-reared females than in its absence as reflected in scanning and walking frequencies and in the mean distance traversed (Fig. 2A, C, and D). Solitary-reared males that were crowded from fledgling to maturity (24 d) were most responsive. All behaviors that were quantified were significantly more pronounced in the presence than absence of the solitary female, and significantly more insects arrived at the target female when compared to the control ($t=2.39$, $df=38$, $P<0.05$). Interestingly, the 24-d crowded solitary-reared males were more responsive than male counterparts reared under crowded conditions continuously. Crowd-reared (gregarious) females elicited no similar responses from males, as illustrated by the large and significant ($P<0.001$) difference in the proportion of 24-d crowded solitary-reared males that arrived at the cage with solitary- and crowd-reared females, respectively (Fig. 2E).

Responses of Females to Male Olfactory Cues

Figure 3 summarizes the average responses of females in different physiological states to a putative odor signal from solitary-reared male. Comparison of these with those of males (Fig. 2) indicate some similarities, as well as differences between the sexes. The level of responses of females that experienced no crowding was, by and large, comparable to that of corresponding males, and there were no differences between insects in their photophase or scotophase. On the other hand, females that experienced crowding did not demonstrate levels of enhancement of the different behaviors comparable to those observed in the corresponding males. However, two significant differences in the behavioral responses of females (scanning and walking frequencies, Fig. 3A, C) in the presence and absence of the putative olfactory signal 150 cm upwind indicate that solitary females detect the presence of their male counterparts in the absence of the visual cue, although their response activities are relatively subdued.

Responses of Males and Females to Combinations of Olfactory and Visual Cues

Figure 4 summarizes average response data of uncrowded solitary-reared males, solitary-reared males that were crowded for 8 d, and uncrowded solitary-reared females to combinations of olfactory and visual cues of solitary-reared individuals of the opposite sex. The presence of the visual cue enhanced the responses of uncrowded and 8-d crowded solitary-reared males. This is reflected in significant increase in scanning and jumping frequencies (Fig. 4A, B), as well as in the mean distance traversed by the insects (Fig. 4D), in the proportion that traversed >100 cm, and that arrived at the source of the cues (Fig. 4E, F). Incremental effect of crowding is also reflected in higher relative responses of the crowd-reared individuals compared to those of the uncrowded ones. Solitary-reared females also responded more strongly when both visual and olfactory signals were present. This is illustrated in significantly higher responses of released individuals compared to those of insects exposed to only the olfactory signal (Fig. 4B, D) and/or to control (Fig. 4A–F).

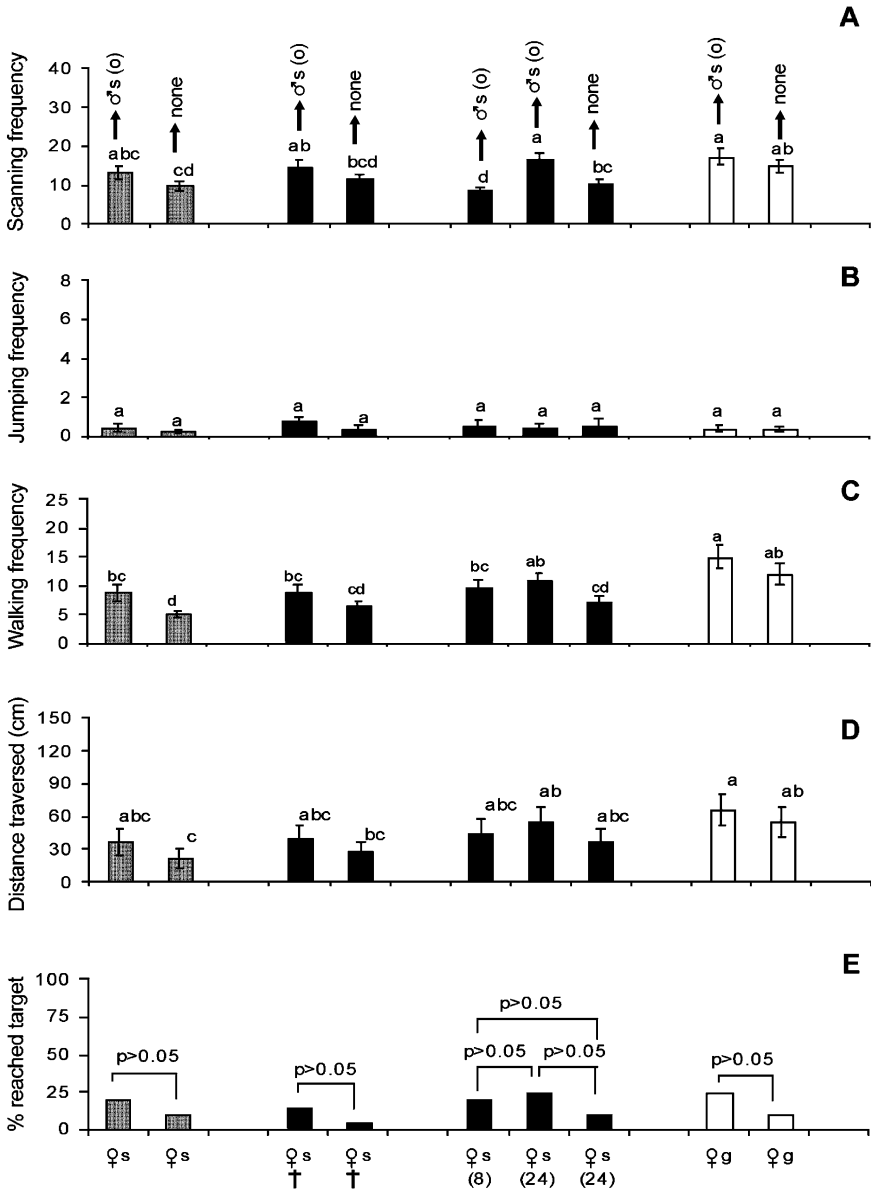

Fig. 3 Responses of mature solitary-reared females, uncrowded and crowded for different periods, and crowd-reared females to hidden solitary-reared males (except where indicated). Status of females released downwind is indicated on the x axis of E: ♀s, solitary female; †, experiment in scotophase; ♀s (8), solitary female crowded for 8 d; ♀s (24), solitary female crowded for 24 d; ♀g, gregarious female. Signal source is indicated in A: ♂s, solitary male; (O), olfactory signal. Columns with the same letter are not significantly different at $P < 0.05$ (ANOVA, LSD test)

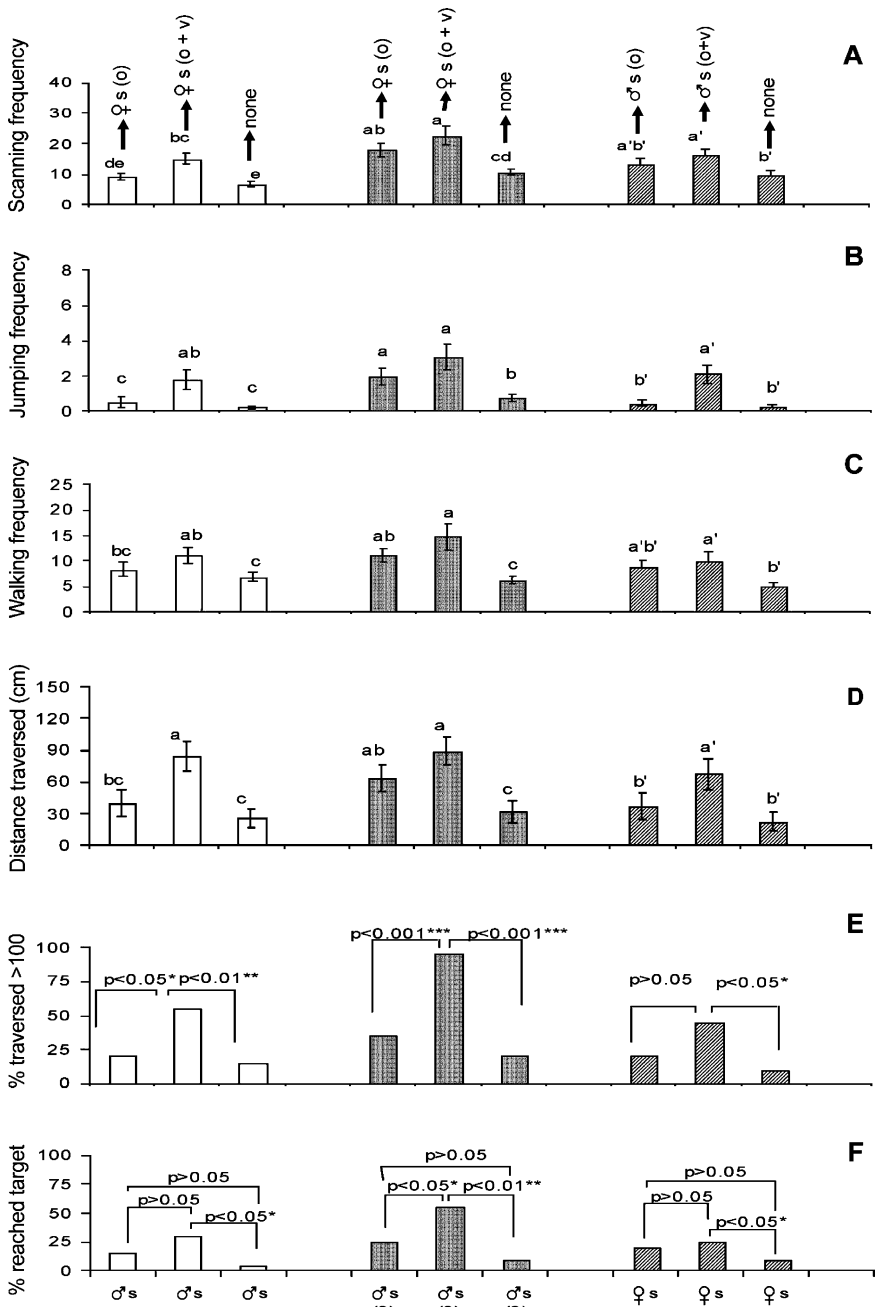

Fig. 4 Responses of mature solitary-reared males, uncrowded and crowded for 8 d, and solitary females to visual ± odor cues from solitary-reared females or males (except where indicated). Status of males released downwind is indicated on the x axis of F: ♂s, solitary male; ♂s (8), solitary male crowded for 8 d; ♀s, solitary female. Signal source is indicated in A: ♀s, solitary female; ♂s, solitary male; (O), olfactory signal; (O + V), olfactory + visual signals. Columns with the same letter are not significantly different at $P < 0.05$ (ANOVA, LSD test)

Close-range Behavioral Observations

The behavior of solitary-reared males and females closer to the insect-cage upwind, with both visual and olfactory cues of the opposite sex, differed. A significant percentage (60%) of the males arrived close to and physically contacted the cage and climbed on it compared to 10% in the control ($t = -3.89$, $df = 18$, $P < 0.001$). Within ~5 cm of the cage, males typically spent several minutes in a resting position, scanning and massaging/cleaning antennae and eyes, before swiftly approaching the caged female. The female moved away from the approaching male, and this was followed by successive attempts by the male to get to the female, with the latter moving away each time. On the other hand, although 80% of the test females came within 5- to 10-cm range of the caged male ($t = -4.48$, $df = 18$, $P < 0.001$), none contacted the cage. Most stood scanning in the direction of the caged male. However, 30% of the females approached the cage several times and groomed their eyes, antennae, or forewings.

Discussion

Our results indicate that, in the presence of olfactory signal alone, the responses of solitary-reared males to females are relatively subdued (Fig. 2). When a visual cue was included, there was significant increase in the attraction of the males (as reflected in scanning and jumping frequencies, and in the distance traversed upwind to the females). Similarly, solitary-reared females also responded more strongly when a visual cue associated with the male augmented the olfactory signal, although, in this case, the increases in female responses were somewhat weaker (Fig. 4). These results confirm our expectation based on observations in a greenhouse arena and in the field that both male and female solitary insects actively participate in mutually locating one another. Close-range observations also show that, on finding each other, they demonstrate sex-specific stereospecific behaviors, with the male as the more aggressive partner.

Previous investigations by Ochieng' et al. (1998) found that solitary adults had more antennal olfactory sensilla than their gregarious counterparts. There was no difference between sexes. Greenwood and Chapman (1984) obtained similar results in *Locusta migratoria*. The mutual responses of solitary-reared male and female desert locusts to the olfactory cues of each other are consistent with these findings and suggest that other locust species may also demonstrate similar mate location mechanism. Interestingly, two types of olfactory sensilla have been found on the antenna of *L. migratoria*, (Ameismeier, 1987). Type A has between 20 and 30 neurons, which probably function in recognition of plant odors. Type B has only three neurons that are more typical of pheromone sensilla (Ameismeier, 1987).

Our study also demonstrates that solitary-reared males and females that experience crowding exhibit enhanced responses to olfactory cues (Fig. 2). Indeed, solitary-reared males that were crowded from the fledgling stage were more successful in locating solitary-reared females than their counterparts that had been continuously crowd-reared. Solitary-reared females that were crowded also showed small increases in some of their responses (e.g., scanning and walking frequencies) to the olfactory signal from solitary-reared males, although, in this case, these were

not significantly different from those of continuously crowd-reared females (Fig. 3). These responses became more pronounced in the presence of the visual signal (Fig. 4). These results provide an additional insight into the mechanism that underlies the genesis and spread of gregarization in a reproductively active solitary population. Although the density of such a population is low, habitat heterogeneity, such as patchy distribution of food plants and perching sites, may promote crowding in isolated microenvironments (Bouaichi et al., 1996; Deng et al., 1996). Some phase-related traits, such as aggregation behavior (Roessingh and Simpson, 1994; Bouaichi et al., 1995) and emission of gregarious-phase aggregation pheromones (Deng et al., 1996; Hassanali et al., 2005), change rapidly with crowding. The results of our present study indicate that, in such situations, gregarizing adult males and females are likely to seek out and mate with their solitary counterparts, and thereby facilitate their recruitment into the gregarizing population.

Previously, two other processes were identified that may also contribute to horizontal spread of gregarious traits across a solitary population. Njagi et al. (1996) compared the electroantennographic (EAG) and behavioral responses of adults of solitary and crowd-reared desert locusts to the aggregation pheromone produced by gregarious males and its constituents. The general response patterns of the two phases of the insect were found to be similar, suggesting that solitary desert locusts are predisposed to respond positively to the aggregating effect of the pheromone and to join the crowd when they encounter it. Thus, clusters of pheromone-emitting gregarizing locusts in appropriate microenvironments may provide nuclei for recruitment of solitary individuals and spread of gregarious traits in the population (Njagi et al., 1996).

Another interesting process that involves active recruitment of solitary individuals relates to the oviposition preferences of gravid solitary females in the absence and presence of egg pods laid by gregarious females. In surveys in successive breeding seasons at desert locust-breeding habitats around Port Sudan in the Red Sea area, Bashir et al. (2000) found that incoming solitary females oviposited predominantly in the vicinity of annual species of *Heliotropium* and, to a lesser extent, near millet plants. Follow-up experiments in cage arenas in the absence of egg pods from crowd-reared gregarious locusts confirmed this preference for these plants. However, solitary females oviposited preferentially near *gregaria* egg pods, when these were present, like their gregarious counterparts and those *solitaria* that experienced some crowding. Communal oviposition, which is characteristic of gregarious-phase locusts (Popov, 1958; Stower et al., 1958; Uvarov, 1977), ensures temporal and spatial cohesiveness of the succeeding hopper generation. A primer gregarization pheromone associated with egg pods derived from gregarious females and solitary females that experience crowding induces the transformation of developing embryos to the gregarious phase (McCaffery et al., 1998; Malual et al., 2001) and thus facilitates transmission and accumulation of gregarious characters across generations. The preferential attraction of ovipositing solitary females to the *gregaria* egg pods then represents another mechanism exploited by the species to recruit *solitaria* into the gregarizing or gregarious population.

In summation, both male and female solitary-phase *S. gregaria* are attracted to each other by both odor and visual cues. Of special interest is the finding that solitary males and females that experience crowding are more effective in locating solitary mates. This constitutes yet another mechanism of recruiting

solitaria adults into gregarious groups and of facilitating the spread of gregarious characters across a solitary population.

Acknowledgments This work was supported by The Program for Co-operation with International Institutes (SI), formerly DSO, and The Swiss Agency for Development and Cooperation (SDC) through FAO, to which we are most grateful. The assistance provided by Messrs. M. Miti and the late J. Ongudha, ICIPE's Animal Rearing Unit, in rearing the locusts is appreciated.

Abstract Mixing the sex pheromones of the Mediterranean corn borer, *Sesamia nonagrioides*, and the European corn borer, *Ostrinia nubilalis*, results in significantly lower captures of *O. nubilalis* when compared to traps loaded with its pheromone alone. Rubber septa loaded with a constant concentration of the pheromone of *O. nubilalis* and different percentages of the *S. nonagrioides* pheromone (from 1 to 100%) causes dose-dependent antagonism in the field. Electroantennograms of *O. nubilalis* males showed high antennal responses to its own pheromone components, followed by smaller responses to the major, [(Z)-11-hexadecenyl acetate (Z11-16:Ac)], and two minor components [dodecyl acetate (12:Ac) and (Z)-11-hexadecenal (Z11-16:Ald)] of the *S. nonagrioides* pheromone. There was almost no response to the *S. nonagrioides* minor component (Z)-11-hexadecenol (Z11-16:OH). Field tests that used traps baited with the *O. nubilalis* pheromone plus individual components of *S. nonagrioides* showed that Z11-16:Ald causes the antagonism. Adding 1% Z11-16:Ald to the pheromone of *O. nubilalis* reduced oriented flight and pheromone source contact in the wind tunnel by 26% and 83%, respectively, and trap captures in the field by 90%. The other three pheromone components of *S. nonagrioides* inhibited pheromone source contact but not oriented flight of *O. nubilalis* males and did not inhibit capture in the field. Cross-adaptation electroantennogram suggests that Z11-16:Ald stimulates a different odor receptor neuron than the pheromone components of *O. nubilalis*. We conclude that Z11-16:Ald is a potent antagonist of the behavioral response of *O. nubilalis*.

Introduction

Most moth species use sex pheromones for mate finding, with females normally being the signalers and males the responders (Cardé and Baker, 1984). Specificity of sex pheromone composition and response maintains reproductive isolation and prevents costly reproductive mistakes (Löfstedt, 1993). The identity of the pheromone blend is determined by the chemical structure of its components and by their absolute and relative quantities (Jurenka, 2003). Signal specificity is matched by specificity in male response, ensuring correct intraspecific attraction and mating (Birch and Haynes, 1982). The integrity of the female pheromone blend is essential to stimulate upwind responses in conspecific males. An incomplete blend, or a blend lacking the species-specific proportion of components, will fail to attract males of the same species, and may instead attract males of a different species (Cardé and Haynes, 2004). Similarly, the type of pheromone receptor neurons present on the male antennae and the integration of the pheromone information in the brain will determine the pheromone blend to which the males will respond (Todd and Baker, 1999; Hansson, 2002).

Typically, each pheromone receptor neuron type in the male antennae responds maximally to just one pheromone component, so there are as many specific neurons types as there are pheromone components in the blend (Todd and Baker, 1999; Hansson, 2002), although response of a single olfactory neuron to more than one pheromone compound can also occur (Cossé et al., 1998; Baker et al., 2004). Males of some species have olfactory receptor neurons attuned to pheromone components produced not by their own females but by those of other species. In some cases, the addition of heterospecific components to the conspecific blend causes inhibition of male upwind flight. These so-called pheromone (or behavioral) antagonists play a role in maintaining reproductive isolation of closely related species (same genus) sharing common pheromone components, and, therefore, susceptible of mating mistakes (Leal, 1996; Borden, 1997; Mustaparta, 1997; Cardé and Haynes, 2004). In addition, there are cases where pheromone antagonism occurs between species that are not closely related (different genera). For example, baiting individual traps, two components at a time, with all possible combinations of the sex pheromones of *Helicoverpa zea*, *Spodoptera frugiperda*, *Pseudaletia unipuncta*, and *Agrotis ipsilon*, causes a reduction in at least one of the species involved compared with traps baited with the pheromone of just one species (Lopez et al., 1990). Similarly, attraction of *Tetanolita mynesalis* to its own pheromone is inhibited by the presence of the sex pheromone of *Lacinipolia renigera* (Haynes et al., 2002), and the pheromone of *Adoxophyes orana* inhibits the attraction of *Cydia pomonella* (Potting et al., 1999).

The European corn borer *Ostrinia nubilalis* (Crambidae) and the Mediterranean corn borer *Sesamia nonagrioides* (Noctuidae), sympatric moth species in the Mediterranean region, both feed on corn stalks, causing important economic losses (Albajes et al., 2002). Each species uses a unique pheromone blend to attract the other sex, and no cross-attraction exists between the two species. On the Iberian peninsula, the predominant *O. nubilalis* pheromone phenotype is the so-called Z strain which has a 97:3 blend of (*Z*)-11-tetradecenyl acetate (Z11-14:Ac) and (*E*)-11-tetradecenyl acetate (E11-14:Ac) (Sans, 1997). The sex pheromone of *S. nonagrioides* has (*Z*)-11-hexadecenyl acetate (Z11-16:Ac) as the major component and smaller quantities of (*Z*)-11-hexadecenal (Z11-16:Ald), (*Z*)-11-hexadecenol (Z11-16:OH) and dodecyl acetate (12:Ac) (Mazomenos, 1989; Sans et al., 1997; Krokos

et al., 2002). In mating disruption tests against *S. nonagrioides*, we found that the number of larvae of both the target species and *O. nubilalis* decreased in treated fields (Eizaguirre et al., 2002). Combining the pheromones of both species in the same septum revealed the existence of mutual pheromone antagonism: Each species is inhibited by the pheromone of the other species (Eizaguirre et al., 2002).

Pheromone antagonists have potential application as tools in pest control programs (Bengtsson et al., 1994; Borden, 1997; Renou and Guerrero, 2000). The purpose of the present study was to determine which pheromone component(s) of *S. nonagrioides* reduces the response of *O. nubilalis* to its own pheromone. We also wanted to determine if the antagonist compound(s) is (are) perceived by the same or different pheromone receptor neurons as those attuned to the pheromone blend components of the species.

Methods and Materials

Colony Maintenance

The colony of *O. nubilalis* was started with 12 mated females collected in the field (Lleida, Spain, 2003). They were initially held as iso-female lines until 6 to 12 female progeny from each female were analyzed by GC-FID to confirm they were the Z strain. The colony was maintained in an environmental chamber under a 16:8 (light/dark) photoregime at $25 \pm 1^\circ\text{C}$, following the rearing procedure described in Sans (1997).

Chemicals

Z11-14:Ac and E11-14:Ac were purchased from Sigma-Aldrich Química, S.A. (Madrid, Spain). Z11-16:Ac, Z11-16:Ald, Z11-16:OH, and 12:Ac were purchased from Sociedad Española de Desarrollos Químicos, S.A. (SEDQ, Barcelona, Spain). (Z)-9-tetradecenyl acetate (Z9-14:Ac) was purchased from Pherobank (Wageningen, the Netherlands). Compounds were found to be 96–99% chemically pure and >99% isomerically pure by GC analysis.

Field Tests

For the dose–response experiment, varying amounts (0, 1, 10, 50, and 100%) of the *S. nonagrioides* pheromone were added to the *O. nubilalis* pheromone (Table 1A). For the effect of the individual components of the *S. nonagrioides* pheromone, each one of them was added individually to the sex pheromone of *O. nubilalis* in the same proportion at which they occur in the *S. nonagrioides* blend (Table 1B). Trapping experiments were carried out in 2002 (dose–response and individual components) and 2003 (dose–response) in corn (*Zea mays*) fields in Lleida (Spain). There were four plots in 2002 (two per field) and in 2003 (two in one field and one each in two other fields). Each plot consisted of a linear arrangement of traps placed 20 m apart. Plots in the same field were ≥ 20 m apart, and fields were ≥ 2 km apart. Traps were hung 1.5 m from the ground on wood stakes between corn plants at the edge of the fields from June 7 to October 10, 2002, and from July 18 to September 9, 2003. Trap position within a plot was randomized at the start of the experiment. Each week,

Z11-16:OH	–	–	–	8	–	8
12:Ac	–	–	–	–	5	5

^a Septa were loaded with 100 µg of the pheromone of *O. nubilalis* (On) plus (A) the complete *S. nonagrioides* pheromone (Sn) in varying concentrations or (B) the individual components of the *S. nonagrioides* pheromone: Z11-16:Ac (Ac), Z11-16:Ald (Ald), Z11-16:OH (OH) and 12:Ac (12). 100%Sn and Sn have the same composition. Septa loaded just with hexane served as negative controls.

counts were taken and traps were rotated to the contiguous position to avoid position effects, but were not re-randomized. Septa were replaced with new ones in week 14 in 2002, but were not replaced in 2003.

Rubber septa (Sigma-Aldrich Química) were rinsed with hexane for 1 hr, let dry overnight, and stored until used. Septa were pierced with an acetone-rinsed 5-cm-long wire. Each septum received 50 µl of the treatment solutions after which it was let dry for 30 min in a laboratory hood. Each septum was wrapped in aluminum foil and septa from the same treatment were placed in the same ziplock plastic bags and put in a cooler with ice. In the field, septa were taped by the wire to the underside of lids of green, white, and yellow universal moth traps (Biagro, Valencia, Spain). A different pair of rubber gloves was used to handle each treatment septa. A piece of plastic material loaded with insecticide (Dichlorvos[®]) was placed in the bottom of each trap to kill the trapped males.

The data were analyzed with ANOVA after being transformed ($\sqrt{x+1}$). For the test of concentrations, the terms in the model were lure, year, and lure × year. For the test of the effect of individual compounds, lure was the only term in the model. Differences among means were analyzed with Tukey's means separation test. In this and all other tests, except for those in the wind tunnel, the analyses were performed with the SAS statistical package (SAS Institute, 2000).

Wind Tunnel

The wind tunnel was a $2 \times 0.5 \times 0.5$ m ($l \times w \times h$) aluminum frame with glass walls on all four sides. A fan blowing air into the tunnel was placed in one of the two open ends (upwind end), and an extractor was connected to the other end (downwind end). Mosquito screen sealed both ends to prevent moths from escaping. One of the lateral glass walls had two sliding doors to access the inside of the tunnel. Regulating the speed of fan and extractor created a laminar flow inside of the tunnel of 0.3 m/sec throughout. Incoming air passed through a 1-cm-thick glass wool filter before entering into the tunnel. The glass bottom of the cage rested on black cardboard. Illumination, which was kept at the minimum necessary to see the moths, was provided by a 36-W fluorescent red light placed in the ceiling of the room and covered with a white cloth so that its intensity was 1.80 and 1.48 lx at the top and bottom of the tunnel, respectively. Temperature in the wind tunnel room was maintained at $24 \pm 1^\circ\text{C}$ by means of a heating/cooling unit, whereas relative humidity was ambient. A hood extracted air continuously, thus minimizing contamination of the room air with pheromone.

Treatment blends (Table 2) were loaded onto hexane-rinsed rubber septa, the solvent was allowed to evaporate, and the septa were kept individually in hexane-rinsed vials and stored at -20°C until used. At least 8 hr before the scotophase of observation, 3-d-old males were placed in individual 3×6 cm ($w \times h$) metal mosquito-screen cages and provided with 10% sugar water on a cotton pad. They were brought to the darkened wind tunnel room at least 15 min before the test started. Male response was observed between the third and the fifth hour of the scotophase. At the time of the test, a treatment septum was placed on a 10×10 cm galvanized metal top plate of a 16×6 cm ($h \times \text{diam}$) 1-cm-grid galvanized-wire platform that was centered on the floor at the upwind end of the tunnel. The caged males were placed individually on a similar metal platform 1.4 m downwind from the pheromone source. Each treatment blend was presented consecutively to two to three individual males before changing to a new treatment. Forty males were tested

Table 2 Quantity (micrograms) of *S. nonagrioides* sex pheromone components in *O. nubilalis* pheromone lures used in wind tunnel tests to determine their antagonist effect on *O. nubilalis*

Compound	Treatment name ^a									
	On	Ac	OH	12	0.1% Ald	0.3% Ald	1% Ald	3% Ald	10% Ald	Sn

12:Ac	–	–	–	2	–	–	–	–	–	2

^aSepta were loaded with 40 μg of the *O. nubilalis* pheromone alone (On), with individual components of the *S. nonagrioides*: pheromone [Z11-16: Ac (Ac), Z11-16:Ald (Ald), Z11-16:OH (OH) and 12:Ac (12)], or with the sex pheromones of *S. nonagrioides* (Sn).

for each treatment and each male was tested only once. The treatment septa were replaced for new ones after 20 insects were tested.

After release, male behavior was observed for 2 min. Behaviors recorded included oriented flight (upwind zigzagging flight on the pheromone plume), contacting the pheromone source, and attempting copulation with the pheromone dispenser. Ryan's multiple range test for proportions (Ryan, 1960) was used to compare the treatments within each response category.

Electrophysiology

Males (2- to 4-d-old) were taken out of the rearing chamber during the scotophase shortly before being tested. They were immobilized with an insect pin and one of their antennae was detached with fine forceps. The proximal end of the antenna was placed in the narrow end of a Pasteur pipette filled with saline solution (0.2 M KCl). Several terminal segments of the distal end of the antenna were excised, and the blunt end was placed in a second capillary. Gold wires, 1-mm diam, connected the saline-filled capillaries to an electroantennogram (EAG) probe/preamplifier (PR-05, Syntech, Hilversum, the Netherlands) and IDAC-02 (Syntech) signal interface box. The antennal preparation (inside a steel mesh screen wired to the ground socket of an electric outlet) was introduced into a 7-mm-diam Teflon[®] tube, which carried humidified room air continuously at 1 l/min. Puffs of test samples were delivered through a hole in the tube with an air compressor that produced a flow of 0.3 l/min. The samples (10 μ l) were loaded onto hexane-rinsed and twice-folded rectangular filter paper pieces (1.5 cm²) placed into the wide section of a Pasteur pipette. The electric signal generated by the antenna was acquired in a PC that was equipped with a data acquisition board (Syntech) and EAG 2000 (Syntech) data analysis software.

EAG Calibration Curve

The calibration curve started with the blank (hexane), followed by the positive control (1 μ g pheromone of *O. nubilalis*). Then 0.1 μ g of each of the pheromone components of *S. nonagrioides* and *O. nubilalis*, followed by 1 and 10 μ g of the same components. Solvent and positive control were puffed every 3-4 test samples and at the end of the run. The order of the treatments was randomized between antennae. Each sample was puffed three times (puff duration ca 0.25 sec), and their average constituted the experimental unit. The Teflon[®] tube was rinsed with acetone at the end of each day. The experiment was replicated on 20 antennae using two different pieces of filter paper with a given test sample. Pipettes were stored at -20°C between uses. To control for variation among antennae, the average amplitude of each set of three EAG responses was divided by the average EAG amplitude of the nearest set of three puffs of the positive control. Comparison among treatments was performed on transformed data ($\sqrt{x+1}$) using a general linear model (GLM) with compound, concentration, and compound \times concentration as the terms of the model. Following GLM, a least square means analysis and the slice option (SAS Institute, 2000) were used to determine the significant differences between the means of all the treatment combinations.

Fig. 1 The number of *O. nubilalis* males captured in traps baited with 100 µg of its own pheromone alone (0%Sn) or with increasing percentages of the *S. nonagrioides* pheromone (1%Sn, 10%Sn, 50%Sn, and 100%Sn). Control traps (HEX) were loaded with hexane. Different letters indicate differences among treatments after Tukey’s mean separation test ($P < 0.05$)

Fig. 2 The number of *O. nubilalis* males captured in traps baited with 100 µg of its own pheromone alone (On), its own pheromone plus individual components [Z11-16:Ac (Ac), Z11-16:OH (OH), 12:Ac (12), and Z11-16:Ald (Ald)] or the complete pheromone blend of *S. nonagrioides* (Sn). Control traps (HEX) were loaded with hexane. Different letters indicate differences among treatments after Tukey’s mean separation test ($P < 0.05$)

Cross-Adaptation EAG

The experiment consisted of two parts. In the first, a 1.5-cm long, 5-mm internal diam section of Teflon[®] tube containing a piece of filter paper loaded with 10 μ l of hexane was introduced into the humidified airstream passing over the antenna, upstream from the point where the puff would be applied. The response of a fresh antenna to the pheromone components of *O. nubilalis*, Z11-14:Ac and E11-14:Ac, a known antagonist (Z9-14:Ac) (Glover et al., 1989), Z11-16:Ald, and hexane was recorded by applying three puffs 20 sec apart of each treatment, with 1 min between treatments. In the second part of the experiment, the short section of tube containing the hexane filter paper was replaced by a new one containing one of the adapting stimuli. At 2 to 3 min after the adapting stimulus was introduced, the response of the same antenna to the same sample puffs was measured again, maintaining the same treatment order as before. The antenna was then discarded. Each antenna was considered a replicate of an adaptation treatment. The order of the puff treatments for each replicate was randomized among antennae. The section of the pipette exposed to the adapting stimulus was rinsed with acetone after each set of three puffs. We used concentrations of adapting odors that, as determined in preliminary tests, caused some adaptation but did not impair antennal response (0.01 μ g Z11-14:Ac, 0.1 μ g E11-14:Ac, 0.1 μ g Z9-14:Ac, 1 μ g Z11-16:Ald), and concentrations of test stimuli that were 10 times higher to obtain discernible EAG responses in the adaptation conditions. To estimate the amount of adaptation the mean of the three puffs of a given treatment was divided by the mean of the three puffs of hexane. This normalized EAG response after adaptation was divided by the equivalent response before adaptation (= adaptation index). The lower the index value, the higher the effect of the adapting stimulus. Ideally, a value of 1 means no adaptation. The data were transformed [$\log(x + 1)$] and analyzed with ANOVA followed by a planned means comparison test (Tukey's) ($N = 18$).

Results

Field Tests

Year had no effect on the captures ($df = 1, 47, F = 3.20, P = 0.083$) and there was no significant lure \times year interaction ($df = 5, 47, F = 1.07, P = 0.394$) in the data that were pooled (Fig. 1). Captures of *O. nubilalis* in traps loaded with its pheromone were reduced to a level similar to that of hexane traps when 10% or more of the complete *S. nonagrioides* pheromone was added to the blend ($df = 5, 47, F = 15.38, P < 0.001$). The only pheromone component of *S. nonagrioides* that decreased significantly the captures of *O. nubilalis* in the field, to a level comparable to the hexane traps, was Z11-16:Ald ($df = 6, 27, F = 18.94, P < 0.01$) (Fig. 2).

Wind Tunnel Tests

As in the field test, Z11-16:Ald (at 1% or more) was the only pheromone component of *S. nonagrioides* that caused a significant reduction in the percentage of *O. nubilalis* orientating to its own pheromone ($P < 0.05$) (Fig. 3). All the pheromone components of *S. nonagrioides*, at the same concentration that they

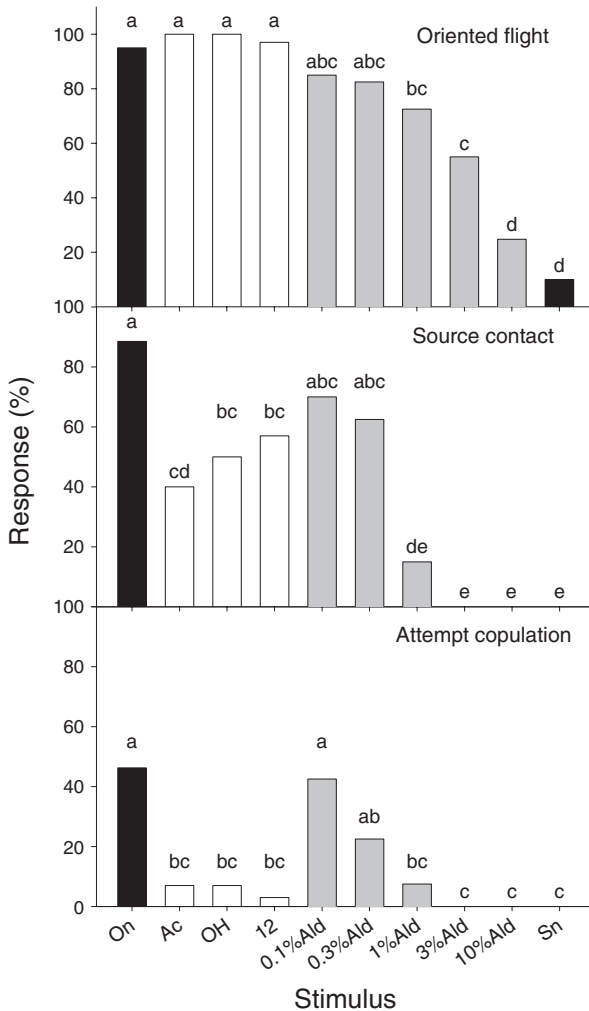

Fig. 3 The different behavioral responses (oriented flight, contact, and attempted copulation with the pheromone source) of *O. nubilalis* males in the wind tunnel to its own pheromone alone (On), its own pheromone plus individual components [Z11-16:Ac (Ac), Z11-16:OH (OH), 12:Ac (12), and Z11-16:Ald (Ald)] or the complete pheromone blend of *S. nonagrioides* (Sn). For Z11-16:Ald, five concentrations (0.1–10%) were used. Different letters indicate significant differences among treatments within each behavioral category (Ryan’s test, $P < 0.05$)

occur in the blend, caused reduction in the percentage of males that contacted ($P < 0.05$) or attempted copulation ($P < 0.05$) with the lure. As with oriented flight a minimum of 1% of Z11-16:Ald was necessary to reduce both contact and attempted copulation with the septum.

EAG Calibration Curve

Both concentration and compound had an effect on EAG peak amplitude ($df = 2, 359, F = 252.45, P < 0.01$, and $df = 5, 359, F = 143.27, P < 0.01$, respectively). The

Table 3 Mean (\pm SE) and means separation of EAG responses of *O. nubilalis* male antennae to three concentrations of its own pheromone components and those of *S. nonagrioides*

Compound ^a	Dose ^b		
	0.1 μ g	1 μ g	10 μ g
Z11-14:Ac	0.45 \pm 0.02 aC	0.82 \pm 0.03 aB	1.19 \pm 0.09 aA

interaction was significant ($df = 10, 359, F = 11.35, P < 0.01$) due to the much higher response of some of the treatments at the highest concentration (Table 3). The highest EAG responses were to the main components of the pheromone, followed by 12:Ac and Z11-16:Ald, depending on the concentration. At the lowest 0.1 μ g

Fig. 4 Effect of adaptation of *O. nubilalis* male antennae on its response to conspecific pheromone components and behavioral antagonists. The adaptation index reflects the decrease of the antennal response after it has been exposed to the adapting stimulus, shown on the top of each graph. Different letters within each graph indicate differences among adaptation indexes using Tukey's mean separation test ($P < 0.05$)

pheromone concentration the difference among treatments was not as marked as at the 10 μg concentration. The lowest response was obtained with Z11-16:OH at any concentration.

Cross-Adaptation EAG

Exposing the antenna to a continuous flow of a pheromone compound resulted in a significant lower response to a puff of this compound than to a puff of most of the other components (Fig. 4). Z11-14:Ac adapted the antenna more to itself than any other compound ($df = 3$, $F = 6.71$, $P < 0.001$), whereas E11-14:Ac ($df = 3$, $F = 6.73$, $P < 0.001$), Z9-14:Ac ($df = 3$, $F = 7.89$, $P < 0.001$), and Z11-16:Ald ($df = 3$, $F = 5.63$, $P < 0.001$) caused greater adaptation to themselves than to some of the other pheromone components (Table 3).

Discussion

Z11-16:Ald is the only pheromone component of *S. nonagrioides* that reduces the attraction of *O. nubilalis* to its own pheromone. The antagonism in the field probably occurs at long range, as Z11-16:Ald was the only pheromone component of *S. nonagrioides* that reduced both oriented flight in the wind tunnel and trap captures in the field. However, the other *S. nonagrioides* components reduced source contact in the wind tunnel, although less strongly than Z11-16:Ald. The small antagonistic effect of these compounds could explain why the 1% Z11-16:Ald field blend (treatment 10%Sn), which included them, reduced trap captures by 90%, whereas the 1% Z11-16:Ald tunnel blend (treatment 1% Ald), which did not include them, reduced oriented flight only by 26%. This finding explains why mating disruption against *S. nonagrioides* using different blends of its sex pheromone components caused a reduction in the population of *O. nubilalis* only when Z11-16:Ald was present in the blend (Eizaguirre et al., 2002).

In addition to Z11-16:Ald several other compounds are known to antagonize the response of *O. nubilalis*. For instance, the minor component of the Z strain, E11-14:Ac, when present in a larger than natural proportion, and (*E*)-9-tetradecenyl acetate (E9-14:Ac) act as antagonists (Klun and Robinson, 1971; Klun et al., 1979). A 0.1% mixture of (*Z*)-9-dodecenyl acetate (Z9-12:Ac) or Z9-14:Ac added to a 100:3 blend of Z11-14:Ac and E11-14:Ac reduces captures of *O. nubilalis* in the field by 50% (Struble et al., 1987). Further tests with these two compounds and their *E* isomers in the wind tunnel showed that just 1% of any of them in the blend reduced oriented flight from 97 to 26–42% compared to the pheromone alone, and contact with the source from 95 to 2–61% (Glover et al., 1989). The strongest antagonist in these studies was Z9-14:Ac, and its antagonistic strength, both in the field (Struble et al., 1987) and in the wind tunnel (Glover et al., 1989), was similar to the level we have found for Z11-16:Ald.

Single-sensillum recording (SSR) has revealed three types of pheromone receptor neurons in the antenna of *O. nubilalis* males, two that respond, respectively, to the pheromone components Z11-14:Ac and E11-14:Ac, and a third type that responds to the behavioral antagonist Z9-14:Ac (Hansson et al., 1987). Our cross-adaptation EAG test showed that each of these compounds really only adapted the antenna to that specific compound, validating the method, which has been used in previous

insect pheromone studies (Gemeno et al., 2003). The new antagonist, Z11-16:Ald, one of the minor pheromone components of *S. nonagrioides*, also caused a significantly higher adaptation to this compound than to the pheromone components of *O. nubilalis*, suggesting that Z11-16:Ald is perceived by a specific odor receptor neuron that is different from those tuned to the pheromone components of *O. nubilalis*. There also was moderate cross-adaptation between the two antagonists, Z11-16:Ald and Z9-14:Ac, which suggests both might be detected by the same olfactory receptor neuron. However, this seems unlikely given that, with some exceptions, pheromone receptor neurons are narrow in their specificity of response (Todd and Baker, 1999), and these two compounds have different functional groups. Clearly, in order to resolve this question additional SSR tests need to be performed.

Although there are many examples of pheromone antagonism among pairs or groups of species, the adaptive significance has only been demonstrated in a few cases. For example, *H. zea* males have neurons that respond to Z11-16:Ald and Z9-16:Ald that are produced by conspecific females, as well as one attuned to Z9-14:Ald, a compound that is produced by *H. virescens*. Z9-14:Ald acts as an antagonist to *H. zea*, which benefits both species as cross-attraction and mating is possible, given they both have Z11-16:Ald as the major compound in their respective pheromone blends (reviewed by Mustaparta, 1997). Similar cases of adaptive antagonism have been described in other moths (Cardé and Haynes, 2004) and beetles (Leal, 1996; Borden, 1997).

Although there are some exceptions (Potting et al., 1999), many examples of interspecific antagonism among unrelated species have not come from research specifically studying this phenomenon, but rather from mixing pheromone blends for other purposes (Lopez et al., 1990; Haynes et al., 2002) or from mating disruption tests (Eizaguirre et al., 2002). Despite using the same host plant and having some seasonal overlap, there is little apparent selection pressure for the evolution of behavioral antagonism between *O. nubilalis* and *S. nonagrioides*, as they belong to different families, differ in size, do not share pheromone compounds, and mate at different times of the night. Consequently, an adaptive explanation for the existence of this antagonism may be the result of other species with which they both interact. In the case of *S. nonagrioides*, there is a sympatric sister species, *S. cretica*, whose pheromone consists of Z9-14:Ac and Z9-14:OH, and the former is a behavioral antagonist for *S. nonagrioides* (G. Rotundo, personal communication). Additional research looking at a number of different species will have to be examined in order to rigorously test this hypothesis.

Acknowledgments We thank A. Escué, R. Gigato, J. Safont, R. Vaquera, and P. Vigata for technical support and the farmers for letting us use their fields. Abstract Several studies have shown intraspecific geographical variation in the composition of sex pheromones. Pheromone lures from North America and Europe were not effective against the fall armyworm *Spodoptera frugiperda* (Smith, 1797) (Lepidoptera: Noctuidae) in Brazil, so we examined the composition of the sex pheromone produced by females from Brazilian populations. Virgin female gland extracts contained (*Z*)-7-dodecenyl acetate (*Z*7-12:Ac), (*E*)-7-dodecenyl acetate (*E*7-12:Ac), dodecyl acetate, (*Z*)-9-dodecenyl acetate, (*Z*)-9-tetradecenyl acetate (*Z*9-14:Ac), (*Z*)-10-tetradecenyl acetate, tetradecyl acetate/(*Z*)-11-tetradecenyl acetate (*Z*11-16:Ac), and (*Z*)-11-hexadecenyl acetate. The relative proportions of each acetate were 0.8:1.2:0.6:traces:82.8:0.3:1.5:12.9, respectively. This is the first time that *E*7-12:Ac has been reported from the pheromone gland of *S. frugiperda*. Only three compounds, *Z*9-14:Ac, *Z*7-12:Ac, and *E*7-12:Ac, elicited antennal responses, and there were no differences in catch between traps baited with either *Z*7-12:Ac + *Z*9-14:Ac or *Z*7-12:Ac + *Z*9-14:Ac + *Z*11-16:Ac blends. However, the *Z*7-12:Ac + *Z*9-14:Ac + *E*7-12:Ac blend was significantly better than *Z*7-12:Ac + *Z*9-14:Ac, indicating that *E*7-12:Ac is an active component in the sex pheromone of the Brazilian populations of *S. frugiperda*.

Introduction

The fall armyworm *Spodoptera frugiperda* (Smith) (Lepidoptera: Noctuidae) is an important economic pest of maize and other grass crops in North America, Central America, and parts of South America (Andrews, 1988). In Brazil, this species causes substantial damage in various crops, such as sugarcane and sorghum, and is the most important pest in maize causing yield reduction up to 34% (Cruz et al., 1996). At present, despite the negative environmental impact, as well as negative human and animal health effects, pesticides are the preferred means of controlling this pest. However, success is limited because of the location of larvae when feeding on the host plant. More effective and ecologically acceptable means of control are required.

The sex pheromone of *S. frugiperda* has been studied extensively with (Z)-9-tetradecenyl acetate (Z9-14:Ac) being the first pheromone component reported (Sekul and Sparks, 1967), whereas later studies have reported additional components (Jones and Sparks, 1979; Mitchell et al., 1985; Tumlinson et al., 1986; Descoins et al., 1988). However, blends that proved successful in trapping fall armyworm males in North America and Europe performed poorly when tested in Brazil (Cruz et al., unpublished results), Costa Rica (Andrade et al., 2000), and Mexico (Malo et al., 2001).

Moth sex pheromones are species-specific communication systems for mate location and would be under intense stabilizing selection when selection pressures are similar for all populations (Hansson et al., 1990). However, significant intraspecific geographic variation in the pheromone composition of insects, especially moths, has been reported (Anglade et al., 1984; Löfstedt et al., 1986; Hansson et al., 1990; Löfstedt, 1990; Tóth et al., 1992; Miller et al., 1997; Andrade et al., 2000; El-Sayed et al., 2003). These are probably the result of different selective pressures acting on allopatric populations of the same species. Thus, the failure to effectively capture Brazilian fall armyworm males with European and North American lures may be caused by geographic variability in the sex pheromone. Furthermore, in the case of *S. frugiperda*, there are at least two morphologically indistinguishable host-plant-specific strains (Pashley et al., 1985, 1992; Pashley, 1986; Levy et al., 2002) that are also present in Brazil (Busato et al., 2002). Therefore, we undertook a study of the sex pheromone of Brazilian *S. frugiperda*, in both laboratory and field experiments, and developed a short and efficient synthetic route for the preparation of the pheromone components.

Methods and Materials

Insect Rearing

The colony of *S. frugiperda* was established at the Insect Bioassay Laboratory of the Universidade Federal de São Carlos, Brazil, using pupae collected in maize plantations at Piracicaba, in São Paulo State, Brazil. All specimens were from the second

generation that had been reared on a pinto bean-based artificial diet (Parra, 1986). The pupae were sexed, placed in individual plastic vials (6 × 6 cm diam), and then held in an incubation chamber under a reversed 12:12 hr light/dark photoperiodic cycle, at 25 ± 1°C, 70 ± 5% relative humidity, until the adults emerged.

Pheromone Extraction

During peak calling activity, about the 4th hour of the second scotophase (Tumlinson et al., 1986), the abdominal tips, with pheromone glands, were excised from virgin females after emergence and extracted for 24 hr in hexane. The supernatant was collected and stored in dark microvials with Teflon[®]-lined screw caps at –20°C until needed. Five extracts of 24, 30, 30, 31, and 36 pheromone glands were prepared.

Chromatographic Analysis

Gland extracts and synthetic solutions were analyzed on a Shimadzu 17-A chromatograph, equipped with a DB-1 column (30 m × 0.25 mm, i.d. 0.25 μm; J&W Scientific) coupled to Shimadzu QP 5000 mass spectrometer using helium as carrier gas. Split (synthetic standards) and splitless (gland extracts) injections of 2 μl of the sample and standard solution [(Z)-7-dodecenyl acetate (Z7-12:Ac), (E)-7-dodecenyl acetate (E7-12:Ac), dodecyl acetate (12:Ac), Z9-14:Ac, and (Z)-11-hexadecenyl acetate (Z11-16:Ac)] were performed at 250°C. The initial oven temperature was 50°C for 1 min, then increased to 230°C at a rate of 5°C/min, and finally to 280°C at a rate of 25°C/min. The final temperature was retained for 21 min. Electron impact mass spectra were monitored at 70 eV in the *m/z* range of 33–250.

The geometric isomers were separated on a Shimadzu 17-A chromatograph with a flame ionization detector (FID) equipped with a 30 × 0.25 mm, i.d. 0.25 μm DB-5 column (J&W Science) using H₂ as carrier gas. The oven temperature program was 50°C for 1 min up to 145°C at a rate of 3°C/min, then to 230°C at 5°C/min, and finally to 280°C at 30°C/min, where it was maintained for 21 min. The coinjection (isothermal analyses at 100°C) was carried out by injecting simultaneously 2 μl of the gland extract and 1 μl of a diluted standard solution containing E7-12:Ac and Z7-12:Ac.

Coupled Gas Chromatography–Electroantennographic Detection

Pheromone extracts were subjected to gas chromatography–electroantennographic detection (GC-EAD) analyses, using a Shimadzu 17-A gas chromatograph, equipped with a DB-5 column (30 m × 0.25 mm, i.d. 0.25 μm; J&W Scientific) and a Syntech electroantennography system (Hilversum, The Netherlands). The same chromatographic conditions as for the GC–mass spectrometry (MS) analyses were used for the chromatographic separation. The FID was kept at 280°C, whereas the temperature of the transfer capillary was maintained at 290°C to avoid condensation.

Electrophysiology

Electroantennogram (EAG) recordings of Z7-12:Ac, Z9-14:Ac, and Z11-16:Ac alone and in various combinations were tested at 0.01, 0.10, 0.25, 0.50, 0.75, 1.00, 10.00, and 100.00 mg/ml, using antennae of 1- to 2-d-old *S. frugiperda* males. The

antenna was stimulated with 0.3-sec puffs of purified and humidified air (1.2 l/min) delivered through a Pasteur pipette, containing a filter paper strip (ca. 0.8 cm), impregnated with 5 μ l of the test solution. Puffs from a filter paper plus solvent were used as control stimulus. The test compounds (Z7-12:Ac, Z9-14:Ac, and Z11-16) alone were used at increasing concentrations, i.e., a range of doses starting from the lowest to the highest, and blends were applied randomly. All test compounds were applied at intervals of 30 sec. Hexane stimulation was made at the beginning and at the end of every series of EAG experiments. The Syntech EAG software calculated the normalized values automatically.

Synthesis of Pheromone Components

Unless otherwise noted, all commercially available reagents were purchased from Aldrich Chemical Co. and were purified, when necessary, according to the usual procedures described in the literature. The infrared (IR) spectra refer to films and were measured on a Bomem M102 spectrometer. ^1H and ^{13}C NMR spectra were recorded on both a Bruker ARX-200 (200 and 50 MHz, respectively) and a DRX-400 (400 and 100 MHz, respectively). Mass spectra were recorded on a Shimadzu GCMS-QP5000. Analytical thin-layer chromatography was performed on a 0.25- μm film of silica gel containing fluorescent indicator UV₂₅₄ (Sigma-Aldrich). Flash column chromatography was performed using silica gel (Kieselgel 60, 230–400 mesh, E. Merck). Gas chromatography was performed in a Shimadzu GC-17A with H_2 as carrier and using a DB-5 column.

Preparation of bromoalcohols 2: The diol (65 mmol), HBr 48% (8.2 ml, 78 mmol), and benzene (180 ml) were mixed and refluxed for 12 hr in a 250-ml flask with Dean-Stark and reflux condensers. Once the temperature reached rt, an ice bath was added to precipitate out the excess diol. The solid was filtered and washed with chilled benzene. The crude product was employed in the next step after concentration *in vacuo* without further purification.

1-Bromo-8-octanol (2a): 83% yield. IR (film): ν_{max} (cm^{-1}) = 3352, 2930, 2857, 1464, 1249, 1053. ^1H NMR (400 MHz, CDCl_3): δ (ppm) = 3.69 (t, 2H, J = 6.6 Hz), 3.41 (t, 2H, J = 6.8 Hz), 1.90 (quint, 2H, J = 8.0 Hz), 1.60 (quint, 2H, J = 6.6 Hz), 1.5–1.2 (m, 8H). ^{13}C NMR (50 MHz, CDCl_3): δ (ppm) = 25.51, 28.03, 28.70, 29.19, 32.76(2C), 34.02, 62.99. MS (70 eV): m/z (%) = 55 (100), 69, 83, 109, 111, 148, 150, 162, 164.

1-Bromo-10-decanol (2b): 78% yield. IR (film): ν_{max} (cm^{-1}) = 3367, 2927, 2856, 1460, 1366, 1245, 1041. ^1H NMR (200 MHz, CDCl_3): δ (ppm) = 3.63 (t, 2H, J = 6.4 Hz), 3.40 (t, 2H, J = 6.8 Hz), 1.85 (quint, 2H, J = 6.8 Hz), 1.50–1.70 (m, 2H), 1.20–1.50 (m, 12H). ^{13}C NMR (50 MHz, CDCl_3): δ (ppm) = 62.97, 34.00, 32.79 (2C), 29.47, 29.35 (2C), 28.71, 28.13, 25.70. MS (70 eV): m/z 55 (100%), 69, 83, 97, 135, 137, 148, 150, 162, 164.

1-Bromo-6-hexanol (2c): 75% yield after purification by column chromatography in silica gel and hexane: ethyl acetate 20:1 as eluent. IR (film): ν_{max} (cm^{-1}) = 3343, 2900, 1696, 1453, 1247, 1058. ^1H NMR (200 MHz, CDCl_3): δ (ppm) = 3.64 (t, 2H, J = 6.4 Hz), 3.42 (t, 2H, J = 6.6 Hz), 1.88 (quint, 2H, J = 6.6 Hz), 1.56 (quint, 2H, J = 6.7 Hz), 1.3–1.7 (m, 4H). ^{13}C NMR (50 MHz, CDCl_3): δ (ppm) = 62.17, 33.90, 32.65, 32.43, 27.86, 24.87. MS (70 eV): m/z 55 (100%), 67, 69, 83, 92, 94, 106, 108, 134, 136.

Alkylation of 1-hexyne with bromoalcohols **2**: At -20°C , 1-hexyne (1 mmol) was placed in a 25-ml flask containing THF (2 ml) under N_2 atmosphere, and then an *n*-BuLi solution in hexane (2.2 mmol) was added dropwise. The bath temperature was allowed to rise to 0°C over 30 min, then returned to -30°C , at which time a solution of the bromoalcohol **2** (1 mmol) in HMPA or DMI (2 ml) was added dropwise. Water was added, and the mixture was extracted with ethyl ether (3×15 ml). The organic layer was washed with an aqueous solution of HCl 10% (3×10 ml) and brine (3×10 ml), dried over NaSO_4 , and concentrated *in vacuo*. The crude product was purified by flash chromatography in silica gel with hexane/ethyl acetate 6:1 as an eluent (see Table 1).

9-Tetradecyn-1-ol (**3a**): IR (film): ν_{max} (cm^{-1}) = 3338, 2930, 2857, 1462, 1331, 1056. ^1H NMR (200 MHz, CDCl_3): δ (ppm) = 3.6 (t, 2H, $J = 6.7$ Hz), 2.52 (s, 1H), 2.13 (t, 4H, $J = 5.8$ Hz), 1.32–1.55 (m, 16H), 0.9 (t, 3H, $J = 7.1$ Hz). ^{13}C NMR (50 MHz, CDCl_3): δ (ppm) = 80.07 (2C), 62.68, 32.63, 31.19, 29.28, 29.06 (2C), 28.71, 25.66, 21.84, 18.65, 18.35, 13.53. MS (70 eV): m/z 54, 67, 81, 96 (100%), 110, 121, 135, 167.

11-Hexadecyn-1-ol (**3b**): IR (film): ν_{max} (cm^{-1}) = 3347, 2924, 2857, 1460, 1227, 1056, 745. ^1H NMR (200 MHz, CDCl_3): δ (ppm) = 3.6 (t, 2H, $J = 0.5$ Hz), 2.13 (t, 4H, $J = 6.0$ Hz), 1.29–1.55 (m, 20H), 0.90 (t, 3H, $J = 6.9$ Hz). ^{13}C NMR (50 MHz, CDCl_3): δ (ppm) = 80.15 (2C), 62.8, 32.68, 31.23, 29.35 (4C), 28.48, 25.90, 25.71, 21.88, 18.71, 18.40, 13.6. MS (70 eV): m/z 55 (100%), 69, 83, 102, 116, 123, 147, 152, 194.

7-Dodecyn-1-ol (**3c**): IR (film): ν_{max} (cm^{-1}) = 3376, 2932, 2863, 1455, 1364, 1225, 1053, 913, 733. ^1H NMR (200 MHz, CDCl_3): δ (ppm) = 3.53 (t, 2H, $J = 6.5$ Hz), 2.72 (s, 1H), 2.07 (t, 4H, $J = 6.7$ Hz), 1.28–1.52 (m, 12H), 0.9 (t, 3H, $J = 6.8$ Hz). ^{13}C NMR (50 MHz, CDCl_3): δ (ppm) = 80.15 (2C), 62.48, 32.50, 31.15, 29.00, 28.53, 25.23, 21.81, 18.57, 18.31, 13.49. MS (70 eV): m/z 54, 67(100%), 81, 93, 110, 121, 153.

Hydrogenation of alkynols **3**: Quinoline (0.6 ml) and Lindlar reagent (0.3 g) were added to a solution of alkynol **3** (14.3 mmol) in methanol (30 ml), and the resulting suspension was hydrogenated at rt under hydrogen atmosphere for 6 hr. The mixture was filtered, washed with ethyl ether (3×10 ml), and the filtrate was then washed with a 1 M aqueous solution of HCl (3×10 ml), saturated solution of CuSO_4 (3×10 ml), and brine (2×10 ml). The solvent was evaporated at reduced pressure to provide the desired product.

(*Z*)-9-Tetradecen-1-ol (**4a**): 85% yield. IR (film): ν_{max} (cm^{-1}) = 3338, 2926, 2857, 1459, 1046, 715. ^1H NMR (200 MHz, CDCl_3): δ (ppm) = 5.16–5.32 (m, 2H), 3.50 (t, 2H, $J = 6.5$ Hz), 2.85 (s, 1H), 1.8–2.0 (m, 4H), 1.45 (quint, 2H, $J = 6.3$ Hz), 1.1–1.3 (m, 14H), 0.89 (t, 3H, $J = 7.0$ Hz). ^{13}C NMR (50 MHz, CDCl_3): δ (ppm) = 129.7 (2C), 62.46, 31.84, 30.65, 29.63, 29.36 (2C), 29.13, 27.05, 26.77, 25.70, 22.20, 13.83. MS (70 eV): m/z 55(100%), 67, 82, 96, 109, 123, 138, 166, 194.

Table 1 Alkylation reaction of 1-hexyne with bromoalcohols **2** (Fig. 2) in different solvents^a

Entry	Bromoalcohol 2 (n)	Yield (%)	
		HMPA	DMI
1	5	90	87
2	7	90	91
3	9	83	88

^a Bromoalcohol **2** was added in dry HMPA or DMI and 1-hexyne in dry THF.

(*Z*)-11-Hexadecen-1-ol (**4b**) and (*Z*)-7-Dodecen-1-ol (**4c**) were obtained as described above and employed in the acetylation reaction without further purification or characterization.

(*E*)-7-Dodecen-1-ol: Small pieces of sodium metal (0.35 g, 15 mmol) were added to liquid ammonia (20 ml) held at -70°C . This was briskly stirred until all the sodium had dissolved to give a blue-colored solution, at which time a solution of alcohol **3c** (0.14 g, 0.75 mmol) in THF (0.5 ml) was added. The reaction was followed by GC analyses. The ammonia was allowed to evaporate, saturated ammonium chloride solution was cautiously added, and then the reaction mixture was extracted with ether (3×15 ml). The organic layer was washed with brine (30 ml), dried over MgSO_4 , filtered, and evaporated *in vacuo*. The residue was chromatographed on silica gel (hexane/ethyl acetate, 95:5), and 0.127 g of the (*E*)-7-dodecen-1-ol was obtained (90% yield). IR (film): ν_{max} (cm^{-1}) = 3320, 2920, 2860, 1465, 1040. ^1H NMR (200 MHz, CDCl_3): δ (ppm) = 5.28–5.47 (m, 2H), 3.64 (t, 2H, $J = 6.4$ Hz), 1.85–2.05 (m, 4H), 1.1–1.7 (m, 13H), 0.88 (t, 3H, $J = 6.6$ Hz). ^{13}C NMR (50 MHz, CDCl_3): δ (ppm) = 130.46, 130.13, 63.03, 32.75, 32.49, 32.25, 31.82, 29.57, 28.89, 25.59, 22.18, 13.94.

Acetylation of alcohols **4**: Alcohol **5** (7 mmol), acetic anhydride (2.0 ml, 21 mmol), pyridine (2.8 ml), and hexane (35 ml) were mixed in a 125-ml flask, stirred at rt for 8 hr, before adding ethyl ether (50 ml) and then washing the organic layer with a 1 M aqueous solution of HCl (3×50 ml) and 1 M NaOH (3×50 ml). The solvent was removed under reduced pressure, and the residue was purified by flash chromatography on silica gel with hexane/ethyl acetate 9:1 as the eluent.

(*Z*)-9-Tetradecenyl acetate (**5a**): 90% yield, isomeric purity >99% by GC. IR (film): ν_{max} (cm^{-1}) = 3002, 2928, 2857, 1743, 1461, 1367, 1239, 1040, 721. ^1H NMR (200 MHz, CDCl_3): δ (ppm) = 5.26–5.42 (m, 2H), 4.05 (t, 2H, $J = 6.7$ Hz), 1.9–2.1 (m, 7H), 1.5–1.7 (m, 2H), 1.15–1.45 (m, 14H), 0.89 (t, 3H, $J = 7.0$ Hz). ^{13}C NMR (50 MHz, CDCl_3): δ (ppm) = 171.2, 129.8 (2C), 64.6, 31.9, 29.7, 29.4, 29.2 (2C), 28.6, 27.14, 26.9, 25.9, 22.32, 20.96, 13.96. MS (70 eV): m/z 55(100), 61, 67, 82, 96, 110, 124, 151, 194.

(*Z*)-11-Hexadecenyl acetate (**5b**): 91% yield in two steps, isomeric purity >99% by GC. IR (film): ν_{max} (cm^{-1}) = 3002, 2927, 2856, 1743, 1461, 1366, 1239, 1040, 721. ^1H NMR (200 MHz, CDCl_3): δ (ppm) = 5.25–5.50 (m, 2H), 4.04 (t, 2H, $J = 6.7$ Hz), 1.85–2.1 (m, 7H), 1.60 (quint, 2H, $J = 6.7$ Hz), 1.1–1.4 (m, 18H), 0.89 (t, 3H, $J = 6.9$ Hz). ^{13}C NMR (50 MHz, CDCl_3): δ (ppm) = 171.05, 129.77 (2C), 64.56, 31.93, 29.72, 29.48 (3C), 29.23 (2C), 28.58, 27.14, 26.87, 25.88, 22.30, 20.88, 13.93. MS (70 eV): m/z 55, 67, 82, 96 (100), 110, 124, 138, 152, 166, 180, 222.

(*Z*)-7-Dodecenyl acetate (**5c**): 85% yield in two steps, isomeric purity >99% by GC. IR (film): ν_{max} (cm^{-1}) = 3003, 2930, 2859, 1742, 1460, 1367, 1239, 1041, 725. ^1H NMR (200 MHz, CDCl_3): δ (ppm) = 5.23–5.4 (m, 2H), 4.05 (t, 2H, $J = 6.6$ Hz), 1.95–2.1 (m, 7H), 1.62 (quint, 2H, $J = 6.5$ Hz), 1.25–1.45 (m, 10H), 0.89 (t, 3H, $J = 6.8$ Hz). ^{13}C NMR (50 MHz, CDCl_3): δ (ppm) = 171.00, 129.92, 129.48, 64.48, 31.87, 29.52, 28.79, 28.52, 26.98, 26.83, 25.75, 22.25, 20.83, 13.87. MS (70 eV): m/z 55, 61, 67, 81 (100), 96, 123, 138, 152, 166.

(*E*)-7-Dodecenyl acetate: isomeric purity >99% by GC. IR (film): ν_{max} (cm^{-1}) = 3010, 2935, 2860, 1740, 1453, 1368, 1045, 730. ^1H NMR (200 MHz, CDCl_3): δ (ppm) = 5.15–5.40 (m, 2H), 4.05 (t, 2H, $J = 6.6$ Hz), 2.04 (s, 3H), 1.50–2.00 (m, 4H), 1.05–1.50 (m, 12H), 0.89 (t, 3H, $J = 6.8$ Hz). ^{13}C NMR (50 MHz, CDCl_3): δ (ppm) = 171.40,

130.52, 130.05, 64.61, 32.43, 32.23, 31.80, 29.45, 28.70, 28.57, 25.76, 22.16, 20.95, 13.89. MS (70 eV): m/z 55, 61, 67, 81(100), 96, 123, 138, 152, 166.

Field Experiments

All tests were conducted in Embrapa experimental maize plantations at Sete Lagoas, Minas Gerais State, Brazil. Pherocon 1C traps were suspended at the top of the plant canopy (100 cm above ground level) at 20-m intervals. In all trials, traps were emptied every second day. They were baited with red rubber septa (Aldrich Chemical Co.) impregnated with pheromone components in hexane. We ran the following trials to compare the efficacy of:

- (1) Z7-12:Ac + Z9-14 (0.01:1.00 mg) and Z7-12:Ac + Z9-14:Ac + Z11-16:Ac (0.01:1.00:0.10 mg). There were three replicates run over 26 d.
- (2) 10, 1, and 0.1 mg of Z7-12:Ac + Z9-14:Ac + Z11-16:Ac [at a 1:100:15 (m/m) ratio]. There were five replicates run over 24 d.
- (3) 10, 1, and 0.1 mg of Z7-12:Ac + Z9-14:Ac [at 1:100 (m/m) ratio]. There were five replicates run over 24 d.
- (4) Z7-12:Ac + Z9-14:Ac (0.01:1.00 mg), E7-12:Ac + Z9-14:Ac (0.01:1.00 mg), and Z7-12:Ac + E7-12:Ac + Z9-14:Ac (0.01:0.01:1.00 mg). There were 5 replicates run over 28 d.

In the last three trials, traps baited with either rubber septa impregnated with hexane or two virgin females, provided with 10% sucrose solution as food source, were used as controls. The treatments were replicated in a Latin square design (Perry et al., 1980).

Statistical Analysis

The mean values of the EAG responses calculated automatically by software EAG for Windows, as well as the data from the first field trial, were submitted to one-way analysis of variance (ANOVA) and compared using Tukey's test ($P < 0.05$). The last three field experiments were submitted to two-way ANOVA and compared using Tukey's test ($P < 0.05$).

Results

The virgin female gland extracts of Brazilian *S. frugiperda* showed seven peaks with spectral characteristics of long-chain acetates (Fig. 1). The two largest peaks, 4 and 7, were identified, based on mass spectral analysis, retention times compared with known synthetic standards, and index comparisons, as Z9-14:Ac and Z11-16:Ac, respectively. The mass spectrum of peak 5 indicated an acetate with one double bond based on the retention index data reported by Marques et al. (2000) and was identified as (Z)-10-tetradecenyl acetate (Z10-14:Ac). Mass spectrum of peak 6 showed characteristics of saturated and unsaturated long-chain acetates (abundance of the m/z 61, M-60), suggesting a coelution of (Z)-11-tetradecenyl acetate (Z11-14:Ac) and tetradecyl-1-ol acetate (14:Ac). This assumption was supported by the similarity of our results with the retention index data of these two compounds

Fig. 1 Chromatogram of the gland extract of *Spodoptera frugiperda* virgin females, analyzed on a DB-1 column. Identification of peaks: (1) Z7-12:Ac, (2) E7-12:Ac, (3) 12:Ac, (4) Z9-14:Ac, (5) Z10-14:Ac, (6) 14:Ac/Z11-14:Ac, and (7) Z11-16:Ac. ($N = 30$)

reported by Marques et al. (2000). The last three acetates present in minor quantities were identified as Z7-12:Ac (peak 1), E7-12:Ac (peak 2), and 12:Ac (peak 3) using mass spectrum analysis and retention time comparisons and coinjection with the synthetic compounds (Fig. 2). While confirming the presence of these geometric isomers of the dodecanyl acetate by using a prolonged temperature program during the GC separation, we found another substance in trace quantities coeluting with Z9-12:Ac, but, given the small quantities, were unable to carry out any further analyses. The relative proportions of Z7-12:Ac, E7-12:Ac, 12:Ac, Z9-12:Ac, Z9-14:Ac, Z10-14:Ac, 14:Ac/Z11-14:Ac, and Z11-16:Ac in gland extracts of virgin females were 0.8:1.2:0.6:traces:82.8:0.3:1.5:12.9, respectively.

The straight chain (C_{10} – C_{16}) alcohols or acetates with a double bond that are found in many sex pheromones are typically prepared by a Wittig reaction or by alkylation of an acetylene with an alkyl halide followed by selective reduction. However, the Wittig reaction is not as stereoselective as the alkylation route,

Fig. 2 Synthetic route for the preparation of the sex pheromone components of *S. frugiperda*

Fig. 3 Co-injection of gland extract of *S. frugiperda* virgin females and with standard solution containing *E7-12:Ac* and *Z7-12:Ac* analyzed on a DB-1 column (30 × 0.25 mm; 0.25 μm under isothermal conditions at 100°C)

Fig. 4 Coupled gas chromatogram–electroantennogram (GC-EAD) of a male *S. frugiperda* antenna, stimulated by a gland extract of virgin female *S. frugiperda* ($N = 36$)

whereas the alkylation route usually includes a protection of the bromoalcohol as tetrahydropyranyl ether resulting in a decreased overall yield.

Mitra and Reddy (1989) synthesized Z9-14:Ac in ten steps starting from an alkylation of the dianion of 4-butyne-1-ol, prepared with two equivalents of n-BuLi in THF-HMPA, with 1-bromopentane that gave a 60% yield of 3-octyn-1ol. Lo and Chao (1990) substituted HMPA, which is quite toxic, for DMI as solvent in the alkylation step of ω -tetrahydropyranyloxy-1-alkynes with bromoalkanes in the synthesis of Z9-14:Ac and Z11-16:Ac.

We present an alternate four-step synthetic method for this type of compound employing alkylation of alkynes with bromoalcohols in HMPA at -30°C . We also investigated DMI as a solvent, and the alkylation occurred equally well (Fig. 3 and Table 1). Thus, using this methodology, Z9-14:Ac, Z7-12:Ac, and Z11-16:Ac, pheromone components of *S. frugiperda*, have been efficiently prepared.

Fig. 5 Coupled GC-EAD of a male *S. frugiperda* antenna, stimulated by a mixture of synthetic pheromone blends: (a) Z7-12:Ac, Z9-14:Ac, and Z11-16:Ac; (b) E7-12:Ac, Z9-14:Ac, and Z11-16:Ac

Fig. 6 Mean values (\pm SD) of EAG responses of *S. frugiperda* males to individual compounds Z7-12:Ac, Z9-14:Ac, and Z11-16:Ac in different concentrations (0.01, 0.1, 0.25, 0.5, 0.75, 1.0, 10.0, and 100.0 mg/ml) and control (hexane). For any given compound, the mean values with the same letter are not significantly different at $P < 0.05$ based on Tukey’s test ($N = 10$)

The strongest EAD response from the pheromone gland extract was elicited by the major sex pheromone compound Z9-14:Ac (Fig. 4). We were unable to separate the geometric isomers Z7-12:Ac and E7-12:Ac, so the second peak (Fig. 4) could be the sum of the depolarizations from both compounds, as the two induced responses when antennae were stimulated by mixtures of synthetic Z7-12:Ac, Z9-14:Ac, and Z11-16:Ac (Fig. 5a) and E7-12:Ac, Z9-14, and Z11-16:Ac (Fig. 5b).

Over the range of concentrations from 0.01 to 100 mg/ml, Z11-16:Ac never showed greater electrophysiological activity than hexane, whereas Z7-12:Ac and Z9-14:Ac gave significantly higher responses than controls at concentrations of 0.5 mg/ml and above (Fig. 6).

Fig. 7 Number ($X \pm$ SD) of *S. frugiperda* males captured in Pherocon 1C traps baited with Z7-12:Ac + Z9-14:Ac (0.01:1.00 mg), Z7-12:Ac + Z9-14:Ac + Z11-16:Ac (0.01:1.00:0.10 mg), or hexane solvent (three replicates and 13 collections). Mean values with the same letter are not significantly different (one-way ANOVA followed by Tukey’s test; $P < 0.05$)

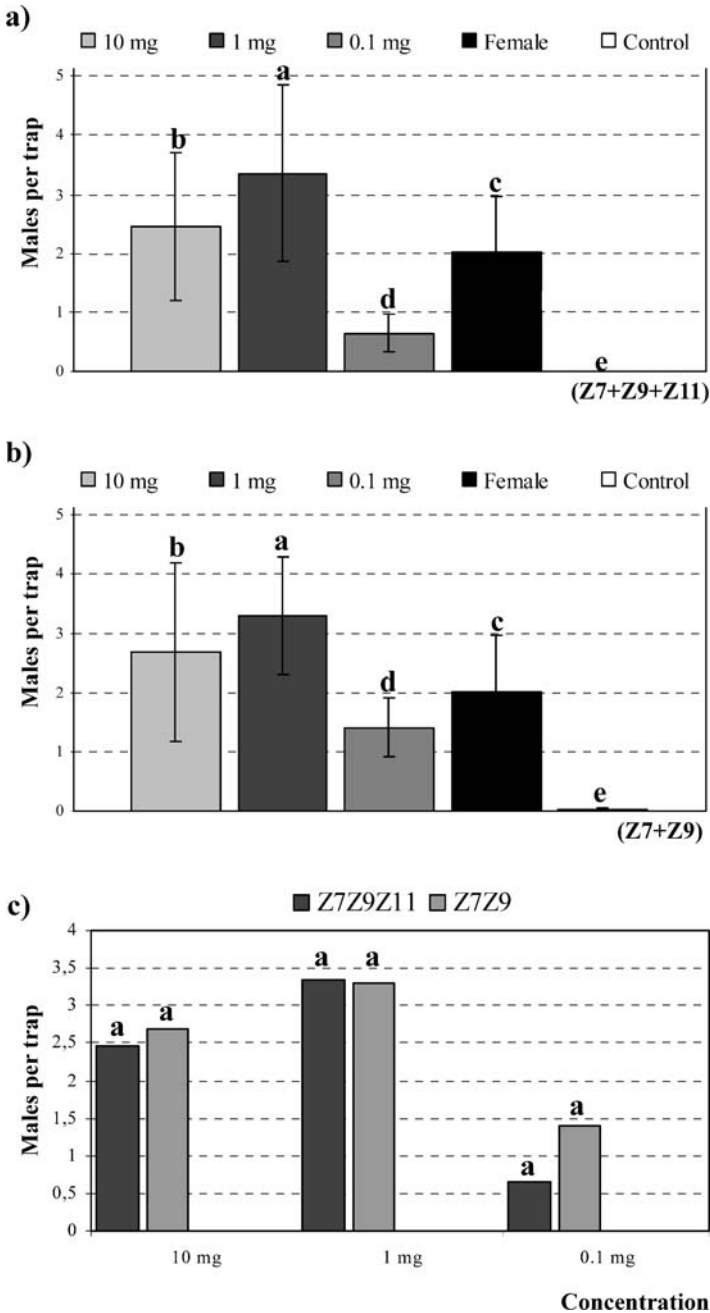

Fig. 8 Number ($X \pm SD$) of *S. frugiperda* males captured in Pherocon 1C traps baited with: (a) Z7-12:Ac + Z9-14:Ac + Z11-16:Ac (1:100:15 ratio) at doses of 10, 1, and 0.1 mg, hexane solvent, and two virgin females (five replicates and 12 collections); (b) Z7-12:Ac + Z9-14:Ac (1:100) at doses of 10, 1, and 0.1 mg, hexane solvent, and two virgin females (five replicates and 12 collections); (c) Z7-12:Ac + Z9-14:Ac + Z11-16:Ac (1:100:15 ratio) and Z7-12:Ac + Z9-14:Ac (1:100 ratio) at doses of 10 g, 1 g, and 0.1 mg, respectively (five replicates and 12 collections). Mean values with the same letter are not significantly different (two-way ANOVA followed by Tukey's test; $P < 0.05$)

Fig. 9 Number ($X \pm SD$) of *S. frugiperda* males captured in Pherocon 1C traps baited with Z7-12:Ac + Z9-14:Ac at ratios of 0.01:1.00 mg, E7-12:Ac + Z9-14:Ac at ratios of 0.01:1.00 mg, Z7-12:Ac + E7-12:Ac + Z9-14:Ac at ratios of 0.01:0.01:1.00 mg, hexane solvent, and two virgin females (five replicates and 14 collections). Mean values with the same letter are not significantly different (two-way ANOVA followed by Tukey's test; $P < 0.05$)

Pherocon 1C traps, baited with either Z7-12:Ac + Z9-14:Ac (0.01:1.00 mg) or Z7-12:Ac + Z9-14:Ac + Z11-16:Ac (0.01:1.00:0.10 mg), captured similar numbers of males and, in both cases, were significantly higher than controls (Fig. 7). All concentrations of Z7-12:Ac + Z9-14:Ac + Z11-16:Ac (1:100:15 ratio) captured significantly more males than controls, and the two higher concentrations out-competed virgin females. The 1-mg lure was more effective than either the 0.1- or 10-mg ones (Fig. 8a), in the latter case probably because of receptor saturation. Similar patterns were observed with different concentrations of two- and three-component blends (Fig. 8), with all concentrations tested catching more than controls, and the higher doses performing better than virgin females (Fig. 8a,b). The addition of Z11-16:Ac to Z7-12:Ac and Z9-14:Ac did not increase trap catches (Fig. 8c), which is contrary to the results of Andrade et al. (2000) in Costa Rica, where Z11-16:Ac did result in a slight increase in trap efficacy. However, the addition of E7-12:Ac to the binary mixture resulted in a significant increase in the number of males captured (Fig. 9).

Discussion

The pheromone glands of *S. frugiperda* from North America were found to contain Z7-12:Ac, Z9-12:Ac, Z9-14:Ac, and Z11-16:Ac (Mitchell et al., 1985; Tumlinson et al., 1986; Descoins et al., 1988), whereas in Guadeloupe (Caribbean), the main components reported were Z9-12:Ac, Z9-14:Ac, and Z11-16:Ac (Andrade et al., 2000). In the present study, we also found Z9-14:Ac and Z11-16:Ac but for the first time report the presence of E7-12:Ac, present in higher quantities than Z7-12:Ac.

Malo et al. (2004) reported that Z9-14:Ac and Z9,E12-14:Ac evoked larger EAG responses than Z7-12:Ac in male antennae of *S. frugiperda*, from Mexico, whereas Z11-16:Ac and Z9,E11-14:Ac did not differ from the control hexane. The antennae of *S. frugiperda* males from Costa Rica respond to Z11-16:Ac (cited as unpublished

results of R. Gries in Andrade et al., 2000) but not in our studies, as significant EAG responses were only observed to Z9-14:Ac, Z7-12:Ac, and E7-12:Ac (Figs. 4 and 5). A comparison of our EAG data with those from North and Central America, together with the results of our field trials, supports the idea that different geographic pheromone races exist in *S. frugiperda*, as reported in other noctuids (Löfstedt et al., 1986; Tóth et al., 1992; Wu et al., 1999; Gemeno et al., 2000). These findings are important for the practical use of pheromones for monitoring of *S. frugiperda* populations in Brazil, and the Z7-12:Ac, E7-12:Ac, and Z9-14:Ac (0.01:0.01:1.00 mg, respectively) blend is currently being tested in integrated pest management of the fall armyworm in Brazilian maize crop.

Abstract 6-Methoxy-benzoxazolin-2(3H)-one (MBOA) inhibited the germination of cress (*Lepidium sativum* L.) seeds at concentrations greater than 0.03 mM. Inhibition was overcome by sucrose, suggesting that MBOA may inhibit sugar metabolism in cress seeds. Induction of α -amylase activity in seeds was also inhibited by MBOA at concentrations greater than 0.03 mM. Inhibition of both germination and induction of α -amylase activity increased with increasing concentrations of MBOA, and the extent of germination correlated positively with the activity of α -amylase in the seeds. MBOA added to a reaction mixture for α -amylase assay did not affect enzyme activity, indicating that MBOA does not inhibit *in vitro* α -amylase activity. Cress seeds germinated approximately 16 hr after incubation, and inhibition of α -amylase by MBOA occurred within 6 hr after incubation. These results suggest that MBOA may inhibit the germination of cress seeds by inhibiting the induction of α -amylase activity, because α -amylase plays a key role in the conversion of reserve carbohydrate into soluble sugars, a prerequisite for seed germination.

Introduction

6-Methoxy-benzoxazolin-2(3H)-one (MBOA) was first found in *Croix lacryma-jobi* L. (Koyama, 1955) and later in several graminaceous plant species such as wheat, corn,

and maize (Niemeyer, 1988). Benzoxazolinones, including MBOA and their precursor hydroxamic acids, have been recognized as resistance agents in plants because of their phytotoxic activity on insects (Dowd and Vega, 1996; Bravo and Copaja, 2002), fungi, and bacteria (Frey et al., 1997; Yue et al., 1998; Glenn et al., 2002).

MBOA and related compounds have also attracted attention because of their allelopathic effects (Barnes and Putnam, 1987; Inderjit and Duke, 2003; Belz and Hurlle, 2004). MBOA inhibits the germination and growth of several plant species (Pérez, 1990; Hayashi et al., 1994; Kato-Noguchi et al., 1998; Kato-Noguchi, 2000). At concentrations greater than 0.03 mM, MBOA inhibits the germination of *Digitaria sanguinalis* (L.) SCOP, *Lolium multiflorum* LAM, and *Pheleum pretense* L. (Kato-Noguchi, 2000). However, the physiological mechanism of MBOA on germination inhibition is not understood.

This study focused on the mechanism of inhibition of seed germination by MBOA. α -Amylase is considered to be essential for seed germination because this enzyme triggers starch degradation in the endosperm and enables seeds to germinate and grow (Perata et al., 1992, 1997; Vartapetian and Jackson, 1997). It is possible that MBOA inhibits germination because of its inhibition of α -amylase activity in seeds. Thus, the effects of MBOA on germination and α -amylase activity in cress seeds were investigated.

Methods and Materials

Plant Material

Seeds of cress (*Lepidium sativum* L.) were sterilized in a 2% (w/v) solution of sodium hypochlorite for 15 min and rinsed (4 \times 's) in sterile distilled water. All further manipulations were carried out under sterile conditions. MBOA (purchased from Sigma; 0.001, 0.03, 0.1, 0.3, 1, or 3 mM, final concentrations in Tween 20 solution described below) was dissolved in a small volume of methanol and added to two sheets of filter paper (No. 1, Merck) in a 9-cm Petri dish. The solvent was allowed to evaporate in a draft chamber for 1 hr. The filter paper in the Petri dish was then moistened with 4 ml of 0.05% (v/v) aqueous Tween 20. Sucrose (1 mM) was added into the medium in the Petri dish. Fifty seeds of cress were arranged on the filter paper and the Petri dishes were sealed. After incubation in the dark at 25°C for 6–48 hr, the lengths of emerged radicles of cress seeds were measured with a ruler. Seeds were considered to have germinated when their radicles emerged. Experiments were repeated three times, and the mean, standard error (SE), *t*-test value, and regression coefficient were calculated. For determination of α -amylase activity, cress seeds were harvested, frozen immediately in liquid N₂, and freeze-dried.

Pulse Treatment of MBOA

Cress seeds were incubated with 0 or 3 mM MBOA in 0.05% (v/v) aqueous Tween 20 solution in the dark at 25°C for 24 hr as described above. Then, the seeds were rinsed (5 \times 's) with sterile distilled water, transferred onto two sheets of fresh filter paper moistened with fresh Tween 20 solution containing 0 or 3 mM MBOA, and grown under the same conditions for 24 hr.

Extraction and Assay of α -Amylase

Freeze-dried cress seeds (10 seeds for each determination) were ground to a fine powder in a mortar by use of a pestle. The powder was homogenized with 1.5 ml of ice-cold 100 mM HEPES–KOH (pH 7.5) solution containing 1 mM EDTA, 5 mM $MgCl_2$, 5 mM dithiothreitol, 10 mM $NaHSO_3$, and 50 mM bovine serum albumin. The homogenate was centrifuged at $30,000 \times g$ for 30 min; the supernatant was heated with 3 mM $CaCl_2$ at $75^\circ C$ for 15 min to inactivate β -amylase and α -glucosidase (Sun and Henson, 1991; Guglielminetti et al., 1995), then used for α -amylase assay.

α -Amylase was assayed by measuring the rate of generation of reducing sugars from soluble starch. Appropriate dilutions of enzyme preparations were made, and 0.2 ml of the diluted enzyme was added to 100 mM sodium acetate (0.5 ml; pH 6.0) containing 10 mM $CaCl_2$. The reaction was initiated with 2.5% (w/v) soluble starch (0.5 ml). After incubation at $37^\circ C$ for 15 min, the reaction was terminated by adding 40 mM dinitrosalicylic acid (0.5 ml) containing 400 mM NaOH and 1 M K–Na tartrate and then placing immediately into a boiling water bath for 5 min. After dilution with distilled water, the absorbance at 530 nm (A_{530}) of the reaction mixture was measured and reducing power evaluated using a standard curve obtained with glucose (Guglielminetti et al., 1995). Before MBOA was added to the assay, it was first dissolved in differing concentrations of dimethyl sulfoxide, then diluted to 0.001, 0.03, 0.1, 0.3, 1, or 3 mM with the reaction mixture. Experiments were repeated five times, with four assays for each determination.

Results and Discussion

Effects of MBOA on Germination

Radicles of control seeds emerged about 16 hr after sowing. MBOA inhibited germination, with germination completely inhibited by 3 mM MBOA (Fig. 1). When the length of cress radicles was plotted against the logarithm of MBOA concentration, there was a good logistic concentration–response curve (Fig. 2). At concentrations greater than 0.03 mM, MBOA inhibited the growth of cress radicles significantly. The concentration required for 50% inhibition of radicle growth was 0.18 mM (calculated from the regression equation of the concentration–response curve). These results suggest that MBOA inhibited the cress germination process and that the inhibition was increased with increasing MBOA concentrations (Figs. 1

Fig. 1 Effects of MBOA on the germination of cress seeds. Cress seeds were incubated with MBOA in the dark at $25^\circ C$ for 48 hr

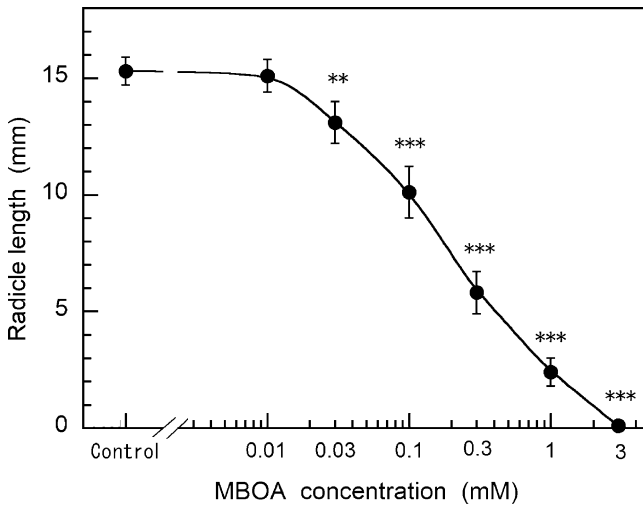

Fig. 2 Effects of MBOA on radicle length of cress seeds. Cress seeds were incubated with MBOA in the dark at 25°C for 48 hr. Means \pm SE from three independent experiments with 50 plants for each determination are shown. **Significant at $P < 0.01$, *** Significant at $P < 0.001$ level as compared with the control seedlings

and 2). MBOA also inhibits germination in several other plant species (Pérez, 1990; Kato-Noguchi, 2000), and uptake of MBOA by plant seeds is significantly faster than uptake of its precursor hydroxamic acid, 2,4-dihydroxy-7-methoxy-2H-1,4-benzoxazin-3(4H)-one (Pérez, 1990).

Germination inhibition by MBOA was overcome by addition of sucrose to the medium (Fig. 3), which suggests that inhibition may not be due to a direct

Fig. 3 Effect of sucrose on MBOA-induced inhibition of cress germination. Seedlings were incubated with 0.3 mM MBOA in the presence and absence of 1 mM sucrose in the dark at 25°C for 24 hr. Control seeds were incubated without MBOA and sucrose. Seeds were considered as germinated if their radicles emerged. Other details as for Fig. 2

influence of MBOA molecules themselves. Considering this observation, MBOA may inhibit sugar metabolism in the seeds because soluble sugars such as maltose and sucrose must be produced continuously from reserve starch to maintain the germination process (Ricard et al., 1998; Saglio et al., 1999; Guglielminetti et al., 2000).

Germination was inhibited when cress seeds were transferred into a solution containing 3 mM MBOA from one without MBOA (0 to 3 mM MBOA; Fig. 4). This suggests that MBOA is able to inhibit the germination process even after radicle emergence. In contrast, after the transfer of seeds into a solution without MBOA from one containing 3 mM MBOA, germination was initiated and radicles began to grow (3 to 0 mM MBOA; Fig. 4). This result indicates that 3 mM MBOA did not kill seeds, and that MBOA absorbed by seeds may be metabolized and detoxified in seeds (Inderjit and Duke, 2003; Glenn et al., 2003; Sicker et al., 2003). However, cress seeds did not germinate at concentrations greater than 300 mM, even after transfer into a solution without MBOA (data not shown).

Effects of MBOA on α -Amylase Activity

MBOA inhibited α -amylase activity in cress seeds at concentrations greater than 0.03 mM (Fig. 5). α -Amylase activity could be fitted to a logistic concentration-response curve when plotted against the logarithm of MBOA concentration. The concentration required for 50% inhibition of activity was 0.16 mM. This value was almost the same as the concentration required for 50% inhibition of radicle growth (Fig. 2).

MBOA was added into the α -amylase reaction mixture, but the enzyme activity was not affected by MBOA in the assay mixture (data not shown), indicating that MBOA does not directly inhibit *in vitro* α -amylase activity. Evaluating α -amylase

Fig. 4 Effects of pulse treatment of MBOA on cress germination. Cress seeds were incubated with 3 mM MBOA (or 0 mM) in the dark at 25°C for 24 hr, and then the seeds were transferred to medium of 0 mM MBOA (or 3 mM MBOA), and grown for 24 hr. ○, 0 to 0 mM MBOA; ●, 0 to 3 mM MBOA; □, 3 to 0 mM MBOA; ■, 3 to 3 mM MBOA. *** Significant at $P < 0.001$ level as compared between ● and ○, and □ and ■. Other details as for Fig. 2

Fig. 5 Effects of MBOA on α -amylase activity in cress seeds. Cress seeds were incubated with MBOA in the dark at 25°C for 48 hr. Means \pm SE from five independent experiments with four assays for each determination are shown. Other details as for Fig. 2

induction at the protein level, as influenced by MBOA showed an increase in inhibition with increasing MBOA concentrations. In addition, both concentration–response curves (Figs. 2 and 5) indicate that length of cress radicles is positively correlated with α -amylase activity in seeds.

Figure 6 shows changes in α -amylase activity in cress seeds after sowing. The activity in control seeds (0 mM MBOA) was low at time 0 and increased as germination proceeded. Radicles emerged about 16 hr after sowing. MBOA

Fig. 6 Changes in α -amylase activity in cress seeds. Cress seeds were incubated with MBOA in the dark at 25°C. Means \pm SE from five independent experiments with four assays for each determination are shown. Other details as for Fig. 2

inhibited the induction of α -amylase activity within 6 hr after sowing, and the inhibition was greater with increasing MBOA concentrations. At 48 hr, the activities in seeds treated with 0.1 and 0.3 mM MBOA were 58 and 32% of that in control seeds, respectively, whereas the activity in seeds treated with 3 mM MBOA remained almost unchanged.

Although the α -amylase activity in control cress seeds increased continually (0 to 0 mM MBOA; Fig. 7), the rate of increase was reduced when cress seeds were transferred into 3 mM MBOA from a solution without MBOA (0 to 3 mM MBOA; Fig. 7), suggesting that MBOA may slow down the increase in α -amylase activity even after radicle emergence. In contrast, enzyme activity increased after transfer to 0 mM MBOA from a solution containing 3 mM MBOA (3 to 0 mM MBOA; Fig. 7) and radicles of these seedlings resumed a growth rate similar to that of untreated seedlings (Fig. 4). This suggests that α -amylase activity in cress seeds correlates well with the germination process (Figs. 4 and 7), and the induction of α -amylase may occur after MBOA is metabolized and detoxified, as suggested above.

Starch breakdown during seed germination is triggered by α -amylase that catalyzes the hydrolysis of α -1,4 glucan linkages to produce maltose and larger oligosaccharides (Beck and Ziegler, 1989; Vartapetian and Jackson, 1997). α -Amylase induction in many seeds is regulated by gibberellin at the transcriptional level (Ritchie and Gilroy, 1998). Inhibition of α -amylase activity by MBOA occurred within 6 hr after sowing (Fig. 6). Considering that radicles emerged around 16 hr after sowing, this inhibition may not be too late to inhibit the translation process of α -amylase.

Although it is possible that MBOA inhibits gibberellin biosynthesis, inhibitors of gibberellin biosynthesis do not inhibit the increase in α -amylase production during germination (Groselindemann et al., 1991). During germination, gibberellin precursors stored in seeds are mobilized, and the gibberellin produced triggers α -amylase induction (Groselindemann et al., 1991; Ritchie and Gilroy, 1998). Thus,

Fig. 7 Effects of pulse treatment of MBOA on α -amylase activity in cress seeds. Means \pm SE from five independent experiments with four assays for each determination are shown. Other details as for Fig. 4

MBOA may inhibit α -amylase induction in antagonism with gibberellin-induced events by affecting the α -amylase translation process rather than inhibition of gibberellin biosynthesis. Abscisic acid inhibits α -amylase induction in antagonism with gibberellin-induced events in this manner (Ritchie and Gilroy, 1998).

Germination Inhibition and α -Amylase Activity

Plant germination is a complex phenomenon involving many genes and enzymes. However, amyolytic breakdown of reserve starch in seeds is thought to be a prerequisite for seed germination and subsequent seedling growth. Starch breakdown during seed germination is principally triggered by α -amylase (Beck and Ziegler, 1989; Thomas, 1993; Conley et al., 1999).

During germination, respiration accelerates to produce metabolic energy and biosynthetic precursors for constructing cell structures (Perata et al., 1997). Therefore, soluble sugars that are readily used in respiration must be continuously supplied to maintain respiratory metabolism. However, the amount of utilizable soluble sugars in seeds is usually very limited (Ricard et al., 1998; Saglio et al., 1999; Guglielminetti et al., 2000). α -Amylase plays a major role in the conversion of reserve starch into soluble sugars during germination (Beck and Ziegler, 1989; Vartapetian and Jackson, 1997). Induction of α -amylase is essential to maintain active respiratory metabolism, which produces energy and carbon skeletons for the biosynthesis of new cellular components. Therefore, induction of α -amylase is a prerequisite not only for seed germination, but also subsequent seedling growth until photosynthesis is sufficient to support growth (Beck and Ziegler, 1989; Thomas, 1993; Conley et al., 1999).

MBOA inhibited seed germination and induction of α -amylase in cress seeds. Furthermore, α -amylase activity in the seeds reflected the extent to which they had completed the germination process. These results suggest that MBOA inhibits the induction of α -amylase, which is one possible mechanism of MBOA inhibition of the germination process. The observation that exogenously applied sucrose overcame the inhibitory effect of MBOA supports this hypothesis.

Letter from the Editor-in-Chief

Since 2000, the *Journal of Chemical Ecology* has occasionally published special issues devoted to a single topic. Previous instances include: Allelopathy, September 2000; Aquatic Biology, October, 2002; and Molecular Chemical Ecology, December, 2004. These issues have been well received by the readership, and in many cases have both improved the quality of submitted papers, and moved research in the subdisciplines forward. This issue consists entirely of papers in Mammalian Chemical Ecology. Both invited and contributed papers are included.

The invited papers result from the International Mammalogical Congress held in Sapporo, Japan in August 2005 and focus on mammalian countermeasures against plant metabolites. Some contributed papers complement that theme, and others range from odor perception and mammalian pheromones, to improved methodology for chemical assays. It is a unique collection of work that is certain to provoke discussion, stimulate interest, and likely move the discipline in new directions.

The idea of the special issue was proposed by Editorial Board member William Foley of the Australian National University in Canberra. He has diligently worked with us since inception as a motivating force, a reviewer, and an editor to insure that the issue had broad appeal and appeared in a timely fashion. We acknowledge this major contribution with thanks and appreciation. We hope that *Journal of Chemical Ecology* readers find the issue educational, useful, and provoking.

John T. Romeo
Editor-in-Chief

Preface

This issue of *Journal of Chemical Ecology* focuses on aspects of the chemical ecology of mammals. The issue grew from a Symposium of the 9th International Mammalogical Congress held in Sapporo, Japan, in August 2005, entitled “Mammalian countermeasures against plant secondary metabolites.” This issue contains all but one of the invited papers in that Symposium, but we also are able to include several contributed papers directly related to the Symposium theme as well as a range of other papers, which illustrate the breadth of chemical ecology work on mammals.

Our purpose in initiating the Sapporo Symposium was to summarize current knowledge on the measures that mammals employ to counter plant defenses, in particular chemical defense mediated by plant secondary metabolites (PSMs). Thanks to a long history of studying the subject, we know that plants have evolved an enviable range of defenses. These include altering the foraging behavior of animals, depressing the efficiency of digestion, and ultimately impinging on growth, reproduction, and survival. In contrast to our knowledge of the chemical armory of plants and the variation it shows within species, we have a limited and scattered knowledge about the measures animals employ to counter PSMs. Here lies the key to understanding variation in reproductive success and, thus, mammalian evolution. For example, animals that can cope with particularly noxious diets can use feeding niches that remain beyond the reach of most other animals. There is no doubt that this field of chemical ecology is a fertile one for studying both theoretical and applied aspects of the interactions between animals and plants.

To further our understanding of the coevolution between plants and mammalian herbivores, we need to focus on the likely intraspecific variation in animals. For example, do some individuals or some populations tolerate the effects of PSMs better than others do? There are many examples of heritable variation in plant traits that affect herbivores and of insect traits that enable them to eat those plants. Regrettably, there are few examples where knowledge of variation among individuals has helped explain interactions between mammals and their food plants.

The fate of ingested PSMs provides a good example of the difficulties of exploring variation among individual animals. Ingested PSMs must be transformed to less toxic compounds and readied for excretion in the feces or urine. Toxicological studies in domestic species provide some guide to the types of metabolites we might expect a wild animal to produce. In most mammalian herbivores, however, significant microbial metabolism often precedes or follows enzymatic modification of the ingested compound by liver cytochrome P450 enzymes. Thus, as well as measuring the concentration of PSMs ingested, we also need to quantify the products of many excretory pathways.

Knowledge of the molecular targets and countermeasures that mammals use against PSMs provides the link to studying variation among individuals in enzyme activities and genes. The power of molecular approaches to understanding

variations in the susceptibility of mammals to PSMs is illustrated by the recent discoveries of bitter taste receptors and evidence of their variation among human populations.

We hope that the papers in this issue give readers an overview of the important types of mechanisms in the battles between plants and animals, but more importantly that they inspire them to quantify variation both between and within species. If so, we will improve our understanding of the coevolutionary relationships between mammals and plants.

Behavioral Strategies of Mammal Herbivores Against Plant Secondary Metabolites: The Avoidance–Tolerance Continuum

Glenn R. Iason · Juan J. Villalba

Abstract We review the evidence for behavioral avoidance of plant secondary metabolites (PSMs) and identify how, and the circumstances under which it occurs. Behavioral strategies of avoidance of PSM can only be fully understood in relation to the underlying physiological processes or constraints. There is considerable evidence that animals learn to avoid PSMs on the basis of negative postingestive effects. The extent to which this process determines foraging choices is limited by the ability of animals to experience the consequences of their behaviors and associate particular cues in foods with their specific effects in the body. The proposed learning mechanisms require that animals must at least “sample” plants that contain PSMs. They do not completely avoid PSMs, but there is evidence that they restrict their ingestion to within limits that they are physiologically able to tolerate, and that the amounts of PSM ingested result from a balance between toxicological considerations and the nutrient content of the plant material. These limits are influenced by the kinetics of PSM elimination, which underlies patterns of bite and patch selection from plant parts to landscapes. We suggest that altering spatial location of feeding (to alternative food patches or alternative foods within patches, including plant parts), and temporal distribution of feeding activity, by either cessation of feeding or by continuing to feed, but on alternative foods, can both lead to reduction of the intake and toxic effects of PSMs. We propose that the strategy of avoidance or reduction of intake of PSMs coevolved with the animal’s ability to physiologically tolerate their ingestion, and that avoidance and tolerance are inversely related (the avoidance–tolerance continuum). The animals’ propensity and ability to seek alternatives also vary with the dispersion of their food resources. Further work is required to test these proposals and integrate temporal and spatial aspects of foraging behavior and its nutritional consequences in relation to PSMs.

Introduction

Mammalian herbivores are adapted to the ingestion of plants from which they derive the nutrients and energy for body maintenance, growth, and reproduction. A major problem to their nutrition is posed by the concomitant presence of plant secondary metabolites (PSMs), which are organic compounds usually considered to have no function in the primary metabolic processes of the plant, but which are known to mediate interactions with other organisms including plant defense against pathogens and herbivores (Rosenthal and Berenbaum, 1991). PSMs as a whole are highly diverse, with some representatives occurring in almost all higher plants, particularly dicotyledons (Bate-Smith and Metcalf, 1957; Jung et al., 1979). Their structural and chemical properties vary within and among the many different classes of compounds requiring them to be metabolized by numerous different routes (Scheline, 1991), and leading to a wide range of possible physiological effects on mammals (McArthur et al., 1991; Scheline, 1991). Most, but not all, of these effects are negative (Iason, 2005), including inhibition of digestion (Robbins et al., 1987), toxicity to many organs and tissues (Babich and Davis, 1981; Cheeke, 1988; Fenwick, 1989; Zhu et al., 1992; Vanleeuwen et al., 1995), acidosis (Foley et al., 1995), sodium imbalance (Pehrson, 1983; Reichardt et al., 1990), and diuresis (Dearing et al., 2001).

An early categorization of plant defenses considered them to be “quantitative” such as condensed tannins, thought to act in a dose-dependent manner, and toxic “qualitative” lower molecular weight compounds, whose actions were thought not to be dose-dependent (Feeny, 1976; Rhoades and Cates, 1976). This idea dominated ecological considerations for two decades. However, it is now accepted that all PSMs act in a dose-dependent fashion, and follow toxicological principles, although the forms of the functions, and thresholds and maximum tolerable concentrations differ widely (Timbrell, 1991). Although plant secondary compounds that are acutely toxic in small doses (Garland and Barr, 1998; Acamovic et al., 2004) should be avoided by herbivores, most observations suggest that mammals ingest at least some PSMs, but maintain their levels of intake of them within a range that is physiologically tolerable (Provenza, 1996; Foley et al., 1999). When an animal’s ability to excrete and detoxify PSMs is exceeded, it suffers toxicosis (Freeland and Janzen, 1974), the physiological effects of which are much greater than the costs of detoxification and excretion of compounds ingested at levels that lie within the normal range that can be readily detoxified and excreted (Iason and Murray, 1996). Therefore, in general, mammalian herbivores regulate their ingestion of PSMs, rather than completely avoid them. We propose that the ingestion or avoidance of PSMs should be considered as a behavioral strategy that is integrated with their physiological ability to detoxify and excrete them.

There are now numerous studies and reviews demonstrating that PSMs can underlie a reduction in intake of a single diet type (e.g., Bryant et al., 1983) or avoidance of a PSM-containing food source relative to other available foods either under experimental (e.g., Provenza et al., 1990) or field conditions (Palo and Robbins, 1991; Hjältén and Palo, 1992). To counteract the negative effects of PSMs,

which depend on the dose ingested, mammals must either partially or completely avoid ingestion of them and/or detoxify and eliminate them from their bodies. We review the behavioral means by which mammalian herbivores might limit their intake of PSMs, taking a process-based approach to interpret how these adaptations are underlain by physiological and pharmacological limitations and principles. We then propose a framework that integrates behavioral strategies for avoidance of PSMs with physiological avoidance and tolerance of their effects (the avoidance–tolerance continuum).

Limiting Ingestion of PSMs by Behavioral Means

Herbivorous animals need to feed on plants to obtain nutrients and energy for maintenance, growth, and reproduction. The overall determinants of choice and amounts of food items ingested are likely to be multifactorial. There are many correlative studies that have identified PSMs as determinants of diet choice by mammals, but a wealth of evidence suggests that the choices made by herbivores reflect both the concentration of PSM and nutrients in available food plants (Bergeron and Jodoin, 1987; Marquis and Batzli, 1989; McArthur et al., 1993; Barton and Whiten, 1994; Gauthier and Hughes, 1995; Rodgers and Sinclair, 1997). There are several ways in which PSMs might influence foraging behavior, the most significant of which are considered below.

Although the intake of food usually decreases with increasing concentrations or amounts of PSM (Lawler et al., 2000; Boyle and McLean, 2004), few studies have investigated the effects of PSMs on herbivore foraging decomposed into the specific parameters included in the process-based models of the intake-plant biomass (functional response) relationship (Spalinger and Hobbs, 1992; Gross et al., 1993). Experimental manipulations have shown the precise effects of plant spinescent defenses against mammals, as reducers of bite mass and bite rate (Gowda, 1996), and where secondary metabolites form a significant component of the mass of plant material, such as condensed tannins in woody plants, then they are likely to dilute the mass of nutrient-containing food ingested at each bite, thereby decreasing the foraging efficiency. To date, equivalent experiments with PSMs in whole plants have yet to be performed, but fine-scale temporal distribution of foraging behavior in relation to PSMs in artificial diets was recently quantified (Wiggins et al., 2003). Artificial diets enriched with PSMs can be a useful tool to demonstrate avoidance of PSMs (Tahvanainen et al., 1985) or to assess nutritional effects (Iason and Palo, 1991; Stapley et al., 2000), but they do not permit the study of normal foraging processes, including, for browsing herbivores, fine-scale selection among plant parts (Hofmann, 1989), habitats, and food patches (Bailey et al., 1996). Detailed behavioral responses to PSMs in natural forages are difficult to quantify, partly because of problems posed by acquisition of suitable plant material of known chemical composition. With increasing concentrations of sideroxylonol, a formylated phloroglucinol compound (FPC) of eucalypts, ringtail possums (*Pseudocheirus peregrinus*) decreased their total intake, rate of intake, and intake per feeding bout, and increased their cumulative time spent feeding (Lawler et al., 2000; Wiggins et al., 2005). Although PSM concentrations and composition vary among plant species and between tissues of the same species, they also covary with other parameters of relevance to animal foraging such as nutrient content, fibrousness, or relevant

physical parameters such as stem diameters (Reichardt et al., 1990; Shipley et al., 1999). Attribution of causality to PSMs is therefore difficult. Experimental manipulation of PSMs for quantification of their effects on fine-scale foraging processes will be most effective when plant material is available in which contrasting PSM concentrations or types are present, probably manipulated within a species by selection or genetic modification, independently of other characteristics.

A hierarchy of routes by which PSMs affect foraging behavior has been identified. These routes range from preingestive stimuli (Pass and Foley, 2000), e.g., taste and smell (Elliott and Loudon, 1987; Eppe et al., 1996) to postingestive mechanisms that involve feedback from reduced digestibility, or postabsorptive effects of PSM (Foley et al., 1999). The preingestive mechanisms are likely to act rapidly (e.g., via stimulation of the trigeminal nerve) to determine whether or not a food is eaten, whereas the postingestive mechanisms involve a lag before being sensed initially and take longer to affect foraging. The process of learning to forage can involve interactions between pre- and postingestive stimuli, for example, associating preingestive stimuli with postingestive consequences.

Effect of Postingestive Consequences on Subsequent Behavior

To survive in a world where concentrations of nutrients and toxins change in time and space requires that individuals experience the consequences of their behaviors and constantly modify those behaviors accordingly. Both *preferences* and *selection* (Hodgson, 1979) are probably the result of both positive influences of the nutrient and negative influences of the PSM content of the available foods (Foley et al., 1999; Villalba et al., 2002). A role for previous learning as a determinant of food choices is, however, particularly likely when PSMs are involved, since negative stimuli may produce stronger learning responses than positive ones (Ginane et al., 2005). Toxins ingested with food typically reduce the likelihood of future ingestion due to the negative effects of those chemicals on different metabolic and cellular processes in the consumer.

Physiological Basis for the Integration of the Senses and the Consequences of Feeding

The chemical senses interact with the body through neurophysiological feedback loops (Garcia, 1989; Scott, 1990; Provenza, 1995). The information generated in the gastrointestinal tract is carried to the CNS mainly by the vagus (parasympathetic) and splanchnic (sympathetic) afferent nerves. Afferent nerves for taste converge with visceral afferent nerves in the nucleus tractus solitarius (NTS) of the brain stem. These nerves then proceed from the NTS to the limbic system and from the limbic system to the cortex and back to the NTS (Ricardo and Koh, 1978; Barber and Burks, 1987). Thus, anatomical evidence supports the notion that information from the gastrointestinal tract and taste converge in the CNS, suggesting that how animals evaluate a particular taste is shaped by information on consequences, i.e., postingestive feedback. Taste and postingestive feedback are associated by an affective processing system (Garcia, 1989). This system causes changes in preference that depend on whether the effect on the animal is aversive or positive. The net result is a modified incentive to eat food. Affective changes in acceptability of food, through taste–feedback interactions occur automatically, in the absence of any cognitive

association or memory of the feedback event. Even when animals are anesthetized, postingestive feedback can still alter ingestive behavior. It has been shown that when sheep eat a nutritious food and then receive a toxin dose during deep anesthesia, they become averse to the food (Provenza et al., 1994). Thus, preference changes despite knowledge of the cause of the feedback event. On the other hand, *food selection* involves cognitive choices or decisions among alternatives, which involve cortical processes. The cognitive system integrates the odor and sight of food with its taste. Animals use the senses of smell and sight to differentiate among foods, and to select or avoid foods whose effect on the internal milieu is either positive or aversive (Provenza, 1995). The net result is behavior modification. Together, affective and cognitive processes enable animals to modify their diet as a function of their physiological state and the chemicals present in the environment.

Conditioned Food Aversion as a Mechanism to Prevent Toxicosis

Food intake and diet composition can be modified by herbivores learning to associate negative effects, such as nausea resulting from administration of emetic drugs, with particular food types (Provenza, 1995, 1996), and these conditioned food aversions have also been shown by using secondary metabolites (Provenza et al., 1990; Kyriazakis et al., 1997, 1998). Food aversion learning is the process by which after eating or drinking a specific food, a physiological event or physiochemical agent causes nausea (Garcia, 1989) that is then associated with the flavor of the food. Aversions are usually specific to a particular food, even though an animal may have eaten a meal of several foods (Burrirt and Provenza, 1991), and the aversive effect increases with the concentration of the aversive stimulus, for example, by ruminants in response to lithium chloride (Dutoit et al., 1991). Conditioned aversions in rats can occur within minutes of eating, or gradually over days and weeks (Garcia, 1989). They can be acquired in one single pairing of taste with malaise, and last for a long time even when malaise does not occur for hours after food is consumed (Garcia and Kimeldorf, 1957; Burrirt and Provenza, 1991). Nevertheless, it has been shown that when averted animals saw nonaverted animals eating the conditioned food, they began to sample this food, and eventually the aversion extinguished, as no subsequent adverse reaction followed the ingestive behavior (i.e., social facilitation; Ralphy, 1997). Extinction of a conditioned food aversion can occur rapidly when the target food is familiar instead of novel (Burrirt and Provenza, 1996; Kimball et al., 2002). Likewise, lack of alternative foods decreases the persistence of the aversion (Kimball et al., 2002).

Several mechanisms operate to allow animals to associate specific foods with the postingestive effects of PSMs even when several alternatives are available at the same time, as in diverse plant communities. Learning initially what to eat or not eat, can often be by way of experienced social models, like their mother distinguishing novel from familiar foods (Burrirt and Provenza, 1996). Novel foods are evaluated cautiously by the animal within a meal. Sheep have been shown to acquire an aversion to the novel food when toxicosis followed a meal of several familiar foods and a novel food (Burrirt and Provenza, 1989, 1991). Although the proximity in time between a behavior and its consequences is a key principle of animal learning (Yearsley et al., 2006), this can be overridden by the novelty of a food. Negative effects are associated with novel rather than familiar foods, even if they were not the most recently ingested (Provenza et al., 1993). For example, when toxicosis followed

a meal of five foods, one novel and one that had made them ill in the past, sheep subsequently completely avoided the novel food and markedly decreased their intake of the food that made them ill in the past; but they did not avoid the other three familiar foods (Burritt and Provenza, 1991). This also illustrates the effects of previous experience (Burritt and Provenza, 1996). Previously extinguished food aversion to a familiar food can be readily relearned even 3 years following the initial feeding event (Burritt and Provenza, 1991, 1996).

Flavor discrimination and generalization also allow animals to rapidly identify potentially toxic foods. For example, when lambs were offered cinnamon-flavored rice and then experienced toxicosis, they reduced their preference for cinnamon-flavored rice. When they were subsequently offered wheat, which they prefer, but with cinnamon flavor added, they refused to eat the cinnamon-flavored wheat. Thus, the lambs generalized an aversion from rice to wheat based on a common flavor—cinnamon (Launchbaugh and Provenza, 1993).

Limits of Learning Ability

If animals can learn conditioned food aversions, then why do they sometimes over ingest PSMs and even die from toxicosis? There are several possible reasons for imperfection in their system of learning. Free-ranging herbivores, especially generalists, often encounter and eat several foods during a meal (Zahorik and Houpt, 1981; Van Wieren, 1996), which has been shown to interfere with their ability to associate specific foods with their consequences (Duncan and Young, 2002). This is particularly true for ruminants and other foregut fermenters in which ingested food enters a relatively large fermentation organ that imposes transformations and delays prior to absorption.

To condition a food aversion, the agent ingested must affect the emetic system of the midbrain and brain stem (Garcia, 1989), so learning will not occur if the toxin does not stimulate the emetic system. When the ingested dose of PSM needed to produce the physical response is higher than the toxic dose, it similarly cannot produce a learned response (Molyneux and Ralphs, 1992), e.g., sesquiterpene lactones in bitter rubberweed (*Hymenoxys odorata*) and sneezeweed (*Helenium hoopesii*) have a cumulative effect, and stimulation of the emetic system frequently develops only after a lethal quantity of plant has been consumed.

Sheep in unfamiliar environments prefer familiar to novel foods, even if the familiar foods have previously caused toxicosis (Burritt and Provenza, 1997), e.g., animals familiar with PSM-containing plants in unfamiliar environments may consume amounts of PSMs beyond their capacity of detoxification. These processes would be expected to contribute to cases of acute toxicosis caused by PSMs. These typically involve cases where the plant or the herbivore, often a domestic species, has been introduced or translocated to a new area (Garland and Barr, 1998; Acamovic et al., 2004). They consequently lack the coevolutionary history known to be crucial in shaping the plant–herbivore interaction (Feeney, 1991).

Preingestive Processing of Forage

At least two examples are available of animals processing their forage prior to ingestion. These behaviors may be energetically costly but are hypothesized to manipulate forage quality in the animal's favor, including reduction of the effects of

PSMs. Meadow voles (*Microtus pennsylvanicus*) form piles of clipped twigs of coniferous trees, prior to ingesting them 2 or more days later, after which time their condensed tannins and total phenolic levels are reduced (Roy and Bergeron, 1990). Similar processes are thought to reduce the negative effects of forage phenolics in the hay-piles formed by pikas (*Ochotona princeps*) (Dearing, 1997). The processes of oxidation and complexation of PSMs occur naturally during decomposition, and it is hypothesized they may reduce the reactivity of PSMs rendering them less biologically active when ingested. However, the benefits of these strategies in relation to concomitant changes in nutrient value of the forage have not been rigorously tested in wild mammals. Removal of buds of arctic birch trees by snowshoe hares represents a prior manipulation of plants, hypothesized to reduce the intake of associated resinous material (Bryant and Kuropat, 1980), but it also has the disadvantage of removing the most nutrient-rich part of the twig (Palo et al., 1992).

Spatial Patterning of Foraging; Seeking to Limit PSM Ingestion

Seeking alternative foods is a common means by which animals either avoid or reduce ingestion of those food types containing high concentrations of PSMs. The degree to which animals must move their feeding location varies from a small shift of biting another part of the same plant containing lower concentrations of PSMs, or ingesting an alternative individual of the same or another species at the same location, to shifting to another feeding station, patch, or habitat (Bailey et al., 1996). There are numerous examples of contrasting PSM composition and concentration in different plant parts within species (Waterman et al., 1980) and associated demonstrations of their efficacy as determinants of avoidance of those parts (Bryant et al., 1983; Reichardt et al., 1984; Sinclair et al., 1988; Jogia et al., 1989). Patterns of selection and foraging processes at the larger patch scale derive to a large extent from smaller-scale bite processes, but also from multiple biotic and abiotic environmental considerations such as topography, shelter, sociality, and predator avoidance. PSMs have been implicated in patch-scale foraging processes most effectively when the patches are definable separate entities such as individual trees. Influences of PSMs on patch residence times have been demonstrated in red deer (*Cervus elaphus*) feeding on sitka spruce (*Picea sitchensis*) trees; although initial selection of the trees was based upon tree size, deer foraged for less time and removed less from those trees containing higher concentrations of monoterpenes, before moving to an alternative tree (Duncan et al., 1994). Moose also select trees on an individual basis rather than at the level of the stand (Danell et al., 1991). Use of individual trees leading to aggregated animal distributions was recently demonstrated in koalas (*Phascolarctos cinereus*). The size of the Eucalypt trees (*Eucalyptus* spp.) is the primary determinant of visitation frequency, which is also significantly positively related to foliar nitrogen concentration and negatively related to concentrations of formylated phloroglucinol compounds (FPCs) (Moore and Foley, 2005). This provides a further example that PSMs are merely one aspect of multifactorial determinants of the foraging process.

Temporal Patterns of Foraging Activity

It has been suggested that cattle can limit their ingestion of toxic alkaloids in larkspur pellets by alternating periods of a few days of high ingestion with a period

of low ingestion, when offered only a single food type (Pfister et al., 1997). Similarly, a cyclical, saw-toothed pattern of food intake between days has been observed in common brushtail possums (*Trichosurus vulpecula*) offered only a pelleted diet treated with the FPC jensenone (Stapley et al., 2000). These cyclical patterns are presumably caused by accumulation of toxins that leads to inappetence, during which the normal processes of detoxification and excretion reduce the toxic loads. Where absorption of a PSM is rapid, as in the case of the brushtail possum and the common eucalypt metabolite, 1-8-cineole, plasma concentrations of the compound and its metabolites increase rapidly, and subsequently decline rapidly due to metabolic clearance when foraging ceases, remaining low until the subsequent foraging bout (McLean and Duncan, 2006). When concentration of cineole increased in an artificial diet, the foraging parameters affected were the increased number of foraging bouts, and an overall slower rate of ingestion of food (Wiggins et al., 2003). Similarly, sheep ceased feeding when levels of 1,8-cineole in blood exceeded a critical threshold, and they resumed eating only after toxin concentrations in the body declined due to detoxification and elimination (Dziba et al., 2006). A model of the pharmacokinetic parameters associated with these processes shows the powerful effect of temporal phasing of foraging activity on the animal's ability to regulate its internal concentrations of PSMs below particular limits (Foley et al., 1999).

Integrating Temporal and Spatial Patterns of Foraging Activity

Despite our increasing knowledge on the role of PSMs as determinants of food quality, and an awareness of the spatial variation in PSMs (Lawler et al., 2000), relatively little consideration has been given to their importance in determining spatial ecology of herbivores (Scrivener et al., 2004). An understanding of the pharmacokinetics of PSM ingestion and excretion (Boyle and McLean, 2004) can be integrated with knowledge of rates of encounter and ingestion of PSMs in the environment (Fig. 1). This is likely to be a function of the herbivore's rates and directions of movement, and the characteristics of the PSM-containing patches such as their PSM concentrations and their size and shape, as well as the quality of the alternative forages. The longer the time interval an herbivore is exposed to a single food, then at least theoretically, the higher the likelihood of it correctly associating that food with its postingestive consequences (Yearsley et al., 2006). This leads to the hypothesis that an animal's spatial and temporal patterns of patch residency and toxin ingestion, and the pharmacokinetic characteristics of detoxification, interact to determine its decision making in relation to PSMs.

Dietary Mixing to Reduce the Effects of PSMs

An influential theory for diet diversity in mammalian herbivores is that by mixing food types, animals can avoid overingestion of a particular toxin and thereby limit the toxic effects suffered (Freeland and Janzen, 1974). This has been tested in several studies that show that animals are able to ingest a greater total amount of foods containing PSMs, when allowed to choose between them, than when offered the foods one at a time. It is implicit that once a particular pathway of PSM detoxification is saturated, then foraging on that food type and on others containing PSMs requiring the same pathway should cease, whereas foraging on alternatives containing PSMs

Fig. 1 Integration of temporal kinetics of processing PSM, with spatial patterns of foraging. Note the scale of the spatial patch sizes, determine the path length and rate of change of PSM-containing foraging bouts (darker patches) with bouts in non PSM-containing patches (paler patches). This in turn influences the temporal pattern of exposure of the animal to the PSM, a toxic threshold being more likely to be exceeded in the case of larger PSM patches, and longer foraging bouts within them (source: A.J. Duncan, unpublished data).

requiring other pathways would be permissible. Although choice experiments suggest this to be the case (Freeland and Winter, 1975; Dearing and Cork, 1999; Burritt and Provenza, 2000; Wiggins et al., 2003; Villalba et al., 2004), the critical test of the proposed underlying mechanism, by using PSMs whose metabolism by the animal is known, is yet to be undertaken. However, a crucial first step has been the recent demonstrations that brushtail possums are sensitive to their own detoxification capacity, and vary their food intake accordingly (Marsh et al., 2005).

A diverse diet leads to greater diversity of ingested phytochemicals that may also lead to mutual toxin neutralization or inactivation, which in turn could reduce susceptibility to PSMs. Rats eat more of a combination of foods containing tannins and saponins because tannins and saponins chelate in the intestinal tract, reducing the negative effects of both components (Freeland et al., 1985). If a mammal can evolutionarily or contemporarily learn to avoid certain plant parts because they lower its fitness due to PSM-related effects, it may also learn to seek out certain plant parts, or other substance in the environment because they raise its fitness (Janzen, 1978). The effects of condensed tannins, such as quebracho, in reducing digestibility by binding with dietary protein or digestive enzymes can be counteracted by concomitant ingestion of polyethylene glycol (PEG), which preferentially binds with tannin (Kumar, 1992; Waghorn and Shelton, 1995). In experimental tests, sheep increased their intake of PEG, as tannin concentrations in their diet increased (Provenza et al., 2000). They discriminated the “medicinal” effects of PEG from “nonmedicinal” substances by selectively increasing intake of PEG after eating a meal high in tannins (Villalba and Provenza, 2001). Sheep have also been shown to forage in locations where PEG is present, rather than where it is absent, when offered nutritious foods high in tannins in different locations (Villalba and

Provenza, 2002). Thus, interactions among PSM-containing foods could lead to complementary relationships such that eating a combination of foods may exceed the benefit of consuming any one food in isolation. However, evidence for food choices being driven by these interactions between naturally occurring PSMs is currently lacking. Similarly, it has been proposed that consumption of soil rich in kaolin by African elephants assists the animals in the digestion of browse, through its ability to detoxify the high concentration of PSMs found in tropical forest trees (Houston et al., 2001).

Evidence for Neutrality or Positive Selection for PSMs

Some studies have reported finding no effect of measured PSMs on foraging (Rangen et al., 1994), but examples of positive selection for PSMs are rare. However, the preference for natural forages by roe deer (*Capreolus capreolus*) is positively correlated with the presence of protein-binding phenolics (Tixier et al., 1997). Although roe deer exhibited lower rates of ingestion of artificial diets containing high concentrations of hydrolyzable tannins, compared with a control diet with no tannins, they ate relatively more of the diet to which moderate levels of hydrolyzable tannins had been added (Verheyden-Tixier and Duncan, 2000). We might expect that on occasions, no selection against PSMs will be found, due to the herbivore being effectively counteradapted to suffer no negative effects from their ingestion, for example, due to the roe deer's large salivary glands that secrete saliva containing a tannin-nullifying protein (Duncan et al., 1998). Positive selection, however, is—in this case—inexplicable, in that there is no demonstrated nutritional advantage in ingestion of hydrolyzable tannins, compared to an otherwise identical control diet containing none. However, it could be hypothesized that levels of PSMs that are low enough not to cause a detrimental effect, should occasionally be ingested as they may induce or maintain adaptation of the gut microflora or the animal's enzyme systems. This would protect against future ingestion of larger quantities that may be unavoidable, should foraging options be restricted. This bet-hedging strategy for ingestion of small amounts of PSM has yet to be tested, or distinguished from a general sampling strategy that provides updated information to the animal about the quality of available alternative foods.

It is known that low forage concentrations and low ingested doses of condensed tannins can be nutritionally advantageous by binding with and protecting ingested protein from rumen degradation, allowing it to dissociate from the tannin in the small intestine, thereby increasing its availability to the animal (Barry and Manley, 1984; Barry et al., 1986). Although the conditions under which such ingestion provides a nutritional advantage are quite narrow, this may explain the occasional reports of positive selection for condensed tannins, and ingestion of small amounts of tannin-rich foods (Iason, 2005). Condensed tannins are similarly thought to provide some protection against intestinal helminths, either by positively affecting immunity via nutritional benefits, or by directly inhibiting the parasites (Barry et al., 2002; Marley et al., 2003), in which case herbivores may be using the PSM-containing forages to self-medicate (Athanasiadou and Kyriazakis, 2004). Finally, many PSMs including phenolics have antioxidant properties as well as prooxidant detrimental effects (Appel, 1993), and may, therefore, account for the positive selection of PSMs. This has yet to be demonstrated.

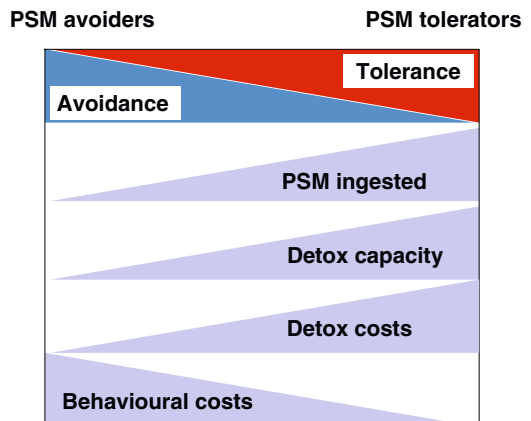

The Triangular Relationship

The examples above demonstrate that there is relatively little reason to suspect that at low levels in plants, PSMs should have a major, or indeed any, influence on mammal herbivore foraging. When PSM concentrations are low, other plant and animal characteristics can determine the overall quality of the food and the amounts of it that are eaten (Foley et al., 1999). The variation in food intake at low levels of dietary PSM is, therefore, high. At higher concentrations, however, the relative power of the effects of PSMs gains preeminence in determining foraging behavior, and they have a demonstrable negative influence on food selection and amounts ingested, leading to the so-called triangular or polygonal relationship with PSM concentration (Danell et al., 1990; Lawler et al., 2000; Scrivener et al., 2004). This is an important step in formulating our expectations of the effects of PSMs on foraging behavior, providing the appropriate perspective on how their effects integrate with other factors.

A Synthesis of Anti-PSM Strategies: The Avoidance–Tolerance Continuum

The way in which mammals trade off the behavioral and ecological costs of avoidance of PSMs with the alternative costs of detoxification, toxicosis, or other negative consequences of ingesting them, forms the basis of a framework that describes their strategy of circumventing PSMs: the avoidance–tolerance continuum. We hypothesize that the processes of detoxification and excretion, and behavioral avoidance are inversely related (Fig. 2). Both incur costs that are contrasting in nature; the former are metabolic and require provision of enzymes for detoxification such as the cytochrome P450 enzymes, and substrates for conjugation prior to excretion (Brattsten et al., 1977; Guengerich, 1997). The behavioral costs are hypothesized to consist mainly of reduced rates of intake arising from greater selectivity to avoid PSMs within food patches, by seeking alternative plant parts or alternative plant species, and/or by greater traveling or searching time for patches of

Fig. 2 Avoidance–tolerance continuum: illustrating the hypothesized negative relationship between the two extreme strategies

food or habitats containing higher nutrient levels or lower amounts of PSM (Hjältén and Palo, 1992; Hulbert et al., 1996; Iason et al., 1996; Wallis De Vries et al., 1998). This latter strategy is also likely to result in greater mortality risk.

At one extreme of the avoidance–tolerance spectrum is the strategy of complete avoidance of PSMs, while at the other extreme is that of no behavioral avoidance but strong physiological adaptation or tolerance to ingested PSMs. In reality, few if any, species are likely to be at the extremes of the continuum, ingesting no PSMs, or being completely without an upper physiological limit of tolerance requiring no behavioral avoidance; most likely they lie somewhere along the continuum between these extremes. Adaptation to PSMs, for example, by induction of enzymes for detoxification or salivary tannin-binding proteins on exposure to absorbed toxins (Pass et al., 2001) or condensed tannins (Mehansho et al., 1987), respectively, can shift an individual animal toward the tolerator end of the continuum. Such changes often take place seasonally with dietary change in response to changing composition of available and ingested food (Iason and Van Wieren, 1999). Conversely, the behavioral equivalent of this physiologically based counter adaptation is processes of associational learning to avoid PSM-containing foods and their negative consequences. This can effectively shift an individual toward the avoidance end of the continuum.

The avoidance–tolerance continuum maps approximately onto the grazer–browser continuum (Hofmann, 1989; McArthur et al., 1991), with avoiders including the grass and roughage feeders that relatively infrequently encounter or ingest PSM-rich food [e.g., sheep (*Ovis aries*), cattle (*Bos primigenius taurus*), topi (*Damaliscus lunatus*), oribi (*Ourebia oribi*)] compared to browser or concentrate selectors [e.g., roe deer (*C. capreolus*), bushbuck (*Tragelaphus scriptus*), greater kudu (*T. strepsiceros*)], which occupy habitats dominated by PSM-rich woody plants. When proposing the classification of ruminant herbivores according to their ecophysiological foraging and digestive strategy into bulk-roughage feeding “grazers” and selective browsers, Hofmann (1989) suggested that “grazers” avoid PSMs, whereas the more selective “browsers” are better able to deal with PSMs via physiologically based detoxification mechanisms. However, this provides a paradox since the browsers undoubtedly exploit more PSM-rich food sources (Iason and Van Wieren, 1999) despite their having finer mouthparts, more suitable for fine-scale selection and avoidance of PSMs (Perez-Barberia and Gordon, 2001). Similarly, the grazers’ avoidance of PSMs is—despite their having broader mouthparts—less conducive to selective foraging (Perez-Barberia and Gordon, 2001). Avoidance of PSMs can, therefore, take place either at the larger spatial scale by avoidance of the habitat, or at the finer scale by selective foraging within habitats, or both. Mammals can be generally avoiders of PSMs, but still highly selective foragers within habitats containing few PSMs [e.g., oribi, and most lagomorphs such as the European rabbit (*Oryctolagus cuniculus*), or European hares (*Lepus europaeus*)]. It is hypothesized that the selection between patches as a means of avoiding PSMs is likely to be more developed in animals close to the “avoiders” end of the continuum, such as cattle, rather than in the “tolerators.” However, recent evidence has shown that even koalas, a marsupial folivore strongly specializing in and adapted to PSM-rich foliages, discern between trees, being less likely to select those with lower concentrations of formylated phloroglucorinol compounds (Moore and Foley, 2005). This suggests that even those considered most specialist in being adapted to ingest PSMs probably have some upper limit of ingestion that influences their foraging behavior. Similarly, although selective avoidance of PSMs within patches

may occur in species lying anywhere in the continuum, it must be predominant among those that do not avoid PSMs at the habitat or patch scale. Any animal that selects positively for PSMs when balancing intake of PSM-rich food against nutrient intake (see above) must be able to tolerate those ingested levels, and is unlikely to be at the avoider end of the spectrum. As well as these foraging consequences of PSMs acting through seeking alternative forages elsewhere in space, animals that ingest PSMs may adjust the temporal distribution of their foraging activity in order to allow clearance of ingested and absorbed PSMs from the body prior to resumption of feeding activity (Foley et al., 1999).

We suggest that the animal's behavioral strategy against PSMs is intimately associated with its physiological strategy, and cannot be interpreted in isolation. It remains a challenge for nutritional ecologists to integrate and understand the relative magnitudes of the behavioral costs of avoidance with the physiological costs of ingestion of PSMs. We should remember that while we celebrate herbivores' ability to continue feeding and avoid toxicity of PSMs, the plants are simultaneously causing either considerable behavioral or physiological inconvenience, or both.

Acknowledgments We thank participants at the IMC symposium on Mammal strategies against PSMs for helpful discussion, Alan Duncan and Iain Gordon and two anonymous referees for critical and helpful comments. Abstract Mammalian herbivores, particularly browsers and folivores, encounter and consume a range of plant chemical defenses [plant secondary metabolites (PSMs)] on a regular basis. The physiological regulation of PSM ingestion and the resulting behavioral responses of mammalian herbivores directly affect their feeding decisions and the subsequent foraging strategies that they adopt. Generalist mammalian herbivores are hypothesized to consume a generalized diet because of physiological limitations of their detoxification systems. The consumption of a generalized diet is proposed to enable toxin (PSM) dilution through the use of multiple detoxification pathways. We tested the predictions of the detoxification–limitation hypothesis by offering two chemically different plant species, *Eucalyptus regnans* and *E. globulus*, to a generalist mammalian folivore, the common brushtail possum (*Trichosurus vulpecula*), as single- and mixed-species diets. By feeding more efficiently, brushtail possums benefited more, through increased intake, on the mixed-species diet than on either of the single-species diets. We argue that frequently switching between chemically diverse foliage reduces the physiological constraints imposed by a PSM-rich diet and enables more efficient feeding. The

behavioral responses of brushtail possums were consistent with the proposed physiological constraints of a chemically defended diet, offering support for predictions of the detoxification–limitation hypothesis. We suggest that feeding behavior of herbivores may be a useful indicator of the physiological constraints imposed by a chemically defended diet.

Introduction

By consuming plants, herbivores encounter a range of plant physical and chemical defenses (Feeny, 1970; Bryant and Kuropat, 1980). Plant chemical defenses, or plant secondary metabolites (PSMs), predominantly occur throughout woody plants as highly diverse compounds, both structurally and functionally. Ingestion of PSMs can incur physiological costs that include digestibility reduction (Robbins et al., 1987), toxicity (Pfister et al., 1997), and acidosis (Foley, 1992). To exploit woody plants, mammalian browsers (e.g., roe deer, *Capreolus capreolus*; Tixier and Duncan, 1996) and folivores (e.g., common brushtail possum, *Trichosurus vulpecula*; Kerle, 1984) must be able to process and deal with these chemical defenses. Mammalian browsers and folivores (hereafter referred to as herbivores) are indeed able to subsist on a chemically defended diet through a range of physiological and behavioral adaptations (Cork and Foley, 1991; McArthur et al., 1991).

Following ingestion and absorption, most PSMs must be detoxified to reduce the detrimental effects that they pose. Mammalian herbivores have evolved a series of detoxification pathways that convert absorbed PSMs into more hydrophilic and polar compounds through oxidation, reduction, or hydrolysis (phase I reactions), making them easier to excrete and/or preparing them for conjugation with an endogenous molecule (phase II reactions), again enhancing excretion (Sipes and Gandolfi, 1991). However, there are several limitations of these detoxification processes. Detoxification pathways rely on a series of rate-limited reactions, which, in turn, govern how much a herbivore can ingest per unit of time (Freeland and Janzen, 1974). Mammalian herbivores have been shown to regulate PSM ingestion at or below a proposed threshold level (Pfister et al., 1997; Lawler et al., 1998; Boyle and McLean, 2004). The inability to tightly regulate ingestion below a particular threshold may result in toxicosis, internal malaise, and, if severe enough, may even be fatal to the animal (Freeland and Janzen, 1974). Whereas most PSMs must be detoxified to aid in their excretion, the reactions involved can generate strong organic acids (Sipes and Gandolfi, 1991), which themselves may cause disturbances to a herbivore's acid–base status and, subsequently, disruptions to physiological and biochemical processes (Chilcott and Hume, 1984; Foley, 1992). All acid metabolites must, therefore, be buffered and excreted from the body (Foley et al., 1995). Detoxification of PSMs, through associated metabolic and excretory pathways, is an energetically expensive process (Cork and Foley, 1991; Freeland, 1991).

The capacity to which herbivores efficiently detoxify PSMs governs their subsequent feeding strategies. Only when a herbivore is able to minimize the energetic costs of detoxification (Sorensen et al., 2005), and efficiently metabolize and excrete ingested PSMs (Boyle et al., 1999), is it able to specialize on a relatively

homogenous diet. A generalized feeding strategy is by far the most common feeding approach adopted by mammalian browsers and folivores (Freeland, 1991). The consumption of a generalized diet is hypothesized to ensure adequate nutritional balance (Westoby, 1978). Acting over a much shorter timeframe, the detoxification–limitation hypothesis proposes that a generalized diet of chemically diverse plants enables toxin dilution, through the use of multiple detoxification pathways (Freeland and Janzen, 1974). Consistent with this hypothesis, research has shown that generalist folivores perform better on mixed than single forage diets through increased intake (Dearing and Cork, 1999; Wiggins et al., 2003). Explicit testing of the detoxification–limitation hypothesis is difficult because of limited knowledge of the mechanisms by which herbivores detoxify specific PSMs (Marsh et al., 2005).

Predictions of the detoxification–limitation hypothesis offer insight and understanding into the foraging decisions made by generalist mammalian herbivores. Consumption of a PSM-rich diet imposes direct physiological constraints to the herbivore. These constraints, in turn, should govern how generalists behaviorally respond to their diet, through the selection and mixing of different items. We have recently demonstrated that a folivore's rate of intake, and the frequency of switching between two chemically different plant species, was essential for maximizing intake (Wiggins et al., 2006). These feeding strategies were hypothesized to be directly related to the folivore's blood plasma PSM concentrations, a direct physiological constraint to the herbivore. A herbivore's feeding behavior is likely to be pivotal in how it responds to its dietary physiological constraints and could be used as an indicator of such constraints. Thus, the simultaneous investigation of three factors (intake, physiological responses, and behavioral responses) of herbivores to a mixed diet should enable us to evaluate predictions of the detoxification–limitation hypothesis. We know of no previous studies that have directly integrated these three components concurrently. Such integration is essential for the development of a more thorough understanding of the feeding decisions, and ultimately the foraging strategies, adopted by generalist mammalian herbivores.

We set out to test predictions of the detoxification–limitation hypothesis, in an attempt to explain why generalist mammalian herbivores are able to perform better on a chemically diverse diet than on a single species diet. We offered two chemically different plant species, *Eucalyptus regnans* and *E. globulus* (Wiggins et al., 2006), to a generalist mammalian folivore, the common brushtail possum (*T. vulpecula*), as single- and mixed-species diets. The four specific aims of this study were to (1) demonstrate differences in chemistry between the two eucalypt species; (2) determine whether intake was greater on the mixed- than single-species diets; (3) compare urinary characteristics between diet treatments as a crude indicator of the physiological status of the animals (e.g., pH, titratable ions, ammonia, urea); and (4) quantify differences in feeding behavior relative to maximizing intake.

Methods and Materials

Animals and Diet

Six adult brushtail possums (*T. vulpecula*), three males and three females [3.34 ± 0.59 kg (body weight mean \pm SD)], were collected from Hobart (Tasmania,

Australia), housed in a covered outdoor enclosure in individual mesh cages ($4.3 \times 1.7 \times 2.5$ m) at the School of Zoology, University of Tasmania, and provided with a nest box and logs for above-ground runways. Animals were maintained on a basal diet that was 18% dry matter (DM), consisting of [as % fresh matter (FM)] 46% apple, 35% silver beet, 10% carrot, 5% lucerne (ground to pass through a 1-mm sieve), and 4% raw sugar. Fruit and vegetable constituents were mixed in a food processor, then combined with dry ingredients. Food was provided at levels sufficient for maintenance (McArthur et al., 2000) and so was freshwater daily.

Feeding Trial

Possums were initially offered 50% of maintenance requirements of a basal diet and *E. regnans* and *E. globulus* sapling foliage *ad libitum* for 5 d, 1 wk before the trial. They received 120% basal diet two nights directly before the trial. Foliage was collected from Geeveston, Tasmania, and stored with stems in freshwater in a 5°C cool room. The feeding trial consisted of three treatment diets fed to possums in a balanced crossover design (Ratkowsky et al., 1993). The treatment diets were (1) *E. regnans* and (2) *E. globulus* single-species diets and (3) *E. regnans* and *E. globulus* mixed diet. Foliage was fed *ad libitum* in 300-g bunches, provided fresh each day. Each treatment was run for 4 consecutive nights, and immediately followed by 4 “rest” nights where possums were offered 120% basal diet to ensure they maintained body weight during the trial. Foliage intake was measured daily and expressed as grams dry matter per kilogram of body mass for each possum [$\text{g DM} (\text{kg BM})^{-1}$].

Foliage Properties

Two control bunches of foliage per species per night were pooled and subsampled for physical and chemical analyses to confirm that foliar secondary chemical properties differed. Foliage was assayed for DM, leaf toughness, nitrogen, fiber, oils, and phenolics.

Dry Matter

Subsamples of foliage were oven-dried at 55°C for 48 hr to determine percentage dry matter (% DM).

Leaf Toughness

Five leaves per species per night were sampled at three sections of the leaf (upper, middle, and lower) by using a dual tension gauge portable penetrometer (Chatillon, John Chatillon & Sons, Inc., NY, USA). Units are an index only, expressed as total grams of force required to puncture the thickness of foliage using a 1-g, 0.60-mm pin (Sands and Brancatini, 1991).

Nitrogen

Foliage was oven-dried at 55°C for 48 hr and ground to pass through a 1-mm sieve by using a cyclone grinder, then further oven-dried at 70°C for 24 hr. Following this,

a sulfuric acid and hydrogen peroxide digest was performed following methods of Lowther (1980). Digested samples were colorimetrically analyzed for nitrogen (QuikChem reference 10-107-06-2E, Lachat Instruments, WI, USA) on a continuous flow injector analyzer (QuikChem 800, Lachat Instruments). Results are expressed as % DM.

Fiber

Ground samples were analyzed for plant cell-wall components of neutral detergent fiber, acid detergent fiber, and lignin following methods in the ANKOM^{200/220} Technology Operator's Manual (1997). Results are expressed as % DM.

Total Oils

Fresh-frozen foliage was thawed prior to oil and phenolic assays. Oils were extracted following methods modified from Jones et al. (2002). Briefly, 1 g of foliage was cut into 1-cm² pieces and soaked in 10 ml dichloromethane for 1 hr. Extracts were analyzed by combined gas chromatography–mass spectrometry (GC-MS) as detailed in O'Reilly-Wapstra et al. (2004). Total ion currents were determined for the sum of all oil components (total oils) and the heptadecane internal standard. Results for total oils were standardized by dividing by the internal standard. Results are expressed as mg “cineole equivalents” per g DM.

Total Phenolics

One gram of foliage was cut into 1-cm² pieces, homogenized with a Polytron Homogenizer (POLYTRON[®] MR2100, Kinematica AG, Switzerland) in 20 ml acidified (pH 1) methanol (Close et al., 2001), and then boiled for 1.5 min. Samples were extracted overnight at 5°C in the dark, centrifuged at 10,000 rpm for 7 min, and analyzed by high-performance liquid chromatography, detailed in O'Reilly-Wapstra et al. (2004). Differences between major classes of phenolic compounds, the hydrolyzable tannins, and the formylated phloroglucinol compounds (FPCs) only were identified. Representative chromatograms of oils and phenolics were used as a visual reference to demonstrate differences in PSM composition between *E. regnans* and *E. globulus*.

Urine Collection

On night 4 of each treatment, four of the six possums (because of logistic constraints) were placed in individual metabolism cages (60 × 60 × 45 cm) for 24 hr for urine collection at the School of Pharmacy, University of Tasmania. Possums were fed with their allocated treatment diets of fresh foliage overnight. Urine was collected into containers held in liquid nitrogen and frozen immediately, then stored at –20°C until later analysis. Animals were acclimatized to the metabolism cages for a 24-hr period 1 week before commencement of the feeding trial. Urinary properties of pH, titratable ions, ammonia, and urea were measured for *N* = 3 possums because of low urinary output of one animal during the collection period. Ammonia and urea methods were modified methods of Faulkner and King (1970). The titratable ion variable was based on the concept of titratable acids (Foley, 1992).

pH

Urine samples were thawed and pH was measured with a TPS digital pH meter.

Titrateable Ions

Either 0.5 M HCl (for basic urine solutions) or 0.01 M NaOH (for acidic urine solutions) was used to titrate urine samples to pH 7.4 (neutral). Titrations were performed at 20°C, and results are expressed as mmol l⁻¹ to pH 7.4.

Ammonia

Tubes were set up with 0.1, 0.4, and 1.0 ml of 1:10 dilutions of urine and made up to 1.0 ml with deionized H₂O. Tubes containing a standard ammonium sulfate solution [800 nmol NH₄⁺ ml⁻¹; derived from 53 ml of 0.1% ammonium sulfate (Ajax Chemicals, Sydney, Australia) solution diluted in 1 l deionized H₂O] were also set up. To each tube, 5 ml of phenol–nitroprusside reagent [10.0 g phenol (May & Barker Ltd., Dagenham, England) and 0.05 g sodium nitroprusside (May & Baker Ltd.) dissolved in 1 l deionized H₂O] were added and mixed by vortex. Following this, 5 ml of NaOH–hypochlorate reagent [5.0 g NaOH (Sigma, St. Louis, MO, USA) and 44 ml of 4% sodium hypochlorite (Aldrich, Milwaukee, WI, USA) dissolved in 1 l deionized H₂O] were added to tubes and mixed by vortex. Tubes were incubated at 37°C for 30 min, and absorbance was read at 570 nm against the reagent blank. Results are expressed as μmol d⁻¹.

Urea

Tubes were set up with 0.1, 0.4, and 1.0 ml of 1:500 dilutions of urine and made up to 1.0 ml with deionized H₂O. Tubes containing a standard urea solution [250 nmol ml⁻¹; derived from 30.0 mg urea (AnalaR[®], Kilsyth, Australia) diluted in 2 l deionized H₂O] were also set up. To each tube, 0.1 ml of urease suspension [100.0 mg urease [Sigma] dissolved in 100 ml phosphate–EDTA buffer [made from 2.0 g Na₂EDTA (BDH Chemicals Ltd., Poole, England) and 5.7 g anhydrous Na₂HPO₄ (Ajax Chemicals, Auburn, Australia) dissolved in 100 ml deionized H₂O, adjusted to pH 6.5 with 1 M HCl (Ajax Chemicals), then made up to 200 ml with deionized H₂O]], stored on ice, were added and mixed by vortex, then incubated at 37°C for 15 min. Following this, 5 ml of phenol–nitroprusside reagent were added to tubes and mixed, followed by 5 ml of NaOH–hypochlorate reagent (see *Ammonia* in [Methods and Materials](#)), with tubes mixed by vortex. Tubes were incubated at 37°C for 30 min, and absorbance was read at 570 nm against the reagent blank. Results are expressed as μmol d⁻¹.

Feeding Behavior

Feeding behavior was measured for all six possums from nights 1–3. Animals were filmed nightly from 18:00 until 08:00 hr using individual B&W Bullet CCD Cameras (equipped with a Samsung[™] sensor, JayCar, Hobart, Tasmania), one camera per cage. Each camera was connected to a Panasonic[®] Video Cassette Recorder (Series NV-FJ630). An 80-W red flood lamp (Osram Par 38, manufactured in EC) was

positioned in each cage for enhanced visibility. Video footage was recorded directly onto BASF E-300 cassette tapes by using extended long-play recording speed. Data from video footage were summarized using The Observer[®] (v 4.1, Noldus Information Technology, The Netherlands, 2002). Behavioral variables were calculated using The Observer[®] and Microsoft[®] Excel (Microsoft Corporation, 1997). These variables were (1) time from first to last feeding bout (incorporating nonfeeding activity); (2) total feeding time; (3) rate of intake; (4) number of feeding bouts; (5) time per feeding bout; (6) intake per feeding bout; (7) total number of switches; and (8) the frequency of feeding bouts within which switching occurred. A single feeding bout was defined as the time from the possum's first bite to the end of its last chew, with at least 1 min of nonfeeding directly following this last chew (Wiggins et al., 2006). Total number of switches was a count of switches between plant species, which could occur both during and between feeding bouts. The frequency of feeding bouts within which switching occurred was calculated by dividing the total number of "switching bouts" per night by the total number of feeding bouts for that night. Switching behavior could only be measured on the mixed diet. Results for all intake and behavioral variables are expressed as mean values \pm standard errors (SE).

Statistical Analyses

The average of 3 d data for each treatment for all six possums was used in the analyses. Dependent variables of intake and aspects of feeding behavior were tested against the independent variables of possum, treatment, period, and carryover, using the general linear model procedure (PROC GLM) in SAS (SAS v6.12, SAS Institute Inc. 1989), following the methods of Ratkowsky et al. (1993). The Wilk-Shapiro statistic, normal probability plots, and standardized residual plots all indicated normality of the data. When an effect was significant, pairwise comparisons of the least-squares means were made by using the Tukey-Kramer adjustment. Data for three possums from d 4 were used for urine analysis. Dependent variables of intake, pH, titratable ions, ammonia, and urea were tested against the independent variables of possum, period, and treatment (PROC GLM, SAS Institute Inc. 1989). Differences between foliar physical and chemical properties of *E. regnans* and *E. globulus* were also tested (PROC GLM, SAS Institute Inc. 1989).

Results

Foliage Chemistry

Leaf percentage DM, leaf toughness, and nitrogen were similar between *E. regnans* and *E. globulus* foliage (Table 1). Of the primary constituents, only fiber differed between the two species (Table 1). Of the secondary metabolites, *E. regnans* contained higher levels of total oils than *E. globulus* (Table 1). Of the 15 major oil compounds identified, only one compound, bicyclogermacrene, was present in both plant species, with amounts similarly low in both species (Fig. 1). There were also major differences in phenolic profiles between plant species. The FPCs peaking between 9 and 11 min in *E. globulus* are not present in *E. regnans* (Fig. 2), whereas differences in the early major peaks indicate the presence of different hydrolyzable

tannins in each species (peaks substantially differ from 1 to 4 min and from 4 to 6 min between the foliage species).

Intake

Possoms consumed substantially more foliage on the mixed- than on the single-species diets ($F_{2,17} = 14.99$, $P = 0.001$; Fig. 3).

Urinary Properties

Possoms produced a slightly acidic urine on *E. globulus* foliage, alkaline on *E. regnans* foliage, and urine at relatively neutral pH on the mixed diet ($F_{2,8} = 9.20$, $P = 0.032$; Fig. 4). Urine from the *E. regnans* single-species diet required the greatest titration to return it to neutral pH ($F_{2,8} = 7.68$, $P = 0.043$). Urinary properties of ammonia ($F_{2,8} = 0.95$, $P = 0.458$) and urea ($F_{2,8} = 1.42$, $P = 0.343$) were not significantly different between diets (Fig. 3).

Feeding Behavior

Possoms spent longer feeding on the mixed and *E. globulus* single-species diets than on the *E. regnans* single-species diet ($F_{2,17} = 20.15$, $P = 0.002$; Fig. 5a). They ate faster on the mixed diet than the respective single-species diets ($F_{2,17} = 4.53$, $P = 0.049$; Fig. 5b). Possoms did not alter the number of feeding bouts per night (mean 11.8 ± 1.3 , $P = 0.209$), but their time per feeding bout ($F_{2,17} = 7.55$, $P = 0.014$; Fig. 5c) and intake per feeding bout ($F_{2,17} = 8.09$, $P = 0.008$; Fig. 5d) were least on *E. regnans* and generally greater on the mixed diet. There was no difference between the time

Fig. 3 Total intake [g DM (kg BM)^{-1}] of *E. regnans* and *E. globulus* foliage by brushtail possums across diet treatments. Values are least-squares means with SE bars for total intake. Letters that differ are significantly different ($\alpha = 0.05$ after Tukey-Kramer adjustment for multiple comparisons)

from the first to last feeding bout in response to treatment diets (mean 7.0 ± 0.2 hr, $P = 0.113$).

On the mixed diet, possums switched between foliage both within and between feeding bouts 10.6 ± 0.9 times per night. Of these, 46% of switches (4.4 ± 0.4) occurred within feeding bouts, whereas 54% (6.3 ± 0.4) occurred between feeding

bouts. Of the within-bout switching figure, possums switched more often after 50% of their total feeding bouts had passed (3.0 ± 0.2 times) than before (1.5 ± 0.2 times; mean difference 1.2 ± 0.2 , $P = 0.001$).

Discussion

Foliar Chemical Properties

Foliar secondary chemical constituents of total oils and total phenolics differed substantially between *E. regnans* and *E. globulus*, as demonstrated by the minimal overlap in the major oils identified for either species and the absence of known herbivore feeding deterrents, the FPCs (O'Reilly-Wapstra et al., 2004), in *E. regnans*. There were also differences in the types of hydrolyzable tannins present in either species. This result confirms major differences between the foliar secondary chemistry in the two species, as previously demonstrated (Wiggins et al., 2006).

Herbivore Urinary Status

Consumption of each diet treatment generated different urinary characteristics in the common brushtail possum (*T. vulpecula*). Brushtail possums produced highly alkaline urine on the *E. regnans* single-species diet, slightly acidic urine on the *E. globulus* single-species diet, and relatively neutral urine on the mixed diet. Previous studies have shown that the consumption of *Eucalyptus* diets generally creates acidic urine to varying degrees, as a result of high buffering activity (as indicated by levels of ammonia excretion) because of organic acid production from the metabolism of dietary terpenes (Hamm and Simon, 1987; Foley, 1992; Foley et al., 1995). Interestingly, the consumption of *E. regnans* did not generate an acid urine. In fact, it was highly alkaline and showed similarities with urine of both brushtail possums and desert woodrats (*Neotoma stephensi* and *N. albigula*) consuming an artificial maintenance diet of fruit and vegetable matter (Dearing et al., 2000; Wiggins et al., unpublished data). The generation of alkaline urine may explain why the urinary properties of pH, ammonia, and urea indicated minimal disturbances to the acid–base status of possums feeding on *E. regnans*, as these measurements have only previously been used to demonstrate changes in the physiological properties of acid urine (e.g., Foley, 1992). Therefore, with the examination of acid and alkaline urine, titratable ions appear to be the most relevant indicator of herbivore physiological status. What the urinary results do suggest, more importantly, is that possums deal with dietary PSMs in *E. regnans* differently from *E. globulus* (confirming our premise for using these two species to test the effects of mixed diets).

Intake and Behavioral Responses

Brushtail possums ate more on a mixed diet of *E. regnans* and *E. globulus* foliage than on their respective single-species diets. This result is consistent with previous research (Dearing and Cork, 1999; Wiggins et al., 2003, 2006) and offers support for the predictions of the detoxification–limitation hypothesis (Freeland and Janzen, 1974). Marsh et al. (2006) recently demonstrated that brushtail possums were only able to eat more on a mixed PSM diet, compared with their respective single-PSM

diets, when individual PSMs were metabolized by using different (major) detoxification pathways. Brushtail possums were unable to eat more on a mixed diet when the PSMs were metabolized with competing detoxification pathways (Marsh et al., 2006). The fact that intake of the mixed diet in our trial was greater than either single-species diet indicates that the chemical properties of *E. regnans* and *E. globulus* foliage were sufficiently diverse to impose different physiological (detoxification) constraints to brushtail possums.

Brushtail possums ate more on the mixed-species than either of the single-species diets by eating faster, while tending to spend more time and eating more per feeding bout. They frequently switched between both species of foliage on the mixed diet, with the number of within-bout switches increasing in the latter half of their feeding bouts. By frequently switching between foliage on the mixed diet, possums may have been able to overcome the short-term intake constraints because of the toxic effects of each species. Wiggins et al. (2006) proposed that diet switching was a direct behavioral response to the detoxification limitations of a PSM-rich diet. That is, when intake on one species is constrained because of saturation of specific detoxification pathways, possums can continue feeding on the other species. They demonstrated that brushtail possums were only able to maximize their intake when able to frequently switch between dietary species during their nightly feeding activities: when foliage time and availability constraints were imposed on possums, they were unable to maintain intake (Wiggins et al., 2006). Results of this current study expand on this hypothesis through a more detailed investigation of the frequency and occurrence of dietary switching.

By switching between foliage more frequently during the latter half of their feeding bouts, we suggest that brushtail possums were responding to the accumulation of PSMs and/or detoxification metabolites over their nightly feeding timeframe. Brushtail possums have been shown to regulate dietary 1,8-cineole ingestion so as not to exceed a critical threshold level over a 3-hr feeding timeframe, but cineole metabolites accumulated throughout that sampling period (Boyle et al., 2005). Cessation of feeding on one plant species may have been a direct response to blood PSM levels that were nearing, or had indeed reached, a specific critical threshold level. By immediately switching to the next available plant species, possums may have been attempting to regulate PSM ingestion of *E. regnans* while continuing to feed on *E. globulus*. Increasing the frequency of this switching behavior during the latter stages of their feeding activities presumably reflects that detoxification limitations were at their most critical stages for both species of foliage. This result strengthens the argument that diet switching in a generalist mammalian folivore is a behavioral response to detoxification limitations of a PSM-rich diet (Wiggins et al., 2006).

The ability to frequently switch between foliage, which was not an option on the single-species diets, enabled possums to feed more efficiently, through a faster feeding rate and greater feeding bout size and length. These behavioral responses to a physiologically constraining diet represent an important facet that helps explain why, and how, generalist mammalian herbivores are able to benefit from a chemically diverse diet.

In summary, the common brushtail possum was able to benefit from the consumption of a chemically diverse diet, even over a short feeding timeframe. Possums fed more efficiently on a mixed- than on a single-species diet and achieved increased intake. We propose that diet switching is a behavioral strategy adopted by *T.*

vulpecula as a direct response to the physiological limitations of detoxification pathways, enabling them to efficiently consume a chemically diverse diet.

This integration of dietary chemical properties, animal physiological, and behavioral data has enabled us to test predictions of the detoxification–limitation hypothesis. Herbivore feeding behavior (e.g., diet switching) may be a useful indicator of the physiological constraints (e.g., detoxification limitations) imposed by a PSM-rich diet. Understanding the underlying processes that govern the intake of generalist herbivores is important: the way in which a herbivore is physiologically constrained by its diet, and the resulting behavioral responses, will directly impact on the herbivore's foraging decisions, and subsequently their foraging energetics.

Acknowledgements We thank Hugh Fitzgerald and Kit Williams for technical assistance, Julien Wiggins for help with experimental procedures, and Sue Brandon and Ann Wilkinson for analytical assistance. This research was approved by the University of Tasmania's Animal Ethics Committee (Permit Number A6700) and Parks and Wildlife Service (Permit Number FA 02119). Research was funded by an Australian Postgraduate Award and the CRC for Sustainable Production Forestry.

Salivary Proteins as a Defense Against Dietary Tannins

Abstract Tannins, a diverse group of water-soluble phenolics with high affinity to proteins, are widely distributed in various parts of plants, and have negative effects in herbivores after ingestion. Some mammalian species are thought to counteract tannins by secreting tannin-binding salivary proteins (TBSPs). Several types of TBSPs are found in the saliva of laboratory animals, livestock, and wildlife. Among them, proline-rich proteins (PRPs) and histatins are effective precipitators of tannins. It is widely accepted that, at the least, PRPs act as a first line of defense against tannins. Many observations support this idea: *in vitro* affinity of PRPs to tannins is far higher than that of other proteins such as bovine serum albumin; complexes formed between PRPs and tannins are stable even under the conditions in the stomach and intestine; and PRP production is induced by ingesting tannins. It is believed that species that usually ingest tannins as part of their natural diets produce high levels of PRPs, whereas species not exposed to tannins produce little or no PRPs. This hypothesis is generally supported, although studies on TBSPs in wildlife are limited. This work stresses the importance of gathering basic information on such items as the characteristics of unidentified TBSPs, and seasonal and geographical variations in PRP production.

Introduction: Tannins and Mammalian Countermeasures

Tannins, which are among the most widespread plant secondary metabolites (PSMs), are a diverse group of water-soluble phenolic compounds with high affinity for proteins. They are broadly distributed in various parts of plants (Blytt et al., 1988; Bernays et al., 1989; Waterman and Mole, 1994). On the basis of their chemical structures, tannins can be divided into two major groups: condensed and hydrolyzable (Zucker, 1983). Condensed tannins are oligomers and polymers of

flavan-3-ols that are linked by C–C bonds and thereby difficult to hydrolyze. In contrast, hydrolyzable tannins are esters of polyols (usually glucose) with simple phenolic acids, such as gallic acid or hexahydroxydiphenic acid, and are readily hydrolyzed by acidic or basic conditions as well as by esterase enzymes.

Ingestion of tannins is known to cause various types of negative effects in mammalian herbivores, such as reduction in digestibility (Robbins et al., 1987; Chung-MacCoubrey et al., 1997; Shimada and Saitoh, 2003), damage to the gastrointestinal mucosa and epithelium (Blytt et al., 1988), kidney or liver failure (Fowler and Richards, 1965), and endogenous nitrogen loss (Blytt et al., 1988; Shimada and Saitoh, 2003). It has long been believed that tannins primarily act as protein digestion inhibitors by binding dietary proteins and digestive enzymes (see review by Zucker, 1983). However, recent studies have revealed that tannins do not bind to digestive enzymes in *in vivo* situations, because digestive enzymes are usually protected from tannins by occurring in a particulate membrane-bound form (Blytt et al., 1988; Bernays et al., 1989; Skopec et al., 2004). Instead, ingested tannins probably bind salivary proteins and the mucosa and epithelium of the gut. This may cause endogenous nitrogen loss, thereby reducing protein digestibility. Moreover, phenolic acid released by hydrolysis of tannins can be absorbed from the intestine and cause acute toxicity, such as necrosis and kidney and liver failure (Fowler and Richards, 1965; Niho et al., 2001). For these reasons, tannins should now be regarded not as digestion inhibitors that act relatively mildly, but as toxins that have acute negative effects on herbivores.

Animals can use both preingestive and postingestive countermeasures against dietary tannins. Avoiding highly tanniferous species or parts of plants is the simplest preingestive countermeasure. This behavior has been frequently reported in various taxa, such as ungulates (Cooper and Owen-Smith, 1985), rodents (Shimada and Saitoh, 2003), lagomorphs (Clausen et al., 1990; Dearing, 1997), and primates (Takemoto, 2003). Some herbivores have been shown to regulate their rates of intakes of tannins or other PSMs in order to circumvent overloading of one detoxification pathway (Dearing and Cork, 1999; Burritt and Provenza, 2000; Foley and Moore, 2005). Furthermore, reduction of tannin levels in plants through leaching during the hoarding period can be considered as a preingestive countermeasure (Dearing, 1997). Postingestive countermeasures, which mammalian herbivores are known to use, include the secretion of tannin-binding proteins in saliva, increased gastrointestinal mucus production, degradation of tannins by microorganisms in the gut, activation of detoxifying enzymes, and increased capacity of intestinal permeability glycoprotein (see reviews by McArthur et al., 1991; Dearing et al., 2005). These are thought to be key elements in overcoming, or at least mitigating, the negative effects caused by tannins.

This review concerns tannin-binding salivary proteins (TBSPs) as a defense against dietary tannins. TBSPs, which are defined as proteins secreted in saliva that have high affinity for tannins, can bind readily to dietary tannins in the oral cavity and are thought to prevent the tannins from interacting with other proteins (McArthur et al., 1995; Bennick, 2002). TBSPs interact with ingested tannins in the first stage of digestion. This feature stresses the importance of TBSPs in counteracting tannins, because the behavior of ingested tannins in the gastrointestinal tract may be inevitably regulated by these early encounters with TBSPs. In the last two decades, a considerable number of studies have been undertaken on TBSPs (Ann and Carlson, 1985; Asquith et al., 1985; Austin et al., 1989; Robbins et al., 1991;

Glendinning, 1992; Carlson, 1993; Hagerman and Robbins, 1993; Bacon and Rhodes, 2000; Gehrke, 2001; Isemura, 2003). However, most have been conducted on humans and laboratory animals. This is partly because TBSPs originally attracted attention in the field of dental science and nutrition. As a consequence, information on TBSPs in wildlife is still limited and scattered. In addition, studies on TBSPs have been relatively biased toward *in vitro* data, such as genetics, amino acid compositions, protein structures, and *in vitro* affinity to tannins. Thus, the straightforward question—to what extent TBSPs would be effective in overcoming the potential negative effects of tannins in herbivores—is still open, even in laboratory animals.

The aims of this review are to summarize the information on TBSPs (obtained mostly in laboratory animals) and to discuss the significance to wildlife of producing TBSPs.

General Characteristics of Tannin-Binding Salivary Proteins

Two families of salivary proteins, proline-rich proteins (PRPs) and histatins, are generally recognized as TBSPs. However, there is evidence for the presence of other, different types of proteins. These are characterized by their high affinity to tannins, but they differ greatly in terms of molecular size, amino acid composition, structure, and taxonomic distribution in mammals.

Proline-Rich Proteins

PRPs were first detected in human saliva (Mandel et al., 1965). They have also been found in the saliva or salivary glands of several laboratory animals and wildlife (Table 1). In these mammals, PRPs are thought to be the most prevalent group of proteins in the saliva; PRPs account for 70% of all salivary proteins in humans (Mehansho et al., 1987b) and 74% of those in the Japanese wood mouse *Apodemus speciosus* (T. Shimada, unpublished data).

The molecular weights of PRPs are estimated to range from a low of 5000 to over 25,000 (McArthur et al., 1995; Bennick, 2002). As their name suggests, the amino acid composition of PRPs is unique in that the content of proline is markedly high. Proline comprises at least 20% of total amino acid content of PRPs (Kauffman and Keller, 1979; Mole et al., 1990). Some species, such as humans, rats, and mice, produce PRPs containing about 40% proline (Mehansho et al., 1983, 1985; Mole et al., 1990). In light of the fact that most types of proteins contain, at most, 5% proline (Schulz and Schirmer, 1979), PRPs have a markedly characteristic amino acid composition. They are also rich in glycine, glutamine, and glutamic acid. Mole et al. (1990) compared the amino acid compositions of PRPs from several species and found that in all cases the sum of the quantities of these four amino acids accounted for 70–90% of the total protein. These four amino acids, especially proline, are the so-called alpha-helix breakers, which prevent proteins from forming secondary structures. As a consequence, PRPs do not have any recognizable conformational structures, thereby existing in solution as extended random coils (Hagerman and Butler, 1981; Murray and Williamson, 1994). This feature may enable PRPs to universally bind various types of tannins that have a variety of shapes and sizes.

PRPs are encoded by tissue-specific multigene families. The nucleotide sequences of PRP cDNAs from mouse (Clements et al., 1985), rat (Ziemer et al., 1984), human

^a These columns indicate the presence of inducibility of TBSP synthesis by intake of tannins or by injection of a β -agonist.

^b Proline-rich proteins (PRPs).

^c Any types of TBSPs have not been found.

^d The presence of TBSPs has been confirmed, but the detail characteristics have not been investigated.

^e The presence of TBSPs, which belong neither to PRPs nor to histatins, has been confirmed.

(Maeda et al., 1985), and crab-eating macaque (Oppenheim et al., 1987), and PRP genes from mouse (Ann and Carlson, 1985), hamster (Ann et al., 1987), and human (Kim and Maeda, 1986) have been reported. All proteins encoded by cDNAs and genes share a common structure consisting of a signal peptide, a transition region, a repeat region, and a carboxyl terminal region. The single peptides and repeated regions exhibit marked homologies among these species, whereas the transition regions and carboxyl terminal regions vary largely (Ann and Carlson, 1985; Clements et al., 1985; Ann et al., 1987). In mice, the PRP gene family is located on chromosome 8 (Azen et al., 1984). In humans, the PRP family is encoded by only six genes located on chromosome 12 (Maeda, 1985; Maeda et al., 1985); two encoding acidic PRPs, and four encoding basic and glycosylated PRPs (Kim and Maeda, 1986). Many of the proproteins encoded by these genes are subsequently cleaved before secretion, giving rise to a large number of secreted PRPs (Lyons et al., 1988). Consequently, more than 20 PRPs are present in human saliva (Bennick, 2002).

PRPs are generally classified as basic (BPRPs) or acidic (APRPs) (McArthur et al., 1995; Bennick, 2002). APRPs are composed of two major regions: the core C-terminal region, comprising 70–80% of the molecule, and the highly acidic N-terminal region. BPRPs are structurally equivalent to the C-terminal region of APRPs. The N-terminal region of APRPs contains little proline, and thereby the proline level of the whole molecule is higher in BPRPs than in APRPs. In humans, BPRPs are secreted only from the parotid glands, whereas APRPs are secreted from all salivary glands, including the parotid, submandibular, and sublingual glands (Kauffman and Keller, 1979). A similar observation has been made in rabbits (Ferreira et al., 1992). This phenomenon may, therefore, be common in mammals that produce salivary PRPs.

BPRPs, in general, have a much higher affinity to tannins than APRPs (Lu and Bennick, 1998), and the main function of BPRPs is regarded as counteracting dietary tannins (Bacon and Rhodes, 2000; Chan and Bennick, 2001). In contrast, APRPs act primarily in maintaining oral homeostasis. An extensive argument for the evolution of the different types of PRPs can be found in the review by McArthur et al. (1995); they hypothesized that the ancestral type is APRPs whose main function is maintaining oral homeostasis, and that BPRPs evolved later when mammals began to consume a diet with a high content of tannins. Interestingly, it has been proved that variation in the molecular structures within BPRPs and APRPs does not largely influence the affinity of PRPs to tannins (Lu and Bennick, 1998).

The affinity of PRPs to tannins differs among mammalian species. It is estimated as 5–80 times higher than that of bovine serum albumin (BSA) and 1000 times higher than that of lysozyme (Asquith et al., 1987; Austin et al., 1989; Mole et al., 1990). This high affinity enables PRPs to act as a first line of defense. Because tannins bind preferentially to PRPs, even in the presence of excessive amounts of other proteins of lower affinity (Asquith and Butler, 1985), PRPs can form stable complexes with tannins in the oral cavity. They thereby prevent tannins from interacting with other proteins, such as enzymes or those in the mucous membranes and epithelia, and then degrading into noxious phenolic compounds (Robbins et al., 1991; Hagerman and Robbins, 1993). The tannin–PRP complexes are also stable in the gastrointestinal tract, and most of the complexes formed are excreted in the feces (Mitaru et al., 1984; Skopec et al., 2004). These reactions of PRPs may present both quantitative and qualitative nitrogen savings to animals. The amount of protein

needed to bind all the tannins can be reduced. In addition, the four major amino acids of PRPs are all nonessential in mammals. This means that nonessential amino acids from PRPs are excreted instead of the dietary or endogenous essential amino acids (McArthur et al., 1995).

Interestingly, some species produce salivary proteins, which are rich in proline, but do not show the high affinity to tannins (Mole et al., 1990). For instance, salivary proteins in some marsupials, such as koalas and common ringtail possums, contain about 30% of proline, but their affinity to tannins is a tenth of that of BSA. Similar observations were also obtained in cattle and pigs (Mole et al., 1990). Some modifications in these proteins, such as extensive glycosylation, might reduce the affinity to tannins. If so, these nontannin-binding proline-rich proteins might include an important clue for studies on the evolutionary process of tannin-binding PRPs. These nontannin-binding proline-rich proteins cannot be regarded as TBSPs because of the lack of high affinity to tannins. Thus, in this review, this type of “proline-rich proteins” is not regarded as PRPs in the following discussion.

Another notable feature of PRPs is that their synthesis is induced by the presence of β -agonists and tannins, but this response varies among species (Table 1). PRPs are constitutively produced at high levels in humans and mule deer (Oppenheim et al., 1971; Austin et al., 1989). In contrast, in rats, mice, and hamsters, synthesis of PRPs is induced by injection of the β -agonist isoproterenol (Mehansho and Carlson, 1983; Mehansho et al., 1985, 1987a). This reaction is also found in the Japanese wood mouse (T. Shimada, unpublished data). PRP synthesis can also be induced by ingesting tannins. This response has so far been confirmed exclusively in rodent species, such as rats (Mehansho et al., 1983), mice (Mehansho et al., 1985), root voles (Juntheikki et al., 1996), and Japanese wood mice (Shimada et al., 2004). In black rhinos, the induction of TBSP synthesis by tannins has also been demonstrated (Clauss et al., 2005). Their TBSPs may also be PRPs, although this has not yet been examined. Interestingly, in hamsters, PRP synthesis is induced by β -agonist injection, but not by ingestion of tannins (Mehansho et al., 1987a). This induction mechanism supports the importance of PRPs as a defense against dietary tannins.

Histatins

Histatins are a group of relatively small proteins with high affinity to tannins; their molecular weight is, in general, less than 5000 (Yan and Bennick, 1995). Histatins are found only in the saliva of humans and some primates (Sabatini et al., 1989; Bennick, 2002). Histatins are characterized by a high content of histidine, which accounts for about 25% of all amino acids present (Yan and Bennick, 1995).

Unexpectedly, histatins in human saliva account for only 2.6% of all salivary proteins (Sugiyama and Ogata, 1993). They readily bind both hydrolyzable and condensed tannins (Yan and Bennick, 1995). The affinity of histatins to tannic acid is estimated to be twice that of gelatin, which is an effective binder of tannic acid. Furthermore, the complexes with tannins are stable in the gut. These findings indicate that histatins may act as defenses against dietary tannins, as do PRPs. However, PRPs are likely to be more important than histatins in defense against tannins if both of them are secreted coincidentally in an animal, because their levels of secretion in saliva are very different.

Histidine is regarded as an essential amino acid for most mammals, but its essentiality in adult humans is supposed to be relatively low (Schmidt-Nielsen,

1997), and it is regarded as semiessential. Assuming that other primates have similar requirements for histidines, this low essentiality of histidine might have enabled the evolution of histatin production in primates, although there is a possibility that histatins may be found in other taxonomic groups.

Other Types of TBSPs

PRPs and histatins are two major groups of TBSPs, but some researchers have found other types of salivary proteins with high affinity to tannins. First, Mole et al. (1990) investigated the presence of TBSPs in several mammals, including laboratory animals, livestock, and wildlife. In the saliva of white-tailed deer, they found TBSPs whose affinity to tannins was six times that of BSA. These salivary proteins contained only 7% proline, and the sum of the four amino acids (proline, glycine, glutamine, and glutamic acid) accounted for only 29% of the total. The molecular weight of these proteins was estimated to be over 10,000. These findings suggest that the salivary proteins from white-tailed deer are neither PRPs nor histatins.

In cattle saliva, Makkar and Becker (1998) found salivary proteins with high affinity to tannins: about six times that of BSA. Their proline content was only 6.5%, and the sum of the four amino acids accounted for about 31% of the total. Ingesting tannins did not alter the amino acid compositions or the affinity of these TBSPs to tannins. These authors speculated that the primary role of these proteins might not be to defend the animals against dietary tannins. Interestingly, Austin et al. (1989) and Mole et al. (1990) did not detect TBSPs in cattle saliva, even with the same isolation methods used by Makkar and Becker (1998).

Gehrke (2001) found TBSPs in the saliva of the fallow deer whose affinities to tannic acid and quebracho tannins (condensed tannins) were almost twice those of cattle saliva. These proteins contained 13% of proline, and the sum of the four amino acids accounted for 35.3% of the total. This proline content is lower than typical PRPs but relatively high as a usual protein. The author concluded that these TBSPs were not PRPs.

It is unknown whether such salivary proteins possess any evolutionary relationship to PRPs or histatins. However, the presence of several types of TBSPs suggests that parallel evolution may have occurred at least several times in herbivorous mammals, that some salivary proteins that originally had other functions may have incidentally acquired a high affinity to tannins and thus consequently have come to act as a defense mechanism against dietary tannins.

TBSPs in Relation to Feeding Niches

The possibility that TBSPs act as defense products against dietary tannins has promoted surveys of the presence of these proteins in various species of mammals. Some of these have tried to link the presence or affinity of TBSPs to the feeding niches of those animals. Table 1 shows the summary of previous studies that examined the presence of TBSPs in various mammalian species. Among 33 species examined, TBSPs are found in 26 species, including two controversial ones—cattle and sheep. The wide prevalence of TBSPs in various taxa implies a staple role in counteracting dietary tannins. Characterizations of TBSPs have been carried in 16

species, but include only 8 species of wild mammals. Thus, our knowledge of TBSPs is quite limited for wildlife.

It is hypothesized that animals with high tannin contents in their natural diets have developed high levels of TBSPs, but that those with low tannin contents produce little or no TBSPs (McArthur et al., 1995; Fickel et al., 1998; Clauss et al., 2005). In general, the leaves of monocots and forbs contain less tannin compared to fruits, seeds, and the leaves of shrubs and trees (Waterman and Mole, 1994). Thus, the above hypothesis implies that browsers, frugivores, and omnivores produce TBSPs at high levels, but grazers should have only small amounts.

Among rodents, rats, mice, and hamsters, which are all omnivores, are confirmed as secreting PRPs (Table 1). Furthermore, Shimada et al. (2004) found PRPs in the saliva of the Japanese wood mouse (an omnivore that is close to being frugivorous). Root voles, which are supposed to be intermediate between grazers and browsers, also produce PRPs in their saliva (Juntheikki et al., 1996). In contrast, meadow voles (grazers) have neither PRPs nor other types of TBSPs (Dietz et al., 1994).

Among ungulates, Austin et al. (1989) found TBSPs in the saliva of mule deer (intermediate), but not in cattle (grazers) or sheep (grazers). Mole et al. (1990) also reported similar results: white-tailed deer (intermediate) produce TBSPs, but sheep and cattle do not. Furthermore, Gehrke (2001) examined the affinity of TBSPs in six species of ungulates and found that a browser (roe deer) and intermediates (reindeer, fallow deer, and musk ox) produce TBSPs with higher affinity to tannins than grazers (cattle and mutton). Similarly, the recent study by Clauss et al. (2005) also supports this hypothesis by comparing the affinity of TBSPs in three species of rhinos with different feeding niches: Indian rhinos (intermediate) and black rhinos (browsers) produce TBSPs with higher affinity than do white rhinos (grazers).

Hagerman and Robbins (1993) examined the affinity between various types of tannins and crude saliva from the moose, beaver, mule deer, and American black bear by using an electrophoretic tannin-binding assay. Interestingly, the black bear (omnivore) produced the most effective TBSPs, which showed high affinity to all types of tannins: linear and branched condensed tannins and two types of hydrolyzable tannins (gallotannin and ellagitannin). TBSPs from the mule deer (intermediate) were more specific than those from the black bear; they could bind to all types of tannins other than ellagitannin. The moose (intermediate) produced TBSPs that bound only to linear condensed tannins. They also found that TBSPs from the beaver also bound only to linear condensed tannins, but their affinity was much lower than those from the mule deer. The main food of beavers is the bark and sapwood of the aspen, birch, willow, and alder, which are tannin-free or contain relatively low levels of condensed tannins.

In this regard, the above hypothesis is mostly supported. However, as already noted, some contradictory studies have found unclassified TBSPs in the saliva of cattle and sheep, which are typical grazers (cattle, Makkar and Becker, 1998; Gehrke, 2001; sheep, Vaithiyanathan et al., 2001).

We note, however, that there are some obstacles that may complicate such comparative studies. The first of such barriers are methodological differences found in various studies—methods for extracting salivary proteins, examining the presence of TBSPs, and quantifying the affinity. Each method likely has a different sensitivity and applicability. Thus, comparisons between different studies require care. Second, these previous comparative studies did not necessarily deal with the same types of TBSPs. In other words, the presence or affinity of TBSPs that may have originated

from different evolutionary processes may complicate the examination of the hypothesis. For instance, among the four species examined in the study of Hagerman and Robbins (1993), the characteristics of TBSPs were determined only in the mule deer and moose, which have been confirmed to have PRPs (mule deer, Austin et al., 1989; moose, Gehrke, 2001). It is possible that TBSPs from the other two species may not have been PRPs. To investigate the evolutionary relationships among feeding niches and salivary proteins as defenses against dietary tannins, we need to characterize the TBSPs in each species.

***In Vivo* Effectiveness of TBSPs**

There are sufficient data to show that TBSPs, and especially PRPs, bind effectively to both condensed and hydrolyzable tannins *in vitro* (Mehansho et al., 1987b; Bennick, 2002). *In vitro* evidence cannot always be applied *in vivo*, because some factors that differ between *in vitro* and *in vivo* situations—such as the state of tannins in the diet and the presence of other dietary chemicals—may interfere with the *in vivo* reaction between tannins and TBSPs. Furthermore, the production of TBSPs may inevitably involve costs *in vivo* that are not considered in *in vitro* conditions (McArthur et al., 1995; Clauss et al., 2003). Thus, to evaluate the significance of TBSPs in counteracting dietary tannins, we need to examine their *in vivo* effects. However, the evidence that TBSPs are effective *in vivo* is limited, partly because it is difficult to measure levels of TBSPs nondestructively. Hereafter, I focused on PRPs, because data on this topic are lacking in other TBSPs.

Glendinning (1992) first demonstrated the significance of PRPs in dealing with tannins *in vivo* by using mice injected with isoproterenol (a β -agonist) to enhance PRP secretion. The isoproterenol-injected mice exhibited a greater preference for a tannin-rich diet compared to controls. Mole et al. (1993) found that injection of a β -antagonist (propranolol), which prevents PRP synthesis, amplified the negative effects of tannins in rats. Recently, Skopec et al. (2004), using fecal proline level as an index of secreted PRPs, demonstrated clearly that induction of PRP synthesis in rats reduces the negative effects of dietary tannins by preventing tannins from breaking up into small phenolics and being absorbed. In a similar way, Jansman et al. (1994), also using rats and fecal proline level as an index, revealed that PRPs are effective as defenses against tannins, but that this defense is incomplete when dietary tannins are not readily extracted from the diet during chewing. In addition, Shimada and coworkers (2004, 2006) suggested the significance of PRPs in counteracting tannins in terms of interindividual differences in secretion levels of PRPs in the Japanese wood mouse: individuals with high levels of PRPs were less sensitive to tannins in acorns.

Until now, *in vivo* evidence noted above has been obtained only from rodents. It is noteworthy that all of these rodents can induce PRP synthesis by ingesting tannins. This inducibility is presumably an adaptive mechanism that reduces the costs arising from PRP production in animals whose natural diet varies in tannin content. In other words, the *in vivo* effectiveness of PRPs as defenses against tannins is mostly untested in animals that, unlike rats and mice, do not have this feedback mechanism to reduce the costs involved in PRP synthesis. This topic is further discussed in the [next section](#).

Cost and Inducibility of PRP Synthesis

In this section, strategies for producing PRPs are argued in the light of the costs and inducibility of PRP synthesis. Production of PRPs may involve some costs in terms of metabolism and nitrogen balance. PRPs are poorly digested, because many peptide bonds involving proline are difficult to cleave (Muenzer et al., 1979; McArthur et al., 1995). Thus, production of excess PRPs may have a nitrogen cost, even if they consist mostly of nonessential amino acids.

There is some evidence for costs arising from PRP production. In rats, Haghight et al. (1996) found that injection of a β -agonist induced PRP synthesis, but by 15 d after the end of injections the production of PRPs had ceased. My colleagues and I have obtained similar results in the Japanese wood mouse (Shimada et al., unpublished data). The rapid termination of PRP synthesis observed in these studies implies that it is costly to keep producing them. Furthermore, Skopec et al. (2004) have demonstrated nitrogen costs involved in producing PRPs: the apparent nitrogen digestibility of a diet containing 3% pentagalloyl glucose (a hydrolyzable tannin) in PRP synthesis-induced rats was over 20% lower than in control rats. This reduction in nitrogen digestibility may be mostly attributable to excretion of the PRP–tannin complexes.

The costs of producing PRPs may be overcome by the benefits of PRPs when animals consume diets containing tannins. However, if the diet is tannin-free or includes little tannin, animals may still incur the costs involved in PRP production. Induction of PRP synthesis in response to tannin injection may reduce the costs of production. Animals whose natural diets vary in tannin content may benefit from such a feedback mechanism (McArthur et al., 1995; Bennick, 2002). The inducibility of PRP synthesis by tannins seems to have been reported only in rats, mice, root voles, and Japanese wood mice. As expected, the natural diet of the two wild rodents (excluding rats and mice) varies seasonally (Juntheikki et al., 1996). For instance, the Japanese wood mouse varies its primary food items seasonally; in summer these are soft plant parts or small invertebrates, and in autumn and winter these are seeds or acorns, which generally contain considerable amounts of tannins (Tatsukawa and Murakami, 1976; Shimada, 2001).

In contrast, some mammalian species lack this feedback mechanism, thereby secreting PRPs constitutively at relatively high levels (Austin et al., 1989). It has been hypothesized that the feedback mechanism may not have evolved or may have become lost in those animals whose diets constantly contain high tannin contents (Bennick, 2002; Clauss et al., 2005). Unfortunately, only two species have been reported to use this latter strategy—humans and mule deer—and there is, therefore, much to examine in regard to the above hypothesis. The tannin content of the natural diet of mule deer is likely to vary among seasons, because their diet varies seasonally (Sowell et al., 1985). If mule deer cannot adjust their levels of secretion of PRPs in accordance with their intake levels of tannins, they may suffer the costs of unnecessary PRP synthesis. Nonetheless, do they keep producing PRPs at a high level in any season? The inducibility of PRP synthesis in mule deer has been examined in captive animals by the semiquantitative method (Austin et al., 1989). Thus, the above question is still open, and it may be too early to conclude that such a wasteful strategy is adaptive for animals.

To understand the strategies of PRP production in accordance with tannin intake, it should be helpful to examine the variations in PRP production among populations

as well as among seasons, because levels of tannins in the natural diets will vary among populations even within a species. However, only a few researchers have addressed this topic; Juntheikki (1996) found that the binding affinity of TBSPs to tannins of Scandinavian moose was higher than that of North American moose.

Conclusions

TBSPs, and especially PRPs, probably act as a first line of defense against dietary tannins in far more mammalian species than have already been reported. However, our knowledge of TBSPs in wild animals is limited and is also biased toward *in vitro* data. Detailed characterizations of TBSPs in each species and further comparative studies among species, populations, or seasons will reveal the relationships between feeding niches and production of TBSPs and shed insight on the process of evolution of different types of TBSPs.

Acknowledgments I am grateful to T. Saitoh, T. Matsui, and R. Osawa for helpful discussions, two anonymous reviewers for useful comments, and Bill Foley for offering me the chance to write this review. This study was supported in part by Grants-in-Aid (no. 17570027) from the Ministry of Education, Science and Culture of Japan.

Abstract We studied the defense mechanisms against the negative effects of tannins in acorns by using the Japanese wood mouse (*Apodemus speciosus*) and acorns of a Japanese deciduous oak *Quercus crispula*, which contain 9.9% tannins on a dry weight basis. For the experiment, we allocated 26 wood mice into two groups: acclimated ($N = 12$) and nonacclimated ($N = 14$). Mice in the nonacclimated group were fed only acorns for 10 d after 4 wk of receiving a tannin-free diet. In contrast, mice in the acclimated group received ca. 3 g acorns daily in addition to the tannin-free diet for the first 4 wk, then they were fed only acorns for 10 d. Body weight, food intake, and digestibility were monitored. In addition, the amount of salivary proline-rich proteins (PRPs) and abundance of tannase-producing bacteria (TPB) in the feces of mice were measured. Of the 14 mice in the nonacclimated group, 8 died, whereas only 1 of the 12 in the acclimated group died. During the first 5 d of feeding acorns only, mice in the nonacclimated group lost, on average, 17.5% of their body mass, while those in the acclimated group lost only 2.5%. Food intake, dry matter digestibility, and nitrogen digestibility were higher in the acclimated group than in the nonacclimated group. The results indicate that wood mice can mitigate the negative effects of tannins by acclimation. Path analysis revealed that increased

Introduction

Chemical defense mediated by plant secondary metabolites (PSMs) is one of the most studied resistance mechanisms against herbivory. In the last two decades, impressive progress has been made in describing the effects of specific PSMs on herbivores. These effects are usually adverse and may include altered foraging behaviors and depressed efficiency of digestion, growth, and reproduction (Palo and Robbins, 1991). Nevertheless, we still have limited and scattered information about the countermeasures that herbivores use to overcome the effects of specific PSMs. The elucidation of these countermeasures will contribute to better understanding of the evolution of consumers and their interaction with plants. For example, animals that can cope with particularly noxious diets can use feeding niches that are unavailable to other animals.

Acorns of some *Quercus* species contain considerable amounts of tannins (Shimada, 2001; Kirkpatrick and Pekins, 2002). Tannins, one of the most widespread PSMs, are a diverse group of water-soluble phenolics with high affinity for proteins. They have several detrimental effects on herbivores: reduction in digestibility (Robbins et al., 1987a; Chung-MacCoubrey et al., 1997), damage to the gastrointestinal mucosa and epithelia (Bernays et al., 1989), kidney or liver failure (Fowler and Richards, 1965), and loss of endogenous nitrogen (Blytt et al., 1988; Bernays et al., 1989).

Nonetheless, the idea persists that acorns are a nutritional resource for wildlife, especially for forest-dwelling rodents. There are many reports describing the positive relationships between the acorn crop and rodent population densities (Jensen, 1982; Elkinton et al., 1996; McShea, 2000; Crespin et al., 2002). We have noted, however, that several studies have failed to find such positive relationships (Miguchi, 1988; Schnurr et al., 2002; Hoshizaki and Miguchi, 2005).

Recent studies reveal that acorns of some oak species can cause intense negative effects on forest-dwelling rodents, which consume acorns as a regular part of their diet (Chung-MacCoubrey et al., 1997; Shimada and Saitoh, 2003). In their feeding experiment, Shimada and Saitoh (2003) found that most Japanese wood mice (*Apodemus speciosus*), that were fed solely *Quercus mongolica* var. *grosseserrata* acorns, which contain 8.6% tannins [tannic acid equivalent (TAE)] on a dry weight basis, showed a marked decrease in food intake, lost body weight, and eventually died. The authors concluded that the negative effects were attributable to tannins rather than to nutrient deficiency or an insufficient supply of dietary energy. Complicating the picture is the fact that the wood mouse is known to forage intensively for acorns in autumn (Wada, 1993; Miguchi, 1994). Studies of the stomach contents revealed that seeds or acorns (a starch-containing diet) were the dominant item from autumn to winter (Ohta et al., 1976; Tatsukawa and Murakami, 1976; Sone et al., 1986).

These inconsistent findings imply that under natural conditions, *A. speciosus* displays some behavioral or physiological countermeasures to mitigate the negative

effects of tannins. Shimada et al. (2004) suggested that in *A. speciosus*, acclimation to tannins reduces their negative effects. We believe that acclimation, which the animal might achieve through a gradual increase in tannin intake, is a probable hypothesis for explaining how *A. speciosus* could overcome harm by tannins. Acclimation might be generated through a variety of processes. Two likely mechanisms are the induction of tannin-binding salivary proteins and the growth of tannase-producing bacteria in the enterobacterial flora.

Various mammalian species produce salivary proteins that have high affinity for tannins (Hagerman and Robbins, 1993; McArthur et al., 1995; Shimada, 2006), including *A. speciosus* (Shimada et al., 2004). Although there are several types of tannin-binding salivary proteins, proline-rich proteins (PRPs) are prevalent and well studied in mammals (Bennick, 2002). One of their key roles is thought to be defense against tannins by preventing them from interacting with other proteins, such as enzymes or those in the mucous membrane and gastrointestinal epithelia (Mehansho et al., 1987; Robbins et al., 1987b, 1991; Hagerman and Robbins, 1993; Fickel et al., 1998). In this way, PRPs may play a role in acclimation to tannins. In rats, induction requires several days after the initial ingestion of tannins (Mehansho et al., 1983; Skopec et al., 2004). Acclimation to a high tannin diet may require a gradual increase in tannin intake.

Tannase-producing bacteria (TPB) can degrade the complex between proteins and hydrolyzable tannins. They are known to exist in the cecum of some mammalian species, including koalas and ringtail possums (Osawa and Sly, 1992; Osawa et al., 1993). Koalas digest leaves of eucalyptus, which have a high tannin content, without any apparent severe damage, partly due to the activity of these bacteria (Osawa et al., 1993). Again, acclimation is important, with tannin ingestion appearing to increase the proportion of these bacteria in the enterobacterial flora (Osawa, 1991). The presence of two types of bacteria in *A. speciosus* has been recently demonstrated (Sasaki et al., 2005)—one is a gram-positive cocci identified as *Streptococcus gallolyticus*, and the other is a newly discovered gram-positive *Lactobacillus* sp.

In an earlier study (Shimada et al., 2004), we suggested the effectiveness of acclimation in reducing the negative effects of tannins, but we did not address the underlying mechanism. We did this in the present study, by feeding acorns of *Q. crispula* (synonymous to *Q. mongolica* var. *grosseserrata*) to two groups of *A. speciosus*, one of which was preexposed to tannins, while the other was not. We also investigated the relationship between the level of PRPs or TPB and the weight changes or digestibility of wood mice fed acorns.

Methods and Materials

Wood Mice and Acorns

Wood mice were caught in October 2002 in Kyoto, central Japan (34°48'N, 135°46'E). They were weighed, housed separately in plastic cages with 400 ml paper bedding (Alpha-dri, Shepherd), and were allowed free access to distilled water under regulated environmental conditions (20°C; photoperiod, 12 L:12 D). Humidity was not controlled and ranged from 50 to 80% during the experiment.

Acorns of *Q. crispula* were collected in October 2002 in Akita prefecture, in northern Japan (39°49'N, 140°18'E), because *Q. crispula* near Kyoto did not produce sufficient acorns during that year. Sound acorns that were free of deterioration and

Table 1 Nutritional constituents and tannin contents of the acorns of *Quercus crispula* used in the experiment

Water	Crude protein	Crude fat	Crude ash	Crude fiber	NFE	Tannin astringency
49.6	6.1	1.5	2.4	1.7	88.4	9.9

NFE: nitrogen-free extract.

Water content is expressed as percent of wet weight; the other values are given as per dry weight. Tannin astringency measured by the radial diffusion method (Hagerman, 1987) is expressed as tannic acid equivalent (%).

insect damage were stored at 4°C before being fed to the mice. Nutrient composition of the acorns is given in Table 1 (analytical procedures are the same as those in Shimada, 2001). Crude proteins and ash were determined by using an NC analyzer (NC-800, Sumika Chemical Analysis Service, Ltd.) and a muffle furnace set at 550°C, respectively. Crude fat (the diethyl ether extraction method) and crude fiber (the insoluble fraction after dissolving in sulfuric acid and sodium hydroxide; Robbins, 1983) were measured by Japan Food Research Laboratories. Nitrogen-free extract (NFE) was determined as a residual fraction of the other nutrients. Tannin astringency (i.e., the protein-precipitating ability, expressed as TAE) was measured by the radial diffusion method (Hagerman, 1987). The acorns used in this experiment averaged 9.9% TAE of tannins. Although we did not identify the types of tannins in these acorns, it is likely that they are mainly hydrolyzable tannins (Chung-MacCoubrey et al., 1997).

Feeding Experiment

Wood mice were allocated into two groups: acclimated and nonacclimated. The acclimated group ($N = 12$; eight male and four female mice) received a tannin-free diet and ca. 3 g shelled acorns daily during the 4-wk preexposure period (20% of that eaten in an earlier experiment; Shimada and Saitoh, 2003), whereas the nonacclimated group ($N = 14$; nine male and five female mice) received only the tannin-free diet. The composition of the tannin-free diet closely matched that of *Q. crispula* acorns in all major constituents except tannins (details of this diet are in Shimada and Saitoh, 2003). The preexposure period began on the day of capture and lasted 28 d. Immediately after the preexposure period, we started the acorns-only feeding period (10 d), the first day of which we denoted day 0. During this time, both groups of wood mice were given nothing except as many shelled acorns as they were willing to eat. Body weight on day 0 did not differ significantly between the acclimated and nonacclimated groups ($X \pm SD$; acclimated group, 44.2 ± 6.6 g; nonacclimated group, 42.0 ± 6.6 g; Mann–Whitney U test, $z = 0.94$, $P = 0.35$).

All feces and uneaten diet were collected each morning, dried at 105°C, and later weighed to determine food intake and apparent dry matter digestibility. Dried feces were milled, and nitrogen measured by using an NC analyzer to evaluate apparent nitrogen digestibility. Preliminary tests indicated no difference in the nitrogen content of dried and fresh feces. Weight change during the acorn-feeding period was determined on days 0 and 5. Specific weight changes were calculated as

$$\text{specific weight change} = (BW_t - BW_0)/BW_0,$$

where BW_t denotes body weight on day t and BW_0 represents initial weight.

Dry matter intake (DMI), fecal nitrogen content, apparent dry matter digestibility (DMD), and apparent nitrogen digestibility (ND), were determined by using data from days 1 to 5; the data for day 0 were omitted because they could be subject to carryover effects of the prior diet. In the case of mice that died before day 5, we used data based on the diets supplied on days 1 until the day before the day of death.

Saliva Collection and Estimation of PRP Production

Saliva was individually collected from all mice 3 d before the beginning of the acorn-feeding period. Wood mice were anesthetized with xylazine hydrochloride combined with ketamine hydrochloride and injected intraperitoneally with carbachol ($100 \mu\text{g kg BW}^{-1}$) to enhance the secretion of saliva. An anesthetized mouse lying on its back was held on a plastic board that was slightly inclined toward the head. Saliva flowing down the palate was collected by using a micropipette until flow stopped. The saliva was immediately weighed, and the flow rate (ml min^{-1}) was calculated from the volume of saliva collected during the first 10 min after the beginning of saliva secretion. We assumed that the specific gravity of crude saliva was the same as that of water. Saliva was stored at -80°C .

PRPs were extracted from the saliva as trichloroacetic acid (TCA)-soluble proteins (Robbins et al., 1987b). We mixed 0.2 ml saliva from each sample with an equal volume of 10% TCA. After a 20-min incubation at 4°C , the TCA-saliva solution was centrifuged at $17,000 \text{ g}$ for 20 min, and the supernatant was collected. The residue was mixed with 0.2 ml 10% TCA, and the supernatant was collected again after centrifugation. The supernatant fraction was neutralized with sodium hydroxide and dialyzed against distilled water by using dialysis tubing (Spectrapore 4D; molecular weight cutoff of $12\text{--}14 \times 10^3 \text{ Da}$). The dialyzate was diluted to 5 ml with distilled water, and the protein content of this solution was measured by the Bradford method (Bradford, 1976) using BSA (fraction V, fatty acid free, Sigma) as the standard. To quantify the ability to generate PRPs, we defined the PRP-secreting capacity ($\text{mg min}^{-1} \text{ kg body weight}^{-1}$; Fickel et al., 1998; Shimada et al., 2004) as follows: PRP-secreting capacity = (concentration of PRPs in saliva \times saliva flow rate)/body mass.

Isolation of TPB

Fresh fecal pellets were individually collected from mice on the day of capture to assess the presence of TPB as previously described (Sasaki et al., 2005). The fecal sample (ca. 50 mg wet weight) from each mouse was emulsified with sterile physiological saline by using a homogenizer and a vortex test tube mixer. A series of 10-fold dilutions (10^1 to 10^5) of the emulsified sample was made in saline and from each dilution, 0.1 ml was spread onto tannic acid-treated brain-heart infusion agar (T-TBHIA) plates. Inoculated plates were incubated anaerobically in Anaero-Pack (Mitsubishi Gas Chemical Co., Inc., Tokyo, Japan) at 37°C for 5 d. After incubation, we counted those colonies that had a clear zone extending beyond their edges, indicating apparent bacterial degradation of tannin-protein complexes. Colonies of two types of TPB were distinguished by their appearance: colonies of *S. gallolyticus* [a tannase-producing *Streptococcus* (TPS)] are 3–5 mm in diam with distinct clear zones, whereas colonies of *Lactobacillus* sp. [a tannase-producing *Lactobacillus* (TPL)] are 2–3 mm in diam with less-distinct clear zones (Sasaki et al., 2005). We monitored the number of TPB colonies once per week until the beginning of the

acorns-only feeding period. The number of colonies was expressed in logarithmic form per gram of fresh feces.

Data Analyses

Fisher's exact probability test was used to test differences in frequency of survival between the acclimated and nonacclimated groups. Differences in weight change, components of digestion, PRP-secreting capacity, and the number of TPB colonies between the two groups were tested by using Mann–Whitney U tests.

Causal relationships among variables in the feeding experiment were assessed by path analysis to clarify the mechanisms causing acclimation to tannins. We regarded weight change from days 0 to 5 as a measure of acclimation. In other words, we supposed that wood mice that successfully acclimated to tannins would gain weight or at least have less weight loss. We built the path diagram based on three hypotheses: (1) weight change in mice would be influenced by the intake and digestibility of acorns, (2) digestibility would be influenced by intake, and (3) intake and digestibility would in turn be influenced by PRP-secreting capacity and the abundance of TPS and TPL.

Although this experiment involved two variables (DMD and ND) as a measure of digestibility, we used DMD in our hypothetical model because DMD—including the digestibility of protein, fat, and carbohydrate—may better explain body weight changes than ND, which indicates only protein digestibility. Apart from this, there was a strong correlation between DMD and ND ($r = 0.892$).

We conducted path analysis by using the program AMOS version 5.0 (Arbuckle and Wothke, 1999; Arbuckle, 2003) to calculate and test the statistical significance of path coefficients and to assess the goodness-of-fit of the model.

Results

Survival

During the acorns-only feeding period (10 d), 1 of the 12 mice (8.3%) in the acclimated group and 8 of the 14 mice (57%) in the nonacclimated group died. In the

Table 2 Weight change, survival rate, intake, and digestion in *A. speciosus* that were fed acorns

Statistical analyses were conducted using Mann–Whitney U test, except for the number of surviving individuals.

†Fisher's exact probability test, * $P < 0.01$, ** $P < 0.001$.

acclimated group, one mouse died on day 3. In the nonacclimated group, one died on day 2; two died on each of days 3, 4, and 5; and one died on day 7 after substantial loss in body weight. The difference in survival between the two groups was significant (Fisher’s exact probability test, $P = 0.015$; Table 2).

Body Weight

Figure 1 shows the daily changes in body weight of the wood mice. Body weight decreased in all individuals of the nonacclimated group; the change ranged from -26% to -15% . In contrast, in the acclimated group, 5 of the 12 mice gained weight, and 7 lost weight, with changes in body weight ranging from -16% to 12% . Average weight change from days 0 to 5 was -2.5% in the acclimated group and

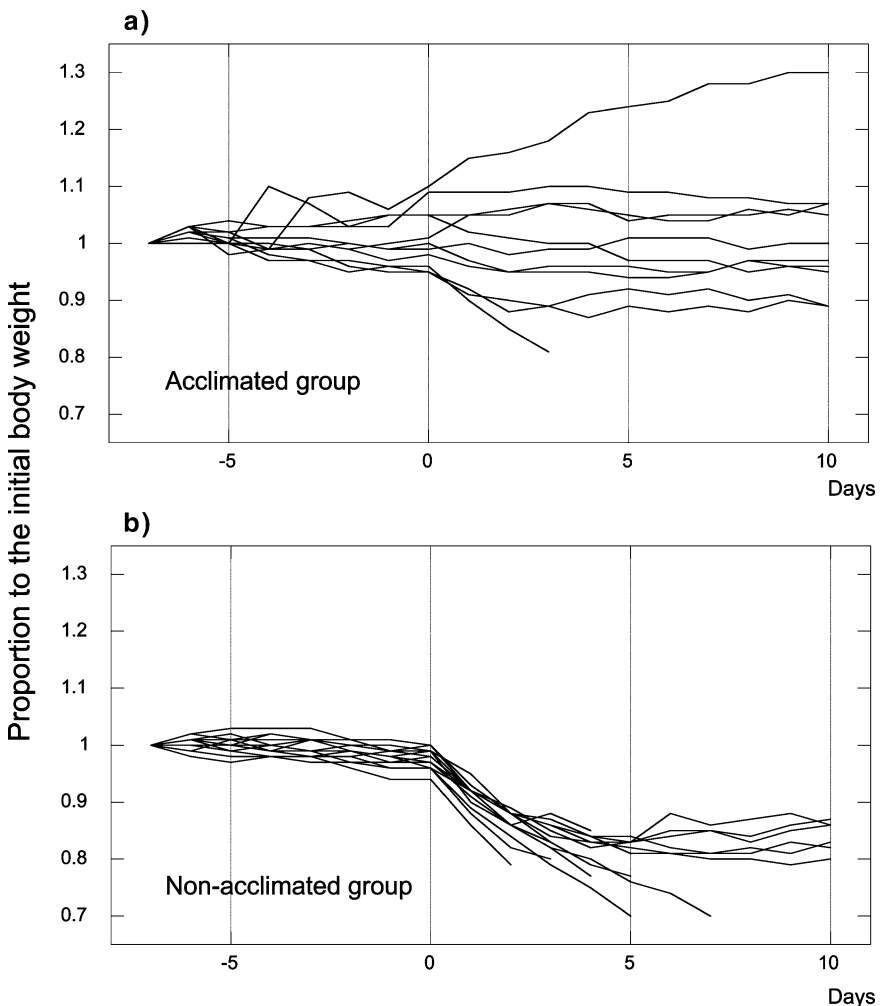

Fig. 1 Changes in body weight of *Apodemus speciosus*. Body weight is expressed as ratio to the body weight on day -7 . Mice in both groups ate only acorns from day 0. Each line shows the body weight of an individual wood mouse

–17.9% in the nonacclimated group (Table 2). This difference was statistically significant (Mann–Whitney U test, $z = 4.1$; $P < 0.001$).

Digestibility

Mice in the in the acclimated group ate 75% more than their counterparts in the nonacclimated group (Table 2) and produced feces with 36% more nitrogen. DMD and ND were 12% and 87% better in the acclimated group; these differences were statistically significant (Table 2).

Production of PRPs

Mice in the acclimated group secreted significantly more saliva and produced it 30% faster than those in the nonacclimated group (Table 3). The concentration of PRPs in saliva also appeared to be higher in the acclimated group than in the nonacclimated group; this difference, however, was not significant. Furthermore, PRP-secreting capacity in the acclimated group was 59% greater than in the nonacclimated group.

Isolation of TPB and Changes in the Number of Colonies

On the day of capture, TPS were isolated from the feces of 17 of the 26 wood mice (65%), whereas TPL occurred in the feces of all individuals. During the preexposure period, however, TPL disappeared from the feces of four mice (one in the acclimated group and three in the nonacclimated group). The animal in the acclimated group that lost TPL in its feces died during the acorns-only feeding period after losing 16% of its body weight.

Figure 2 shows the changes in the numbers of TPS and TPL colonies isolated from feces of the wood mice. The number of TPS colonies per gram of feces ($X \pm SD$, in logarithmic form) at the time of capture (day –28) was 5.05 ± 3.18 for the acclimated group and 3.55 ± 3.25 for the nonacclimated group, compared with 4.59 ± 2.85 for the acclimated group and 4.39 ± 3.99 for the nonacclimated group at the end of the preexposure period (day 0). The number of TPS colonies did not differ between the two groups at either the time of capture (Mann–Whitney U test, $z = 1.33$; $P > 0.1$) or the end of the preexposure period ($z = 0.91$, $P > 0.1$).

Statistical analyses were conducted using Mann–Whitney U test. * $P < 0.05$, ** $P < 0.01$, †: $0.05 < P < 0.1$.

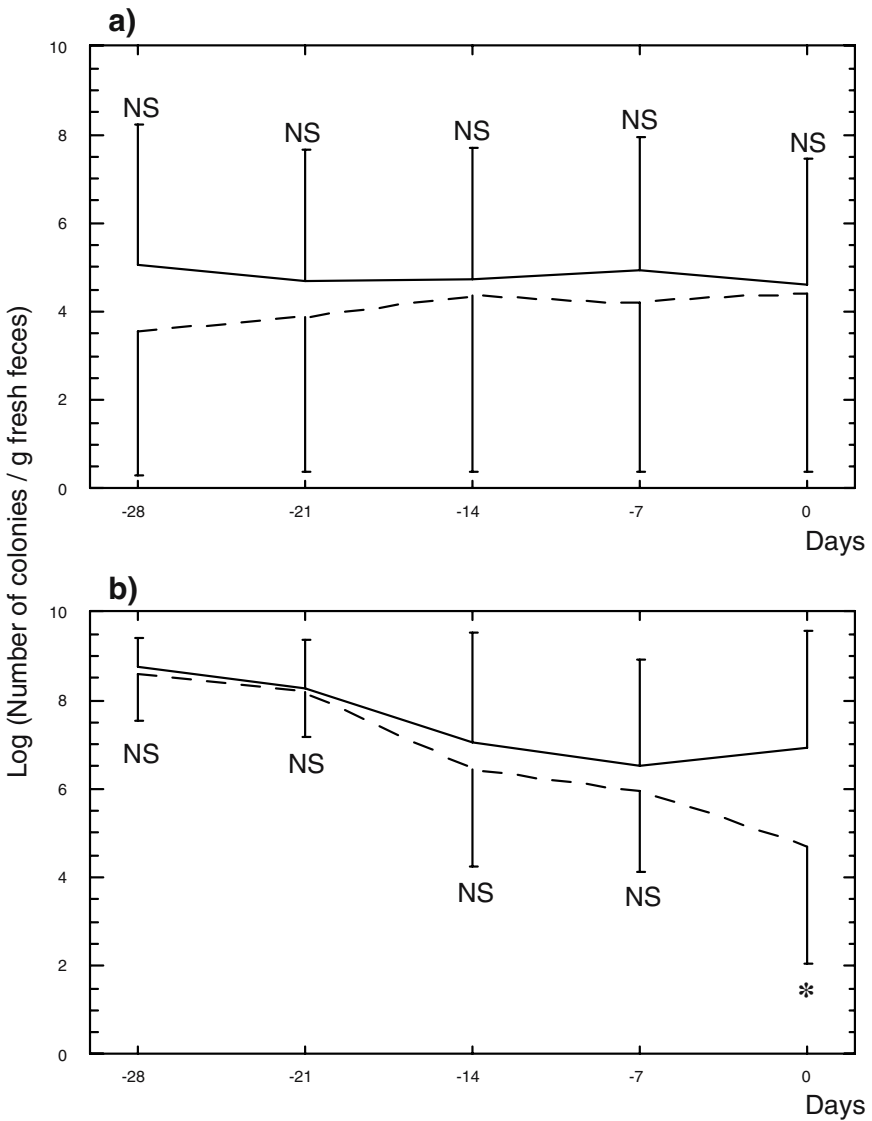

Fig. 2 Changes in the numbers of colonies of (a) TPS (tannase-producing *Streptococcus*) and (b) TPL (tannase-producing *Lactobacillus*) isolated from feces of the wood mouse, *A. speciosus*. Solid and dashed lines represent the acclimated and nonacclimated groups, respectively. Error bars represent SD. The results of Mann–Whitney *U* test between the two groups are shown by the letter beside the error bars (NS: not significant, **P* < 0.05). Mice were captured on day –28 and fed solely acorns from day 0

The two groups had a similar number of TPL colonies ($z = 0.48, P > 0.5$) at the time of capture (8.77 ± 0.63 for the acclimated group and 8.58 ± 1.06 for the nonacclimated group). By the end of the preexposure period, this had dropped to 6.93 ± 2.64 for the acclimated group and 4.71 ± 2.67 for the nonacclimated group, a significant difference between groups ($z = 2.35, P = 0.0185$) (Fig. 2).

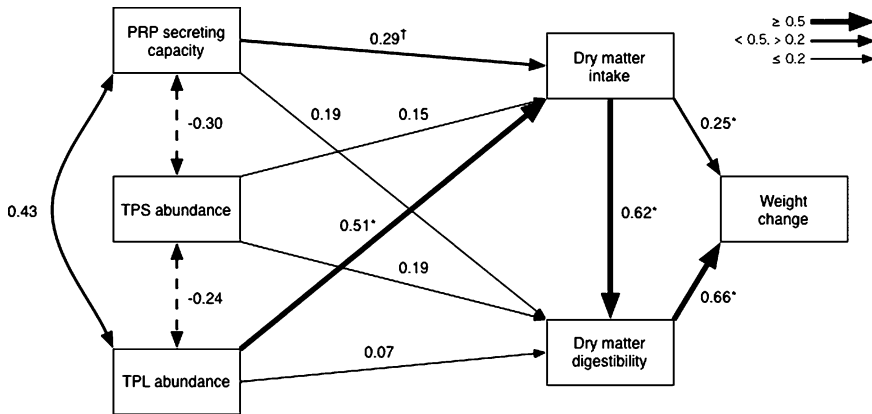

Fig. 3 Path diagram representing the influences on weight changes in the wood mouse, *A. speciosus*, that were fed acorns. Numbers above or beside the arrow refer to standardized path coefficients. Path coefficients significantly different from 0 are marked with symbols (*: $P < 0.01$, †: $0.05 < P < 0.1$). Continuous lines indicate positive effects and dashed lines negative effects, with the magnitude of the coefficient determining their width. A path with double-headed arrow denotes a correlation between the two connected variables

Path Analysis

Figure 3 shows the path diagram representing the hypothetical model of the causal relationship between variables in the acorn-feeding experiment. The goodness-of-fit test revealed that this model is statistically valid ($\chi^2 = 3.08$, $df = 3$, $P = 0.38$). The coefficient of determination for weight changes was 0.74, indicating that the model explains 74% of the variance in weight changes. The direct and indirect effects of DMI on weight change were significant, and thereby the total effect was highly significant (Table 4). DMD also influenced weight changes. In addition, PRP-secreting capacity had a positive effect on weight change (Table 4). Although PRP-secreting capacity did not have a significant direct path to both DMI and DMD, the total effect of PRP-secreting capacity on DMD was significant (Table 5). TPL abundance also positively influenced weight changes, but TPS abundance did not (Table 4). Likewise, TPS abundance did not significantly influence either DMI or DMD (Table 5). TPL abundance had a direct path to DMI but not to DMD, indicating that it could influence weight change primarily through DMI. The total

effects of TPL abundance on DMI and DMD were at least marginally significant, (Table 5). The relationships between weight changes and PRP-secreting ability or the abundance of TPLs are shown in Fig. 4.

Discussion

Effectiveness of Acclimation

The wood mice that were allowed to acclimate to tannins were better able to counteract the negative effects of tannins. This was evident in the mortality data, wherein 8 of the 14 nonacclimated mice died during the acorns-only feeding period, whereas only 1 of 12 mice in the acclimated group died (Table 2). All animals in the non-acclimated group lost much weight, while, except for one animal, those in the acclimated group lost little weight (Fig. 1). Furthermore, acclimated animals ate more and digested the dry matter and nitrogen better than nonacclimated ones (Table 2), even though they excreted feces with 36% more nitrogen than those excreted by mice in the nonacclimated group (Table 2). We speculate that fecal nitrogen content indicates the effectiveness of defense against tannins by PRPs. In rats, the increase in fecal nitrogen due to ingesting tannins comes mainly from PRPs, which form

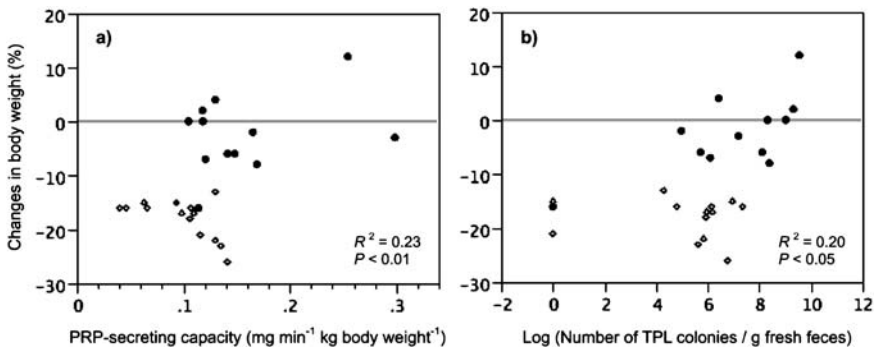

Fig. 4 Relationships between changes in body weight and (a) PRP-secreting capacity or (b) the abundance of TPL colonies in fresh feces in the wood mouse, *A. speciosus*, that were fed acorns. The data of TPL abundance were obtained on the first day of the acorns-only feeding period (day 0). Solid circles and open squares represent individuals in the acclimated and nonacclimated groups, respectively

complexes with tannins and are excreted in the feces (Eggum and Christensen, 1975). Thus, fecal nitrogen content appears to be a useful indicator of the success of PRPs in blocking tannins. Indeed, our preceding study (Shimada et al., 2004) found a significant positive correlation between PRP-secreting capacity and fecal nitrogen content in wood mice fed acorns.

These findings indicate that if *A. speciosus* have time to acclimate to acorn tannins, they can successfully negate their effects. In fact, all but one of the mice in the acclimated group appeared to be as healthy after the acorns-only feeding period as they were after eating the tannin-free diet supplemented with a few acorns. The exception was a mouse that lost TPL from its feces early during the preexposure period and died during the acorns-only feeding period after losing substantial weight. It may be that, unlike the other mice, the mouse might have somehow failed to accommodate enough exogenous TPL to cope with its dramatic dietary change. Consequently, this animal's response to tannins resembled those of mice in the non-acclimated group. As discussed below, acclimation to tannins may be linked to an increase in the abundance of TPL.

Mechanisms of the Acclimation

Path analysis yielded clues to the mechanisms underlying the acclimation. Weight change, which is regarded as an indicator of the extent of acclimation, was primarily affected by DMD and DMI (Fig. 3, Table 4). This result is understandable, because increased DMD and DMI lead to increased retention of dietary nutrients and energy (Robbins, 1983). Moreover, the PRP-secreting capacity and abundance of TPL were proved to positively influence weight changes in wood mice, whereas the abundance of TPS did not have a significant effect on weight change and, by extension, acclimation to tannins (Fig. 3, Table 4). These findings suggest that increases in both PRPs and TPLs are the underlying causes of acclimation to tannins in *A. speciosus*.

Acclimation by PRPs

PRPs are thought to defend animals against dietary tannins. They form stable complexes with tannins in the oral cavity, thereby preventing them from interacting with other proteins and degrading into noxious phenolic compounds (Robbins et al., 1991; Hagerman and Robbins, 1993; Fickel et al., 1998). In laboratory rats and mice, ingesting tannins is known to cause enlargement of the parotid glands and increased secretion of PRPs (Mehansho et al., 1985). Our *A. speciosus* probably responded in a similar way, as indicated by mice in the acclimated group secreting more PRPs than those in the nonacclimated group (Table 3).

This response probably takes several days to occur. For instance, Mehansho et al. (1983) used electrophoretic analysis to confirm that rats began to synthesize PRPs 3 d after they first ingested tannins. Likewise, Skopec et al. (2004) reported that rats started to produce PRPs in the first 8–10 d after encountering tannins. Thus, wood mice may require a gradual increase in tannin intake to tolerate the high concentrations in acorns.

Recent studies have been unveiling the *in vivo* roles of PRPs as a tannin defense. Shimada et al. (2004) found that *A. speciosus* exhibited acclimation to tannins during feeding on acorns and, in parallel, increased production of PRPs. They also

observed that wood mice producing more PRPs ate more and digested their diet better and consequently lost less weight. In rats fed radiolabeled pentagalloyl glucose (PGG), a hydrolyzable tannin, Skopec et al. (2004) demonstrated that PGG habituation increased the production of PRPs, which in turn increased the fecal excretion of PGG by forming stable PGG–PRP complexes. In this manner, PRPs may reduce the toxicity of PGG by minimizing the absorption of polyphenolic or its hydrolysis products. These observations support our hypothesis that PRPs may be one of the underlying causes of acclimation to tannins observed in the present study.

In our study, PRP-secreting capacity was used as an index of the level of PRP production instead of PRP concentration in saliva or salivary glands, which was often used in past studies (Robbins et al., 1987a; Mole et al., 1990). It has been well-documented, in laboratory rats and mice, that ingesting tannins causes the induction of PRP synthesis (Mehansho et al., 1985). Our results are the first to show that the ingestion of tannins can cause an increase in saliva flow rate as well (Table 3). To estimate the potency of PRPs as a tannin defense, it is presumably better to use PRP-secreting capacity, the product of PRP concentration and saliva flow rate, than PRP concentration alone. Another informative index to estimate the potency of PRPs is to measure the binding ability of PRPs or crude saliva to standard tannins (Austin et al., 1989; Clauss et al., 2005). The combination of PRP-secreting capacity with the salivary tannin-binding ability should be useful in future studies of the defensive role of salivary PRPs against tannins.

Acclimation by TPB

TPB can degrade complexes between proteins and hydrolyzable tannins and thereby transform these complexes into bioavailable forms for the host organism. Our results suggest that TPL (but not TPS) may be one of the underlying causes of acclimation to tannins in *A. speciosus*. This idea is supported by the following. First, TPL is far more prevalent than TPS in the feces of the wood mouse (Fig. 2). Second, the abundance of TPL in feces, but not of TPS, was related to the amount of tannins ingested by the mice. In addition, at capture, all wood mice had TPL, but 35% did not have TPS. Unlike TPS, TPL may be a key to enable mice to use acorns as a staple food source. The abundance of TPL decreased markedly while the wood mice were fed the tannin-free diet (Fig. 2). This finding shows that wood mice need to ingest tannins continuously to maintain a rich population of TPL. Interestingly, path analysis indicated that the abundance of TPL could positively influence body weight change in the wood mouse through DMI but not DMD. It is unlikely that TPL directly increases DMI in the wood mouse. It is likely that complicated physiological feedback mechanisms, which were not assumed in the path diagram (Fig. 3), are involved in the acclimation process.

TPL may complement the defense provided by PRPs. Ingested tannins are supposed to be blocked by PRPs in the oral cavity. Wood mice, however, would lose endogenous nitrogen if they could not metabolize the nitrogen-rich tannin–PRP complexes before their excretion (Shimada, 2006). In other words, while defense by PRPs may occur at the cost of endogenous nitrogen loss, we hypothesize that TPLs reduce this by degrading tannin–PRP complexes into forms suitable for recycling. Thus, PRPs and populations of TPL may both be essential to *A. speciosus* for protection against the deleterious effects of tannins.

Conclusion

The preceding discussion addresses how *A. speciosus* could overcome the negative effects of tannins in acorns through acclimation that allows them to increase their production of PRPs and establish viable populations of TPL. Acclimation, however, is not the only tannin countermeasure that *A. speciosus* might adopt. There are other hypotheses that explain how plant consumers could counteract tannins. One of the prevailing hypotheses is that consumers manipulate tannin concentrations by caching acorns, but some studies argue against this (Dixon et al., 1997; Koenig and Faeth, 1998; Shimada, 2001). Two other hypotheses, which are untested in *A. speciosus*, can be raised. One is that consumers regulate their intake of specific PSMs to circumvent overloading of any one detoxification pathway by feeding on a broad range of diets (Freeland and Janzen, 1974). The other is that, under natural conditions, consumers compensate for the decrease in nitrogen and energy digestibilities due to tannins by selective foraging on protein-rich diets, such as the larvae of the acorn weevil (Johnson et al., 1993). These two hypotheses should be evaluated in *A. speciosus*.

A. speciosus relies on acorns most extensively from late autumn to winter, when other resources, such as berries, the soft parts of plants, and invertebrates, are scarce (Tatsukawa and Murakami, 1976; Sone et al., 1986). If it did not feed on tannin-rich acorns, the mouse might find it difficult to survive winter in oak-dominated forests. Acquiring an effective defense against tannins may allow *A. speciosus* to survive and flourish in the temperate forest in Japan.

Acknowledgments We are grateful to Y. Segawa for assistance in laboratory work, Y. Takahata for instruction regarding the microbiological experiments, H. Itô for advice concerning path analysis, K. Hoshizaki for help in collecting acorns, I. Wallis for revising the manuscript, and two anonymous reviewers for instructive comments and discussion. All procedures in the field and laboratory followed the Guidelines for Animal Experimentation established by Japanese Association for Laboratory Animal Science. This study was supported in part by Grants-in-Aid (nos. 17570027 and 17370006) from the Ministry of Education, Science and Culture of Japan.

Abstract The recent discovery of efflux transporters in the gut has revolutionized our understanding of the absorption and bioavailability of pharmaceuticals and other xenobiotics in humans. Despite the celebrity of efflux transporters in the areas of pharmacology and medicine, their significance is only beginning to be realized in the area of plant–herbivore interactions. This review integrates reports on the importance of gut efflux transporters to diet selection by herbivores. The diets of herbivores are laden with toxic plant secondary metabolites (PSMs) that until recently were thought to be processed almost exclusively by detoxification enzymes in the liver. We describe how efflux transporters in the gut may play a critical role in regulating the absorption of PSMs in herbivores and dictating diet selection. Recent studies suggest that the role of efflux transporters in mediating diet selection in herbivores may be as critical as detoxification enzymes. In addition to diet selection, gut efflux transporters have implications for other aspects of plant–animal interactions. They may be significant components of the evolutionary arms race that influences chemical diversity in plants. Furthermore, in agricultural systems, gut efflux transporters may play an important role in the effectiveness of pesticides. This synthesis paper introduces a new direction in plant–herbivore interactions by providing a complementary mechanism, regulated absorption, to detoxification that may define tolerance to PSMs by herbivores.

Introduction

Two central foci in plant–herbivore interactions have been identified to explain the diversity of plant chemical defenses as well as the variation in herbivore tolerance to defenses. Much progress has been made in identifying and quantifying plant secondary metabolites (PSMs), as well as understanding their influence on herbivore feeding (Freeland and Janzen, 1974; Palo and Robbins, 1991; Rosenthal and Berenbaum, 1992; Cheeke, 1998; Foley et al., 1999). Diversity in PSMs has been attributed to the need of plants to defend themselves against a wide range of herbivores and pathogens (Berenbaum et al., 1991; Fritz and Simms, 1992; Berenbaum, 1995, 1999). In contrast, relatively little progress has been made with respect to the other central goal, i.e., explaining the variation in tolerance to PSMs by herbivores. Variation in detoxification capabilities has long been suggested as the underlying mechanism responsible for differential tolerances to PSMs among herbivores (Freeland and Janzen, 1974; Foley et al., 1999; Pass et al., 2001; Karban and Agrawal, 2002; Li et al., 2004). However, individuals and species with the highest PSM tolerance do not always have the highest activity levels of detoxification enzymes (Neal, 1987) or the highest rates of PSM elimination. For example, *Neotoma stephensi*, a juniper specialist, can tolerate more juniper and PSMs in juniper than its generalist counterpart, *N. albigula* (Sorensen et al., 2005), but it does not have a faster rate of juniper PSM elimination from the blood (Sorensen and Dearing, 2003).

We propose that, in addition to enzymatic detoxification, variation in mechanisms that regulate absorption of PSMs in the intestine may further explain the variation in herbivore tolerance to PSMs. Although the importance of PSM absorption in herbivores is not a new concept, previously proposed mechanisms have focused on passive barriers in the gut such as peritrophic membranes (PMs) (Lehane, 1997; Barbehenn, 2001). In this work, we argue that in addition to passive barriers, herbivores can actively transport PSMs out of enterocytes and back into the lumen of the gut, limiting PSM absorption. We refer to this process and its predicted influence on the foraging behavior of herbivores as the “regulated absorption model.” We identify a plausible mechanism for regulated absorption and provide evidence that this mechanism can influence PSM tolerance in herbivores. In addition, we propose that regulated absorption of PSMs may further our understanding of chemical diversity in plants. Throughout, we provide several testable hypotheses regarding the role that regulated absorption plays in influencing the interactions between PSMs and herbivores. This synthesis paper introduces ecologists to a new direction in plant–herbivore interactions by providing a complementary mechanism, regulated absorption, to detoxification that may define tolerance to plant secondary metabolites by herbivores.

Introduction to Regulated Absorption

Ingestion of PSMs presents a physiological challenge for herbivores. PSMs that are ingested and absorbed exert a variety of deleterious effects on tissues and organs (Polya, 2003). Furthermore, the toxicity of PSMs is typically concentration-dependent and is therefore correlated with both the quantity of PSM ingested and the quantity of PSM that is absorbed and available throughout the body via the general circulation (Schumacher-Henrique et al., 2003; Orafidiya et al., 2004).

Because of the ubiquity of secondary metabolites in plants, herbivores cannot simply avoid them, but must employ mechanisms that minimize their levels in the circulation. Detoxification is currently regarded as the major physiological process that regulates the pharmacological distribution of PSMs in the body (Rosenthal and Berenbaum, 1992; Foley et al., 1999). In general, the process of detoxification biotransforms toxic PSMs into water-soluble metabolites that can be readily excreted. Although detoxification can lead to the formation of more toxic metabolites, the detoxification process typically results in a reduction in concentrations of toxic PSMs in the body. Moreover, several studies on insects have demonstrated that increased levels and activity of detoxification via enzymes are correlated with increased intake levels of certain PSMs in various herbivores. For example, the induction of cytochrome P-450 monooxygenases by PSMs, xanthotoxin and nicotine, is associated with high tolerance to these in the corn earworm (*Helicoverpa zea*) and tobacco hornworms (*Manduca sexta*), respectively (Snyder and Glendinning, 1996; Li et al., 2000; Sasabe et al., 2004). Although several studies have investigated detoxification enzymes in mammalian herbivores (Boyle et al., 1999, 2000a,b; Pass et al., 1999, 2001, 2002; Ngo et al., 2000; Lamb et al., 2001, 2004), few have directly linked higher PSM tolerance with higher detoxification enzyme activity in mammals (Miranda et al., 1991).

Although detoxification clearly plays a significant role in enhancing the excretion of PSMs and is predicted to facilitate PSM intake in herbivores, it is not the only mechanism that can regulate PSM concentrations in the body. For PSMs to gain access to tissues and organs, absorption across the gastrointestinal tract must first occur. Therefore, mechanisms in the gut that limit absorption provide the first line of defense against ingested PSMs. Detoxification in the intestine, whether via enzymes from microbes (Scheline, 1973; Jones and Megarrity, 1986; Hammond, 1995; Bhat et al., 1998) or the herbivore (Rosenthal and Berenbaum, 1992; Ilett et al., 1993; Watkins, 1997; Berenbaum, 1999; Von Richter et al., 2004), can regulate the absorption and subsequent distribution of ingested PSMs in herbivores. However, several studies demonstrate that many ingested PSMs that possess chemical properties conducive to absorption are neither detoxified nor absorbed in the gut (Ohmart and Larsson, 1989; Southwell et al., 1995; Schmidt et al., 2000; Cooper, 2001). For example, ingested terpenes, highly lipophilic PSMs, are excreted unchanged in the feces of two species of herbivorous mammals (*Neotoma* spp.; Sorensen and Dearing, 2003) and in frass of insects (Gómez et al., 1999; Müller and Hilker, 1999; Evans et al., 2000; Southwell et al., 2003). Physical barriers that limit the passive diffusion of PSMs across the gut, such as the peritrophic matrix and surfactants, have been the only mechanisms proposed to explain this phenomenon (Lehane, 1997; Barbehenn and Martin, 1998; Barbehenn, 2001). However, insights from biomedical and pharmaceutical research suggest that active transport of xenobiotics, including PSMs, out of enterocytes and into the gut lumen is also common and provides an efficient barrier against the absorption of lipophilic xenobiotics.

Mechanisms of Regulated Absorption

Despite the lack of attention from scientists who study plant–herbivore interactions, the biochemical mechanisms that actively regulate the absorption of ingested compounds are well known to medical scientists (Hunter and Hirst, 1997; Sharom,

1997; Watkins, 1997; Benet and Cummins, 2001; Doherty and Charman, 2002; Schinkel and Jonker, 2003). The molecules best known for their capacity to regulate the absorption of xenobiotics are collectively known as ATP-binding cassette (ABC) transporters. Permeability glycoprotein, or P-glycoprotein (P-gp), is encoded by the Multidrug Resistance (MDR) gene, and is one of over 200 ABC transporters that has been identified as playing a significant role in regulating bioavailability, or tissue distribution, of xenobiotics (Dietrich et al., 2003; Chan et al., 2004). Like other ABC transporters, P-gp is primarily expressed in the apical membrane of cells in barrier tissues, including the intestine, liver, kidney, testes, uterus, and blood-brain barrier. However, unlike other ABC transporters, P-gp is not substrate-specific and is capable of transporting a variety of structurally diverse compounds, including natural products (Sharom, 1997; Seelig and Landwojtowicz, 2000; Schinkel and Jonker, 2003). Although P-gp is a promiscuous transporter, most P-gp substrates are organic, relatively lipophilic, and contain polar or nonpolar domains (i.e., amphipathic, Sharom, 1997; Schinkel and Jonker, 2003).

P-gp is a major factor influencing the relationship between dose, blood concentration, and response of many orally administered drugs in humans (Van Zuylen et al., 2000; Ayrton and Morgan, 2001; Funakoshi et al., 2003). In general, individuals with higher quantities of P-gp exhibit lower blood concentrations and greater fecal excretion of certain orally administered drugs (Debenham et al., 1982; Van Zuylen et al., 2000). P-gp is also known to govern the bioavailability of many drugs resulting in lower pharmacological effect (Van Asperen et al., 1996; Jonker et al., 1999; Schinkel, 1999). P-gp reduces the bioavailability of ingested xenobiotics in three ways (Fig. 1). First, it can directly limit absorption by actively effluxing ingested xenobiotics out of cells against a concentration gradient via an ATP-dependent pump (Sharom, 1997; Dietrich et al., 2003). Second, it can indirectly

Fig. 1 Schematic representation of the functional role of P-glycoprotein (P-gp) and cytochrome P-450 3A (CYP3A) in regulating the absorption of ingested xenobiotics (X, i.e., drugs or plant secondary metabolites) in the gastrointestinal tract (GIT). P-gp and CYP3A can regulate the absorption of ingested xenobiotics (X) and detoxification metabolites (Xm) resulting in fecal excretion of these molecules via three scenarios. Ingested xenobiotics that are substrates of P-gp can be directly effluxed out of cells by P-gp (A). CYP3A metabolizes xenobiotics, which may result in absorption of the xenobiotic metabolite across the basolateral membrane (B). Finally, if the xenobiotic metabolite is a P-gp substrate, P-gp can efflux the metabolite out of cells (C)

reduce the bioavailability of ingested xenobiotics by regulating concentrations of intracellular xenobiotics to levels within the capacity of associated detoxification enzymes in cells, particularly cytochrome P-450 3A enzymes (Watkins, 1997; Ayrton and Morgan, 2001; Benet and Cummins, 2001). P-gp and CYP3A are colocalized in the villus tip of enterocytes, share many of the same substrates, and demonstrate broad overlap in substrate specificities (Kim et al., 1999; Katoh et al., 2001; Zhang and Benet, 2001). These attributes suggest that P-gp and CYP3A act in concert as a barrier to drug absorption. Finally, P-gp can efflux detoxification metabolites out of cells, thereby reducing the absorption of potentially toxic metabolites in addition to ingested parent xenobiotics (Katoh et al., 2001). In terms of drug therapy, mechanisms that limit absorption, enhance excretion, and minimize delivery of drugs to target tissues are medically problematic. For example, P-gp present in the transmembrane of cancer cells prevents the absorption of chemotherapeutic drugs (Lin and Yamazaki, 2003). Furthermore, because P-gp is a promiscuous transporter, it effluxes a wide range of anticancer drugs out of cells, resulting in the multidrug resistance phenomenon in cancer patients (Bellamy, 1996; Sparreboom et al., 2003). However, the same mechanisms that limit drug distribution in humans may also minimize the distribution of deleterious PSMs and prove beneficial to herbivores. In the following sections, we provide evidence that P-gp, or similar active transporters, may be employed by herbivores to enhance excretion and limit the bioavailability of ingested PSMs.

Evidence for Efflux Transporters in Herbivores

The first line of evidence that active transporters such as P-gp may be present in herbivores is the ubiquity and conservation of P-gp-like molecules among organisms. P-gp has been identified within mammals (humans, mice, rats, primates, dogs) and among distantly related taxa, such as bacteria, nematodes, insects, fish, birds, and plants (Dudler and Hertig, 1992; Lanning et al., 1996a; Davies et al., 1997; Barnes, 2001; Doi et al., 2001; Saier and Paulsen, 2001; Buss et al., 2002; Smith and Prichard, 2002; Mikkaichi et al., 2004). Furthermore, the sequence of P-gp is highly conserved across taxa (UCS Genome Bioinformatics website, <http://genome.ucsc.edu>). For example, the P-gp homologue in the plant, *Arabidopsis thaliana*, shares seven of nine introns with mammalian P-gp to within a few nucleotides (Dudler and Hertig, 1992). The shared sequence, organizational structure, and function of P-gp among distantly related organisms indicate that insect and mammalian herbivores will likely have P-gp homologues. Although empirical studies on P-gp in herbivores are minimal, the few species that have been investigated do possess P-gp or P-gp-like mechanisms. For example, P-gp-like transporters have been identified in the tobacco budworm, and appear to actively transport xenobiotics out of cells in these insects (Lanning et al., 1996a; Gaertner et al., 1998). Studies on herbivorous woodrats also demonstrate that several species of mammalian herbivores possess P-gp (Green et al., 2004).

A second piece of corroborating evidence is that a large number of PSMs that are potentially consumed by herbivores are substrates for P-gp (Patel et al., 2004; Zhou et al., 2004). Alkaloids, such as vinblastine from *Vinca rosea* (periwinkle, Burns, 1972; Sharom, 1997) and more recently, piperine from black (*Piper nigrum* Linn) and long pepper (*P. longum* Linn), are P-gp substrates (Bhardwaj et al., 2002).

Others include diterpene from *Euphorbia* (spurges, Hohmann et al., 2002; Appendino et al., 2003), phenolic glycosides from foxglove (*Digitalis lanata*, Kim et al., 1999; Katoh et al., 2001; Funakoshi et al., 2003), curcumin from *Curcumin longa* (Limtrakul et al., 2004), ginsenosides from ginseng (Choi et al., 2003; Kim et al., 2003), catechins from green tea (*Camellia sinensis*, Wang et al., 2002), bergamotol from grapefruits (Ohnishi et al., 2000; Wang et al., 2001), and hypericin from Saint John's wort (*Hypericum perforatum*, Wang et al., 2004).

The third line of evidence that active transporters such as P-gp are present in intestines of herbivores is the excretion of unmetabolized PSMs in the feces. A single study demonstrated that mammals (*Neotoma* spp.) excrete large quantities of ingested PSMs unmetabolized in the feces (Sorensen et al., 2004). Other examples of fecal excretion of unchanged compounds are found in herbivorous insects. For example, a large proportion of ingested nicotine is excreted unmetabolized in the feces of several insects specializing on tobacco (Self et al. 1964a,b; Snyder et al., 1994). Several other insect herbivores excrete terpenes in the feces that are identical in chemical structure and proportion to those found in the plants they consume (Gómez et al., 1999; Evans et al., 2000).

We propose that active transport of PSMs out of enterocytes is a plausible explanation for the fecal excretion of many unmetabolized PSMs in herbivores. Although passive barriers, such as peritrophic membranes (PMs), may be important in limiting the absorption of large complex PSMs, such as tannins (Barbehenn, 2001), these barriers would not be effective against small lipophilic compounds. Many of the PSMs excreted unmetabolized in the feces of herbivores, such as terpenes, are small molecules, highly lipophilic and, therefore, not likely to be passively filtered by PMs. Moreover, PMs cannot explain the excretion of terpenes unchanged in the feces of mammalian herbivores (Sorensen et al., 2004) because mammals do not possess PMs (Lehane, 1997). Instead, the excretion of many unmetabolized PSMs in the feces of herbivores is likely attributable to an active transporter such as P-gp. In support, a nicotine pump similar to P-gp has been identified in both malpighian tubules and in the blood–brain barrier of the tobacco hornworm (Murray et al., 1994; Gaertner et al., 1998). Finally, the strong correlation between the lipid solubility of a compound and its ability to interact with P-gp suggests that lipophilic PSMs are substrates for transporter proteins (Zamora et al., 1988; Schinkel and Jonker, 2003).

Although the excretion of unmetabolized lipophilic PSMs in the feces suggests that P-gp-like mechanisms are present in herbivores, the majority of studies fail to detect large quantities of unmetabolized PSMs in the feces of herbivores (Foley et al., 1987; Boyle et al., 1999, 2000a,b). We argue that these results do not necessarily indicate that most herbivores do not possess or utilize transporter proteins to minimize PSM bioavailability. Instead, the lack of unmetabolized PSMs in the feces may be attributable to the complex interactions between transporter proteins, detoxification enzymes, and microbes in the intestine prior to absorption. PSMs that are not absorbed may be detoxified or degraded by enzymes or microbes in the hindgut prior to excretion. For example, detoxification enzymes, particularly cytochrome P-450 3A, are locally associated and share substrate affinity with P-gp (Watkins, 1997; Kim et al., 1999; Zhang and Benet, 2001; Doherty and Charman, 2002). In addition, intestinal microbes from a variety of herbivores are known to metabolize and degrade PSMs (Carlson and Breeze, 1984; Jones and Megarrity, 1986; Hammond, 1995). Specifically, many microbes metabolize and degrade

lipophilic terpenes (Harder and Probian, 1995; Misra et al., 1996), which are likely P-gp substrates. Therefore, it is possible for P-gp to regulate the absorption of ingested PSMs in herbivores, but unmetabolized PSMs in the feces would not be present because of detoxification and modification of PSMs by enzymes and microbes prior to excretion. Alternatively, the rate of absorption of highly lipophilic compounds may exceed the rate of efflux by P-gp-like mechanisms resulting in absorption of PSMs that are actually P-gp substrates.

New Directions

It is essential to identify ways to isolate the contribution of active transport proteins in regulating PSM absorption in herbivores to better understand foraging constraints and disparate foraging strategies among herbivorous species. In this work, we suggest several areas of future research for chemical ecologists to better understand the interactions between PSMs and herbivores. Because of the preponderance of research on the function of P-gp, the following hypotheses will focus on assays and predictions for P-gp, but could be potentially applied to any efflux transporter protein.

The first needed area of research is to test the overall presence and level of transporter proteins in herbivores by using molecular techniques. The presence and quantity of particular proteins such as P-gp can be determined by using a combination of Western blots and quantitative polymerase chain reactions (qPCR). Western blots with monoclonal antibodies have been used to quantify P-gp in a variety of organisms, including herbivorous woodrats (Scheffer et al., 2000; Barnes, 2001; Doi et al., 2001; Green et al., 2004). Application of this method is accessible to a number of species because of the high conservation of monoclonal antibodies across species. Although this approach has been successfully applied to several species of animals, a potential limitation is the possible cross-reaction with proteins other than P-gp (Van Den Elsen et al., 1999) and the semiquantitative nature of the assay. Quantification of P-gp mRNA provides a more robust approach to identify and quantify P-gp in specific species of herbivores. Because sequences have not been determined for many wild species, species-specific sequences must be generated. In general, this process involves designing primary PCR primers from homologous sequences of nearest relatives, sequencing and verifying PCR products against known homologues to confirm identity, and then designing species-specific probes for qPCR. This approach was successfully used for plants (Dudler and Hertig, 1992; Yazaki et al., 2001; Sasaki et al., 2002), and will likely provide similar success in other species. An example of sequence alignment for a P-gp-like gene in plants and mammals is found in Dudler and Hertig (1992) and can provide an initial starting place for designing primers. In addition, homologous sequences can be designed based on P-gp (often referred to as MDR) gene alignments generated from the UCS Genome Bioinformatics website (<http://genome.ucsc.edu>). Quantitative PCR is beneficial in that it provides P-gp specificity and an opportunity to identify particular changes in P-gp sequence with respect to species, foraging strategies, and the type of PSM consumed. Quantification of P-gp-like transporters should not be restricted to segments of the gastrointestinal tract and should include studies in “barrier” tissues, such as the Malpighian tubules, liver, kidney, brain, testes, and uterus.

Given the likely applicability of these assays for P-gp quantification in herbivores, several hypotheses can be tested. First, these assays can be used to indirectly test the hypothesis that specific PSMs ingested by herbivores are substrates for P-gp. In general, ingestion of P-gp substrates yields an increase in P-gp concentrations (Benet and Cummins, 2001; Fromm, 2003, 2004; Lin and Yamazaki, 2003; Zhou et al., 2004). Determining whether a PSM is a P-gp substrate can be further verified with *in vitro* assays that use P-gp expressing cell lines (Varma et al., 2003; Moaddel et al., 2004; Wang et al., 2004) and/or *in vivo* studies that use P-gp knockout mice (Schinkel et al., 1997).

Second, assays can be employed to test the hypothesis that specialist herbivores rely on regulated absorption to a greater extent than generalist herbivores. Several studies that investigate the excretion of unchanged metabolites indirectly support this hypothesis. For example, the juniper specialist (*N. stephensi*) excreted a larger proportion (28%) of orally ingested alpha-pinene, the predominant PSM in juniper, in the feces than a closely related juniper generalists (*N. albigula*; 15%, (Sorensen et al., 2004). Similarly, specialist koalas excreted 15% of ingested eucalyptus oils, primarily composed of terpenes, in the feces (Eberhard et al., 1975) compared to 3% in a generalist counterpart, the brushtail possums (Foley et al., 1987). These results emphasize the need to quantify and compare P-gp activity, PSM intake, and fecal excretion of PSMs in additional specialist and generalist herbivores. Analytical techniques for quantification of unchanged PSMs include gas chromatography and high-pressure liquid chromatography; however, specific analysis is dependent on the chemistry of the particular PSM.

Quantitative assays can also be used to investigate the hypothesis that mechanisms regulating PSM absorption are positively correlated with expression of P-450 enzymes, specifically CYP3A, in the intestine. This prediction is based on the observation of large substrate overlap in CYP3A and P-gp within some species (Kim et al., 1999; Benet and Cummins, 2001; Katoh et al., 2001; Zhang and Benet, 2001). Furthermore, these molecules are typically located near one another and are thought to function in tandem. Chemical and physiological ecologists could, therefore, simultaneously compare P-gp and CYP3A levels along with the excretion of unmetabolized and metabolized PSMs in the feces when determining the role of P-gp in herbivory.

Finally, the ability to sequence, quantify, and test substrate affinity for P-gp makes it possible to investigate how generalists cope pharmacologically with a chemically diverse diet. Generalists are typically exposed to a wide and unpredictable array of PSMs because they consume taxonomically, and therefore, chemically diverse plant species, whereas specialists typically consume higher concentrations of a less diverse spectrum of PSMs because they consume plants within a narrow taxon range. It is theorized that generalists possess greater structural and functional flexibility in counterdefense mechanisms against PSMs (Gatehouse, 2002; Li et al., 2004). Greater polymorphisms in P-450 detoxification enzymes have been identified in a population of generalist insect herbivores (*H. zea*), and these are associated with wider substrate breadth compared to a population of specialists (*Papilio polyxenes*; Li et al., 2004). We predict that investigation on P-gp sequence and substrate affinity will reveal that generalist populations have greater P-gp polymorphisms that broaden substrate affinity compared to specialists. These tests will further describe the molecular and genetic disparity in counterdefenses between specialist and generalist herbivores.

Transporter proteins may not only be involved in the excretion of PSMs in feces, but may also explain the mechanisms for their sequestration in insects. Many herbivores “shuttle” ingested PSMs against a concentration gradient and sequester them unmetabolized in diverticular pouches, defensive glands, or hemolymph (Eisner et al., 1974; Müller and Hilker, 1999; Schmidt et al., 2000; Nishida, 2002; Pasteels and Hartmann, 2004). To date, no specific transporter has been implicated for the movement of these PSMs. However, there is recent evidence that selective transport systems are responsible for sequestration of certain metabolites in tissues of insects (Pasteels and Hartmann, 2004). In addition, transporter proteins have been proposed as a mechanism employed by plants to sequester PSMs in vacuoles, thereby protecting plant cells from the consequences of PSM exposure (Debeaujon et al., 2001; Sakai et al., 2002).

P-gp and Secondary Compound Diversity

P-gp transporters and the secondary compounds that interfere with them may be key factors that contribute in part to the bewildering diversity of chemical defenses in plants. The astounding diversity of secondary compounds in many species of plants is thought to be the result of a biochemical “arms race,” or reciprocal evolution between plants and herbivores (Berenbaum et al., 1991; Fritz and Simms, 1992; Berenbaum, 1995, 1999; Castellanos and Espinosa-Garcia, 1997). The presence and abundance of P-gp transporters in their guts could represent an evolutionary counterresponse on the part of herbivores that reduces the physiological effect of secondary compounds by decreasing the quantity of “potent” PSM absorbed into the tissues. As a consequence of P-gp transporters, plants may have evolved secondary compounds that directly interfere with P-gp transporters that thereby enhance toxicity through increased absorption of potent secondary compounds. We refer to the P-gp inhibitors as “potency enhancers” because they act to increase the absorption of compounds that are biologically potent, or bioactive. Examples of PSMs that reduce the effectiveness of P-gp and enhance the absorption of potent compounds include furanocoumarins from grapefruits (Ohnishi et al., 2000; Wang et al., 2001; Honda et al., 2004), quercetin in oaks and birches (Shapiro and Ling, 1997; Conseil et al., 1998), and diterpenoids in spurge (Hohmann et al., 2002; Appendino et al., 2003). Although no work exists on the synergism between “potency enhancers” that inhibit P-gp and secondary compound diversity, some plant species with P-gp inhibitors also produce potent lipophilic compounds (e.g., terpenes in grapefruit) that could be P-gp substrates. Obviously, more research is necessary to critically evaluate these speculations.

In contrast, secondary compounds have been described that activate P-gp transporters, thereby reducing absorption of other compounds (Dürr et al., 2000; Perloff et al., 2001). For example, in *in vitro* experiments with cell cultures, the administration of hypericin extracted from St. John’s wort elevates P-gp expression by 700% and significantly decreases the absorption of P-gp substrates (Perloff et al., 2001). The object of that study, as well as the others, was to identify compounds that interfere with the absorption of pharmaceuticals. Thus, the amount of activators applied may be far greater than the natural concentration of these compounds in plant tissues. Whether P-gp-activating compounds have synergistic effects on cooccurring secondary compounds at natural concentrations in plants when consumed by herbivores has not been examined. In theory, P-gp activators should

reduce the bioavailability of other coingested secondary compounds that are P-gp substrates. The adaptive significance to the plant of P-gp-activating compounds is not obvious. However, if P-gp activating compounds are produced at active concentrations in plants, the possibility exists that generalist herbivores take advantage of such compounds to reduce the absorption of secondary compounds from other plants in their diet. Thus, foraging behavior of herbivores may ultimately depend on the presence or absence of PSMs that are P-gp substrates, as well as on the presence of P-gp inhibitors and activators.

Broader Implications

Exploring how PSMs interact with transporter proteins and the relative role of these interactions in PSM tolerance in herbivores will not only contribute to understanding plant–herbivore interactions, but will likely have farther reaching applications. For example, the identification of PSMs that inhibit transporter proteins may contribute to a more efficient drug therapy. For example, a major complication in cancer therapy is due to multidrug resistance in cancer cells afforded by P-gp (Bellamy, 1996; Ambudkar et al., 2003). There is a pressing need to identify natural products and synthesize drugs that directly inhibit P-gp without concomitant toxicity to normal cells. Integration of knowledge from chemical ecologists who can predict which plants are most likely to possess P-gp inhibitors, and knowledge from pharmacologists who can predict which molecules are most likely to inhibit P-gp could facilitate the identification of compounds that enhance chemotherapy. Specifically, ecological knowledge of plant defenses and those acted on by active transporters may advance drug discovery. For example, assuming that P-gp is important in regulating the absorption of potent PSMs and that P-gp may be more important in specialist herbivores than generalists (Green et al., 2004; Sorensen et al., 2004), we can predict that leaves fed on by specialists contain compounds that are P-gp substrates, but are also likely to be potent drugs for humans. Moreover, we propose that individual plants or leaves within a host plant that are avoided by specialists may contain potency enhancers, compounds that inhibit the function of P-gp. We suggest that by applying the relationship between foraging strategies of herbivores and regulated absorption, a model can be used to efficiently target plants that contain potent compounds or potency enhancers. Further research into this area of plant–herbivore interactions could reveal the bioprospecting potential of herbivores.

Identifying active transporters in herbivores and PSMs that block the function of transporters could also be important in controlling both plant and animal pest species. Several pesticides, herbicides, anthelmintics, acaricides, and amebicides are P-gp substrates (Abu-Qare et al., 2003; Schinkel and Jonker, 2003). In addition, the absorption of many of these pesticides is limited by P-gp-like activity in insects (Lanning et al. 1996a,b; Buss et al., 2002; Srinivas et al., 2004) and plants (Windsor et al., 2003). The prevalence of P-gp may, therefore, help explain insect and plant resistance to pesticides and herbicides. Manipulation of transporters that regulate toxin absorption could be applied to development of more effective pest control agents. For example, pesticides that are P-gp substrates might be more effective if they were administered along with known P-gp inhibitors. This practice could result

in higher quantities of pesticides absorbed per unit exposure, thereby reducing the amount of pesticide used and/or increasing the susceptibility of insects to pesticides.

Abstract alpha-Pinene is the dominant monoterpene in *Juniperus monosperma*. Wood rat species in the genus *Neotoma* that consume *J. monosperma* vary in their inclusion of it in their wild diet and in their tolerance of whole *J. monosperma* or alpha-pinene in laboratory feeding trials. A proposed mechanism for variable tolerance is a difference in absorption of alpha-pinene from the small intestine that is mediated by the intestinal transporter permeability glycoprotein (Pgp). To determine if alpha-pinene is a Pgp substrate, we tested whether it can competitively inhibit Pgp and thereby increase the accumulation of a known Pgp substrate (digoxin) in (1) everted sleeves of small intestine from *Neotoma stephensi*, a juniper specialist, *N. albigula*, a sympatric generalist that consumes juniper, *N. cinerea*, a more distantly related generalist, and Sprague-Dawley rats, and (2) in Caco-2 cells that over express Pgp. We also measured Pgp ATPase phosphate production in transfected insect membrane vesicles exposed to alpha-pinene. We found no significant increase in digoxin accumulation with competitive inhibition experiments, and no increase in phosphate production with transfected membranes, at any concentration of alpha-pinene up to 100 μ M. To test whether other compounds in juniper affect Pgp activity, we acclimated five *N. stephensi* to a juniper diet for 5 d, but found no significant effect

Introduction

Mammalian herbivores differ in their tolerance of defensive chemicals found in plant diets (Atsatt and Ingram, 1983; Mead et al., 1985; Mangione et al., 2000). Within the *Neotoma* genus of wood rats (Edwards and Bradley, 2002) are both dietary generalists and specialists that consume plant species high in defensive compounds (Atsatt and Ingram, 1983; Dial, 1988; Edwards et al., 2001). *Neotoma albigula* (Hartley), a generalist, and *N. stephensi* (Goldman), a juniper specialist, are sympatric, and in the field *N. stephensi* includes more *Juniperus monosperma* leaves in its diet (Dial, 1988). In captivity, *N. stephensi* voluntarily consumes more *J. monosperma* and maintains body mass on diets of higher concentration of alpha-pinene, the dominant monoterpene in *J. monosperma*, than *N. albigula* (Dearing et al., 2000).

Sorensen and Dearing (2003), using a pharmacokinetic approach, found that *N. stephensi* exhibits a lower plasma concentration of alpha-pinene than *N. albigula* after oral gavage. Additionally, Sorensen et al. (2004) found that *N. stephensi* excreted more unchanged alpha-pinene in the feces than *N. albigula* when both species were either fed a juniper diet or gavaged with a single dose of alpha-pinene. These data implicate a barrier to intestinal absorption.

The hypothesized mechanism is a difference in the activity of permeability glycoprotein (Pgp). This member of the ATP-binding cassette (ABC) superfamily, is a 170-kDa membrane bound protein that actively pumps out numerous potentially toxic endogenous and exogenous compounds as soon as they diffuse into the cell membrane (Ambudkar et al., 1999, 2003). Pgp has been implicated as an important factor in the ability of cells exposed to a single drug/xenobiotic to develop resistance to a broad range of structurally and functionally unrelated drugs/xenobiotics. This has been termed multidrug resistance (MDR) or multixenobiotic resistance (MXR) (Kurelec, 1992; Hunter and Hirst, 1997). Initially discovered in cancer cells, Pgp has since been found on the secretory side of normal cells associated with secretion, absorption, or barrier function such as blood–brain barrier, blood–testis barrier, placenta, small intestine, pancreas, colon, adrenal cortex, kidney, and liver in humans and rodents (Hunter and Hirst, 1997; Ambudkar et al., 1999), and with gills and eggs in aquatic species (Bard, 2000).

In our previous work, we found the activity of Pgp summed over the small intestine to be higher in *N. stephensi* than in *N. albigula* (Green et al., 2004), which is consistent with their feeding behavior in both the field and laboratory. Thus, we hypothesized that alpha-pinene is recognized by Pgp and we tested this hypothesis in three ways. First, we determined if racemic alpha-pinene can competitively inhibit Pgp as indicated by increased accumulation of a known Pgp substrate, digoxin (Sababi et al., 2001; Stephens et al., 2001), in everted sleeves of small intestine. We made these measures in *N. albigula* and *N. stephensi*, and included a

congeneric generalist not known to consume *J. monosperma*, *N. cinerea* (Ord), to broaden our phylogenetic comparison, and Sprague-Dawley rat, a species we have used extensively in everted sleeve experiments. The everted sleeves of small intestine from wood rats and Sprague-Dawley rats were previously shown to exhibit the predicted increased accumulation of digoxin when exposed to a known Pgp inhibitor, cyclosporin A (CsA), and maintained both structural and functional integrity (Green et al., 2004, 2005). Second, we used the same indicator of competitive inhibition in a human colon carcinoma cell line (Caco-2) that overexpresses Pgp and is commonly used in the investigation of Pgp substrates (i.e., Chiou et al., 2001). Third, we eliminated unknown variables associated with tissue sections or whole cells by determining the effect of racemic alpha-pinene on phosphate production from Pgp ATPase activity in Pgp transfected membranes (Sarkadi et al., 1992; Ambudkar et al., 1999).

Pgp can be induced by ingestion of Pgp substrates (Salphati and Benet, 1998; Sandstrom and Lennernas, 1999), and may recognize alpha-pinene or some other compound(s) in *J. monosperma*. To investigate the possible induction of Pgp activity by juniper ingestion, we acclimated one group of *N. stephensi* to a diet high in juniper and measured the same endpoints as we did in animals on a control diet.

Methods and Materials

Chemicals

We purchased [^3H]digoxin and [^{14}C]polyethylene glycol (PEG; MW = 4000) from Perkin-Elmer Life and Analytical Sciences (Boston, MA, USA), [^{14}C]D-glucose and [^3H]L-glucose from Moravsek (Brea, CA, USA), cyclosporin A from Qbiogene, Inc. (Carlsbad, CA, USA), and phloridzin and a (1:1) racemic mixture of alpha-pinene from Sigma Aldrich (St. Louis, MO, USA).

Animals and Diets

We purchased Sprague-Dawley rats from Harlan Sprague-Dawley (Madison, WI, USA) and housed them in temperature-controlled facilities in the Department of Wildlife Ecology, University of Wisconsin–Madison with access to water and food *ad libitum*. Specialist (*N. stephensi*) (4 male, 6 female) and generalist (*N. albigula*) (4 male, 3 female) wood rats were trapped outside the south border of Wupatki National Park, 45 km NE of Flagstaff, AZ, USA (35°30'N, 111°27'W). The diets of these species were described in an extensive study by Dial (1988). We trapped *N. cinerea* (2 male, 3 female) at a private residence near Heber City, Summit Co., UT, USA. *N. cinerea* is a dietary generalist (Johnson and Hansen, 1979; Hauffer and Nagy, 1984; Frase and Sera, 1993), and the caches of *N. cinerea* used in this study suggested they were foraging on *Opuntia* clades, sagebrush (*Artemisia tridentata*) and various nonnative garden plants. Animals were transported to the University of Utah Animal Facility and were individually housed in shoe box cages (48 × 27 × 20 cm) with bedding and cotton batting at 20°C on a 12 L:12 D photoperiod. Animals were in captivity for 6–12 mos prior to the experiment. All animals on the control diet were fed Teklad ground rabbit chow (formula 2120) and water *ad libitum*. *N. stephensi* on the juniper diet were fed a rabbit chow based diet with

progressively increasing juniper (5, 25, 25, 70, and 70% juniper by dry mass, collected from Flagstaff, AZ, USA) over 5 d, a sufficient time to induce Pgp based on studies in cell lines (Fardel et al., 1996) and in rats (Salphati and Benet, 1998; Sandstrom and Lennernas, 1999), and which is a level of juniper on which *N. stephensi* are known to maintain body mass in the laboratory (M.D. Dearing, unpublished data). Based on weights prior to inclusion of juniper in the diet and immediately before the everted sleeve experiments, we found that *N. stephensi* maintained body mass over the 5-d dietary exposure (repeated-measures ANOVA, $F_{1,3} = 3.944$; $P = 0.141$).

All experiments on wood rats conformed to University of Utah IACUC protocol # 04-02012. All experiments on Sprague-Dawley rats conformed to University of Wisconsin–Madison IACUC protocol # A-07-6900-A00991-3-04-00.

Measures of Pgp Activity Using Tissue Accumulation of Digoxin

For tissue preparation and mounting, we closely followed the procedures described in Karasov and Diamond (1983) and Karasov et al. (1985) and reported by Green et al. (2005). Briefly, animals were euthanized with CO₂; then intestine from the stomach to the caecal attachment was quickly removed (4–6 min) and flushed with ice-cold Ringer solution (in mM: 50 mannitol, 100 NaCl, 4.7 KCl, 2.5 CaCl₂, 1.2 KH₂PO₄, 1.2 MgSO₄, and 20 NaHCO₃, gassed with 95% O₂ and 5% CO₂, 290 mOsm). After the intestine length was measured, the intestine was everted, and short sleeves (1.5 cm long) were cut and then mounted on stainless steel rods by tying the tissue down over grooves exactly 1 cm apart while kept in cold Ringer gassed with 95% O₂/5% CO₂. Limited intestinal length as well as concerns about experiment length precluded the use of all treatments in all animals. See Table 1 for allocation of samples among treatments.

Everted sleeves were first preincubated in 37°C Ringer solution bubbled with 95% O₂/5% CO₂ for 2 min (Pgp assays) or 10 min (D-glucose uptake) that contained either test compounds or vehicle control to maximize tissue exposure to our treatments. The tissue was then incubated in 8 ml gassed Ringer at 37°C in a flat-bottomed water-jacketed test tube with spinning stir bar to reduce and control the unstirred layer thickness (Karasov and Diamond, 1983). Incubation solution included radiolabeled probe ([³H]digoxin (9.1 kBq/ml) for measuring Pgp activity; Sababi et al., 2001; Stephens et al., 2001), or [¹⁴C]D-glucose (1.1 kBq/ml) for measuring D-glucose uptake activity) and marker solutes to correct for both non-absorbed probe in adherent mucosal fluid and diffusive flux ([¹⁴C]polyethylene glycol (PEG), MW = 4000; 1.1 kBq/ml) for Pgp measures, or [³H]L-glucose (31.4 kBq/ml), for D-glucose measures) (Karasov and Diamond, 1983). After 12 min (Pgp assay) or 4 min (D-glucose uptake), tissues were removed and then either blotted (Pgp assay) or rinsed in stirred cold Ringer and then blotted (D-glucose uptake). The mounted tissue was removed, weighed, incubated in 1 ml of tissue solubilizer (Soluene-350; Packard, Meriden, CT, USA), and counted in 10 ml of scintillation cocktail (Ecolume; Packard) with 0.5% by volume acetic acid on a Beckman LS 5801 (Beckman Coulter, Inc.) with channels set to minimize spill (counts of the alternate isotope appearing in the same counting channel) and programmed with a standard curve to correct for background quench. Calculation of digoxin accumulation followed (Karasov and Diamond, 1983), and for simplicity of expression, we assumed a digoxin concentration of 1 fmol/μl incubation solution (it was actually approxi-

Table 1 Allocation of everted sleeves to the different treatments in the proximal, mid, and distal sections of the small intestine of wood rats and Sprague-Dawley rats on control or juniper diets

Gut section	Proximal			Mid			Distal

mately 0.75 fmol/ μl), yielding units of fmol digoxin accumulated per milligram tissue. Total intestine mass was estimated as the product of the summed mass of the sixteen 1-cm tissues and the ratio of total intestine length: 16 cm.

We have previously determined that wood rat and Sprague-Dawley rat intestinal sleeves maintain structural integrity during the experimental procedure (Green et al., 2004, 2005). To verify the functional integrity and to check for the nonspecific effects of known and putative inhibitors, we measured the ATP-dependent mediated D-glucose uptake over the same combined preincubation and incubation time in adjacent tissues exposed to alpha-pinene (100 μM), vehicle control (0.15% ethanol), and phloridzin (1 mM), a known inhibitor of the intestinal glucose transporter SGLT-1, as previously described (Green et al., 2004, 2005).

Digoxin accumulation in the tissue is a balance between passive diffusion into and Pgp-mediated export out of the cells, so the desired measure of Pgp activity was the difference between digoxin accumulation in the presence of a maximal inhibitory concentration of a competitor of digoxin export, cyclosporin A (CsA) (Lan et al., 1996), and the accumulation in the absence of CsA (0.15% ethanol vehicle control), similar to Sababi et al. (2001). Pgp transport was maximally inhibited by 10 μM CsA in the rodent species on control diet (Green et al., 2004), and we verified this with *N. stephensi* on juniper diet by conducting a dose response with CsA [1, 5, 10 μM , and saturated ($\sim 15 \mu\text{M}$)] in the midintestine. To estimate intestinal Pgp capacity, which is activity summed over the entire small intestine, we used 10 μM CsA to determine Pgp activity in the proximal, mid, and distal intestinal sections. Because intestinal mass was not significantly different between the two dietary groups of *N. stephensi* (one-way ANOVA: $F_{1,7} = 1.771$, $P = 0.225$), any difference in Pgp capacity would be reflected in the Pgp activity along the intestinal tract.

Lacking radiolabeled alpha-pinene, we tested whether racemic alpha-pinene competitively inhibits the exclusion of our known Pgp substrate, [^3H]digoxin. We used racemic alpha-pinene because we lacked data on which enantiomer is found in *J. monosperma* and wished to account for both possibilities. We incubated intestinal sleeves of the midgut with alpha-pinene at concentrations that approximated 10 and 100 μM made by adding the appropriate amount of a 1000 \times solution in ethanol directly to the stirring incubation solution. These chosen concentrations bracket the concentration estimated to reach the intestine after gavage of 34.32 μg alpha-pinene/ml peanut oil used in a previous experiment, and corresponds to the amount in a full meal of *J. monosperma* (Sorensen and Dearing, 2003). Because of the volatility of alpha-pinene, we measured the loss from incubation solution over time by subsampling incubation solution every 2 min after an initial dose at the target concentration of alpha-pinene (i.e., 100 μM) and measured alpha-pinene concentration by using gas chromatography as described by Sorensen and Dearing (2003). We determined that adding half the initial amount every 2 min during both preincubation and incubation kept levels near to the desired dose (range approximately: 5–10 μM for the “10 μM ” dose, and 50–100 μM for the “100 μM ” dose). Vehicle control matched these additions with ethanol.

Caco-2 Cell Experiments

[^3H]Digoxin accumulation was measured in Caco-2 cell monolayers (passage 3–10; ATCC, Manassas, VA, USA) exposed to 1, 3, 10, 30, and 100 μM alpha-pinene made by diluting a 1000 \times solution in ethanol with cell media. First, cells were

washed twice with serum-free, phenol red-free Dulbecco's modified Eagles media (DMEM; Sigma Aldrich, St. Louis, MO, USA) and media replaced with phenol red-free DMEM containing 1% fetal bovine serum (FBS) and vehicle control (5% ethanol), or alpha-pinene (1, 3, 10, 30, 100 μM final concentration) for 30 min ($N = 4$ wells/treatment). Then, digoxin uptake was measured by adding [^3H]digoxin (37 kBq/ml) in base media with 1% FBS 45 min before the end of the trial. Subsamples (50 μl) of media were removed for specific activity, and the remainder of solution was aspirated and cells washed twice with 1 l ice-cold phosphate-buffered saline (PBS). Cells were solubilized in 0.5 ml 0.5 N NaOH and 200- μl aliquots were mixed with 200 μl 0.5 M HCl and counted on a Beckman LS 3800 (Beckman Coulter, Inc.) scintillation counter. Decays per minute were scaled to protein level in the wells, determined by spectrophotometrically comparing a 5- μl aliquot of solubilized cells from each well to bovine serum albumin standards.

Phosphate Release Assay with alpha-Pinene

Verapamil-stimulated, vanadate-sensitive ATPase activity associated with Pgp was assayed as described by the manufacturer (BD Biosciences, Woburn, MA, USA). Briefly, insect cell membranes containing human Pgp (BD Gentest Recombinant MDR1 microsomes; BD Biosciences, Woburn MA, USA) were used to assess Pgp ATPase activity in the presence and absence of vanadate and vehicle control (1% ethanol), verapamil (60 μM), a known Pgp substrate and positive control, or alpha-pinene at the same concentrations used in the everted sleeve experiments (10, 100 μM). Pgp membranes were added to reaction media (50 mM Tris-MES, 2 mM EGTA, 50 mM KCl, 2 mM dithiothreitol, 5 mM sodium azide, 5 mM MgATP) with and without 100 μM sodium orthovanadate and the test compound. The ATPase activity measured in the presence of orthovanadate represents non-Pgp ATPase activity and is subtracted from activity measured in the absence of orthovanadate. The reactants were incubated at 37°C for 20 min and terminated by the addition of 10% SDS and Antifoam A. Hydrolysis of ATP was measured on a spectrophotometric microplate reader (Dynatech MR-5000) as the release of inorganic phosphate (absorbance at 800 nm).

Statistical Analyses

When possible, we analyzed treatment effect in the everted sleeve experiments with repeated-measures ANOVA and examined interactions between treatment and species or diet. In experiments with Caco-2 cells, phosphate release assay, and everted sleeves when all treatments were not represented in every animal, we used one-way ANOVA. Effect of treatments on mediated D-glucose uptake was tested with a general linear model with treatment as a factor, and species and diet as interactions with treatment. In everted sleeves, the experimental unit was the individual rodent, while in the Caco-2 cell experiment and phosphate release assay the experimental unit was the well. We used Fisher's LSD for pairwise comparisons when global tests resulted in $P < 0.05$. A value of $P < 0.05$ was considered significant and $0.05 < P < 0.10$ a trend. All data are reported as mean \pm SE, N = sample size.

Plots of residuals were visually inspected to verify a random distribution. We used Systat 10 (SPSS Inc., Chicago, IL, USA) for analyses.

Results

Neither of our test compounds, CsA (15 μM) or alpha-pinene (100 μM), affected mediated [^{14}C]D-glucose uptake in any rodent species on control diet, or *N. stephensi* on the juniper diet, whereas uptake was significantly inhibited by phloridzin (1 mM) ($P = 0.005$), the specific inhibitor of the SGLT-1 Na/glucose cotransporter (general linear model, $F_{3,71} = 3.9$; $P = 0.013$, followed by pairwise comparisons, interactions not significant). One *N. cinerea* and one *N. stephensi* on juniper diet were removed from the study due to loss of functional integrity in intestinal sleeves as indicated by uniformly low [^{14}C]D-glucose uptake.

Consistent with our previous results in rodents on control diet (Green et al., 2004, 2005), net accumulation of [^3H]digoxin, corrected for adherent label, increased sublinearly with increasing concentration of CsA in the solution for intestinal sleeves of *N. stephensi* on the juniper diet, reaching an asymptote by 10 μM (Fig. 1; one-way ANOVA, $F_{4,11} = 11.4$; $P = 0.001$, followed by pairwise comparisons). There was no significant variation in Pgp activity along the intestinal tract for *N. stephensi* on either diet (Fig. 2; repeated-measures ANOVA, control, $F_{2,8} = 3.3$; $P = 0.091$; juniper, $F_{2,6} = 0.31$; $P = 0.748$), and there was no significant difference in Pgp activity/mg tissue between *N. stephensi* on different diets in proximal (one-way ANOVA,

Fig. 1 Difference in digoxin accumulation (fmol/mg tissue) between midintestinal sleeves exposed to cyclosporin A (1, 5, 10, ~ 15 μM) and vehicle control (0.15% ethanol) during 2-min preincubations and 12-min incubations in *Neotoma stephensi* fed a diet containing *Juniperus monosperma* ($N = 2$ –5 sleeves/concentration). The difference shows a sublinear increase that reaches an asymptote by 10 μM (one-way ANOVA, $F_{3,8} = 5.736$; $P = 0.022$, followed by pairwise comparisons). Different letters (a, b) indicate significant differences between concentrations ($P < 0.01$). Points are mean \pm SE

Fig. 2 Pgp activity (fmol digoxin excluded/mg tissue) along the intestinal tract in *N. stephensi* on control ($N = 5$) and juniper diet ($N = 4$) as determined by the difference in digoxin accumulation in intestinal sleeves exposed to ethanol vehicle control or 10 μM CsA during 2-min preincubations and 12-min incubations. There was no significant difference along the tract in either diet group (repeated-measures ANOVA, intestinal section: $F_{2,14} = 2.486$; $P = 0.119$, intestinal * section diet: $F_{2,14} = 0.500$; $P = 0.617$) and no difference in Pgp activity between diet groups in the proximal (one-way ANOVA, $F_{1,7} = 0.678$; $P = 0.437$), mid ($F_{1,7} = 0.332$; $P = 0.582$), or distal ($F_{1,7} = 0.130$; $P = 0.729$) sections. Points are mean \pm SE

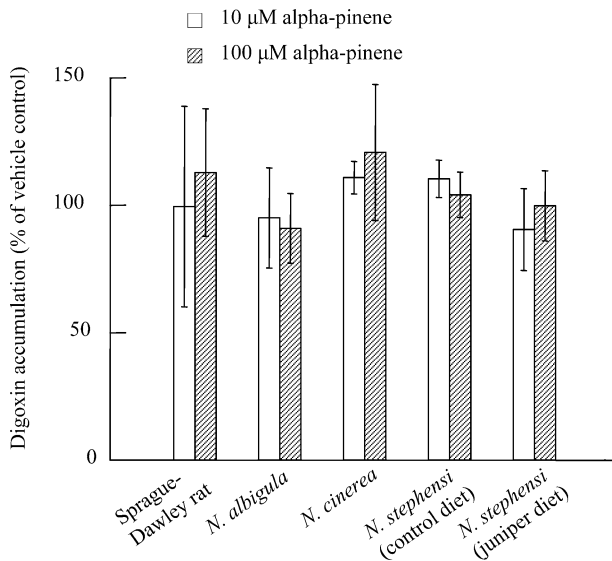

Fig. 3 Digoxin accumulation as percent of ethanol vehicle control in midintestinal sleeves exposed to alpha-pinene (10, 100 μM) during 2-min preincubations and 12-min incubations in Sprague-Dawley rats ($N = 4$), *Neotoma albigula* ($N = 7$), *N. cinerea* ($N = 3$), and *N. stephensi* on control ($N = 5$) and juniper diet ($N = 4$). There was no significant difference in digoxin accumulation in any group (repeated-measures ANOVA, $F_{2,36} = 0.150$; $P = 0.861$; interactions were not significant). Values are mean \pm SE

$F_{1,7} = 0.68$; $P = 0.437$), mid ($F_{1,7} = 0.33$; $P = 0.582$), or distal ($F_{1,7} = 0.13$; $P = 0.729$) sections (Fig. 2). Several tissue sections from one *N. stephensi* on juniper diet were damaged during the procedure eliminating this animal from the comparison with control diet and some samples from the dose–response curve. With no difference in intestinal mass (one-way ANOVA, $F_{1,7} = 1.77$; $P = 0.225$), we conclude that acclimation to a juniper diet over 5 d does not induce intestinal Pgp activity. The mean Pgp activity in proximal and midintestine of *N. stephensi* on juniper diet was lower than *N. stephensi* on the control diet, opposite of what would be expected if induction occurred, suggesting that a larger sample size would not affect this conclusion.

Accumulation of digoxin in mid-intestinal sleeves was not affected by alpha-pinene at 10 or 100 μM in any of the rodent species on control diet, or in *N. stephensi* on the juniper diet (Fig. 3; repeated-measures ANOVA, $F_{2,36} = 0.15$; $P = 0.861$; interactions not significant). This indicates that alpha-pinene does not competitively inhibit exclusion of digoxin by Pgp in wood rats or Sprague-Dawley rats over the range of concentrations tested.

We also measured digoxin accumulation in Caco-2 cells with and without alpha-pinene (1, 3, 10, 30, 100 μM) to test the ability of alpha-pinene to competitively inhibit Pgp in a commonly used and sensitive human cell line. alpha-Pinene, at 1 μM , yielded one extreme outlier, which was removed from analysis. We ob-

Fig. 4 Digoxin accumulation in Caco-2 cells exposed to cyclosporin A (5 μM), vehicle control (5% ethanol), or racemic alpha-pinene (1, 3, 10, 30, and 100 μM) for 75 min with [^3H]digoxin added 45 min before the end of the trial. Values are means \pm SE of 4 wells/treatment, except at 1 μM alpha-pinene where $N = 3$ wells. Decays per minute in cells were scaled to total protein in the wells. Significant differences from control in pairwise comparisons after one-way ANOVA ($F_{6,20} = 37.1$; $P < 0.001$) are indicated by ($\dagger P < 0.001$)

Fig. 5 Phosphate production from Pgp ATPase activity in Pgp transfected insect membranes exposed to verapamil (60 μM), racemic alpha-pinene (10, 100 μM), and vehicle control (1% ethanol). Values are means \pm SE of three replicates per treatment. Significant differences in pairwise comparisons after one-way ANOVA ($F_{3,8} = 16.607$; $P = 0.001$) are indicated by ($\dagger P < 0.05$) and ($\ddagger P < 0.005$)

served the expected increased accumulation of digoxin with the known Pgp substrate, cyclosporin A (5 μM), but no difference in digoxin accumulation between control and alpha-pinene at any concentration (Fig. 4; one-way ANOVA, $F_{6,20} = 37.1$; $P < 0.001$, followed by pairwise comparisons).

Phosphate Release Assay with alpha-Pinene

We observed the expected increase in phosphate release with our positive control, verapamil (60 μM), a known Pgp substrate, while alpha-pinene had no effect at 10 μM , and actually resulted in a decrease in phosphate release at 100 μM (Fig. 5; one-way ANOVA, $F_{3,8} = 16.61$; $P = 0.001$, followed by pairwise comparisons). These data, along with the Caco-2 cell-line results, indicate that alpha-pinene is not a substrate for human Pgp. The decrease in phosphate production by 100 μM alpha-pinene implies inhibition of ATPase activity.

Discussion

Although our previous results indicated a correlation between intestinal Pgp capacity and the tolerance of a *J. monopserma*-dominated diet (Green et al., 2004), we failed to establish a link between Pgp and alpha-pinene, the dominant

monoterpene in *J. monosperma*. Digoxin accumulation in wood rat intestine, Sprague-Dawley rat intestine, and Caco-2 cells was not affected by exposure to alpha-pinene. Phosphate released from ATPase activity did not show an increase in the presence of alpha-pinene at 10 μM , and 100 μM alpha-pinene actually decreased phosphate production, indicating an inhibition of ATPase activity. The possibility remains that wood rat Pgp may recognize alpha-pinene, but that digoxin has higher affinity for Pgp preventing inhibition by alpha-pinene in the everted sleeve and Caco-2 cell-line experiments. This would also require that the Pgp assay with human Pgp is not a valid surrogate for investigating wood rat Pgp. The best way to address this possibility would be to use radiolabeled alpha-pinene as the probe and CsA as the inhibitor, or to develop another method that measures alpha pinene concentration in tissue (i.e., gas chromatography). Another potential method would be to measure the accumulation of a probe of lower affinity than digoxin (i.e., propranolol; Lan et al., 1996) in everted wood rat intestinal sleeves with alpha-pinene as the potential inhibitor. A negative result, however, would still leave the question of relative affinities.

The highly lipophilic alpha-pinene molecule ($\text{C}_{10}\text{H}_{16}$, $\log K_{\text{ow}} = 4.83$; Li et al., 1998) is not ideal for recognition by Pgp. Although Pgp does recognize a number of compounds characterized as lipophilic, the majority appears to be amphipathic with polar oxygen or nitrogen groups attached (Ford and Hait, 1990; Hunter and Hirst, 1997; Ambudkar et al., 1999). Some diterpenes have been found to interact with Pgp (Hohmann et al., 2002; Appendino et al., 2003), but they have polar groups attached to the ring structure. It may be that one or more of the phase I metabolites of alpha-pinene are recognized by Pgp and are pumped back into the intestinal lumen. We would expect, however, that this would still result in competitive inhibition of Pgp and an increased accumulation of digoxin in both the everted sleeve and Caco-2 cell experiments. Furthermore, microbial conversion of a metabolite back to the parent compound is unlikely and, therefore, would not explain the difference in parent compound found in the feces of the two wood rat species (Sorensen et al., 2004).

The larger question of tolerance to a diet high in *J. monosperma* may involve compounds other than alpha-pinene. *N. albigula* decreased food intake and exhibited decreased urine pH after acclimating over 9 d to a diet containing alpha-pinene at a level corresponding to a 100% juniper diet (Dearing et al., 2000). Despite a decreased food intake, *N. albigula* did not lose significant body mass. In contrast, *N. albigula* and, to a lesser extent, *N. stephensi* lost significant body mass on a diet consisting of artificial diet (15% of maintenance levels) and *J. monosperma* leaves *ad libitum*. Both artificial diets with and without alpha-pinene matched nutrient levels of juniper.

In another plant herbivore system, Lawler et al. (1999) found that the feeding deterrence of common ringtail possums (*Pseudocheirus peregrinus*) and common brushtail possums (*Trichosurus vulpecula*) by the Eucalyptus terpene, 1,8-cineole, is a conditioned flavor aversion due to its association with the postingestive effects caused by diformylphloroglucinol compounds, such as jensenone. Could alpha-pinene serve a similar purpose in juniper as cineole does in Eucalyptus?

Because there may be other compounds in juniper that interact with Pgp, we also measured Pgp activity in *N. stephensi* acclimated to a juniper diet. We did not observe induction in Pgp activity, which suggests at least three possible explanations. (1) Although 5 d are sufficient to induce Pgp in laboratory rat studies using known Pgp substrates (Salphati and Benet, 1998; Sandstrom and Lennernas, 1999),

possibly the level of Pgp substrate(s) in juniper are not sufficient to induce Pgp on the same time scale. (2) *N. stephensi* maintains a high constitutive level of Pgp that is not inducible. Our previous results indicate that *N. stephensi* showed higher Pgp capacity than *N. albigula* when on a control diet (Green et al., 2004) in support of a high constitutive level of Pgp. Of interest would be whether the generalist, *N. albigula*, exhibits induced levels of Pgp when acclimated to a juniper diet. We lacked sufficient individuals to test this possibility. (3) Possibly Pgp does not recognize any component of *J. monosperma*, and our previous results on intestinal Pgp capacity are purely correlational. We consider this unlikely due to the long list of Pgp substrates and modulators, but a test would be to use extracts of *J. monosperma* in everted sleeve, Caco-2 cell line, and/or phosphate release experiments.

In addition to the possibility that other compounds besides alpha-pinene may be involved in juniper tolerance is the potential that other mechanisms besides Pgp may be involved. The difference in intestinal Pgp capacity between *N. stephensi* and *N. albigula* is only one difference in the arsenal of biochemical defense mechanisms of wood rats. Although Sorensen and Dearing (2003) did not see any difference in elimination rate of alpha-pinene in these two species, other results indicate they may detoxify compounds differently (S. Haley, unpublished data; Dearing et al., 2000, 2002). Could these species biotransform juniper toxins differently producing metabolites that differ in toxicity? Recently, more membrane-bound transport proteins related to Pgp have been described, and as many as 10 have been implicated in a cell's ability to defend against toxins (Taipalensuu et al., 2001; Scotto, 2003). If wood rats vary in Pgp activity and activity of phase I and II detoxifying enzymes, then they may vary in activity of other transporters or defense mechanisms that could result in the observed variability in juniper tolerance. Adding to the variation in the function of these mechanisms is a possible variation in the regulation of mechanisms that may be coordinated at the gene level (Scotto, 2003). A full understanding of the interplay between ingested toxins and the biochemical defense mechanisms in mammalian herbivores may require techniques that can simultaneously measure the activity of a myriad of proteins, or the corresponding genes. Efforts using DNA microarray analyses are currently underway. The difficulty in finding an explanation for the observed differences in alpha-pinene absorption and *J. monosperma* tolerance between *N. stephensi* and *N. albigula* highlights the challenges we face.

Abstract Plant secondary metabolites (PSMs) are a major constraint to the ingestion of food by folivorous and browsing herbivores. Understanding the way in which mammalian detoxification pathways are adapted to deal with PSMs is crucial to understanding how PSMs influence ingestive behavior of herbivores and hence their fitness and the impact that they have on vegetation. Pharmacological concepts can provide insights into the relationship between the absorption and metabolic fate of PSMs and ingestive behavior. Lipophilic PSMs will be absorbed into the bloodstream and must be removed fast enough to prevent their accumulation to toxic levels. Elimination depends on their metabolism, usually by cytochrome P450 enzymes, to more polar metabolites that can be excreted by the kidney. The concentration of PSM in blood (C) is a better measure of exposure to a toxin compared to the amount ingested because there can be great variability in the rate and degree of absorption from the gut. C rises and falls depending on the relative rates of absorption and elimination. These rates depend in part on metabolic and transport processes that are saturable and liable to inhibition and induction by PSMs, indicating that complex interactions are likely. Herbivores can use diet choice and the rate and amount of PSM consumption to prevent C from reaching a critical level that produces significant adverse effects.

Introduction

Herbivory is a widespread feeding habit of terrestrial vertebrates. Among the Eutherian mammals, most of the Artiodactyls and Perrisodactyls including the Bovids, Equids, and Cervids are exclusively herbivorous. The Lagomorphs and some Rodents also subsist on a diet largely composed of plants (Williams and Kay, 2001). Among the marsupials, herbivory is also widespread within the Diprotodontia, including many examples of herbivorous mammals, such as the macropods and possums (Hume, 1999). Plant material is generally a diffuse source of nutrients, and large amounts of material need to be ingested to maintain the metabolism of herbivorous mammals (Iason and Van Wieren, 1999). As a result, these mammals can consume a high proportion of plant biomass production and hence have an important influence on ecosystem function (Hester et al., 2006).

Because of plants' immobile nature and vulnerability to herbivory, strong selection pressure exists to evolve antiherbivory adaptations (Rhoades, 1979). Antiherbivory strategies diverge along the lines of the major division within the plant kingdom. Monocotyledonous plants (e.g., grasses and sedges) tolerate herbivory; their basal meristems reduce the impact of grazing on plant survival by facilitating regrowth (McNaughton, 1983). Dicotyledonous plants tend to have chemical and physical defenses that discourage herbivory (Bryant et al., 1991). Chemical defense is manifest in the evolution of a large array of phytochemicals that appear to have minimal function in the primary metabolism of plants (Rosenthal and Berenbaum, 1991). These so-called plant secondary metabolites (PSMs) include alkaloids, terpenes, phenolics, glucosinolates, and cyanogenic glycosides. Mammalian herbivores that ingest PSMs are liable to suffer a variety of adverse effects including reductions in nutrient availability and toxicity.

In this review, we consider the effects of PSMs on the ingestive behavior of herbivores, by using a pharmacological perspective. We also review the mechanisms used by herbivores to overcome plant defenses and avoid PSM toxicity, and consider how the pharmacokinetics of PSMs may influence ingestive behavior.

Plant Secondary Metabolites as Drugs

Modern pharmacology arose from the traditional use of plant products as medicines, and even today many therapeutic drugs are plant secondary metabolites (e.g., morphine, digoxin, atropine, ephedrine, artemisinin, vincristine, paclitaxel) or PSM derivatives (e.g., codeine, buprenorphine, warfarin, docetaxel). The principles surrounding the absorption, distribution, metabolism, and excretion of phytochemicals are the same, whether they are considered in the context of the delivery of drugs to target tissues in humans, or the detoxification of PSMs by mammalian herbivores. These two views of PSMs, as drugs and as chemical defenses, have been independently pursued, and we argue here that an exchange of concepts will benefit both of these disciplines. In particular, pharmacological concepts can provide insights into the relationship between ingestive behavior and the absorption and elimination of dietary PSMs. Conversely, the study of the chemical ecology of plant/herbivore interactions can provide insights to pharmacologists by considering the evolutionary context in which physiological mechanisms for metabolism of modern drugs arose.

A Note on Terminology

A drug may be broadly defined as any chemical that produces a biological effect on a human or animal, including both therapeutic and toxic effects (which are often produced by the same substance at different doses). Many PSMs are known to have drug effects as medicines, toxins, or antifeedants, but others have not had any such effects characterized. A xenobiotic is a chemical that may be present in animal tissues following absorption from the environment, but that lacks nutritional value. Xenobiotics include PSMs, synthetic drugs, and agricultural and other industrial chemicals. Where possible we have referred to literature on PSMs, but for much of the discussion on pharmacology we found no PSM data available, and we have used findings on synthetic drugs and other xenobiotics.

Effects of Plant Secondary Metabolites on Herbivores

Gastrointestinal Effects

Some PSMs remain in the gut where they may have local adverse effects. Condensed tannins, for example, are large polar molecules that cannot cross the gastrointestinal epithelium and are, therefore, not absorbed (Terrill et al., 1994). Tannins have an astringent taste and can bind and reduce the absorption of dietary proteins. Formyl phloroglucinols (e.g., jensenone, sideroxydonal) are aldehydes that react so rapidly with amine groups on proteins and other cellular constituents that they are not absorbed from the gut (McLean et al., 2004). However, these reactions result in adverse effects, mediated through serotonin release, which deter herbivory (Lawler et al., 1998; Wiggins et al., 2005). These locally acting PSMs will not be further considered in this review.

Systemic Effects

Many PSMs are lipophilic in character and can pass readily through the cell membranes of the gastrointestinal epithelium and be absorbed into the bloodstream, in which they will be delivered around the body to produce effects at distant sites. For example, morphine and digoxin stimulate chemoreceptors in the *area postrema* of the brainstem, resulting in nausea (Saito et al., 2003). In some cases, vomiting ensues leading to removal of unabsorbed toxin. Emetic agents can also act in the gut, via the release of serotonin and substance P from enterochromaffin cells, exciting sensory neurons that project to the *area postrema* and other parts of the brainstem (Saito et al., 2003). Stimulation of the emetic center is also associated with the development of conditioned flavor aversions that deter herbivores from repeated ingestion of toxic plants (Zahorik et al., 1990). PSMs can target other organs with specific toxicity; for example, digoxin causes cardiac arrhythmias, pyrrolizidine alkaloids produce multiple organ toxicity and cancers (Fu et al., 2004), and terpenes cause depression of the central nervous system (Falk et al., 1991; Tibballs, 1995). PSMs can also target particular systems, such as cholinergic neurotransmission that is blocked by atropine (which occupies the muscarinic receptors of acetylcholine) and enhanced by physostigmine (which inhibits

Fig. 1 General shape of the log concentration–effect curve

acetylcholinesterase). Sublethal toxicity can deter future feeding through learned aversions (Provenza, 1995) and taste associations (Pass and Foley, 2000).

Pharmacodynamics: How Effect Depends on Concentration of Drug

The effect of a drug generally depends on the size of the dose taken and the consequent concentration produced at site(s) of action in the body (Wilkinson, 2001). The relationship between the log concentration of drug and its effect is sigmoidal rising to an asymptote (Fig. 1; Ross and Kenakin, 2001). Note that there is a dynamic range where the effect is sensitive to changes in concentration; a characteristic maximum effect (E_{\max}); and at low concentrations the effects are minimal or zero. We hypothesize that herbivore metabolic adaptations and ingestive behavior are directed toward preventing the concentration of PSMs in the body from exceeding tolerable levels.

Potency

Drugs and other PSMs differ markedly in their potency, measured by the amount (or concentration) required to produce a particular effect. For example, digoxin and atropine act therapeutically in humans at submilligram doses, whereas the doses of salicin (once used as an analgesic) and quinine are 1000 times greater. Among antifeedant PSMs, terpenes and phenolics are present at high concentrations in *Eucalyptus* leaf (up to 12% and 40% dry matter, respectively; Cork and Sanson, 1991), but the major antifeedant effect against marsupial folivores is exerted by formylphloroglucinols, which are present at significantly lower concentrations (mostly below 4% dry matter; Moore et al., 2004; Moore and Foley, 2005).

Tolerance

Continued exposure to a drug can lead to tolerance: a reduced effect that is usually due to an adaptation by cells to the presence of the drug. This happens especially with drugs that act on the central nervous system, which for example becomes less sensitive to alcohol and nicotine in regular drinkers and smokers, respectively (Le Houezec, 1998; Nutt, 1999). Tolerance to alcohol can develop to such an extent that

Fig. 2 Blood concentration of cineole after an oral dose (100 mg/kg) administered to a brush-tail possum. Methods are given in Boyle et al. (2002)

individuals can survive normally lethal blood levels (Davis and Lipson, 1986), as well as tolerance to opioids in that addicts may take 50 times the normal dose, an amount which could be lethal for an opioid-naïve person (O'Brien, 2001). However, not all drugs elicit tolerance, as for example the doses of digoxin, warfarin, and atropine-like drugs that do not need to be increased with their continued therapeutic usage (Hardman et al., 2001).

Pharmacokinetics: How the Concentration of Drug Changes with Time After Dose

Absorption of Plant Secondary Metabolites

Absorption from the gut is usually by passive diffusion down a concentration gradient (Wilkinson, 2001). The speed of membrane permeation depends on the lipid solubility of the PSM. Some PSMs are substrates for active transporters, for example, glucosides that can be absorbed by the sodium-dependent glucose transporter SGL1, whereas glycosides of other sugars (e.g., rhamnose) are not transported (Manach et al., 2004). In general, glycosides must be hydrolyzed to be absorbed as the more lipophilic aglycone.

Most active PSM transport is by less specific efflux transporters such as P-glycoprotein (P-gp), which pumps foreign molecules out of the central nervous system and out of the body and into the gut, bile, and urine (Lin and Yamazaki, 2003).

Concentration in Blood

After an oral dose of a drug, its concentration in the body, which is usually measured in the blood or plasma (C), rises to a maximum (C_{\max}) and then falls (Fig. 2). The drug is distributed by the blood around the body and enters tissues where enzymes may convert it into metabolites that diffuse back into the blood and may be excreted in urine. Some metabolites that are formed in the liver are secreted into the bile and excreted in the feces (e.g., menthol glucuronide; Yamaguchi et al., 1994).

For many drugs, the time course of the effects following an oral dose will be described by a combination of the curves in Figs. 1 and 2. For example, the speed of onset of effects will depend on the rate of increase in concentration, and the maximum effect will be some function of C_{\max} . Pharmacokinetic–pharmacodynamic models incorporate change in concentration with time after a dose and the concentration–effect curve, and aim to describe the time–effect relationship (Meibohm and Derendorf, 1997). The overall scheme is illustrated below

$$\text{Dose rate} \xrightarrow{\text{PK}} C \text{ in body} \xrightarrow{\text{PD}} \text{Effects} \quad (1)$$

where PK is pharmacokinetics, PD is pharmacodynamics, and C is concentration.

The concentration at the tissue site of action usually cannot be directly measured, but the rise and fall in the concentration in blood plasma over time is a better measure of tissue exposure to a drug compared to the dose (which is the amount ingested over a given period of time, and gives far less data than a series of blood concentrations). Furthermore, there are many factors—such as body size and composition, and the rates of absorption and elimination—that affect the relationship between dose and concentration in the blood, which are often highly variable. Wilkinson (2001) gives a good introduction to pharmacokinetics, and there are specialist texts that give a detailed treatment (e.g., Rowland and Tozer, 1995; Shargel and Yu, 1999).

The concentration of a drug in blood relates best to its effect when it acts rapidly and reversibly. In other circumstances, there may not be a simple relationship between blood concentration and effect. For example, there can be delays if the equilibration between blood and tissue site of action is slow (as with some opioids; Lotsch et al., 2004), and the relationship between concentration and effect may be complicated if tissue sensitivity changes over time (as with levodopa; Deleu et al., 2002). Furthermore, the effects can persist after a drug has been eliminated from the blood if it is bound in tissues, or its actions are not reversible (e.g., irreversible enzyme inhibition or cell death). Sometimes the biological activity of a compound is attributable to its metabolite, as outlined below.

Elimination of Plant Secondary Metabolites

It is self-evident that herbivores must remove ingested PSMs from their body or risk their progressive accumulation to harmful levels. Metabolism and excretion are the processes used to eliminate PSMs from the body. Because the terrestrial kidney conserves water by extensively reabsorbing it from the renal tubules, lipophilic substances that can freely permeate the tubular epithelium are also extensively reabsorbed (Wilkinson, 2001). Thus, the more lipophilic a PSM, the more readily it will be absorbed from the gut and the less efficiently it will be excreted by the kidney. Animals possess a battery of enzymes that can transform lipophilic xenobiotics into water-soluble metabolites that are more readily excreted by the kidney.

Metabolism of Plant Secondary Metabolites

The enzymes that metabolize xenobiotics are considered to have evolved in herbivores in response to the formation of defensive chemicals by plants (Gonzalez and

Nebert, 1990; Lewis et al., 1998). Compared to the enzymes of intermediary metabolism, they are characterized by a remarkable lack of substrate specificity, enabling them to metabolize a chemically diverse range of PSMs and, incidentally, other xenobiotics. Thus, humans use the same group of enzymes to metabolize therapeutic drugs, whether of plant origin or the newly created products of synthetic chemistry.

The major type are the cytochrome P450 enzymes (CYPs), which are responsible for most oxidative metabolism of xenobiotics (Wilkinson, 2001). P450 genes are found in virtually all organisms, and the enzymes they code for are responsible for many different reactions: some plant P450 enzymes are involved in the synthesis of the plant defense chemicals that are subsequently catabolized in the animal by other related enzymes of the same superfamily (Werck-Reichhart and Feyerreisen, 2000).

The overall pattern of P450 genes is the same in humans and the puffer fish, and has been conserved despite 420 million yr of separate development (Nelson, 2003). Despite the similarities in P450 gene families among mammals, there is variation in the individual orthologous forms of P450 enzymes, probably driven by dietary differences, giving rise to marked differences between species in xenobiotic metabolism (Shimada et al., 1997; Lewis et al., 1998; Boyle et al., 1999, 2000, 2001; Machala et al., 2003). Within species, there can also be polymorphic and sex differences in P450 activity that, combined with individual differences in diet and associated induction processes, can result in significant individual differences in xenobiotic metabolism (Lewis et al., 1998; Ayrton and Morgan, 2001; Weaver, 2001; Weinshilbom, 2003).

The major sites of xenobiotic metabolism are the gastrointestinal endothelium, the liver, and the kidney (Parkinson, 2001; Doherty and Charman, 2002). In the case of ruminant herbivores, which have a bacterial fermentation chamber anterior to major sites of absorption, microbial biotransformation of PSMs in the rumen is an important mechanism for PSM metabolism (Carlson and Breeze, 1984). Because lipophilic PSMs are absorbed in the small intestine, they escape contact with the colonic bacteria of hindgut fermenters. However, many PSMs are polar (e.g., glycosides) and poorly absorbed, and are subject to bacterial metabolism in the colon (Manach et al., 2004). For example, quercetin-3-rutinoside (rutin) is hydrolyzed to the flavonol quercetin, which is partly absorbed intact and partly metabolized to hydroxy acids that are then absorbed (Olthof et al., 2003; Rechner et al., 2004).

Tissue level xenobiotic metabolism is divided into two phases: functionalization (Phase 1) and conjugation (Phase 2) (for a detailed account of xenobiotic biotransformation, see Parkinson, 2001). Phase 1 reactions serve to introduce or free a functional group, such as $-OH$, $-NH_2$, or $-COOH$. Most Phase 1 reactions involve a variety of oxidations catalyzed by P450 enzymes, but hydrolyses are also important for many PSMs such as esters, amides, and glycosides. In Phase 2, functional groups on xenobiotics or their metabolites are used to form adducts with endogenous substances, such as glucuronic acid, sulfate, glycine, or glutathione. The resulting conjugate is typically much more polar than its precursor, limiting its reabsorption from the renal tubules. Additionally, it may be a substrate for active transport into the renal tubules or bile duct, which can greatly increase the rate of elimination (Lin and Yamazaki, 2003; Lee and Kim, 2004).

Is Metabolism Detoxification?

In general, xenobiotic metabolism acts on lipophilic substrates that are converted into more polar, and, therefore, more readily excreted, metabolites. In changing the

chemical structure of a xenobiotic, metabolism usually changes the biological activity, but this does not always result in detoxification because there are many examples where the metabolite is active (Zhou et al., 2004a).

For example, P450 oxidation of pyrrolizidine alkaloids generates reactive metabolites that form adducts with protein and DNA, resulting in hepatotoxicity and carcinogenicity (Fu et al., 2004). Rumen bacterial biotransformation can also lead to activation of xenobiotics. For example, *S*-methyl cysteine sulfoxide, found in cruciferous plants, is metabolized in the rumen to dimethyl disulfide, which causes hemolytic anemia (Smith, 1980).

Induction and Inhibition of Metabolism and Transport

Competition between substrates can result in inhibition of metabolism (Lin and Lu, 2001; Weaver, 2001), especially with low-capacity pathways such as glycine conjugation (Moriwaki et al., 2005). Mechanism-based inhibition occurs when an enzyme produces a reactive product that binds to the enzyme and inactivates it (Weaver, 2001). The furanocoumarins in grapefruit juice, for example, inactivate enterocyte CYP3A, which can result in clinically significant increases in oral absorption of drugs (e.g., cyclosporin) that are extensively metabolized by this enzyme (Dresser and Bailey, 2003). Recovery depends on enzyme regeneration and takes a few days (Greenblatt et al., 2003).

Some xenobiotics bind to receptors in the cell nucleus leading to increased synthesis of certain xenobiotic-metabolizing enzymes, a process called induction (Lin and Lu, 2001; Weaver, 2001). Unlike enzyme inhibition, which is almost immediate, induction takes some days or weeks while the new protein is synthesized for the full effect to be seen (Hollenberg, 2002). The increased amount of enzyme enables faster metabolism of substrates, and is clearly a useful adaptation to a diet with changing PSM content. St John's wort (*Hypericum perforatum*) contains hyperforin, which activates the nuclear pregnane X receptor—thereby inducing the expression of CYP3A4, an enzyme that metabolizes most drugs (Moore et al., 2000). St John's wort also induces the intestinal efflux transporter P-gp, and both mechanisms contribute to the lowered blood levels of substrate drugs (Dresser et al., 2003). The full manifestation of the effects of St John's wort and other PSMs are complex, and depend on species, tissue, dose, timing, and PSM composition (Zhou et al., 2003, 2004b). Glucosinolates found in cruciferous plants also cause the induction of P450s (Bonnesen et al., 1999) following their hydrolysis in the digestive tract to active metabolites such as isothiocyanates.

Inducers are also substrates for the enzymes they induce (Hollenberg, 2002) and can act as competitive inhibitors of other reactions while present and bound to the active site. This is demonstrated in the brushtail possum, in which pretreatment for 10 d with a mixture of dietary terpenes induced hepatic P450 enzymes, resulting in faster *in vitro* metabolism of both the terpenes (1,8-cineole and *p*-cymene) and other substrates (Pass et al., 1999, 2001, 2002). When the inducing terpenes were added to liver enzyme preparations, they potently inhibited the metabolism of 1,8-cineole (Pass and McLean, 2002).

The consequences for PSM metabolism (and P-gp transport) by herbivores that consume large amounts of PSMs in their diet may be a complex result of induction (from recent exposure to inducing PSMs) and inhibition (by competitively inhibitory PSMs currently consumed and mechanism-based inhibitors recently consumed).

Dietary exposure of ruminant herbivores to PSMs can also lead to induced adaptation of the rumen microbial population, which can result in large changes in rates of metabolism and hence bioavailability. Such adaptation is generally presumed to depend on changes to microbial population structure in response to altered substrate availability. Thus, for example, the presence of oxalate salts in the diet of ruminant herbivores leads to the proliferation of *Oxalobacter formigenes*, a bacterial species capable of degrading oxalates (Allison et al., 1985). Adapted animals are tolerant to dietary oxalate exposure, and rates of degradation increase with increases in dietary exposure (Duncan et al., 1997).

Pharmacokinetic Factors Influence Plant Secondary Metabolite Concentration and Effects

The ingestive behavior of a herbivore effectively determines the PSM dosage rate (amount ingested per time), but the concentration in blood will depend as well on the relative rates of absorption and elimination, which are liable to considerable variability among species and individuals.

Some xenobiotics are extensively metabolized in the gut lumen, gut wall, and liver so that only a fraction of the oral dose reaches the systemic circulation (Wilkinson, 2001; Doherty and Charman, 2002). This fraction, termed the bioavailability (F), can be calculated from the ratio of the areas under the concentration–time curve after oral and intravenous dosing. Low values are inherently variable (Hellriegel et al., 1996), and a change in F from, say, 0.03 to 0.06 effectively doubles the amount of xenobiotics that reaches most of the body.

Limits to Consumption of PSMs

Herbivorous mammals typically eat in bouts separated by periods of not eating, and the total meal may take several hours (Arnold, 1981). The presence of PSMs in food plants presents a risk of toxicity to herbivores but, in most cases, it is presumed that they are able to limit consumption of toxic plants before they cause toxicity. Cases of clinical signs of toxicity among wild herbivores in their natural range are unusual. The means by which herbivores discern the toxicity of plants and avoid overconsumption are not well known, and we have developed a model system by using 1,8-cineole and the brushtail possum to address this. The monoterpene 1,8-cineole (cineole) is present in many species of *Eucalyptus* leaf as well as a number of conifer species (Von Rudloff, 1975). When brushtail possums were fed an artificial diet containing 2% cineole, the size of each bout was limited by the blood cineole concentration, since feeding stopped when this reached a critical level (Fig. 3; Boyle et al., 2005). The blood concentration depends on the amount of cineole ingested (i.e., the dose), its speed of absorption, and its bioavailability. Thus, the size and frequency of bouts, and the rate of eating during a bout may be governed by a negative feedback effect from the concentration of blood cineole or its metabolites.

Repeated ingestion of PSMs will lead to accumulation if some remains in the body after the previous feeding bout. The extent of accumulation depends on both the rate of ingestion (i.e., dose rate) and the rate of elimination. If an animal eats at

Fig. 3 Blood concentrations of cineole (○) in the brushtail possum in relation to eating a diet containing 2% cineole (—). From Boyle et al. (2005)

a constant rate, the PSM will accumulate to a steady state when the (usually first-order) elimination rate equals the intake rate. This is because the first-order rate of elimination will increase with the concentration of PSM (up to a concentration that saturates the enzymes).

$$\begin{array}{l} \text{PSM ingestion} \rightarrow C \rightarrow \text{Elimination rate} = k \cdot C \\ \text{(constant rate)} \qquad \qquad \qquad \text{(first order)} \end{array} \quad (2)$$

Because the elimination rate ($k \cdot C$) changes with C , the efficiency of elimination of a xenobiotic is better expressed by using the clearance concept, borrowed from renal physiology (Wilkinson, 2001). Clearance (CL) is the volume of blood or plasma from which a drug has been completely removed per unit time, and its value remains constant for any one individual and occasion so long as first-order conditions pertain. Clearance enables the steady-state concentration (C_{ss}) to be calculated for any constant dosing rate.

$$\text{Dosing rate} = \text{CL} \cdot C_{ss} \quad (3)$$

Continued accumulation of even low-potency PSMs will eventually lead to adverse effects. The consumption of PSMs on a daily basis will be limited by the capacity of the animal to eliminate them and their metabolites. This will depend on the rates of metabolism and renal excretion.

Implications of Pharmacokinetics of PSMS for Patterns of Ingestive Behavior

We have seen that, in a pharmacological context, circulating concentrations of drugs can serve as a useful approximation of drug concentrations at target tissues, and we argue that a similar approximation is useful in the context of herbivores and PSMs. Herbivores can avoid exceeding thresholds of plasma PSM concentrations by various means. First, spreading their feeding bouts on particular toxic plants throughout the day, or over longer periods, will reduce the probability of toxic thresholds being exceeded (Foley et al., 1999). There is evidence that consumption of toxic plants on 1 d influences intake rates on subsequent days, with cattle showing cyclical patterns of consumption to maintain circulating concentrations of toxins below toxic thresholds (Pfister et al., 1997). At shorter time-

scales, however, there is less evidence that herbivores alter patterns of ingestive behavior, including meal frequency, in response to PSM concentrations (Wiggins et al., 2003; Sorensen et al., 2005). A temporal distribution of feeding on a toxic plant species is likely to be facilitated by a dispersed spatial distribution of the plant. Large patches of toxic plants limit the potential for consuming alternative plants and may, therefore, limit intake potential. For example, extensive stands of invasive plants such as sagebrush (*Artemisia* spp.) are difficult to control by herbivory; smaller patches are more readily consumed presumably since alternative food sources may allow herbivores to maintain toxin concentrations below critical thresholds (Heady, 1964; Provenza et al., 2003).

Critical thresholds for particular toxins may also be avoided through diet mixing. The toxin dilution hypothesis (Freeland and Janzen, 1974) has been around for a long time, but never adequately tested (Iason and Villalba, 2006, this issue). It is certainly true that herbivores consume more food when offered a choice of foods containing different PSMs than when offered foods containing a single PSM (Burritt and Provenza, 2000; Wiggins et al., 2003), and Wiggins et al., 2006 (in this issue) have shown that leaf consumption is greater when two chemically dissimilar plants are offered together rather than either one alone. This phenomenon, however, has not yet been linked to circulating concentrations of PSMs that would demonstrate that animals are maintaining toxins below toxic thresholds through diet mixing.

Induction and inhibition of PSM metabolism also has implications for patterns of ingestion. Ruminant herbivores are generally cautious when they encounter novel foods, and this may be an adaptive mechanism to allow time for induction of enzymes responsible for PSM metabolism. Such induction may occur at the level of the gut microflora or the liver. Adapted animals consume more toxic plants than nonadapted ones (Duncan et al., 2000). Indeed, diet mixing, or occasional sampling of novel foods, may be an adaptive strategy for maintaining enzymes in an induced state to give maximum future protection against toxicity when encountering novel plants.

Pharmacological Model of Herbivory

Fig. 4 A model showing the pharmacological factors that affect herbivory

Conclusion

A pharmacokinetic approach to the study of PSM metabolism has much to offer in terms of quantifying the impact of PSMs on large herbivores under different feeding scenarios and to suggest explanations for observed patterns of feeding behavior. Much of the research on the pharmacokinetics of PSMs derives from the pharmacological literature, and some of the methods and understanding of drug metabolism now need to be adopted by ecologists to advance the field of plant/animal interactions. A range of factors relating to the physiology of the subject influence the fate of drugs following their ingestion (Fig. 4). These include the state of enzyme induction/inhibition (Lin and Lu, 2001), genetic factors (Weinshilboum, 2003), disease states (Rodighiero, 1999), and the age of the animal (Woodhouse, 1992; Kinirons and O'Mahony, 2004) and its nutritional status (Walter-Sack and Klotz, 1996; Ioannides, 1999). Improved understanding of how such factors influence the metabolism of plant secondary compounds in herbivores would help to improve our understanding of the influence of PSMs on ingestive behavior. Of particular interest are the questions surrounding the kinetics of toxin elimination and how this relates to the kinetics of feeding behavior at a range of temporal scales.

Acknowledgments Our thanks to Takuya Shimada and Bill Foley for convening the symposium and stimulating the writing of this review, and to Glenn Iason for useful comments on a draft manuscript. We are also grateful to our coworkers, in particular, Rebecca Boyle and Sue Brandon. This work has in part been supported by the Australian Research Council.

Abstract The dominant theory in the field of mammalian herbivore–plant interactions is that intake, and therefore tolerance, of plant secondary metabolites (PSMs) is regulated by mechanisms that reduce absorption and increase detoxification of PSMs. Methods designed by pharmacologists to measure detoxification enzyme activity, metabolite excretion, and most recently, drug absorption, have been successfully applied by ecologists to study PSM intake in a variety of mammalian study systems. Here, we describe several pharmacological and molecular techniques used to investigate the fate of drugs in human that have potential to further advance knowledge of mammalian herbivore–plant interactions.

Introduction

The application of pharmacological techniques has significantly advanced the field of plant–animal interactions. Much of the success stems from the overlap between human–drug interactions and plant–animal secondary metabolite (PSM) interactions. Humans and other animals experience constant and unavoidable exposure to foreign chemicals, or xenobiotics. Xenobiotics include both manufactured and natural chemicals such as drugs, pollutants, and PSMs. Regardless of xenobiotic origin, the mechanisms by which humans and other animals process xenobiotics that enter the body are similar, and this overlap provides the platform from which these

two fields can be integrated. Pharmacological techniques developed for human-drug studies have been most aggressively applied to insect–PSM interactions, and those reviews are found elsewhere (Rosenthal and Berenbaum, 1992; Berenbaum, 1999; Karban and Agrawal, 2002). Here, we focus on the less-explored aspects of pharmacology in understanding mammalian herbivore–PSM interactions.

In general, pharmacologists define the mechanisms by which animals process ingested xenobiotics by four major parameters: absorption, distribution, metabolism (detoxification), and excretion, or collectively ADME, each of which is described in detail elsewhere (Gibaldi and Perrier, 1982; Neubig, 1990; Boroujerdi, 2001; Hayes, 2001; Klaasen and Watkins, 2003). Tolerance to a particular xenobiotic is maximized in individuals that possess mechanisms to minimize absorption and distribution and maximize metabolism and elimination of xenobiotics. The relationship between ADME parameters and xenobiotic tolerance largely explains the variation in therapeutic efficacy of drugs in humans, and has the potential to account for the variation in the foraging ecology of mammalian herbivores. For humans, high tolerance to drugs afforded by low absorption, low distribution to target organs, and high metabolism and excretion results in lower therapeutic efficacy. For mammalian herbivores, high tolerance to PSMs afforded through these same mechanisms results in potentially greater intake of plants containing PSMs.

The general concepts of ADME have only recently been applied to study PSM tolerance and foraging behavior of mammalian herbivores, despite Freeland and Janzen's (1974) introduction of these concepts over 30 years ago. This delay is likely the result of numerous factors, including the cost of conducting pharmacological studies, the daunting task of searching the extensive pharmacological literature, and the complexity of investigating the complex mixtures of xenobiotics in plants. Despite these challenges, several ecologists have employed pharmacological techniques to investigate certain aspects of ADME in mammalian herbivores, primarily metabolism and excretion (McManus and Ilett, 1977; Bolton and Ahokas, 1997a,b; Boyle et al., 1999a,b; Pass et al., 1999, 2001, 2002; Stupans et al., 1999, 2001; Liapis et al., 2000; Ngo et al., 2000, 2003; Mangione et al., 2001; McLean et al., 2001; Pass and McLean, 2002; Lamb et al., 2004). Excretion of PSM metabolites has been largely used to measure metabolism qualitatively. However, to fully understand how PSMs influence the foraging behavior of mammalian herbivores, absorption and distribution (primarily in the blood) must also be considered. In this review, we provide summaries of several pharmacological techniques of ADME that can be used to understand the fate of PSMs in mammalian herbivores. Although ADME parameters are interconnected, absorption and metabolism receive the majority of attention, as they tend to guide the design of studies on distribution and excretion. Our goal is to introduce ecologists interested in studying interactions of PSMs and mammalian herbivores to pharmacological concepts and techniques that can advance the field. To that end, we outline the basic principles of absorption, metabolism, and distribution (as it relates to absorption and metabolism), and how they apply to several hypotheses important to studies of mammalian herbivores.

Absorption

Absorption is the first parameter of ADME that may significantly affect diet selection in mammalian herbivores. Mammalian herbivores may reduce absorption

of PSMs through various mechanisms, but here we focus on efflux transporters in cells lining the gut. Studies of efflux transporters, such as permeability glycoprotein (Pgp), are revolutionizing our understanding of the absorption of pharmaceuticals and other xenobiotics in humans (Bellamy, 1996; Hunter and Hirst, 1997; Sharom, 1997; Stein, 1997; Watkins, 1997; Benet et al., 1999; Schinkel, 1999; Silverman, 1999; Scheffer et al., 2000; Ayrton and Morgan, 2001; Benet and Cummins, 2001; Saier and Paulsen, 2001; Washington et al., 2001; Zhang and Benet, 2001; Melaine et al., 2002; Ambudkar et al., 2003; Dietrich et al., 2003; Fromm, 2003; Lin and Yamazaki, 2003a,b; Schinkel and Jonker, 2003; Sparreboom et al., 2003; Chan et al., 2004; Fromm, 2004; von Richter et al., 2004). Prior to the discovery of efflux transporters, absorption of compounds across the gut was thought to occur passively. We now know that transporters in the gut actively efflux xenobiotics, thereby preventing absorption. Research in this area is intensely active, with over 200 papers published on Pgp's impact on drug absorption and bioavailability in 2005. Despite the celebrity of efflux transporters in the areas of pharmacology and medicine, they have only recently been recognized in the area of herbivore–PSM interactions (Murray et al., 1994; Lanning et al., 1996a,b; Sorensen and Dearing, 2003; Green et al., 2004). An overview of the mechanisms and role of efflux transporters in effluxing PSMs and influencing plant–herbivore interactions is found in Sorensen and Dearing (2006, this issue). Here, we summarize specific assays that directly or indirectly investigate efflux transporters and their role in regulating absorption of PSMs in mammalian herbivores. Studies on efflux transporters as regulators of PSM absorption should first focus on quantifying these transporters in the gastrointestinal tract and testing PSMs as substrates for efflux transporters in enterocytes. However, efflux transporters are found in a variety of barrier tissues including the blood–brain barrier, liver, kidney, testes, and uterus.

Direct Quantification of Efflux Transporters

A combination of Western blots and quantitative polymerase chain reaction (qPCR) is used to determine the presence and quantify gene expression of efflux proteins in various tissue types. These assays can be used to test hypotheses of mammalian herbivore feeding preferences and tolerances. The exceptional tolerance to PSMs by dietary specialists may be, in part, attributed to reduced absorption afforded by efflux transporters. The most celebrated efflux transporter, Pgp, has been fully quantified by using monoclonal antibodies in a variety of organisms including herbivorous mammals (Dudler and Hertig, 1992; Murray et al., 1994; Sangster, 1994; Lanning et al., 1996a,b; Barnes, 2001; Doi et al., 2001; Keppler and Ringwood, 2001; Lee et al., 2001; Saier and Paulsen, 2001; Yazaki et al., 2001; Bard et al., 2002; Buss et al., 2002; Smith and Prichard, 2002; Sasaki et al., 2002; Green et al., 2004). An additional approach is to quantify mRNA of efflux transporters via qPCR (Wong and Medrano, 2005) by using species-specific primers. These primers are often designed from known sequence homology between species (for sequence information, see UCS Genome Bioinformatics website, <http://genome.ucsc.edu>). The benefits and constraints of each approach are described elsewhere (Sorensen and Dearing, 2006, this issue), but each has been applied to a variety of distantly related species and, therefore, holds promise for further investigation of efflux transporters in mammalian herbivores. Although the majority of assays designed to quantify efflux transporters focus on Pgp,

several exist, and new transporters are continuously being identified and should be considered as the field progresses.

Indirect Investigation of Efflux Transporters

Investigating the proportion of PSM ingested that is excreted unchanged in the feces is an indirect method to assess the role of efflux transporters. In general, a herbivore is fed a PSM or whole plant tissue, and the absolute amount of each PSM ingested is quantified (Sorensen et al., 2004). Feces are collected from the animal following intake of PSMs, and the quantity of unchanged (unmetabolized) PSM in the feces is determined. The assumption is that unchanged PSM in excreta represents PSMs that were not absorbed. Such data would indirectly indicate that some mechanism regulated the absorption of the ingested PSM. However, lack of unchanged PSM in the feces is not necessarily indicative of a limited role of efflux transporters. The PSM may indeed be a substrate for transporters, but is acted on by metabolizing enzymes or microbes prior to defecation. Another confounding factor associated with fecal studies is that positive results do not reveal the mechanism responsible for regulating absorption. A variety of mechanisms regulate absorption of ingested PSMs, and each is reliant on the physiochemical properties of the PSM. For example, the peritrophic membrane of insects (Lehane, 1997; Barbehenn, 2001) and tannin-binding salivary proteins (TBSPs) in mammals (McArthur et al., 1995; Skopec et al., 2004) act to regulate absorption of large complex PSMs, such as tannins. However, both peritrophic membranes and TBSPs are not effective regulators of the absorption of lipophilic compounds. Therefore, fecal excretion of unchanged lipophilic molecules (i.e., those with high partition coefficients), such as terpenes and alkaloids, may be a result of efflux transporters. Promising evidence that efflux transporters may play a role in regulating absorption of PSMs is that several PSMs (e.g., alkaloid vinblastine from periwinkle, *Vinca rosea*, Sharom, 1997) and diterpenes from spurges (*Euphorbia* spp., Hohmann et al., 2002; Appendino et al., 2003) are substrates for Pgp. A list of Pgp substrates, inhibitors, and inducers from plants is given in Sorensen and Dearing (2006, this issue) and Zhou et al. (2004).

Testing PSMs as Efflux Transporter Substrates

A variety of *in vitro* assays are available to test whether PSMs are substrates for efflux transporters. Monolayer cell systems have been developed to positively identify xenobiotics as substrates, inhibitors, and inducers of efflux transporters (Brayden, 1997; Bjornsson et al., 2003; Weiss et al., 2003; Fröhlich et al., 2004). Although many cell lines are specifically designed to overexpress Pgp, they can be selected to express a variety of different efflux transporters. Results from established cell lines and a particular PSM are compared with known transporter substrates (Sharom, 1997; Seelig and Landwojtowicz, 2000; Polli et al., 2001; Bjornsson et al., 2003). Although efflux monolayer systems are regarded as the standard for identifying transporter substrates, other techniques include ATPase activity assays (Scarborough, 1995; Litman et al., 1997; Schmid et al., 1999) and calcein-AM fluorescence assays (Liminga et al., 1994; Tiberghien and Loor, 1996). Each has advantages and disadvantages compared to efflux monolayer systems that

are reviewed elsewhere (Polli et al., 2001). Although these *in vitro* assays provide a noninvasive approach to screen PSMs as substrates for efflux transports, results from such studies can be confounded. First, results may not necessarily translate to the organism of interest. Identifying which efflux transporter a PSM interacts with in cell-based systems containing multiple transporter proteins is another complication. In addition, *in vitro* studies may not correspond to *in vivo* studies. Therefore, follow-up studies need to isolate cells and tissues from the herbivore of interest (Green et al., 2004, 2005), and/or researchers should conduct *in vivo* experiments (described below in [Blood Distribution](#)) to confirm the role of efflux transporters in mammalian herbivores.

Metabolism

Once a PSM enters the blood stream, metabolism becomes the most important factor in ADME, and directly affects distribution and excretion. In general, the faster an herbivore metabolizes a given PSM, the more quickly it clears it from the body and, thus, the greater its tolerance should be for the PSM. In the following paragraphs, we outline the various techniques that can be utilized to study the metabolism or detoxification of PSMs by mammalian herbivores. Before discussing pharmacological techniques, we briefly touch on the overall process of detoxification in mammals and the general groups of enzymes involved.

Detoxification Pathways

Mammalian detoxification is split into a two-phase process. Phase I, or functionalization, contains a suite of enzymes that act on xenobiotics by adding functional groups. Oxidation and reduction are two of the most common types of chemical reactions carried out by functionalization enzymes. The family of enzymes called cytochrome P450s (CYPs) is one of the largest and best studied groups of functionalization enzymes that carries out oxidation reactions in mammals. The functionalization of xenobiotics has three possible outcomes: (1) the metabolite becomes sufficiently water-soluble to be excreted in bile or urine; (2) the metabolite becomes more reactive and more toxic than the parent compound; or (3) the metabolite is further detoxified by phase II enzymes. Phase II, or conjugation, contains a suite of enzymes that add a water-soluble conjugate, often a sugar or amino acid moiety. These conjugates make the xenobiotic more water-soluble so that it can be excreted in urine or bile. The detoxification system of vertebrate herbivores is reviewed in Dearing et al. (2005), and a complete description can be found in Casarett and Doull's Toxicology (Klaassen and Watkins, 2003). Although the overall outcome of the detoxification system is relatively straightforward, i.e., to make xenobiotics more water-soluble for excretion, regulation of the detoxification system is complicated and dynamic. Up- and down-regulation of enzyme content and activity occur frequently and rapidly, on the order of days, in response to the presence of xenobiotics in the blood (Hollenberg, 2002; Bock and Köhle, 2004). Therefore, carefully designed studies are needed to identify the importance and relative capacity of specific detoxification pathways that mammalian herbivores use to metabolize ingested PSMs.

Analysis of Metabolites

Several studies have documented the metabolites produced and excreted when either whole plant material or purified PSMs are fed to mammalian herbivores (Boyle et al., 1999a,b; Mangione et al., 2001; McLean et al., 2001). Depending on the chemical nature of the PSM, gas chromatography, mass spectrometry, or high-performance liquid chromatography can be used to analyze the metabolites produced. Metabolites can be analyzed in blood or urine. Depending on the size and nature of the herbivore, one type of sample may be easier to collect than the other. Metabolite studies are an excellent first step in studying mammal–PSM interactions. Whereas characterizing metabolites gives potential clues as to which pathways may be involved in the detoxification of PSMs, these types of studies are more qualitative than quantitative with respect to rate and route of detoxification.

Enzyme Assays

Another technique frequently used in pharmacology that lends itself well to studying nonmodel species is measuring the amount of liver detoxification enzymes. Total CYP content can be measured in a spectrophotometric assay (Hayes, 2001) that yields an overall view of one of the most important groups of phase I enzymes in mammalian herbivores. To measure the CYP content, fresh liver tissue is required, making this type of study usually a lethal endpoint one. However, if the mammalian herbivore were large enough, a liver biopsy may be possible. The liver tissue is homogenized and differentially centrifuged to separate the microsomal (endoplasmic reticulum) fraction from the cytosolic fraction. The CYP content is measured in the microsomal fraction of the liver. A number of labs studying mammalian herbivores have used total CYP content as an assay, and these results are summarized in Table 1. Total CYP content can be used to determine the detoxification ability of a single species (Bolton and Ahokas, 1997a,b;

Table 1 Total cytochrome P450 contents in the livers of mammalian herbivores

Species	Status	Diet	P450 content	Reference
Koala ($N = 4$) (<i>Phascolarctos cinereus</i>)	Wild	Eucalyptus	0.87 ± 0.18	(Stupans et al., 1999)
Tammar wallaby ($N = 6$) (<i>Macropus eugenii</i>)	Wild	Grazer	0.24 ± 0.04	(Stupans et al., 1999)
Quoakka ($N = 8$) (<i>Setonix brachyurus</i>)	Captive	Lab diet	0.95 ± 0.08	(McManus and Ilett, 1977)
Kangaroo ($N = 10$) (<i>Macropus fuliginosus</i>)	Wild	Browser	0.47 ± 0.05	(McManus and Ilett, 1977)
Brushtail possum ($N = 4$) (<i>Trichosurus vulpecula</i>)	Captive	Control lab diet	0.27 ± 0.04	(Pass et al., 1999)
Brushtail possum ($N = 4$) (<i>Trichosurus vulpecula</i>)	Captive	Terpene lab diet	0.41 ± 0.02	(Pass et al., 1999)
Brushtail possum ($N = 20$) (<i>Trichosurus vulpecula</i>)	Wild	Eucalyptus	0.90 ± 0.06	(Bolton and Ahokas, 1997a)
Stephens woodrat ($N = 4$) (<i>Neotoma stephensi</i>)	Wild	Juniper	1.74 ± 0.25	(Lamb et al., 2004)

Lamb et al., 2004), and also for comparative studies among species on different diets (McManus and Ilett, 1977; Stupans et al., 1999), as well as species on different diets (Pass et al., 1999).

In addition to measuring total CYP content, a number of researchers have measured the activity of specific detoxification enzymes in wild herbivores (Bolton and Ahokas, 1997a,b; Pass et al., 1999; Stupans et al., 1999, 2001; Liapis et al., 2000; Ngo et al., 2000, 2003; Lamb et al., 2004). Enzyme-specific substrates are used to determine the activity of individual enzymes of interest. The disappearance of the substrate or the appearance of metabolites is generally measured spectrophotometrically. Enzyme activity assays are robust methods that lend themselves well to nonmodel species studies and interspecies comparisons. Hayes (2001) is an excellent reference for enzyme activity assays. A table containing liver CYP enzyme activities in selected species and associated references can be obtained from Xenotech, Lenexa, KS, USA (<http://xenotechllc.com>).

Although enzyme assays are robust in nature, they require expensive equipment (e.g., homogenizers, spectrophotometers for turbid solutions, high-speed centrifuges) that might not be a part of a standard ecology lab. Careful selection of the detoxification enzymes to analyze is important because the activity assays can be time consuming and expensive. Another limitation of enzyme activity assays is that they exist for only a subset of the more than a hundred detoxification enzymes. The most thorough studies typically measure the activities of about 10 detoxification enzymes. A carefully designed study with well-chosen enzymes can lead to useful intraspecific or interspecific comparisons. Studies on urinary or blood metabolites can be used to guide the selection of enzyme assays. Comparing the detoxification enzyme activities of mammalian herbivores on different diets will allow ecologists to understand not only how the PSMs are detoxified, but also potentially how the herbivore regulates detoxification enzymes.

Researchers can also use PSMs directly in microsomal assays. The PSM can be added to the microsomal fraction, and its disappearance or the appearance of metabolites can be measured over time (Pass et al., 2001, 2002; Pass and McLean, 2002). This assay measures the combined activities of all detoxification enzymes present in the microsomal fraction but does not elucidate the particular enzymes by which detoxification occurs. However, this approach will give an idea of the speed and capacity of a herbivore's detoxification system for a particular PSM.

A noninvasive approach to rapidly screen PSMs of interest as substrates for various metabolizing enzymes and guide future enzyme studies is to use commercially available hepatocytes or recombinant enzymes and specific probe substrates (LeCluyse, 2001). The approach can be used to test which metabolic pathways are most likely to metabolize a specific metabolite and also which are produced without the use of live mammalian herbivores. Hepatocytes are advantageous in that they represent the "true" physiological environment of the organism from which they are derived (e.g., human, rat, insect, and frog). Recombinant enzymes, on the other hand, are more readily available, less expensive, and the results are not confounded by metabolic processes other than those from the enzyme of interest. One limitation of using hepatocytes and recombinant enzymes is that they only indicate whether the PSM is a substrate for an enzyme from the organism from which the enzyme was isolated. Enzymes in the herbivore of interest may differ significantly in their interaction with the same PSM. These studies are useful as an initial screen to predict which enzymes may be

responsible for PSM metabolism in the herbivore of interest prior to whole animal studies. Although time and resource intensive, researchers can isolate, culture, develop hepatocytes, and design recombinant enzymes directly from mammalian herbivores (Mankowski et al., 1999; Gardmo et al., 2005; Jung'a et al., 2005).

Gene Expression

An alternative strategy to determine how PSMs are processed by mammals is to quantify expression of detoxification enzyme genes. The three major techniques used to analyze gene expression are Northern blots, qPCR, and microarrays. Northern blots involve running mRNA samples on a gel and using specially designed probes to identify and quantify the mRNA of interest on the gel (Belin, 1998; Sabelli, 1998). Northern blots have been used successfully for the genus *Neotoma* with probes designed for laboratory rats (Lamb et al., 2001, 2004). Ecologists studying herbivores closely related to a model species may also be able to take advantage of predesigned probes. However, for herbivores not closely related to a model species, genes of interest will need to be sequenced to design appropriate probes. Quantitative PCR is a relatively new technique that can also be used to study gene expression of detoxification enzymes. As in quantification of efflux transporters, specific primers are needed for the reactions to ensure that the only double-strand DNA produced is from the gene of interest (Wong and Medrano, 2005). Both Northern blots and qPCR can be used to study how PSMs affect the regulation of the detoxification system by quantifying changes in gene expression of detoxification genes. Depending on quantity of sample, equipment access, budget, etc., ecologists can decide between Northern blots or qPCR.

Microarrays

Microarrays hold promise for investigating detoxification systems on a much larger scale (Gibson, 2002; Meyer and Gut, 2002; Gracey and Cossins, 2003; Klaper and Thomas, 2004; Thomas and Klaper, 2004; Tittiger, 2004). Microarrays are a cutting-edge technology in the field of genomics that allow for the parallel analysis of the expression of thousands of genes. Representative sequences of genes are printed in high density onto a solid surface, often a glass microscope slide. A number of commercial arrays made for model organisms are available, and cross-species hybridization works well between closely related species (Gonzalez and Nebert, 1990; Enard et al., 2002; Moody et al., 2002). Therefore, the commercial rat, mouse, or human arrays may be acceptable for a number of mammalian herbivores. To perform microarray analysis, extracted RNA is reverse-transcribed, fluorescently labeled, and hybridized to the array. The arrays are then scanned by specialized scanners, and the intensity and color of the spot at each gene are related to the abundance of the gene transcript in the sample. The popularity of microarrays as a technique for studying gene expression has led most major research universities to develop core facilities that perform microarray experiments for a fee; therefore, specialized equipment is not needed. Even with a core facility, the cost of microarray experiments is considerable. Arrays cost ~\$200–400; a single experiment with 10 individuals and two treatments (i.e., 20 samples) can easily cost between \$2000–8000 depending on the experimental design and the array. Although the laboratory methods for running a microarray are straightforward, the data analysis

can be overwhelming because microarrays produce data for thousands of genes. Therefore, careful planning of the experimental design and analysis is essential before starting a microarray experiment (Churchill, 2002; Reiner et al., 2003; Yang et al., 2003; Woo et al., 2004; Khatri and Drăghici, 2005). A well-designed microarray experiment will not only give a fairly complete picture of gene regulation occurring in response to PSMs, but also provide a number of candidate genes for further studies.

Gene Sequencing

Whereas quantitative differences in gene products produce detoxification differences within and between species, qualitative differences in gene products because of sequence differences may also play a large role in the variation of detoxification abilities. The field of pharmacogenomics examines the relationships between polymorphisms in detoxification genes and their effects on drug detoxification and disease susceptibility in humans (Puga et al., 1997; Nebert and Roe 2001; Meyer, 2004). Polymorphisms within human populations can lead to 30- to 40-fold differences in detoxification of drugs and xenobiotics (Nebert and Dieter, 2000). The plant–insect interaction community has also studied the effects of differences in sequences in detoxification genes on herbivore detoxification capacity (e.g., Li et al., 2004). With the advent of automated sequencing facilities at most research universities, comparative sequencing is a relatively straightforward procedure. Sequencing projects will lead to increased understanding of detoxification differences both within and between different species of mammalian herbivores as well as to the discovery of novel detoxification genes. For example, a novel CYP has been reported in koalas, CYP4A15 (Ngo et al., 2000; Stupans et al., 2001).

Hypnotic State Assays

Although the application of the assays described in the previous sections holds promise for exploring the metabolism of PSMs in mammalian herbivores, they often require a lethal endpoint and are, therefore, not feasible for many researchers working on mammals. Several nonlethal assays have recently been borrowed from pharmacology by ecologists that allow for repeated measures of detoxification capacity in mammals. Hypnotic state assays measure the length of time an animal spends in a drug-induced hypnotic state (or loss of righting reflex) as a proxy for detoxification capacity for a specific enzyme. This assay is often used in the investigation of new pharmaceuticals (Sasaki, 1994; Konishi et al., 2002; Kim and Shin, 2005) to determine whether detoxification of a novel compound will cause interactions with other drugs through competition for the same detoxification pathways. In such studies, a dose of the compound is administered prior to the hypnotic agent, and the length of the hypnotic state is measured. Drug interactions are considered possible if administration of the compound increases the length of time the animal spends in a hypnotic state compared to the control treatment, i.e., when only the hypnotic agent is delivered. Because the detoxification pathways of the hypnotic agents have been established, but those of the novel compound typically have not, the results can be used to infer putative detoxification pathways for the novel compound.

Sleep time under hexobarbital and paralysis time under zoxazolamine are two of the more common agents used for hypnotic state assays (Sasaki, 1994; Koizumi et al., 2001). For either assay, the compound is injected intraperitoneally. After losing the ability to right itself, the animal is placed on its back with its head elevated, and the length of time (typically 20–300 min) the animal remains in this state is measured. As there is considerable variation among individuals and sexes, sample sizes greater than 8 for each sex are advisable for comparative studies.

Hypnotic state assays can easily be applied to detoxification of PSMs by mammalian herbivores. The potential safety of PSMs for use as pharmaceuticals has been assessed with hypnotic state assays (Wada et al., 1993; Oliveira et al., 2005). Two significant benefits of this assay compared to other pharmacological approaches (e.g., microsomal assays) are that it is relatively noninvasive and nonlethal. Because different sleep agents are acted on by different detoxification enzymes (e.g., hexobarbital by CYP2B; zoxazolamine by CYP1A), these assays can be used to measure the capacity or role of particular pathways. The assays can also be performed under field conditions, as well as repeatedly to permit comparative studies between animals on different diets, treatments, or from various populations.

Blood Distribution

Pharmacokinetic Studies

Pharmacokinetics (PK) is a nonlethal approach that evaluates the distribution of PSM in the blood (or plasma). In general, PK is the study of the time course of xenobiotic absorption, distribution, metabolism, and excretion and can be used to compare these attributes among mammalian herbivores under various conditions. PK studies require collection of serial samples of blood, tissues, urine, or feces, as well as strong analytical chemistry skills or access to radiolabeled PSMs for quantification. In general, the animal is given an intravenous and/or oral administration of a PSM, and the subsequent increase and decrease of its concentrations in body compartments are measured over time. Blood is the most commonly used and informative compartment investigated, but organs and excreta can also be evaluated to provide information on the time course and fate of PSMs and their metabolites. PK experiments require that the herbivore be catheterized or that researchers have sufficient sample sizes to generate a blood concentration–time curve from single blood collections from the orbital sinus, tail vein, or venous punctures from different animals. Pharmacokinetics in blood provides information on clearance, half-life, bioavailability, total exposure [i.e., area under the curve (AUC)], and apparent volume of distribution of the PSM (Fig. 1). The detailed calculations and relationships among these parameters are available elsewhere (Gibaldi and Perrier, 1982; Neubig, 1990; Boroujerdi, 2001). Recent PK studies have illustrated the link between PSM concentrations in the diet, feeding behavior, foraging strategy, and metabolism and absorption in mammalian herbivores (Sorensen and Dearing, 2003; Boyle and McLean, 2004). Here, we outline additional hypotheses that can be generated and tested by using PK studies.

Fig. 1 Schematic representation of possible pharmacokinetic (PK) results following intravenous (IV, dashed line) and oral (solid line) administration of a plant secondary metabolite (PMS) to an animal in a linear scale (see Gibaldi and Perrier 1982; Neubig 1990; Boroujerdi 2001). Data are based on first-order kinetics and a one-compartmental model. Resultant PSM concentrations over time may be derived from blood, plasma, tissue, bile, feces, or urine. The time profile is dependent on feasibility, but reliable PK data should adhere to the following criteria: (1) initial time points should be collected more frequently than latter time points; (2) blood collections should be collected out to at least five half-lives; and (3) total blood collection should be <10% of total blood volume of the herbivore. PK parameters obtained from IV and oral dosing are defined in Table 2

Absorption

Pharmacokinetic studies can be used to assess absorption. For example, if oral half-life ($t_{1/2}$, hr) is longer than intravenous half-life and/or if bioavailability is low, then the distribution of the PSM may be influenced by the absorption process. Ecologists can take advantage of the established list of substrates for efflux transporters as positive controls, inhibitors, and inducers (Sharom, 1997; Seelig, 1998; Seelig and Landwojtowicz, 2000; Polli et al., 2001; Bjornsson et al., 2003) to investigate regulated absorption of PSMs. Studies can be designed that administer a PSM in the diet and then compare food intake, PSM blood concentrations, and fecal excretion

Table 2 Pharmacokinetic parameters that can be determined from intravenous (IV) and oral dosing of a PSM to a mammalian herbivore (Gibaldi and Perrier, 1982; Neubig, 1990; Boroujerdi, 2001)

PK parameter	Symbol	Definition	Calculation
Clearance (mL/min/kg)	Cl	Efficiency of drug elimination from the blood	$\text{Dose}_{\text{IV}} / \text{AUC}_0^\infty$
Half-life (hr)	$t_{1/2}$	Time it takes for concentration of PSM to decline 50%. This is referred to as the “terminal half-life”	$1.0693 \times V_d / \text{Cl}$
Area under the curve (min*mg/mL)	AUC_0^∞	Area under the plasma concentration–time curve from time 0 to infinity. Considered as an index of exposure to the PSM	$\int_0^\infty C \cdot dt$, where C is PSM concentration
Apparent volume of distribution (mL/kg)	V_d	Hypothetical volume of body fluid dissolving the xenobiotic at the same concentration as that in the plasma	$\text{Dose}_{\text{IV}} / C_0$, where C_0 is the concentration of PSM at time 0
Bioavailability (%)	F	The fraction of the dose absorbed	$(\text{AUC}_{\text{oral}} \cdot \text{Dose}_{\text{IV}}) / (\text{AUC}_{\text{IV}} \cdot \text{Dose}_{\text{oral}})$

of the PSM with and without the administration of a known inhibitor or inducer of the efflux transporter. If the PSM is a substrate for a transporter, then coadministration of the metabolite with a transporter inhibitor should result in decreased intake of diet containing the PSM, increased blood concentrations of the PSM, longer half-life, and decreased excretion of unchanged PSM in the feces.

Metabolism

Pharmacokinetic studies can also be used to assess metabolism. Faster clearance (Cl, in ml/min/kg) indicates faster rates of metabolism. Therefore, clearance rates can be evaluated to test whether dietary specialists or animals with evolutionary history with PSMs have higher detoxification capacity than dietary generalists or animals naive to PSMs (Sorensen and Dearing, 2003). The use of inhibitors of detoxification enzymes can also be employed in PK studies to evaluate the role of specific detoxification pathways on PSM clearance. Parameters can be compared between herbivores administered a PSM with an inhibitor (or inducer) of the putative metabolizing enzyme to that of herbivores administered the PSM without the inhibitor. Such studies are currently underway in brushtail possums (McLean, personal communication) and take advantage of the litany of enzyme substrates as positive controls, inhibitors, and/or inducers (<http://medicine.iupui.edu/flockhart/table.htm>; Newton et al., 1995; Tucker et al., 2001; Bjornsson et al., 2003; Sorensen and Dearing, 2006, this issue). PK studies can also be used to determine if a PSM interacts with a specific metabolizing enzyme that uses known substrates. For example, the CYP3A inhibitory properties of a PSM can be evaluated by comparing *in vivo* blood concentrations of a well-known CYP3A substrate, midazolam, orally administered with and without oral administration of a PSM (Bjornsson et al., 2003). If plasma levels of midazolam are higher with the PSM compared to without it, then the metabolite would be considered a strong inhibitor of CYP3A. Inhibition can be a result of either competitive or noncompetitive interactions with the enzyme of interest, and further studies are then required to elucidate the type of inhibition (Bjornsson et al., 2003). In contrast, if plasma concentrations of midazolam are lower with the PSM than without it, this suggests that it may induce CYP3A and therefore aid in midazolam clearance.

Tissue Affinity

Pharmacokinetic studies can also provide information on PSM affinity for tissues by evaluating the apparent volume of distribution (V_d , in L/kg) following intravenous PSM administration. A V_d that is higher than the water volume of the animal (0.7 L/kg, Davies and Morris, 1993) suggests high tissue affinity and is usually associated with a long half-life of the PSM. Potentially, a higher V_d may be a characteristic of PSMs that bind with tissues by interacting with specific receptors. For example, cannabinoids from *Cannabis sativa* have a high V_d (Samara et al., 1988), are distributed in the brain, and have high affinity and selectivity for G-protein-coupled cannabinoid receptors (Grotenhermen, 2005). In addition, the phenolics from *Eucalyptus jensenii* are thought to mediate the feeding behavior of mammalian herbivores via serotonin action on 5HT3 receptors (Lawler et al., 1998). We predict that these phenolics will also have high brain distribution and a large V_d . Distribution studies could guide research into which receptors are targeted by

PSMs and help identify the mechanisms responsible for PSM-related changes in behavior and physiology in mammalian herbivores.

Summary

Over three decades ago, Freeland and Janzen (1974) proposed that the feeding strategies of mammalian herbivores were governed by their detoxification systems. Since then, surprisingly few researchers have examined metabolism of PSMs in wild herbivores, and even less have examined the role of absorption or distribution. The objective of this review was to provide a brief overview of assays typically used in pharmacology that can be applied to research on mammalian herbivores. We would like to point out that as in pharmacology, no single assay can uncover the complexities of the fate of xenobiotics in mammalian herbivores. Each technique has benefits and limitations. The most informative future studies will integrate several of these *in vitro* and *in vivo* techniques to yield a comprehensive understanding of how mammalian herbivores process PSMs. The particular suite of techniques that will result in the most useful information is dependent on the particular questions asked and the study system. Lastly, because many of the techniques described herein require expensive equipment and/or reagents as well as technical expertise, we encourage novices to visit a laboratory that regularly performs the technique and to establish collaborations with pharmacologists and toxicologists.

Acknowledgments Funding was provided by NSF International Research Fellowship INT-0301898 to J. S. Sorensen and NSF IBN0236402 to M. D. Dearing. We thank K. Smith for assistance with manuscript preparation. Two anonymous reviewers provided insightful comments. Finally, we thank R. Osawa, W. J. Foley, and T. Shimada for organizing a productive symposium at the IX International Mammalogical Congress in Sapporo, Japan, where these ideas were discussed.

The Detoxification Limitation Hypothesis: Where Did it Come From and Where is it Going?

Abstract The detoxification limitation hypothesis is firmly entrenched in the literature to explain various aspects of the interaction between herbivores and plant toxins. These include explanations for the existence of specialist and generalist herbivores and for the prevalence of each of these. The hypothesis suggests that the ability of mammalian herbivores to eliminate plant secondary metabolites (PSMs) largely determines which plants, and how much, they can eat. The value of the hypothesis is that it provides a clear framework for understanding how plant toxins might limit diet breadth. Thus, it is surprising, given its popularity, that there are few studies that provide experimental support either for or against the detoxification limitation hypothesis. There are two likely reasons for this. First, Freeland and Janzen did not formally propose the hypothesis, although it is implicit in their paper. Second, it is a difficult hypothesis to test, requiring an understanding of the metabolic pathways that lead to toxin elimination. Recent attempts to test the hypothesis appear promising. Results suggest that herbivores can recognize mounting saturation of a detoxification pathway and adjust their feeding accordingly to avoid intoxication. One strategy they use is to ingest a food containing a toxin that is metabolized by a different pathway. This demonstrates that careful selection of food plants is a key to existing in a chemically complex environment. As more studies characterize the detoxification products of PSMs, we will better understand how widespread this phenomenon is.

Introduction

Free-ranging mammalian herbivores can usually feed from a wide variety of plants, but most do not forage at random. Rather, they make careful choices about what they eat. Ultimately, these choices need to provide the animal with its nutritional requirements for maintenance, growth, and reproduction, without causing harm. It is well known that captive herbivores can select a balanced diet if given a variety of foods containing different individual nutrients (Wang and Provenza, 1997; Aranda et al., 2000; Scott and Provenza, 2000) or different concentrations of a given nutrient (Shariatmadari and Forbes, 1993; Gous and Swatson, 2000). No doubt, free-ranging herbivores can do the same. There is an important difference, however, between captive and wild animals: the latter must obtain their nutrients from plants that often have potentially toxic chemicals. Put simply, herbivores need to eat plants, but plants have developed many chemicals, known as plant secondary metabolites (PSMs), that act as defensive agents. Not surprisingly, given the diversity of plants, PSMs are extremely diverse and widespread and often occur in sufficient quantities to harm, or even kill, any animal that might eat it. As Freeland and Janzen (1974) point out, however, it is much easier to find animals that eat plants known to contain toxins than to find animals that can avoid them entirely. It seems that herbivores cannot reliably avoid ingesting PSMs, and instead have evolved a suite of mechanisms to counter their effects (Fig. 1).

There is no doubt that PSMs can influence feeding by mammalian herbivores, reducing food intake, altering dietary preferences, and sometimes even killing the animal (Foley et al., 1999). However, because of the difficulties in studying these interactions with wild animals, most of the evidence comes from domestic or captive animals. For example, cattle ingesting large amounts of alkaloids from rangeland plants or cardiac glycosides from oleander can die (Galey et al., 1998; Pfister et al., 2001). A less extreme example is of lambs that choose to eat less of a diet containing terpenes than one free of terpenes (Villalba and Provenza, 2005). Another scenario is of researchers feeding natural diets, but with only a partial understanding of the PSMs that the animal faces. *Eucalyptus* foliage, which is well known as a rich source of tannins, phenolics, and terpenes (Moore et al., 2004), to list just a few PSMs, is a prime example. Increasing concentrations of formylated phloroglucinol compounds (FPCs) in eucalypt foliage restrict feeding by marsupial folivores, but at any concentration of FPCs, there is typically wide variation in food intake (Wallis et al., 2002; Marsh et al., 2003; Moore et al., 2005). This implies that compounds other than FPCs also influence feeding.

The depression of food intake by PSMs is not uniform. There are other instances where animals have shown almost no response to extremely high dietary PSM concentrations. For example, common brushtail possums (*Trichosurus vulpecula*) maintained their food intake when the dietary concentration of rutin (a glycoside of quercetin) increased from 0 to 27% of dry matter (Marsh et al., 2006). Perhaps even more bizarre is the decline in feeding when brushtail possums are given a diet containing small amounts of free amino acids (DeGabriel et al., 2002; Marsh et al., 2005). In this case, the nutrients (amino acids) appear to be behaving as toxins.

The seemingly impossible complexity of plant–animal interactions may explain why the detoxification limitation hypothesis, emanating from a review by Freeland and Janzen (1974) some 30 years ago, has become so popular with so little conclusive testing. The hypothesis seems reasonable on an intuitive level, but

Fig. 1 Schematic of the possible fates of PSMs encountered by herbivores. Availability of alternative foods and the current detoxification capacity of the herbivore are some examples of factors that may influence whether a herbivore chooses to ingest a particular PSM. Because these factors can change, it may choose differently at different times. However, once a PSM has been ingested, its fate will depend on the particular PSM–herbivore combination

further understanding of the processes involved, as well as more specific testing, will further strengthen and refine it.

The Fate of Plant Secondary Metabolites

Animals have many defenses against PSMs (Fig. 1), the first being avoidance of plants that contain them. This may be a learned response (Provenza, 1996) or an initial reaction to the aversive sensory properties of the PSM (Foley et al., 1999). The second line of defense is to retain the PSM in the gastrointestinal tract and perhaps modify it there. This strategy might be a physiological response of the animal, or it might occur through a synergistic association with microbes. The responses of animals that ingest tannins provide examples of both mechanisms. Mule deer (*Odocoileus hemionus*) respond to tannins by producing proline-rich salivary proteins that bind them (Robbins et al., 1991), whereas koalas (*Phascolarctos cinereus*) have a symbiotic relationship with tannin-degrading bacteria (Osawa et al., 1993).

However, a great many PSMs have features that enable ready absorption from the gut—they are lipid-soluble, nonpolar, and nonionic at physiological pH (McLean and Duncan, 2006). Unless detoxified and eliminated from the body, these compounds will eventually reach harmful concentrations, although there are instances where metabolites are more toxic than the original compound (Tamási et al., 2003). For excretion in the urine—the typical mode of removal for metabolites with a molecular weight less than 500—detoxification processes convert the molecule to one that is water-soluble, contains polar groups, and is ionic at physiological pH (McLean and Duncan, 2006). Larger molecules are usually excreted in the bile and may even be reactivated to the original compound in the gut (Dearing et al., 2005).

Biotransformation (usually leading to detoxification) of PSMs occurs mainly in the liver in two phases that may occur independently or simultaneously and involve many enzymes. Phase I enzymes typically catalyze reactions such as oxidation, reduction, or hydrolysis, whereas those in phase II conjugate PSMs to polar molecules, known as conjugates. In the context of the detoxification limitation hypothesis, it is important to realize that any herbivore will potentially have many metabolic pathways in both phases to cope with the chemical diversity it might encounter (Dearing et al., 2005; McLean and Duncan, 2006). For example, there are more than 17 families of cytochrome P450 enzymes involved in oxidation reactions (Lin and Lu, 2001) and a similarly diverse range of enzymes that conjugate compounds to glucuronic acid (Radomska-Pandaya et al., 1999).

The particular sequence of reactions leading to the elimination of a compound is called the detoxification pathway. As with any chemical reaction, a pathway may become saturated for various reasons, including a depletion of enzyme or cosubstrate, resulting in the accumulation of the PSM. Thus, the time required for detoxification depends on the rate of detoxification, the concentration of PSM in the plant, the amount ingested, the proportion absorbed, and the interactions between PSMs and the physiological state of the animal, to name just a few (McLean and Duncan, 2006).

What is the Detoxification Limitation Hypothesis?

The detoxification limitation hypothesis has its origins in the seminal paper by Freeland and Janzen (1974). The paper emphasizes the complexity of the interactions between animals and PSMs, but, interestingly, the authors do not propose a hypothesis that they specifically call “the detoxification limitation hypothesis.” Instead, they finish their review with a section entitled “Hypothetical feeding behavior” in which they summarize their expectations as follows:

Generalist herbivores should: (1) treat new foods with extreme caution; (2) be able to learn quickly to eat or reject particular foods; (3) have the capacity to seek out and eat plants containing highly specific classes of nutrients; (4) have to ingest a number of different staple foods over a short period of time; (5) preferentially feed on the foods with which they are familiar, and continue to feed on them for as long as possible; (6) prefer to feed on foods that contain only minor amounts of toxic plant secondary compounds; and (7) have searching strategies and a body size that neither maximize the number of types of foods

that are potentially available nor maximize the total amount of food eaten, but rather compromise between these two functions.

The hypothesis as we know it was more formally delivered in a later review. Freeland (1991) suggested that:

Feeding behavior of herbivorous mammals is thus dependent on the individual mammal's capacity to detoxify and/or tolerate the biological effects of particular individual or combinations of plant secondary metabolites. Metabolites that cannot be detoxified/tolerated are likely to be avoided, while those that can be successfully detoxified are likely to be consumed. The rate at which a particular plant metabolite is detoxified is of obvious importance in determining how much a mammal eats per unit time.

The hypothesis itself has been given different names by different researchers. Some mention its predictions without giving it a name (Provenza, 1995; Foley et al., 1999; Burritt and Provenza, 2000), whereas others call it “Freeland and Janzen's hypothesis” (Iason, 2005), the “toxin dilution hypothesis” (Behmer et al., 2002; Singer et al., 2002; Duncan et al., 2003; Miura and Ohsaki, 2004), the “toxin avoidance hypothesis” (Dearing and Schall, 1992; Cassini, 1994), or the “detoxification limitation hypothesis” (Dearing and Cork, 1999; Sorensen and Dearing, 2003; Wiggins et al., 2006). It appears that the first study to propose the name “detoxification limitation hypothesis” was Dearing and Cork (1999).

Although it is more than 30 years and more than 500 citations since Freeland and Janzen, few studies have provided conclusive experimental support either for or against the hypothesis. Many researchers acknowledge that the detoxification limitation hypothesis can potentially explain aspects of the feeding behavior of herbivores (e.g., Freeland and Winter, 1975; Freeland et al., 1985; Freeland and Saladin, 1989; Dearing and Cork, 1999; Foley et al., 1999; Hagele and Rowell-Rahier, 1999; Burritt and Provenza, 2000; Behmer et al., 2002; Singer et al., 2002; Wiggins et al., 2003; Miura and Ohsaki, 2004; Rogosic et al., 2006). None of these studies, however, had the information required to rigorously test the hypothesis. This aside, if we are to understand the influence of PSMs on animal feeding, and thus their ecology, there is need for a hypothesis, and by far the most popular is the detoxification limitation hypothesis.

What Does the Detoxification Limitation Hypothesis Predict about Animal Feeding?

There appear to be three main ways that detoxification limitations might influence an animal's feeding behavior. The first suggests that feeding rates depend on the rates at which herbivores can detoxify PSMs. If rates of ingestion exceed rates of detoxification, then PSMs will accumulate. The consequences of a link between feeding and detoxification rates are twofold. First, the herbivore will need to alter its rate of feeding with changing concentrations of a PSM in the food to keep the rate of ingestion of the PSM stable (Fig. 3). Second, because detoxification systems are dynamic, an animal must adjust its rate of feeding to suit its current detoxification state, which depends on a myriad of factors discussed by Freeland and Janzen (1974)

and elsewhere (e.g., Foley et al., 1999; Dearing et al., 2005). For example, exposure to a PSM often induces the production of specific enzymes involved in detoxification (Pass et al., 1999; Boyle and McLean, 2004). An animal should alter its feeding behavior whenever the rate of detoxification changes (Fig. 2).

The second prediction of the detoxification limitation hypothesis is that specialist herbivores should be better at detoxifying the PSMs they encounter than should generalists. Specialist herbivores rely on few plants for most of their food, whereas generalist herbivores tend to eat many different plants, even when one is abundant. Generalist herbivores are much more common than specialists, probably because they do not have to rely on a limited food source for all of their lives (Freeland and Janzen, 1974). Where specialist and generalist herbivores occur sympatrically, however, such as koalas and possums in the eucalypt forests of southeastern Australia, the dietary niches of each may indicate their differing abilities to detoxify the PSMs in their food.

Finally, the detoxification limitation hypothesis suggests that because generalist herbivores are less efficient than specialists at detoxifying the PSMs that are found in a group of related plants, they must obtain their nutrients from a wider variety of plants (Sorensen and Dearing, 2003). This variety of foods, which we will refer to as “diet mixing,” is thought to increase the amount that a generalist herbivore can eat. For diet mixing to succeed, the detoxification limitation hypothesis assumes that the PSMs ingested from different plants are metabolized by separate pathways. However, even the detoxification of an individual PSM is complex, with many using several pathways for detoxification. This is illustrated in Table 1, showing the detoxification pathways that brushtail possums use for six PSMs. It shows that some PSMs share pathways, and so, when ingested simultaneously, may interact. For example, two PSMs partially overlap when they are both absorbed into the bloodstream, transformed by different processes during phase I, but then conjugated with the same molecule, such as glucuronic acid, in phase II. In contrast, an animal may ingest a food rich in benzoic acid, which is rapidly absorbed and detoxified by conjugation with glycine. It might simultaneously ingest a food rich in tannins, which combine with salivary proteins and remain in the gut pending excretion (Robbins et al., 1991). Discounting any interaction in the gut, there appears little competition between the two PSMs for detoxification. The response in feeding should

Fig. 2 The hypothetical rate of feeding and of PSM ingestion by a herbivore, for which food intake is limited by the rate of PSM detoxification. If the detoxification rate increases, we would expect that the rate of PSM ingestion would also be able to increase, allowing food intake (or the rate of feeding) to be maintained at the maximum to a higher PSM concentration. The dashed lines show changing feeding rates as PSM concentrations increase, and the solid lines show how this is linked to rates of PSM intake

Table 1 The percentage of PSMs ingested by brushtail possums that were metabolized by a given pathway in 24 hr

	1,8-Cineole	<i>p</i> -Cymene	Benzoic acid	Salicin	Orcinol	Rutin
Hydrolysis (I)				80		71
Oxidation (I)	33	51		22		71
Glycine conj. (II)		trace	90	10		
GA conj. ^a (II)	16	28	5	63	66	69

Most of the tested PSMs were metabolized by multiple mechanisms, and in some cases, both phase I and II reactions occurred (reaction type indicated in parentheses). Some columns add to more than 100% because the same molecule underwent multiple modifications. Adapted from Marsh et al., (2006).

^a GA = glucuronic acid.

presumably correlate with the degree of competition for detoxification between the PSMs.

Can Detoxification Limitations Influence Feeding Rates?

There is little evidence either supporting or refuting any of the predictions of the detoxification limitation hypothesis. This does not discount the importance of PSMs and detoxification limitations in the interactions between herbivores and plants, but

Fig. 3 (a) The detoxification limitation hypothesis suggests that the feeding behavior of a herbivore should aim to keep the amount of unmetabolized PSM in the blood below a threshold amount (dashed line). (b) If a herbivore ingests a PSM faster than it can detoxify it, then the concentration in the blood will exceed the threshold and poisoning could occur. The amount of unmetabolized PSM present at any time is a result of a combination of the rate of ingestion, the degree and rate of absorption, and the rate of detoxification. The black bars indicate times at which the herbivore is feeding, and the solid line tracks the hypothetical amount of unmetabolized PSM in its blood as it ingests a PSM with its food, and subsequently detoxifies it

rather demonstrates that it is difficult to elucidate their contribution to feeding. For example, slow rates of detoxification may explain why many mammalian herbivores ingest threshold amounts of PSMs (e.g., Pfister et al., 1997; Wang and Provenza, 1997; Lawler et al., 2000; Mangione et al., 2000; Stapley et al., 2000). In order to show that the feeding decisions of herbivores depend on the rate of detoxification, however, it is necessary to know how the herbivore of interest, in a certain physiological state, detoxifies a particular compound.

The “drink-driving” laws in many countries illustrate clearly the idea that the rate of ingestion of a substance determines toxicity (Fig. 3). It is possible to imbibe alcoholic drinks and drive a motor vehicle as long as the rate of metabolism of the alcohol equals the rate of ingestion. Ingesting alcohol at a faster rate, so that the blood alcohol concentration exceeds 50–80 mg per 100 ml, makes one unfit to drive, whereas raising the blood alcohol content to 300–400 mg per 100 ml may be lethal. This system appears simple because it involves a single toxin for which the pathway of detoxification is well known. However, recommended alcohol intakes differ for males and females, and tolerance to alcohol can differ widely among individuals in a population and among populations (Norberg et al., 2003). Other enzymes for drug metabolism show similar interindividual variability (Mulder, 1995; Lin and Lu, 2001), and different mammalian species may metabolize a particular drug at different rates and sometimes in differing ways (Walton et al., 2001), illustrating the complexity of detoxification. It is apparent that a defined experimental system is necessary to test the detoxification limitation hypothesis. Only then can we answer simple questions about interactions between herbivores and toxins, before tackling ones that are more complex. These might include questions about how toxins interact with each other and with other systems, such as the gut microbes.

Study Systems for Testing the Detoxification Limitation Hypothesis

A system for testing an animal’s feeding response to any toxin has several requirements. First, it requires a species that is easy to keep in captivity, usually in a metabolism cage, and is easy to maintain on an artificial diet. The diet should provide all of the animal’s nutrient requirements, be free of plant toxins, and be easily manipulated to provide, for example, different concentrations of nutrients or plant cell walls. Finally, the toxin should be a substance that the species typically encounters in the wild. It is necessary to know its mode of detoxification in the animals in question, and it must be possible to obtain enough toxin for well-replicated feeding experiments. The factor that usually prevents researchers from proving the detoxification limitation hypothesis is not knowing detoxification pathways.

Proof of the Detoxification Limitation Hypothesis

There appears to be only one study of mammalian herbivores that satisfies the requirements for a study system and shows that the rate of detoxification influences the rate of feeding. In this study, Marsh et al., (2005) fed common brushtail possums a basal diet consisting mainly of fruit and cereals, and they manipulated the concentrations of both benzoate and glycine. Benzoate is eaten by wild brushtail possums, and it is also known that a variety of animals, including brushtail possums, detoxify it by conjugation with glycine (Bridges et al., 1970; Awaluddin and

McLean, 1985). Furthermore, the rate of conjugation of benzoate depends on the supply of glycine (Griffith and Lewis, 1923; Amsel and Levy, 1969; Gregus et al., 1993). The key finding of Marsh et al., (2005) was that possums eating a diet containing both benzoate and glycine detoxified the benzoate faster and ate more than when eating a similar diet without the glycine. In other words, the rate of detoxification determined the rate of feeding. Thus, plant toxins do not have a fixed effect on feeding, but rather, their effect will depend on the animal's current detoxification state.

There is also at least one study in invertebrates showing that feeding depends on the rate of detoxification. In this study with tobacco hornworms (Snyder and Glendinning, 1996), piperonyl butoxide slowed the detoxification process by inhibiting cytochrome P450 enzymes, which are important in phase I reactions. The hornworms responded by eating less of a diet containing the plant toxin nicotine.

Both of the previous examples illustrate extremely simple cases that show a link between rates of detoxification and feeding rates. There is a need for more manipulative studies to examine a wide range of apparently simple interactions, but also to delve into complexities, such as interactions among plant toxins, and to separate effects that are not attributable to the rates of detoxification. By this, we mean that rates of feeding may depend on the concentrations of PSMs in plants but be independent of the rates of detoxification. One example is of plants that contain bitter or spicy compounds, for which the main consequence of ingestion is the stimulation of capsaicin receptors that cause a burning sensation (Jakubas and Mason, 1991; Pass and Foley, 2000). Another is of plants containing compounds that stimulate nausea or satiety receptors causing feeding to stop. For example, McLean et al., (2004) propose that some of the compounds found in eucalypt foliage are not absorbed from the gut, but cause the enterochromaffin cells to release serotonin, which leads to nausea and the cessation of feeding.

Another important condition that we know little about is the interaction between physiological state and detoxification limitations. In particular, animals with higher nutrient requirements, such as those living in the cold or reproducing, must eat more, but avoid physiological damage. This may be complicated. For example, a nocturnal animal lactating during the summer may have to eat much more in a short night, with less opportunity to spread feeding to aid detoxification. Stapley et al., (2000) examined the tolerance to a plant toxin in the face of higher nutrient requirements by comparing feeding in brushtail possums housed at 4°C or at 18°C. As expected, those in the cold ate more of a basal diet than did those living in the warm environment. However, both groups of possums ate the same amount of a diet containing jensenone, a toxin from eucalypt foliage. This indicates that possums habituated to the cold did not acquire any mechanisms for detoxifying this particular PSM faster, suggesting that similar animals in the wild would need to seek different options.

How Do Animals Overcome the Limitations Imposed by Plant Toxins?

If plant toxins can reduce feeding and even kill certain animals, then it is clear that herbivores must have mechanisms to circumvent them. The strategies of specialist and generalist herbivores may differ, but still be equally effective ways of obtaining the required nutrients without succumbing to intoxication. The detoxification

limitation hypothesis suggests that the ability to detoxify large quantities of PSMs from a single source defines a specialist herbivore. No studies, however, have shown that a specialist herbivore is able to detoxify the PSMs in its food faster than a generalist herbivore that also eats that food. Although specialist wood rats (*Neotoma* spp.) ingest more juniper PSMs than do generalists (Dearing et al., 2000), they cope with them by absorbing less from the gut, rather than detoxifying them faster (Sorensen and Dearing, 2003). But the overall result is the same—the specialist herbivore can ingest more PSMs without toxic effects. The folivores of *Eucalyptus* provide another example. The specialist koala oxidizes the terpenes, 1,8-cineole and *p*-cymene, more than does the generalist possum (Boyle et al., 1999, 2001), but it is unknown whether this speeds the rate of detoxification. Instead, what it may do is keep other pathways free for the detoxification of PSMs ingested simultaneously (Boyle et al., 2001) and thus minimize competition.

Because limitations of detoxification may force generalist herbivores to obtain their nutrient requirements from a variety of plants and plant parts, these animals should be skilled at selecting diets that spread the PSM load over their repertoire of detoxification pathways. As a consequence, presenting a herbivore with several foods containing PSMs that use different detoxification pathways should allow them to eat more. Although Freeland and Janzen (1974) specifically targeted mammalian herbivores in their predictions, the detoxification limitation hypothesis has attracted as much attention from those explaining why generalist invertebrate herbivores mix their diets (e.g., Hagele and Rowell-Rahier, 1999; Behmer et al., 2002; Singer et al., 2002; Miura and Ohsaki, 2004).

This appealing field of research has been the most common way in which researchers have attempted to test the detoxification limitation hypothesis (Freeland and Winter, 1975; Freeland et al., 1985; Freeland and Saladin, 1989; Dearing and Cork, 1999; Hagele and Rowell-Rahier, 1999; Burritt and Provenza, 2000; Behmer et al., 2002; Singer et al., 2002; Wiggins et al., 2003; Miura and Ohsaki, 2004; Marsh et al., 2006; Rogosic et al., 2006). However, it has not proved particularly fertile, probably because many experiments do not satisfy the stringent requirements needed for the study system. Although most of these studies show that generalist herbivores can eat more when offered a choice between two distinct diets, it is difficult to interpret them because they generally feed PSMs whose detoxification remains undescribed. Simply providing animals with foods with a variety of flavors or textures stimulates them to eat more than they would if given just one of these foods (Rolls et al., 1981; Treit et al., 1983; Clifton et al., 1987; DiBattista and Sitzer, 1994; Ginane et al., 2002). This indicates that different sensations alone can influence feeding behavior and reiterates the importance of devising robust systems when testing diet mixing aspects of the detoxification limitation hypothesis.

The importance of understanding modes of detoxification is borne out in the results of Burritt and Provenza (2000). Lambs did not eat more when offered two diets containing sparteine (a quinolizidine alkaloid) and saponins (triterpenoid glycosides extracted from *Quillaja* bark) or quebracho condensed tannins and saponins than when offered a single diet with one of the additives. The obvious interpretation is that all compete directly for detoxification, leaving no scope for a change in feeding behavior. This interpretation, however, requires knowing the detoxification pathways involved.

We set forth to test diet mixing in relation to limitations on detoxification (Marsh et al., 2006), taking advantage of pharmacological studies of PSM metabolism in

common brushtail possums (Table 1). By knowing the detoxification pathways, we could roughly predict the degree of competition for detoxification that might occur when characterized compounds were ingested simultaneously. Thus, we could predict how possums should respond when offered a choice between two PSMs, compared to the amount they ate of a diet containing only one of the compounds. For example, we expected possums to eat more if allowed to choose between diets containing PSMs metabolized by distinct pathways than if offered two diets with the same PSM or containing different PSMs that compete directly for detoxification (Marsh et al., 2006). The results were appealing in that the feeding responses of possums usually matched our predictions. For instance, possums did not eat any more than when given the choice between diets containing either 1,8-cineole or *p*-cymene (Marsh et al., 2006), which are both detoxified by oxidation followed by conjugation with glucuronic acid (Table 1). In contrast, giving possums a choice between the basal diet supplemented with 1,8-cineole or with benzoate (no competition for detoxification; Table 1) enabled them to eat significantly more (Marsh et al., 2006), indicating the benefits of diet mixing.

Problems with Understanding the Role of Detoxification in Diet Mixing

Although many of the predictions in the diet mixing experiment with possums were correct, others did not match the experimental findings. For example, possums offered a choice between salicin and orcinol, two compounds that are excreted as conjugates with glucuronic acid (Table 1), ate more food than possums offered either of the compounds singly (Marsh et al., 2006). Thus, there did not appear to be competition for detoxification. Do these findings refute the detoxification limitation hypothesis, or do they indicate a poor understanding of the system? We feel that the latter explanation is probably true.

There are many difficulties in understanding the links between diet mixing and detoxification limitations. First, it is necessary to understand the meaning of “competition,” which implies competition for a limiting resource. This means that there can be no competition when unlimited supplies of a resource, such as an enzyme or cosubstrate, exist. Brushtail possums detoxify *p*-cymene mainly by oxidizing it, but conjugate some with glucuronic acid and a trace with glycine (Boyle et al., 1999). This implies that *p*-cymene would compete strongly for detoxification with compounds that also undergo oxidation, but would have little influence on the rates of detoxification of compounds that are conjugated with glycine. However, if there is a shortage of glycine, then this conjugation step may become limiting. Thus, it may be difficult to measure whether two PSMs compete for detoxification because a series of processes eliminate most PSMs, and the limiting step needs to be identified for each.

Further complicating the picture is that there may be limited competition for detoxification between two compounds that appear to be metabolized by the same process. This is because a finer-scale definition of detoxification pathways would focus on the individual enzymes and enzyme families that carry out a broad class of reactions. For example, more than 17 families of cytochrome P450 enzymes have been characterized (Lin and Lu, 2001). Thus, oxidation reactions may involve quite separate cytochrome P450 enzymes and thereby reduce competition. If one knows the chemical pathways that detoxify a PSM, then *in vitro* experiments, such

as those of Pass and McLean (2002), can probably convey much information about competition.

Another problem is that some compounds can inhibit the detoxification of others, without ever competing for enzymes or cosubstrates. For example, furocoumarins inhibit cytochrome P450 enzymes (Baumgart et al., 2005) and can thus inhibit the detoxification of compounds requiring oxidation by these specific enzymes.

On an even broader scale, all pathways are fuelled by energy, and depletion of cellular energy could act as a limit to detoxification. Gregus et al., (1996) showed that a depletion of liver ATP reserves can slow the rate of detoxification of benzoate. Thus, even compounds that do not compete for any common enzymes or cosubstrates might still influence the rates of detoxification of other PSMs. Detoxification pathways may never truly be independent of others, but instead may be separated by differing degrees. This might explain why possums fed with PSMs that did not compete for detoxification still ate less than they did of a basal diet free of PSMs (Marsh et al., 2006).

How Are Detoxification Limitations Detected?

Measuring changes in food intake is a simple way of showing that a toxin influences feeding. However, this finding tells us nothing about the workings of the PSM—why it reduces feeding and how the animal knows it is there. One crucial area that previous discussions of the detoxification limitation hypothesis do not address is how animals detect excessive intake of one toxin, and then make the decision to eat food containing a different toxin. If an animal ingests a PSM at a rate that exceeds its detoxification capacity, it must trigger a feedback signal that stops the animal eating that food. Presumably, other signals exist that tell an animal whether it has met its caloric or protein needs. These signals interact so that the animal obtains its nutritional needs without experiencing toxicosis.

The details of these signals are not well known. Although several have been proposed, experimental evidence is mostly lacking. One likely signal is nauseous feedback, stimulated by PSM-linked increases in neurotransmitter activity in the gut or brain. Provenza et al. have drawn attention to this possibility through an extensive series of papers suggesting that aversive learning is a basis to herbivores choosing their diets (e.g., Provenza et al., 1992, 1998; Provenza, 1995, 1996). In support of this concept, Aldrich et al., (1993) found that a nonselective dopamine antagonist, metoclopramide (which in humans attenuates nausea and vomiting), allowed sheep to eat more endophyte-infected tall fescue. Further support comes from the study of Lawler et al. (1998) with marsupials fed with the *Eucalyptus* PSM jensenone. Injecting the human antinausea/antivomiting drug, ondansetron, a selective 5-HT₃ receptor antagonist, enabled these animals to ingest more jensenone, suggesting that the signal monitoring the consumption of jensenone involved the release of serotonin (5-HT). Both Lawler et al., (1998) and McLean et al., (2004) speculated that damage to cells in the stomach or small intestine led to the release of serotonin from enterochromaffin cells, which bound to 5-HT₃ receptors locally, initiating a cascade of events that triggered nausea.

Because nausea is effective at conditioning aversions to foods or flavors (Provenza, 1995), it might signal impending toxicoses in other situations. If so, it might be a more widespread signal that lets animals recognize their limits and make

appropriate feeding decisions. Marsh et al., (2005), however, showed that ondansetron failed to attenuate the reduction in feeding by brushtail possums fed with benzoate-rich diets. This suggests that other mechanisms, apart from nausea, signal detoxification limitations in that system. One possible mechanism is a change in blood pH because of the formation of organic acids from conjugation reactions (Foley et al., 1995).

However, before placing too little, or too much, emphasis on the emetic system, it is important to note that the emetic system is complex, and little is known about the neurochemistry of nausea. Nausea and vomiting can be triggered by input to the emetic center from the chemoreceptor trigger zone (CTZ), neurotransmitters in the gastrointestinal tract, the cerebrocortical pathway (responsible for learned associations), or the vestibular pathway (body positional changes such as in motion sickness; Rhodes and McDaniel, 2001). Furthermore, serotonin acting at the 5-HT₃ receptor is only one of many neurotransmitter–receptor combinations that can lead to nausea and/or vomiting. Other combinations that elicit emetic responses to stimuli include substance P and tachykinin NK₁ receptors (Gardner et al., 1996), acetylcholine and muscarinic receptors (Takeda et al., 1993), dopamine and D₂ receptors (Harrington et al., 1983), as well as histamine and H₁ receptors (Takeda et al., 1993). The gastrointestinal tract, the CTZ, and the emetic center are all rich in these receptors (Rhodes and McDaniel, 2001). New selective drugs that target specific receptors are appearing as knowledge increases. We suggest that more studies, targeting a variety of potential receptors, will help us to understand how widespread nausea might be in regulating the ingestion of PSMs by animals.

The Cost of Detoxification

Presumably, if there were no costs of detoxification, then there would be few limitations to the processes. Instead, arguments about limitations of detoxification imply that it is costly to animals. There is good evidence that this is true. Cork (1981) calculated that koalas use about 25% of their fasting glucose entry rate to excrete glucuronide conjugates. In research with sheep, Lowry et al., (1993) showed that the conjugation of phenolic acids with glycine, to form hippuric acid, resulted in them losing almost 20% of their digestible nitrogen intake in urine. These detoxification costs are a cost of foraging, little different from increases in search times. Thus, from an optimal foraging perspective, one might predict that animals should eat a food only when the nutritional benefits outweigh the costs of detoxification.

If there is a cost of detoxification that influences an animal's fitness, then there needs to be a currency to measure it. The complexities of detoxification mean that researchers have largely avoided calculating the energy exchanges in individual chemical reactions, in favor of integrative measures, such as whole-body energy expenditure. For example, Iason and Murray (1996) gave sheep intraruminal infusions of orcinol and found that their basal metabolic rate (BMR) increased by 5%. This was rather small compared with voles (*Microtus pennsylvanicus*) consuming diets containing gallic acid, whose BMR increased by up to 22% (Thomas et al., 1988). More recently, Sorensen et al., (2005) used wheel-running behavior and measures of energetics to quantify detoxification costs in two species of wood rats (*Neotoma* sp.). Both the BMR and locomotor activity of the specialist

species of wood rat dropped as they ate more juniper, whereas the generalist reduced only locomotor activity.

These studies illustrate that detoxification consumes energy that the animal could use for another function. They also illustrate the strengths and the weaknesses of using energy as the currency for measuring the cost of detoxification. The obvious advantage of using energy is that it allows the integration of the costs of many different processes. The main disadvantage is that free-living animals can make subtle metabolic changes that are difficult to measure and may obscure the costs of detoxification. The drop in BMR and activity by wood rats is one example. Another is the research of White and Lawler (2002), who used the change in the heat increment of feeding on browse, relative to that of feeding on hay, to estimate the energy cost of detoxification for muskoxen (*Ovibos moschatus*). For some species of browse, they found that reductions in ruminal methane production (and its subsequent loss by eructation) partially compensated for the energy cost of detoxifying secondary compounds. The opportunity for tradeoffs and compensations in energy metabolism across different species of browse makes it a poor currency for measuring the cost of detoxification.

We suggest that measuring whole-body protein turnover might be a better way of estimating the costs of detoxification. Whole-body protein turnover measures the cost of the synthesis and turnover of proteins and is strongly related to metabolic rate because protein synthesis is energetically expensive (Waterlow, 2006). Whole-body protein turnover is more integrative of the range of processes that occur during detoxification than simple measurements of nitrogen or energy balance because it includes intermediary metabolism, amino acid activation, and associated processes such as RNA turnover (Waterlow, 2006). For example, protein is required for synthesis of cytochrome P450 and other detoxification enzymes. That many of the enzymes involved in detoxifying PSMs are inducible suggests that they are costly to maintain.

Changes in protein turnover should translate directly into changes in protein requirements and, so, are easier to incorporate into models of diet selection than are measurements of energy loss. They can also integrate many different detoxification processes. Animals can excrete some phenolic glycosides with a minimal apparent energy cost (McLean et al., 2001), but there may be costs that are not immediately obvious and need to be paid for later. For example, these compounds may increase protein requirements through damage to the kidney's filtration processes (Garner et al., unpublished data), through uncoupling of oxidative phosphorylation (Singleton and Kratzner, 1969), and through acid–base adjustments arising from the excretion of organic acids of detoxified metabolites (Foley et al., 1995).

Changes in whole-body protein turnover during various types of immune challenges suggest major costs of maintaining the immune system (Klasing and Calvert, 2000). These appear to have an evolutionary basis because there are direct links between the increased protein requirements of these challenges and compelling models of diet selection (Lee et al., 2006). PSMs have complex effects on the immune systems of mammals (Allen et al., 2003). This indicates that we need to view detoxification costs more broadly, and that separating detoxification costs from other potential costs, such as immune responses, is probably artificial. Accordingly, we recommend that effort be given to measuring whole-body protein turnover of animals fed with diets containing either purified PSMs or, more usefully, complex mixtures typical of those found in most browse plants.

Applying the Detoxification Limitation Hypothesis to Wild Herbivores

This review of the detoxification limitation hypothesis has so far considered the case of the captive animal given a limited choice of foods. In contrast, wild animals face situations that are not nearly so simple. The feeding behavior of wild herbivores depends on many factors in addition to forage quality. These include social interactions, nutritional status, and the need for a home range with other qualities, such as a den or shelter. Clearly, determining whether wild herbivores feed according to the predictions of the detoxification limitation hypothesis is difficult. Even so, in this section, we outline some of the factors that researchers might consider when studying how free-living herbivores might mix several plant toxins in their diet. Foremost among them is the spatial distribution of plant defenses, which are presumably important because they influence costs, such as search times.

There is growing evidence that the spatial distribution of defense variation affects feeding choices (Hjalten et al., 1993; Alm Bergvall and Leimar, 2005). Nevertheless, few studies provide evidence that the spatial patterns required for such behaviors exist in nature (Covelo and Gallardo, 2004; Brenes-Arguedas and Coley, 2005). In the case of diet mixing, it is essential for variation to occur at a relevant scale for herbivores—presumably within a home range. A patchy distribution could increase the cost of diet mixing because animals would be unlikely to encounter chemically different food plants in the same patch or stand. Herbivores might prefer areas where diverse food is available, such as between patches, or where different food species overlap.

Another interesting difference in the environments of captive and wild herbivores is that those of the latter may provide mechanisms that enable the animal to cope with toxins. For thousands of years, humans have used a variety of methods to render plant toxins harmless. Herbivorous animals sometimes do the same. Perhaps the most obvious is removing toxic plant parts before ingestion. Other techniques include eating substances that are not normally considered food to negate the effects of plant toxins. One of the best examples is of parrots practicing geophagy—the ingestion of soil. By carefully selecting soils rich in particular clays, with a high capacity for binding plant toxins, the birds avoid absorbing the toxins from the gut (Gilardi et al., 1999). The abundance and distribution of such resources clearly impinge on the nutritional ecology of the herbivores that can use them.

Although the amount eaten of a plant should ultimately depend on an animal's ability to detoxify PSMs, its initial selection may be driven by other factors. The amount of feeding an individual plant attracts probably depends on the characteristics of the surrounding matrix of plants (Atsatt and O'Dowd, 1976; Milchunas and Noy-Meir, 2002; Alm Bergvall et al., 2006). Thus, the nutritional and toxic characteristics of a plant may influence how herbivores use neighboring plants (Villalba and Provenza, 2005). From a plant's perspective, the benefits and costs of defense need to consider both the individual and the community it inhabits (Tuomi and Augner, 1993). Likewise, the foraging strategy of the animal should account for this. One example is that sheep were more likely to graze a relatively unpalatable shrub when the surrounding plants were palatable (Rousset and Lepart, 2003).

To understand the role of detoxification in nature, there is a need for detailed studies of the feeding behavior and population dynamics of wild animals, in relation to the distribution of PSMs in their food plants. One approach might be to use data from feeding studies with captive animals to predict the palatability of wild plants

and then to follow this up by comparing the expected patterns of use with the observed patterns. Recently developed methods for studying spatial autocorrelation (Double et al., 2005) can detect the scale and intensity of patchiness in PSM distributions (Andrew et al., unpublished data), which can then be related to herbivore behavior.

In summary, the initial testing of the detoxification limitation hypothesis on wild herbivores requires a simple system consisting of a specialist herbivore eating a diet whose PSMs are well characterized. An example of this approach is that used by Marsh et al. (unpublished data), who fitted koalas with radiocollars equipped with microphones, enabling the constant monitoring of both the animals' location and the amount that they ate. By sampling foliage from all of the trees in the area, they could then examine a koala's feeding pattern in relation to the chemistry of its environment. They found that the chemistry of foliage influenced the choice of trees by koalas, as well as the amount of food eaten.

Conclusions

Some 30 years after Freeland and Janzen's seminal paper on the interactions between herbivores and plant toxins, the hypothesis it gave rise to, detoxification limitations, is entrenched in the literature but remains inadequately tested. There are thousands of plant toxins and a wide variety of metabolic systems to render them less potent, making the study of the interactions complex. Some PSMs require similar modes of detoxification and are said to compete, whereas the animal metabolizes others by pathways that appear to be independent. In between these modes, however, are detoxification pathways that compete to differing degrees and are much harder to understand. In fact, because all are fueled by energy, it may be that no pathway is truly independent of another. It is impossible to study all of the systems of detoxification, and there is little to gain from trying. However, further investigations of the detoxification limitations of herbivores feeding on PSM-rich diets, and how they detect these, are likely to advance our understanding of the interactions between animals and plants.

Abstract In grazing systems, forage availability is a function of herbivore density, which can influence an animal's ability to be selective. In turn, the influence of food availability on selectivity has the potential to influence plant biodiversity. We hypothesized that the ability of herbivores to mix toxin-containing foods in their diets is a function of the availability of nontoxic foods and the nutritional characteristics of the toxin-containing foods. We evaluated this hypothesis in two trials simulating different diet qualities (high-quality foods in trial 1, low-quality foods in trial 2). Within each trial, the four treatment groups were offered with different amounts of nutritious, familiar foods—10, 30, 50, and 70% of *ad libitum* intake—but were offered with *ad libitum* access to toxin-containing foods. Each lamb was presented with five foods, including three toxin-containing unfamiliar foods (terpenes, tannins, and oxalates) and two nutritious familiar foods (alfalfa and barley). In trial 1, as the availability of nutritious familiar foods decreased, animals ate more of all three toxin-containing foods. As the availability of nutritious alternatives increased, the pattern of selection shifted from terpenes to tannins and oxalates. In trial 2, animals also ate more toxins as the availability of nutritious alternatives decreased, but their pattern of diet mixing changed. Low availability of nutritious alternatives resulted in the animals eating more oxalates. During preference tests when all five foods were offered *ad libitum*, animals fed with 10, 30, 50, and 70% of *ad libitum* intake from trial 1 ate 49, 47, 41, and 38% of the three toxin-containing foods, respectively. The lower diet quality in trial 2 affected intake of the toxin-containing foods such that animals fed with 10, 30, 50, and 70% of *ad libitum* intake ate 37, 36, 29, and 27%, respectively, of the three toxin-containing foods. Thus, the quality of toxin-containing foods and the availability of nutritious alternatives interacted to modify the pattern of diet mixing by lambs.

Introduction

Herbivores modify environments by selectively consuming foods (Palo and Robbins, 1991), and the process of diet selection is shaped by intricate interactions between nutrients, toxins, and animal experience (Hanley, 1997; Provenza et al., 2003a; Villalba et al., 2004). Nutrients and toxins both influence the kinds and amounts of foods eaten as animals strive to meet nutritional needs (Westoby, 1978), and regulate their intake of toxins (Freeland and Janzen, 1974; Villalba et al., 2002a). Experiences early in life, of both the social and physical environments, shape behavior, influence gene expression (McCormick et al., 2000; Duffy et al., 2002), and improve performance by inducing neurological, morphological, and physiological changes in animals (Piersma and Lindstrom, 1997; Schlichting and Pigliucci, 1998). Such plasticity enables adaptation to different environmental conditions and implies that different conditions influence how an animal perceives diet and habitat quality (Davis and Stamps, 2004). These dynamics influence the structure and diversity of plant communities (Provenza et al., 2003a,b).

Herbivores learn to forage (goats, Distel and Provenza, 1991; lambs, Green et al., 1984; and cattle, Wiedmeier et al., 2002), but how they learn to mix their diets given a variety of alternatives is poorly understood (Provenza et al., 2003b). The availability of alternative plants likely increases the difficulty of distinguishing beneficial or deleterious relationships involving toxin–toxin, nutrient–toxin, and nutrient–nutrient interactions. Such interactions influence the amount of nutrients and toxins an animal can ingest (Freeland and Janzen, 1974; Illius and Jessop, 1995; Banner et al., 2000), as well as preferences for foods that differ in nutrients and toxins (Villalba et al., 2002a,b). In addition, interactions among toxins can either increase or decrease consumption of combinations of foods that contain toxins (Schmidt et al., 1998; Dearing and Cook, 1999; Burritt and Provenza, 2000; Provenza et al., 2003a; Villalba et al., 2004).

We hypothesized that the ability of herbivores to mix toxin-containing foods in their diets is a function of the availability of nontoxic foods and the nutritional characteristics of toxin-containing foods. Based on these hypotheses, we predicted that young animals exposed to high availability of nutritious alternatives would consume less novel toxin-containing foods, thus impeding their acquisition of diet-mixing behavior. In contrast, we predicted that young animals exposed to low availability of nutritious alternatives would learn to consume more of the novel toxin-containing foods.

Methods and Materials

The objective of these studies was to determine the degree to which sheep mix an array of unfamiliar toxin-containing foods with familiar high-quality foods when the familiar foods were available in different amounts: 10, 30, 50, and 70% of the animal's intake capacity. The toxins were present in a high-quality (trial 1) or a low-quality (trial 2) base food. Trial 1 was conducted from June 24, 2002 to July 31, 2002, and trial 2 from August 6, 2002 to September 12, 2002. The studies were conducted at the Green Canyon Ecology Center, located at Utah State University in Logan, UT, USA, and were approved by the Animal Care and Use Committee at Utah State University.

We used a different set of 32 lambs in each trial. Lambs were commercial crossbreds of both sexes, 4–5 mo old. In trial 1, they averaged 40 kg (SE = 0.73) body mass, and in trial 2, they averaged 37 kg (SE = 1.03) body mass. They were inexperienced with the toxins at the start of each trial, as well as with the ingredients of the base food that contained the toxins. Lambs were individually penned with free access to trace mineral salt blocks and freshwater. They were individually penned 10 d prior to initial exposure, during which they received alfalfa pellets *ad libitum* and barley (300 g/lamb/d).

High-Quality Foods

We used five foods in this study: three unfamiliar and two familiar to the lambs. The three unfamiliar, high-quality test foods were formulated with the same ingredients, but 0 isoenergetic (2.9 ± 0 Mcal/kg, NRC 1985) and isonitrogenous (126 g CP/kg; NRC, 1985). The ingredients and compositions of the diets were as follows: (1) tannin diet (76% beet pulp, 9% soybean meal, and 15% quebracho tannin); (2) terpene diet (52.8% beet pulp, 26% grape pomace, 14% soybean meal, 1.82% camphor, 1.1% 1-8-cineole, 0.12% methacrolein, 0.06% *p*-cymene, and 4.1% vegetable oil); and (3) oxalate diet (67.5% beet pulp, 20% grape pomace, 11% soybean meal, and 1.5% oxalic acid). The remaining two familiar, high-quality foods were (4) a 50:50 mix of ground alfalfa and ground barley (3.2 Mcal/kg and 14% crude protein) and (5) ground alfalfa (2.5 Mcal/kg and 15% crude protein).

Low-Quality Foods

Three low-quality foods also were formulated to be isoenergetic (2.3 ± 0 Mcal/kg; NRC, 1985) and isonitrogenous (63 g CP/kg; NRC, 1985), with the same ingredients and different concentrations and types of toxins. The ingredients and compositions of the diets were as follows: (1) tannin diet (58.5% beet pulp, 25% grape pomace, 1.5% soybean meal, and 15% quebracho tannin); (2) terpene diet (35.8% beet pulp, 51% grape pomace, 6% soybean meal, 1.82% camphor, 1.1% 1-8-cineole, 0.12% methacrolein, 0.06% *p*-cymene, and 4.1% vegetable oil); (3) oxalate diet (50.5% beet pulp, 45% grape pomace, 3% soybean meal, and 1.5% oxalic acid). The other two foods were the same familiar foods (alfalfa/barley; alfalfa) offered in the previous trial.

Food ingredients in both test diets were ground to 2- to 3-mm particle size to facilitate mixing. Toxins were in crystalline (oxalic acid, camphor), powder (tannin), or liquid (1,8-cineole, methacrolein, *p*-cymene) form. Volatilization of the terpenoids was minimized by daily mixing in vegetable oil prior to mixing them with the remaining ingredients. The concentrations of toxins in the test diets were selected according to the amount of toxins sheep can ingest in 1–4 hr (Villalba et al., 2004).

Trial 1: Toxins in a High-Quality Food

This trial consisted of 7 d of preconditioning and 21 d of conditioning. During the 7 d of preconditioning, lambs were offered with the two familiar foods *ad libitum* from 0800 to 1200 hr, after which refusals were collected and weighed. Animals then were stratified into four groups of eight animals according to their individual total intake of the two familiar foods. Animals from these groups were then randomly

allocated to one of the four treatments. For the next 21 d, animals in treatments 1, 2, 3, and 4 received, respectively, 10, 30, 50, and 70% of the average total intake during preconditioning. The proportions of these two familiar foods were based on the average intakes of each animal during the pretrial. For example, a lamb in treatment 1 that ate on average 1000 g of ground alfalfa/barley and 500 g of ground alfalfa received 100 g of the alfalfa/barley mix and 50 g of the ground alfalfa during the trial. Lambs were offered with the three unfamiliar (toxin-containing) foods *ad libitum*.

During the 21 d of conditioning, all five foods were offered from 0800 to 1200 hr. No other foods were offered for the remainder of the day. At 1200 hr, refusals were gathered and weighed, and intake of each of the five foods was recorded for each animal. Lambs were weighed individually at the beginning and end of the 21-d conditioning period.

Trial 2: Toxins in a Low-Quality Food

Trial 2 occurred immediately after trial 1 with a new set of 32 lambs. Conditioning for trial 2 followed the same protocol as for trial 1, the only difference being the reduced quality of the test diets that contained the toxins.

Preference Tests for Trials 1 and 2

For 2 d immediately after conditioning in each trial, animals had *ad libitum* access to all five foods from 0800 to 1200 hr. Refusals were collected and weighed, and individual intake was recorded. Following that preference test, animals were fed with alfalfa pellets (*ad libitum*) and barley (300 g/lamb/d) for 7 d. This period allowed all animals to be on a comparable plane of nutrition. Following this period, another 2-d preference test was conducted.

Statistical Analyses

The statistical design for the analysis of variance (ANOVA) during the conditioning period and the preference tests was a split-plot with day as a repeated measure. At the whole-plot level, there were four treatments (10, 30, 50, and 70% restriction) with eight lambs nested within each of the four treatments. At the subplot level, there were five foods and their interaction with treatment. Day ($N = 21$ during conditioning and 2 during preference tests) was the repeated measure. Intake was converted to grams of food ingested/kg MBW ($\text{kg}^{0.75}$) to account for differences in body mass within and between trials. When F values were significant ($P < 0.05$), differences in means were analyzed with the least significant difference test. ANOVA was performed using the MIXED procedure in SAS (SAS; Littell et al., 1996).

Results

Trial 1 Conditioning

The availability of alternatives influenced the diet selection of lambs. The total amount of toxin-containing foods ingested by lambs in treatments 1 and 2 (61 and

59 g/kg^{0.75}) was greater than for treatments 3 and 4 (43 and 46 g/kg^{0.75}; $P < 0.005$). As the availability of nutritious alternatives—alfalfa and barley—increased, the total amount of toxin-containing foods consumed decreased.

Intake of the individual toxin-containing foods also varied among treatments (Fig. 1). Consumption of the terpene-containing food was higher for lambs in treatment 1 than for any of the other treatment ($P < 0.005$). The intake of oxalate-containing food also was higher in treatment 1 than in treatments 2 and 3 ($P < 0.05$;

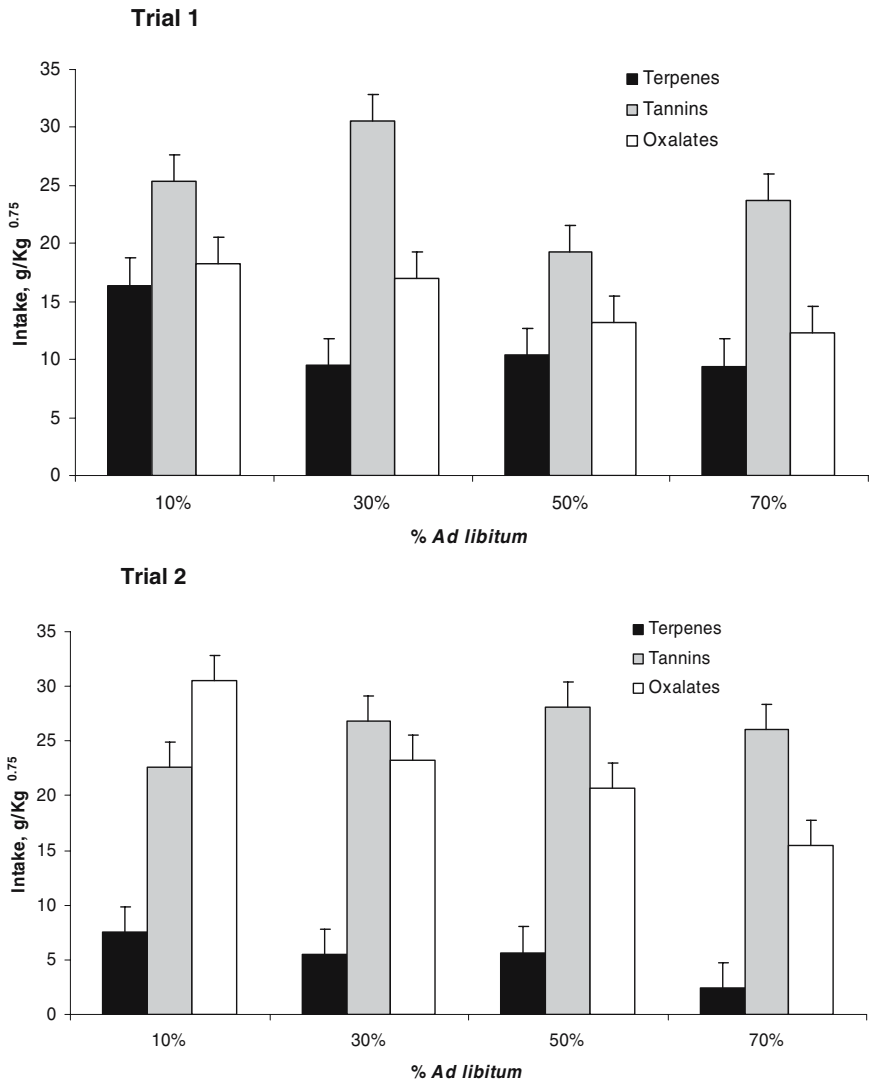

Fig. 1 Intake [means and standard errors (2.3)] by lambs of foods containing terpenes, tannins, or oxalates during conditioning in trial 1 (high quality) and trial 2 (low quality). Treatments 1–4 received, respectively, 10, 30, 50, and 70% of the *ad libitum* average consumed during preconditioning in alfalfa and alfalfa/barley

Fig. 1). Lambs in treatment 2 ate more of the tannin-containing food than lambs in treatments 1, 3, and 4 ($P < 0.05$; Fig. 1). Within each of the four treatments, intake of the tannin-containing food was higher than intake of the terpene or oxalate-containing foods ($P < 0.005$). For treatment 2, intake was higher for oxalates than terpenes ($P < 0.005$; Fig. 1).

The average daily weight gain did not differ among treatments as the availability of alternatives increased ($P > 0.05$). The trial average increase was 0.102 kg/lamb/d.

Trial 1 Preference

Restriction during conditioning increased preference for the toxin-containing foods. Given *ad libitum* access to all five foods, lambs showed higher preference for the three toxin-containing foods in treatments 1 (49%) and 2 (47%) than in treatments 3 (41%) and 4 (38%; $P < 0.05$). Total intake of the toxin-containing foods did not differ from that of the nutritious familiar alternatives for any of the groups ($P > 0.05$).

Intake of the terpene-containing food was greater in treatments 1 and 3 than in treatments 2 and 4 ($P < 0.05$; Fig. 2). Lambs in treatment 2 consumed more tannin-containing food than lambs in treatments 3 and 4 ($P < 0.05$). Lambs in treatment 1 consumed more tannin-containing food than those in treatment 3 and more oxalate-containing food than those in treatment 4 ($P < 0.05$; Fig. 2). The intake of alfalfa and alfalfa/barley did not differ among treatments ($P > 0.05$; Fig. 2).

Preference was greater in all treatments for the tannin-containing food than for the terpene or oxalate-containing foods ($P < 0.05$; Fig. 2). In treatments 1 and 4, intake was greater for the oxalate than the terpene-containing food ($P < 0.05$; Fig. 2). The alfalfa/barley mix was preferred by all treatments ($P < 0.005$), whereas the intake of alfalfa was less than the tannin-containing food in treatments 1, 2, and 4 ($P < 0.005$).

Trial 2 Conditioning

Lambs were influenced by the availability of alternatives and the poorer diet quality. The amount of total toxin-containing foods ingested decreased as the availability of alternatives increased, such that lambs in treatments 1–3 (61, 56, and 54 g/kg^{0.75}, respectively) ate more total toxin-containing foods than lambs in treatment 4 (44 g/kg^{0.75}; $P < 0.005$). Lambs in treatment 1 also consumed more total toxin-containing foods than those in treatment 3 ($P < 0.05$).

Consumption of individual toxin-containing foods also varied among treatments (Fig. 1). The intake of the oxalate-containing food was greater for lambs in treatment 1 than treatments 2–4 ($P < 0.05$) and greater in treatments 2 and 3 than in treatment 4 ($P < 0.05$). Lambs in treatment 1 also consumed more terpene-containing food than lambs in treatment 4 ($P < 0.05$), whereas those in treatment 3 ingested higher amounts of the tannin-containing food than lambs in treatment 1 ($P < 0.05$).

The intake of individual toxin-containing foods also varied (Fig. 1). Lambs ate the least of the terpene-containing food ($P < 0.005$). In treatment 1, intake of the oxalate-containing food was highest, whereas in treatments 3 and 4, consumption of the tannin-containing food was highest ($P < 0.005$). Lambs in treatment 2 ate similar amounts of the tannin and oxalate-containing foods ($P > 0.05$).

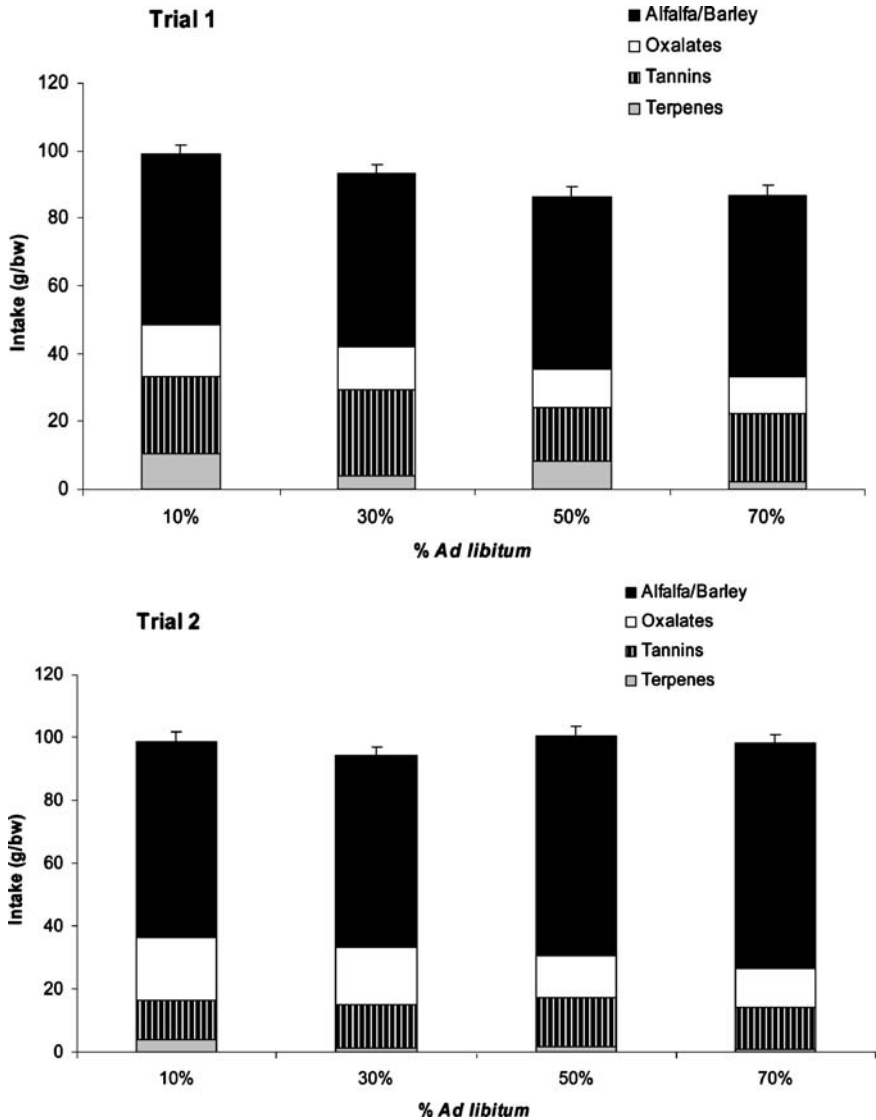

Fig. 2 Intake [means and standard errors (2.9)] of four diets—terpenes, tannins, oxalates, and alfalfa/barley (50:50) plus alfalfa—offered simultaneously and *ad libitum* to lambs during preference tests that occurred immediately after lambs were conditioned with toxin-containing foods of high quality (trial 1) and low quality (trial 2)

Patterns of use of toxin-containing foods varied between trials 1 and 2 (Fig. 1). Animals in trial 1 ate large amounts of tannins, whereas those in trial 2 ate large amounts of tannins and oxalates. Lambs in treatments 1–3 all ate more oxalates in trial 2 than in trial 1 ($P < 0.005$). All lambs ate more oxalates than terpenes in trial 2, and this pattern was most pronounced in lambs in treatment 1 that ate more oxalates than tannins or terpenes ($P < 0.005$; Fig. 1). Finally, intake of terpenes by treatments 1, 3, and 4 decreased from trials 1 to 2 ($P < 0.05$).

The average daily weight gain in trial 2 did not differ among treatments ($P > 0.05$). However, lambs gained less in trial 2 (0.015 kg/lamb/d) than in trial 1 (0.102 kg/lamb/d; $P < 0.005$).

Trial 2 Preference

While preference continued to be influenced by the availability of alternatives, the lower diet quality in trial 2 affected intake of the toxin-containing foods. Lambs in treatments 1 (37%) and 2 (36%) showed higher preference for the toxin-containing foods than lambs in treatments 3 (29%) and 4 (27%; $P < 0.05$). The total amount of toxin-containing foods consumed and the total amount of safe foods consumed during the preference tests did not differ ($P > 0.05$).

Intake of individual toxin-containing foods varied among treatments. Lambs in treatment 1 consumed more oxalate than those in treatments 3 and 4 ($P < 0.05$), and lambs in treatment 2 consumed more oxalates than those in treatment 4 ($P < 0.05$; Fig. 2). Preferences did not differ among treatments for the terpene and tannin-containing foods ($P > 0.05$; Fig. 2). Preference for the alfalfa/barley mix was lower in treatment 1 than treatments 3 and 4 and lower in treatment 2 than in treatments 1, 3, and 4 ($P < 0.05$; Fig. 2).

Within each of the four treatments, preference for the terpene-containing food was lower than for the other two toxin-containing foods ($P < 0.005$). Within treatment 1, preference was higher for the oxalate-containing food than for the tannin-containing food ($P < 0.005$; Fig. 2). As in trial 1, all lambs preferred the alfalfa/barley mix to other foods ($P < 0.005$). Alfalfa intake was higher than the tannin-containing food in treatment 2 ($P < 0.05$), higher than the oxalate-containing food in treatment 3 ($P < 0.05$), and higher than both tannin and oxalate-containing foods in treatment 4 ($P < 0.05$).

The preference for toxin-containing foods also varied between trials (Fig. 2). Lambs ate more oxalate and less terpene during conditioning in trial 1 than in trial 2, and this pattern persisted during the preference trial. Treatments 1 and 2 consumed more oxalate and less terpene than they did during trial 1 ($P < 0.05$). Additionally, lambs in treatments 1, 2, and 4 had a lower preference for tannin in trial 2 than in trial 1 ($P < 0.05$). Lambs in trial 2 also ate more alfalfa/barley mix (treatments 1, 3, and 4, $P < 0.05$) and more alfalfa (treatments 2 and 4, $P < 0.05$; and treatment 3, $P < 0.05$).

Discussion

We hypothesized that the ability of herbivores to mix toxin-containing foods in their diets is a function of the availability of nontoxic foods and the nutritional characteristics of toxin-containing foods. Based on this hypothesis, we predicted that young lambs exposed to high availability of nutritious alternatives would consume less novel toxin-containing foods, thus impeding their acquisition of diet-mixing behavior. In contrast, we predicted that young lambs exposed to low availability of nutritious alternatives would learn to consume more of the novel toxin-containing foods.

In our studies, both the quality of the toxin-containing food and the availability of alternatives affected the acquisition and retention of diet-mixing behavior. Animals consistently ingested more of the three toxin-containing foods during both conditioning and preference trials, as the availability of high-quality foods decreased and the quality of the foods containing the toxins increased (Figs. 1 and 2). Given an adequate level of nutrition, the toxin-containing diets we used complement one another in that lambs eat much more when offered a meal of three foods (tannins, terpenes, and oxalates) than they do in a meal of two foods (tannins–terpenes, tannins–oxalates, or terpenes–oxalates), and they eat much more in a meal of two foods than when they are offered only one of the foods (Villalba et al., 2004). According to optimal foraging theory, herbivores should forage on plants that maximize energy intake per unit effort (Stephens and Krebs, 1986), and they should either eat or ignore food depending on the density of other more profitable foods (the zero–one rule, Stephens and Krebs, 1986; or the none-or-all rule, McNamara and Houston, 1987). According to this rule, animals should not exhibit partial preferences for poorer quality foods. However, generalist herbivores typically do exhibit partial preferences (Stephens and Krebs, 1986; Belovsky and Schmitz, 1991; Belovsky et al., 1999), and several explanations have been proposed (McNamara and Houston, 1987; Illius et al., 1999; Provenza et al., 2003b). Our study provides evidence that partial preferences depend on prior foraging experience and nutrient–toxin interactions.

Experience and the availability of alternative foods both influence diet mixing, as illustrated in trials where lambs with 3 mo of experience mixing tannin, terpene, and oxalate-containing foods were compared with lambs with no previous experience with the same foods (Villalba et al., 2004). As in the present study, all lambs were offered five foods, including the toxin-containing foods and two nutritious alternatives—ground alfalfa and barley. However, in contrast to this study, which limited the availability of familiar foods to 10, 30, 50, or 70%, that study provided half of the lambs with 200 g (restricted to approximately 20–25% of *ad libitum*) and half with *ad libitum* access to the familiar foods. Lambs lacking experience with the toxin-containing foods, and given the nutritious alternatives *ad libitum*, ate much less of the toxin-containing foods than lambs with restricted alternatives (66 vs. 549 g/d). Experienced lambs also ate less of the toxin-containing foods if they were given *ad libitum* rather than restricted access to alternatives (809 vs. 1497 g/d). In both cases, the availability of nutritious alternatives and previous mixing experience influenced how much of the toxin-containing foods were consumed. In both trials, animals learned to mix toxin-containing foods with nutritious alternatives if nutritious alternatives were heavily restricted.

In this study, as diet quality decreased from trials 1 to 2, animals with the lowest availability of nutritious alternatives switched from tannin- to oxalate-containing foods (Fig. 1). This may be caused in part by detoxification processes, which impose nutritional costs by depleting the body of protein and glucose (Illius and Jessop, 1995, 1996) and inhibiting nitrogen utilization (Robbins et al., 1987a,b, 1991). These costs can deter feeding by herbivores (Dziba et al., 2006; Marsh et al., 2005). While knowledge of the effects of most toxin-containing foods in the body and their elimination pathways is incomplete (Foley et al., 1999; Villalba et al., 2002b), there is evidence that many terpenes are metabolized in the liver (Foley et al. 1999), that tannins bind to proteins in the diet (Robbins et al., 1991), and that oxalates are detoxified primarily by rumen microbes (Cheeke and Schull, 1985). Thus, we

speculate that lambs may have relied more on hepatic and dietary mechanisms of detoxification when their diets were of higher quality, consuming more terpenes and tannins. Additionally, lambs may have been less sensitive to protein-binding tannins when they ate the higher diet quality. When diet quality was reduced, lambs consumed more food with oxalates, evidently relying more on ruminal detoxification and adaptation to consume oxalates (Cheeke and Schull, 1985). Finally, a decrease in diet quality reduced total intake of the three toxin-containing foods regardless of the availability of alternatives. Presumably, the low-quality diet reduced the supply of nutrients needed for both ruminal and hepatic detoxification processes, which, in turn, reduced the amount of toxin-containing foods the animals could ingest.

Our findings suggest that different grazing regimes may influence how animals forage. Herbivore density influences forage availability, which can influence the way animals select foods (Provenza et al., 2003a,b; Villalba et al., 2004). Animals in this study with greater access to nutritious alternatives ate less of the toxin-containing foods, regardless of diet quality (Figs. 1 and 2). These densities increased selective foraging and prevented animals from discovering complementarities among toxin-containing plants. In contrast, higher herbivore densities may decrease selectivity and facilitate the use of less palatable species, which can lead to herbivores learning about complementary relationships among toxin-containing species (Provenza et al., 2003a). During preference tests in these trials, animals restricted to the lowest levels of nutritious alternatives ate the toxin-containing foods despite having *ad libitum* access to the two safe familiar foods (Fig. 2). Use of chemically defended species could alter successional momentum, preventing less palatable species from increasing in dominance (Villalba et al., 2004) and potentially influencing plant biodiversity (Provenza et al., 2003a).

How animals learn about a foraging environment can influence diet breadth. Herbivores that experience toxin-containing foods while on a high plane of nutrition show a higher preference for them than animals on a low plane of nutrition (Baraza et al., 2004). Consequently, an animal's physiological state, which is influenced by biochemical diversity, including nutrient availability, is a context further shaping foraging behavior. This biochemical diversity, which includes less palatable species, may allow herbivores to discover and utilize suboptimal but complementary food alternatives, offering multiple foraging pathways from which to meet their nutritional requirements while consuming less palatable species (Singer et al., 2002; Villalba et al., 2004). In this study, animals conditioned with low levels of nutritious alternatives and high diet quality ate significantly more of the three toxin-containing foods than animals conditioned with high levels of nutritious alternatives and lower diet quality (Fig. 1).

Finally, diet-mixing behavior did not adversely influence animal performance. Animals that experienced the lightest restrictions ate more safe foods, but did not gain more weight than animals forced to consume higher amounts of toxin-containing foods (trials 1 and 2). Thus, above a threshold of restriction, animals did not eat other alternatives when the amounts of food were high enough to survive. In contrast, below a threshold of restriction, animals consumed toxin-containing foods. Possibly, because complementarities were present, they developed new foraging strategies. However, when the quality of the toxin-containing food declined (trial 2), the amount of nutrients ingested may not have been enough to allow for detoxification and growth. Thus, intake and preference for the toxin-containing foods declined as did animal performance.

Abstract Goats foraging on Mediterranean shrubs containing secondary compounds (toxins) may consume a variety of shrubs that contain different phytotoxins, thereby increasing shrub intake and avoiding toxicosis. We conducted eight experiments to examine whether goats offered different mixtures of shrubs containing different phytotoxins (tannins and saponins) would consume more shrub biomass than goats offered one shrub a single phytotoxin (tannin or saponin). In the first three experiments, goats fed a mixture of three tannin-rich shrubs (*Quercus ilex*, *Arbutus unedo*, and *Pistacia lentiscus*) ate more foliage than goats offered only one shrub (23.2 vs. 10.7 g/kg BW; 25.2 vs. 13.4 g/kg BW, and 27.9 vs. 7.9 g/kg BW), regardless of tannin concentration in individual shrub species. Goats also consumed more foliage when offered the same three tannin-rich shrubs than when offered the saponin-rich shrub *Hedera helix* (25.4 vs. 8.0 g/kg BW). However, goats offered a mixture of the same three tannin-rich shrubs consumed less foliage than goats offered a mixture of two shrubs containing tannins and saponins: *Quercus* and *Hedera* (21.6 vs. 27.1 g/kg BW), *Arbutus* and *Hedera* (21.8 vs. 27.1 g/kg BW), and *Pistacia* and *Hedera* (19.7 vs. 22.0 g/kg BW). Comparison of intake of shrubs containing only tannins or saponins to intake of shrubs containing both tannins and saponins indicated that goats consumed more total biomass when fed with shrubs with both classes of compounds than with either tannins or saponins alone. results suggest that goats can increase intake of Mediterranean shrubs high in secondary compounds by selecting those with different classes of phytotoxins. Simultaneous ingestion of shrubs containing tannins and saponins may promote chemical interactions that inhibit toxic effects of these phytotoxins in the intestinal tract. In addition to complementary interactions between tannins and saponins, biological diversity within Mediterranean maquis vegetation also plays a positive role in increasing shrub intake by goats.

Keywords Mediterranean shrubs · Maquis · Biodiversity · Secondary compounds · Tannins · Saponins · Goats

Introduction

Goats are primary consumers of the Mediterranean maquis vegetation and thereby shape the diversity, structure, and dynamics of these extensive ecosystems (Naveh, 1972; Hodgson and Illius, 1996; Kaiser, 2000). Vegetation of these plant communities usually consists of 20–25 shrubby species (Rogosic, 2000), and its diversity, function, and stability depend on biological/biochemical links between plant and animal components of these ecosystems (Dziba et al., 2005). Plants possess a variety of flavor intensities and nutritional qualities that influence diet selection by herbivores (Villalba and Provenza, 2000). Olfactory, gustatory, visual, and tactile stimuli are important sources of information that herbivores use to detect potentially nutritious or toxic plants (Augner and Bernays, 1998). Collectively, the phytochemicals in a plant give rise to the characteristic flavor of a shrub species. Traditionally, food selection has been attributed to the innate ability of animals to sense specific flavors, nutrients, and toxins in plants through taste and smell (Rhoades, 1979), but food preference is a learned process involving complex relationships between flavor and postingestive effects of the plant (Provenza et al., 1998).

Given the diversity of plant cues that herbivores typically encounter, their ability to learn to recognize food and to generalize over food cues are important traits (Augner et al., 1998). Herbivores learn to prefer food flavors associated with macronutrients (Ralphs et al., 1995; Villalba and Provenza, 1999) and to avoid flavors paired with toxins (Ralphs, 1992). Once flavor–postingestive feedback associations have been learned, herbivores use visual and olfactory cues to recognize specific plants (Launchbaugh and Provenza, 1993), and they generalize preference and aversion across familiar cues for nutrients and toxins (Launchbaugh et al., 1993).

Goats foraging on Mediterranean shrubs that contain secondary compounds may consume a variety of foods to avoid toxicosis (Freeland and Janzen, 1974). Different toxins have different physiological effects on herbivores (Cheeke, 1998), and herbivores are equipped with various physiological mechanisms to counter toxins (McArthur et al., 1991). A varied diet composed of plant species containing different kinds of nutrients and toxins may increase food intake and animal production by enabling individuals to select plants that are biochemically complementary (Freeland et al., 1985; Rogosic et al., 2003). The objective of this study was to examine the effect of feeding Mediterranean shrubs containing varying concentrations of tannins and/or saponins on intake by goats.

Methods and Materials

Study Shrubs and Animals

The four major shrub components of goat diets in the Mediterranean maquis plant community *Orno-Quercetum ilicis* (Horvatić, 1958) were examined in these experiments. These shrubs include *Quercus ilex* L. (Fagaceae), *Arbutus unedo* L. (Ericaceae), *Pistacia lentiscus* L. (Anacardiaceae), and *Hedera helix* L. (Araliaceae). *P. lentiscus* has the highest tannin index (1.50), followed by *A. unedo* (1.26) and *Q. ilex* (0.96). Other secondary compounds in these shrubs include a cyclic diterpene alcohol and quinic acid (*Q. ilex*), arbutoside and ethyl gallate (ethyl 3,4,5-trihydroxybenzoate; *A. unedo*), terpenes [including α -pinene, β -pinene, camphene, *trans*-caryophyllene, cubebene (or a similar sesquiterpene), and cadinene], and fatty acids (*P. lentiscus*; Rogosic and Clausen, unpublished data). *H. helix* is reported to contain a mixture of pentacyclic terpenoids (Burrows and Tyrl, 2001) classified as genins, monodesmosides (α -hederin and β -hederin), or bidesmosides (hederacosides C and B). This complex mixture is often referred to as saponins.

We conducted eight trials at an experimental station 25 km from Split, Croatia, in the central area of the Adriatic seaside. Experimental animals were Alpine goats (mean body weight = 24.2 kg) with experience on grazing on Mediterranean shrublands near the Croatian coast. Animals were penned (1.5 × 2 m) individually. All shrubs offered were hand-harvested each week in the same location. Leaves and 1-yr old twigs, 10 cm long, were clipped and placed in bags. Within an hour, the plant material was ground to 1-cm length with a chipper, mixed for uniformity, placed in woven, polyethylene feed sacks, and refrigerated at 4°C. Every morning before the trial, bags of shrubs to be fed that day were removed from cold storage and offered immediately to animals.

Conditioning

Prior to the experiments, baseline intake of alfalfa pellets was determined for each animal on days 1–5. After baseline intake was established, all goats ($N = 12$) were offered all four shrubs simultaneously from 0900 to 1300 hr for 5 d. Shrub intake was monitored, and goats were stratified into two experimental groups ($N = 6$) based on total shrub intake. The same 12 goats were used in all experiments, and treatment groups were not changed between experiments. Between experiments, goats were fed with alfalfa pellets and barley at maintenance level for 3 d.

During experiments, goats received 100 g of barley from 0800 to 0830 hr and were offered 200 g of each shrub species simultaneously in separate feeders from 0900 to 1500 hr daily for 7 d. Feeders were monitored at 30-min intervals, and additional shrub biomass was placed in empty boxes. At 1500 hr, feed refusal was weighed and shrub consumption was calculated, and goats were fed with 550 g of alfalfa pellets. Throughout experiments, animals had free access to trace mineral blocks and freshwater.

Experiments 1–3

The objective of the first three experiments was to determine if goats consuming three high-tannin shrubs varying in nutrients and flavor would consume more biomass than goats offered only one shrub. Total intake when offered *Q. ilex*, *A.*

unedo, and *P. lentiscus* was compared to intake of only *Q. ilex*, *A. unedo*, or *P. lentiscus* in experiments 1–3, respectively.

Experiment 4

The objective of experiment 4 was to determine if goats offered the same three high-tannin shrubs would consume more biomass than goats offered one shrub (*H. helix*) containing saponins.

Experiments 5–7

The objective of experiments 5–7 was to determine if goats offered three shrubs containing tannins would consume more foliage than goats offered two shrubs containing two different classes of toxins (tannin and saponins). Intake of three shrubs (*Q. ilex*, *A. unedo*, and *P. lentiscus*) was compared to intake of two shrubs (*Q. ilex* + *H. helix*, *A. unedo* + *H. helix*, or *H. helix* + *P. lentiscus*) in experiments 5–7, respectively.

Experiment 8

The objective of experiment 8 was to determine the influence of saponins in *H. helix* on biomass intake of the three high-tannin shrubs. Intake of the three high-tannin shrubs was compared to intake of the same three shrubs + *H. helix*.

Statistical Analyses

The total daily shrub intake in each experiment was used as the dependent variable in the analysis. The experimental design for all eight experiments was a completely random design. Animals were a random factor in the mixed model analysis (SAS, 2000). The model included the two experimental groups (group 1 vs. group 2), shrub species (in different experimental groups), and the species \times group interaction. The model also used days as a repeated measure with all other interactions included. All analyses on shrub intake were adjusted for body weight (g/kg BW). Data were analyzed by using analysis of variance (SAS, 2000), and means were separated using least significance differences ($P < 0.05$).

Results

In the first three experiments, goats fed with a mixture of three tannin-rich shrubs ate more foliage ($P < 0.01$) than goats offered only one shrub, regardless of concentration of tannins in the individual shrub (Fig. 1; experiments 1–3). In experiment 1, goats offered shrubs *Quercus*, *Arbutus*, and *Pistacia* ate more foliage ($P < 0.01$) than goats offered only *Q. ilex* (23.18 ± 2.62 vs. 10.66 ± 1.52 g/kg BW). Intake of *Q. ilex* did not differ between the two groups (9.49 ± 0.99 vs. 10.66 ± 1.52 g/kg BW). Goats offered the same three shrubs in experiment 2 also ate more foliage ($P < 0.01$) than goats offered only *A. unedo* (25.23 ± 2.53 vs. 13.36 ± 2.3 g/kg BW). Likewise, *Arbutus* biomass intake did not differ between groups (12.75 ± 2.7 vs. 13.36 ± 2.3 g/kg BW). In experiment 3, consumption was again greater ($P < 0.01$) for goats

Fig. 1 Intake of goats (g/kg BW) fed with different combinations of high-tannin (*Quercus ilex*, *Arbutus unedo*, and *Pistacia lentiscus*) and/or high-saponin *Hedera helix* shrubs; N = 6 in each group. Standard error bars refer to total intake

fed the mixture of tannin-rich shrubs than for goats fed *P. lentiscus* (27.88 ± 1.72 vs. 7.85 ± 1.05 g/kg BW). In contrast to experiments 1 and 2, intake of *P. lentiscus* differed ($P < 0.01$, Fig. 1; experiment 3) between groups (6.22 ± 0.64 vs. 7.85 ± 1.05 g/kg BW). Goats with a choice of the same three tannin-rich shrubs also consumed more foliage ($P < 0.01$) than those receiving the saponin-rich shrub *H. helix* (Fig. 1; experiment 4; 25.37 ± 1.16 vs. 7.99 ± 0.93 g/kg BW).

Goats provided the mixture of three tannin-rich shrubs consumed significantly less foliage than those offered only two shrubs containing tannins or saponins (Fig. 1; experiments 5–7). In experiment 5, goats consumed more biomass ($P < 0.01$) when fed *Quercus* and *Hedera* than the group offered the three high-tannin shrubs (27.11 ± 2.03 vs. 21.64 ± 2.37 g/kg BW). Likewise, in experiment 6, goats receiving *Arbutus* and *Hedera* ate more ($P < 0.01$) than those offered *Arbutus*, *Quercus*, and *Pistacia* (27.05 ± 1.59 vs. 21.77 ± 0.89 g/kg BW). In experiment 7, goats fed the high-tannin mixture again consumed more foliage ($P < 0.05$) than those fed *Pistacia* and *Hedera* (22.03 ± 1.37 vs. 19.68 ± 1.6 g/kg BW). Cumulatively, the results of experiments 5–7 indicate that combinations of two shrubs containing both classes of phytotoxins resulted in a complementary interaction and greater intake than three shrubs containing only tannins. Goats ate more *Quercus* ($P < 0.01$) in experiment 5 when fed in combination with a saponin-containing shrub than in experiment 1 when fed either by itself or in combination with other high-tannin shrubs (12.29 ± 1.23 vs. 10.66 ± 1.52 or 8.49 ± 1.15 g/kg BW). Goats ate more *Arbutus* when fed in conjunction with *Hedera* (experiment 6) than when fed with two other high-tannin shrubs (experiment 2; $P < 0.01$; 14.01 ± 1.14 vs. 10.82 ± 0.76 g/kg BW), although intake of *Arbutus* in experiment 6 did not differ from experiment 2 when offered alone (14.01 ± 1.14 vs. 13.36 ± 2.3 g/kg BW; $P < 0.01$). Goats ate more *Pistacia* in experiment 7 in conjunction with *Hedera* than in experiment 3 when fed two other high-tannin shrubs (7.89 ± 0.64 vs. 6.22 ± 1.72 g/kg BW; $P < 0.01$), but intake of *Pistacia* in experiment 7 with *Hedera* did not differ ($P < 0.01$) from experiment 3 when *Pistacia* was fed alone (7.89 ± 1.05 vs. 7.85 ± 0.64 g/kg BW). Intake of *H. helix* was much lower ($P < 0.01$) in experiment 4 than in experiments 5–7 when fed in conjunction with a tannin-containing species (7.99 ± 0.93 vs. 14.82 ± 2.03 ; 13.04 ± 1.59 ; 14.14 ± 1.37 g/kg BW). In experiment 8, goats offered all three tannin-rich shrubs plus the saponin-rich *H. helix* ate more foliage ($P < 0.01$) than goats offered only the tannin-rich shrubs (34.06 ± 2.06 vs. 20.78 ± 0.99 g/kg BW). Tannin-rich shrubs increased the intake of *H. helix*, and conversely, *H. helix* positively influenced the consumption of tannin-rich shrubs.

Discussion

Plant phytochemicals play important ecological roles in plant defenses (Bryant et al., 1991), plant classifications (Levin, 1971), palatability (Provenza et al., 1992), phytotoxicity (Pfister et al., 1994), and perhaps in fire ecology (Naveh, 1974). Tannins and saponins are two of the major groups of phytochemicals in Mediterranean shrubs. Tannins suppress shrub intake by reducing macronutrient digestibility and causing illness (Pritchard et al., 1992; Reed, 1995). Moreover, tannins bind to proteins, cell walls, and cell solubles (Kumar and Vaithiyathan, 1990) and adversely affect rumen microbial and intestinal enzyme activity (Silanikove et al., 1996; Rogosic et al., 2005a), and consequently reduce ruminal volatile fatty acids (Makkar et al., 1995). Clinical signs of saponin toxicity include vomiting, excess salivation, and diarrhea, indicating both liver and digestive tract irritation (Harshberger, 1920). *H. helix* has also been reported to cause abortions in sheep and goats (Bondi et al., 1973). Specific roles of saponins involve modification of gut microbes, particularly in ruminants (Gee et al., 1993). Saponins suppress rumen protozoa by binding to cholesterol in the protozoa cell membrane, causing the

organisms to lyse and die (Makkar et al., 1998). Likewise, saponins can damage intestinal mucosal cells by altering cell membrane permeability and interfering with active transport (Gee et al., 1989), an effect that is dependent on the structure of the individual saponin molecule (Johnson et al., 1986).

The first four experiments were designed to determine if goats offered a combination of three shrubs containing different concentration of tannins and presumably differing nutritional profile and flavor would consume more foliage than goats offered only one of those shrubs (experiments 1–3) or a shrub containing saponins (experiment 4). Goats offered a choice of three shrubs (experiments 1–3) containing different concentrations and types (molecular weights) of tannins consumed more foliage than goats offered each of these shrubs individually, regardless of tannin concentration in shrubs. Mule deer also consumed more sagebrush (*Artemisia tridentata*) and juniper (*Juniperus osterosperma*; plants high in different kinds of terpenes) than when consuming sagebrush or juniper alone (Smith, 1959). Phytochemicals such as tannins and terpenes apparently differ in their physiological effects and/or are detoxified by different means. The concentrations and specific molecular composition of toxins in Mediterranean shrubs fed to goats probably influences toxin satiation, which is not fixed but dynamically determined by the physiological state of an animal relative to the quality and quantity of nutrients and toxins available (Villalba et al., 2002). In essence, toxins cause herbivores to eat a variety of plants to meet their needs for nutrients because the pathways of detoxification are saturable (Freeland and Janzen, 1974; Foley et al., 1999). *H. helix* contains significant levels of saponins; these bitter, toxic compounds protect this shrub from browsing herbivores by affecting their feeding behavior (Rogosic et al., 2003). Goats offered three tannin-rich shrubs in experiment 4 ate more biomass than goats fed only *H. helix*. These results are consistent observations that a greater number of shrub species in the diet increase intake (Smith, 1959; Rogosic et al., 2005a,b).

The complementarity of tannin-rich shrubs and a saponin-rich shrub positively influenced biomass intake in experiments 5–7. Goats provided with a choice between shrubs containing tannins and saponins were able to consume combinations of the shrubs that may have reduced aversive feedbacks associated with consumption of either toxin alone. Our results are consistent with this hypothesis. Goats offered two shrubs containing different classes of secondary compounds (tannins and saponins) consumed more foliage than goats offered three shrubs that all contained only tannins. Complementary interactions between shrubs containing tannins and saponins (experiment 8) further support the idea that biochemical diversity (higher number of shrubs species in the diet) has a positive influence on shrub intake, enabling animals to better meet nutritional needs and avoid toxicity. Tannins, saponins, and other allelochemicals may form complexes within the intestinal tract, given that they form chelation complexes in *in vitro* systems (Freeland et al., 1985). Intestinal binding of tannins with saponins may minimize toxic effects by reducing absorption. Simultaneous consumption of plants containing chemical chelators (e.g., tannins) and those containing other toxins may provide a mechanism for reducing both pre- and postabsorption toxicity. If herbivores use phytochemical interactions as a means of neutralizing toxins, this mechanism could be important regarding management of ruminants on Mediterranean rangelands.

As each of these shrubs presumably exhibits different flavors, as well as different concentrations of nutrients and toxins, the flavor–nutrient–toxin interaction may also

explain why the efficacy of plant defenses varies with the mixture of plants, and why chemical attributes of a single shrub species must be considered within a larger context of the plant community. For a given plant compound, preference may range along a continuum from strongly aversive if nutrients and toxins are not complementary to strongly positive if nutrients and toxins (e.g., tannins and saponins) are complementary. Understanding the role of plant phytochemicals and their interactions will lead to a greater understanding of the influence of biochemical diversity on grazing herbivores and the effect of herbivores on plant diversity, both of which could have important implications for management of natural grazing ecosystems.

Abstract Frugivorous bats from the Old and New World use odor cues to locate and assess fruit condition. We hypothesized that Egyptian fruit bats (*Rousettus aegyptiacus*) use as odor cues those volatile compounds that increase in emission rate as fruit ripens. We examined whether the smell of fermentation products may indicate the degree of ripeness to fruit bats. We analyzed volatile compounds in the headspace (the gas space above a fruit in a closed container) of dates (*Phoenix dactylifera*) and rusty figs (*Ficus rubiginosa*), both of which are consumed by fruit bats, to elucidate which compounds originate from fermentative pathways and to determine which change in emission rate during ripening. Ethanol, acetaldehyde, and acetic acid were the only volatile compounds detected as products of fermentation in both fruits. In dates, emission rates of these compounds increased during maturation, whereas in rusty figs, they decreased or remained constant. Methanol, although not a fermentation product, increased in emission rate during ripening in both fruits. We found that *R. aegyptiacus* was neither attracted nor deterred by the smell of methanol at any of the concentrations used. Although the odor of ethanol emanating from food containing concentrations similar to those found in ripe fruit did not attract the bats, at relatively high concentrations ($\geq 1\%$), the smell of ethanol deterred them. Thus, ethanol at high concentrations may serve as a signal for bats to avoid overripe, unpalatable fruit.

Introduction

Frugivory has evolved separately in two lineages of bats: Pteropodidae from the Old World and Phyllostomidae from the New World. Olfaction is an important sense for fruit-eating bats in both families, and several studies suggest that both groups use odors emitted from fruits to locate and evaluate their palatability (Laska and Schmidt, 1986; Rieger and Jakob, 1988; Acharya et al., 1998; Luft et al., 2003). However, little is known about the chemical compounds used by frugivorous bats to find fruits and to assess their quality.

Fruit-eating bats generally prefer ripe fruit to unripe or overripe unpalatable fruit, as defined by using anthropomorphic criteria (Fleming et al., 1977; Kalko et al., 1996; Korine and Kalko, 2005). This implies that, in nature, frugivorous bats choose fruit emitting volatile compounds within a particular range of concentrations. If frugivorous bats use these compounds as odor cues, they may be able to discern variation in their emission rates to assess fruit condition.

As fruit ripens, a variety of chemical and structural changes take place, including either synthesis or degradation of carbohydrates, lipids, proteins, and mRNAs and the production of pigments and flavor-imparting compounds (Sharaf et al., 1989; Tucker, 1993). Given that the perception of flavor involves the senses of touch, smell, and taste (Rohan, 1972), the flavor of fruit depends on the complex interaction of sugars, organic acids, phenols, and more specialized flavor compounds, including a wide range of volatiles. The profile of volatile compounds for a fruit is usually complex, and may include alcohols, aldehydes, esters, and other chemical groups (Nursten, 1970).

Several fruit-eating primates and one Neotropical fruit bat are sensitive to the odor of aliphatic alcohols (Laska, 1990; Laska and Seibt, 2002). Moreover, Laska and Seibt (2002) suggested that fruit-eating mammals are specifically sensitive to aliphatic alcohols that are products of microbial fermentation in fruit, and these may serve as indicators of fruit ripeness. Indeed, several studies have shown that fruit flies (Hoffmann and Parsons, 1984), fruit-eating beetles (Rochat et al., 2000), butterflies (Utrio and Eriksson, 1977), and moths (Cosse et al., 1994) use the smell of ethanol and other products of fermentation, alone or combined, to find food.

We hypothesized that fruit-eating bats use volatile compounds that change in emission rate during ripening as odor cues to discern fruit palatability. Accordingly, we predicted that food emitting volatile compounds at concentrations close to those emitted by ripe fruit will attract fruit bats. Fruit bats will not respond to food emitting volatile compounds at concentrations similar to unripe fruit, and will be deterred by emissions from overripe, unpalatable fruit.

Methods and Materials

Experimental Animal

The Egyptian fruit bat *Rousettus aegyptiacus* (Pteropodidae) (mean adult body mass = 145.3 ± 2.6 SE g) is the only fruit bat found in Israel. It feeds mainly on fleshy

fruit, in particular on figs (*Ficus* spp.), as well as on leaves and pollen (Korine et al., 1999). We used Egyptian fruit bats from a colony maintained on the Sede Boqer Campus of Ben-Gurion University of the Negev. Bats were kept in an outdoor flight cage ($5 \times 4 \times 2.5$ m) that could be ventilated and cooled with an evaporative swamp cooler. The cage's chicken-wire sides were covered with cloth that provided 80% shade. Diet consisted of locally purchased, seasonal fleshy fruit, such as melons, watermelons, apples, mangos, and bananas that were provided *ad libitum*.

Plant Material and Collection of Volatile Compounds

We used two species of fruit consumed by Egyptian fruit bats in the wild: the rusty fig *Ficus rubiginosa* (Family Moraceae) and the date *Phoenix dactylifera* (Family Areaceae) (Korine et al., 1999). Based on skin color, fruits were classified as unripe or ripe. Unripe fruit of both species were either green or yellow. Ripe rusty figs were red to dark red, and ripe dates were brown. After collection, fruits were sealed in plastic bags and cooled to 2–5 °C and transported to the Life Science Trace Gas Facility of Radboud University of Nijmegen, where the volatiles were measured within 5 d of collection by proton-transfer reaction mass spectrometry (PTR-MS).

PTR-MS is based on the soft ionization of volatile substances by proton transfer reactions from H_3O^+ ions (Lindinger et al., 1998). PTR-MS measures volatile organic compounds at concentrations down to 0.1 ppbv in real time (~1 sec). We used a modified version of the system described by Boamfa et al. (2004). Signals generated by the PTR-MS are proportional to the trace gas concentrations in the sample air. After calibration of the PTR-MS, we determined acetaldehyde, ethanol, and methanol concentrations (in ppbv) at 1 atm pressure and room temperature. By accounting for the flow rate (1.0 l hr^{-1}), the molar mass of each compound, and the fresh mass of the fruit, we calculated the emission rates.

Glass cuvettes containing the fruit samples were continuously flushed (1.0 l hr^{-1}) with clean, dry air, or with nitrogen gas containing a low oxygen concentration. The outlet flow was connected directly to the PTR-MS. Measurements were made in air and 22 °C to simulate the natural conditions in which bats would smell the volatiles. We switched from air to nitrogen gas for 3–5 hr to induce fermentation and to identify the gasses emitted. Identification of the gasses was based on the mass of the compounds, isotope ratios, and solubility in water. In addition, we used the difference in compound fragmenting behavior when the drift field (i.e., the kinetic energy of the reactant ions in the proton-transfer reaction cell) was varied (Steeghs et al., 2004). To further examine the emitted gasses, several fruits were sealed in vials for 2–6 hr, and the headspace was analyzed with a GC-MS (Polaris Q, Thermo Finnigan).

Ethanol and Methanol as Odor Cues

In the flight cage, we exposed bats to ethanol or methanol in either distilled water or commercial mango juice (Prigat®) presented in a six-way food-choice device. We used distilled water, which provides a neutral background not related to fruit, as a control. Mango juice is attractive for bats and contains little methanol (<0.001%) or ethanol (0.01–0.015%). Six identical feeders were suspended from the corners of a hexagon of cardboard (40-cm side) that was secured to the ceiling of the flight cage. The apparatus was designed to mimic conditions in which a bat forages for fruit on the same branch of a fruiting plant or on branches of different plants that are close together.

To enable bats to learn to use the feeders, we habituated them for 1–3 d during which we filled a single, randomly chosen feeder with mango juice. During the experiments, two randomly chosen feeders were filled with treatment mixtures. They were filled with 15 ml of fluid, to a level that did not allow the bats to see the contents while flying in the cage. After the bat had inspected the cage, or had flown or hovered around the feeders, we recorded the first feeder on which it chose to alight. Because the food was not visible to the bats, we assumed that they selected the feeder by its odor. If the bat went directly to one of the feeders after being released, we disqualified the trial. Trials lasted 1–10 min but usually for less than 6 min. In total, we used 20 bats in the experiments; however, if a bat did not fly around the cage within 10 min of being freed into it, we replaced the animal with another. The observations were performed under dim red light between 18:00 and 02:00 hr.

We made the following experimental comparisons: (1) ethanol in water vs. water; (2) ethanol in fruit juice vs. fruit juice; (3) methanol in water vs. fruit juice; and (4) methanol in fruit juice vs. fruit juice. Comparisons 1 and 3 were designed to evaluate whether ethanol or methanol by themselves could act as odor cues. Comparisons 2 and 4 tested whether ethanol or methanol either encouraged or discouraged a bat's food choice relative to a constant background odor of a particular fruit. We prepared mixtures of distilled water or mango juice with ethanol or methanol a few minutes before the start of an experiment.

Preliminary experiments (Sánchez et al., 2004) showed that the amount of ethanol in wild fruits eaten by fruit bats varies between 0.02 and 0.2% in unripe fruit and between 0.1 and 0.7% in ripe fruit. In the present study, we used v/v mixtures of ethanol in water or mango juice at concentrations of 0, 0.01, 0.1, 0.3, 0.5, 0.7, 1, and 2%. The concentrations of methanol in wild fruit are unknown, although the methanol concentration in ripe melon, *Cucumis melo*, a fruit readily eaten by bats, is ~0.03% (our own measurement). Therefore, we mixed methanol in water or mango juice at 0.001, 0.01, 0.1, and 1%. We did two sets of trials, one with ethanol and the other with methanol. In each set, the order of presentation of the treatments was randomly chosen.

Statistical Analyses

Spearman's rank correlation method (Zar, 1999) was used to examine the relationships between the emission rates of the volatile compounds and stage of ripening. In addition, we used binomial tests (Zar, 1999) to analyze the results of the odor experiments, assuming that trials were independent. $P < 0.05$ was chosen as the lowest acceptable level of significance.

Results

Volatile Compounds Emission under Low Oxygen Conditions

Under aerobic conditions, 14 volatile compounds emitted from dates and rusty figs were detected, with atomic mass units between 30 and 103. Of these, only ethanol, acetaldehyde, and acetic acid increased in the headspace of both dates and rusty figs at low $[O_2]$ (Fig. 1A–D). In both species, acetaldehyde and ethanol were considerably more abundant than acetic acid.

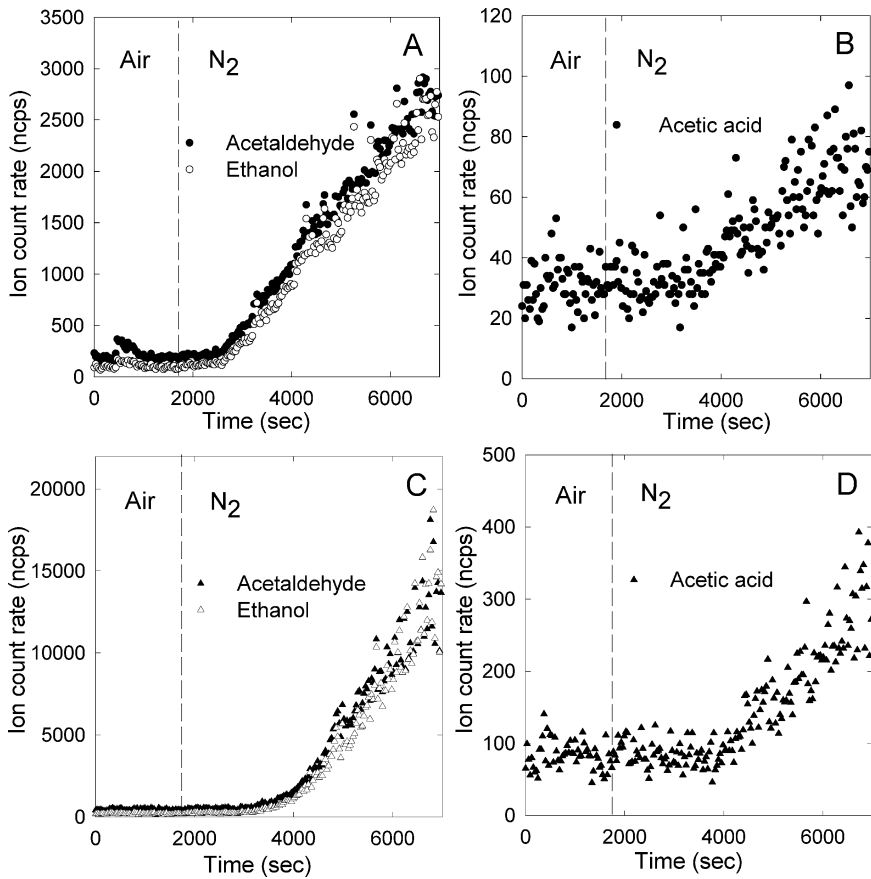

Fig. 1 The change from ambient air to low oxygen conditions (N₂ treatment) increased the emission of acetaldehyde and ethanol (A), and acetic acid (B) from dates (*Phoenix dactylifera*), as well as from rusty figs (*Ficus rubiginosa*) (C, D). Ion count rate is expressed in normalized counts per second (ncps), i.e., the count rate referenced to a fixed number of primary H₃O⁺ ions

Changes in Ethanol, Acetaldehyde, Acetic Acid, and Methanol Emission during Ripening

The emission rates of ethanol, acetaldehyde, and acetic acid in the headspace of dates were positively correlated with stage of ripening. In contrast, the emission rates of ethanol and acetaldehyde in rusty figs significantly decreased during ripening (Table 1). The emission of acetic acid was not significantly correlated with stage of ripening (Table 1). In fruit of both species, the emission rate of methanol was positively correlated with stage of ripening (Table 1).

Ethanol as an Odor Cue

Bats were not attracted to any of the mixtures of ethanol in water compared to water alone (Fig. 2A). At low concentrations of ethanol (0.01, 0.1, 0.3, 0.5, and 0.7%), they had no preference for mango juice mixed with ethanol over mango juice alone (two-

Table 1 Correlations between the emission rates of ethanol, acetaldehyde, acetic acid, and methanol and the stage of ripening of dates and of rusty figs

Dates	Emission rates for dates (ng hr ⁻¹ g ⁻¹ fresh fruit) (mean ± SE)				Rank-Spearman correlation coefficient	<i>P</i>
	Unripe green (<i>N</i> = 3)	Unripe yellow (<i>N</i> = 4)	Ripe brown (<i>N</i> = 5)

Fig. 2 Comparison of the responses of Egyptian fruit bats in odor experiments to (A) ethanol in water vs. water and (B) ethanol in mango juice vs. mango juice. In (A), *no choice* means that the bat inspected the feeders but did not settle on any of them, and *empty feeder* means that after inspecting the feeders and the bat settled on an empty feeder. Asterisks denote significant differences ($P < 0.05$) from binomial tests

tailed binomial test, $P > 0.05$ in all cases, Fig. 2B). However, they preferred the mango juice alone over mango juice mixed with ethanol at 1 and 2% (two-tailed binomial test, both $P < 0.05$). These results indicate that Egyptian fruit bats might use the smell of ethanol to assess food quality by recognizing it when present in relatively high concentrations and also that alone it does not serve as a short-distance attractant.

Methanol as an Odor Cue

Bats visited feeders with mango juice more often than feeders containing methanol in water (one-tailed binomial test, all $P < 0.05$, Fig. 3A). They had no preference for mango juice mixed with different amounts of methanol compared to mango juice alone (two-tailed binomial test, all $P > 0.05$, Fig. 3B). Thus, they were neither at-

tracted nor deterred by the smell of methanol at any of the concentrations used in the experiments.

Discussion

We analyzed the volatile products of fermentation emitted by dates and rusty figs to test the hypothesis that compounds changing in emission during ripening may be used as odor cues by fruit-eating bats. We identified three volatile compounds produced by fermentation in both dates and rusty figs: ethanol, acetaldehyde, and acetic acid. However, we certainly did not identify all gaseous fermentation products from these fruits. A wide variety of volatiles are known to be produced during microbial fermentation in fruit, including acids, alcohols, esters, aldehydes, ketones, and polyols (Mangas et al., 1994; Vidrih and Hribar, 1999; Fleet, 2003). Further experiments with

more fruit samples and for longer times under low $[O_2]$ might help to identify more compounds.

Emission rates of ethanol, acetaldehyde, and acetic acid in dates all increased from one stage of ripening to the next. The opposite occurred with ethanol and acetaldehyde in rusty figs, whereas no changes in the emission rate of acetic acid during maturation were detected. Given that ethanol and acetaldehyde are the main products of fermentation in both dates and rusty figs, and that their emission rates change during ripening, these molecular species appear to be good candidates with which to test our hypothesis.

In contrast to acetaldehyde, for which only toxic effects are known, ethanol is both a nutrient, at low concentrations, and a toxin, at high concentrations (Fadda and Rossetti, 1998; Lieber, 2000). Ethanol may have both short- and long-term positive effects on a frugivorous animal (Dudley, 2000, 2002). In addition, ethanol concentration in fruit is correlated with its sugar content (Dominy, 2004; Dudley, 2004; Senesi et al., 2005), and it increases during ripening in several species consumed in the wild by Egyptian fruit bats (Sánchez et al., 2004).

Based on the above, we hypothesized that ethanol emitted by food serves as an odor cue to Egyptian fruit bats. The bats were not attracted by the smell of ethanol in water or in mango juice at concentrations similar to those in ripe fruit, compared to mixtures without ethanol. Sánchez et al. (2004) suggested that the presence of yeasts in fruit, via the ethanol they produce, could increase the probability of visits by potential seed dispersers; therefore, over evolutionary time the fostering of yeast growth may have been incorporated into the reproductive strategy of fleshy fruited plants. We did not find evidence, however, to support this hypothesis.

Janzen (1977) suggested that microorganisms and frugivorous vertebrates compete for sugars present in fruit. Consequently, decay-causing microorganisms produce compounds toxic to vertebrates, and vertebrates may have developed the means to detect those compounds. Our data support Janzen's hypothesis in that ethanol at concentrations greater than 1%, which often characterizes overripe unpalatable fruit, elicited avoidance in Egyptian fruit bats. Thus, our results suggest that ethanol at high concentrations is used as an odor cue aiding fruit bats to identify low-quality fruit.

In addition, the emission rate of methanol changed during maturation, both in dates and rusty figs. The increase in methanol is related to fruit softening because of the action of the enzyme pectin methylesterase (PME; Lefever et al., 2004). PME catalyzes the demethoxylation of cell-wall pectins, and its synthesis increases during fruit ripening (Frenkel et al., 1998; Supriyadi et al., 2003). Given that methanol emission rate is related to changes in fruit quality, we suspected that methanol might be used as an odor cue by fruit bats, particularly as an indicator of unpalatability because of its toxic effects. However, in contrast to our prediction, fruit bats were neither attracted nor deterred by the smell of methanol in water or mango juice at any concentration.

Cutaneous exposure to methanol, its inhalation, or ingestion can be deleterious because methanol is oxidized into formaldehyde and then to formic acid. The metabolic acidosis that characterizes methanol poisoning may cause reduced level of alertness, visual impairment, and even death (Shusterman et al., 1993). Nevertheless, not all mammal species are equally sensitive to methanol. Primates appear to be highly sensitive to it because of their limited ability to catalyze formic acid to carbon dioxide (Black et al., 1985). In contrast, rodents are far less sensitive because they are competent at metabolizing formic acid (Makar and Tephly, 1976; Black et al., 1985). It

seems that Egyptian fruit bats are not sensitive to methanol at the levels presented in our experiments.

We isolated the effect of the smell of two common aliphatic alcohols present in fruit. Our results partially support the hypothesis that volatile compounds that change in emission during fruit ripening may be used as odor cues by fruit bats. So far, we have no evidence that either ethanol or methanol attracts fruit bats, but rather our results suggest that the smell of ethanol at high concentrations may help them to recognize unpalatable fruit. The possibility still exists that either ethanol or methanol acts as attractant to fruit bats in synergy with other volatile compounds. Indeed, mixtures of different products of fermentation are known to attract fruit-eating moths (Cosse et al., 1994) and beetles (Rochat et al., 2000). In addition, ethanol and methanol might also act as long-distance cues to fruit bats for finding patches of fruiting plants, rather than as short-distance cues for assessing fruit quality.

Finally, although both ethanol and methanol at high concentrations are likely toxic to Egyptian fruit bats, these animals may behaviorally respond more to the possible consequences of ethanol ingestion than to the toxic effects of methanol. Thus, future studies on the physiology of ethanol and methanol pharmacokinetics in Egyptian fruit bats may help us to understand their behavior while selecting food.

Acknowledgments We thank A. Zabari, A. Fennec, and R. Glukhikh for their help capturing and maintaining the bats and to Prigat International Ltd. for contributing mango juice. We also thank two anonymous reviewers for constructive comments. Abstract Mammalian scent marking is often associated with territorial defense. However, males and females may demonstrate different activity patterns and play different roles. Female mammals nurture the young during lactation, while males purportedly perform other tasks more frequently, such as territorial maintenance and defense. This paper investigates the contribution made by mated pairs of adult males and females to territorial scent-marking in the obligate monogamous Eurasian beavers (*Castor fiber*). We hypothesized that both sexes should show territorial behavior, and predicted that they deposit a higher proportion of scent marks at borders. We also hypothesized that a sexual dimorphism exists due to reproductive constraints on the females, and predicted that males should invest significantly more in scent-marking behavior than females during summer. We obtained behavioral data by radio tracking six mated pairs of Eurasian beavers during spring and summer 2000–2001 on two rivers in southeastern Norway. Our results showed that both males and females clustered their scent marks near territorial borders, but males deposited a larger number of scent marks than females and spent more time at borders. Males were also found to have a higher scent marking rate and scent marks per night than females during summer, but not during spring. Overall, scent marks per night were higher in males than females. We conclude that both males and females Eurasian beavers carry out territorial behavior by scent marking, but males carry a larger part of the territorial defense during summer when females lactate. Our results are discussed in the light of the codefense hypothesis.

Introduction

Several nonexclusive hypotheses have been proposed to explain why animals scent-mark (see Back et al., 2002). Scent marks might serve several functions, which may change or vary with time of year or location of the mark. However, it is widely accepted that mammals scent mark their territories to advertise their occupancy and ownership of the territory (e.g., Gosling, 1982; Sillero-Zubiri and Macdonald, 1998), but it is still under debate how scent marks actually function in terms of territory maintenance (Gorman, 1990; Gosling, 1990; Richardson, 1991, 1993).

The “scent-matching” hypothesis posits that scent marks provide an olfactory link between a resident owner and his territory, and that this enables intruding animals to recognize the chance of escalated conflicts (Gosling, 1982; Gosling and Roberts, 2001). By matching the scent of a territory owner with those of nearby scent marks, an intruder employs the unique property of olfactory signaling that includes the provision of both a historical and a spatial record of a territorial individual’s behavior. Territory owners can thus signal their status to intruders in a way that cannot be mimicked and that is to their advantage in subsequent encounters (Gosling, 1982). Intruding animals (independent of gender), upon entering a foreign territory, quickly discover that the area is already occupied, as scent marks are placed at the border (Gorman and Mills, 1984; Richardson, 1993). The threat of being detected and possibly becoming involved in a fight should keep intruders to the border region, when it does not completely deter them from intruding (Sliwa and Richardson, 1998). According to the hypothesis, territory owners should also remove or replace marks of others (Gosling, 1986). It is, thus, crucial that both sexes maintain their scent marks in such a way that maximizes the success of matching (see Gosling, 1986; Gosling and Roberts, 2001; Roberts and Lowen, 1997). This is achieved both by replenishing their own scent marks on a regular basis and by removing or replacing marks of competitors within their territory (Roberts, 1998; Rich and Hurst, 1999).

Both sexes usually scent mark in mammals (e.g., Gosling and Roberts, 2001). However, males and females may demonstrate different activity patterns and play different roles. Female mammals nurture the young during lactation, while males purportedly perform other tasks more frequently, such as territorial maintenance and defense. If one sex ranged further than the other did, the former may encounter more intruders or unmarked regions and respond by marking at higher rates. Selection could then favor individuals of this sex with relatively larger or more active scent structures (Rosell and Schulte, 2004). Also, a seasonal difference in scent marking activity may have been developed due to energy constraints on females during summer.

The Eurasian beaver (*Castor fiber*) is a typical obligate monogamous species (Wilsson, 1971; Kleiman, 1977). They defend territories, invest in their territories by the construction of dams and lodges, have young with an extended period of maturation, and the adult male exhibits a relatively high degree of both direct and indirect parental care (Wilsson, 1971; Rosell, 2002). They live in family units consisting of an adult pair and their offspring (Wilsson, 1971; Nolet and Rosell, 1994). Breeding pairs maintain long-term pair-bonds and copulate during January–March (Wilsson, 1971). Kits are born on average on June 1, and the adult male as well as subadults of both sexes help rearing them (Wilsson, 1971). Some behavioral differences in adult males and females have been observed, especially during spring and summer when young are reared (Wilsson, 1971). Two recent studies on mated male and female Eurasian beavers suggest that males have significantly larger kernel

home ranges during the whole tracking period (March–August) and after parturition (Herr and Rosell, 2004), and that males allocate significantly more time to travel (Sharpe and Rosell, 2003).

In beavers, there are no external differences between the sexes except for visible nipples in lactating females (Wilsson, 1971). Both sexes possess two anal glands and two castor sacs where retention of urine creates the fluid castoreum (Rosell, 2002). During scent marking of their territories, castoreum is deposited on scent mounds or on the ground (Rosell and Sundsdal, 2001). The number of scent marks is significantly higher in spring when subadults disperse (Rosell et al., 1998). The anal gland secretion is occasionally deposited; however, its role in territorial scent marking is not yet fully understood (Rosell and Bergan, 1998; Rosell and Sundsdal, 2001). Both sexes and all age classes (>5 mo) participate in scent marking (Wilsson, 1971).

A variety of hypotheses have been assumed for scent marking in the two beaver species, i.e., the Eurasian beaver and the North American beaver (*C. canadensis*) (see review in Rosell, 2002). However, by testing alternative hypotheses, Houlihan (1989) confirmed the territorial function of North American beaver scent marks and rejected other interpretations (see also Schulte, 1998). Scent marking in the Eurasian beavers likewise serves a territorial function (Rosell, 2002). Scent marks are concentrated near territorial borders, apparently to maximize the signal effect to potential trespassers on or before entering the territory (Rosell et al., 1998; Rosell, 2002).

More information is needed about frequency of marking by different group members (age, social status, and sex) and behavioral context in which the signal is deposited. In this scenario and given the obligate monogamous nature of the Eurasian beaver, it is interesting to investigate whether scent marking behavior is similar between the sexes and if a seasonal difference exists. Previous studies on sex differences in scent marking in North American beavers have either focused on the reaction to experimentally constructed scent marks (Butler and Butler, 1979; Svendsen and Huntsman, 1988; Müller-Schwarze and Houlihan, 1991), or when based on direct observation of scent marking, included unequal numbers of males and females (Buech, 1995). Only anecdotal information exists on Eurasian beavers, based on animals in captivity (Wilsson, 1971). None of the studies above used observations of mated pairs.

This paper investigates the contribution made by mated pairs of adult males and females to scent marking in Eurasian beavers. We hypothesized that both sexes should show territorial behavior and predicted that they deposit a higher proportion of scent marks at borders. We also hypothesized that a sexual dimorphism exists due to reproductive constraints on the females, and predicted that males should invest significantly more in scent-marking behavior than females during summer. We examined the sexual dimorphism issue by presenting the rate of marking, activity patterns, and the marking context.

Methods and Materials

Study Area and Study Animals

We collected data in Eurasian beaver territories along the Gvarv and Saua Rivers in Telemark, southeastern Norway, during spring and summer of 2000 and 2001. Both rivers meander through a semiagricultural and mixed forest landscape. The Saua River forms part of the Telemark Canal, and at either end of the area studied are

canal locks and weirs. The Gvarv River follows a more natural flow regime and discharges into Lake Nordsjø, part of which forms a section of one of the territories. Both rivers are either too wide for beavers to build dams or too deep to make it necessary. Beavers have inhabited the area since the 1920s (Olstad, 1937). Hunting pressure within the study area is either very low or nonexistent, and the beavers are used to human presence.

Subjects consisted of 12 Eurasian beavers ($\bar{X} \pm SD$ weights: males = 21.3 ± 1.4 kg; females = 22.8 ± 2.6 kg), which were the reproducing pairs in six territories. Assessment of pairs was based on previous trapping records of weights, incidence of lactation, and behavioral observations (F. Rosell, unpublished data). We caught animals from a boat, by using landing nets, during September, March, and April 1999–2001 (Rosell and Hovde, 2001). Permission for capture, handling, and surgical procedures was provided by the Norwegian Experimental Animal Board and the Norwegian Directorate for Nature Management. Licensed veterinarians carried out all surgical procedures. To facilitate handling and tagging, each beaver was placed head first into a cloth sack and restrained while another researcher applied ear tags by maneuvering the beaver's ear out through a small hole cut in the sack. No beavers responded aggressively while confined in the sack; they tended to remain comparatively docile, and none was visibly injured by the procedure. Individuals were tagged with numbered plastic ear tags (3.5 cm; Dalton Continental, Lichtenvoorde, The Netherlands) or Monel metal ear tags (1.5 cm; National Band and Tag Co., Newport, KY, USA) or both. Each beaver was weighed, implanted with a microchip measuring 1 cm (Destron 490, St. Paul, MN, USA) in the neck, and sexed by the color of the anal gland secretion (Rosell and Sun, 1999; Rosell and Bjørkøyli, 2002). We assumed that all females gave birth during both 2000 and 2001 based on observations of nipple size, presence of kits, sound of kits inside the lodge, and transport of branches into the lodge during July (Wilsson, 1971).

During September, March, and April, prior to the 2000 field season, beavers from five of the six pairs studied were implanted with an Alterra TX30.3A1 intraperitoneal 30 MHz radio transmitter (63 g) equipped with temperature and movement sensor [Alterra (IBN/DLO), AA Wageningen, the Netherlands] (Ranheim et al., 2004). To recover completely, all animals were allowed a minimum of 1 wk before tracking began. However, the behavior and movement of the beavers did not appear to be affected by the implanted transmitters, except for the first 2 d when more time was spent inside the lodges. The transmitter signal was detected by using a one-element loop antenna (Alterra) and an Icom IC-R10 receiver (Icom Inc., Osaka, Japan). Signal reception range varied between 300 and 600 m from a boat (Nolet and Rosell 1994). In April 2001, the last two beavers (plus one with an failed intraperitoneal transmitter) were fitted with external tail transmitters (Advanced Telemetry Systems Inc., Isanti, MN, USA; Model 16 M ear tag for beaver tail, weight = 38 g) operating at 142 MHz (F. Rosell, unpublished data). Belt pliers were used to perforate the tail approximately 10 cm from the base of the tail and 3.1–2.4 cm from the lateral edge. The transmitter was secured with a bolt, washer, and nut. A plastic holder was inserted to facilitate the withdrawal of the bolt when the transmitter was recovered. The beavers were released near the capture site less than 10 min after capture. Animals showed normal behavior less than 15 min after their release. Signals were detected with a handheld RX-98 H tracking receiver with built-in foldable antenna (TVP Positioning AB, Lindsberg, Sweden). Mean ($\pm SD$) signal reception range from a boat was 353 ± 112 m (F. Rosell, unpublished data).

Ethical Considerations

Please refer to Sharpe and Rosell (2003) and Herr and Rosell (2004) for detailed information on animal welfare issues and Ranheim et al. (2004) for descriptions of surgical procedures.

Data Collection

The study was conducted between March 7 and August 8, 2000, and between April 8 and July 31, 2001. Three beaver pairs were followed during both years, two additional pairs only in 2000, and one extra pair only in 2001. On average, each beaver was followed 6.8 nights (range 4–10), adding to a total of 82 nights, equally divided between males and females. Data were collected by a two-person team (one observer and one recorder). A boat with outboard motor was used to follow the beavers. During dark periods, a spotlight was used to illuminate the animals. Noise from the engine and the light did not seem to affect normal behavior in the beavers as long as they were approached with care (Nolet and Rosell, 1994; Rosell and Hovde, 2001, personal observation). Binoculars were used when needed. Focal animal sampling (Altmann, 1974; Martin and Bateson, 1999) was used, and a single beaver was followed throughout each observation night. The predetermined focal animal was initially located in its daily resting place by the signal from its radio transmitter. After the animal emerged, the observation team attempted to stay in visual contact with it throughout the night. Whenever an animal disappeared from view, the radio signal was used to locate it again. Both members of a pair were followed on consecutive nights in order to obtain “paired observations” and to reduce the effects of seasonal changes in weather conditions and behavior. Which member of a pair was to be followed first was determined at random by tossing a coin.

Beavers are nocturnal and usually have one activity period during each night (Wilsson, 1971; Nolet and Rosell, 1994). Thus, an observation session began when the focal animal emerged from its daily resting place in the evening and was terminated after the break of dawn when the animal had spent ≥ 30 min inside a lodge or burrow. This period of activity was defined as the “principal activity period” (Corp et al., 1997). If a beaver left its daily resting place undetected, the activity period was set to begin midway between the last time the animal was known to be in the resting place and the time it was discovered to have left. The same procedure was used to determine the end of the period. Behavior was continuously recorded throughout observation sessions and classified into eight categories (Altmann, 1974; Martin and Bateson, 1999) along with time and position (Table 1). We assigned the last behavioral pattern prior to scent marking and the first after scent marking as the “context prior” and “context after,” respectively. Positions were recorded on a 1:5000-scale map of the study area. During each observation night, seven environmental variables were recorded every 2 hr: air temperature ($^{\circ}\text{C}$), water temperature ($^{\circ}\text{C}$), precipitation (presence/absence), moon (presence/absence), mist (presence/absence), cloud cover (pct.), and wind (5 categories).

Scent Marking Rate and Scent Marks per Night

We used scent marking rate (SMR) and scent marks per night (SM/night) to compare scent marking activity between male and female beavers. To obtain

Table 1 Categories of Eurasian beaver behavior and description of each category

Behavior category	Description of behavior
Swimming	Swimming for more than 2 min in one direction or more than 25 m
Scent marking	Depositing castoreum, including behavior initiating scent marking
Foraging	On land foraging, eating food, or diving for aquatics
Grooming	Grooming own fur
Amicable interaction	Nosing, social grooming, “play wrestling,” ^a and other social interactions between family members
Agonistic interaction	Chasing, biting, “stick display,” ^b or other agonistic behavior towards nonfamily or family members
On bank	Entering bank for a shorter or longer period, sitting, walking, or sniffing the ground, but without performing any other characteristic behavior
Other	Any behavior not mentioned above

^a Moving of the head in a circle in an exaggerated manner, signaling to a group member (Wilsson, 1971).

^b A display behavior involving the use of tools where the beaver holds an object, usually a stick, in its mouth while moving its upper body rapidly up and down (Thomsen et al., unpublished data).

standardized scent marking rates, we divided the number of scent marks by the length (in hours) of the principal activity of the beaver, subtracted by the time the animal was either out of sight, or its behavior could not be deduced. Nightly visits to lodges or burrows were included, as scent marking has not been reported to occur here. Males had longer activity periods than females ($\bar{X} \pm \text{SD}$ min/night: males = 570.0 ± 97.5 ; females = 493.0 ± 144.7 ; Wilcoxon signed ranks test: $W = 725.5$, $P < 0.001$). Therefore, a rate like SMR will not reflect the actual contribution of a beaver to the total number of scent marks deposited each night. Thus, we also compared scent marks per night (SM/night). Before doing so, we checked whether we had managed to keep track of males and females equally well, i.e., whether the percentage of time we had the beaver “in sight” (see above) during the principal activity period was the same for both sexes. Not surprisingly, we had more minutes of “in sight” data on males due to the longer principal activity periods ($\bar{X} \pm \text{SD}$ min/night: males = 495.0 ± 112.1 ; females = 442.0 ± 131.3 ; $W = 683.5$, $P = 0.001$). However, the percentage of time we had the beaver in sight was equal between the sexes albeit marginal ($\bar{X} \pm \text{SD}$ percent: males = 86.2 ± 0.083 ; females = 89.8 ± 0.068 ; $W = 280.0$, $P = 0.051$). Thus, we chose to use the visible counts of scent marking instead of adjusting them for time not in sight.

We divided our data into two periods: (1) spring (before parturition) and (2) summer (from parturition onwards). Parturition usually takes place around June 1, and was chosen as the division date (Wilsson, 1971; F. Rosell, unpublished data).

Spatial Distribution

Beaver territories can be considered as one-dimensional, as only a narrow strip of land is used along riversides (Nolet et al., 1994). Locations of territory borders used in this study were obtained from Campbell (2000) and Herr and Rosell (2004), who established borders based on minimum convex polygons (MCP) by fixes found during radio tracking performed concurrently with this study. We divided each beaver territory into two zones: (1) “border”—100 m bank length on both riversides

at shared borders, (2) “core”—the central part of the territory. A territory with two neighboring territories would have 400 m of border length. Border length did not vary considerably with territory size and a fixed length of 100 m bank length was used in all cases. Overlap between territories is minimal (Herr and Rosell, 2004), and 100 m bank length is, therefore, sufficient to encompass overlapping sections. Furthermore, the territories of pair members overlapped on average by $81.6 \pm 14.0\%$ SD (Herr and Rosell, 2004).

Data Analysis

Normality was tested by using Shapiro-Wilk test (SPSS Inc., 1999) and homogeneity of variance by using Levene’s test (Dytham, 1999). If assumptions about continuity, normality, and homogeneity were met, parametric tests were used. When assumptions of normality could not be met even after transformation of data, the equivalent nonparametric tests were used. SMR and SM/night were normality-distributed for overall year data and thus one-way ANOVA could be used to compare scent marking between pairs and Pearson correlation to investigate correlations within pairs (Sokal and Rohlf, 1995). We choose to use the nonparametric Wilcoxon signed ranks tests to compare SMR and SM/night between males and females due to the low sample size and problems of obtaining normality during seasons (Sokal and Rohlf, 1995). The sampling unit for paired statistics was the individual beaver in order to avoid the “pooling fallacy” (Martin and Bateson, 1999), which implies not to treat repeated measures of the same subject as independent samples. Chi-square tests were used to analyze spatial distribution of scent marks (Sokal and Rohlf, 1995). Before statistical testing, expected frequencies of scent marks in each zone were adjusted for bank length, as core bank lengths were much larger than border bank lengths. Spearman rank correlation was used to compare the context of male and female scent marking (Sokal and Rohlf, 1995). Data from males and females were pooled to obtain enough data in each behavioral category. Spearman rank correlation was used to control for environmental influences. Bonferroni adjustment for multiple comparisons was applied because of the high number of correlations (Sokal and Rohlf, 1995). Two-tailed tests were used in all analyses and $P < 0.05$ was used as the level of significance. Statistical tests were run in SPSS version 10.0 (SPSS Inc., 1999) and Analyze-it (version 1.71).

Results

Territorial Function

A total of 806 scent marks (SM) were registered (males = 480, females = 326; Table 2). Three animals (two males and one female) were the main contributors to the total number of scent marks deposited, with 20.5, 26.8, and 28.7%, respectively (Table 2). Those three animals came from two pairs (L2a and L2b), that accounted for 55.5% and 29.4% of all scent marks deposited by the six pairs (Table 2). The remaining four pairs each contributed 6.1% or less. Both SMR and SM/night varied significantly between pairs (one-way ANOVA; SMR: $F_{5,6} = 11.17$, $P = 0.005$; SM/night: $F_{5,6} = 12.81$, $P = 0.004$). Within pairs, male and female SMR and SM/night were correlated (Pearson correlation; Spring: $R^2 = 0.88$, $N = 6$, $P = 0.019$; Summer: $R^2 = 0.92$, $N = 6$, $P = 0.010$).

Table 2 Number of observation nights in six Eurasian beaver territories, number of scent marks observed, and relative contribution (in percent) to total number of scent marks within pairs, between pairs and between pairs with the sexes combined

Territory	Nights	No. scent marks		Contribution within pairs (%)		Contribution between pairs (%)		Contribution between pairs—sexes combined (%)
		Male	Female	Male	Female	Male	Female	
L1	14	27	2	93.1	6.9	3.3	0.2	3.6
L2a	20	231	216	51.7	48.3	28.7	26.8	55.5
L2b	18	166	72	69.6	30.4	20.5	8.9	29.4
L5	8	27	21	57.1	42.9	3.5	2.6	6.1
L6	14	18	11	62.1	37.9	2.2	1.4	3.6
N2	8	11	4	73.3	26.7	1.4	0.5	1.9
SUM	82	480	326					

All but four scents marks (three made by two females, one by a male) were deposited within the marker's own territory (border zone included). Males and females scent marked significantly more in the border zones than expected when compared to the time spent in border and core zones (Table 3, males: $\chi^2 = 1101.429$, $df = 1$, $P < 0.001$; females: $\chi^2 = 1142.360$, $df = 1$, $P < 0.001$). Both sexes also scent marked significantly more in the border zones than would be expected if the deposition had been according to bank length (Table 3, males: $\chi^2 = 935.348$, $df = 1$, $P < 0.001$; females: $\chi^2 = 696.193$, $df = 1$, $P < 0.001$).

Sexual Dimorphism

Within each pair, most scent markings observed were made by males, with the percentage ranging from about 52% to 75% (except for pair L1 where the male

Table 3 Scent marking by male and female Eurasian beavers in the border and core zones of their territories

	Border	Core
Males		
Obs ^a	311	168
Exp ^b	64/72	415/407
% ^c	64.9	35.1
Females		
Obs	231	92
Exp	39/53	294/270
%	70.9	29.1

^a Observed number of scent marks.

^b Expected number if scent marks had been randomly distributed according to time in zone/length of bank in zone.

^c Observed number of scent marks in percent.

Number of scent marks observed and number of scent marks expected according to time spent in each zone and expected according to bank length of the border and core zones, respectively.

made more than 90% of all scent marks; Table 2). There was no difference in SMR between the sexes when looking at the overall study period [Fig. 1a(I)]. However, this was attributable to only one female having a higher rate of marking than her mate. SM/night was significantly higher in males than females [Fig. 1b(I)]. From spring to summer, five males increased their marking rates and, of these, four males had a higher SM/night during summer. Among the females, a similar pattern was observed with four females having a higher SMR and five a higher SM/night in summer than in spring. In the couple from territory L2a, both SMR and SM/night dropped considerably between seasons [Fig. 1a(I–II) and b(I–II)]. During summer, both SMR and SM/night was significantly higher in males than in females. During spring there was no difference in SMR with two females having a higher rate than their mates. The same trend was observed for SM/night; however, only one female caused the difference [Fig. 1a(I–II) and b(I–II)].

Males and females deposited the same proportion of their scent marks in border and core zones (Table 3, $\chi^2 = 0.818$, $df = 1$, $P = 0.366$). However, males spent significantly more time in the border zones than females and spent a significantly higher proportion of their total activity time there (Table 4). This was also true when looking at the spring season. In the summer season, only absolute time was significantly different between the sexes, whereas proportion of time spent at borders was marginally nonsignificant (Table 4). Males would deposit more scent marks and females less scent marks than would be expected if the sexes had contributed equally to scent marking in each zone (Table 3, border: $\chi^2 = 9.993$, $df = 1$, $P < 0.001$; core: $\chi^2 = 19.167$, $df = 1$, $P < 0.001$).

^b June 1–August 8 (after parturition).

Significant results ($P < 0.05$) are marked with an asterisk.

All eight behavioral contexts of scent marking (Table 5), both before and after, were correlated between males and females (before: $r_s = 0.82$, $N = 8$, $P = 0.012$; after: $r_s = 0.86$, $N = 8$, $P = 0.006$). There was a correlation between behavior before and after scent marking in both sexes (males: $r_s = 0.72$, $N = 8$, $P = 0.045$; females: $r_s = 0.90$, $N = 8$, $P = 0.002$). The most common context of scent marking in both sexes, before and after scent marking, was swimming (32.8–37.9%). The second most common context was scent marking (30.0–34.3%), i.e., about one third of scent markings would be succeeded by renewed scent marking (multiple marking). All but 1 of 122 (0.82%) and 1 of 91 (1.01%) multiple markings made by males and females, respectively, occurred at borders. Foraging came third (14.8–21.2%). All other events contributed with less than 6%.

Table 5 Behavioral context of scent marking by Eurasian beavers

Behavior ^a	Males	Males	Females	Females
	Prior	After	Prior	After
Swim	33.0	37.9	32.8	37.2
SM	30.0	30.0	34.3	32.9
Forage	21.2	15.3	18.9	14.8
Agonistic	4.7	3.9	1.9	1.8
Amicable	3.0	3.0	3.4	2.2
On bank	3.0	3.0	4.9	5.8
Groom	2.7	2.5	1.9	1.1
Other	2.5	4.4	1.9	4.3
Number of events	406	406	265	277

^a See Table 1 for description of behaviors.

Percentage distribution of behaviors prior to and after scent marking events and number of events recorded in each category, data from each sex pooled. SM: scent marking.

SMR was not correlated with any of the weather variables nor with date in either sex (Spearman correlation with Bonferroni method for multiple comparisons: r_s , all $P > 0.05$). This was also true for each season separately.

Discussion

Territorial Function

The “scent-matching” hypothesis has received support from studies of scent marking in both the North American beaver (Sun and Müller-Schwarze, 1998) and Eurasian beaver (Rosell, 2002; Rosell and Bjørkøyli, 2002; Rosell and Steifetten, 2004). By scent matching, competitors or mates match the odor from scent marks with the odor of conspecifics they encounter (Gosling, 1982; Gosling and McKay, 1990). Thus, it is crucial that both sexes maintain their scent marks in such a way that maximizes the success of matching (see Gosling, 1986; Roberts and Lowen, 1997; Gosling and Roberts, 2001). The high proportion of scent marks deposited at borders by both sexes confirms that scent marking serves a major function in territorial defense in Eurasian beavers (e.g., Nolet and Rosell, 1994; Rosell, 2002). Also, all (except one) multiple makings occurred at borders. This is in accordance with our first hypothesis and prediction and in agreement with earlier studies on the Eurasian beaver (Rosell et al., 1998; Rosell, 2002). However, in these studies, no information about sex was provided. Both sexes of beavers frequently replenish their own scent marks on a regular basis (this study) and remove or replace marks of competitors within their territory (e.g., Rosell, 2002), further supporting the hypothesis.

A high degree of individual variation in scent marking was found in this study, varying more between pairs than within. Moreover, scent marking behavior was correlated between mated pairs. Thus, apparently the sex of the beaver has less influence on scent marking than scent marking by their mate. This suggests that marking rates in beavers are regulated by the individual beaver in response to outside stimuli, and that both members of a pair respond in a similar way to these stimuli. Number of scent marks varies spatially and temporally in populations of most species of mammals and can be correlated with food availability, breeding activity, levels of dominance, and individual density (Gosling, 1990). It is possible that differences in these factors between the territories in the present study may explain the differences in scent marking. Furthermore, the two territories with the highest degrees of marking (L2a and L2b) were assumed to have an ongoing dispute over position of territory borders, possibly due to a split into two separate territories.

Sexual Dimorphism

Our second hypothesis that a sexual dimorphism exists as a result of reproductive constraints on females was only partly supported. The low sample size may have resulted in low statistical power and an inability to detect any further differences. Also, a wide application of our findings to other habitats should be carried out with some caution. Nevertheless, the data provide no convincing evidence of any biological effects that were undetected by statistical analysis (i.e., means, median, and percentages for males and females were similar).

Overall (spring and summer), SM/night was significantly higher in males than in females. Males were also found to have a higher SMR and SM/nights than females during summer, but not during spring. This is in accordance with our prediction. Scent marking involves investment both in terms of time and energy (Gosling, 1986). For instance, scent marking at higher intensity has been shown to reduce growth rate and body size in mice (Gosling et al., 2000). Patrolling the territory in connection with scent marking is time-consuming and could be physically costly for beavers. It seems likely that males invest more time in territorial defense than females during the breeding period, because males do not need extra energy to accommodate a developing a fetus and cannot initially provide direct care to newly born offspring. Kits are born during summer and are reliant on milk from the female (all females were assumed to give birth in our study). Thus, females are more constrained by parental care than males, and have less time and energy to spend on territorial activities. Lactation and infant care impose heavy burdens and constraints on female mammals (e.g., Campbell and Reece, 2002).

This coincides with our observation that males deposited a significantly larger number of scent marks and spent more time at borders. This finding is also in accordance with that of Sharpe and Rosell (2003), who—in a study concordant with ours—showed that males spend more time traveling, and with Rosell and Schulte (2004), who suggested that a difference in territorial behavior between male and female has led to differential investment in scent structures. They suggested that females have larger castor sacs (low flushing rates) and smaller anal glands (infrequent use) because of reduced employment of both glands for territorial purposes, whereas males have the opposite configuration because of enhanced use of both glands in territorial demarcation. Hence, behavioral dimorphism might select for morphological dimorphism in signal producing structures, even in an obligate monogamous species.

Codefense

Our results coincide with the general picture of obligate monogamous mammals where both sexes participate in the defense of a joint territory (Clutton-Brock, 1989). Most mammals are intrasexually territorial, but several findings suggest that beavers are both intra- and intersexually territorial. Adult beavers of both sexes countermark where other conspecifics (of both sexes) have marked (Rosell, 2002; Rosell and Steifetten, 2004). A display (“stick display”) used in territorial context is used both intra- and intersexually (Thomsen et al., unpublished data). Beavers are able to recognize the concept of “relatedness” by a pheromone in the anal gland secretion. This would deter extrapair copulations (EPCs) by females, since the mate would be able to detect young unrelated to him and could treat them unfavorably or potentially kill them, and consequently favor monogamy (Sun, 2003). Furthermore, it would make mate change during the breeding season unlikely because the kits would be exposed to risk of infanticide if a stranger of either sex enters the territory, although definite proof of infanticide in beavers is lacking (however, see Haines, 1955). Since beavers evolved in northern latitudes and mating occur in late winter, when mobility is restricted by environmental conditions, male roving costs would also be high (Nolet and Rosell, 1994) and therefore the potential for EPCs is low.

For a territorial species like the beaver, there are benefits in codefending the territory (e.g., Mathews, 2002). No other socially monogamous rodent shows the

same degree of construction activities or foraging and food storage behavior as the beaver (Baker and Hill, 2003). The benefits of defending a large territory rather than only the immediate vicinity of the lodge likely arise from the long-term payoff of reducing the rate of resource depletion within the site and thus increasing the long-term viability of the territory (Campbell et al., 2005). These authors argue that the settlement pattern and reproductive history have a lasting impact on the territorial system of beavers due to a combination of low adult mortality, high dispersal costs, and avoidance of resource depletion. All these factors lower the individual energy investment in defense and reduce the risk of being evicted from the territory. Male beavers exhibit a relatively high degree of both direct and indirect parental care (Wilsson, 1971; Rosell, 2002)—for instance, males will bring food to offspring. Hence, defending a territory could be seen as an effort to secure a breeding space with adequate food resources to support a pregnant female and later offspring, ultimately increasing the males' reproductive success (Clutton-Brock, 1989). Likewise, territory defense by females is likely to be resource defense (Clutton-Brock, 1989).

Thus, cooperation between male and female should raise the odds of maintaining control over a large resource-rich territory in which their young can be successfully raised. Male parental care, combined with the benefits of defending a larger territory, could have led to the evolution of codefense and consequently a high degree of monomorphism in scent marking. Further studies comparing allocation by either sex to territorial behavior (e.g., scent marking) outside the breeding season could confirm the hypothesis that females contribute less to the defense during certain times of the year due to reproductive constraints.

Acknowledgments We thank Frode Bergan, Orsolya Bozsér, Ruairidh D. Campbell, Jan Herr, Bjørnar Hovde, Bruno Pinto, and Fiona Sharpe for assistance in the field, and Jon M. Arnemo and Birgit Ranheim for conducting the implant operations. The study was financially supported by Telemark University College. The experiments comply with the current laws of the country in which they were performed.

The Frequency of Occurrence of Acyclic Monoterpene Alcohols in the Chemical Environment does not Determine Olfactory Sensitivity in Nonhuman Primates

Abstract Using a conditioning paradigm, the olfactory sensitivity of five spider monkeys, three squirrel monkeys, and three pigtail macaques for six acyclic monoterpene alcohols that differ markedly in their frequency of occurrence in plant odors was assessed. The results showed that: (1) all three primate species have a well-developed olfactory sensitivity for acyclic monoterpene alcohols; (2) squirrel monkeys are significantly more sensitive for members of this class of odorants than the other two species and are able to detect all six odorants at concentrations below 0.1 ppm; and (3) there is a lack of positive correlations between olfactory sensitivity and the abundance of the acyclic monoterpene alcohols in flower odors and etheric oils. The results lend support to the growing body of evidence that suggests between-species comparisons of the number of functional olfactory receptor genes or of neuroanatomical features are poor predictors of olfactory performance. The findings do not support the hypothesis that olfactory sensitivity for members of a chemical class may be related to the frequency of occurrence of such odorants in a species' chemical environment.

animal's chemical environment (Hudson, 1999). Several studies both in human subjects (Möller et al., 1999; Dalton et al., 2002) and in animal models (Wang et al., 1993; Voznessenskaya et al., 1994; Yee and Wysocki, 2001), for example, have demonstrated that repeated exposure to a particular odorant selectively increases an organism's sensitivity to that odorant. This raises the possibility that differences in the frequency of occurrence of odorants in the chemical environment of a species might at least in part account for the observed differences in olfactory sensitivity both within and between species. This hypothesis is supported by reports that show that spider monkeys, squirrel monkeys, and pigtail macaques are markedly more sensitive to acetic esters (Laska and Seibt, 2002a; Hernandez Salazar et al., 2003) and aliphatic aldehydes (Laska et al., 2003a,b, 2006) than to ketones (Laska et al., 2005c) and carboxylic acids (Laska et al., 2000, 2004). Whereas the former two classes of odorants are found in a large variety of fruit odors, the latter two classes are only rarely found as components of potential primate food odors (Maarse, 1991). Unfortunately, there is only limited knowledge as to differences in the frequency of occurrence of individual members of the aforementioned substance classes in the chemical environment of the three primate species.

Terpenes comprise by far the largest class of volatile chemicals in plant odors, and at least in human subjects, they often determine the characteristic odor quality of flowers, fruits, and etheric oils emanating from the vegetative parts of plants (Burdock, 2001). Gas chromatographic analyses of a large number of flower odors (Knudsen et al., 1993) and etheric oils (Kubeczka, 2002) have demonstrated that certain members of this class of volatiles differ markedly in their frequency of occurrence in plant odors, despite their similarity in chemical structure.

It was the aim of the present study to test the hypothesis that olfactory sensitivity for members of a chemical class may be related to the frequency of occurrence of such odorants in a species' chemical environment. To this end, we tested three species of nonhuman primates for their ability to detect six acyclic monoterpene alcohols that differ markedly in their abundance in flower odors and etheric oils. All three primate species include a considerable proportion of plant material in their diets (Caldecott, 1986; Cant, 1990; Lima and Ferrari, 2003). Employing odorants that share a number of molecular features, such as sum formula and oxygen-containing functional group, and differ from each other in others, such as stereoisomery, position of a functional group, or presence/absence of a double bond, allowed us to additionally address the question of the impact of these features on detectability of odorants.

Methods and Materials

Animals

Testing was carried out by using five adult female spider monkeys (*Ateles geoffroyi*), three adult male squirrel monkeys (*Saimiri sciureus*), and two adult males and one adult female pigtail macaques (*Macaca nemestrina*). All animals had served as subjects in previous olfactory experiments and were familiar with the basic test procedure. The animals of a given species were not genetically closely related to each other. Conditions of the animals' maintenance have been described in detail elsewhere (Laska and Seibt, 2002a; Hernandez Salazar et al., 2003).

Behavioral Tests

The experimental procedures for assessing olfactory detection thresholds in the three primate species have been described in detail elsewhere (Laska and Hudson, 1993; Hübener and Laska, 2001; Laska et al., 2003a,b). Briefly, the animals were tested by using a food-rewarded instrumental conditioning paradigm. Olfactory detection thresholds were determined by testing the animals' ability to discriminate between increasing dilutions of an odorant used as the rewarded stimulus (S+) and the odorless solvent diethyl phthalate alone used as the unrewarded stimulus (S-). In each test trial, each monkey sniffed at both options, and then decided for one of the alternatives by performing an operant response that, in the case of a correct decision, was food-rewarded. Ten such trials were conducted per animal and session, and at least three sessions per experimental condition were performed.

Odorants

A set of six odorants belonging to the class of acyclic monoterpene alcohols was used (Table 1). The rationale for choosing these substances was to assess the monkeys' sensitivity for odorants that have been shown to differ markedly in their frequency of occurrence in flower odors (Knudsen et al., 1993) and etheric oils (Kubeczka, 2002), thus allowing us to assess whether olfactory sensitivity correlates with abundance of these odorants in the chemical environment of the three species tested here. At the same time, the six odorants are structurally similar to each other, i.e., they share certain molecular properties, such as sum formula and type of functional group, and differ in other properties, such as stereoisomery, position of a functional group, or presence/absence of a double bond, thus allowing us to assess the impact of these structural features on detectability (Fig. 1). Acyclic monoterpene alcohols act as attractants for pollinators (Pichersky and Gershenzon, 2002; Raguso, 2004). All chemicals were obtained from Fluka (Taufkirchen, Germany) and had a nominal purity of at least 99%. They were diluted by using odorless diethyl phthalate as the solvent.

Table 1 Odorants used and their percentage of occurrence in flower odors and etheric oils

Veridical name	Chemical name	Percentage of flower odors ^a	Occurrence in etheric oils ^b
Linalool	3,7-Dimethyl- <i>trans</i> -1,6-octadien-3-ol	15.0	85.4
Geraniol	3,7-Dimethyl- <i>trans</i> -2,6-octadien-1-ol	4.8	48.8
Nerol	3,7-Dimethyl- <i>cis</i> -2,6-octadien-1-ol	3.9	31.7
Citronellol	3,7-Dimethyl-6-octen-1-ol	2.0	17.1
Lavandulol	2-Isopropenyl-5-methyl-4-hexen-1-ol	0.2	7.3
Myrcenol	2-Methyl-6-methylene-7-octen-2-ol	0.0	0.0

citronellol

myrcenol

lavandulol

Data Analysis

In the method described here, the animal had two options: (1) to correctly open the container that carries the positive stimulus (hit) and (2) to open the container that carries the negative stimulus (false alarm). For each individual animal, the percentage of hits from the best three consecutive sessions per dilution step, comprising a total of 30 decisions, was calculated and taken as the measure of performance. Significance levels were determined by calculating binomial z -scores corrected for continuity from the number of correct and false responses for each individual and condition.

Correlations between olfactory threshold values of a given species (individual scores per stimulus were used), and the frequency of occurrence of the odor stimuli in plant material was calculated by using the Spearman rank-correlation test. Across-species comparisons of performance were conducted by using Mann–Whitney U tests for independent samples. All tests were two-tailed, and, if not otherwise mentioned, the alpha level was set at 0.05.

Results

Spider Monkeys

Figure 2 shows the performance of the spider monkeys in discriminating between various dilutions of a given acyclic monoterpene alcohol and the odorless solvent. All five animals distinguished dilutions as low as 1:10,000 geraniol, 1:3000 nerol, 1:1000 linalool, 1:30,000 citronellol, 1:30,000 myrcenol, and 1:100,000 lavandulol from the solvent (binomial test, $P < 0.05$), with single individuals even scoring better.

The individual spider monkeys demonstrated similar threshold values, and with three of the six odorants (nerol, myrcenol, and lavandulol), they differed only by a dilution factor of 3 between the highest- and the lowest-scoring animal. In the case of citronellol, they even showed identical threshold values.

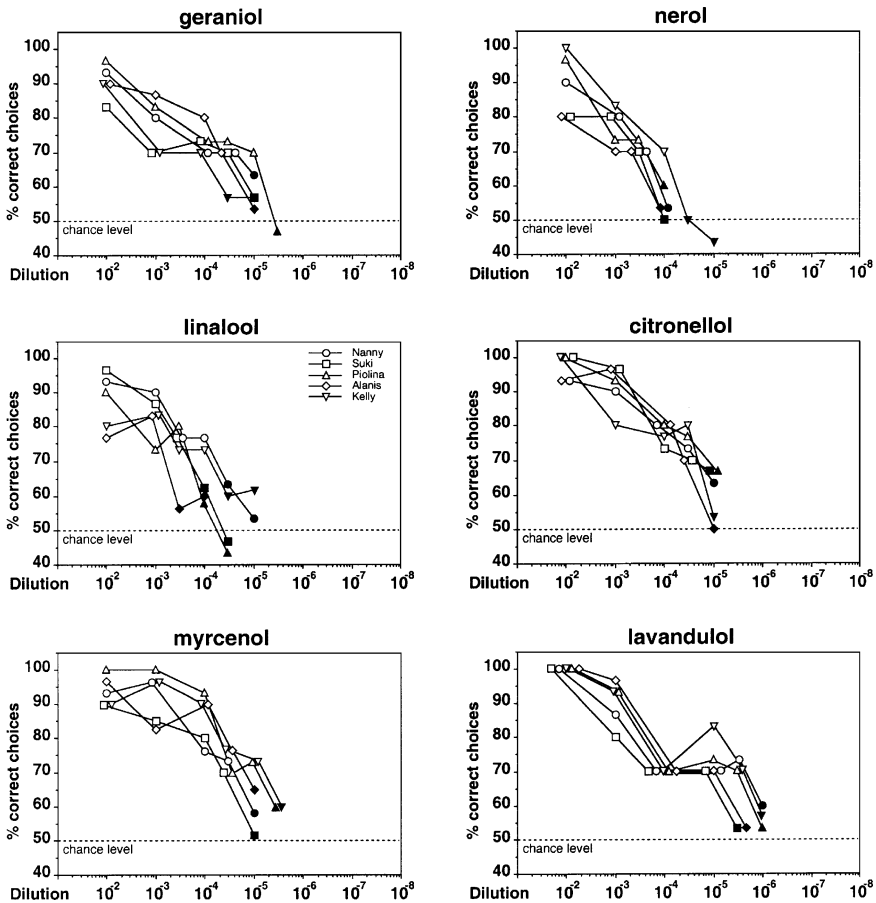

Fig. 2 Performance of five spider monkeys in discriminating between various dilutions of a given acyclic monoterpene alcohol and the odorless solvent. Each data point represents the percentage of correct choices from 30 decisions. The three different symbols represent data from each of the five individual animals tested. Filled symbols indicate dilutions that were not discriminated significantly above chance level (binomial test, $P > 0.05$)

sensitivity for a given odorant between individuals comprised a dilution factor of 10, and was found with geraniol and linalool.

Table 2 summarizes the threshold dilutions for the five spider monkeys and shows various measures of corresponding vapor phase concentrations (Weast, 1987), to easily compare the data obtained in the present study to those reported by other authors that used one of these convertible measures. With only one exception, threshold dilutions correspond to vapor phase concentrations below 1 ppm.

A significant negative correlation between the olfactory sensitivity of the spider monkeys for the six acyclic monoterpene alcohols tested and their frequency of occurrence in plant odors was found (Spearman, $r_s = -0.62$, $P < 0.001$). This means that the animals were more sensitive to monoterpene alcohols that presumably occur less frequently in their chemical environment compared to monoterpene alcohols that occur more frequently.

Squirrel Monkeys

Figure 3 shows the performance of the squirrel monkeys in discriminating between various dilutions of a given acyclic monoterpene alcohol and the odorless solvent. All three animals distinguished dilutions as low as 1:30,000 geraniol, 1:300,000 nerol, 1:30,000 linalool, 1:3 million citronellol, 1:300,000 myrcenol, and 1:10 million lavandulol from the solvent (binomial test, $P < 0.05$), with single individuals scoring even better.

Individual squirrel monkeys generally demonstrated similar threshold values, and with three of the six odorants, they differed only by a dilution factor of 3 (lavandulol), 10 (citronellol), or 33 (myrcenol) between the highest- and the lowest-scoring animal. The largest difference in sensitivity for a given odorant between individuals comprised a dilution factor of 1000 and was found with geraniol.

Table 3 summarizes the threshold dilutions for the three squirrel monkeys and shows various measures of corresponding vapor phase concentrations (Weast, 1987). In all cases, threshold dilutions correspond to vapor phase concentrations below 0.1

Table 2 Olfactory detection threshold values in spider monkeys expressed in various measures of vapor phase concentrations

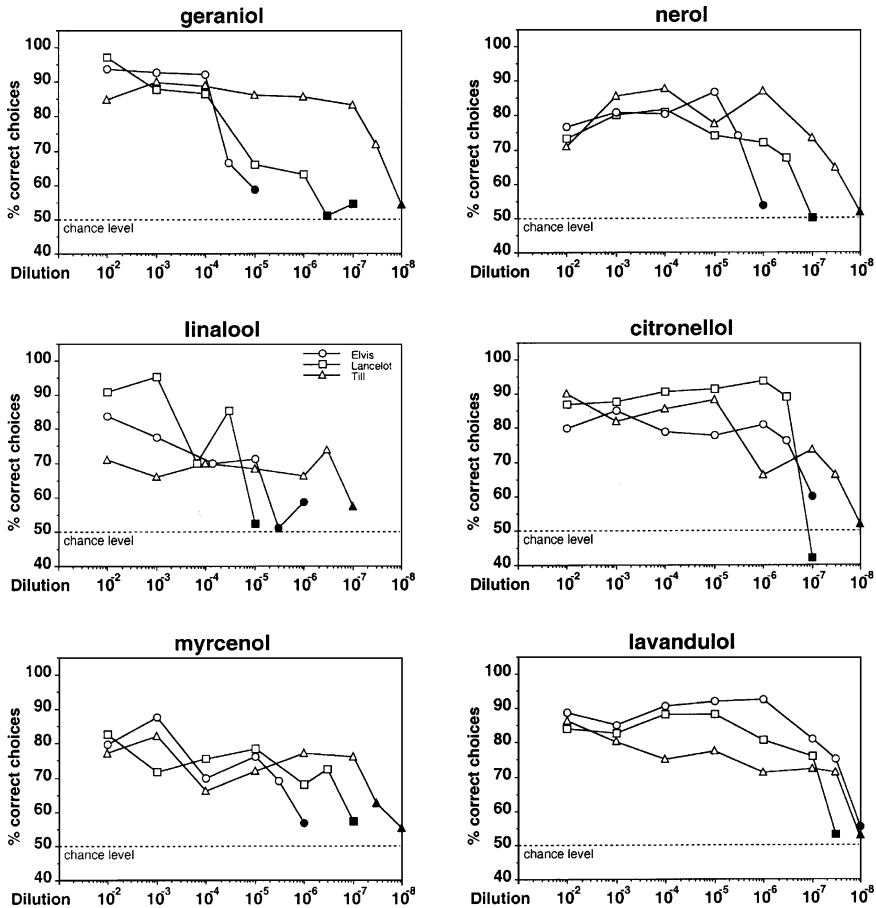

Fig. 3 Performance of three squirrel monkeys in discriminating between various dilutions of a given acyclic monoterpene alcohol and the odorless solvent. Each data point represents the percentage of correct choices from at least 30 decisions. The three different symbols represent data from each of the three individual animals tested. Filled symbols indicate dilutions that were not discriminated significantly above chance level (binomial test, $P > 0.05$)

ppm, and with citronellol and lavandulol, the animals were even able to detect concentrations below 1 ppb.

A negative correlation between the olfactory sensitivity of the squirrel monkeys for the six acyclic monoterpene alcohols tested and their frequency of occurrence in plant odors was found that fell short of statistical significance (Spearman, $r_s = -0.40$, $P = 0.09$).

Pigtail Macaques

Figure 4 shows the performance of the pigtail macaques in discriminating between various dilutions of a given acyclic monoterpene alcohol and the odorless solvent. All three animals distinguished dilutions as low as 1:100,000 geraniol, 1:30,000 nerol, 1:10,000 linalool, 1:10,000 citronellol, 1:1000 myrcenol, and 1:1000 lavandulol from the solvent (binomial test, $P < 0.05$), with single individuals scoring even better.

N indicates the number of animals.

The individual pigtail macaques generally demonstrated similar threshold values, and with three of the six odorants, they differed only by a dilution factor of 10 (myrcenol and lavandulol) or 30 (linalool) between the highest- and the lowest-scoring animal. The largest difference in sensitivity for a given odorant between individuals comprised a dilution factor of 300 and was found with citronellol.

Table 4 summarizes the threshold dilutions for the three pigtail macaques and shows various measures of corresponding vapor phase concentrations (Weast, 1987). With only one exception, threshold dilutions correspond to vapor phase concentrations below 1 ppm.

A positive correlation between the olfactory sensitivity of the pigtail macaques for the six acyclic monoterpene alcohols tested and their frequency of occurrence in plant odors was found that fell short of statistical significance (Spearman, $r_s = +0.39$, $P = 0.10$).

Across-Species Comparison of Performance

Considering all six odorants combined, the squirrel monkeys performed significantly better, i.e., showed lower detection thresholds than both the spider monkeys and the pigtail macaques (Mann–Whitney, $P < 0.001$). Furthermore, with all six odorants, the squirrel monkeys displayed the lowest individual detection threshold among the three primate species. No significant difference was found between the averaged performance of the spider monkeys and the pigtail macaques with the six acyclic monoterpene alcohols (Mann–Whitney, $P > 0.05$).

Discussion

The results of this study demonstrate, for the first time, that spider monkeys, squirrel monkeys, and pigtail macaques have a well-developed sensitivity for monomo-

lecular odorants belonging to the class of acyclic monoterpene alcohols. These findings are in line with earlier studies that used the same methods and animals that showed that these species have a well-developed olfactory sensitivity for carboxylic acids (Laska et al., 2000, 2004), acetic esters (Laska and Seibt, 2002a; Hernandez Salazar et al., 2003), aliphatic alcohols (Laska and Seibt, 2002b; Laska et al., 2006), aliphatic aldehydes (Laska et al., 2003a,b, 2006), and ketones (Laska et al., 2005c), and that squirrel monkeys have excellent olfactory discrimination capabilities (Laska and Freyer, 1997; Laska and Hudson, 1995; Laska and Teubner, 1998; Laska et al., 1999a,b, 2005b). Thus, the present results lend further support to the idea that olfaction may play a significant role in the regulation of behavior in these primate species.

Although only between three and five animals per species were tested, the results appear robust, as interindividual variability was remarkably low and generally smaller than the range reported in studies on human olfactory sensitivity, i.e., within three

N indicates the number of animals.

orders of magnitude (Stevens et al., 1988). In fact, for the majority of substances tested, there was only a factor of 3 or 10 between the threshold values of the highest- and the lowest-scoring animal of a species. Furthermore, with all substances tested, the animals' performance with the lowest concentrations presented dropped to chance level, suggesting that the statistically significant discrimination between higher concentrations of an odorant and the odorless diluent was indeed based on olfactory perception and not on other cues.

Figure 5 compares the olfactory detection threshold values obtained with the spider monkeys, squirrel monkeys, and pigtail macaques for the substances tested to those from human subjects. Although such across-species comparisons should be considered with caution, as different methods may lead to widely differing results (Hastings, 2003), it seems admissible to state that human subjects do not generally perform poorer than the nonhuman primates tested—despite the fact that the relative size of the human olfactory brain structures devoted to processing olfactory information is markedly smaller than that of the squirrel monkey, spider monkey, or the pigtail macaque (Stephan et al., 1988), and despite the fact that the number of functional olfactory receptor (*OR*) genes in *Homo sapiens* (≈ 350) is considerably smaller than that of *M. nemestrina* (≈ 700) and of *S. sciureus* and *A. Geoffroyi* (≈ 1000) (Rouquier et al., 2000; Glusman et al., 2001; Gilad et al., 2004). It should be mentioned that the threshold values of the human subjects for the acyclic monoterpene alcohols as depicted in Fig. 5 represent mean values (van Gemert, 2003), whereas the data points of the nonhuman primates represent individual threshold values found in the present study. Nevertheless, with four of the six substances tested, the human subjects demonstrated mean threshold values that were lower than the lowest individual threshold values of the spider monkeys.

Similarly, pigtail macaques generally did not perform poorer than spider monkeys, again despite the fact that the relative size of the olfactory bulbs and the number of functional *OR* genes in Old World primates are smaller than in New

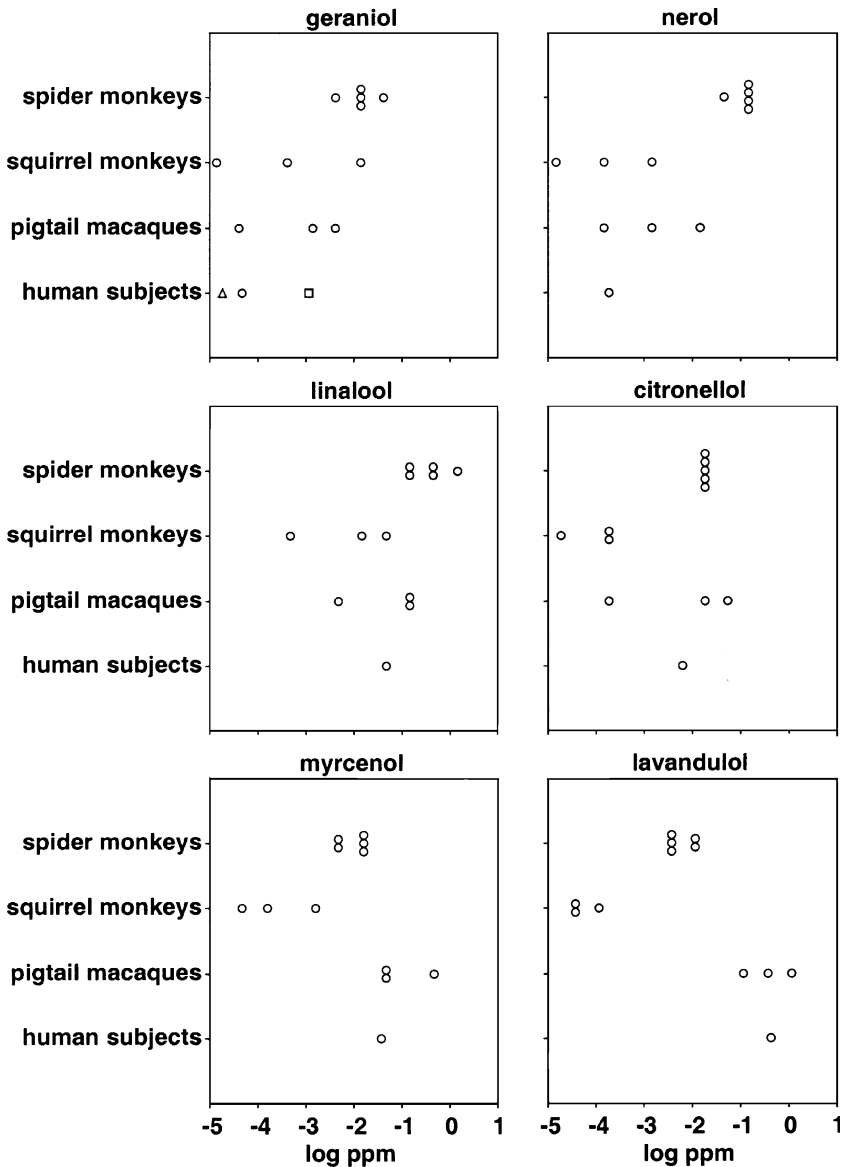

Fig. 5 Comparison of the olfactory detection threshold values (expressed as vapor phase concentrations) of the squirrel monkeys, the spider monkeys, and the pigtail macaques for the acyclic monoterpene alcohols tested to those of human subjects (van Gemert, 2003). Data points of the three monkey species represent individual threshold values, and data points of the human subjects represent mean values. Data points of the mouse (empty triangle; Schmidt, 1982) and the pig (empty square; Dorries et al., 1995) for geraniol are depicted in the same line as the human data and represent the lowest individual threshold values per species

World primates (Rouquier et al., 2000). These findings are in line with earlier studies that showed human subjects not to generally perform poorer in detecting aliphatic alcohols (Laska and Seibt 2002b) and carboxylic acids (Laska et al., 2000,

2004) compared to nonhuman primates, and Old World primates not to generally have a poorer sensitivity for aliphatic alcohols (Laska and Seibt, 2002b) and aldehydes (Laska et al., 2003a,b) than New World primates.

Thus, the present findings lend additional support to the notion that, at least within the order of primates, allometric comparisons of olfactory brain structures or differences in the number of functional *OR* genes do not allow us to draw generalizable conclusions as to olfactory sensitivity of any two species.

Unfortunately, only few data on olfactory sensitivity for acyclic monoterpene alcohols in nonprimate mammals are available. Figure 5 shows that squirrel monkeys, pigtail macaques, and human subjects are at least as sensitive for geraniol as the pig and the mouse, both species being regarded as having a particularly well-developed sense of smell. The findings are in line with earlier studies that reported all three primate species tested here to be at least as sensitive as, and with some substances even considerably more sensitive than, species such as the dog or the rat in detecting acetic esters (Laska and Seibt, 2002a; Hernandez Salazar et al., 2003) and aliphatic alcohols (Laska and Seibt, 2002b), although these nonprimate mammals possess relatively larger olfactory bulbs and do not show a reduction in their number of functional *OR* genes (Olender et al., 2004). This suggests that, here too, no reliable predictions as to species differences in olfactory performance between primate and nonprimate mammals are possible.

Our finding of a lack of significant positive correlations between olfactory sensitivity in spider monkeys, squirrel monkeys, and pigtail macaques and the frequency of occurrence of the acyclic monoterpene alcohols in flower odors and etheric oils is in contrast to our hypothesis, and the significant negative correlation found with the spider monkeys is difficult to understand. However, several possible explanations should be considered. First, we cannot exclude the possibility that the flower odors and etheric oils that have been analyzed for their contents of acyclic monoterpene alcohols (Knudsen et al., 1993; Kubezcka, 2002), although they include a large variety of plant species, may not be representative for the chemical environment of the primate species tested here. Thus, future studies should aim at assessing the specific composition of the volatile substances present in the habitat of the animal species under investigation.

Second, it might be that differences in ecological relevance rather than differences in frequency of occurrence of odorants may determine differences in olfactory sensitivity both within and between species. Pheromones, for example, have repeatedly been shown to be perceived (either by the main or the accessory olfactory system) at dramatically lower concentrations by species for which they serve a specific behavioral function compared to species for which this is not the case (Wyatt, 2003). Similarly, prey species have been shown to be much more sensitive to the odor of a predator compared to nonprey species (Laska et al., 2005a). Thus, future studies should aim at assessing the potential relevance of particular odorants in different behavioral contexts with a given species of animal.

Finally, it might be that the odorants tested here may be too similar to each other in their molecular structure to interact with sufficiently different subsets of olfactory receptor types to cause marked differences in sensitivity within a given species. This idea finds some support from a within-species comparison of performance with the different odorants. Geraniol and nerol, for example, represent stereoisomers; that is, they are identical in structure except for *cis-trans* isomery (see Fig. 1), and none of the three species tested here differed markedly in respective thresholds for these

two odorants. Similarly, spider monkeys, squirrel monkeys, and pigtail macaques showed similar detection thresholds for nerol and citronellol, suggesting that the presence or absence of a double bond (see Fig. 1) had little influence on detectability of these odorants. However, there were several cases in which the position of the functional alcohol group (see Fig. 1) clearly affected olfactory sensitivity (e.g., lavandulol and geraniol with the pigtail macaques, nerol and myrcenol with the spider monkeys, and lavandulol and linalool with the squirrel monkeys). Future studies should aim at assessing whether structural similarity of stimuli is restricted to the class of odorants tested here or whether this may represent a more general phenomenon.

In summary, the results of this study provide further evidence of a well-developed olfactory sensitivity in three species of nonhuman primates. The findings lend additional support to the suggestion that between-species comparisons of neuroanatomical features or of the number of functional *OR* genes are poor predictors of olfactory performance. Furthermore, the findings do not support the hypothesis that olfactory sensitivity for members of a chemical class may be related to the frequency of occurrence of such odorants in a species' chemical environment. We suggest that differences in the behavioral relevance of odorants and/or differences in the degree of structural similarity may account for both within- and between-species differences in olfactory sensitivity.

Abstract We report the volatile composition of the body scent of male C57BL/6J mice in comparison to the volatile composition of their urine. From a total of 67 components, nitromethane, propanoic acid, dimethyldisulfide, 1-octene, 1-hexanol, hexanoic acid, indole, α - and β -farnesene, and one unidentified component were observed only in the volatiles from the body of mice. On the other hand, 3-penten-2-one, 3-methyl-2-buten-1-ol, 3-methyl-cyclopentanone, *p*-xylene, 3-hepten-2-one, 2,3-dehydro-exo-brevicommin, benzylmethylketone, and 13 unidentified components were only found in urine volatiles. All other substances were present in the volatiles of both mice and their urine. Aliphatic aldehydes from pentanal to decanal were prominent mouse odor components. Because receptors for these aldehydes have been extensively characterized in the main olfactory organ, these components may be important for mice in recognizing their conspecifics.

Keywords Aliphatic aldehydes · Odorant · Odorant receptor · Urine volatiles · Mouse body scent · Odor composition

Introduction

Social signaling between mice involves volatile and nonvolatile components present in secretions from the skin, the reproductive tract, and in urine. Volatile cues recognized from a distance interact with the main olfactory system. In contrast, the vomeronasal system requires direct contact and sniffing for activation (Luo et al., 2003) and it can therefore process chemical cues independent of their volatility. A number of low molecular mass volatile compounds have been characterized that elicit specific behavioral responses. These compounds are perceived either through the main or the accessory olfactory organ (reviewed in Brennan and Keverne, 2004; Stowers and Marton, 2005). However, compared to the explosive increase in knowledge on the molecular and cell biology of the olfactory system following the cloning of the receptor genes (summarized by Julius and Katz, 2004), considerably less effort has been directed toward the analysis of the complex mixtures of volatile and nonvolatile chemicals that are used by mice for recognition of kin or territory, in reproduction, or for behavioral responses such as fear and aggression. This situation motivated us to compare the volatiles in the mouse body scent vs. urine-derived volatiles.

Body scent, which may be important for recognition of mice from a distance, has so far not been analyzed. In contrast, there are several reports of the composition of urine odor. Miyashita and Robinson (1980) identified 94 volatiles collected by a cryogenic trapping procedure from urine of male Swiss Webster mice. In the study of Schwende et al. (1986), volatiles were flushed from urine of male BALB/c mice by helium gas and collected on Tenax-filled tubes. Subsequent gas chromatography/mass spectroscopy (GC/MS) led to the characterization of 61 components, among them several substances considered to be mouse pheromones (reviewed by Novotny, 2003). Singer et al. (1997) and Willse et al. (2005) extracted urine pools collected from male C57BL/6 mice with ether, and analyzed the concentrated extract by GC/MS, eventually finding 50 volatile components. Finally, Lin et al. (2005) combined solid phase microextraction (SPME) of urine volatiles from male BALB/c mice with GC/MS and reported 131 components. This variability in the number of detected volatiles reflects differences in odor collection procedures, as well as the choice of the mouse strains and the diet used for raising the animals. In addition, there is surprisingly limited agreement in the chemical identity of the components described in these reports.

In this study, we present the odor composition of the body scent of mice in comparison to the volatile composition of urine odor. This comparison revealed both odor-source-specific and common components, and raises questions regarding the formation and function of mouse volatiles.

Methods and Materials

Mice

Male C57BL/6J mice were raised under specific-pathogen-free conditions at the Max-Planck-Institut für Immunbiologie (Freiburg, Germany), or purchased from Charles River Wiga Deutschland GmbH (Sulzfeld, Germany). Germ-free male C57BL/6 mice and corresponding controls raised under specific-pathogen-free

conditions were provided by Dr. B. Jilge (Tierforschungszentrum, Universität Ulm, Ulm, Germany).

To standardize the volatile components with respect to diet, randomly picked animals were kept singly in cages for 3–4 wk in ventilated hoods and fed on “Diät C 1000” (Altromin, Gesellschaft für Tierernährung GmbH, Lage, Germany) composed of casein, corn starch, saccharose, cellulose, vitamins, mineral substances and trace elements. At the time of body scent and urine collection, the mice were 12–13 wk old. The germ-free and corresponding control mice (three animals each) were used for mouse volatile and urine collection directly upon arrival.

Collection of Volatiles

Sampling of volatiles was performed under conditions that minimized the introduction of contaminants, e.g., from plastic materials. Mouse odor was collected from a horizontal stainless steel cylinder (length 14 cm, ID 9.8 cm) closed at one end, and supplied with a copper-ring-sealed ultrahigh vacuum flange on the other end (Fig. 1). Synthetic air (hydrocarbon-free; Messer-Griesheim, Sulzbach, Germany) was blown via a Mass Flow Controller GFC171 (ANALYT-MTC, Müllheim, Germany) at a rate of 200 ml/min through a charcoal filter (Small Cartridge ACCOSORB, Messer-Griesheim) attached to an inlet at the closed end of the cylinder into a stainless steel pipe (length 12 cm, 5 mm diameter) running parallel to the inner wall of the cylinder. The mouse volatiles were collected from the circulating air into freshly conditioned adsorption tubes (Tenax TA stainless steel prepacked sample tubes, Cat. No. N930-7005, Perkin-Elmer Instruments, Rodgau, Germany) directly connected to an outlet located opposite the inlet. Similarly, urine volatiles were collected at a flow rate of 100 ml air/min from custom-made, round-bottom glass dishes fitting into smaller stainless steel cylinders (length 11 cm, ID 3.8 cm) of otherwise similar design. By arranging a second Tenax or Carbotrap 300 tube (Cat. No. N930-7000) in tandem with the Tenax tube, it was shown that only minor amounts of highly volatile and polar compounds such as triethylamine (#1 in Table 1) were not completely adsorbed in the first tube.

Urine was collected at room temperature overnight from groups of three mice placed in metabolic cages (Tecniplast, Hohenpeißenberg, Germany) and then stored at -20°C . During urine collection, the animals were supplied with water but no food. The urine samples were normalized to a creatinine concentration of 0.12 mg/ml by the addition of water. Volatiles were collected from 1 ml adjusted urine for 4 hr; during this time, about half of the sample evaporated. Between collections from

70	49.71	Diethylphthalate, contaminant	82	100	

Serial nos. 1 to 70 were assigned to peaks with average retention times indicated. Volatiles were identified by comparison with entries in the MS data bank and by comparison with standards. Components of unknown structure are defined by the mass and relative abundance (in brackets) of characteristic fragments. Three components (peak nos. 9, 29, and 70) were consistently observed contaminants. The occurrence of volatiles in both mouse and urine odor, or either in mouse or urine odor is indicated as a percentage of all samples analyzed [22 chromatograms derived from nine different groups of mice for body odor and 26 chromatograms for urine odor involving 11 urine samples from 11 different groups of C57BL/6J mice, cf. [Supplementary Material](http://dx.doi.org/10.1007/s10886-006-9091-2) (available for this article at <http://dx.doi.org/10.1007/s10886-006-9091-2> and is accessible for authorized users)]. Components previously identified are marked: (a) Schwende et al. (1986), Novotny et al. (1999a,b); (b) Miyashita and Robinson (1980); (c) Singer et al. (1997); (d) Montag et al. (2001).

different urine samples, the glass dishes and steel cylinders were rinsed with water and heated to 120°C for at least 1 hr.

Three mice were stimulated to urinate on paper tissue and the mice were then placed into the steel cylinder. Volatiles were collected for 1 hr. The vessel was then opened, inspected for the presence of urine, and the mice were again stimulated to urinate. Volatile body odor components were then collected for another hour in a fresh sample tube. Between collections with the next group of mice, the cylinder was rinsed with water and heated as described above. We had to eliminate some early mouse odor measurements due to urine contamination, which was subsequently prevented by the optimized procedure.

Analysis of Volatiles by Gas Chromatography/Mass Spectrometry

The volatiles were desorbed from the sample tubes in a Thermal Desorption System (Perkin-Elmer ATD400) and then separated by gas chromatography on an Agilent J&W DB-5 column (60 m × 0.25 mm, 0.25 μm; temperature program: 35°C for 5 min; 35–220°C at 3.75°C/min; 220–265°C at 7.5°C/min; 265°C for 3 min) in a Hewlett-Packard GC interfaced to an HP 5973 Mass Selective Detector.

Chromatograms were evaluated for 72 peaks in the following way. A data bank was set up from the mass spectra of all detectable peaks in two urine and three mouse odor chromatograms, which was then used to evaluate all other chromatograms for corresponding components. This procedure allowed reliable sorting of major components but was less successful for minor components. Because the retention times varied by 0.1–0.2 min for different chromatograms, assignments of the respective components required the individual comparison of retention time and mass spectra for all peaks in all chromatograms. Components were tentatively identified by comparison with the NIST 98 Mass Spectral Library (National Institute of Standards and Technology, Gaithersburg, MD, USA). Identities of some components were confirmed by comparisons of retention times and mass spectrum with those of commercially available or donated standards as detailed in Table 1. 6-Hydroxy-6-methyl-3-heptanone was synthesized according to the procedure described by Novotny et al. (1999a), using pyridinium chlorochromate (18 hr at room temperature in CH₂Cl₂) instead of CrO₃/aq. H₂SO₄ as the oxidant.

Results

Collection and Analysis of Volatiles

Using stainless steel vessels and highly purified air, we were able to eliminate most contaminants during volatile analysis (compare spectra in the upper panels of Fig. 2). Three remaining contaminants derived from the absorption tubes (peaks #9, 29, and 70, cf. Table 1) were useful landmarks in the chromatograms, and their abundance showed little variation. Typical chromatograms for mouse body and urine volatiles are shown in the lower panels of Fig. 2. Because the composition of urine volatiles may depend on the chow used for feeding (Brown et al., 1996), mice were kept individually on a synthetic diet for several weeks before the experiments. To obtain sufficient amounts of material for analysis in an adequate time, we always collected the body scent or the urine from groups of three randomly picked mice. We did not

Fig. 2 Representative GC/MS spectra. (A) Spectrum obtained from an absorption tube directly after conditioning. (B) Spectrum obtained after volatile collection from the empty steel cylinder for 4 hr. (C) Volatiles collected for 1 hr from three mice. (D) Volatiles collected in 4 hr from urine

observe aggressive acts between these mice in the metabolic cage during urine collection. Although we cannot exclude aggressive behavior during mouse scent collection in the closed steel cylinder, we consider this unlikely because hair release caused by biting was not observed.

Our major concern was whether the collected mouse body volatiles were contaminated by urine components. We observed that the typical urine component 2,3-dehydro-exo-brevicommin (peak #57, cf. Table 1), which binds to the major urinary proteins (MUPs, Bacchini et al., 1992; Novotny et al., 1999b), was only detected in those chromatograms where the mice had urinated in the stainless steel vessel. When we stimulated the mice to urinate before insertion into the vessel, we consistently prohibited obvious urination in the vessel and did not detect 2,3-dehydro-exo-brevicommin in the spectra of mouse volatiles. However, small amounts of urine may be visually undetectable because marks may quickly dry in the air flux in the cylinder. Assuming that two abundant MUP ligands, 6-hydroxy-6-methyl-3-heptanone (peak #27) and 2-*sec*-butyl-4,5-dihydrothiazole (peak #62), are released solely in the urine and not excreted by MUP-producing glands (e.g., the submaxillary gland), a very rough estimate for the contribution of urine volatiles to the mouse body scent can be obtained from the ratio of the relative peak areas in the GC/MS spectra. The ratio of the medians for the mouse body and urine scents is 0.025 and 0.024 for peaks #27 and 62, respectively (Fig. 4 and Supplementary Material), suggesting that the mouse body volatiles may be contaminated by 2.5% of the urine volatiles collected from 1 ml urine (corresponding to a volume of 25 μ l). This limitation must be taken into account when comparing the mouse and urine scent data. However, for less abundant urine volatiles such as 2,3-dehydro-exo-brevicommin, this contamination falls below the detection level in the mouse body scent.

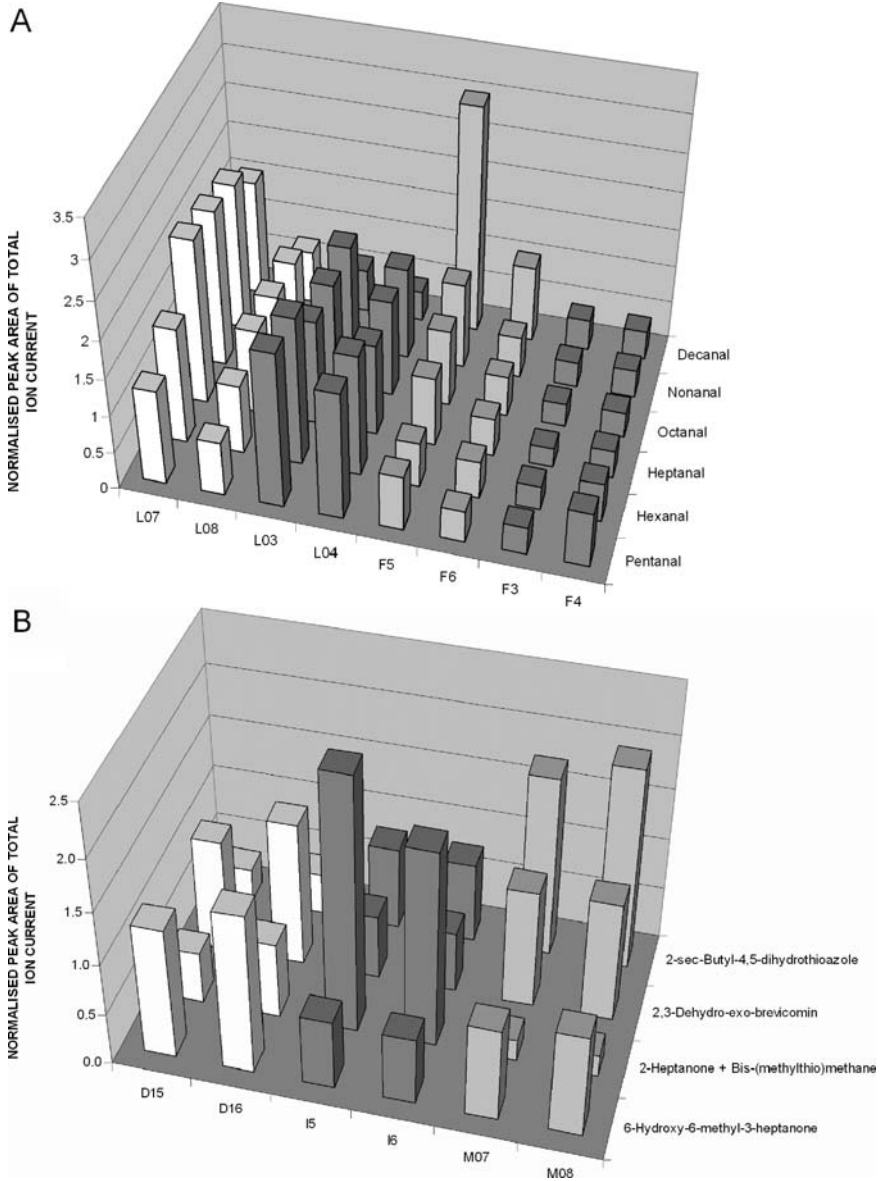

Fig. 3 Representative examples for demonstrating the reproducibility of the odor collection experiments. (A) Normalized peak areas of the total ion current for C₅–C₁₀ aldehydes. Odor was collected from three C57BL/6J mice for 1 hr (F3) and directly thereafter for another hour (F4) or from another three C57BL/6J mice (F5 and F6). A third group of this strain was used for collecting the samples L03 and L04, and 3 d later for samples L07 and L08. Average values of the peak area for the total ion current of the eight measurements were 0.16 for pentanal, 1.12 for hexanal, 0.59 for heptanal, 0.78 for octanal, 2.98 for nonanal, and 0.17 for decanal. (B) Normalized peak areas of the total ion current for pheromones. Note that bis-(methylthio)methane is not considered a pheromone, but overlaps with the 2-heptanone peak in the chromatogram. Double determinations (D15/D16, I5/I6, and M07/M08) from three urine samples collected from three animals each are shown. Average values of the peak areas for the total ion current of the eight measurements were 0.57 for heptanone + bis-(methylthio)methane, 3.87 for 2-sec-butyl-4,5-dihydrothiazole, 1.02 for 2,3-dehydro-exo-brevicomin, and 112.19 for 6-hydroxy-6-methyl-3-heptanone

In view of the large variability in the abundance of many components, it was important to document the reproducibility of successive mouse odor and duplicate urine odor measurements. As an example, Fig. 3A depicts the normalized abundance of *n*-aliphatic aldehydes from C₅ to C₁₀ in mouse body odor. Volatiles were collected from groups of three C57BL/6J mice for 1 hr (e.g., F3) and then for another hour (e.g., F4). With some exceptions, the agreement between successive samplings was reasonably good (compare equally marked pairs). However, for different groups of mice, aldehyde abundance varied by a factor of 5–10 (compare differentially marked pairs). Similar variability was observed in volatiles collected from urine samples normalized to a constant creatinine concentration (Fig. 3B). The four candidate pheromones chosen as examples differed in abundance by a factor of up to 10 when comparing urine samples from different groups of mice (compare differentially marked pairs). However, collection of volatiles from the same urine preparation was consistently reproducible (compare equally marked pairs). We concluded from these experiments that under our standardized conditions, variability in abundance was primarily attributable to the odor source rather than to the procedures used for collection and analysis of volatiles.

Composition of Volatiles

Taken together, we evaluated 22 chromatograms derived from 9 different groups of mice for body odor and 26 chromatograms for urine odor involving 11 urine samples from 11 different groups of C57BL/6J mice (Table 1 and [Supplementary Material](#)). A few measurements were performed with germ-free mice and controls raised under specific-pathogen-free conditions. All chromatograms were evaluated for the 67 components plus the three contaminants listed in Table 1. These 67 components were therefore characteristic of the total ensemble of samples analyzed in this study. The entire data set can be inspected in the [Supplementary Material](#). Table 1 also indicates the fraction from all measurements where a given volatile could be detected.

Prominent in the list were acids (#6, 13, 24, 30, 32, 48), ketones (#2, 6, 8, 11, 14, 18, 27, 31, 38, 43, 51, 63), aldehydes (#12, 26, 40, 46, 54, 61, 65), and alcohols (#2, 7, 10, 17, 21, 22, 33, 37, 49, 59), as well as components considered to be mouse pheromones (#27, 38, 57, 62, 68, 69; Novotny, 2003). The structures of about one third of the components remain to be identified. Nitromethane (#4), propanoic acid (#13), dimethyldisulfide (#19), 1-octene (#25), 1-hexanol (#37), hexanoic acid (#48), indol (#67), α - and β -farnesene (#68 and 69), and one unidentified component (#64) were only observed in the volatiles from mouse body scent. On the other hand, 3-penten-2-one (#18), 3-methyl-2-buten-1-ol (#22), 3-methyl-cyclopentanone (#31), *p*-xylene (#36), 3-hepten-2-one (#43), 2,3-dehydro-exo-brevicommin (#57), benzylmethylketone (#63), and 13 unidentified compounds (#7, 23, 34, 35, 39, 47, 50, 52, 55, 56, 58, 60, and 66) were only found in urine volatiles. All other substances were present in the volatiles of both mice and their urine.

Although we did only a few experiments with mice fed on a conventional chow under germ-free or, as a control, specific-pathogen-free conditions, some observations are noteworthy. Mouse odor components (#4, 6, 12, 13, 20, 24, 26, 27, 30, 32, 33, 36, 40, 46, 48, 51, 54, 61, and 65) and urine odor components (#2, 6, 11, 12, 14, 15, 16, 18, 26, 27, 28, 39, 40, 41, 42, 43, 44, 45, 46, 52, 53, 54, 57, 61, 62, and 65) were clearly present in germ-free animals. This set includes the aliphatic aldehydes, which

were therefore derived from the mice rather than their bacterial flora. One compound exclusively detected in germ-free mouse scent was 2-furanmethanol (#33). A more detailed comparison of germ-free and specific-pathogen-free mice would require a larger data set.

Figure 4 shows the medians and the quartile ranges on a logarithmic scale for all those components that were detected in more than 80% of the measurements (18 mouse body odor and 29 urine components). Small quartile ranges, e.g., for urine peaks #2, 11, 43, 44, and 46, indicated a good reproducibility in the detection of

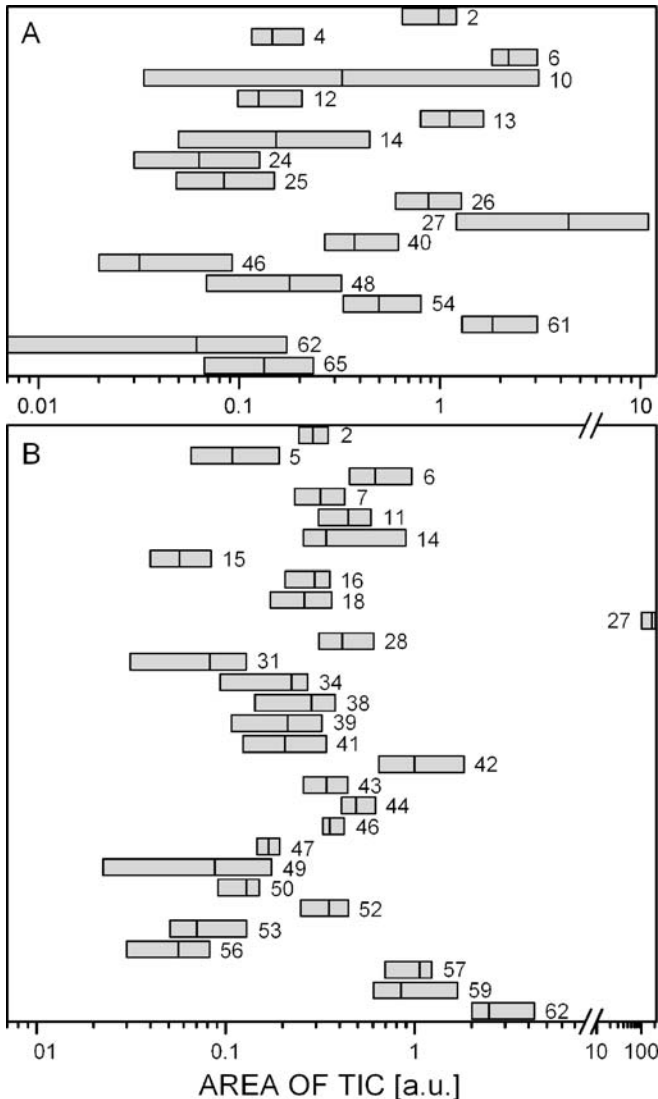

Fig. 4 Relative abundance of selected volatiles collected from the body of mice (A) or their urine (B). The peak area of the total ion current (TIC) is plotted on a logarithmic scale. The numbers refer to those listed in Table 1. Lengths of the horizontal bars represent the interquartile range of the measurements; median is indicated by a vertical bar within the horizontal bars

these volatiles. On the other hand, components such as mouse volatiles #10, 14, and 27 were highly variable in abundance. Inspection of the data after normalization to the medians suggested that the abundance of urine volatiles was less variable than the mouse volatiles (not shown).

Discussion

To our knowledge, the present study represents the first report on the composition of mouse body scent. Although most volatiles are present in both body and urine odors, several components were specific to one or the other scent. We find it intriguing that the mouse odor reproducibly contained aliphatic aldehydes from C₅ to C₁₀ as prominent components, because odorant receptors for these aldehydes are found in abundance in the main olfactory epithelium and they have been characterized in detail (Zhao et al., 1998; Krautwurst et al., 1998; Araneda et al., 2000, 2004; Kaluza and Breer, 2000). Behavioral experiments using these aldehydes may show that they are important to mice in recognizing their conspecifics. Interestingly, short-chain aldehydes have also been found in human odor (Bernier et al., 2000; Haze et al., 2001; Curran et al., 2005). These aldehydes can be produced through oxidative degradation of monounsaturated fatty acids such as palmitoleic acid and vaccenic acid (Haze et al., 2001), which are secreted by sebaceous glands. In the rat, these aldehydes have been detected in extracts from the preputial gland (Sioni et al., 2005).

Another remarkable observation is that the abundance of some components, e.g., 1-methoxy-2-propanol (#10), 6-hydroxy-6-methyl-3-heptanone (#27), phenol (#49), and methylphenol (#59) varied over a range of 10- to 100-fold in different experiments (Fig. 4 and [Supplementary Material](#)). This finding suggests the occasional discharge of these components, either spontaneously or in response to environmental or social cues. Triggers for the release of these components and their source remain to be defined.

It is puzzling that there is little overlap between the volatile components identified by different investigators in mouse urine. Therefore, reported volatile composition may strongly depend on the method used for odor collection and analysis as well as the type of mouse strain and diet used in the experiments. In Table 1, those compounds that have previously been identified are marked. However, many volatiles found in this study have not been described previously and *vice versa* (Miyashita and Robinson, 1980; Schwende et al., 1986; Singer et al., 1997; Montag et al., 2001; compare also Willse et al., 2005; Lin et al., 2005). We used a synthetic diet for feeding the mice, which should reduce the complexity of volatiles, and we have tried to rigorously exclude contaminants during odor collection. In addition, control experiments showed that the absorption tubes used for odor collection were efficient. These efforts toward a standardization of the methodology were successful, in that the set of observed components was generally reproducible for the body and urine scents of C57BL/6 mice, but there was a large variation in abundance such that minor components frequently were not detected (Table 1 and [Supplementary Material](#)).

We confirmed the presence of putative pheromones known to be present in male urine (2-*sec*-butyl-4,5-dihydrothiazole, 2-heptanone, 2,3-dehydro-*exo*-brevicomin, and 6-hydroxy-6-methyl-3-heptanone). Two further pheromones, α - and β -farne-

sene, which are secreted by the preputial gland (Novotny et al., 1990), were detected in some mouse samples but not in urine samples. We also did not detect the recently identified semiochemical (methylthio)methanethiol, a component of very low abundance (Lin et al., 2005).

In view of the importance of the mouse as a model for mammalian behavior and for the analysis of recognition and processing of olfactory signals, a better standardization for the collection and analysis of volatiles released by the animals and their urine appears desirable.

Acknowledgments We thank Dr. H. Mossman (Freiburg) for providing mice, K.Mori (Tokyo), C. Mucignat (Padova), and P. Landolt (Wapato, Wa) for donating standards, and Dr. J. Kopka (Berlin) for help in the interpretation of mass spectra. Helpful suggestions by Dr. M. Wandel and Prof. K.P. Haderler and technical help by A. Hohneder and B. Pömmel are gratefully acknowledged. P.O. thanks the Max-Planck-Gesellschaft for generous support.

Abstract The urine of the cheetah, *Acinonyx jubatus*, is almost odorless, and probably for this reason, it has not attracted much attention from scientists. Using gas chromatography–mass spectrometry, we identified 27 and 37 constituents in the headspace vapor of the urine of male and female cheetah, respectively. These constituents, composed of hydrocarbons, short-chain ethers, aldehydes, saturated and unsaturated cyclic and acyclic ketones, 2-acetylfuran, dimethyl disulfide, dimethyl sulfone, phenol, myristic acid (tetradecanoic acid), urea, and elemental sulfur, are all present in the headspace vapor in very small quantities; dimethyl disulfide is present in such a low concentration that it cannot be detected by the human nose. This is only the second example of elemental sulfur being secreted or excreted by an animal. It is hypothesized that the conversion of sulfur-containing compounds in the cheetah's diet to elemental sulfur and to practically odorless dimethyl sulfone enables this carnivore to operate as if “invisible” to the olfactory world of its predators as well as its prey, which would increase its chances of survival.

Mammalian semiochemicals · Elemental sulfur

Introduction

Although cheetah, *Acinonyx jubatus*, can reach a speed of more than 100 km/hr in seconds (Caro, 1994), they are exposed to severe competition for survival because they lack the physical strength to guard their territory and protect their young against stronger predators. In some nature reserves, predation accounts for more than 40% mortality in cheetah litters (Eaton, 1974). Cheetah are territorial, mostly solitary, animals with enormous home ranges. The average size of the home range of

a female on the Serengeti plains is about 830 km². Male territories are about 4.5% of that of female territories (Caro, 1994). Male and female cheetah leave territorial marks by spraying objects with urine. Females in heat squirt urine on bushes, tree trunks, and rocks to attract males (Macdonald, 1984), but marking behavior is more common in males. Consensus has not been reached as to the function of this behavior in males. Both sexes as well as cubs take great interest in marks left by a strange male, and there is convincing evidence suggesting that territorial marking is a mechanism whereby contact and conflict between family groups, which could result in injury or death, is avoided (Eaton, 1974).

Probably because the urine is almost odorless, it has not elicited much interest from scientists. Continuing our research on the semiochemicals of mammals (Burger, 2005), we attempted a comprehensive chemical characterization of the volatile fraction of the urine of the cheetah.

Methods and Materials

Sample Collection

Urine was collected from four captive male cheetah (Cheetah Outreach Facility, Spier Wine Estate, Stellenbosch, South Africa) by catching sprayed urine in a glass beaker. Bladder urine was obtained from an anesthetized female by catheterization. These cheetah were kept in enclosures varying in size from about 100 × 50 m to 85 × 70 m with wire mesh fences and were fed a diet of chicken. On one occasion, urine was collected from two wild males at the research station of the Cheetah Conservation Fund, Otjiwarongo, Namibia. The urine samples were frozen as quickly as possible and kept at -25°C until used for analysis.

Analytical Techniques

Volatile constituents of the urine were sampled by sorptive sample enrichment in polydimethylsiloxane (PDMS) rubber by using a sample enrichment probe (SEP) (Burger et al., unpublished data) followed by thermal desorption in the injector of a gas chromatography–mass spectrometry (GC–MS) instrument (GC–MS, Carlo Erba QMD 1000). The volatile organic constituents were also extracted from the urine with dichloromethane (Merck, Residue Analysis Grade) for retention-time comparison (co-elution) with authentic synthetic compounds and quantification of the elemental sulfur and some of the less volatile compounds extracted from the urine. The concentration of the sulfur in cheetah urine was determined by GC–MS with sulfur as external reference.

Bioassays

Thick, green paper sheets (350 × 230 mm) were uniformly wetted on one side with 6 ml of a colloidal sulfur solution (3 µg S/ml) and air-dried to produce test papers coated on one side with 18 µg of sulfur, equivalent to approximately 18 ml of urine. Controls were prepared by wetting paper sheets with water, fresh cheetah urine, or with solutions of various odorants such as benzeneethanethiol and orange juice.

Bioassays were done at the Spier Cheetah Outreach Facility with four male and three female cheetah that were reasonably tame and accustomed to human visitors. Wet and dry sulfur-treated papers, wet and dry water-treated controls, and papers wetted with cheetah urine or with other odorants were presented 3 m apart along one of the fences of an enclosure where a cheetah was likely to spot and inspect it. The attention the cheetah paid to each test paper and control, as well as any peculiar behavior, was noted. Tests were also done at the Tygerberg Zoo with a breeding pair of wild cheetah, as well as a breeding pair each of the following species: lion (*Panthera leo*), Bengal tiger (*P. tigris*), caracal (*Felis caracal*), wild cat (*F. silvestris lybica*), and wild dog (*Lycaon pictus*).

Results and Discussion

Enrichment of the organic volatiles in the headspace of cheetah urine by using the SEP technique and GC–MS analysis of the enriched volatiles gave a total ion chromatogram (TIC) (Fig. 1) and mass spectra that could be used for the identification of most of the headspace constituents.

Urea (**35**) extracted from the headspace of the urine appears in the TIC as a broad peak at a retention time of 49.2 min, and cyanuric acid (2,4,6-trihydroxy-1,3,5-triazine) (**39**) as a broad peak at a retention time of 92.0 min. This compound is formed when urea is heated to temperatures above its melting point, and it was concluded that its presence in the TIC shown in Fig. 1 is due to the partial conversion of the urea to cyanuric acid in the injector of the GC–MS instrument. The saddlelike elution profile between these two peaks shows that this process continued to take place in the column during the chromatographic process. Some of the compounds listed in Table 1 were detected in the headspace vapor of the urine of only one of the sexes. The dimethyl disulfide (**9**) is present in the urine in such a small quantity that it could not be detected by the human nose.

Fig. 1 TIC of volatile constituents extracted for 69 hr at 40°C from the headspace vapor of the urine of a female cheetah with a device in which 140 μ l of PDMS rubber was used, desorbed for 5 min at 220°C in the injector of the GC–MS system, and analyzed on a 40 m \times 0.3 mm glass capillary column coated with PS-089 (DB-5 equivalent) by using a temperature programming rate of 2°C/min from 40°C to 280°C

^a Arranged in order of elution from an apolar column.

^b Formed from urea in the injector and on the column of the GC–MS instrument.

We were surprised to find elemental sulfur in all of the urine samples from cheetah males and from one female cheetah. Sulfur is not detected by GC when a flame ionization detector (FID) is employed. However, the cyclic S₆ (**37**) and S₈ (**40**) forms of the element can be separated and quantified by GC–MS analysis. In the present investigation, small quantities of S₆ and larger quantities of S₈ were found in

the headspace vapor and in dichloromethane extracts of the urine of both sexes. Employing sulfur as external standard, it was found that the concentration of sulfur in the urine of male cheetah with unlimited access to water is approximately 1 µg/ml. Sulfur is not an artifact formed from dimethyl disulfide because it was not detected when dimethyl disulfide was subjected to GC–MS analysis, either under the analytical conditions employed in the present investigation or under thermally harsher conditions.

It was not possible to determine the concentration of the highly volatile constituents of the urine because they were largely lost when the extract was concentrated and could not be detected in GC and GC–MS analyses. The less volatile constituents, dimethyl sulfone (**20**), benzaldehyde (**23**), phenol (**25**), acetophenone (**29**), and 2-nonanone (**30**) were present in concentrations of about 250, 1.5, 0.6, 1.4, and 1.5 ng/ml, respectively, in the extracted material. Although 2-piperidone (δ -valerolactam) was not detectable in the urine headspace vapor, it was identified as the major organic constituent of cheetah urine at a concentration of 1.7 µg/ml.

Several explanations can be offered for the presence of sulfur in cheetah urine. It is unlikely that this element could be a sex pheromone of the species because sulfur is present in the urine of both male and female cheetah. In view of the enormous home ranges of these animals, use of sulfur as a territorial-marking pheromone, or a component of such a pheromone, would have the advantage that it is much more persistent than the quite volatile organosulfur compounds present in the urine of other felids. It is also possible that the conversion of sulfur-containing proteins to elemental sulfur is just an alternative mechanism by which sulfur is excreted in its elemental form instead of being excreted as organosulfur compounds, as in many other felids. The conversion of organosulfur compounds to sulfur and dimethyl sulfone, also a practically odorless compound, could allow cheetah (especially females with small cubs that from a very early age accompany the female on hunts) to live in closer proximity to their prey than would otherwise be possible. In this regard, it has been found that organosulfur compounds derived from a protein-rich diet could be a cue by which prey can distinguish a potential predator (Epple et al., 1993; Nolte et al., 1994). If, as mentioned above, sulfur is at the same time used as a territorial-marking substance, it would imply that the cheetah must be equipped to detect sulfur much better than do their predators. With the limited information available from bioassays with cheetah in captivity, there is no proof that this could be the case.

Ideally, these possibilities should be tested by investigating the responses of male and female cheetah, other carnivores, and typical prey species to cheetah urine and sulfur in various combinations under completely natural conditions in the wild. This was impossible in the present investigation. It is not known which, and to what extent, urine constituents play a role in the sexual and territorial behavior of the cheetah, and there is no positive control that could have been used in experiments to determine the reaction of cheetah and other carnivores to cheetah urine and sulfur. In some exploratory experiments that were nevertheless done [with four male and three female cheetah at the Spier facility, as well as breeding pairs of wild cheetah, lion (*P. leo*), Bengal tigers (*P. tigris*), caracal (*F. caracal*), African wild cats (*F. silvestris lybica*), and wild dogs (*L. pictus*), at the Tygerberg Zoo], sulfur and cheetah urine elicited practically no response either in cheetah or in the other carnivores. Other odorants, especially benzeneethanethiol, elicited stronger

responses than male cheetah urine or sulfur. In an environment that must be saturated with semiochemical messages, no significance can be attached to the results of these bioassays as far as the possible role of sulfur as a component of a territorial-marking pheromone is concerned. On the other hand, our hypothesis—that the conversion of sulfur-containing compounds in their diet to elemental sulfur enables cheetah to operate as if “invisible” to the olfactory world of their predators as well as their prey—was not refuted by the results of these bioassays.

The secretion of elemental sulfur by a carabid beetle (Meinwald and Attygalle, personal communication) is the only other known example of the production of elemental sulfur by an animal. It is possible that sulfur is not so rare in animal excretions and secretions, but that it has been overlooked in the urine and/or feces of other species, as it is not detected by FID. It is hoped that biologists will be motivated by the discovery of sulfur in the urine of the cheetah to look for it in other biological material and to consider its possible role in other biological systems.

Acknowledgments We thank the Cheetah Outreach Facility for permission to collect urine from cheetah and to conduct bioassays with the animals, Tygerberg Zoological Garden for permission to conduct bioassays with cheetah and several other carnivore species, and the Cheetah Conservation Fund for cheetah urine. Stellenbosch University and the National Research Foundation, Pretoria, South Africa, funded the research.

Abstract Near-infrared reflectance spectroscopy was used to analyze nutrient composition of tropical and subtropical seagrasses in Queensland, Australia, as part of a broader study of impacts of grazing by dugongs on seagrass. Seagrass samples of 10 species were collected, transported to the laboratory, and separated into leaf and root/rhizome fractions. They were dried, ground, and near-infrared spectra (400–2500 nm) were collected. We used partial least-squares regression to develop calibration equations relating spectral data to standard compositional analyses performed in the laboratory. These compositional analyses focused on attributes believed to be important determinants of nutritional quality of marine vertebrate herbivores (nitrogen, organic matter, neutral detergent fiber, acid detergent fiber, lignin, neutral starch, water-soluble carbohydrates, and *in vitro* dry matter digestibility). Calibration equations for each attribute were developed separately

for (1) roots/rhizomes and (2) leaves, irrespective of plant species. An equation that combined both plant parts was equally robust. These studies demonstrated the utility of near-infrared spectroscopy in providing rapid and cost-effective analysis of marine plants, which, in turn, permits a rigorous statistical approach to be applied to studies of foraging by marine herbivores.

SEL	standard error of laboratory determination (=analytical precision)
r^2	simple coefficient of determination

Introduction

Analysis of nutrient content of vegetation is a key step in many ecological studies in marine environments. However, conventional methods of such analyses are frequently time consuming and expensive. In particular, replication and longitudinal experiments can be compromised because of the difficulty of conducting nutrient analyses over time. This constraint is particularly serious when studying the nutritional plant quality for those herbivorous species that may eat a variety of food plants growing under a variety of conditions.

Near-infrared reflectance spectroscopy (NIRS) offers an unrivalled potential to address these issues (Foley et al., 1998) and has become a widely used method for analyzing agricultural and food products. Advantages offered are analytical speed, no or minimal sample preparation (Osborne et al., 1993; Shenk and Westerhaus, 1993b), low cost, high precision, and suitability for longitudinal studies. Foley et al. (1998) reviewed the basics of NIRS, which essentially depends on establishing a statistical relationship between the spectrum of near-infrared light reflected by a sample and a set of standard laboratory analyses of components of interest. Defined chemical bonds absorb light at characteristic wavelengths. Once this relationship has been established, the concentration of constituents of interest in any new samples can be analyzed solely by collecting and processing spectra from the samples.

We were interested in several nutritional attributes of different species of seagrass available to herbivorous dugongs (*Dugong dugon* Müller; Mammalia, Sirenia) in tropical Australia as part of a broader study (Aragones, 1996) of the effect of grazing on seagrass community structure. That study generated 1165 samples for which we sought information on eight nutritional components—a total of 9320 determinations. This was beyond the capacity of our or any other laboratory to complete, and so we investigated whether NIRS would allow us to keep our preferred experimental designs at a much-reduced cost.

In this paper, we show that NIRS can be successfully used to analyze nutrient concentration and *in vitro* digestibility of many seagrass species sampled from diverse

habitats and localities in tropical and subtropical Australia. In addition, we evaluate implications of our results for further applications of this technique to seagrass—herbivore interactions and seagrass ecology. We conclude that NIRS can be used reliably to analyze seagrass nutrients and could be applied to many ecological studies.

Methods and Materials

Seagrass Collection

Samples of seagrasses were collected in tropical Australia including the Great Barrier Reef region and the Gulf of Carpentaria, and subtropical south Queensland (Moreton and Hervey Bays). The collection comprised 10 species (with two species having two morphs), representing the diversity of regional seagrasses: *Halophila ovalis* (R. Brown) Hooker, *H. minor* (Zollinger) den Hartog, *H. spinulosa* (R. Brown) Ascherson, *H. decipiens* Ostenfeld, *H. tricostata* Greenway, *Halodule uninervis* (Forsskal) Ascherson (narrow- and wide-leaf morphs), *Cymodocea rotundata* Ehrenberg and Hemprich ex Ascherson, *C. serrulata* (R. Brown) Ascherson and Magnus, *Syringodium isoetifolium* (Ascherson) Dandy, and *Zostera capricorni* Ascherson (narrow- and wide-leaf morphs). We included samples from several experimental treatments (grazing, cropping, and fertilization; Aragones, 1996) as well as material from unmanipulated plots established to measure variation in nutrients because of season, depth, and locality. Most samples came from intertidal beds, but a small subset was collected with SCUBA at Pipon Island (14°7'S, 144°32'E) down to 30 m. We collected a total of 1165 samples.

Sample Preparation

Samples were washed and cleaned of adherent substrate in clean seawater and sorted into species. All were divided into leaf and root/rhizome fractions, except for *H. tricostata* and *H. decipiens*, where leaves and roots/rhizomes were combined because their leaves are so small. Fractions were placed in labeled paper bags and dried to constant mass in a forced draft oven at 60°C. Each sample was ground through a 1-mm screen in a Cyclone mill (Udy Corporation, Fort Collins, CO, USA) and stored in a polyethylene jar. One week prior to collection of NIRS (see below), we opened and equilibrated samples in a chamber maintained at 11% r.h. and 12°C. This ensured that moisture content of all samples was similar (Shenk and Westerhaus, 1993b).

Routine NIRS Scanning and Analyses

Collection of Spectral Data

Near-infrared reflectance spectroscopy is commonly used in agriculture, and standard methods have been developed (Anon, 1995). In our work, we followed these standard procedures carefully and so only briefly detail our procedures.

We acquired spectra of all samples using a near-infrared reflectance spectrophotometer (Model 6500, NIR Systems, Silver Springs, MD, USA), equipped with a

spinning-cup module, housed in a room maintained at $22 \pm 1^\circ\text{C}$ and $55 \pm 5\%$ r.h. We acquired the mean spectrum from two 25-mm standard cells collected to a set RMS error (using first-derivative spectral data), of 50μ absorbance units. Spectral data were collected from 400 to 2498 nm at an interpolated data gap of 2 nm. This ensured collection of spectral data of high precision (Shenk and Westerhaus, 1993b). Reflectance (R) readings were converted to absorbance (A) values: $A = \log(1/R)$. The instrument was maintained and operated, spectral data manipulated, and calibrations developed using the NIRS3 software package (Shenk and Westerhaus, 1992).

Many of our samples were too small (~ 0.5 – 2.0 g) for use of standard cells. We made three “micro” ring cups that allowed collection of spectra from these samples. These cups had the same external dimensions as standard ring cups supplied commercially (ISI, Port Matilda, PA, USA), but the internal dimensions were reduced by 70%. We made the cups from black anodized aluminum and spectrally matched, spectroscopic-grade quartz glass (Behmn, Dayton, OH, USA) in front of each cell. We routinely used “micro” cells for samples as small as 0.3 g throughout the project, once we verified spectral data for the same samples scanned in each cell type did not differ.

NIRS Analysis

Selection of the Calibration Set for Chemical Analyses

We chose a subset of samples for detailed chemical analyses (calibration set) using the algorithms CENTER and SELECT (Shenk and Westerhaus, 1991a,c). These algorithms use principal component analysis and Mahalanobis distances (Mahalanobis, 1936) to rank spectra relative to the population average. This procedure captures a subset of the full spectral (and hence chemical) variation present in the data set.

Samples for the calibration set were selected over several months because sample collection was designed to be cumulative through time due to the limitations of the study. Processing of samples was slow because each field sample had to be sorted first into different plant species, and then each into fractions (leaves vs. roots/rhizomes). The first 200 samples represented a diversity of seagrasses of various species and morphs, collected from various sites and depths. We selected 70 of these samples for initial detailed chemical analyses. Once we had acquired spectra from all 1165 samples that were collected for the studies described by Aragonés (1996), we again used the SELECT algorithm to select further 118 samples. We included 10 further samples identified as population outliers by their Mahalanobis distances, bringing the final calibration set to 198 samples. In several instances, there was insufficient sample for all chemical analyses, and so we selected the nearest neighbor, again based on Mahalanobis distances, for inclusion in the calibration set.

A Comparison between Leaf or Root/Rhizome and Whole Plant-Based Calibrations

Samples selected for the calibration set were divided into two groups: leaves and roots/rhizomes. Thus, two options were possible for calibration: a separate calibration for each of the fractions of leaves or roots/rhizomes, and a whole plant calibration, combining both fractions. Accordingly, we evaluated whether calibra-

tion equations developed for a single plant part were superior to a broad-based calibration developed with multiple plant parts. Plant part calibrations were developed separately for leaves or roots/rhizomes. A broad-based calibration was developed combining both plant fractions, as well as a few detrital matter samples. We assumed that leaves and roots/rhizomes samples selected in the broad-based calibration also would have been chosen in separate selections for each plant part because they were part of the same population. Thus, they would have still been representative of each group. Grouping by plant part rather than species was the simplest possible division, as our samples included 10 separate species. Predictions from single-product calibrations (i.e., roots/rhizomes or leaves) were compared to those of the broad-based calibration equations by comparing their standard error of cross validation (SECV), r^2 , regression slope, and “bias.” Bias is an estimate of the mean difference between laboratory-determined and NIRS-predicted values for calibration or monitoring sets (Smith and Flinn, 1991). Bias confidence limits were set to distinguish between no bias and a bias no greater than $1.0 \times$ standard error of calibration (SEC) with 90% confidence when using a two-tailed type 1 error probability of 0.10 (Shenk and Westerhaus, 1993a). Shenk and Westerhaus (1993a) suggested that if bias were greater than the confidence limit, the calibration set may be insufficient and should be expanded.

Chemical Analysis (Laboratory Reference Methods)

Samples in the calibration set were analyzed for eight constituents. We assayed organic matter (OM) by burning a sample in a muffle furnace at 550°C for 4 hr. Total nitrogen (N) was assayed using a semi-micro Kjeldahl method calibrated against ammonium sulfate standards. Cell-wall constituents of seagrass have been implicated as important determinants of feeding by several authors (Lanyon and Marsh, 1995a; Preen, 1995), and we measured them as neutral detergent fiber, acid detergent fiber, and acid lignin using an ANKOM plant fiber analyzer (ANKOM, Fairport, NY, USA; Komarek, 1994) following Van Soest et al. (1991). Total water-soluble carbohydrates were extracted using 80% aqueous ethanol and water (Radojevic et al., 1994) and quantified as fructose equivalents using the anthrone reaction (Jermyn, 1975). Insoluble material remaining from this extraction was analyzed for starch enzymatically using a commercial total starch assay kit (Megazyme Total Starch Kit; Megazyme, Australia). We solubilized any resistant starch with dimethyl sulfoxide prior to enzymatic treatments. Finally, we measured *in vitro* dry matter digestibility of each sample (Choo et al., 1981) in ANKOM filter bags. The *in vitro* digestibility method attempts to simulate digestive processes in herbivorous mammals using the enzymes pepsin and cellulase and is potentially useful as a way of integrating all individual assays of each sample.

Accuracy of NIRS analyses depends entirely on accuracy of analyses of the calibration set. Therefore, to ensure the quality of data in the calibration set, we analyzed all samples in duplicate and repeated those that differed by more than 2% for N and 5% for other measures. Additionally, a randomly chosen subset ($N = 20$) of laboratory samples (called the laboratory validation set) was reanalyzed in duplicate to estimate precision of analyses. All analyses were expressed on a percent dry weight basis. A correlation analysis between calibration and laboratory validation analyses (sets) was performed for each reference method.

Table 1 Composition of seagrass used to construct calibration equations

Species	Part	Nitrogen	Organic matter	Neutral detergent fiber	Acid detergent fiber	Acid lignin	Starch	Water-soluble carbohydrate	<i>In vitro</i> digestibility

All values expressed as % dry matter: mean (SE).

NIRS Calibrations

A calibration model for each of the constituents of interest was developed by regression of spectral absorbances and chemical analyses of each sample. We assessed a number of different regression methods including multiple linear regression and partial least-squares regression, but in all instances, modified partial least-squares (MPLS) regression (Martens and Naes, 1989; Shenk and Westerhaus, 1991b,c) was superior. MPLS uses all spectral data in contrast to alternative approaches such as multiple linear regression that uses a small subset of spectral data. We applied several transformations [calculation of first derivative (Osborne et al., 1993) and detrending (Barnes et al., 1989)] to the spectral data to remove the effect of particle size differences and to minimize autocorrelations between spectral measurements. These are recommended standard procedures (Anon, 1995).

The MPLS approach requires cross validation to prevent overfitting (i.e., using too many terms in the equation) and to select the optimum number of terms for each calibration equation (Osborne et al., 1993). Cross validation involves dividing the sample set into N groups and performing calibration on $N - 1$ groups with the remaining group being used as an independent validation set. This exercise is repeated until all samples have been cross-validated and residuals of each prediction are pooled to provide an SECV. A final regression model is then fitted to the data using the number of factors determined by the cross-validation procedure. Cross validation is an efficient procedure because all samples are used for both calibration and validation and avoids the need to set aside samples for a validation set (Osborne et al., 1993; Shenk and Westerhaus, 1993a). Another advantage of cross validation is that outliers from prediction residuals are identified readily (Shenk and Westerhaus, 1991a, 1993a; Osborne et al., 1993).

Table 2 Performance of combined plant part calibration equations for estimating the nutritional composition of seagrass

Component	N	Mean	Range	SEL	SEC	SECV	SECV/ SEL	r^2	Bias	Bias limit
Nitrogen	198	1.15	0.38–3.60	0.06	0.07	0.08	1.33	0.99	−0.01	0.04
Organic matter	192	61.4	32.0–77.4	2.00	1.93	2.17	1.08	0.96	0.01	1.16
Neutral detergent fiber	198	34.2	19.2–59.8	2.54	2.14	2.79	1.10	0.94	0.00	1.28

Acid lignin	195	13.0	2.1–30.2	3.18	3.11	3.35	1.05	0.73	0.31	1.86
Starch	175	5.6	0.2–30.6	0.90	1.08	1.25	1.40	0.98	−0.36	0.65
Water-soluble carbohydrate	184	1.7	0.01–7.95	0.55	0.58	0.60	1.09	0.90	0.02	0.35
<i>In vitro</i> dry matter digestibility	198	86.7	62.7–98.1	2.48	2.52	2.76	1.11	0.86	−0.19	1.45

All values expressed as % dry matter. Number of samples used in the calibration (N), standard errors of laboratory analysis (SEL), calibration set (SEC), cross validation (SECV), ratio of SECV to SEL, bias, and limits of the bias associated with NIRS equations developed using a combined population of plant fractions (leaf + root/rhizome).

Predictions from Calibration Equations

Calibration equations obtained from MPLS regressions with cross validation for each nutritional attribute were used to predict constituent values of the entire sample population using the PREDICT algorithm of the NIRS3 software (Shenk and Westerhaus, 1992). These calibrations were monitored statistically for performance. Linear regressions of predicted values (\hat{Y}) vs. laboratory reference values (X) were determined for each constituent. Other statistics (r^2 , SEC, SECV, bias and bias confidence limits calculated as percentage of means, and slope) were computed through NIRS3 (Shenk and Westerhaus, 1992).

Results

Details of composition of the 198 samples used in the calibration set are presented in Table 1. There was no significant difference (paired t test, range of $P = 0.856$ – 0.072 ; $N = 20$) in predicted values for any of the eight constituents for material from large samples (>2 g) scanned in standard cells or small amounts (0.3–0.5 g) of the same material scanned in micro cells. The lower P value (0.072) was for water-soluble carbohydrates, values for which tended to vary little, and thus there is a greater tendency for the comparisons to approach significance. We also examined correlations between the values from the large and small cells. In all cases, the correlations were very close to 1, so we are satisfied that our estimates of composition of small samples of seagrass leaf and rhizome are valid.

Table 3 Performance of plant part specific calibration equations for estimating the nutritional composition of seagrass

Component	Roots and rhizomes fraction					Leaf fraction				
	N	SECV	r^2	Bias	Bias limit	N	SECV	r^2	Bias	Bias limit

<i>In vitro</i> dry matter digestibility	104	2.78	0.91	-0.07	1.34	74	2.03	0.78	-0.26	0.96

Standard errors of cross validation (SECV), simple coefficient of determination (r^2), bias of the prediction, and limits of the bias associated with NIRS analysis of nutrient composition and *in vitro* digestibility using single plant-fraction prediction equations for root and rhizome fractions of seagrass.

^a See results for explanation of high bias estimate.

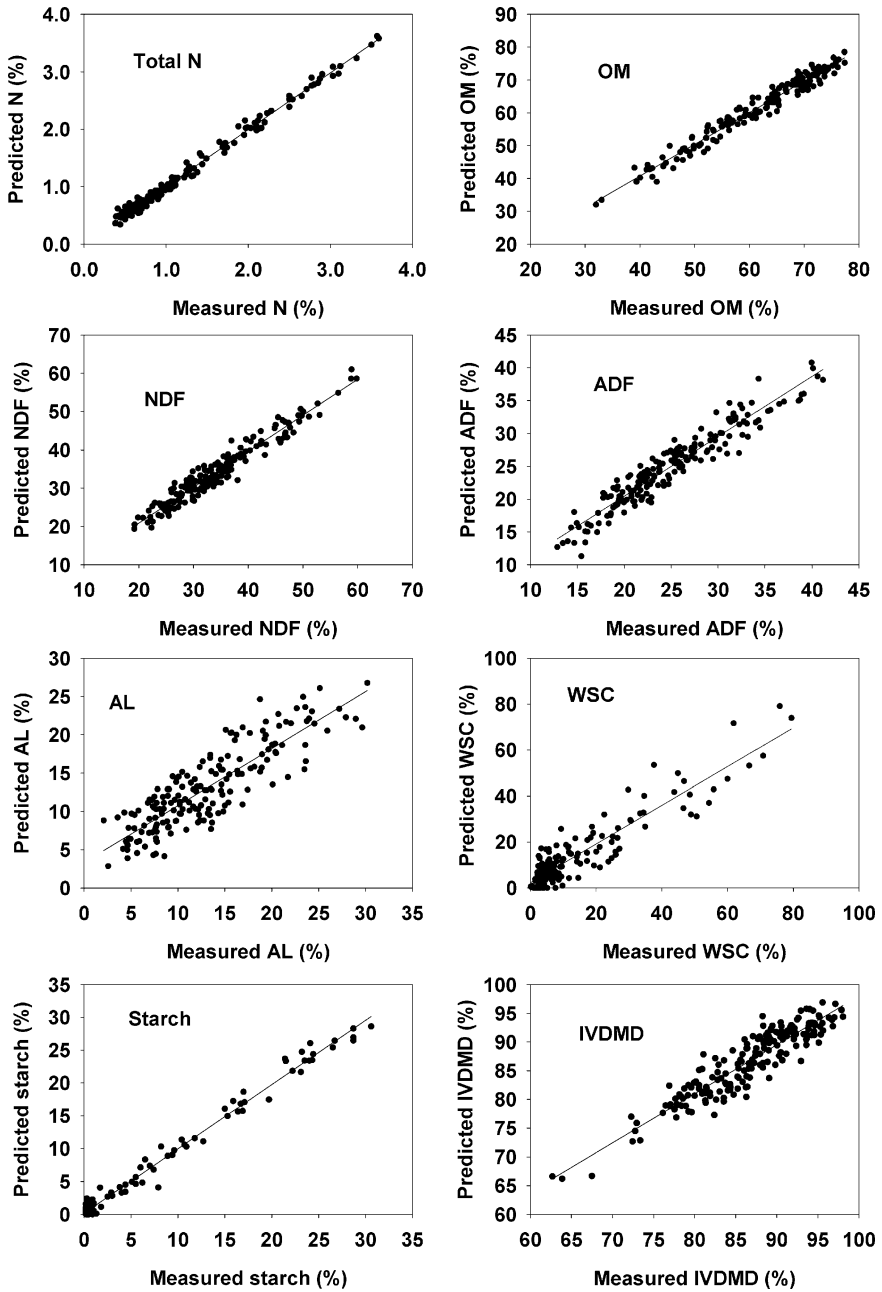

Fig. 1 Relationship between the nutritive value of seagrass measured in the laboratory and value predicted by near-infrared spectrometry. All values are expressed as % dry matter. For statistics, see Table 2

Laboratory precision [standard error of laboratory determination (SEL)] generally was excellent (Table 2) but was best for those constituents that were best characterized chemically. For example, acid lignin is a poorly defined, heterogeneous material that is difficult to analyze and had a relatively high SEL ($\bar{x} = 12.95$; SEL = 3.18). In contrast, total *N* is well defined and easy to analyze and had a relatively low SEL ($\bar{x} = 1.15$; SEL = 0.06).

Final or “global” calibration equations, developed by combining all samples irrespective of plant fraction or species, performed as well as those developed separately for roots and rhizomes (combined) and leaves (Tables 2 and 3). Only two constituents, organic matter and neutral detergent fiber, had consistently lower SECVs using calibrations based on single plant fractions than those determined from calibrations based on combining all samples. The calibration equation for starch in seagrass leaves was poor—reflected by an $r^2 = 0.26$. This was caused primarily by the small range of values for starch in leaves of seagrasses (0.2–0.8% starch of dry matter). In contrast, starch in roots and rhizomes was up to 30% of dry matter, and these data strongly influenced performance of the global equation.

The global set of MPLS-based calibration equations was superior to other regression methods in terms of SECV and coefficient of determination. Overall performance of calibration equations for the different constituents and *in vitro* digestibility of seagrasses was excellent (Table 2 and Fig. 1). This is best reflected by the closeness of the SECV/SEL ratio to 1.0. SEL values usually were low, reflecting precision of routine laboratory analyses. Proximity of values of the SECV/SEL ratio to unity (Table 2) confirms that NIRS analysis lost little precision relative to standard laboratory analytical techniques. Predicted values for all components except acid lignin agreed closely with the laboratory reference values and had r^2 values >0.90.

Discussion

This study has shown that NIRS is a suitable and powerful technique for measuring nutrient composition and *in vitro* digestibility of seagrass. The key advantage of using NIRS is that sampling regimes can be developed that satisfy statistical and biological criteria without being unduly constrained by the logistics of making traditional laboratory measurements of a large number of samples. In the context of the broader study for which these methods were developed (Aragones, 1996), only 17% of the total samples collected were subject to traditional laboratory analyses, and NIRS was used to predict the remaining 83%. This led to major savings of time and money.

Collecting duplicate spectra from a single sample takes at most 1–2 min, and, depending on how instrument software is configured, results for all calibrated constituents appear within seconds. Of course, developing calibration equations takes time, but selecting a suitable subset of samples to use in the calibration equation and validating the calibration equation take only a matter of hours in addition to standard laboratory work to chemically analyze the subset. Clearly, NIR analysis is suitable for larger data sets rather than those containing only a few samples.

A second advantage is that calibration equations are available for future studies, so that there will be no need to analyze an additional large sample set. We believe

that analysis of some samples from a future study is important to check that all new samples fall within the bounds of the existing calibration population. If not, then the calibration set can be expanded as we demonstrated here.

This study introduced several innovations that make NIRS particularly useful for ecological research in marine environments. First, development of a microsample cell demonstrated that multiple analyses could be made on small amounts of material. Sample cells for NIRS have been developed for a wide range of materials, and there is little constraint on the type and amount of material that is needed to collect spectra. In marine studies, there is often only a small amount of material available, especially from manipulative studies, and demonstration that NIRS can be used successfully for samples as low as 0.3 g of dry matter is significant. A current study (Bité and Lawler, unpublished data) is using even smaller samples with success using spinning cup inserts made by the manufacturers of the spectrophotometer.

Second, we have shown that broad-based or global calibration equations are just as good as those restricted to plant fractions. Traditionally, NIRS-based calibration equations have been narrow. For example, in analysis of protein in wheat grain, equations often are developed for wheat harvested in a single season at a single site (Batten, 1998). In contrast, especially ecological studies in marine environments usually focus on compositional changes across years, across sites, and among species (e.g., Lanyon and Marsh, 1995b). Our development of broad-based equations that incorporated leaves, roots, and detritus suggests that the method is particularly powerful for ecological studies.

Some studies (e.g., Meuret et al., 1993; Shenk and Westerhaus, 1993b) also have shown that whole plant-based calibrations differ only slightly from single-product calibrations. Smith and Flinn (1991) suggested that although development of broad-based calibrations is tedious, broad-based equations are more cost-effective than conventional techniques. This suggests that an initial broad-based calibration is more useful to develop, and expands with additional small extension populations, as required, than to gather another large set of samples for development of a specific new calibration each time this need arises. Shenk and Westerhaus (1993a) noted that development of global calibrations was made possible only by technological advances in desktop computing and software. This approach will be important for wildlife nutritional studies. The ability to limit calibrations to one equation per constituent, rather than one per constituent per plant part, will also increase the savings of adopting NIRS.

In NIRS, there always will be a trade-off between developing a robust equation of wide applicability and one that is tailored precisely to a particular set of conditions. For example, we were careful to ensure that all our samples were equilibrated to an equivalent dry matter content before scanning. This is because water has a strong absorbance in the near-infrared spectra, and this absorption can mask other absorbances that may be of interest. Similarly, we were careful to use a single, specified grinder and to keep that grinder in good order so that we produced a uniform particle size. Additional robustness of a calibration equation can be achieved by including variation for particle size and sample moisture. For example, if samples were to be prepared and scanned in several different laboratories, these issues might be accorded more weight. A small amount of precision may be sacrificed for a more robust equation, depending on the uses to which the equation is to be put. Potential users of this technique should not necessarily try to emulate the detail of the approaches that we used for equation development, but any laboratory

analyst has to think carefully about an equation's end use before deciding what analytical precision and accuracy are acceptable.

Acknowledgments This work formed part of the Ph.D. thesis of L.A., who was supported by a scholarship from the Australian government through AUSAID. Data collection was facilitated by grants from the Great Barrier Reef Marine Park Authority and James Cook University. We thank the Great Barrier Reef Marine Park Authority for permission to conduct scientific research within the Marine Park and Ms. M. Bissell and Ms. D. Haffner for help in the laboratory.

Abstract The protein precipitation assay used by Robbins et al., (1987) *Ecology* 68:98–107 has been shown to predict successfully the reduction in protein availability to some ruminants due to tannins. The procedure, however, is expensive and laborious, which limits its utility, especially for quantitative ecological or nutritional applications where large numbers of assays may be required. We have modified the method to decrease its cost and increase laboratory efficiency by: (1) automating the extraction by using Accelerated Solvent Extraction (ASE); and (2) by scaling and automating the precipitation reaction, chromatography, and spectrometry with microplate gel filtration and an automated UV–VIS microplate spectrometer. ASE extraction is shown to be as effective at extracting tannins as the hot methanol technique. Additionally, the microplate assay is sensitive and precise. We show that the results from the new technique correspond in a nearly 1:1 relationship to the results of the previous technique. Hence, this method could reliably replace the older method with no loss in relevance to herbivore protein digestion. Moreover, the ASE extraction technique should be applicable to other tannin–protein precipitation assays and possibly other phenolic assays.

Introduction

Plant polyphenolics (tannins) are estimated to be the fourth most abundant biochemical in terrestrial biomass, following cellulose, hemicelluloses, and lignin (Hernes and Hedges, 2000). In rapidly cycling soft tissues such as leaves and needles, tannins can be more abundant than lignin (Hedges and Welikey, 1989; Benner et al., 1990). Because of their prevalence and biological importance, the determination of tannins and their impacts is important in many fields including ecology, nutrition, soil science, and human health (Haslam et al., 1999). With regards to plant–herbivore interactions, the effects of tannins can range from beneficial [e.g., as antioxidants (Hagerman et al., 1998a) and by increasing protein bypass in the foregut of ruminants (Waghorn and Shelton, 1997)] to toxic (Bryant et al., 1992; Reed, 1995; Provenza et al., 2000) or antinutritional (Feeny, 1976; Rhoades and Cates, 1976).

Due to the complexity of tannin interactions, there is currently no single analytical technique that adequately quantitates the suitability of tannin-containing feeds to herbivores. With regards to ruminants, Makkar (2005) recommends employing a suite of assays to assess the potential effects of tannins. Although such a battery of tests reveals much information, to date few tannin assays have been shown to directly correlate to a measurable biological effect in ruminants.

One type of assay that has been successful at predicting a biological effect of tannins in ruminants is protein precipitation. The reduction in protein availability due to tannins has been demonstrated *in vivo* and successfully developed as a laboratory assay (Martin and Martin, 1982; Robbins et al., 1987; Hanley et al., 1992). Subsequent studies have questioned whether the predictive equations conceived by Robbins et al. (1987) and validated by Hanley et al. (1992) for mule deer (*Odocoileus hemionus hemionus*) and black-tailed deer (*O. hemionus sitkensis*) are applicable to other ruminants. Awassi sheep (*Ovis aries*) and crossbred goats (*Capra hircus*) appear less adept at retaining protein when consuming tannin diets (Degen et al., 1995), and results from digestion trials with blue duikers (*Cephalophus monticola*) (Shipley and Felicetti, 2002) may also deviate from the predictions of Robbins et al. (1987). There is considerable observed variability in animal physiological responses to tannins (Martin and Martin, 1984; Robbins et al., 1991; Hagerman and Robbins, 1993), and structural differences are known to affect tannin function (Clausen et al., 1990; Ayres et al., 1997; Kraus et al., 2003). Therefore, such discrepancies to the equations of Robbins et al. (1987) are plausible, and reveal the need to examine carefully the utility of protein precipitation assays, when such assays are appropriate, and for which animals they apply.

The Degen et al. (1995) study investigated Awassi sheep and goats, which may produce few or no salivary tannin-binding proteins (Austin et al. 1989), and thus are understandably less capable of efficient protein digestion when consuming tannin-rich diets compared to deer. However, the Degen et al. (1995) study utilized the protein precipitation assay of Makkar et al. (1988) with “the conditions of Martin and Martin (1982).” The Makkar et al. (1988) assay was shown to correlate well with

the protein precipitation assay outlined in Hagerman and Butler (1978). However, the protein precipitation assay utilized by Robbins et al. (1987) (i.e., the Martin and Martin, 1982 assay) correlated poorly with the Hagerman and Butler (1978) assay at least for some oak species (Martin and Martin, 1982), discrepancies that Martin and Martin (1982) attributed to possible structural and protein-binding variation of the tannins between species. Considering the documented variation in protein precipitation due to tannin structural heterogeneity (Kraus et al., 2003) and the diversity of tannins found in plants, it is not surprising that the correlation between assays and protein digestion *in vivo* is not high. In fact, it emphasizes that the use of alternative assays to predict protein digestion must be carefully validated against the original assays or against *in vivo* data.

In addition, both the Degen et al. (1995) and Shipley and Felicetti (2002) studies include a small sample size of forages, which limits their comparison to the Robbins et al. (1987) predictions for protein digestion. Therefore, it is difficult to say whether the equations of Robbins et al. (1987) are useful for ruminants other than mule deer and black-tailed deer. Regardless, even if these equations are not inclusive of all ruminants, future comparative work on other herbivores with this assay system will lead to greater understanding of tannin chemistry and herbivore digestive efficiency and adaptation.

With regard to the role tannins play in reducing protein availability to ruminants, numerous assays are currently available (see Scalbert, 1992; Waterman and Mole, 1994; Hagerman et al., 1997; Hoffmann et al., 2002; Makkar, 2003; Henson et al., 2004). Makkar (2005) suggests that the radioisotope technique (Hagerman and Butler, 1980; Hagerman et al., 1998b) is particularly attractive for determining protein availability to ruminants because of its sensitivity and recent simplification (Henson et al., 2004). To the best of our knowledge, only the assay used by Robbins et al. (1987) has been directly and quantitatively linked to protein digestion in ruminants. Moreover, the available techniques rely on slow and potentially inefficient extraction methodologies, are not conducive to laboratory automation, and do not minimize waste production.

The goal of this work was to modify the methodology of Robbins et al. (1987) to accelerate and simplify the extraction process by using Accelerated Solvent Extraction (ASE), and to scale the protein-binding assay to a microplate system to improve its efficiency and cost-effectiveness. Our objectives were to optimize the system for time and cost while maintaining the protein-binding sensitivity, equivalence of results, and predictive capabilities of the original method employed by Robbins et al. (1987) for ruminant (e.g., Cervid) herbivores.

Methods and Materials

Reagents and Sample Preparation

Bovine serum albumin (BSA) (Albumin, Bovine, Globulin-free, Catalogue No. A-7638) and Sephadex G-25 (Medium grade, Catalogue No. G25150) were obtained from Sigma (St. Louis, MO, USA). Sephadex G-25 PD-10 columns were obtained from Amersham Biosciences (Piscataway, NJ, USA). Acetate buffer (0.2 M, pH 4.9) was prepared as described by Martin and Martin (1982). All methanol used was HPLC-grade and all water used was 18 Ω Mohm. Leaf and stem samples were

collected in the field, immediately frozen on dry ice, and subsequently lyophilized. The dried samples were ground in a Wiley mill (40-mesh) and stored in airtight containers at room temperature out of direct sunlight until analyzed.

Extraction of Phenolics

Hot aqueous methanol extraction was conducted with a sonicator and heat block as described by Robbins et al. (1987). Briefly, 1 g plant material was extracted $\times 3$ in 15 ml hot aqueous methanol, filtered, and combined. The final solution was brought to 50 ml volume.

ASE extraction was conducted on a Dionex Model ASE-200 solvent extractor using aqueous methanol (50:50, vol/vol) and 11 ml cells with three cellulose filter disks. The extraction consisted of two 5-min static (extraction) periods at 1500 psi N_2 and 100°C. One g plant material was extracted, and the subsequent supernatant from the extractions and washes totaled approximately 30 ml, which were then diluted to 50 ml volume.

For additional comparison, we extracted each sample by using a cold aqueous methanol technique. One g plant material was extracted $\times 4$ (15 min each, 0°C) in a sonicator with aqueous methanol (50:50, vol/vol). The four extracts were combined and brought to 50 ml volume.

Macro BSA Precipitation Assay

The technique of Martin and Martin (1982), as modified by Robbins et al. (1987), was followed. For each plant sample, 1.39 ml of a 1 mg BSA/ml acetate buffer stock solution were combined with four aliquots of plant extract, diluted such that a range between 0.1 and 0.7 mg of BSA was precipitated from the stock BSA solution. Precipitation reactions were allowed to proceed under refrigeration for 12 hr, after which samples were centrifuged. The supernatant was decanted and filtered through a Sephadex G-25 PD-10 column and collected in a clean test tube. The precipitate was washed with 0.51 ml acetate buffer, centrifuged, and the supernatant was decanted into the Sephadex column again. Finally, the column was washed with 3.5 ml buffer to optimize recovery of protein. The filtered supernatant was assayed by using a standard Bradford protein assay (Bradford, 1976). For extraction technique comparison, BSA precipitation capacity was estimated from an optimal dilution (i.e., where precipitation of protein was approximately 50%). This dilution level was determined by trial and error from at least 4 dilution trials per forage. Duplicate extractions and duplicate BSA precipitations for each extraction were conducted to assess the precision and accuracy of the extraction technique. For BSA precipitation assay comparison, precipitation capacity was estimated from a regression of at least three different dilutions of plant extract.

Microplate BSA Precipitation Assay

To conserve materials and automate the protein precipitation assay, we scaled the volumes and concentrations of BSA, plant extracts, and Bradford assay such that all reactions, chromatography, and spectrometry could be carried out in a microplate environment. To do so, aliquots of forage extract between 2.7 and 59.1 μg (dry weight basis) diluted to 100 μl were combined with 150 μl BSA (310 $\mu\text{g/ml}$) in

acetate buffer on a 2 ml well volume microplate. The entire plate was then vortexed, capped, and allowed to precipitate overnight at 4°C. Fourteen standards ranging in concentration from 5.0 to 37.4 µg/ml BSA and two blanks were prepared on each microplate by using aqueous methanol (50:50, vol/vol), 310 µg BSA/ml solution, and acetate buffer, such that volumes of each reagent were identical to that of the unknowns. The following day, a Sephadex filter plate was prepared by pipetting 300 µl Sephadex G-25 slurry (1.0 g/5 ml acetate buffer, allowed to swell for at least 3 hr) into each well of 350 µl cellulose acetate filter microplate (Whatman Unifilter). The Sephadex wells were packed by centrifuging the filter plate (750 g) for 5 min at 20°C, and discarding the filtrate. The sample preparation plate was then centrifuged (750 g, 5 min, 20°C) to sediment the precipitated pellet, and 40 µl supernatant from each well were added to the center of each Sephadex-packed well on the filter plate. The filter plate was then centrifuged (750 g, 5 min, 20°C), and the filtered supernatant was collected on an assay microplate (400 µl flat-bottomed polystyrene). One hundred sixty µl of diluted Coomassie Brilliant Blue G-250 dye reagent [(1 part dye, 4 parts distilled water; Bio-Rad Protein Dye Reagent, Bio-Rad Corporation)] were then added to each well, and the entire plate was carefully vortexed to mix each sample, and centrifuged (500 g, 40 sec, 20°C) to eliminate any bubbles formed during pipetting of the dye. After 6 min incubation (Bradford, 1976), the absorbance at 595 nm was read on a microplate spectrophotometer (Molecular Devices SpectraMax Plus³⁸⁴). Absorbance was transformed into µg of BSA by the use of blanks and a standard curve on each microplate. BSA concentrations of the unknowns were calculated from the standard curve, and precipitated BSA was calculated by difference.

Results

Tannin Extraction Method Comparison

Protein precipitation capacity of plant samples ranged between 0.06 ± 0.01 and 0.61 ± 0.02 mg BSA/mg forage dry matter for the hot methanol extraction method, $0.08 \pm$

Table 1 Bovine serum albumin (BSA) precipitation capacities of eight plants compared by extraction method^a

Plant sample	Extraction method		
	Hot	ASE	Cold
<i>Epilobium angustifolium</i> leaf	0.61 ± 0.02	0.66 ± 0.02	0.37 ± 0.01
<i>Betula papyrifera</i> leaf	0.49 ± 0.02	0.47 ± 0.05	0.27 ± 0.01
<i>Salix pulchra</i> leaf 1	0.33 ± 0.01	0.36 ± 0.01	0.25 ± 0.01
<i>Equisetum sylvaticum</i>	0.33 ± 0.01	0.27 ± 0.02	0.20 ± 0.10
<i>Salix alaxensis</i> stem	0.28 ± 0.01	0.23 ± 0.02	0.17 ± 0.01
<i>Salix pulchra</i> stem	0.22 ± 0.02	0.17 ± 0.02	0.11 ± 0.02
<i>Betula papyrifera</i> stem	0.12 ± 0.02	0.08 ± 0.01	0.07 ± 0.01
<i>Salix pulchra</i> leaf 2	0.06 ± 0.01	0.11 ± 0.00	0.04 ± 0.00

^a Hot extraction was performed as described by Robbins et al. (1987). ASE and cold extraction methods are outlined above. Precipitation capacities are expressed as mean \pm standard deviation. All values are expressed in mg BSA precipitated/mg forage dry matter. $N = 2$ for each plant sample.

Symbols and regression equations for each plant sample type: Δ *Betula papyrifera* stem, $Y = -0.0183 + 0.1093X$; \blacktriangle *Salix pulchra* stem 1, $Y = -0.0018 + 0.1461X$; \times *Salix alaxensis* stem, $Y = 0.0201 + 0.2085X$; \circ *Salix pulchra* stem 2, $Y = -0.0185 + 0.2553X$; \bullet *Salix pulchra* leaf 1, $Y = 0.008 + 0.3213X$; \square *Betula papyrifera* leaf, $Y = 0.011 + 0.3283X$; \blacksquare *Salix pulchra* leaf 2, $Y = -0.0195 + 0.4242X$; \diamond *Epilobium angustifolium* leaf, $Y = -0.0154 + 0.4716X$. Coefficients of determination for all regressions are 0.98 or higher

Fig. 2 Microplate BSA precipitation capacities of eight plant extracts. Symbols and regression equations for each plant sample type: Δ *Betula papyrifera* stem, $Y = -0.8065 + 0.0842X$; \blacktriangle *Salix pulchra* stem 1, $Y = -0.6844 + 0.1411X$; \times *Salix alaxensis* stem, $Y = -0.5096 + 0.1965X$; \circ *Salix pulchra* stem 2, $Y = -0.4995 + 0.2598X$; \square *Betula papyrifera* leaf, $Y = -0.293 + 0.3214X$; \bullet *Salix pulchra* leaf 1, $Y = 0.3488 + 0.3529X$; \blacksquare *Salix pulchra* leaf 2, $Y = 0.3427 + 0.3977X$; \diamond *Epilobium angustifolium* leaf, $Y = -1.0266 + 0.4516X$. Coefficients of determination for all regressions are 0.96 or higher

0.01 and 0.66 ± 0.02 mg/mg for ASE extraction, and 0.07 ± 0.01 and 0.37 ± 0.01 mg/mg for the cold methanol extraction (Table 1). Mean relative error was 7.1% for the hot methanol extraction technique, 7.4% for ASE extraction, and 11.9% for cold extraction.

There was a high correlation and a nearly 1:1 relationship between BSA precipitation capacities of the forages for the ASE extraction and the hot extraction techniques (Table 1, $r^2 = 0.95$, slope = 1.06). The homogeneity of the slope comparing techniques to the line $y = x$ revealed there was no significant difference in BSA precipitation capacity between ASE and hot methanol extraction techniques ($t = 0.46$, $P = 0.66$). The cold extraction technique correlated well with hot extraction ($r^2 = 0.95$) and ASE extraction ($r^2 = 0.94$) BSA precipitation capacities, but less protein was precipitated compared to the hot and ASE extraction techniques (slope = 0.58, $t = -6.53$, $P < 0.001$; and slope = 0.54, $t = -6.86$, $P < 0.001$, respectively).

BSA Precipitation Assay Method Comparison

For the comparison of the macro- and microplate BSA precipitation assays, we reextracted the plant samples by using the ASE extraction method. The macroassay of the eight plant samples revealed BSA precipitation capacities ranging between 0.11 and 0.47 mg BSA/mg forage dry matter, with coefficients of determination for

Fig. 3 BSA precipitation capacity comparison between the macro technique (Martin and Martin 1982; Robbins et al., 1987) and the new microplate technique. Symbols representing each plant sample type: ◇ *Epilobium angustifolium* leaf; ■ *Salix pulchra* leaf 2; ● *Salix pulchra* leaf 1; □ *Betula papyrifera* leaf; ○ *Salix pulchra* stem 2; × *Salix alaxensis* stem; ▲ *Salix pulchra* stem 1; △ *Betula papyrifera* stem

each sample ranging between 0.98 and 0.99 (Fig. 1). In comparison, the microplate method resulted in BSA precipitation capacities of the same plant extractions ranging between 0.08 and 0.45 $\mu\text{g BSA}/\mu\text{g}$ forage dry matter, with corresponding coefficients of determination ranging between 0.96 and 0.99 (Fig. 2).

The BSA precipitation methods were highly correlated, and produced a nearly 1:1 relationship (Fig. 3, $r^2 = 0.98$, slope = 0.99). The homogeneity of the slope comparing techniques to the line $y = x$ revealed there was no significant difference between BSA precipitation capacity techniques ($t = -0.22$, $P = 0.83$).

Discussion

Tannin Extraction Method Comparison

Numerous methods exist for extraction of plant phenolics, but the standardization of a particular technique is integral to preserving the specific phenolic compounds and their reactivities of interest to the analyst (Hagerman, 1988; Cork and Krockenberger, 1991; Waterman and Mole, 1994; Mueller-Harvey, 2001). We show here that ASE extraction of tannins appears to be a suitable alternative to the hot methanol extraction technique used by Robbins et al. (1987) for the BSA precipitation assay. The relationship between extraction techniques is nearly 1:1 and correlation is high (slope = 1.06, $r^2 = 0.95$), suggesting minimal change in the protein precipitation capabilities of the extracted tannins within and between samples when extracted under high pressure and temperature.

The repeatability of the ASE extraction technique compared to the hot methanol technique is nearly identical (7.4% and 7.1% mean relative error, respectively). However, we feel the ASE extraction technique is superior to the manual extraction technique because it is automated and thus minimizes potential human error, and it is rapid and, therefore, allows much higher throughput in the laboratory. The hot methanol extraction technique used by Robbins et al. (1987) is prone to sample spillage and loss due to the boiling aqueous methanol solutions. Moreover, although we used 11 ml cells in our ASE, which constrained our extractions to approximately 1 g of dried plant material, and resulted in approximately 50 ml final dilutions, smaller cells (1.5 ml volume) are available for the extraction process. The smaller cells could reduce sample size requirements, and reduce final extraction volumes to approximately 10 ml or less. Hence, there are potentially further savings in solvent costs and waste production, while at the same time allowing the investigator to use much smaller samples (i.e., individual leaves) to obtain equivalent information. As a precaution, however, we feel that analyzing small samples of potentially nonhomogeneous solids can be a major source of experimental error, so there may be advantages to using 1 g samples of the dry solid.

It is likely that ASE extraction of tannins is a useful extraction technique for other popular protein precipitation assays (i.e., Makkar et al., 1988; Hagerman et al., 1998b; Henson et al., 2004) and possibly other phenolic assays (see Scalbert, 1992; Waterman and Mole, 1994; Hagerman et al., 1997; Makkar, 2003). Further investigation into the usefulness of ASE for polyphenolic extraction and use in alternative assays is recommended.

BSA Precipitation Assay Method Comparison

As noted earlier, several assays are currently available for the investigation of protein–tannin binding interactions, and each assay has its advantages and disadvantages. Many binding assays appear to provide similar results (e.g., Martin and Martin, 1982; Hagerman, 1987). Nevertheless, to our knowledge, only the binding assay developed by Martin and Martin (1982) and used by Robbins et al. (1987) has been directly and quantitatively linked to protein digestion in ruminant herbivores. Protein binding capacities of our optimized microplate assay and the Robbins et al. assay were nearly identical (Fig. 3), strongly suggesting that the two techniques are equivalent, and that the microplate assay should be as reliable and accurate in predicting protein digestion in ruminants as the Robbins et al. (1987) assay.

The microplate protein–tannin binding assay was developed in large part to reduce the costs of the assay as well as to increase laboratory efficiency. The macrotechnique used by Robbins et al. (1987) and others requires the use of at least four PD-10 chromatographic columns as well as numerous other laboratory consumables for each plant sample (e.g., numerous pipette tips, several disposable UV–VIS spectroscopy cuvettes, test tubes, and substantial amounts of Bradford dye reagent). Alternatively, the microplate assay technique can accommodate at least 10 samples per 96-well plate, and requires substantially smaller amounts of reagents and Sephadex G-25 per sample. Although the microplate technique consumes 3 microplates per run (including a relatively expensive filter plate), it reduces overall laboratory consumable expenses 8-fold (e.g., \$25 per sample for the Robbins et al. assay vs. \$3 per sample for the microplate assay, at current prices), and generates approximately 6-fold less organic waste.

Likewise, the microplate assay reduces laboratory preparation time by nearly half, particularly because many operations can be performed by using a multichannel pipettor, and because the spectroscopy and its analysis is automated and rapid. Moreover, the microplate method lends itself to robotic automation, making possible further and substantial reductions in preparation time. Robotic plate preparation would likely increase precision of the assay as well.

Although we attempted to optimize and automate all aspects of the microplate assay, we are certain that further optimization and automation can be accomplished. We were least satisfied with the preparation and quality of the Sephadex column beds, and we expect that improvements in this process will lead to more precise results. A consistent Sephadex gel bed volume and density is critical to the cleanup and consistent recovery of the samples prior to protein assay, and their preparation by using the slurry method requires practice and care. We recommend the use of a column loader (such as that produced by Millipore) and powdered G-25 Sephadex beads for preparing the filter plate gel columns. With our current filter plate system, a column loader delivering approx. 60–65 μl of beads would be ideal, but unfortunately, loaders are currently only available for 45 or 80 μl deliveries.

In summary, we have shown that the combination of ASE extraction and the microplate BSA precipitation assay produces virtually equivalent results to the methods used by Martin and Martin (1982) and Robbins et al. (1987), and the new technique sacrifices minimal precision and accuracy. Consequently, the new technique preserves the predictive capabilities of the macrotechnique for estimating the protein availability of tanniferous plants to ruminant herbivores. The new technique reduces laboratory time more than 2-fold per sample, and decreases the

cost of the protein–tannin binding assay more than 8-fold. We feel that precision and efficiency can be further improved by using robotic automation, and sample dry weight requirements and chemical waste production may be reduced by using smaller ASE extraction cells. The reduction in cost and the increase in analytical capacity should provide ecologists and ruminant nutritionists greater opportunity at a broader scale than previously feasible for exploring the reduction of available protein to ruminant herbivores due to tannins.

Abstract Plants are able to “notice” insect egg deposition and to respond by activating direct and indirect defenses. An overview of these defenses and the underlying mechanisms is given from a tritrophic perspective. First, the interface between plant and eggs is addressed with respect to the mode of attachment of eggs on the plant surface. It is elucidated which plant cells might respond to components from insect eggs or the egg deposition. The scarce knowledge on the elicitors associated with the eggs or the egg-laying female is outlined. Since endosymbiotic microorganisms are often present on the eggs, and microorganisms are also abundant on the leaf surface, the role of these hidden players for eliciting oviposition-induced plant responses is considered. Furthermore, the question of which physiological and molecular processes are induced within the plant in response to egg deposition is addressed. Second, studies on the response of the herbivorous insect to oviposition-induced plant defenses are outlined. Third, the importance of oviposition-induced plant volatiles and contact cues for host and prey location of parasitoids and predators is discussed in the context of other informative chemicals used by carnivores when searching for food. Finally, physiological and ecological costs of oviposition-induced plant responses are addressed.

Keywords Plant defenses · Oviposition · Egg · Secretion · Endosymbiotic microorganisms · Elicitor · Terpenoids · Green leaf volatiles

Introduction

Most herbivorous insects start attacking a plant by laying eggs on it. For example, many Lepidoptera and folivorous Hymenoptera do not feed upon leaves during the adult stage, but females deposit their eggs on those plants or plant parts where

Table 1 Oviposition-induced plant responses acting directly against the herbivore or addressing the third trophic level

Plant	Herbivore	Effect of egg deposition	Induction by	Elicitor	Induction time	Reference
Direct defenses						
Pea	Bruchids	Neoplasma growth (local response only)	Egg cement No (ovipositional) wounding	3-Hydroxy-propanoates	1 d	Doss et al., 1995, 2000; Oliver et al., 2000
Rice	Planthoppers	Ovicidal substance (local response)	Egg on watery oviposition lesion Ovipositional wounding	Unknown	2 d	Seino et al., 1996; Suzuki et al., 1996
Potato	Colorado potato leaf beetle	Hypersensitive response (local response only)	Egg shell or egg cement No (ovipositional) wounding	Unknown	1 d	Balbyshv and Lorenzen, 1997
Cabbage	Large/small white cabbage butterfly	Hypersensitive response (local response only)	Egg cement No (ovipositional) wounding (?)	Unknown	1 d	Shapiro and DeVay, 1987
	Large white cabbage butterfly	Oviposition deterrence (local response, systemic response indicated)	Egg on undamaged surface No (ovipositional) wounding (?)	Unknown	1 d	Blaakmeer et al., 1994

Indirect defenses						
Elm	Elm leaf beetle	Oviposition-induced volatiles attract parasitoids (local + systemic response)	Egg on surface-damaged leaf Female removes leaf epidermis at oviposition site	Oviduct secretion coating the egg	3 hr–5 d	Meiners and Hilker, 1997, 2000; Meiners, unpublished data
Pine	Pine sawfly	Oviposition-induced volatiles attract parasitoids (local + systemic response)	Egg in slit pine needle Female saws a needle tangentially to lay eggs inside	Oviduct secretion coating the eggs; a small protein or peptide	3 d	Hilker et al., 2002a, 2005
Bean	Bug	Oviposition-induced volatiles attract parasitoids (local + systemic response)	Egg on undamaged surface No (ovipositional) wounding But plus feeding damage	Unknown	3–4 d	Colazza et al. 2004a,b
Brussels sprouts	Large white cabbage butterfly	Oviposition-induced leaf contact cues arrest parasitoids (local response)	Egg on undamaged surface No (ovipositional) wounding	Secretion of accessory gland which glues the egg onto the surface	3–4 d	Fatouros et al., 2005a

hatching larvae will find suitable food. Also, in those herbivores where adults and larvae do not have separate feeding niches, such as, for example, in many herbivorous Coleoptera and Hemiptera, the choice of a plant for egg deposition is the initial step for starting a further generation damaging the plant by feeding activity.

Numerous studies address plant defenses that are induced by feeding herbivores (Tumlinson et al., 1993; Karban and Baldwin, 1997; Agrawal et al., 1999; Dicke and van Loon, 2000; Turlings and Wäckers, 2004). These plant responses start when feeding damage and loss of foliage have already begun. However, a plant is able to act “just in time” to prevent herbivores from feeding at all. Plants have evolved several mechanisms and respond to the very first step of insect attack. Induced direct and indirect plant defenses as responses to insect egg deposition are known. These oviposition-induced reactions aim to rid the plant of eggs and/or kill them, thus preventing feeding damage by the larvae that would hatch from these eggs (Hilker and Meiners, 2002; Hilker et al., 2002b).

Direct plant defenses induced by insect egg deposition may affect either the eggs themselves or the egg-laying female (Table 1). Egg deposition can induce the formation of a neoplasm that elevates the egg from the plant surface. Such exposed eggs easily drop off the plant (Doss et al., 1995, 2000). Rice plants even produce an ovicidal substance that kills the eggs in response to egg deposition by planthoppers (Seino et al., 1996; Suzuki et al., 1996; Yamasaki et al., 2003). Another mechanism to get rid of the eggs is to form necrotic tissue where eggs are laid. Such a hypersensitive response detaches the eggs from the plant surface and makes them fall to the ground. Larvae hatching on the ground suffer a rarely high mortality and rarely find their way back to their host plant (Shapiro and DeVay, 1987; Balbyshev and Lorenzen, 1997). A further direct defense mechanism induced by egg deposition addresses the egg-laying female by rendering those leaves deterrent that already carry eggs or that are adjacent to egg-laden leaves (Blaakmeer et al., 1994).

The known indirect plant defense mechanisms induced by egg deposition act by supporting egg parasitoids to locate their hosts (Table 1). For three tritrophic systems, it has been shown that insect egg deposition induces a plant volatile pattern that attracts egg parasitoids (elm: Meiners and Hilker, 1997, 2000; pine: Hilker et al., 2002a; beans: Colazza et al., 2004a), whereas the study of a further system consisting of *Brassica*, *Pieris*, and *Trichogramma* suggests that egg deposition induces the change of plant surface chemicals, thus arresting the egg parasitoids by contact cues in the vicinity of the eggs (Fatouros et al., 2005a).

Up to now, leaves especially are known as the plant organs responding to insect egg deposition by defensive mechanisms (see Table 1). The only exceptions are fruits, i.e., pea pods forming neoplasms in response to egg deposition (Doss et al., 1995, 2000), and stems of rice plants producing ovicidal benzyl benzoate after egg deposition (Seino et al., 1996). No seeds are known to “whisper for help” (Steidle et al., 2005) by emission of oviposition-induced volatiles, even though small seeds also can emit sufficient amounts of volatiles to attract herbivores, regardless of whether they carry eggs or not (Ignacimuthu et al., 2000). Although it is not known if egg deposition can induce defensive responses in, e.g., seeds, roots, or flowers, we suggest that these and plant organs other than leaves are capable of reacting to the presence of insect eggs and activating effective defensive mechanisms.

Almost all plant organs are well known to be able to form galls when attacked by gall insects (Shorthouse and Rohfritsch, 1992). Whereas numerous plant galls are induced by larval feeding activity in plant tissue, several plant galls are induced by

oviposition or by both ovipositional wounding and larval feeding activity (Rohfritsch, 1992; Hilker et al., 2002b). Gall formation of plants may be considered as a mechanism initially evolved for defensive purposes by isolating the galling insect, which in turn has counteradapted to this plant response and evolved the ability to exploit the growing plant tissue for shelter and nutrition (Zweigelt, 1931). Thus, studies on the response of plant organs other than leaves to insect egg deposition will be necessary to understand the plasticity of plant defenses against this first step of attack by herbivores.

When considering plants in the tritrophic systems studied so far for their response to insect egg deposition, numerous questions on both the mechanisms and ecological functions arise. How does the plant “notice” an egg deposition? Is there any evidence that the egg-laying herbivore female counteradapts or even exploits the plant’s response to egg deposition? How does the egg parasitoid recognize oviposition-induced volatile patterns within a jungle of other volatile cues? How important are these oviposition-induced plant cues for host location behavior of egg parasitoids in comparison to other informative chemicals? In the following, these and other questions will be addressed with respect to molecular, physiological, behavioral, and evolutionary aspects.

The Plant and its Response to Insect Egg Deposition

The Interface between Plant and Eggs

Since so far mostly leaves have been studied and found to display oviposition-induced defenses, a closer morphological view of the interface between leaves and eggs of herbivorous insects is presented here (Table 1). The degree of how tightly an egg is associated with the leaf varies greatly and may also depend on the physicochemical characteristics of the leaf surface (Müller and Riederer, 2005). Eggs may be attached just loosely to a leaf like the eggs of the willow leaf beetle, *Phratora vulgatissima*, which are laid on the lower side of a willow leaf (Fig. 1A, B). In this species, the secretion coating the eggs has only very loose contact with the plant surface. The egg adheres especially to the trichomes of the lower plant surface (Fig. 1C). The eggs of many lepidopteran species are tightly glued onto the lower leaf surface. In *Pieris brassicae*, sometimes surface scratches are visible on Brussels sprouts leaves with eggs (Nina Fatouros, personal communication). In the samples studied here, the surface of Chinese cabbage leaves with eggs has not been observed to be damaged before oviposition (Fig. 1D). The transparent shiny secretion of the accessory glands of *P. brassicae* females is not only found directly associated with the eggs, but also smeared on leaf tissue around the egg mass. Where secretion touches the leaf surface, the tissue becomes brownish (Fig. 1E). It is not yet known whether this is due to the closure of stomata by the secretion (Fig. 1F, G) and subsequent death of the cells, or whether it is a hypersensitive response. In contrast, some herbivorous insects damage the leaf at the site of oviposition. This damage may be limited to the epidermis and the adjacent spongy parenchyma, as has been observed for the elm leaf beetle (Fig. 1H–J). The elm leaf beetle prefers to lay eggs on leaf veins (Meiners and Hilker, 1997), thus getting close to the vascular bundles after removal of the epidermis (Fig. 1K, L). Other herbivorous insects severely damage leaf tissue, as has been described for the egg deposition of pine sawflies, which slit a needle tangentially with the ovipositor, remove parenchymatic tissue, and damage one vascular bundle (Hilker et al., 2002a).

The different degrees of egg attachment on or insertion into leaf tissue suggest that different cells of a leaf are able to perceive the information that an egg has been laid. When eggs of *P. brassicae* just touch the wax layer, egg components eliciting the plant's defensive response probably need to move across the wax layer to the epidermal cell wall (Fatouros et al., 2005a). In the elm leaf beetle, the elicitor inducing the oviposition-induced defense (Meiners and Hilker, 2000) is probably interacting with the parenchymatic tissue. Since sawflies deeply disrupt pine needle tissue, all types of damaged cells (e.g., epidermal cells, parenchymatic tissue, endodermal cells) need to be considered as being able to perceive the information of a recent egg deposition (Hilker et al., 2002a).

Pieris brassicae

Xanthogaleruca luteola

Microorganisms in the Interface between Plants and Eggs

Are leaves, insect eggs, and/or their mothers the only interacting organisms for oviposition-induced plant responses, or are hidden players such as microorganisms involved (Dicke and Hilker, 2003)? When damage is inflicted to leaf tissue prior to oviposition (see Table 1), microorganisms might invade wounds and contribute to the oviposition-induced response. These microorganisms or their products might be transferred from the insect into the wound. Furthermore, microorganisms living on the plant surface where they may occur as symbionts, commensalists, or phytopathogens might be involved in the induction process (Dickinson and Preece, 1976; Morris et al., 1996; Kinkel, 1997; Varma et al., 2004). However, wounding is known to be insufficient to induce indirect defensive responses that attract egg parasitoids. In bean leaves, feeding damage *per se* does not induce the release of volatiles that attract the egg parasitoid *Trissolcus basalis* (Colazza et al., 2004a). Also, feeding damaged elms do not emit volatiles that attract egg parasitoids (Meiners and Hilker, 1997). Neither do the ovipositional wounds conducted by the elm leaf beetle (with the mandibles) or by the pine sawfly (with the ovipositor) induce a volatile pattern to which the respective egg parasitoid responds positively (Meiners and Hilker, 2000; Hilker et al., 2002a). Thus, induction of plant defensive responses by insect egg deposition obviously requires elicitors that are specific for the egg or egg-associated components rather than elicitors produced by microorganisms living on the plant surface.

Plant defensive responses to feeding activity have been discussed as being elicited by components produced by microorganisms in the insect gut and then released via

Fig. 1 Mode of attachment of eggs of herbivorous insects to leaf surface. (A) Egg mass of the willow leaf beetle *P. vulgatissima* on a hairy leaf of *Salix viminalis*. Leaf trichomes (tr). Transparent secretion (s) visible on the top of the eggs. Bar = 500 μ m. (B) Cross section (overview) through a leaf of *S. viminalis* with an egg of *P. vulgatissima* on the lower surface. Overview. ey, egg yolk; ec, egg chorion; l, leaf. Bar = 200 μ m. (C) Close view on cross section through a leaf of *S. viminalis* with an egg (eg) of *P. vulgatissima* on the lower surface. It is just adhered to the trichomes (tr) and hardly has any contact with the lower epidermis (ep). sm, spongy mesophyll; pm, parenchymatic mesophyll; ec, egg chorion; ey, egg yolk. Bar = 50 μ m. (D) Egg mass of *P. brassicae* on the lower surface of a *Brassica oleraceae* leaf. Bar = 1 mm. (E) Egg mass of *P. brassicae* partially removed from the leaf. The red lining shows where the eggs lay prior to removal. Leaf tissue turns brownish underneath the eggs and right next to them around the egg mass. s, shiny transparent secretion. Bar = 1 mm. (F) Cross section (overview) through a cabbage leaf (l) with eggs (ey, egg yolk; ec, egg chorion) of *P. brassicae*. The epidermis (ep) is not damaged. The eggs are closely attached to the epidermis. Bar = 200 μ m. (G) Close view on cross section through a cabbage leaf with eggs of *P. brassicae*. The egg chorion (ec) covered by secretion (s) is tightly attached to the epidermis (ep) and is even covering the stomata (sto). Bar = 50 μ m. (H) Egg mass of the elm leaf beetle *X. luteola* on the lower surface of an elm leaf, *Ulmus minor*. The lower part of the egg mass has been removed. At the place where eggs have been removed, the epidermal wounding (epw) is visible, which a female is conducting at the oviposition site with her mouth parts prior to egg laying. This epidermal wounding is clearly distinguishable from a feeding hole (fh) visible on the lower left side of the photo. Bar = 1 mm. (I) Cross section (close view) through an elm leaf with eggs of the elm leaf beetle. The epidermal cells and spongy mesophyll cells are removed so that the egg with chorion (ec) and secretion (s) adheres to the parenchymatic mesophyll cells (pm). Bar = 100 μ m. (J) Cross section (close view) through an elm leaf without eggs. ep, epidermis; sm, spongy mesophyll; pm, parenchymatic mesophyll cells. Bar = 507 μ m. (K) Cross section (close view) through an elm leaf vein with an egg mass of the elm leaf beetle on it. The epidermal cells and mesophyll cells are removed so that the eggs with their secretion (s) are closely attached to the parenchymatic cells surrounding the vascular bundle (ph, phloem; x, xylem; ec, egg chorion; ey, egg yolk). Bar = 100 μ m. (L) Cross section (close view) through an elm leaf vein without egg mass. The intact vascular bundle is visible with the xylem (x), phloem (ph), and the parenchymatic cells (pc) surrounding the vascular bundle. Bar = 100 μ m

the regurgitate into the plant wound during feeding (Spiteller et al., 2000). However, Tumlinson and Lait (2005) have argued that the bacterial biosynthesis rates of the analogs of eliciting components presented by Spiteller et al. (2000) are much too low to meet the requirements for a necessary rapid elicitor accumulation. Instead, they found evidence that fatty acid amide elicitors are biosynthesized in the membranes of the crop and anterior midgut tissues of lepidopteran larvae (Lait et al., 2003). Up to now, there are no hints that endosymbiotic microorganisms are involved in the production of egg-associated elicitors, even though symbiotic microorganisms are well known to be deposited with the eggs (e.g., Hilker, 1994; Kellner, 2002).

The Elicitor of Oviposition-Induced Plant Responses

If the plant is not wounded by oviposition and eggs just “touch” the plant surface, the components necessary for eliciting an oviposition-induced plant response might act either just via induction by touching or they may need to pass the waxy plant cuticula to reach the epidermal cells.

Plant responses to touch and wind have been summarized by Schaller and Weiler (2002). These responses range from changes of the cytosolic calcium concentration to an increase in ethylene production. Both changes of calcium concentrations (Arimura et al., 2000; Maffei et al., 2004) and accumulation of reactive oxygen species are also well known to occur in response to feeding herbivores (e.g., Felton and Eichenseer, 1999, and references therein).

If just the touch of the plant surface by insect eggs is not sufficient to elicit the defensive response and when no wounding occurs along with egg deposition, then the eliciting components associated with the eggs need to gain access to the plant epidermal cell. Thus, they need to be either highly lipophilic to pass the waxy plant surface, or need to possess the ability to “cut” their way enzymatically through the plant cuticula, or need to be accompanied by components smoothing their way (compare e.g., Rosetto et al., 2003). When the elicitor has reached the epidermal cell wall, it might act via receptors or form channels to enter the cell. Truitt et al. (2004) provide evidence that volicitin, an elicitor from the regurgitate of lepidopteran larvae that induces indirect plant defenses, is binding with a plasma membrane protein of the wounded plant (Alborn et al., 1997). When considering the ability of an elicitor to induce plant volatiles, Engelberth et al. (2000) suggest that formation of “pores” is also a possible mechanism. Several channel-forming components especially from phytopathogenic fungi are known to change permeability of biomembranes (Minardi, 1995; Zimmermann et al., 1999; Engelberth et al. 2000). However, they have not been described yet from insect eggs.

If plant cells are wounded by oviposition, an elicitor might enter them via the disrupted cell membrane. In addition, microwounding of the leaf surface that is visible only at high magnification will need closer consideration in future. For example, insect females might easily scratch the leaf surface by ovipositor hairs when laying eggs. Similarly, crawling of insect larvae also has been found to leave microwoundings on the leaf surface that are only visible by REM (Hall et al., 2004). These “larval footsteps” induce significant plant responses, such as increases of superoxide concentrations and GABA accumulation (Bown et al., 2002).

The chemistry of the elicitor of a direct plant defensive response to egg deposition is known only from bruchid beetles (Table 1). Their eggs laid onto pea pods induce the formation of neoplasms. The elicitors are long-chain α , γ -

monounsaturated C₂₂ diols and α , γ -mono- and diunsaturated C₂₄ diols, mono- or diesterified with 3-hydroxypropanoic acid.

The elicitors of indirect oviposition-induced plant defensive responses studied so far have been detected in the secretion coating the eggs and adhering them to plant tissue. In both the elm leaf beetle and in the pine sawfly, this secretion is produced in the *oviductus communis* (Meiners and Hilker, 2000; Hilker et al., 2002a). When applying these secretions onto artificial wounds of leaf tissue that mimic the wounding applied by the female prior to egg deposition (see above), the oviduct secretion *per se* is able to induce the indirect plant response, and no eggs are necessary for this eliciting process. For the pine sawfly, it has been shown that the oviduct secretion loses its activity when treated with a proteinase. The oviduct secretion only keeps its eliciting activity if kept in Ringer solution. Storage in just water results in a loss of activity. Hemolymph of the pine sawfly has no eliciting activity. A comparison of hemolymph and oviduct secretion by SDS-PAGE revealed that oviduct secretion contains a small protein that is not present in the hemolymph. Therefore, this protein is a candidate component that needs to be isolated and tested for its eliciting activity in future studies by applying it into wounded pine needle tissue like the sawfly females does during oviposition (Hilker et al., 2005).

A further candidate as elicitor of oviposition-induced plant responses might be jasmonic acid (JA), which has been detected inside the eggs of several lepidopteran species in much higher concentrations than in plant tissue or larval diet. “Chorions appear to contain small amounts of JA” (Tooker and De Moraes, 2005). It is not yet known whether JA is indeed present at the very outer surface of the eggs. The fact that the leaf surface is usually not visibly damaged when moths deposit eggs raises the question of how JA can invade the plant cell through a waxy egg chorion and a lipophilic plant cuticle.

Plant physiological and molecular processes that are initiated by an oviposition-associated elicitor are almost a black box. When considering the direct plant response to bruchid eggs, enhanced mitogenesis was observed. However, it is unknown how this is controlled and leads to a neoplasm with limited growth. In rice plants, a specific gene (*ovc*) is induced by egg deposition of a planthopper. This gene is involved in the production of the ovidical substance, benzyl benzoate (Yamasaki et al., 2003). Indirect plant responses to insect egg deposition require modification of the biosynthetic activity of the terpenoid pathways especially, since changes of the quantity and/or quality of the plant’s terpenoid volatiles have been detected for egg-laden bean and elm leaves as well as for pine needles with eggs (Wegener et al., 2001; Mumm et al., 2003; Colazza et al., 2004b). For example, pine needles with eggs emit the sesquiterpene (*E*)- β -farnesene in higher quantities than do egg-free pine needles (Mumm et al., 2003). Current studies address the question of how the increase of (*E*)- β -farnesene in the headspace of egg-laden pine needles is regulated at the molecular level.

Systemically Induced Plant Responses

In elm, pine, and beans (see Table 1), the defensive plant response is not strictly limited to the site of egg deposition, but egg-free leaves adjacent to the site of oviposition also release volatiles attractive for the egg parasitoids. Egg-free leaves adjacent to egg-laden ones might just adsorb the oviposition-induced volatiles produced by egg-carrying

leaves and release them again with some delay. However, it has been proved experimentally that no such adsorbance, but systemic induction, occurs. Egg-free leaves adjacent to egg-laden ones indeed show a systemically induced response (Meiners and Hilker, 2000; Hilker et al., 2002a; Colazza et al., 2004a).

How is the signal systemically transferred in the plant from the egg-laden part to the adjacent egg-free part? Application of jasmonic acid (JA) through the cut elm and pine twig, respectively, revealed that this treatment also leads to a volatile pattern attracting the respective egg parasitoids. Comparisons of the components of the headspace of JA-treated twigs and untreated controls show that the pattern is not identical to the one of oviposition-induced twigs, but very similar. For example, JA-treated pine twigs also show a significant enhancement of the emission of (*E*)- β -farnesene. These results indicate that JA might act as a hormone transferring the information from the oviposition-induced site to adjacent, egg-free parts of the plant.

The Egg-Laying Herbivore

The defensive responses of a plant may deliver not only information on the herbivore presence to the third trophic level, but also on the degree of infestation and the defense status to the herbivores themselves. Several studies are available showing that the emission of leaf volatiles in response to herbivore attack is exploited by the herbivores themselves. As outlined below, most of these studies address the herbivore's response to feeding-induced plant volatiles. We are just starting to analyze the herbivore's behavior in response to oviposition-induced volatiles.

The Herbivore's Response to Feeding-Induced Plant Volatiles

If herbivore-induced plant volatiles convey information on the presence of competitors or the risk of high predation and parasitization, herbivorous insects should avoid such plants. Indeed, herbivorous females about to oviposit can be strongly deterred by feeding-induced plant volatiles. For example, the cabbage looper, *Trichoplusia ni*, is less attracted to cabbage damaged by larval feeding and laid fewer eggs on feeding-damaged plants (Landolt, 1993). In addition, females of *Heliothis virescens* are significantly deterred from oviposition by the nocturnal volatiles of feeding-damaged tobacco plants (De Moraes et al., 2001). Similarly, females of *Manduca quinquemaculata* lay fewer eggs on feeding-damaged and JA-treated plants (Kessler and Baldwin, 2001).

If herbivore-induced plant volatiles inform herbivores about the presence of a suitable host plant or the presence of mates or gregarious partners, they are expected to be attracted to these plants (Loughrin et al., 1996; Ruther et al., 2000). Several studies are available showing herbivore attraction to feeding-induced plants (Landolt, 1993; Harari et al., 1994; Loughrin et al., 1996; Bolter et al., 1997; Dicke and van Loon, 2000; Kalberer et al., 2001; Prokopy and Roitberg, 2001; Horiuchi et al., 2003). For example, female *Plutella xylostella* show oviposition preferences for cabbage plants already damaged by conspecific larvae, even though these plants also attract larval parasitoids. Shiojiri and Takabayashi (2003) suggest that this oviposition behavior of *P. xylostella* may be beneficial for the herbivore since it might result in an encounter-dilution effect against the larval parasitoid.

The Herbivore's Response to Oviposition-Induced Plant Volatiles

As suggested by Kessler and Baldwin (2002), the exploitation of herbivore-induced plant volatiles by the herbivores themselves might favor selection for genetic variation in emission of induced volatile compounds in natural plant populations. In the systems studied so far, the phenotypic variation of induced plant odor is obviously not sufficient to prevent its exploitation by herbivores. For example, studies on the response of the elm leaf beetle to oviposition-induced elm volatiles indicate that this beetle is able to adjust its response to plant volatiles according to the infestation rate.

Females of the elm leaf beetle *Xanthogaleruca luteola* orientate to volatiles of both untreated elm leaves and differently treated ones (treatment by feeding, mechanical damage, oviduct secretion). However, when elm twigs are heavily infested by eggs and additionally damaged by feeding of conspecifics, female *X. luteola* clearly avoid such twigs. Odor from uninfested leaves is significantly preferred to odor from heavily infested leaves (feeding damage and eggs). In contrast, at low infestation levels, the beetle's response changes. Odor from uninfested leaves is no longer preferred, but instead volatiles from elm twigs poorly infested by some conspecifics (feeding damage and egg deposition) become highly attractive. The elm leaf beetle females also prefer to lay eggs upon uninfested leaves over heavily infested ones (Meiners et al., 2005).

The herbivore's response to elm leaf odor in dependence of the infestation level would be especially adaptive if the egg parasitoid's response to oviposition-induced elm leaf odor also follows these dependencies. The egg parasitoid *Oomyzus gallerucae* is attracted by odor from elm leaves with eggs and feeding damage (Table 1). Odor from feeding damaged leaves without eggs does not attract the egg parasitoid (Meiners and Hilker, 1997, 2000). However, we do not know yet whether the egg parasitoid prefers odor from leaves with a high egg load to odor from leaves with few eggs and little feeding damage. If so, the herbivore's risk of egg parasitization at low infestation levels is expected to be lower, thus rendering the herbivore's preference for low-infested leaves over heavily infested ones advantageous.

Elms might differ in their thresholds and lag times to produce and emit induced volatiles. Underwood et al. (2005) show in a model and in a field study that increasing lags and thresholds for the production of induced resistance traits might cause increasing aggregation of herbivores and their damage. Herbivores might have adapted to link the induced plant volatiles (kairomones) with the potential presence of suitable host plants. Local densities of elms, beetles, and parasitoids might determine the outcome of this tritrophic interaction (Meiners et al., 2005).

Egg Parasitoids and Predators

Complexity of Plant Odor and the Role for Host/Prey Location

Indirect oviposition-induced plant responses address egg parasitoids and predators of eggs. Plant volatiles or changes of leaf surface chemicals induced by egg deposition provide reliable information on the presence of hosts and prey. Furthermore, the large plant biomass when laden with eggs releases oviposition-

induced volatile information in quantities that can easily be detected. However, egg parasitoids and predators are also able to respond to volatiles from plants without host eggs (see review by Romeis et al., 2005) or with feeding damage only (Kessler and Baldwin, 2001).

Volatiles from feeding-induced plants do not provide carnivores with information on the presence of eggs, but just give a hint on the infestation of the plant. Carnivores responding to these volatiles are not expected to be specialized to prey upon eggs, but instead to be generalists. If they are specialists, they might be forced to take a chemical detour (Vet and Dicke, 1992) because other cues are not available. Indeed, the generalist carnivorous bug *Geocoris pallens* is attracted by feeding-induced plant volatiles and then preys upon the eggs found on such plants (Kessler and Baldwin, 2001). Among the feeding-induced plant volatiles, the release of the so-called general green leaf volatiles (i.e., C₆ aldehydes, C₆ alcohols and their esters) has been shown in numerous studies to increase after feeding damage (Karban and Baldwin, 1997; Dicke and Hilker, 2003). Also, carnivores specialized on insect eggs have been shown to be attracted by these volatiles. For example, *Trichogramma chilonis* shows a positive response to green leaf volatiles such as (Z)-3-hexenyl acetate and hexyl acetate (Reddy et al., 2002). These volatiles are also known to be emitted in small amounts by uninfested plants, and volatiles from uninfested plants often have been found to act as attractants or parasitization stimuli for *Trichogramma* spp. (for references: see Romeis et al., 2005). Also, surface extracts of leaves without eggs can stimulate parasitization (Nordlund, 1994; Dirie and Gabriel, 1998). However, volatiles from undamaged host plants may also act as repellents for egg parasitoids (Nordlund, 1994; Romeis et al., 1997, 1998). Thus, the response of egg parasitoids to plant volatiles is of high genotypic and phenotypic plasticity (De Jong and Pak, 1984; Bjorksten and Hoffmann, 1998; McGregor and Henderson, 1998). Among the factors influencing the egg parasitoid's response to chemical stimuli, the role of previous experience to these chemicals has been studied intensively (Vet and Dicke, 1992; Steidle and van Loon 2002a,b).

The chemical context in which plant volatiles are perceived is important for a parasitoid's response. During host location, the larval parasitoid *Microplitis croceipes* can learn compounds in a mixture (Meiners et al. 2003). Another braconid wasp, *Cotesia kariyai*, learns a blend of unspecific plant compounds better when it is embedded in a blend of specifically host-induced compounds (Fukushima et al., 2002). This context specificity of the response of parasitoids to plant volatiles seems to play a role when considering responses of egg parasitoids to oviposition-induced plant volatiles.

The olfactory background in which the stimuli are presented can affect recognition of individual compounds (Meiners et al., 2003). Studies on the response of *Chrysonotomyia ruforum* to pine volatiles induced by oviposition of the pine sawfly (Table 1) revealed that it is important for the egg parasitoid to perceive the oviposition-induced volatile together with the background of noninduced pine volatiles. (*E*)- β -Farnesene is the only component detected that occurs in significantly higher quantities in oviposition-induced pine than in egg-free controls (Mumm et al., 2003). However, even experienced egg parasitoids are not attracted to (*E*)- β -farnesene, at either concentration tested. When this sesquiterpene is offered in a mixture with odor from egg-free pine, however, it becomes attractive. Odor from egg-free pine does not attract the parasitoid (Mumm and Hilker, 2005). Thus, to attract this parasitoid it is necessary to contrast the oviposition-induced volatile with

other plant volatiles. Although a background contrast is well known to be important for the perception of color, the importance of background odor has been somewhat neglected so far for the detection of specific volatiles (Smith, 1998; Kelling et al., 2002). However, since induction of plant volatiles by egg deposition often involves small quantitative or qualitative changes of the plant odor, the background context at which these induced volatiles are perceived might be very important to detect them within the plethora of other volatiles.

Time Frame of Oviposition-Induced Plant Responses

Oomyzus gallerucae, the major egg parasitoid of the elm leaf beetle, was shown to respond to volatiles from elm leaves with eggs 3 hr after herbivore egg deposition (Table 1). The attractiveness of odor from elm leaves with eggs vanishes when eggs are being laid for more than 5 d on an elm leaf and are close to larval hatching (Meiners, unpublished data). In other systems, the time scale of indirect plant responses to oviposition is larger. *Chrysonotmyia ruforum*, a eulophid wasp parasitizing the eggs of the pine sawfly *Diprion pini*, is not attracted by odor from pine needles with 1-d-old eggs, but 3 d after egg deposition, odor from pine needles is attractive (Hilker, unpublished data; Hilker et al., 2002a). *T. basalis*, an egg parasitoid of the Southern green stink bug *Nezara viridula*, is attracted to volatiles from egg-laden bean leaves until the host eggs are about 3 to 4 d old. After 5 d, *Nezara* eggs become unsuitable for parasitization (Colazza et al., 2004a).

The studies by Fatouros et al. (2005a) indicate that a trichogrammatid egg parasitoid is arrested by oviposition-induced leaf surface chemicals at a time when eggs are most suitable for parasitization, i.e., 3 d after egg deposition. *Trichogramma brassicae* females most successfully parasitize 3-d-old eggs of the large white cabbage butterfly. About 80% of 3-d-old eggs are parasitized, whereas the rate of successful parasitization of freshly laid eggs and 1-d-old eggs is about 40% and 55%, respectively. The trichogrammatid wasp is also arrested on leaves with freshly laid eggs and 1-d-old eggs. However, this arrestment is due to scales and possibly other deposits left by the ovipositing female. When these host cues have lost their arresting activity 3 d after oviposition, the eggs seem to have induced a change of surface chemicals that act as arrestants at this time. Thus, in this system, the trichogrammatid wasp is first arrested by host cues, and only later, when host eggs have become most suitable, do oviposition-induced leaf contact cues seem to play a role.

All of these examples indicate a fine-tuned and cost-efficient time frame for the release of volatile or contact synomones by egg-infested plants. This is characterized by providing notice of the presence of suitable eggs and by ceasing the emission of synomones when the eggs are unsuitable. This guarantees that parasitoids will respond to an honest signal, and fosters the evolution of perceiving those signals and responding to them.

Oviposition-Induced Synomones and/or Kairomones

What is the importance of host cues and oviposition-induced plant signals for host location? Fatouros et al. (2005a) did not detect an olfactory response of *T. brassicae* to volatiles from Brussels sprouts leaves with eggs. When studying the question of how this wasp locates host eggs from a distance, *T. brassicae* was found to locate mated host female butterflies by the anti-aphrodisiac benzyl cyanide, which the

butterfly male transfers to the female during mating (Andersson et al., 2003). After location of a mated female butterfly, the wasp mounts the female, hitchhikes with her to the oviposition site, and descends as soon as eggs are laid (Fatouros et al., 2005b).

If egg parasitoids do not hitchhike with a host female (Clausen, 1976), highly volatile host female sex pheromones may attract them from some distance (e.g., Zuk and Kolluru, 1998). However, these pheromones just “promise” the presence of laid eggs. Also, aggregation pheromones, chemical cues from scales and frass, which all are known to act as kairomones for egg parasitoids (Vet and Dicke, 1992), just indicate that a host is around, but do not indicate with high reliability the presence of eggs. In contrast, oviposition-induced volatiles released locally and systemically by a large plant biomass reliably indicate the presence of laid eggs. Oviposition-induced plant volatiles, however, are obviously not always induced as soon as eggs are laid (see Table 1). Furthermore, an additional capability of egg parasitoids to respond to kairomones from, e.g., host frass (*O. gallerucae*), host sex pheromones (*Chrysonotomyia ruforum*), or volatiles from host females in the preovipositional state (*T. basalis*, *T. brassicae*) can act as a backup system for the egg parasitoids in cases when plants do not respond or do not respond strongly enough to egg depositions (Meiners and Hilker, 1997; Colazza et al., 1999; Hilker et al., 2000, Fatouros et al., 2005b).

Conclusions

A plant responding to oviposition of herbivorous arthropods is possibly acting early enough to prevent feeding damage by the larvae hatching from these eggs. Such an “early alert” may be especially advantageous for annual plants, which have a much smaller time and biomass budget with which to face feeding damage than perennials (Hilker et al., 2002a). However, trees also respond to insect oviposition by induction of volatiles (Table 1). Recently, oviposition-induced *Pinus sylvestris* was shown to lower photosynthetic activity in needles adjacent to the oviposition site (Schroeder et al., 2005). Thus, induced resistance (affecting the herbivore) might be paid here by reduced tolerance (affecting the plant) (Herms and Mattson, 1992). Further studies are needed that elucidate the costs or benefits of oviposition-induced plant responses with plant reproductive parameters as currency (e.g., fruit set, seed production).

The plant’s investment in “early alert” responses to egg deposition might be wasted if the eggs were to suffer mortality due to unsuitable abiotic conditions, such as, for example, high dryness. We need to study whether a plant is able to perceive egg mortality and stop the inductive process. Further, a plant might be able to minimize costs of induction by limiting the induced response only to a narrow time frame when eggs are most acceptable to egg parasitoids. The study by Fatouros et al. (2005a) on induction of Brussels sprouts by *Pieris* eggs indicates such a narrow time window during which induction by egg deposition occurs. However, other studies, such as the one described above on induction of elm by leaf beetle eggs, show a much broader time frame of induction (Meiners, unpublished data). We do not yet understand which parameters drive the selection of narrow and broad time frames for induction by egg deposition.

When induction of plant defense by insect egg deposition is considered an “early alert” strategy, it might be objected that plants induced by volatiles released from their

neighbor plants respond even earlier, i.e., prior to being encountered by a herbivore. Up to now, chemical information transfer has only been shown between feeding-damaged and undamaged plants (Dicke and Bruin, 2001). However, if a plant could also “listen” to oviposition-induced cues of its neighbor plants, this “information” might be the earliest possible information on the danger of attack by an herbivore. Such “listening” to oviposition-induced cues of the neighbor plant might enhance the inducibility of the nonattacked plant in such a way that it could respond sooner or stronger when egg deposition occurs. We do not know yet whether cues from oviposition-induced plants are able to “inform” non-attacked plants next to egg-laden ones about danger. Future studies also need to elucidate whether oviposition-induced cues are able to act as an early alert in interplant communication.

Finally, we need to examine whether there is a trade-off between induction of plant defenses by oviposition and feeding, or whether these defensive strategies addressing different stages of the herbivore act effectively *in concert*.

Acknowledgments We thank our students Melanie Thiers and Daniel Kämmer for helping us in providing the photo material shown in Fig. 1. We are also grateful for the interesting questions raised by two anonymous reviewers on an earlier version of this manuscript.

Abstract The choice of a suitable oviposition site by female insects is essential for survival of their progeny. Both olfactory and contact cues of the oviposition site may mediate this choice. The polyphagous *Delia platura* (Diptera: Anthomyiidae), a severe agricultural pest of numerous crops, lays eggs in the soil close to germinating seeds. Maggots feed upon the cotyledons. Only little is known about the cues guiding oviposition behavior. In this study, the effects of both olfactory and contact cues of beans (*Phaseolus vulgaris*) on oviposition of *D. platura* females were tested. Egg deposition on germinated beans was preferred to egg deposition on ungerminated beans or on beans in different postgerminating developmental stages. Olfactory cues of germinating beans alone stimulated female flies to lay eggs. Additional contact cues of germinating beans seemed to enhance the response, but the difference was not significant. Surface extracts of germinating beans sprayed on surrogate beans showed that both polar and nonpolar substances stimulated oviposition of *D. platura* flies. Gas chromatography-electroantennographic detection recordings of head space samples of germinating beans showed positive response of females to different compounds. We conclude that olfaction plays a major role when *D. platura* females are searching for oviposition sites. Volatile compounds released from germinating beans such as 4-hydroxy-4-methyl-2-pentanone, 1-hepten-3-one, 1-octen-3-ol, and 3-octanone should be considered as key compounds that mediate oviposition behavior. The use of different sensory modalities by closely related species of *Delia* is discussed.

Introduction

Plant chemicals play an essential role in host plant selection of herbivorous insects and, in particular, in the oviposition choice of females (Städler, 2002). Active compounds include volatiles and contact chemicals with varying polarity that are perceived by different chemosensory organs (Bernays and Chapman, 1994; Städler, 2002). Visual cues such as the shape and color of plants also influence, to a lesser extent, the acceptance or rejection of a plant by insects (Harris and Miller, 1983; Bernays and Chapman, 1994; Schoonhoven et al., 1998). The choice of a plant by females to lay eggs on is essential for the survival of offspring, since the mobility of larvae is often limited (Thompson, 1988; Iyengar and Eisner, 1999; Harris et al., 2001). This is particularly true in some Diptera such as *Delia* spp. (Anthomyiidae) feeding upon plant roots in the soil. *Delia* flies use various sensory modalities to locate a suitable host for their progeny.

D. radicum feeding upon Brassicaceae relies on visual cues. The shape and color of the plant play a role in attracting females. In this species, olfaction is also important to locate oviposition sites. Isothiocyanate released from the host plants is highly attractive and used in traps to catch this pest (Finch and Skinner, 1982). However, olfactory cues alone are not sufficient for females to find and recognize a suitable oviposition site. Also, contact with the leaf surface of cabbage is essential in stimulating the oviposition. Glucosinolates and a thia-triaza-fluorene compound (CIF) are present on the surface of cabbage leaves and stimulate the egg-laying behavior of *D. radicum* females (Roessingh et al., 1997; Hurter et al., 1999; De Jong et al., 2000).

D. antiqua, the onion fly, relies mainly on visual cues and olfaction to lay eggs. A specific compound, dipropyl disulfide, plays an essential role in attracting and stimulating the oviposition in this species (Romeis et al., 2003; Gouinguéné et al., 2005). The determination of the compounds attracting these flies has led to the development of traps to monitor the pest distribution.

The bean seed fly *D. platura* is an important pest in agricultural systems. The maggots mine the roots of various *Fabaceae*, cereals, tubers, and tobacco seedlings (Griffiths, 1991), which can then be attacked by stem rot organisms. Crop yield is usually reduced by 10–30% because of *D. platura* infestation (Finch, 1989; Fleischer and Gesell, 1999; Whalen, 2002), but may even reach 75% when infestation levels are high (Stivers, 1997). In India, where moisture conditions are ideal for the development of the pest, Chaudhary et al. (1987) reported that up to 88% of corn fields were infested. Several pesticides are used to control this fly (Vea et al., 1976; Montecinos et al., 1986; Valenciano et al., 2004). Usually, seeds are treated with synthetic chemical protectants before sowing, thus reducing the risk of *Delia* attack during the germination stage. However, *D. platura* populations often develop resistance to these insecticides (Finlayson and Campbell, 1971; Harris and Turnbull, 1980; Montecinos et al., 1986). Different methods and periods of sowing have been recommended to prevent high infestation (Hough-Goldstein, 1987; Adams et al., 1990; Brust et al., 1997; Valenciano et al., 2004). Finch (1989) noted the importance of developing integrated approaches to control *Delia* pests in vegetable crops as the number of available and efficient insecticides decreases. To attain this aim, a better understanding of the interactions of *D. platura* with its environment is necessary.

Few studies have examined the cues used by *D. platura* females to locate a suitable habitat and host for progeny (Yu et al., 1975; Dindonis and Miller, 1980;

Ishikawa et al., 1983). Germinating peas, moist sand, decomposing organic material, organic fertilizer mix, and fish meal have been shown in behavioral assays to stimulate oviposition of *D. platura* (Reid, 1940; Barlow, 1965). Microorganisms associated with seeds have been suggested to stimulate oviposition, since sterilization of germinating seeds reduced the number of eggs laid by the fly (Eckenrode et al., 1975). The attractiveness of different germinating seeds and their acceptance by *D. platura* as oviposition sites was studied by Yu et al. (1975). They showed that snap beans were most effective in trapping male and female *D. platura* in the field. Under laboratory conditions, squash seeds, snap bean seeds, and lima beans were attractive and stimulated egg laying of *D. platura* females (Yu et al., 1975; Weston and Miller, 1989). However, volatiles from the germinating seeds were not collected to determine the active substances. Aqueous extracts of germinating seeds were shown to stimulate oviposition, but the active compounds were not identified. The authors only indicated that the compounds stimulating the oviposition were nondialyzable, nonlipolyzable, and unextractable with diethyl ester (Yu et al., 1975).

The aim of our study was to further elucidate which sensory stimuli mediate oviposition in *D. platura*. We compared the importance of olfaction and contact in the process of egg laying and determined the compounds in the volatile blend of germinating beans that are perceived by the *D. platura* females. The polarity of oviposition-stimulating contact cues was assessed by extracting beans with different solvents and testing the activity of the extracts. The results obtained are discussed in comparison with other *Delia* species and with respect to further use for monitoring *D. platura*.

Methods and Materials

Insects

Experiments were performed with *D. platura* from our continuous laboratory rearing that originated from pupae supplied by J. Whittlecraft (Agriculture Canada, Southern Crop Protection and Food Centre, London, Ontario, Canada) in 2000, collected in fields around London region. Flies were reared on germinated bean (*Phaseolus vulgaris*, var. Daisy; Schweizer AG, Thun, Switzerland) and fish food (Reid, 1940) on which females deposit eggs; the larvae developed until pupation in the bean roots in a climate chamber ($19 \pm 0.5^\circ\text{C}$, $90 \pm 5\%$ RH, 16:8 L/D). For the experiment, pupae were isolated from the rearing cage, so that new emerging flies never had any contact with beans before the experiments. Flies were provided with 10% sugar solution and a mixture of raw cane sugar, yeast hydrolysate, and water (4:1:1) applied on absorbent tissue strips. For experiments, flies were between 5 and 9 d old.

Plants

Beans (*P. vulgaris*) of the variety Daisy (Schweizer) were placed on wet vermiculite for germination. They were used after 3–4 d, when just the very small root shoot had emerged. Small plants with two leaves were also tested. For the extraction, beans were germinated on moist vermiculite for 4 d in a greenhouse at 20°C and 70% RH.

Extraction of Bean Surface

The method for the surface extraction of beans was adapted from Roessingh and Städler (1990). Beans were soaked in 300 ml chloroform (CHCl_3) for 15 min, and afterwards they were dipped twice in 300 ml methanol (MeOH). The two MeOH extracts were pooled together. CHCl_3 and MeOH extracts were filtered separately and evaporated almost to dryness (Rotavapor, Büchi Labortechnik AG, Flawil, Switzerland). Each dry, extract was diluted in its respective solvent to a specified volume related to the weight of the germinated beans. The extract was expressed in gram bean equivalent (gbe) or gbe/ml, which corresponded to the weight of germinated beans extracted per volume extract.

Oviposition Choice Experiments

Oviposition choice experiments took place in a climate chamber set up under conditions similar to the ones for rearing ($19 \pm 0.5^\circ\text{C}$, $90 \pm 5\%$ RH, 16:8 L:D).

Substrate Effects on Oviposition Behavior

Four substrates were tested simultaneously in a choice test: (1) sand only as control, (2) nongerminated beans, (3) germinating beans, and (4) fish food as organic substrate. Fish food was chosen because it stimulates the development of *D. platura* (Reid, 1940), but it is not clear if it primarily affects the oviposition of the female bean seed flies. The stimuli were placed in a glass cup (5 cm \times 9.5 cm diam) filled with foam (9.5 cm diam \times 2 cm) covered with plastic and a layer of moistened sand (Fig. 1A). Females were able to smell and contact each of the four stimuli tested. The glass cups were placed in a cage (70 \times 70 \times 70 cm) with about 70 female flies and 15 males. Females were allowed to oviposit for 24 hr, and then the eggs laid into the sand of cups with the different treatments were counted. Six replicates were conducted, and the position of the treatments was changed after each egg count.

Effect of Plant Stage on Oviposition Behavior

We tested the importance of the plant development for egg-laying behavior. Flies were given the choice among young germinating beans seeds (3–4 d), advanced germinating beans (5–6 d), young plants (7–9 d, 2 emerging leaves), and sand alone as control. Germinating seeds and young plants were removed from the vermiculite and placed on wet sand and foam in a glass cup. The same conditions with six replicates as in the previous experiment were used.

In all the above-described experiments, female flies could use both olfactory and contact cues.

Comparison of Importance of Olfactory and Contact Cues

To test if olfaction or contact with the sprouting seeds plays a role for oviposition, we gave the flies the choice between three stimuli: (1) germinated beans covered with a screen, so that the flies could not contact plants, (2) germinated beans with complete access to the plant, and (3) sand only.

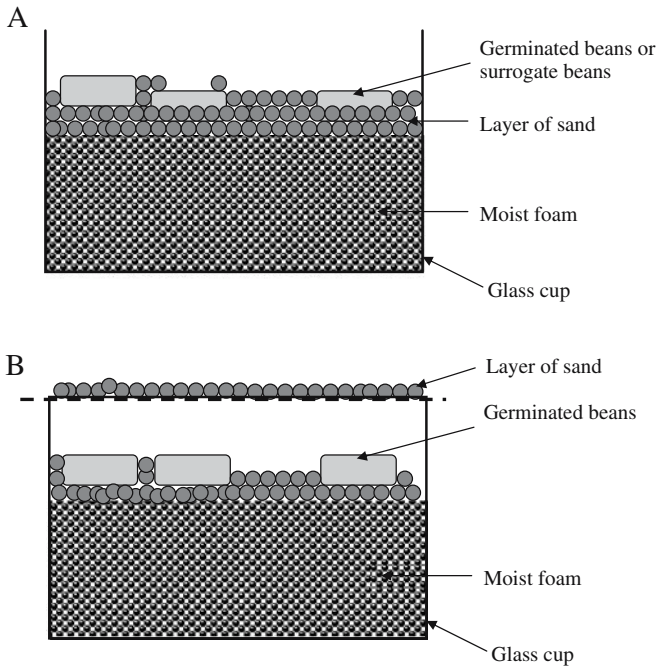

Fig. 1 Schematic diagram of the set-up used in behavioral experiments. (A) Set-up when *D. platyura* is allowed to contact the stimuli. (B) Set-up for testing the effect of olfaction on the oviposition of *D. platyura*

To provide oviposition sites (1), germinating beans were placed in a glass container with moistened foam to prevent desiccation and covered with a screen topped with a layer of moist sand (Fig. 1B). The screen prevented direct contact of flies with germinated beans. The same container with only wet foam and sand was used as a control [oviposition site (3)]. Oviposition site (2) allowing contact with the bean was provided by using the cups described in Fig. 1A. The eggs laid into the sand of these containers were counted after 24 hr. This experiment was replicated six times.

Effect of Bean Extract on Surrogate Beans on Oviposition Behavior

Extracts of plants were tested by using surrogate beans onto which the extracts were sprayed. The surrogate beans consisted of pieces of glass rods of 7 mm diam and 15 mm length. For experiments, they were placed on sand in glass cups. Before use, the surrogates were washed and rinsed with acetone and dried until all solvent trace evaporated.

The extract (see above) was sprayed on glass surrogate beans. Beans, either sprayed with the tested extract or control solvent, were placed on top of a 0.5-cm sand layer. Flies had the choice among a container with MeOH bean extract, CHCl₃ bean extract, MeOH only, CHCl₃ only, and sand only. The experiment ran for 24 hr, then the eggs laid on the differently treated surrogates were collected and counted.

Fractionation of the Preferred Bean Extract

The active MeOH extract was fractionated by using medium-pressure liquid chromatography, with an Rsil C-18 HL column (0.015–0.035 mm, pore size: 90 Å, length: 20 cm; RSL Chromatography Chemie, Vetikon, Switzerland). A volume of 25 ml of MeOH extract (1.73 gbe/ml) was evaporated to dryness, dissolved in 25 ml of water, and applied onto the top of the column. The solvent gradient was 100% water (H₂O), 50% water–50% methanol (MeOH/H₂O), and 100% methanol (MeOH). Eluates of 500 ml were collected with each solvent. The collected fractions were then evaporated under vacuum, and the residuals were dissolved in their initial solvent to 50-ml aliquots. The biological activity of the fractions obtained was tested in the previously described oviposition choice experiments with surrogate beans.

The most active fraction (fraction H₂O/MeOH) was further separated by HPLC equipped with a C-18 column (LiChrospher 100-5 RP-18, 230 mm, Machery-Nagel, Oensingen, Switzerland). Five fractions were collected by using a MeOH–water gradient (100% MeOH, 80:20, 50:50, 20:80, 100% H₂O). Each fraction was collected during 10 min of elution. The resulting five fractions were tested in the choice experiment.

Collection and Analysis of Volatiles From Germinating Beans

The method for collecting volatiles released by germinated beans was adapted from a push–pull odor collection system developed by Turlings et al. (1990). Eighty germinating beans were put in a glass container (described by Gouinguéné et al., 2003), with a filtered and humidified airflow passing over the beans. The air charged with the plant volatiles was pulled through a filter made of Super-Q® (Alltech, Switzerland) to trap the volatiles. Volatiles were desorbed by using 150 µl methylene l methylene chloride (HPLC grade; Biosolve BV, The Netherlands), and the extracts were analyzed with gas chromatography-electroantennographic detection (GC-EAD) as described below followed by gas chromatography-mass spectrometry to determine the identity of the compounds perceived by the flies.

Electrophysiology

GC-EAD recordings were made by using the female antennae. The insect was cooled (5°C) for 10 min. Then, its head was cut and mounted on the indifferent electrode, the tip of the recording electrode touching the tip of the antenna for contact. The GC was equipped with a 5% siloxane column (ZB-5, 30 m, 0.32 mm i.d., 0.25 µm film thickness, Brechbühler, Schlieren, Switzerland), with helium at 25 cm/sec as the carrier gas. The effluent was split with a deactivated three-way press fit splitter (0.32 × 0.32 × 0.32 mm i.d., BGB Analytik Ag, Anwil, Switzerland), followed by 60 cm of deactivated column (0.32 mm ID, BGB Analytik, Anwil, Switzerland). One arm was directed to the FID, and the other to the EAG preparation. The output of the column was heated at 300°C, to avoid condensation of the effluent when the column leaves the GC. The end of the column entered a glass tube blown over with humidified air at 3 cm before the antennal preparation. The airflow in the glass tube was set at 1 l/min. The EAG set up has been described in details by Marazzi and Städler (2004). Ten recordings were made, each with a different female. For compounds perceived by the flies, we calculated the percentage of occurrence of response.

Active compounds were identified by GC (Hewlett Packard HP 6890, Agilent 6890 Series GC system G1530A), coupled to a mass spectrometer (MS) operated in electron impact mode (Agilent 5973 Network Mass Selective Detector; transfer line 230°C, source 230°C, ionization potential 70 eV, scan range 33–280 amu). A 3- μ l aliquot of sample was injected in the pulsed splitless mode onto an apolar capillary column (HP-1, 30 m, 0.25 mm i.d., 0.25 μ m film thickness; Alltech Associates, Inc., USA). Helium at constant pressure (18.55 psi) was used as carrier gas flow. Following injection, the column temperature was maintained at 40°C for 3 min and then increased to 100°C at 8°C/min, and subsequently to 200°C at 5°C/min, followed by a post-run of 5 min at 250°C. Compounds were identified by comparison of their mass spectra with those of the NIST 02 library and by comparison of their spectra and retention times with those of authentic standards.

Contact chemoreceptor recordings were made from sensilla present on the tarsi of the front legs of the flies. Stimuli were tested on the ventrolateral D-sensilla on the third (D_3), fourth (D_4), and fifth tarsomer (D_5) as well as in the ventromedial C-sensillum on the fifth tarsomer (C_5) (terminology according to Grabowski and Dethier, 1954). The technique was recently described by Gouinguené and Städler (2005). Briefly, the cooled female was placed without head in a small depression cut into a Plexiglas cube. The front legs were taped to the surface of the block to expose the ventral side of the tarsi. To avoid desiccation, a humidified air stream (0.5 m/sec, 19–25°C) was directed over the insect preparation. The indifferent glass electrode (tip diameter? 1 μ m) filled with Ringer solution was inserted into the tibia. The spike activity of the stimulated neurons was recorded and analyzed by using a computer and in-house software. All stimuli used in electrophysiological experiments were dissolved in a 1 mM solution of potassium chloride (KCl), which evoked only few spikes. The responses were compared by the total number of spikes, as only one type of spike could be determined in all the recordings. Eight replicates on each sensillum were realized.

Statistical Analyses

In behavioral experiments, the Friedman test was used to check for significant differences between treatments, as the assumptions of data independency may not be respected because of multiple choices offered to the flies (Iman and Davenport, 1980). We used *t*-test to determine if the number of spikes recorded from the tarsal sensilla stimulated with the MeOH extract was significantly different from the response recorded with the KCl control stimulus.

Results

Substrate Effects on Oviposition Behavior

Female flies laid more eggs on sand in which germinated beans were present, but this number was not significantly different from that on fish food (Fig. 2). Nongerminating seed did not stimulate oviposition, thus the visual stimuli (bean shape and color) were not used as oviposition stimuli (Fig. 2). The sand by itself did not stimulate oviposition.

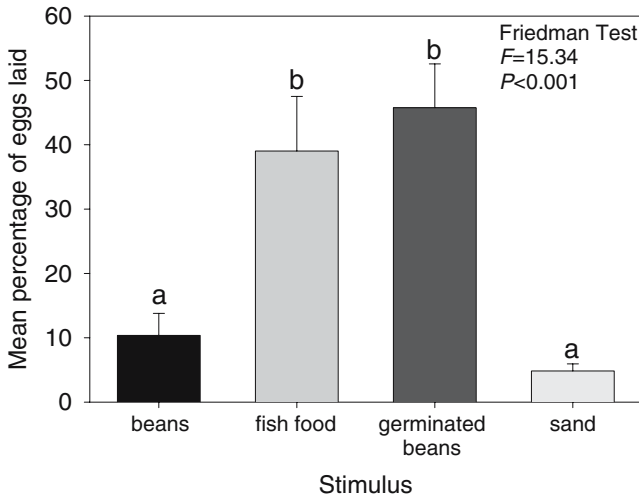

Fig. 2 Oviposition preference of *D. platyura* for different substrates. Friedman test was used to test for significant difference among treatments. Bars represent the mean proportion of eggs laid, and the error bar indicates the standard error. Pairwise comparisons were performed as described by Iman and Davenport (1980), and significant differences between treatments are indicated with letters above bars $N = 6$

Effect of Plant Stage on Oviposition Behavior

No significant difference in the number of eggs laid was found among the three stages of germination of the beans. Young germinating beans (3–4 d old) stimulated the oviposition of *D. platyura* females as much as advanced germinated seeds (5–6 d old) or young plants with already well-developed root systems (Fig. 3). In accordance with the previous experiment, sand alone was not stimulating.

Fig. 3 Bean plant stage influencing oviposition preference of *D. platyura*. Bars and statistics as in Fig. 2. $N = 6$

Fig. 4 Comparison of the effect of contact vs. olfactory perception of volatiles of germinating beans on the oviposition of *D. platura*. Bars and statistics as in Fig. 2. *N* = 6

Olfaction

Females were able to detect the germinating beans since the odor of the host alone stimulated the oviposition (Fig. 4). Contact with the germinated seed did not significantly increase the proportion of eggs laid.

Effect of Bean Extract on Surrogate Beans on Oviposition

The MeOH extract of germinated beans received the most eggs (Fig. 5), and few were deposited on surrogate beans treated with the CHCl₃ extract alone. Interestingly, more eggs were laid on untreated glass beans than on solvent treated controls, which may indicate that the solvents had a deterrent effect (Fig. 5).

Fig. 5 Oviposition preference of *D. platura* for different extracts. Bars and statistics as in Fig. 2. *N* = 6

Fig. 6 Oviposition preference of *D. platura* for the different fractions of the MeOH extract from germinating beans. Bars and statistics as in Fig. 2. $N = 6$

Fractionation of the Preferred Bean Extract

All the three fractions were stimulatory, but significantly more eggs were laid on the surrogate beans treated with the H₂O/MeOH and MeOH fractions than on the control (Fig. 6). The fraction H₂O was not significantly more stimulatory than the control (Fig. 6).

Electrophysiology GC-EAD

Only a few compounds clearly stimulated the receptors (Fig. 7; Table 1). In 78% of the recordings, the response to 4-hydroxy-4-methyl-2-pentanone (d) was present and

Fig. 7 GC-EAD recording from a *D. platura* female stimulated by the odor from germinating beans. This recording is representative of 10 recordings. Identities of active compounds are given in Table 1

Table 1 Identity of the compounds from the odor of germinating beans that were perceived by the antennae of *D. platura*

Peak	Identity	Occurrence of responses (%)	Retention index (ZB-5)
a	Dimethyl disulfide	56	746
b	Hexanol	44	773.2
c	2-Hexanol	33	783.4
d	4-Hydroxy-4-methyl-2-pentanone	78	822.7
e	Unknown	67	836.7
f	Styrene	56	895
g	1-Hepten-3-one	89	985.9
h	1-Octen-3-ol	100	991.2
i	3-Octanone	44	999
j	3-Octanol	22	1007.7
k	Unknown	22	1059.5
l	2-Methoxy-2,5-dimethylpyrazine	33	1064.8
m	Unknown	44	1105.4
n	Unknown	22	1121.2
o	Unknown	44	1236.5

Letters in the first column correspond to those in Fig. 7.

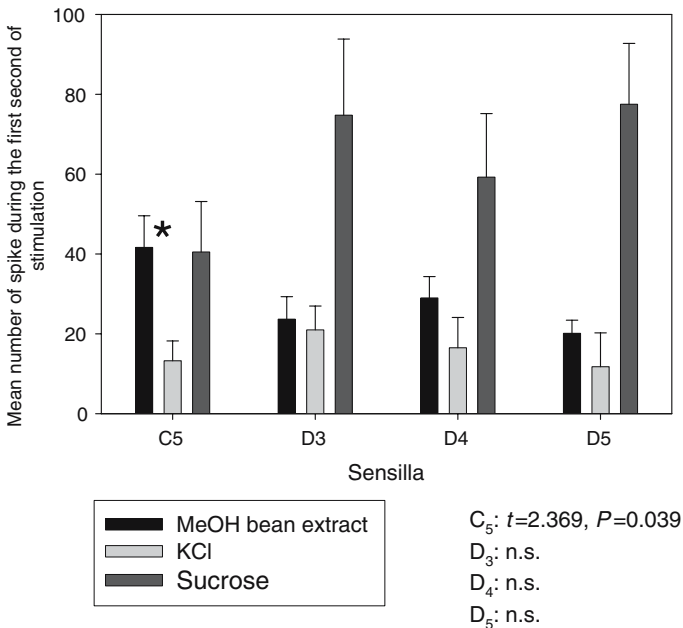

Fig. 8 Tip recordings from *D. platura* prothoracic tarsal sensilla. Bars represent the mean of the number of spikes recorded in the first second of stimulation. Star above bars indicates a significant difference (*t*-test) in the number of spikes recorded due a specific stimulus and the number of spikes from the KCl control. $N = 8$

gave large EAG amplitudes. Most consistent responses were obtained with 1-hepten-3-one (g) and 1-octen-3-ol (h). Responses to 3-octanone (j) were less consistent, but such results should be taken with care, as in many of the recordings the response to this compound may be covered by the large response to 1-octen-3-ol.

Contact Chemoreception

Only the neurons of the C₅ sensillum responded significantly to the MeOH extract. The neurons of the other tarsal sensilla were not stimulated by this extract, as the number of spikes measured was never different from that of the control KCl solution (Fig. 8). Analysis of spike classes revealed that only one class of spikes was recorded in the different recordings.

Discussion

Delia platura females can locate an oviposition site by relying on olfaction alone (Barlow, 1965; Weston and Miller, 1989). The response of the antennae of *D. platura* showed that the female flies responded to different volatiles released from germinating beans, and in particular to octenol and octanone. These two compounds are known to be characteristic for the odor of fungi (Pfeil and Mumma, 1993; Omura et al., 2002). Thus they may be produced and released by the activity of microorganisms associated with seeds or fungi present in the surroundings of germinating seeds. The presence of these organisms were demonstrated to stimulate oviposition in *D. platura* (Eckenrode et al., 1975) and also in *Megaselia halterata*, a phorid fly developing on compost (Pfeil and Mumma, 1993). Further experiments should test different species of plants in order to compare the profile of volatiles emitted by the seeds.

In this study, the same bean variety Daisy was used in the experiments and for rearing the fly colony. Using the same variety for experiments and rearing may have affected the preference of the insects. Collection of volatiles from another variety of beans (var. Cupidon; Schweizer) was also conducted (data not shown), but volatile profiles of var. Daisy and Cupidon revealed only minor differences. The oviposition behavior of flies on bean var. Cupidon did not differ from that on var. Daisy. The olfactory response of *D. platura* to 1-octen-3-ol is interesting. This may be a possible ancestral ability, since this compound has been found to be an attractant for other dipterans that are hematophagous such as mosquitoes or biting flies (Ndegwa and Mihok, 1999; Voskamp et al., 1999; Birkett et al., 2004).

Contact with the plant plays a moderate role in the egg-laying behavior of the females. Interestingly, the neurons sensitive to contact with the host plant seem to be at least partly located on the C₅ sensilla. The recordings show that only one neuron was stimulated by the MeOH extract of germinating beans. The neurons of the other sensilla did not respond to the extract. This is remarkable because in a closely related species, *D. radicum*, the C₅ sensilla also contains a specific neuron responding to a particular compound from cabbage (a thia-triaza-fluorene named CIF), which is also an effective oviposition stimulant of *D. radicum* females (Roessingh et al., 1997; Hurter et al., 1999; De Jong et al., 2000).

D. radicum, a closely related species to *D. platura*, relies on different sensory modalities to locate a suitable host, primarily vision, since the shape and color of

leaves play a role in the attraction of females (Roessingh and Städler, 1990). Olfaction is also important, as specific compounds emitted by Brassicacean plants (isothiocyanates) were shown to attract females (Finch and Skinner, 1982). Contact with the cabbage leaf surface, however, plays a major role in inducing oviposition in this species. The perception of glucosinolates and of the thia-triaza-fluorene compound (CIF) by sensilla located on the tarsae is important for the choice of oviposition sites in *D. radicum* females (Hurter et al., 1999; De Jong et al., 2000). In contrast, *D. antiqua*, which is phylogenetically more closely related to *D. platura*, relies mainly on olfaction (Harris and Miller, 1988; Romeis et al., 2003; Gouinguéné et al., 2005). Females of *D. antiqua* are stimulated to lay eggs only when smelling a volatile compound typical for onion, i.e., dipropyl disulfide. When considering the sensory modalities used to detect a suitable oviposition site, *D. platura* takes an intermediate position between *D. radicum* and *D. antiqua*, as it relies on olfaction to locate germinating beans, but it also perceives nonvolatile compounds from the bean surface to lay eggs, whereas visual cues seem to play no or a minor role. Weston and Miller (1989) mentioned that *D. platura* is under a selective pressure to oviposit on unapparent germinating seeds. Thus, olfaction may be favored over contact. Comparison of the sensory modalities used by closely related insect species could be interesting to determine if the number of modalities used corresponds with a certain degree of specialization.

Future experiments should aim to identify the compounds involved in the contact perception of germinating seeds. Furthermore, 1-octen-3-ol and octanone need to be tested for their effects on attraction and stimulation of the bean seed fly. If these compounds can be proven to be active, they may be used in traps to monitor this pest as is done for other *Delia* species (*D. antiqua*, *D. floralis*, *D. radicum*) that attack vegetable crops (Finch, 1991, 1995; Romeis et al., 2003). In addition to the application perspectives of 1-octen-3-ol to control *D. platura*, the evolutionary aspects of the perception of this compound by both phytophagous and hematophagous insects should require attention in further studies.

Acknowledgments This project was funded by the Swiss National Science Foundation, grant 31-65016.01. We thank Jay Whistlecraft of Agriculture Canada, Southern Crop Protection and Food Centre, London, Ontario, Canada, for providing us with *D. platura* pupae. Bruno Patrian, Agroscope FAW Wädenswil, Pflanzenschutz Chemie, Switzerland, helped with the separation of the nonpolar extract of germinating beans. We are grateful to Ted Turlings, University of Neuchâtel, Switzerland, for providing glass traps to collect volatiles of germinating beans. GC-MS analyses were done with the help of T. Turlings and M.-E. Farine, University of Neuchâtel. We wish to thank Dr. Russell Naisbit for English language assistance and useful comments on the manuscript.

Abstract Developmental changes in plant structure and function can influence both mammalian and arthropod feeding preferences for many woody plant species. This study documents age-related changes that occur in the leaf chemistry of trembling aspen (*Populus tremuloides* Michx., Salicaceae) and discusses implications for the herbivore community and ecosystem processes. We collected leaves from replicate ramets from six age classes (1–25+ yr) in each of seven aspen clones growing in south central Wisconsin, USA. Chemical analyses were conducted to determine concentrations of condensed tannins, phenolic glycosides (salicortin and tremulacin), nitrogen, starch, and soluble sugars. Each variable differed significantly among clones and among age classes. On average, condensed tannin concentrations doubled in the first five years and then remained fairly constant among older age classes. Combined phenolic glycoside (salicortin + tremulacin) concentrations were high in the youngest ramets (ca. 19%) and decreased sharply with age. Developmental changes in tannin, salicortin, and tremulacin concentrations exceeded those of nitrogen and carbohydrates. Developmental shifts of this magnitude, and the age-related tradeoff that occurs between condensed tannins and phenolic glycosides, are likely to have significant influence on the herbivore community of aspen and may influence leaf litter decomposition and nutrient cycling.

Introduction

Plant characteristics, ranging from metabolic processes to morphology, often change through the process of maturation (Jones, 1999). Plant developmental changes can occur rapidly, for example, as leaves mature through a growing season, or slowly, as long-lived perennial plants reach reproductive maturity. These changes can have effects on community interactions. For example, many physical traits contributing to herbivore performance and preference (e.g., thorniness, leaf toughness, resin flow, leaf abscission) change in a predictable manner as plants mature (Brink, 1962; Kozłowski, 1971). Plant chemistry, which can be more important than physical characteristics in determining herbivore host ranges (Schultz, 1988), may also change as plants mature. Comparatively little is known, however, about developmental changes that occur in phytochemical composition as long-lived perennial plants mature.

Plant chemistry is influenced by both genotype and environment and can vary considerably both within species (Lindroth and Hwang, 1996a; Agrawal et al., 1999; Laitinen et al., 2000) and within individual plants (Gill et al., 1995; Orrians and Jones, 2001; Pavia et al., 2002). Within-plant differences in chemical defense can occur as a result of induction (Karban and Baldwin, 1997), leaf maturation (Lindroth et al., 1987; Riipi et al., 2002), somatic mutations in meristematic tissues (Suomela and Ayres, 1994; Gill et al., 1995; Tuskan et al., 1996), and through the process of ontogenetic maturation from juvenile to adult phase (Bryant and Julkunen-Tiitto, 1995; Karban and Thaler, 1999; Erwin et al., 2001; Boege and Marquis, 2005; Laitinen et al., 2005).

Within-species variation in plant chemistry can affect ecological interactions and ecosystem processes. For example, primary plant compounds such as protein and water are critical for herbivore growth and development (Awmack and Leather, 2002), and qualitative or quantitative variation in phytochemical defenses within a species also strongly influences herbivore behavior and performance (Crawley, 1983; Schultz, 1988; Shelton, 2000). At the ecosystem level, phytochemical variation can influence litter decomposition and nutrient cycling rates (Schimel et al., 1996; Hättenschwiler and Vitousek, 2000; Kraus et al., 2003; Madritch et al., 2006).

Chemical variation within a plant may have ecological consequences similar to those of within-species variation (Suomela and Ayres, 1994). Whereas relatively little is known about the effects of development on the chemical content of plants, many studies have found that developmentally based variation can significantly influence herbivore behavior and performance (Kearsley and Whitham, 1989; Swihart and Bryant, 2001; Lawrence et al., 2003). Studies that have measured within-year and between-year (Bryant and Julkunen-Tiitto, 1995; Erwin et al., 2001; Boege and Marquis, 2005; Laitinen et al., 2005) developmentally mediated changes in plant chemistry indicate that such changes can be significant and suggest that these chemical shifts are likely to be ecologically important.

Previous work has demonstrated comparatively high levels of allelochemicals in juvenile compared with mature ramets in some species of Salicaceae (e.g., Bryant, 1981; Reichardt et al., 1990; Martinsen et al., 1998; Brian Rehill,

unpublished data), and two studies have indicated that between-year developmental shifts in phytochemistry may occur in aspen (Basey et al., 1988; Erwin et al., 2001). Evidence also suggests that mammals show preferences for tissues from mature vs. juvenile aspen trees (Basey et al., 1988; Swihart and Bryant, 2001) and establishes reasonable expectations for arthropods and pathogens to be affected by developmental shifts in phytochemistry (Lindroth and Hwang, 1996a; Kearsley and Whitham, 1989, 1998).

This research assessed among- and within-clone variation in trembling aspen (*Populus tremuloides* Michx.) leaf chemistry, and identified developmental patterns of allocation to leaf chemical constituents important for growth and defense. By “developmental,” we refer to long-term or between-year changes in plant chemistry through the process of maturation. We also assessed how such developmental patterns vary among clones because the rate and magnitude of chemical shifts may significantly affect their potential to influence associated herbivore communities and ecological processes.

Trembling aspen is one of the most widely distributed and genetically variable plant species in North America (Mitton and Grant, 1996). Aspen reproduction is often vegetative, via suckering from previously established root systems. Individual ramets (stems) originating from a common root system often vary widely in age and maturity as the clone expands from the central genet (original seedling). After disturbances, such as windfall, fire, or clear-cutting, aspen produces new ramets from surviving root systems. Depending on disturbance types and frequencies, aspen stand demographics can vary greatly at the local and landscape scales. Thus, developmental-based changes in the chemical attributes of this important and widespread tree species may significantly influence its associated communities.

Methods and Materials

Clone Selection and Sampling Protocols

To assess background levels of among-clone variation in aspen leaf chemistry, we haphazardly selected 20 aspen clones from locations throughout Dane Co., Wisconsin, USA. In early June 2002, four reproductively mature trees (ramets >10 yr of age) from each of the 20 clones were sampled for chemical analyses. Using a pole pruner, we haphazardly collected 5–10 leaves from each of at least three locations in the canopy. These 20 clones were subsequently identified as genetically unique on the basis of microsatellite markers (Cole, 2005).

Seven of the 20 clones sampled were suitable (age-distribution) for extensive sampling from ramets of different age classes. For these seven clones, we haphazardly selected and sampled from three individual ramets within each of the following age classes: 0–1, 2–5, 6–10, 11–15, 16–20, and >20 yr. For one of the clones (clone 11), no trees were available over 20 yr old. Leaf samples and diameter and height measurements were taken for each ramet in June 2002. Samples were collected as described above, i.e., 5–10 leaves from at least three locations within the canopy. To avoid the potentially confounding effect of within year variation in chemistry (Lindroth et al., 1987; Riipi et al., 2002), only fully expanded source leaves were used in chemical analyses. Ramet age was determined by counting annual

growth rings on cut ends or, for larger ramets, by averaging ring counts from two tree cores made with an increment borer. Heights were measured with a measuring tape for felled ramets and a clinometer for large standing ramets. Stem diameters were measured with a hand caliper 2 cm above ground level for small ramets (<3 cm diam) and a diameter measuring tape 10 cm above ground was used for large ramets (>3 cm diam).

Phytochemical Analyses

Leaf samples were kept on ice while in the field and returned to the laboratory daily. Samples were flash-frozen in liquid nitrogen, vacuum dried, ground with a Wiley mill through a number 40 mesh, and stored at -20°C . We analyzed leaf tissues for chemical constituents likely to be important in influencing general host or litter quality (condensed tannins, phenolic glycosides, total nitrogen, starch, and sugars). Condensed tannins were assayed using a modified butanol–HCL method described by Porter et al. (1986). Purified aspen condensed tannins served as standards. The phenolic glycosides salicortin and tremulacin were quantified by HPLC as reported by Lindroth et al. (1993), using purified phenolic glycosides as standards. Samples were initially screened for salicin and tremuloidin, but contained little or none of those two compounds. Thus, the value for total phenolic glycosides is the sum of salicortin and tremulacin concentrations. Samples were analyzed for total N (an index of protein) with an elemental analyzer (LECO, St. Joseph, MI, USA). Glycine-*p*-toluenesulfonate was used as a standard in N analyses. Starch and sugar (sucrose + hexose) concentrations were assayed by using enzymatic hydrolysis and the dinitrosalicylic acid method as in Lindroth et al. (2002). All phytochemical variables are reported in the text and figures as percent dry weight.

Statistical Analyses

Statistical analyses were performed by using JMP IN version 4.0.4 (SAS, 2001) and SAS version 8.2. Because this study was conducted on naturally occurring aspen clones, it was not possible to replicate clones. Estimates of within-clone error were achieved by measuring chemistry of multiple ramets (“trees”) from within a clone, either from 1) four mature ramets within a clone (Fig. 1), or 2) multiple trees from within an age class (Figs. 2 and 3).

Phytochemical differences among the 20 mature clones were evaluated by an analysis of variance (ANOVA). The effects of plant age on phytochemical attributes were assessed in a mixed model (Proc Mixed; SAS, 1999). Ageclass was fitted as a fixed effect, and clone was fitted as a random effect. *Post hoc* means comparisons were made for phytochemical concentrations among age classes by using *t* tests and Bonferroni-adjusted probabilities (SAS, 1999). Two different analyses were used to determine whether developmental patterns varied among clones. First, we compared -2 log-likelihoods for models run with and without the random variable “clone.” Chi square tests were used to assess the significance of the clone effect (Zar, 1999). Second, an analysis of covariance (ANCOVA) was used to compare the trajectory (slopes) with which concentrations of phytochemicals differed as plants aged. Tree age (years) was used as the covariate. A significant clone by age interaction indicated that clones showed different developmental trajectories in allocation to phytochemical variables. In our assessments of age-related variation, a

Box-Cox transformation was applied to salicortin and tremulacin values prior to statistical tests to improve normality and homogeneity of variance (Zar, 1999).

Pairwise correlations were examined to identify relationships among phytochemical constituents, size, and age variables (SAS, 2001). Correlations were assessed by using mean values for age classes within clones. The relationship between condensed tannin and phenolic glycoside concentrations was described using quadratic regression.

Fig. 2 Developmental shifts in aspen leaf concentrations of condensed tannins (cond tannins) and phenolic glycosides (salicortin and tremulacin). Symbols represent the average concentration for replicate ramets ($n = 3$) within each of six age classes for the seven clones, respectively. P values refer to the main effect of age class (Proc Mixed). Age classes with different letter are significantly different (Bonferonni-adjusted $P < 0.05$)

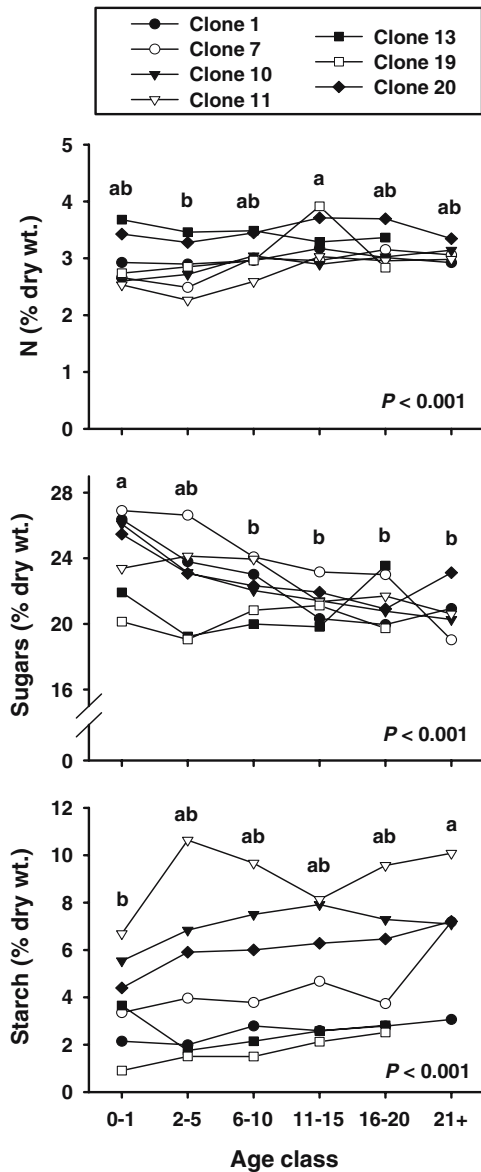

Results

Among-Clone Phytochemical Variation

Leaf chemical constituents of mature ramets varied among the 20 aspen clones (Fig. 1). Condensed tannin concentrations varied 2-fold among clones ($P < 0.001$). Concentrations of salicortin and tremulacin were highly correlated and more variable among clones than were tannins. Salicortin concentrations varied almost 7-fold and tremulacin varied 12-fold among clones ($P < 0.001$). Nitrogen

Fig. 3 Developmental shifts in aspen leaf concentrations of nitrogen (N), sugars, and starch. Symbols represent the average concentration for replicate ramets ($n = 3$) within each of six age classes for the seven clones, respectively. P values refer to the main effect of age class (Proc mixed). Age classes with different letters are significantly different (Bonferroni-adjusted $P < 0.05$)

(N) concentrations were less variable among clones, ranging from 2.8% to 3.6% ($P < 0.001$).

Developmental Patterns Within and Among Aspen Clones

Variation in Growth

Equal-aged ramets from the seven clones differed considerably with respect to height and diameter. An ANCOVA with tree age confirmed differences (height,

$P < 0.001$; diameter, $P < 0.001$). In general, tree size and growth trajectories varied among clones. Separate plots of height and diameter show similar patterns (data not shown).

Variation in Secondary Metabolites

Condensed tannin concentrations increased sharply with age (Fig. 1). Developmental changes occurred primarily between the “0–1” and “2–5” yr age classes, where condensed tannin concentrations increased from 4.5% to an average of almost 14% dry weight (Fig. 2). Phenolic glycoside concentrations also varied among age classes (Table 1), but in contrast to tannins, salicortin and tremulacin concentrations decreased with age, from an average of almost 13% to 1%, and 7% to less than 1%, respectively (Fig. 2). The developmental changes occurred in the first 10 yr, as evidenced by the lack of differences among age classes greater than 10 yr old. Among-clone variation for salicortin and tremulacin was much greater for juveniles than for mature ramets (Fig. 2).

Variation in Nitrogen, Sugars, and Starch

Aspen nitrogen and carbohydrate concentrations also differed among age classes, but the developmental patterns were weak relative to those of tannins and phenolic glycosides (Fig. 3). Nitrogen differed among clones and increased only slightly in more mature ramets (Fig. 3). Average sugar concentrations decreased from 24% in the youngest trees to 19.6% in mature trees. Average starch concentrations were highly variable among clones, ranging from 1.5% to over 8%, and tended to increase in mature trees (Fig. 3).

Variation in Developmental Trajectories

The effects of plant age on phytochemical concentrations varied among aspen clones. For each variable tested, removing the effect of “clone” from the mixed model significantly decreased the goodness of fit (χ^2 tests, $P < 0.001$ for each variable). Looking specifically at the slopes, or rates of concentration change in phytochemical variables, we found that the trajectories of developmental shifts in aspen secondary metabolites were consistent among clones for tannins, but not for

Table 1 Correlation matrix (Pearson) of mean age and aspen phytochemicals, including condensed tannins, total phenolic glycosides (box-cox transformed salicortin + tremulacin), nitrogen (N), sugars, and starch

	Ramet age	Condensed tannins	Phenolic glycosides	N	Sugars
Condensed tannins	0.60***				
Phenolic glycosides	-0.73***	-0.74***			
N	n.s.	n.s.	n.s.		
Sugars	-0.50***	n.s.	0.45**	-0.36*	
Starch	n.s.	n.s.	n.s.	n.s.	n.s.

n.s. = not significant.

n.s.: $P > 0.05$; * $0.01 < P < 0.05$; ** $0.001 < P < 0.01$; *** $P < 0.001$.

Fig. 4 The negative relationship between condensed tannin (cond tannins) and phenolic glycoside (salicortin + tremulacin; phen glycosides) concentrations in aspen leaves from ramets of different ages. Each point represents a single ramet. Quadratic regression provided the best fit ($P < 0.001$)

phenolic glycosides. Condensed tannin concentrations increased with age similarly for the seven clones (i.e., nonsignificant age \times clone interaction; ANCOVA). Clones that contained higher relative tannin concentrations in juvenile ramets also had higher concentrations in mature ramets. Again, the differences occurred in the first five years, after which tannin concentrations showed no consistent pattern of change. The developmental trajectories of salicortin and tremulacin, however, were markedly different among the clones (i.e., significant clone by age interactions; $P = 0.005$ and $P = 0.018$, respectively). The differences in trajectory were largely due to the variability in levels of phenolic glycosides in juvenile ramets. For example, juvenile ramets of clone 20 (0–1 age class) had almost 30% total phenolic glycosides (salicortin + tremulacin), compared with ca. 10% in clone 11. However, in both clones, ramets greater than 20 yr old had less than 2% total phenolic glycosides.

Correlations

Nitrogen was not correlated with tannins or total phenolic glycosides but was negatively correlated with sugar concentrations (Table 1). Sugar concentrations were positively correlated with total phenolic glycosides. A particularly strong negative correlation occurred between tannin and total phenolic glycoside concentrations when all age classes were considered together. The shape and strength of this relationship are described by a quadratic regression in Fig. 4 ($R^2 = 0.568$; $P < 0.001$).

Discussion

Our survey of phytochemical variation among aspen clones in south central Wisconsin indicates that clones occupying similar habitats and growing under similar conditions produce varying concentrations of condensed tannins, phenolic glycosides, and nitrogen. These patterns are consistent with those found in other natural aspen populations growing in northern lower Michigan (Lindroth and Hwang, 1996b) and in northern Wisconsin (Donaldson, 2005).

In common gardens, genetically based differences in condensed tannins and phenolic glycosides among clones are similar in magnitude to those observed here (Lindroth and Hwang, 1996a; Stevens and Lindroth, 2005; Donaldson et al., 2006). Nonetheless, in this study, we are unable to infer what proportion of the observed

variation may be due to genetics rather than to environment. However, phenolic glycosides (the most variable compounds) show relatively little phenotypic plasticity in common gardens (Hwang and Lindroth, 1997; Osier and Lindroth, 2001). Thus, most of the observed variation in concentration among clones may be due to genotype.

Our survey of developmentally based phytochemical variation indicates that stand demographics may add to the overall magnitude of spatial and temporal chemical variation occurring in aspen populations (Erwin et al., 2001). The strong inverse relationship between the developmental trajectories of tannins and phenolic glycosides in aspen creates strikingly different chemical phenotypes among mature and juvenile ramets within a clone that are likely to influence herbivory (Lindroth and Hwang, 1996a; Osier and Lindroth, 2001) and other chemically mediated processes (Lindroth et al., 2002; Madritch et al., 2006). The trend of increasing tannins with age is difficult to explain because we lack sufficient understanding of their functions in aspen (Lindroth and Hwang, 1996a). The biological activity of phenolic glycosides, however, is well established (Lindroth and Hwang, 1996a; Osier and Lindroth, 2001). The fact that leaves of young ramets contain much higher concentrations of these compounds compared with mature ramets may indicate that they have historically experienced more intense selective pressure than have mature ramets (discussed below).

The magnitude of developmentally based phytochemical shifts in condensed tannin and phenolic glycoside concentrations varied among the clones surveyed (i.e., clones showed different developmental trajectories). If this variation is genetically based and heritable, it would suggest that the same evolutionary factors involved in selecting for (or against) chemical traits in aspen may influence the degree to which developmental shifts occur. Spatial or temporal variation in costs and benefits of allocation to tannins and phenolic glycosides among clones and among age classes may explain the observed patterns. For example, temporally variable population densities of insect herbivores or browsing mammals, or spatially variable resource availability, all can potentially affect the relative costs and benefits of producing foliar allelochemicals (Donaldson et al., 2006; Osier and Lindroth, 2006).

Developmental patterns are also visible but far less pronounced for nitrogen, starch, and sugars. This comparative lack of change in primary compounds may reflect that their role in plant physiology is less variable over developmental time than is that of “secondary” compounds.

We recognize that the developmental patterns observed in this study cannot with certainty be attributed solely to ontogeny (genetically programmed developmental changes). Some portion of the variation between juvenile and mature ramets may be due to differences in their respective environments. For example, resource (light, soil nutrients) availability may differ across space occupied by a clone. As discussed above, the short stature of younger ramets may predispose them to browsing (historically and recently). However, in our selection of 0- to 1-yr-old ramets, we specifically selected individuals that were new root sprouts and that had not been previously browsed. Therefore, the most extreme differences between juvenile and mature clones appear not to be a function of recent browsing. Previous defoliation studies also argue against induction as a proximate explanation. Contrary to the patterns we observed, studies have failed to find substantial induction of phenolic glycosides, but do find significant induction of tannins (Osier and Lindroth, 2004; Stevens and Lindroth, 2005).

Another consideration we must make is that our data derive from differently aged ramets of clonally integrated plants. The importance of clonal integration for the chemical composition of ramets may be significant, as ramets may exchange photosynthate, nutrients, and perhaps even compounds signaling herbivore damage (Magyar et al., 2004). Clonal integration, therefore, may influence the costs and benefits of allocation to defense and contribute to both spatial and temporal variation in the chemical profiles of aspen populations. However, considering the number of studies that report strong herbivore preferences for (Basey et al., 1988; Swihart and Bryant, 2001) and phytochemical differences among (Erwin et al., 2001) juvenile and mature trees in this and other systems, we believe that the developmental changes evident in aspen tannin and phenolic glycoside concentrations may be largely a result of ontogenetic shifts in allocation.

Our findings have several potentially important evolutionary and ecological implications that require further investigation. The fact that leaf tissues of young aspen trees are better defended (i.e., higher levels of phenolic glycosides) suggests a greater selective pressure for defense in young trees compared with mature trees. Browsing pressure from mammals is a likely explanation for such patterns. Mammals exert tremendous selective pressure on aspen, particularly on resprouts and seedlings that are accessible to browsers (Swihart et al., 1994; Kay and Bartos, 2000). Furthermore, because the impacts of herbivory on plant survival, growth, and reproduction may be particularly strong during the juvenile phase (Watkinson, 1986), optimal defense theory (Rhoades, 1979) predicts that this selective pressure leads to relatively higher levels of defense in juvenile compared with mature tissues. Indeed, a meta-analysis conducted by Swihart and Bryant (2001) indicates that mammals almost always prefer mature tissues to juvenile tissues of forest trees, including aspen. Our data suggest that mammals may be a primary source of selection explaining the quantitative distribution of phenolic glycosides in aspen.

The most significant arthropod herbivores of aspen, eruptive outbreak species such as forest tent caterpillars, large aspen tortrix, and gypsy moths, generally cause the greatest damage in advanced even-aged stands. During outbreaks, trees are defoliated regardless of their level of commitment to chemical defenses (Mattson et al., 1991; Donaldson, 2005). As a result, defoliating arthropods may present less selective pressure for chemical defenses than previously thought. In fact, this study and other recent work suggest that advanced stands of aspen in the Great Lakes region generally have lower concentrations of phenolic glycosides than previously thought (Fig. 1; Donaldson, 2005), although levels in advanced stands of western aspen are typically high (Donaldson, Lindroth, and Wooley, unpublished data).

Regardless of the evolutionary outcomes of aspen–arthropod interactions, phenolic glycoside concentration is the best predictor of insect performance both among aspen clones (Lindroth and Hwang, 1996a) and among species of Salicaceae (Edwards, 1978; Tahvanainen et al., 1985). Given that trees undergo developmental shifts in phenolic glycoside concentrations that are greater in magnitude than the genotypic variation observed among adult clones, it is likely that these age-related changes have significant impacts on insect behavior, distributions, and populations (Kearsley and Whitham, 1989, 1998; Waltz and Whitham, 1997).

Explaining the marked increase in condensed tannins as aspen trees mature in terms of selective pressure exerted by herbivory is complicated. In fact, the role of condensed tannins in aspen (and many other plant species), although long assumed

to be defensive, is still not well understood (Ayres et al., 1997). Most studies have failed to find a relationship between aspen tannin concentrations and mammalian or arthropod preferences or performance (Lindroth and Hwang, 1996a). Tannins may play diverse “alternative” roles in plants, from defenses against photooxidative stress (Close and McArthur, 2002) and microbial pathogens (Kellam et al., 1992), to modifying local soil processes and nutrient cycling rates (Hättenschwiler and Vitousek, 2000). For example, variation in tannin concentrations can alter leaf litter quality (Lindroth et al., 2002; Madritch et al., 2006). Concentrations of both nitrogen and phenolics (especially tannins) play important roles in litter decomposition and soil nutrient dynamics in forest soils (Schimel et al., 1996; Northup et al., 1998; Hättenschwiler and Vitousek, 2000; Kraus et al., 2003; Schweitzer et al. 2004). In fact, an alternative hypothesis to the role of tannins as antiherbivore defenses posits that they may be adaptive in their capacity to regulate proximal nutrient cycling (Northup et al., 1998).

In summary, developmental shifts in chemical defenses within aspen clones appear to be greater in magnitude than the variation observed among mature clones. We believe that these developmental changes have likely been shaped by evolutionary factors related to herbivory and ecosystem function and hold importance for diverse ecological interactions today. Developmental shifts in chemical composition in this dominant clonal species are likely to contribute to temporal and spatial mosaics of host quality and to influence patterns of community structure and ecosystem function.

Acknowledgments We thank Brian Rehill for thoughtful discussion, comments on the manuscript, and insights about the effects of plant development on phytochemistry and ecological processes. We also thank anonymous reviewers whose comments improved the manuscript. Support for this work was provided from NSF grant DEB-0074427.

Abstract Resource availability, degree of herbivore damage, genetic variability, and their interactions influence the allocation of investment by plants to resistance and tolerance traits. We evaluated the independent and interactive effects of soil nutrients and moisture, and simulated the effects of herbivore damage on condensed tannins (resistance) and growth/regrowth (tolerance) traits of *Terminalia sericea*, a deciduous tree in the Kalahari desert that constitutes a major component of livestock diet. We used a completely crossed randomized-block design experiment to examine the effects of nutrients, water availability, and herbivore damage on regrowth and resistance traits of *T. sericea* seedlings. Plant height, number of branches, internode length, leaf area, leaf mass for each seedling, combined weight of stems and twigs, and root mass were recorded. Condensed tannin concentrations were 22.5 and 21.5% higher under low nutrients and low soil moisture than under high nutrient and high water treatment levels. Tannin concentrations did not differ significantly between control and experimental seedlings 2 mo after simulated herbivore damage. Tannin concentrations correlated more strongly with growth traits under low- than under high-nutrient conditions. No trade-offs were detected among individual growth traits, nor between growth traits and condensed tannins. *T. sericea* appeared to invest more in both resistance and regrowth traits when

grown under low-nutrient conditions. Investment in the resistance trait (condensed tannin) under high-nutrient conditions was minimal and, to a lesser degree, correlated with plant growth. These results suggest that *T. sericea* displays both resistance and tolerance strategies, and that the degree to which each is expressed is resource-dependent.

Keywords Fertilization · Defoliation · Herbivory · Condensed tannins · Compensation · Trade-offs · Plant defenses · Resistance

Introduction

Plants are subjected to a variety of stress factors that affect both their development and survival (Larcher, 1995). On the African savanna, where low nutrient availability and water scarcity are commonplace, herbivory by mammals is also a key factor that may cause significant deviations from conditions of optimal plant life (Du Toit, 1995). In response to these limitations, plants have evolved tolerance and resistance strategies to deal with stress (Mauricio, 2000). Tolerance is the ability of plants to maintain fitness after herbivory in the presence of potentially fitness-reducing stress (Pilson, 2000; Simms, 2000). Resistance traits such as thorns and chemical substances presumably reduce plant acceptability to herbivores (Cooper and Owen-Smith, 1985), thereby reducing the amount of damage that a plant suffers.

Plant defensive strategies are influenced by the availability of resources to the plant (Coley et al., 1985). Any effect on the carbon/nutrient ratio, be it herbivory, changes in soil nutrient condition, water availability, or exposure to light, can cause a change in the total defense level (see review by Stamp, 2003). When trees experience herbivory, a temporary nutrient deficiency is experienced (Luxmore, 1991), which may limit growth more than photosynthesis. Therefore, carbon in excess of growth demand may be shunted into storage and production of resistance traits (see review by Koricheva et al., 1998), while storage may aid tolerance (regrowth) ability (Stowe et al., 2000). Furthermore, excess carbon may increase the production of carbon-based defenses under conditions of low resources, but at little cost to plant fitness (Tuomi, 1992; Ruiz et al., 2002).

Mammalian Herbivory on *Terminalia sericea* Trees in the Kalahari Desert

Terminalia sericea (Combretaceae) is a major contributor of browse for both domestic cattle and goats during the hot-dry season under heavy grazing systems (Katjiua and Ward, 2006). We presumed that browsing on *T. sericea* would elicit carbon-based chemical defenses, given the high light conditions, and poor soil nitrogen and phosphorus concentrations of the Kalahari desert (Mendelsohn et al., 2002). Thus, we reasoned that *T. sericea* would have poor regrowth capacity upon damage because allocations to carbon-based chemical defenses may present an opportunity cost to regrowth capacity (Van der Meijden et al., 1988; Pilson, 2000).

The potential interactions of foliar damage, nutrient availability, and soil moisture content provide an opportunity for us to examine the effects of herbivore damage on the recovery and leaf quality of *T. sericea*. We investigated the effects of

simulated herbivory on the resistance and tolerance traits of *T. sericea* in a fully crossed randomized-block design experiment with 12 factor-level combinations (three levels of herbivory, two levels of fertilizer addition, and two levels of water treatment) across plants derived from five mother plants.

We made the following predictions regarding the levels of condensed tannin (resistance trait): (1) Under conditions of high resource availability, plants will reduce the synthesis of condensed tannin but increase growth rate. (2) Foliar damage to seedlings growing on poor soils will induce greater levels of condensed tannin than on rich soils. (3) Low water and nutrient availability will result in increased condensed tannin at no cost to plant growth. We also predicted the following regarding tolerance traits: (1) Compensation for herbivory is resource-dependent, i.e., compensatory ability will be enhanced under low-resource environments and reduced under high soil nutrient conditions. (2) Tolerance of herbivory is complex and involves trade-offs between tolerance traits that are likely to be expressed under low-resource conditions. (3) The seedling siblings (i.e., from the same mother plants) with high levels of resistance traits will have low levels of tolerance traits and *vice versa*.

Methods and Materials

We investigated condensed tannin levels (resistance trait) of *T. sericea* and its tolerance for partial simulated herbivory among seedlings taken from five mother plants under varying levels of nutrient and water availability in a nursery experiment at the Forestry Research Station in Okahandja, Namibia. Seedlings were raised from seeds collected from 13 individual trees (mother plants) in their natural environment and sown at the end of winter (August 2001) in sterilized river sand. Germination rates and establishment varied considerably among mother plants. Seedlings from five plants with the highest establishment were transplanted and grown in 10-l polythene bags with a surface area of about 0.047 m². Each bag was inoculated with 100 cm³ soil collected under *T. sericea* trees in the field to allow for growth of soil mycorrhizae. Seedlings were grown under nursery conditions for 12 mos, and hardened for 1 mo under reduced solar radiation, and then for 2 wks under full radiation. At this stage, all seedlings were watered to field capacity three times per week. The 2 wk of hardening was necessary because simultaneous exposure to direct radiation and supplementation of fertilizer resulted in the death of seedlings in the pilot phase. Thus, experimental treatments commenced after 2 wks of hardening the plants to direct solar radiation (third week of January 2003) on 15.5 mo-old seedlings and were terminated 3.5 mos later.

We used a completely crossed randomized-block design experiment with two levels of water treatment (low and high), two levels of fertilizer treatment (control and fertilizer addition), and three levels of herbivory (control, low and high). For details of treatment levels, see below. This constituted 12 treatment-level combinations across the five mother plants, with four replicates in each treatment-level combination. Thus, a total of 240 seedlings were used.

For the water treatment, plants were watered once a week (Monday) for the low water level, and three times per week for the high water level. A commercially available fertilizer (N/P/K, 2:3:2) was used for the fertilizer treatment. We applied approximately 4 g of the fertilizer fortnightly over a period of 3 mos (February–

April), which is considered an intermediate level of fertilization. This frequency of application did not only allow for the initial hardening, but also prevented excessive leaching of the nutrients from the sandy soil. The intermediate amount that was applied (30 g/m²) corresponded with those applied by Tilman (1988) and on field plantations in South Africa (J.M.T. Theron, personal communication). Simulated herbivory was administered 1 mo after the application of water and fertilizer treatments. For the low herbivory level, one out of three (33%) leaves was damaged and later removed by hand within an hour of damage, while two out of three (66%) leaves were damaged and also removed in the case of high simulated herbivory. The apical shoot was left intact, as some plants had poor growth and the removal of the apical shoot could have had detrimental effects. Thus, manual defoliation started just below the apical shoot.

The experiment was terminated at the end of April 2003, 1 mo before winter and senescence. Several plant growth parameters, viz. height, leaf area (length and width), number of branches, and internode length, were sampled. Twigs and stems (aboveground biomass), roots (belowground biomass), and leaves were oven-dried at 65°C for 48 hr to obtain dry mass. Whole leaves were counted before drying. Plant height was measured twice, before the experiment started and at the end of the experiment.

Condensed tannin in leaf samples was measured by using a standard acid–butanol protocol (Waterman and Mole, 1994). This method with modification by Hagerman (unpublished data) was applied to extract condensed tannin with 50% methanol. The extract was added to the acid–butanol reagent and heated at 95°C in a boiling bath for 1 hr, then cooled, and absorbance read at 550 nm. Two replicates were used. Condensed tannin concentrations were expressed in quebracho equivalents (% QE) (quebracho is used as a standard and was obtained from A. Hagerman; Hagerman and Butler, 1989). Quebracho tannin is the only readily available condensed tannin. Purified quebracho standard prepared from a single lot of the crude commercial mixture is recommended for use in tannin analysis to minimize differences that may exist among materials provided by even a single supplier (Hagerman and Butler, 1989).

To control the comparison-wise error (see, e.g., Zar, 1984), we performed an overall comparison of the seven dependent variables by using multivariate analysis of variance (MANOVA), with water, herbivory, fertilizer, and their interactions as fixed factors, and mother plants as random factors. The dependent variables used were tannin concentration, leaf area per unit final height, leaf mass per unit final height, change in height during the experiment (per unit initial height), above-/belowground mass, internode length per unit final height, and number of branches per unit final height. Leaf area, leaf mass, internode length, and number of branches were standardized by dividing by final plant height because of strong positive correlations between these variables and final height. Subsequent to the detection of significant effects, *post hoc* univariate analysis (ANOVA) tests were performed. These effects were analyzed in a mixed-model randomized block-design ANOVA (error terms as for model III ANOVA), using Statistica v. 6, GLM procedure. Where appropriate, analyses were followed by a multiple comparisons of means using a Scheffé *post hoc* test. Means are represented \pm 1 standard error, unless otherwise stated. Pearson product–moment correlations were used to determine trade-offs between resistance and tolerance traits and between the various tolerance traits investigated.

Table 1 Multivariate analysis of variance (Manova) of nursery experiment

Factor	Wilk's λ	<i>F</i>	Effect <i>df</i>	Error <i>df</i>	<i>P</i>
Water	0.747	10.55	7	218	<0.001
Herbivory	0.885	1.95	14	436	0.020
Fertilizer	0.531	27.50	7	218	<0.001
Water \times Herbivory	0.875	2.14	14	436	0.009
Water \times Fertilizer	0.978	0.69	7	218	0.678
Herbivory \times Fertilizer	0.885	1.96	14	436	0.019
Water \times Herbivory \times Fertilizer	0.924	1.25	14	436	0.233
Mother Plant	0.240	13.63	28	787.4	<0.001

Dependent variables used in this analysis were as follows: tannin concentration, leaf area per unit final height, leaf mass per unit final height, change in height during experiment (per unit initial height), above/below mass, internode length per unit final height, and no. branches per unit final height. Leaf area, leaf mass, internode length, and no. of branches were standardized by dividing by final plant height because of strong positive correlations between these variables and final height.

Results

MANOVA results revealed a significant overall multivariate effect for water ($df = 7, 218, F = 10.55, P < 0.001$), herbivory ($df = 14, 436, F = 1.95, P = 0.020$), and fertilizer ($df = 7, 218, F = 27.50, P < 0.001$) (Table 1). There were interaction effects for water \times herbivory ($df = 14, 436, F = 2.14, P = 0.009$) and herbivory \times fertilizer ($df = 14, 436, F = 1.96, P = 0.019$). The interaction effects of water \times fertilizer and water \times herbivory \times fertilizer were nonsignificant. The effect of mother plant was significant ($df = 28, 787.4, F = 13.63, P < 0.001$).

Resistance Trait and Growth

Fertilizer addition reduced the production of condensed tannin ($df = 1, 224, F = 26.91, P < 0.001$). Mean \pm SE condensed tannin in the low-resource environment was 22.86 ± 1.229 (% QE) compared to 17.73 ± 0.741 (% QE) on fertilized soils. Thus, tannin levels declined by 22.5% when fertilizer was added. In contrast, fertilizer positively affected all growth traits ($P < 0.005$), with the exception of internode length.

The mean growth of fertilized seedlings was higher than those grown on the control-fertilizer soils (Table 2). The biggest difference in parameters was in

Table 2 Significant ($P < 0.05$) effects of fertilizer treatment on seedling growth (Mean \pm SE)

Growth parameter	Fertilizer treatment	
	Control	Fertilizer addition
Plant height (cm)	17.5 \pm 6.49	46.8 \pm 7.70
Leaf area (mm ²)	913.1 \pm 31.38	1053.6 \pm 27.09
Leaf mass (g)	0.05 \pm 0.000	0.06 \pm 0.002
Branches/height ratio	0.01 \pm 0.000	0.02 \pm 0.001
Number of branches	5.1 \pm 0.23	7.5 \pm 0.26
Above-/belowground biomass ratio	0.2 \pm 0.01	0.3 \pm 0.01

seedling height. Seedlings treated with fertilizer grew 165% taller. Similarly, fertilized seedlings yielded a greater number of branches (48.2%), above-/belowground biomass ratio (31.3%), number of branches/height ratio (29%), leaf area (15%), and leaf mass (14%) than control seedlings.

We predicted that leaf damage on seedlings growing in low-resource environments would induce greater levels of condensed tannin to avoid future damage [resistance prediction (2)]. This was not the case. Although condensed tannin concentration was higher in the low-resource environment, simulated herbivory did not induce higher tannin concentration in the low-resource environment ($df = 2, 224, F = 2.77, P = 0.065$). The interaction of herbivory and fertilizer was also not significant ($df = 2, 224, F = 0.05, P = 0.953$). That is, resource availability did not influence the response of condensed tannin concentration to simulated herbivory.

Water level affected tannin concentration ($df = 1, 224, F = 24.84, P < 0.001$). Tannin concentration was 21.7% higher in the low water treatment ($22.76 \pm 1.092\%$ QE) than in the high water treatment ($17.82 \pm 0.935\%$ QE).

Trade-Offs between Resistance and Growth Traits

We considered trade-offs in seedlings grown in low-resource conditions (low water and control fertilizer, i.e., LW–CF treatment combination) and in high-resource conditions (high water and fertilizer addition treatment, i.e., HW–IF combination). Condensed tannins in the low-resource environments (LW–CF) correlated positively with the majority of growth traits, but negatively with the number of branches/height ratio ($r = -0.376, P = 0.003$) (Table 3). The correlations of condensed tannin with leaf area, leaf mass, seedling height, number of branches, and internode length were significant ($P < 0.05$) and positive, while above-/belowground biomass ratio did not correlate ($P > 0.05$) with tannin concentration. The positive correlation between condensed tannin synthesis and the majority of growth traits is consistent with resistance prediction (3), which predicted that tannin would accumulate at no cost to plant growth in the low-resource environment.

A similar trend was found in the high-resource environment (HW–IF treatment combination) (Table 3). Most correlations were significant ($P < 0.05$) and positive, except for a negative correlation involving the number of branches/height ratio.

Table 3 Correlations of condensed tannin concentrations (% QE) with seedling growth traits, grown under low and high resource environments

Tannin		Growth traits						Above-/below ground biomass
		Leaf area (mm ²)	Leaf dry mass (g)	Height (cm)	No. of branches	Internode length (cm)	No. of branches/height	
Low-resource environment (LW–CF)	<i>r</i>	0.70	0.80	0.44	0.43	0.73	-0.38	-0.10
	<i>P</i>	0.001	0.001	0.001	0.001	0.001	0.003	0.450
High-resource environment (HW–IF)	<i>r</i>	0.66	0.51	0.37	0.39	0.56	-0.35	0.37
	<i>P</i>	0.001	0.001	0.004	0.002	0.001	0.006	0.004

Fig. 1 Effect of simulated herbivory on leaf area. Error bars denote 95% confidence limits, and the different letters indicate significant mean differences at $P < 0.05$

Correlations were generally weaker in the high-resource environments than in the low-resource environment.

Tolerance Traits

We predicted that compensatory ability of previously herbivore-damaged seedlings is resource-dependent [tolerance prediction (1)]. However, there was no significant interaction effect of herbivory \times water \times fertilizer treatments for seedling height ($df = 2, 224, F = 0.61, P = 0.545$), number of branches/height ratio ($df = 2, 224, F = 0.77, P = 0.465$), above-/belowground biomass ratio ($df = 2, 224, F = 2.23, P = 0.110$), internode length ($df = 2, 224, F = 1.36, P = 0.259$), and the number of branches ($df = 2, 224, F = 1.92, P = 0.149$). Thus, no differences existed in the (re)growth rate of these traits among seedlings exposed to control, low, and high herbivory.

Leaf regrowth capacity was resource-dependent. Herbivory reduced leaf area ($df = 2, 57, F = 5.79, P = 0.005$) and leaf mass ($df = 2, 57, F = 8.89, P < 0.001$) when grown under conditions of low water and fertilizer addition levels. Both leaf area (Fig. 1) and leaf mass (Fig. 2) undercompensated (i.e., size upon regrowth was less than the original) equally under the low and high levels of herbivory treatment.

The interaction effect of herbivory \times water on the number of branches was significant ($df = 2, 224, F = 4.35, P = 0.014$). Both low and high simulated herbivory reduced the number of branches produced when seedlings were exposed to the high water treatment level (Fig. 3). The results also indicate that the reduced branches

Fig. 2 Effect of simulated herbivory on leaf dry mass. Error bars denote 95% confidence limits, and the different letters indicate significant mean differences at $P < 0.05$

Fig. 3 Effect of simulated herbivory on the number of branches produced when seedlings were treated with high water levels. Error bars denote 95% confidence limits, and the different letters indicate significant mean differences at $P < 0.05$

produced under herbivory in the high water treatment level did not differ from those produced in the low water treatment level, irrespective of the degree of herbivory.

Trade-Offs among Growth Traits

Resource conditions affected trade-offs among tolerance traits (Tables 4 and 5). Under high stress conditions (LW–HH–CF), leaf mass correlated negatively with above-/belowground biomass ratio ($r = -0.471$, $P = 0.036$) and the number of branches/height ratio ($r = -0.491$, $P = 0.028$) (Table 4). No trade-offs were detected under the least stressful conditions (HW–CH–IF) (Table 5). There were stronger correlations under the high stress conditions (Table 4) than in the least stressful conditions (Table 5).

Negative correlations among growth traits were detected in the intermediate range of stress conditions. For example, leaf area correlated negatively with

Table 4 Correlations between growth traits of seedlings exposed to high stress conditions (LW–HH–CF), using bonferroni-adjusted values of α to control the comparison-wise error (Type I Error) for a large number of correlations

		Leaf area	Leaf mass	Height	Branches	Internode length	Branches/Height
Leaf mass	r	0.81					
	P	<0.001*					
Height	r	0.53	0.49				
	P	<0.001*	0.001*				
Number of branches	r	0.58	0.36	0.46			
	P	<0.001*	0.006	0.002*			
Internode length	r	0.85	0.76	0.51	0.37		
	P	<0.001*	<0.001*	0.001*	0.005		
Branches/height	r	-0.29	-0.49	–	–	-0.51	
	P	0.011	0.001*	–	–	0.001*	
Above/below	r	-0.28	-0.47	-0.10	-0.06	-0.28	0.33
	P	0.011	0.002*	0.032	0.038	0.011	0.007

* α was only considered significant if $P < 0.0024$.

Correlations involving height and the number of branches vs. the number of branches/height were not reported because they were autocorrelated.

Table 5 Correlations between growth traits in seedlings exposed to low stress conditions (HW-CH-IF), using Bonferroni-adjusted values of α to control the comparison-wise error (Type I Error) for a large number of correlations

		Leaf area	Leaf mass	Height	Branches	Internode length	Branches/Height
Leaf mass	<i>r</i>	0.60					
	<i>P</i>	<0.0021*					
Height	<i>r</i>	0.17	0.26				
	<i>P</i>	0.023	0.013				
Number of branches	<i>r</i>	0.48	0.19	0.30			
	<i>P</i>	0.002*	0.020	0.009			
Internode length	<i>r</i>	0.58	0.68	0.26	0.45		
	<i>P</i>	<0.001*	<0.001*	0.013	<0.001*

	<i>P</i>	0.018	0.044	0.003	<0.001*	0.003	0.032

* α was considered significant if $p < 0.0024$.

Correlations involving the number of branches and height vs. the number of branches/height were not reported because they were autocorrelated.

branches/height ratio under HW-HH-IF ($r = -0.59$, $P = 0.006$), LW-LH-IF ($r = -0.51$, $P = 0.021$), and even under LW-CH-CF ($r = -0.51$, $p = 0.023$). Leaf mass correlated negatively with branches/height ratio under LW-CH-CF ($r = -0.56$, $P = 0.010$) and LW-LH-IF ($r = -0.46$, $P = 0.040$).

Mother Plant Resistance and Tolerance Traits

Tannin concentrations differed among mother plants ($df = 4, 180$, $F = 89.28$, $P < 0.001$). Differences in allocation to condensed tannins (resistance trait) among mother plants corresponded linearly with investments into growth traits such as leaf area ($r = 0.91$, $P = 0.03$), leaf mass ($r = 0.94$, $P = 0.02$), height ($r = 0.93$, $P = 0.02$), and internode length ($r = 0.97$, $P = 0.006$). These results contradicted tolerance prediction (3). Tannin synthesis was not correlated with above-/belowground biomass production ($r = -0.27$, $P = 0.657$).

Discussion

Resource Gradients

Seedlings in the resource-poor environments had 22.5% higher condensed tannin concentrations than those grown in high-resource environments. Consistent with this, other studies have shown that plants growing in resource-poor environments maintain a high resistance level against herbivore damage (Gebauer et al., 1998; Osier and Lindroth, 2001). Nutrient-poor soils combined with drought conditions constrain growth more than photosynthesis, and, subsequently, assimilates in excess of growth requirements are shunted into defense (Herms and Mattson, 1992) and

storage (see review by Koricheva et al., 1998). In this study, seedlings under limited soil moisture synthesized higher (21.7%) concentrations of condensed tannins than those in the high soil moisture environment. Such effects of drought conditions have been reported elsewhere (Kouki and Manetas, 2002). The current study showed that drought and poor soil nutrients affect condensed tannin synthesis in a similar manner.

Fertilizer addition to poor soils seems to reduce the ratio of carbon/nutrients available to defense, thereby reducing potential resistance (Kouki and Manetas, 2002), but promoting greater plant growth (Mutikainen et al., 2000). Along an environmental resource gradient, tolerant plants seem to be faced with the dilemma whether to grow faster or to compensate for damage (Hochwender et al., 2000). In this study, fertilizer addition increased seedling leaf area, leaf dry mass, height, number of branches, number of branches/height ratio, and above-/belowground biomass ratio, rather than enhancing compensatory responses to damage.

Inducible Resistance

The effects of herbivory or its interactions with either fertilizer or water treatments did not influence the synthesis of condensed tannins in seedlings. Expression of resistance traits in previously browsed species may take time to reach levels above controls (Larcher, 1995). Initially, browsed plants may show a decline in allocation to resistance traits (stress reaction), followed by mobilization of resources for resistance traits that, depending on the severity and persistence of stress, may recover and exceed the levels of the controls (= overcompensation of resistance), or may revert back to levels similar to that of controls (= full compensation) if stress was light and of short duration (Underwood, 1999), or if sufficient time was allowed without further herbivore damage over the growing season (Katjua and Ward, unpublished data). Severe and persistent herbivore damage may, however, reduce tannin concentrations to levels lower than that of control seedlings (= undercompensation) due to reduced resources (see review by Bergelson and Purrington, 1996). However, our results were not consistent with these studies. This may be because the high simulated herbivory was not frequent enough to deplete plant reserves needed for condensed tannin production.

Resistance vs. Growth Trade-Offs

This study showed no indication of trade-offs between investments into tannin synthesis and the majority of growth traits (leaf area, leaf dry mass, height, and internode length) in the low-resource environments. These results contradicted resistance prediction (3). The negative correlation between condensed tannin content and the number of branches/height ratio in the low-resource environment was also detected in the high-resource environment. Thus, resource availability alone could not explain this negative correlation.

Growth traits such as leaf area, internode length, and above-/belowground biomass ratio correlated positively with condensed tannin concentration. A comparison of these results (Table 3) suggests that investments into resistance traits may be more closely coupled with growth traits in low-resource environments than in high-resource environments. The cost of allocation to resistance traits is expected to

be more evident when plants are grown under stressful conditions (Bazzaz et al., 1987; Herms and Mattson, 1992). It appears that our plants under low-resource conditions had limited investment budgets available for growth and resistance traits, and that investment partitioning between growth and resistance traits could approximate unity with greater resource limitation. Thus, our results yielded no evidence of cost implications for allocations to resistance and tolerance traits. This is consistent with results reported by Ward and Young (2002) on *Acacia drepanolobium* in Kenya.

Tolerance Compensatory Responses

There was no significant interaction effect of water \times herbivory \times fertilizer treatment on seedling height, branches/height ratio, above-/belowground biomass ratio, internode length, and number of branches. The lack of a difference in the regrowth rates of the above growth traits between the control, low, and high simulated herbivory implies that either herbivory had little or no effect on these traits, or that growth capacity was fully compensated. In contrast, leaf compensatory ability was resource-dependent. Leaf area and leaf dry mass undercompensated for growth when grown on the low water and intermediate fertilizer treatments. However, both leaf area and leaf dry mass fully compensated for growth in low-resource environments (= control fertilizer treatment). Hochwender et al. (2000) argued that, because compensatory growth and reproduction are more prevalent in low-resource environments, it contributes greatly to the survival and reproduction of plants in these environments.

In this study, a 31.3% lower above-/belowground biomass ratio was found in seedlings grown on the low-resource environment than in the high-resource environment. Prior investments into storage structures in the low-resource environments are reallocated to sites where new growth is required, thereby enhancing compensatory regrowth (Hochwender et al., 2000). In high-resource environments, compensatory ability is limited or may even be absent, because investments into storage structures are presumably limited by high growth rates. Indeed, plants invest more in aboveground growth than in belowground structures when growing in high-resource environments (Kouki and Manetas, 2002).

Herbivory did not affect the number of branches, possibly because the apical shoots were not damaged during experimentation. There was a significant water \times herbivory interaction effect on the number of branches. Seedlings exposed to low and high herbivory treatments produced fewer branches when given the high water treatment. This is consistent with tolerance prediction (1) that compensatory ability is resource-dependent. Among all growth traits investigated, leaf area and leaf dry mass were most sensitive to herbivore damage.

Trade-Offs among Tolerance Traits

Allocations among growth traits in high-resource environments seem to be flexible and less coupled to the competing demands of the different growth traits (Table 5), than in the low-resource environments (Table 4). In general, our results indicate that: (1) resource conditions, internal or external to the plant, resulting from variability in soil moisture, herbivory, and soil nutrients determine the proportional

allocation of investments among competing growth traits; (2) partitioning of investment appears to be more strongly correlated among competing growth traits in the low-resource environments than in the high-resource environments; and (3) leaf area and leaf mass are the most sensitive traits to allocation shifts in *T. sericea*.

Mother Plant Resistance and Tolerance

The concentrations of condensed tannin (= resistance trait) differed in the same way as the regrowth capacity (= tolerance traits) among the five mother plants. That is, plants with high vigor invested heavily in both resistance and tolerance traits, whereas weak plants invested equally poorly in resistance and tolerance traits. Thus, there was a positive genetic correlation between the levels of resistance and tolerance traits among *T. sericea* mother plants.

Abstract Proanthocyanidins (PAs) or condensed tannins are a major group of phenolic compounds in the leaves of birch trees and many other woody and herbaceous plants. These compounds constitute a significant allocation of carbon in leaves and are involved in plant responses to environmental stress factors, such as pathogens or herbivores. In some plants, PA concentrations are affected by atmospheric carbon dioxide (CO₂) and ozone (O₃) levels that may influence, for example, species fitness, community structure, or ecosystem nutrient cycling. Therefore, a study on the quantitative response of PAs to elevated concentrations of carbon dioxide (CO₂) and ozone (O₃) was undertaken in seedlings of *Betula platyphylla*, *Betula ermanii*, and *Fagus crenata*. Seedlings were exposed to ambient or elevated O₃ and CO₂ levels during two growing seasons in the Kanto district in

Japan. Ten open-top chambers were used for five different treatments with two replicates: filtered air (FA), ambient air (ambient O₃, 43 ppb; ambient CO₂, 377 ppm), elevated O₃ (1.5 × ambient O₃, 66 ppb), elevated CO₂ (1.5 × ambient CO₂, 544 ppm), and elevated O₃ and CO₂ combined. In addition, seedlings growing in natural conditions outside of chambers were studied. Leaf samples were analyzed for total PA concentrations by butanol–HCl assay and for polymeric PA concentrations by normal-phase high-performance liquid chromatography. Total PA concentrations in leaves of all species were similarly affected by different treatments. They were significantly higher in seedlings treated with elevated CO₂ and O₃ combined, and in seedlings growing outside chambers compared with the FA controls. *F. crenata* contained only traces of polymeric PAs, but significant species × treatment interaction was observed in the polymeric PA concentrations in *B. ermanii* and *B. platyphylla*. In *B. platyphylla*, leaves treated with elevated CO₂ + O₃ differed significantly from all other treatments. It was suggested that the strongest effect of elevated CO₂ and O₃ combined on leaf PA contents resulted from the additive effect of these environmental factors on phenolic biosynthesis.

Introduction

Background levels of greenhouse gases, ozone (O₃) and carbon dioxide (CO₂), have continued to increase because of human activities. The total amount of tropospheric O₃ has been estimated to have increased by 36% since 1750. Atmospheric CO₂ has increased more than 30% over the same time (IPCC, 2001). O₃ inhibits plant growth by reduction in net photosynthesis (inhibition of carbon assimilation), causes an imbalance of carbon allocation to plant organs (decreasing yield and nutritive quality of biomass), and increases sensitivity to other environmental stresses such as plant diseases (Reich, 1983; Darral, 1989; Manning and Tiedemann, 1995; Fuhrer and Booker, 2003). CO₂ has direct effects on plant photosynthesis and growth, and enriched CO₂ can alter the concentrations of primary and secondary metabolites in leaves (Lindroth et al., 1993). Furthermore, O₃ stimulates phenylpropanoid metabolism and thus induces accumulation of phenolic compounds, such as flavonoids and tannins in leaf tissues (Jordan et al., 1991; Kangasjärvi et al., 1994; Eckey-Kaltenbach et al., 1994; Booker and Miller, 1998).

Proanthocyanidins (PAs) (also known as condensed tannins) form a class of natural polyphenolic compounds. They are oligomeric and polymeric end products of the biosynthetic flavonoid pathway consisting of chains of flavan-3-ol units linked together mainly by carbon–carbon bonds at C4→C8 or C4→C6. PAs can be classified to six subclasses (procyanidins, prodelphinidins, proflisetinidins, propelargonidins, prorobinetinidins, and proguibourtinidins) based on the substitution pattern of the single flavan-3-ol unit. Birch leaf PAs are procyanidins and prodelphinidins (Ossipova et al., 2001). PAs are the main phenolic compounds in the leaves of certain woody plants and in herbaceous plants. For example, in the mature leaves of mountain birch, PA concentration can be as high as 120 mg g⁻¹ of dry mass that corresponds to approximately 80% of their total phenolic concentration (Ossipova et al., 2001).

PA concentrations typically increase in response to enriched CO₂. For example, enriched CO₂ increased total PA concentrations in *Populus tremuloides*, *Quercus rubra*, and *Acer saccharum* leaves (Lindroth et al., 1993; Kinney et al., 1997). PA concentrations were also increased by elevated CO₂ in *Salix myrsinolia* (Julkunen-Tiitto et al., 1993), *Eucalyptus tereticornis* (Lawler et al., 1997), *Pinus palustris* (Entry et al., 1998), *Pinus taeda* (Gebauer et al., 1998; Booker and Maier, 2001), *Lotus cornutus* (Carter et al., 1999), and *Gossypium hirsutum* (Booker, 2000; Booker et al., 2000). The effect of elevated CO₂ or O₃ levels on total PA concentration in *Betula* sp. leaves has also been investigated (Lavola et al., 1994, 2000; Traw et al., 1996; Lindroth et al., 2001). Experiments with *B. allegheniensis*, *B. populifolia*, *B. pendula*, and *B. papyrifera* seedlings showed that total PA concentrations in leaves of seedlings growing under elevated concentration of CO₂ were significantly higher than those in control leaves (Traw et al., 1996; Lavola et al., 2000; Lindroth et al., 2001; Kuokkanen et al., 2003). In contrast, enriched O₃ did not affect total PA concentrations in birch leaves (Lavola et al., 1994; Lindroth et al., 2001). The strongest effect was observed with combined CO₂ and O₃ treatments. However, in *Gossypium hirsutum*, O₃ treatment did not have a significant effect on leaf PA concentration, but a CO₂–O₃ interaction was observed (Booker, 2000). Jordan et al. (1991) and Booker et al. (1996) have reported that treatment with high O₃ concentrations increases PA concentration in *Pinus taeda* needles.

PAs influence plant–herbivore interactions. They bind and precipitate proteins and polysaccharides and may reduce the suitability of foliage of woody plants for herbivores (Haslam, 1988; Herms and Mattson, 1992). Concentrations of PAs are generally used to quantify resistance levels of woody plants to insects and other herbivores. The total PA concentrations in birch leaves correlate negatively with growth rates in later larval stages of *Epirrita autumnata* (Kause et al., 1999; Ossipov et al., 2001). Therefore, induction of phenolic biosynthesis by elevated levels of CO₂ and O₃, single or combined, may also regulate plant–herbivore relationships.

PAs are commonly quantified as total PA concentrations by using colorimetric methods. These methods are inexpensive and fast, but lack specificity (Rohr, 2002). The butanol–HCl (BH) and vanillin assays are the most commonly used methods. The BH assay uses hydrochloric acid catalyzed depolymerization of PAs in butanol to yield colored anthocyanidins that can be detected spectrophotometrically (Waterman and Mole, 1994). Various limitations for this method have been reported (see, for example, Porter et al., 1986; Scalbert, 1992; Waterman and Mole, 1994; Schofield et al., 2001). The most important are the proportion of water in the reaction mixture and the choice of PA standard. The BH assay should be used with caution for quantification (Schofield et al., 2001). The vanillin method uses the condensation reaction of PAs with vanillin (Rohr, 2002). The reliability of this method can be affected by many factors as listed in Schofield et al. (2001): the type of solvent used, the nature and concentration of acid, the vanillin concentration, the reaction time and temperature, and the PA standard used. Chromatographic methods enable more specific determination and quantification of PAs. We have used reversed-phase high-performance liquid chromatography (RP-HPLC) for analysis of individual shorter-chain PAs (less than tetramers) and normal-phase HPLC (NP-HPLC) for analysis of higher PAs separated by their degree of polymerization (DP; Karonen et al., 2004). PAs in birch leaves are mainly in polymeric form (DP >10), and their concentrations can be easily determined with NP-HPLC (Karonen et al., 2006).

The principal aim of this research was to test some biochemical mechanisms involved in the adaptations of woody plants to an atmospheric pollutant (such as tropospheric O₃) possibly involved in forest decline and to increasing concentrations of atmospheric CO₂. The separate and combined effect of CO₂ and O₃ on the concentrations of total and polymeric PAs in leaves of three woody plant species, *Betula platyphylla*, *Betula ermanii*, and *Fagus crenata*, were evaluated and compared.

Methods and Materials

Study Site

Experiments were carried out at the Akagi Testing Center of the Central Research Institute of Electric Power Industry (100 km north–northwest of Tokyo, Seta county, Gunma prefecture, Japan), 540 m above sea level on the south slope of Mt. Akagi.

Plant Material and Experimental Design

In May 2002, 2-yr-old *B. platyphylla* Sukatchev var. *japonica* seedlings, 3-yr-old *B. ermanii* Cham. seedlings, and 4-yr-old *F. crenata* Blume seedlings were planted individually in pots filled with 12 l of a volcanic ash soil. Trees were grown outdoors at the experimental site until transfer into the chambers. Twenty-four seedlings per species were put into each open-top chamber or ambient plot (AP; outdoor) at the beginning of July 2002. To reduce positional effects, each chamber was divided into four square sections, and seedlings were placed in a fully randomized design within each of these sections. Each spring and summer, all pots were fertilized at a rate of 80–80–80 kg/ha of N–P–K. Seedlings in chambers received subterranean water (pH 7.7) by drip irrigation to the soil, as well as deionized water to the top of plants via mist generating systems.

Exposure to O₃ and CO₂ was conducted by using modified square-greenhouse-type open-top chambers (3.6 × 3.6 m). Advantages of the open-top chamber systems are the ability to control exposure dynamics, an easy definition of the experimental unit, and the possibility to exclude a proportion of ambient O₃ by charcoal filtering of ambient air (Reich, 1987). Chamber walls were transparent glass. Each open-top chamber was equipped with a fan box. Fan boxes were fitted with two fans and two filters containing activated charcoal. Filtered air and treatment gases were fed into a 7.8-m³ space beneath the chamber floor where a thorough mixing of gases occurred before injection into the chamber. Treatment air was introduced into the chamber through holes in the interior. Air supply was sufficient to achieve four changes per min. Injected air was passed through activated charcoal filters. Chamber fans operated continuously (24 hr per day) over the experimental period. Wind velocity at a height of 1.0 m above the floor of chamber ranged from 0.06 to 0.21 m/sec and averaged 0.15 m/sec. Air temperature and gas concentrations were not uniformly distributed within chambers, but deviations were small (about 5%). During the experiment, increases in annual average of mean air temperature inside the chambers as compared with outside were <1°C. Photosynthetic photon flux density inside the chambers was 75% of full sunlight.

Ten open-top chambers were used for five different treatments (two replicates of each): filtered air was passed through activated charcoal (FA), ambient air ($1.0 \times$ ambient O_3), elevated O_3 ($1.5 \times$ ambient O_3), elevated CO_2 ($1.5 \times$ ambient $CO_2 + 1.0 \times$ ambient O_3), and elevated O_3 and CO_2 combined. In addition, two non-chambered APs were established outdoors to test the effect of the chamber. Treatments were conducted from 12 July to 31 October in 2002 and from 26 March to 31 October in 2003. Mean O_3 concentration was 43 ppb in ambient air and 66 ppb in the elevated O_3 treatment during the entire exposure time. Mean CO_2 concentration was 377 ppm in ambient air and 544 ppm in the elevated CO_2 treatment. Additional experimental parameters are shown in Table 1. Ozone was added to the chambers in the $1.0 \times O_3$ and $1.5 \times O_3$ treatments 24 hr per day. Ozone was generated by O_3 generator (model OZ-24-UA; Ebara Corp., Kanagawa, Japan) that used oxygen-enriched dry air as the source gas. Ozonated air was passed through a water scrubber to remove highly reactive by-products such as N_2O_5 before introduction into the air-mixing space. Gas cylinders containing pure liquid CO_2 were used as a source of CO_2 gas. The supply of CO_2 to the chambers in the $1.5 \times CO_2$ treatment was interrupted during the night. Ozone and CO_2 concentrations inside the chambers and in the ambient air were monitored at 3-min intervals by O_3 analyzers (Model 9810; Monitor Labs, Inc., USA) and infrared gas analyzer (Model ZRH; Fuji Electric Corp., Tokyo, Japan), respectively. The air sampling tube was 0.8 m above the floor in the center of the chamber.

Table 1 Average daily CO_2 and O_3 concentrations, mean daily and maximum air temperatures, and mean daily photosynthetic photon flux densities (PPFD) from 21 July to 31 October 2002 and from 26 March to 31 October 2003

	2002	2003
CO_2 concentration (ppm) ^a		
Amb	362	384
$1.5 \times$ Amb	534	549
AP	375	383
O_3 concentration (ppb) ^b		
FA	16	16
Amb	41	44
$1.5 \times$ Amb	61	68
AP	46	46
Mean daily temperature ($^{\circ}C$)		
In the open-top chambers	21	18
Outside the chambers	20	17
Mean maximum temperature ($^{\circ}C$)		
In the open-top chambers	26	23
Outside the chambers	24	21
Mean PPFD ($mol\ m^{-2}\ day^{-2}$)		
In the open-top chambers	17	15
Outside the chambers	22	20

^a Daily 12 hr (0600–1800) average CO_2 concentration in open-top chambers: in ambient CO_2 concentration (Amb) and in the elevated $1.5 \times CO_2$ concentration ($1.5 \times$ Amb); and in an ambient plot outside of the chambers (AP).

^b Daily 12 hr (0600–1800) average O_3 concentration in open-top chambers: in charcoal-filtered air (FA), in ambient O_3 concentration (Amb), and in the elevated $1.5 \times O_3$ concentration ($1.5 \times$ Amb); and in the ambient plot outside of the chambers (AP). O_3 was added to nonfiltered air for 24 hr daily.

Leaf Sampling

Mature leaves were sampled 70 d after the end of bud break in all individual trees in summer 2003: short shoot leaves of *B. ermanii* on 13 June and of *B. platyphylla* var. *japonica* on 20 June, and first-flushed leaves of *F. crenata* seedlings on 8 August. Leaves were collected from two or three lateral branches at the upper part of the seedling from six seedlings per species chamber for a total of 12 samples (seedlings) per treatment. Leaves were frozen in liquid nitrogen and lyophilized. Dry leaf material was ground to powder with a Retsch MM200 Mixer mill and stored at -20°C .

Extraction

Leaf material (30 mg) was extracted in Eppendorf tubes for 30 min with 0.65 ml of 80% aqueous acetone in a planar shaker. The homogenate was centrifuged for 10 min at $8800 \times g$, the clear supernatant was collected, and the insoluble residue was re-extracted once more with 0.65 ml of 80% aqueous acetone and twice with 100% acetone. Extracts were combined, and acetone was removed in a vacuum concentrator (Concentrator 5301, Eppendorf AG, Germany) prior to lyophilization. Lyophilized extracts were dissolved in 1.0 ml of chloroform/80% aqueous methanol mixture (1:1, v/v) and shaken for 25 min in a planar shaker. Following this treatment, 0.5 ml of 20% aqueous methanol was added, and the sample was mixed again for 20 min and centrifuged for 10 min at $8800 \times g$. The aqueous methanol fraction containing polar phenolic compounds was collected, and the methanol was removed by vacuum concentrator prior to lyophilization. The lyophilized fraction was dissolved in 0.7 ml of water, centrifuged for 10 min at $8800 \times g$, filtered through a 0.45- μm PTFE filter, and kept frozen until PA analyses.

Analysis of Proanthocyanidins

Total PA concentrations were analyzed as previously described (Ossipova et al., 2001). A 0.1-ml sample of birch leaf extract and 0.6 ml of water were added to 6 ml of 1-butanol/hydrochloric acid (95:5, v/v) solution. The reaction mixture was heated at 95°C for 2 hr and then cooled to room temperature. Absorbance was measured at 555 nm on Perkin-Elmer Lambda 12 UV/VIS spectrophotometer (Norwalk, CT, USA).

Polymeric PA concentrations were analyzed by using an HP 1090 Liquid Chromatograph (Hewlett-Packard, Palo Alto, CA, USA) equipped with an autosampler, binary pump, column oven, diode array detector, and HP ChemStation data system. The column and chromatographic conditions were previously described (Karonen et al., 2004, 2006). A Merck LiChrospher Si 60 column (250 \times 4 mm i.d., 5 μm) equipped with a precolumn at 37°C was used. Two solvents, dichloromethane–methanol–water–acetic acid (82:14:2:2, v/v) (A) and methanol–water–acetic acid (96:2:2, v/v) (B), were used. An injection volume of 5 μl and a flow rate of 1 ml/min were used. The elution profile was as follows: 0–30 min, 0–18% B in A (linear gradient); 30–45 min, 18–31% B in A; 45–50 min, 31–88% B in A; 50–60 min, 88% B (isocratic). The UV trace was recorded at 280 nm.

Total and polymeric PA concentrations were quantified against purified PA standard, which was isolated and purified from mountain birch leaf extract by column chromatography on Sephadex LH-20, as previously described (Ossipova et al., 2001).

Statistical Methods

The effects of treatments on total and polymeric PA concentrations were tested with mixed analyses of variance where treatments and tree species were included as fixed effects and growth chamber as a random effect. *F. crenata* contained only traces of polymeric PAs and was omitted from the analysis. Mixed models were analyzed with PROC MIXED in SAS 8.2 (SAS Inst. Inc. 1999–2001). The Kenward-Roger Method was used for degrees of freedom and variance components for the type of variance-covariance matrix. The desired pairwise comparisons were made with contrast statements according to the significance of the effects in the model. With significant species \times treatment interaction, the differences between treatments within species and the differences between species within treatments were tested. The normal distribution of model residuals was checked visually and with *Kolmogorov-Smirnov* test. Both TPA and PPA concentrations were log-transformed to meet the assumption of normal distribution of model residuals. Back-transformed least-squares means and their 95% confidence limits were used in the figures.

Results and Discussion

Betula platyphylla, *B. ermanii*, and *F. crenata* seedlings were exposed to ambient or elevated O₃ or/and CO₂ during two growing seasons using the open-top chambers.

Amb, ambient air; AP, outside of the chamber; CO₂, elevated CO₂; CO₂ + O₃, elevated levels of combined CO₂ and O₃; FA, air filtered through the activated charcoals; O₃, elevated O₃; Spec, species; Treat, treatment.

Leaves of seedlings were collected and extracted, and the soluble PAs were analyzed with two different methods, i.e., colorimetric and chromatographic. Total PA concentrations were analyzed by the colorimetric BH assay. This assay reveals the presence of PAs reliably, but should be used with caution for quantification (see above). There was a significant difference in total PA concentrations between treatments, but no difference between species or significant species \times treatment interaction (Table 2). Total PA concentration was highest in CO₂ + O₃ treatment that differed significantly from all other treatments except AP. Total PA concentration was 29% higher in CO₂ + O₃ treatment compared with the FA control. The AP, in turn, had significantly higher total PA concentrations compared to Amb (24% higher), FA (23% higher), and elevated O₃ (19% higher; Table 2, Fig. 1). Earlier, it was noticed that shading of mountain birch trees reduced the concentrations of soluble PAs in leaves (Henriksson et al., 2003). In this study, light intensity inside the chambers was only 75% of the full sunlight, and the reduced levels of PAs in control seedling leaves inside the chambers (Amb and FA) compared to controls outside the chambers (AP) could be a result of the shading effect. Thus, AP seedlings cannot be used as a control for determining effects of elevated CO₂ or O₃ levels on PA concentrations in the leaves.

The chromatographic methods enable more specific determination and quantification of PAs. In birch species, which have grown in Finland, PAs are mainly in the polymeric form (DP > 10), and only traces of oligomeric PAs can be detected in mature leaves (Karonen et al., 2006). Polymeric PA concentrations can be easily determined with NP-HPLC. The clear peak of polymeric PAs was detected in NP-HPLC traces of *B. ermanii* and *B. platyphylla* extracts (Fig. 2) corresponding to our previous studies (Karonen et al., 2006). Beech leaves contained high amounts of oligomeric PAs, but only traces of polymeric PAs (Fig. 2). The amount of polymeric PAs in beech leaves was below the quantification limit of the NP-HPLC method, and, thus, quantification could not be conducted. The effects of tree species and treatment on polymeric PA concentrations are presented in Table 3 and Fig. 1. Significant species \times treatment interactions were observed. In *B. ermanii*, the polymeric PA concentration was highest in the AP seedlings growing outside of chambers, presumably because of the shading effect of the chamber (see above). The polymeric PA concentration was 13% higher in AP seedlings compared with the FA control. In *B. platyphylla*, the highest polymeric PA concentration was found in the leaves of seedlings exposed to elevated CO₂ + O₃. These leaves differed significantly from all other treatments including AP seedlings. Polymeric PA concentration was 27% higher in CO₂ + O₃ treatment compared with the FA control. In comparison of species within treatments, *B. platyphylla* had significantly higher polymeric PA concentration in seedling leaves exposed to elevated CO₂ + O₃ (27% higher) than *B. ermanii*, whereas in the leaves of AP seedlings, the opposite was true (40% lower; Table 3 and Fig. 1). TPA concentrations were always higher compared to PPA concentrations (Fig. 1). This can be a result of different factors. Various limitations have been reported for the BH assay (see above). PA polymers theoretically produce more anthocyanidins than PA oligomers, but the yield does not stay constant when the chain lengthens. It is likely that even if the birch leaf PAs were mainly PPAs, the leaves also contained shorter-chain PAs. These oligomeric PAs were included in TPA concentrations quantified with the BH assay, but not in PPA concentrations quantified with the normal-phase HPLC method.

Fig. 1 Total (TPA) and polymeric (PPA) proanthocyanidin concentrations (mg g⁻¹ of dry weight) in the *Betula ermanii* (A), *B. platyphylla* (B), and *Fagus crenata* (C) leaves under atmospheres of ambient air (Amb), air filtered by activated charcoal (FA), elevated CO₂ (CO₂), elevated O₃ (O₃), and elevated levels of combined CO₂ and O₃ (CO₂ + O₃) in open-top chambers, as well as in the seedlings growing outside of the chamber (AP). Data are presented as means with 95% confidence interval

Previously, Lavola et al. (1994, 2000) and Lindroth et al. (2001) reported that total PA concentrations were higher in CO₂-exposed leaves than in control leaves in *B. pendula* and *B. papyrifera*, but fumigation with O₃ did not affect total PA concentrations. However, in our study, only combined CO₂ + O₃ treatment increased PA levels significantly. In the leaves of *B. ermanii*, the positive effect of CO₂

treatment on polymeric PA concentration was close to significant. These differences could be a result of experimental conditions (open-top chambers instead of field and greenhouse experiments), different sensitivity of birch species to elevated concentrations of CO₂ and O₃, or different methods used for PA quantification. Furthermore, leaf dry mass can be influenced by starch levels in tissues, especially when plants are treated with elevated CO₂, and PA concentrations are calculated on dry mass basis. This so-called dilution effect might partly explain why PA concentrations were not increased at elevated CO₂ levels. Moreover, these data were obtained with small individuals grown under almost optimal light and moisture conditions, and plant stresses other than elevated O₃ or CO₂ were minimized. Therefore, the experimental seedlings were not exposed to a variety of interacting stresses, as is the case in nature. As Reich (1987) stated, we do not know if, or how, water stress, herbivores, pathogens, plant–plant competition, nutrition, shading, temperature fluctuations, or other factors influence the O₃-dose or O₃-uptake relations.

Elevated atmospheric CO₂ levels stimulate photosynthesis and increase carbohydrate availability for synthesis of carbon-based secondary metabolites such as phenolics (Booker, 2000). In contrast to CO₂, O₃ affects primary metabolism by inhibition of photosynthesis, which decreases carbohydrate availability for phenolic biosynthesis (Booker, 2000). However, O₃ may exhibit more specific and positive effects on phenolic metabolism by activating the signaling pathways of defensive mechanisms (Rao et al., 2000). Treatment of plants with elevated O₃ increases the biosynthetic activity of the phenylpropanoid pathway, which plays a significant role in plant defense responses by synthesizing compounds potentially protective against phytopathogens and herbivores (Kangasjärvi et al., 1994). Therefore, both elevated CO₂ and O₃ can activate or affect phenolic biosynthesis in different branches of a plant's metabolic network (both primary and secondary metabolism). Thus, the combined influence of elevated CO₂ and O₃ on the PA level in woody plants was the strongest.

Even if the enriched CO₂ or O₃ level alone did not affect PA concentrations, they still affected the growth of *B. platyphylla*, *B. ermanii*, and *F. crenata* seedlings. It was noticed that at ambient CO₂ concentration with increasing level of O₃, the shoot, root, and total biomass of *F. crenata* were decreased. Decreases in shoot or total biomass were also observed in *B. platyphylla* and *B. ermanii*. Predictably, at ambient O₃ concentration, the increased level of CO₂ caused positive effects on the growth of all three species. The total biomass of *B. platyphylla* and *F. crenata* increased significantly and likewise for the shoot biomass of *B. ermanii*. The interactive effects of enriched O₃ and CO₂ on growth of these tree species were species-specific. Significant interaction was found on the biomass of *B. platyphylla*, but not on the biomass in *B. ermanii* or *F. crenata* (Matsumura et al., 2005). Elevated CO₂ is known to increase biomass production, whereas elevated O₃ suppresses it. Increase or decrease of biomass because of the various gas treatments will affect PA inputs to the soil and thus decomposition and nutrient-cycling processes (Booker et al., 2005).

Abstract Infestation of corn (*Zea mays*) by corn earworm (*Helicoverpa zea*) predisposes the plant to infection by *Aspergillus* fungi and concomitant contamination with the carcinogenic mycotoxin aflatoxin B1 (AFB1). Although effects of ingesting AFB1 are well documented in livestock and humans, the effects on insects that naturally encounter this mycotoxin are not as well defined. Toxicity of AFB1 to different stages of *H. zea* (first, third, and fifth instars) was evaluated with artificial diets containing varying concentrations. Although not acutely toxic at low concentrations (1–20 ng/g), AFB1 had significant chronic effects, including protracted development, increased mortality, decreased pupation rate, and reduced pupal weight. Sensitivity varied with developmental stage; whereas intermediate concentrations (200 ng/g) caused complete mortality in first instars, this same concentration had no detectable adverse effects on larvae encountering AFB1 in fifth instar. Fifth instars consuming AFB1 at higher concentrations (1 µg/g), however, displayed morphological deformities at pupation. That cytochrome P450 monooxygenases (P450s) are involved in the bioactivation of aflatoxin in this species is evidenced by the effects of piperonyl butoxide (PBO), a known P450 inhibitor, on toxicity; whereas no fourth instars pupated in the presence of 1 µg/g AFB1 in the diet, the presence of 0.1% PBO increased the pupation rate to 71.7%. Pupation rates of both fourth and fifth instars on diets containing 1 µg/g AFB1 also increased significantly in the presence of PBO. Effects of phenobarbital, a P450 inducer, on

AFB1 toxicity were less dramatic than those of PBO. Collectively, these findings indicate that, as in many other vertebrates and invertebrates, toxicity of AFB1 to *H. zea* results from P450-mediated metabolic bioactivation.

AFB1	aflatoxin B1
P450	cytochrome P450 monooxygenase
AFBO	AFB1-8,9-epoxide
AFM1	aflatoxin M1
AFL	aflatoxicol
AFQ1	aflatoxin Q1
AFB2a	aflatoxin B2a
AFG1	aflatoxin G1
PBO	piperonyl butoxide
PB	phenobarbital

Introduction

Helicoverpa zea, the corn earworm, is a major pest of corn and a number of other crops throughout the USA; current estimates indicate that this species alone is responsible for losses exceeding 10% in field corn and 50% in sweet corn (Wiseman, 1999). Losses inflicted by *H. zea* infestation can be exacerbated by fungal infections that may accompany *H. zea* damage (Dowd and White, 2002). Among the most devastating are the ear molds that produce aflatoxins, including some of the most active natural carcinogens known (Lillehoj, 1992; Dowd, 1998). Because the maximum tolerance levels for aflatoxins are in the 0- to 20-ppb range for corn grown for human consumption, aflatoxin contamination in the USA is responsible for millions of dollars of crop losses every year [U.S. Department of Agriculture (USDA), 1999].

Aflatoxins are coumarin derivatives that can be classified as either dihydrofurocyclopentenones or dihydrofurolactones. These compounds owe their toxicity to their ability to form irreversible adducts to nucleic acids with the concomitant inhibition of DNA replication and DNA-dependent transcription (Murray et al., 1982). Chronic effects of exposure include decreases in food consumption in pigs, poultry, cattle, and a variety of livestock as well as decreases in milk yields in cattle. Acute and chronic exposures result in a variety of clinical symptoms in humans, including pulmonary edema, abdominal pain, vomiting, convulsions, and, in some cases, coma and death (Newberne and Butler, 1969).

One means of reducing the risk of aflatoxin contamination of corn is to reduce the likelihood of insect damage, which predisposes the plant to fungal infection. Reduction of insect damage through insecticide application and the use of insect-resistant germ plasm (e.g., tight-husked varieties) has had limited success owing to the evolution of resistance to both forms of control (Dowd et al., 1997). Transgenic Bt corn has long been touted as another means of reducing crop damage, but it is unclear how effective it will be (Windham et al., 1999), given that *H. zea* displays a wide range of sensitivity to Bt (Stone and Sims, 1993), and that any level of insect

infestation can facilitate mold establishment leading to mycotoxin contamination of corn (Dowd, 2001).

Although aflatoxins are toxic to a broad range of arthropods (Al-Adil et al., 1972; Wright et al., 1982; Chinnici and Bettinger, 1984; Lillehoj, 1992; Sadek et al., 1996), comparatively little is known about metabolic transformations of aflatoxin in insects that regularly encounter them. Among the enzyme systems responsible for metabolizing these compounds in many vertebrate and invertebrate taxa are the cytochrome P450 monooxygenases (P450s; <http://drnelson.utm.edu>; <http://www.biobase.dk/P450/>). Whereas in some species P450s metabolize aflatoxin B1 (AFB1) to hydroxylated metabolites, including aflatoxin M1 (AFM1), aflatoxin G1 (AFG1), and aflatoxin Q1 (AFQ1), in other species, P450s are responsible for bioactivation of these compounds, catalyzing the epoxidation of the terminal furan ring of AFB1 to yield AFB1-8,9-epoxide (AFBO), a highly genotoxic metabolite (Murray et al., 1982). AFBO owes its toxicity to its ability to bind to DNA to form the predominant 8,9-dihydro-8-(N7-guanyl)-9-hydroxy-AFB1 adduct (Iyer et al., 1994). Hydroxylated metabolites have lower genotoxic or toxic activities than AFB1 in most organisms (Eaton et al., 1988; Ramsdell and Eaton, 1990). The Hikone-R strain of *Drosophila melanogaster*, which is resistant to DDT and other insecticides, produces aflatoxicol (AFL) as a principal metabolite, along with AFM1 and aflatoxin B2a (AFB2a) (Foerster and Wurgler, 1984). Saner et al. (1996) demonstrated that bioactivation of AFB1 was catalyzed by CYP6A2. Lee and Campbell (2000) compared metabolism of AFB1 in larvae of *Amyelois transitella* (navel orangeworm), which are frequently exposed to aflatoxin-contaminated tissue, and *Cydia pomonella* (codling moth), which are rarely exposed to aflatoxins. These authors found that AFL is the major metabolite produced *in vitro* by navel orangeworms; in contrast, codling moths collected in the field produced only trace amounts of AFL, and a laboratory strain produced no detectable metabolites. Neither species produced AFBO as a metabolite, in contrast to vertebrates, which produce this highly mutagenic biotransformation product quite readily. Lee and Campbell (2000) have suggested that the absence of this particular bioactivation is indicative of coevolution between kernel-feeding insects and these toxin-producing fungi.

Although *H. zea* is likely to encounter aflatoxins in corn, as well as in several other host plants (including soybeans *Glycine max*), the degree to which this species has coevolved with mycotoxin-producing *Aspergillus* species is unknown. In this study, we examined the toxicological impact of AFB1 ingestion throughout the larval developmental period and tested the effects of a known inhibitor of cytochrome P450 metabolism, piperonyl butoxide (PBO), as well as a known P450 inducer, phenobarbital (PB; Brun et al., 1996; Maitra et al., 1996; Dunkov et al., 1997; Waxman 1999; Stevens et al., 2000; Li et al., 2002a; Brown et al., 2003), to determine the contributions of these enzymes to aflatoxin toxicity in this species.

Methods and Materials

Chemicals

Aflatoxin B1 and PB were obtained from Sigma (St. Louis, MO, USA). Analytical grade dimethyl sulfoxide (DMSO) was purchased from Fisher Scientific, and PBO was from Tokyo Kasei Kogyo Co. (Tokyo, Japan).

Insects

Helicoverpa zea were individually reared in 30-ml creamer containers on a semisynthetic diet containing wheat germ (Waldbauer et al., 1984) and maintained in an insectary kept at 23–26°C with a photoperiod of 16-hr light/8-hr dark. Bioassays were conducted under the same environmental conditions. At each developmental stage tested, caterpillars were collected within 12 hr of molting to insure age comparability.

Bioassays

Stock solutions of AFB1 were prepared in DMSO at concentrations of 1 ng/μl, 20 ng/μl, 200 ng/μl, 1 μg/μl, and 20 μg/μl; 100 μl of each stock solution were added to 100 g of the semisynthetic diet to obtain final concentrations of 1 ng/g, 20 ng/g, 200 ng/g, 1 μg/g, and 20 μg/g AFB1. Control larvae were fed with the semisynthetic diet containing 100 μl DMSO per 100 g; pilot experiments determined that concentrations of DMSO at levels as high as 0.5% of the diet do not affect development or survivorship (data not shown).

To determine the toxicity of aflatoxin to *H. zea*, artificial diets containing AFB1 at four concentrations were administered in separate bioassays to larvae at three developmental stages—first, third, and fifth instars; 20 larvae were tested in each bioassay. Because pilot studies established that early instars display higher sensitivity to AFB1 (data not shown), first instars were exposed to diets containing AFB1 at concentrations of 1 ng/g, 20 ng/g, 200 ng/g, and 1 μg/g, and third and fifth instars were exposed to diets containing AFB1 at concentrations of 20 ng/g, 200 ng/g, 1 μg/g, and 20 μg/g. The proportions of larvae at each stage of development and the number of dead larvae were recorded daily through pupation, and pupal weights were measured within 48 hr of pupation. Each set of bioassays was replicated three times.

To elucidate the effects of cytochrome P450-mediated metabolism on aflatoxin toxicity, a series of bioassays was conducted whereby AFB1 toxicity was assessed in the presence of an inducer (PB) or an inhibitor (PBO). Stock solutions of PB were prepared in DMSO at a concentration of 0.25 mg/μl PB, and 400 μl of this stock were added to 100 g of the semisynthetic diet to obtain a final concentration of 0.1% PB in the diet. An aliquot of 105 μl commercial PBO (90% purity, 1.06 density) was added directly to 100 g of the diet for a final concentration of 0.1% PBO. Newly molted fourth or fifth instars were assayed separately, with 20 larvae per treatment. Caterpillars were placed on diets containing either 0.1% DMSO (control), 0.1% PBO, 0.1% PB, 1 μg/g AFB1, 1 μg/g AFB1 + 0.1% PBO, or 1 μg/g AFB1 + 0.1% PB and were reared and evaluated as described.

Statistical Analyses

All data were evaluated by one-way analysis of variance with treatment differences among means tested at $P = 0.05$ with Duncan's multiple range test. All data for larval development, pupation rate, and mortality were means from three replicates, with 20 caterpillars/treatment. Because significant differences were found among replicates in pupal weights, this parameter was analyzed independently for each replicate, and representative values from one replicate are reported.

Safety

Aflatoxin B1 is a highly toxic mycotoxin that should be handled with care. Solid AFB1 for calibration should be handled in a biohood, using a nose and mouth mask. Any material and equipment with possible contamination should be handled carefully and with surgical gloves.

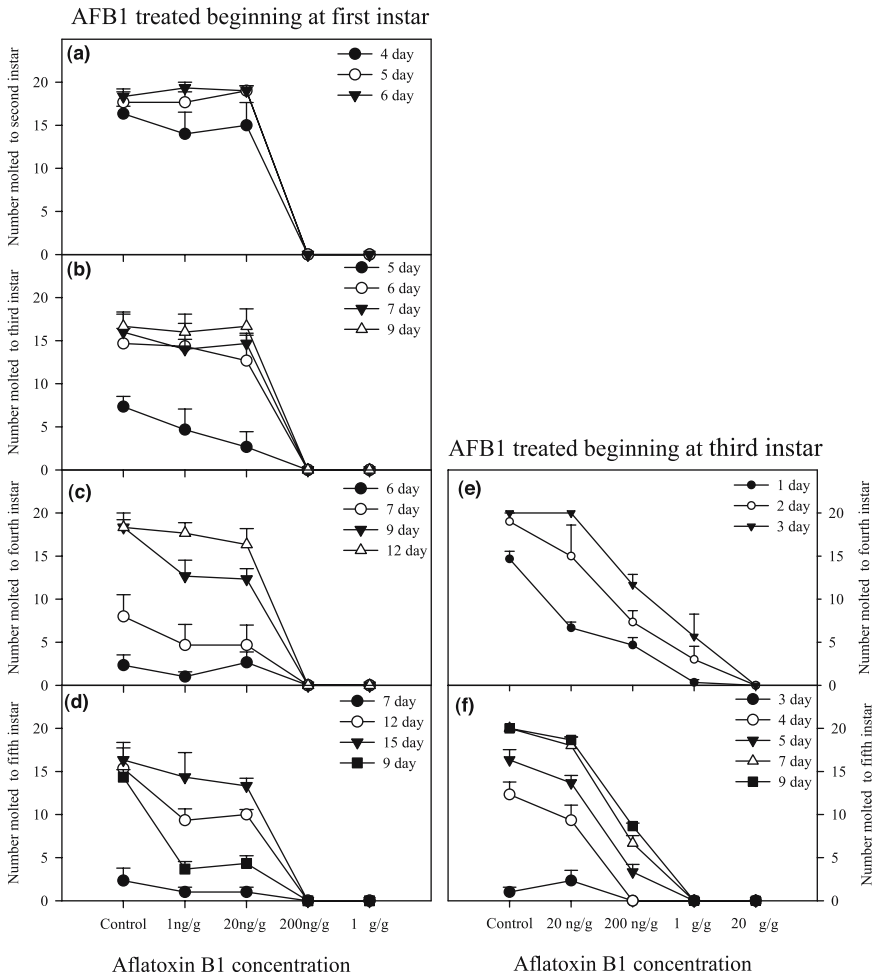

Fig. 1 Development of *H. zea* after exposure to different concentrations of aflatoxin B1 in diet beginning at first instar (a, b, c, d) and third instar (e, f). (a) Number of larvae that have molted to second instar after 4, 5 and 6 days of treatments, (b) number of larvae that have molted to third instar after 5, 6, 7 and 9 days of treatments, (c) number of larvae that have molted to fourth instar after 6, 7, 9 and 12 days of treatments, (d) number of larvae that have molted to fifth instar after 7, 9, 12 and 15 days of treatments, (e) number of larvae that have molted to fourth instar after 1, 2 and 3 days of treatments, (f) number of larvae that have molted to fifth instar after 3, 4, 5, 7 and 9 days of treatments. Each treatment contained 20 caterpillars and each experiment was repeated three times. Values are means + standard errors. Points on each line represent effects of different concentrations of AFB1 on a given day after AFB1 exposure

Results

Toxicity to First Instars

AFB1 at high concentrations strongly inhibited larval growth and development. At a concentration of 200 ng/g, larval mortality was 55% after 9 d ($P = 0.02$) and 100% after 15 d ($P < 0.001$; Figs. 1a–d and 2a). Most larvae died before molting to second instar, and only about 10% of larvae survived to third instar after 12 d. AFB1 at a concentration of 1 $\mu\text{g/g}$ completely inhibited larval development, and all larvae had died within 12 d without molting to second instar ($P < 0.001$; Fig. 2a).

AFB1 at the lower concentrations of 1 and 20 ng/g did not detectably delay the timing of the molt to second instar (Fig. 1a) but did delay developmental progress at all subsequent stages (Fig. 1b–d). Low concentrations of AFB1 also significantly reduced pupation rate ($P = 0.004$ at 1 ng/g and $P < 0.001$ for 20 ng/g) and pupal weight ($P = 0.001$ for 1 ng/g and $P < 0.001$ for 20 ng/g; Fig. 3a and b); after 15 d, mortality was 46.6% on diets containing 20 ng/g AFB1 compared with 18.3% on control diet ($P = 0.029$; Fig. 2a).

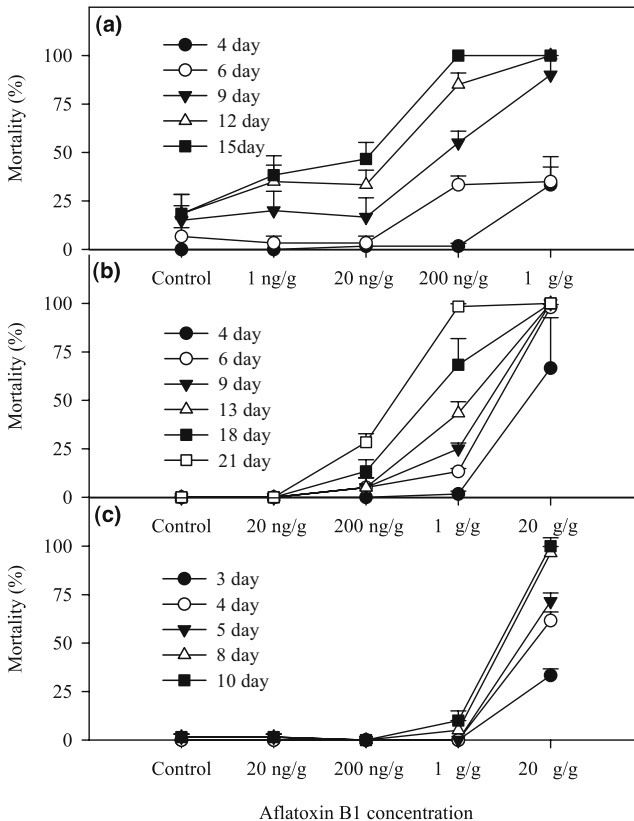

Fig. 2 Mortality of *H. zea* after exposure to different concentrations of aflatoxin B1 in diet beginning at first instar (a), third instar (b), and fifth instar (c). Values are means + standard errors from 20 caterpillars/treatment with three experimental replicates for each

Toxicity to Third Instars

Third instars display greater tolerance to AFB1 than do first instars. Administered to third instar larvae, the lowest concentration (20 ng/g) of AFB1 delayed development as well as pupation (Figs. 1e,f and 3c); pupal weight was also significantly reduced (Fig. 3d), although pupation rate and mortality were unaffected (Figs. 2b and 3c). The intermediate concentration of 200 ng/g AFB1 significantly delayed development (Figs. 1e,f and 3c) and reduced pupal weight to the same extent as did diets containing 20 ng/g AFB1 ($P = 0.411$; Fig. 3d). Mortality rates assessed after 21 d of treatment were 28.5% compared to no mortality for control larvae ($P < 0.001$; Fig. 2b) and were significantly lower than the mortality rate of 55% for first instars consuming AFB1 at this concentration ($P < 0.001$) for 9 d. Pupation rates assessed after 28 d of treatment were 66.7% compared to 100%

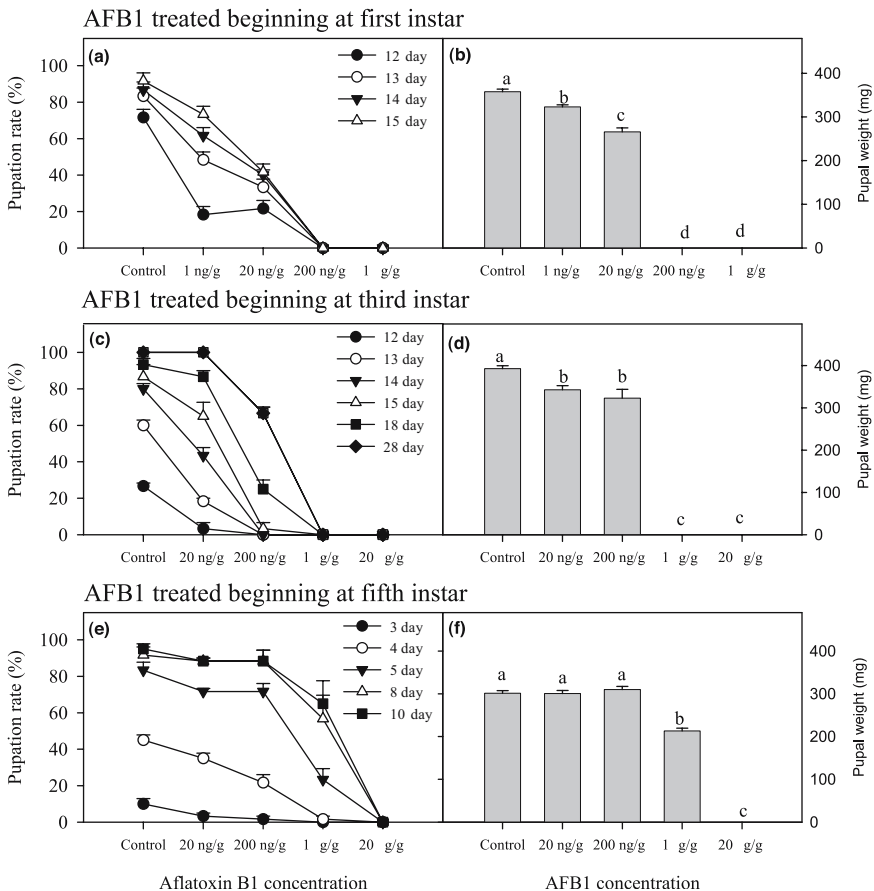

Fig. 3 Pupation of *H. zea* after exposure to different concentrations of aflatoxin B1 in diet beginning at first instar (a, b), third instar (c, d), and fifth instar (e, f). Values for pupation rate are means + standard errors from 20 caterpillars/treatment with three experimental replicates for each. Values for pupal weight are representative of one of the three series of replicates with the number of insects that have pupated for this replicate shown above each bar. Significant differences ($P < 0.05$) in pupal weights among treatments are indicated by different letters above the bars

for control larvae (Fig. 3c). Of the caterpillars that survived the growth delays associated with the treatment of third instars with 200 ng/g AFB₁, several reached pupal weights as high as those on control diets in all three replicate experiments.

Concentrations of 1 µg/g AFB₁ in the diet significantly interfered with development; only about 5% of larvae reached fourth instar, and of these, none developed into fifth instars (Figs. 1e, f and 3c). After 13 d, the larval mortality rate was 44.3%, and after 3 wk, no larvae remained alive (Fig. 2b). At the highest concentration (20 µg/g), no larval development occurred, and mortality was 100% after 6 d of treatment (Figs. 1e, f and 2b).

Toxicity to Fifth Instars

Fifth instar *H. zea* display substantially greater tolerance to AFB₁ than do earlier stages. Administered to fifth instars, the lowest concentrations (20 and 200 ng/g) of AFB₁ delayed pupation only after five or more days of treatment (Fig. 3e) without affecting pupation rate ($P = 0.479$ and 0.499), pupal weight ($P = 0.454$ and 0.245), or mortality ($P = 0.479$ and 0.499 ; Figs. 2c and 3e, f). At concentrations ≥ 1 µg/g AFB₁, however, fifth instar growth and development were affected. At a concentration of 20 µg/g, AFB₁ effected 100% mortality after 10 d (Fig. 2c). Whereas most larvae (83.3%) on control diets had pupated after 5 d, less than one third of larvae on diets containing 1 µg/g AFB₁ had pupated over that time period ($P = 0.011$). In addition, pupal weights on diets containing 1 µg/g AFB₁ were reduced by 29.3% relative to control diets ($P < 0.001$).

Morphological examinations indicated that malformations of pupae occurred when fifth instars consumed diets with 1 µg/g AFB₁ (Fig. 4); in these cases, the pupal molt is arrested so that only the anterior portion of the pupa, from the maxillary region to the anterior abdominal segments, protrudes dorsally from the thoracic and anterior abdominal areas of the persistent larval cadaver. These deformed pupae failed to produce adult moths.

PBO and PB Effects

To determine the role of P450s in the activation and/or detoxification of AFB₁ in *H. zea*, bioassays were conducted by administering AFB₁ alone, AFB₁ in combination with PBO, a P450 inhibitor, or AFB₁ in combination with PB, an inducer of some P450 monooxygenases. As shown in Fig. 5a and b, exposure of fourth instars to 0.1% PBO significantly improved the pupation rates ($P < 0.001$) and pupal weights

Fig. 4 Pupae of *H. zea* without (control) and with aflatoxin B₁ (1 µg/g) in diet beginning at fifth instar

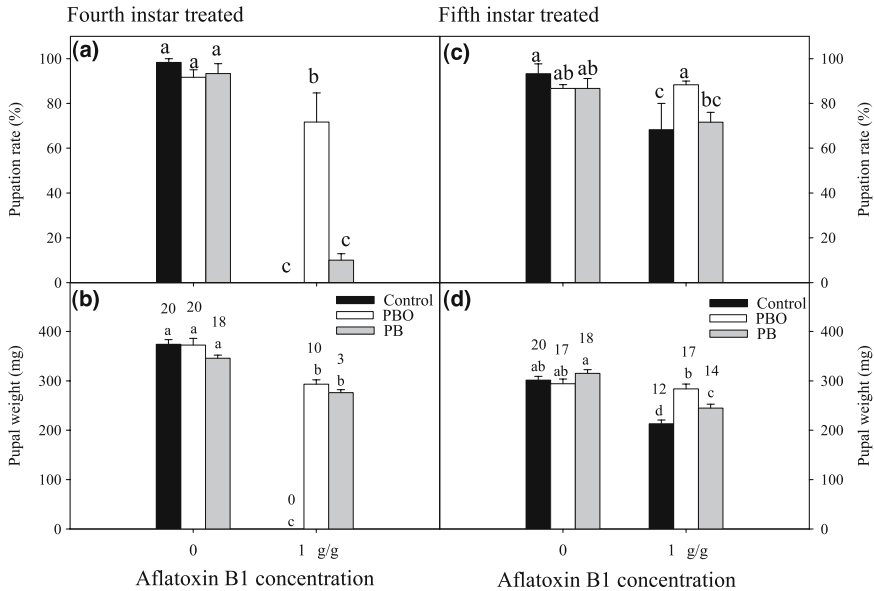

Fig. 5 Effects of piperonyl butoxide (PBO) and phenobarbital (PB) on pupation of *H. zea* exposed to aflatoxin B1 beginning at fourth instar (a, b) and at fifth instar (c, d). Values shown for pupation rate are means + standard error from three replicates with 20 caterpillars/treatment. Values for pupal weight are representative of one of the three series of replicates with the numbers of pupae weighed for this replicate shown above each bar. Significant differences ($P < 0.05$) among treatments are indicated by different letters above the bars

($P < 0.001$) of *H. zea* fed on diets containing 0.1% PBO and 1 $\mu\text{g/g}$ AFB1 compared to *H. zea* on diets containing AFB1 alone. Whereas no fourth instars on diets containing 1 $\mu\text{g/g}$ AFB1 succeeded in pupating, addition of PBO to the diet increased pupation rate of fourth instars to 71.7% ($P < 0.001$; Fig. 5a). In contrast, exposure of fourth instars to 0.1% PB resulted in a pupation rate of only 10% ($P = 0.256$). Pupal weights were not significantly changed by the addition of PB or PBO.

In contrast with fourth instars, which did not successfully pupate on diets containing 1 $\mu\text{g/g}$ AFB1, over 68% of fifth instars on this diet succeeded in pupating. Inclusion of PBO in the diet increased pupation success to 88.3% ($P = 0.044$); at the same time, PBO increased pupal weights to an average of 283.7 mg, compared with an average of 213.0 mg on control diets ($P < 0.001$). Pupation success and pupal weights in the presence of AFB1 and PBO were not significantly different from pupation success and pupal weight of larvae on control diets (Figs. 5c and d; $P = 0.55$ for pupation rate and $P = 0.14$ for pupal weight). In contrast with PBO, addition of PB did not affect pupation rate, although addition of PB to diets containing AFB1 increased pupal weight significantly.

Discussion

Just as insects may possess biochemical mechanisms that confer resistance to insecticides and plant allelochemicals, they may also possess mechanisms for circumventing the toxicity of mycotoxins such as aflatoxins. In one study, resistance

levels among species varied with the likelihood of ecological exposure to these compounds (Lee and Campbell, 2000). Resistance levels may even vary intraspecifically; differences in AFB1 sensitivity were found in wild-type strains of *D. melanogaster* (Llwellyn and Chinnici, 1978; Chinnici and Melone, 1985). The Crimea strain was extremely sensitive, with no adults produced at concentrations of 0.4 mg/l AFB1, whereas eclosion rates exceeded 50% in three other resistant strains in the presence of the same concentrations of AFB1 (Llwellyn and Chinnici, 1978).

Although *H. zea* has a remarkable capacity for metabolizing a broad diversity of plant allelochemicals, as befits its polyphagous diet (Li et al., 2004), its ability to tolerate the mycotoxin aflatoxin is limited, despite its decidedly frequent ecological exposure. Although AFB1 was not acutely toxic to *H. zea* at any stage of development, even at the highest concentration tested (20 µg/g), chronic exposure led to developmental delays, reductions in pupation rates and pupal weights, and higher mortality. The chronic effects of AFB1 ingestion varied depending on the stage of larval exposure, with first instars the most susceptible to AFB1 and fifth instars the most resistant. Exposure of first instars to low levels (1 ng/g) of AFB1 significantly affected development time and pupation rate, whereas pupation rates of third and fifth instars were affected only at concentrations of 200 ng/g and 1 µg/g of AFB1. Exposure of first instars to concentrations of 20 ng/g, representing the maximum levels permitted in grain (USDA, 1998), resulted in prolonged development and reduced pupation rates. Similar developmental effects have been documented in other insects; growth of *D. melanogaster* on AFB1-containing media caused significant protraction in egg-to-adult developmental time (Lalor et al., 1976). In contrast, exposure of fifth instars to substantially higher levels (200 ng/g) of AFB1 did not affect pupation rate, pupal weight, or mortality. Developmental abnormalities in the form of pupal deformities, however, were observed at these higher concentrations, preventing eclosion. AFB1 has previously been reported to cause developmental aberrations, including decreased wing length, in adult *D. melanogaster* (Lalor et al., 1976).

With respect to the mode of action of AFB1, PBO, an effective inhibitor of P450s in many different phyla, significantly decreases the toxicity of AFB1 to *H. zea*, a result consistent with bioactivation of aflatoxin to more toxic derivatives by one or more P450s expressed in fourth and fifth instars. Bioactivation of this sort has been documented for AFB1 in human P450s, with CYP3A4 the predominant protein bioactivating AFB1 to its highly toxic AFB1 *exo*-8,9-epoxide derivative (Ueng et al., 1995); CYP2A6 contributes to some extent in the bioactivation process (Crespi et al., 1990; Yun et al., 1991). In the mouse (*Mus musculus*), bioactivation of AFB1 is mediated by CYP2A5, which is closely related to human CYP2A6 (Pelkonen et al., 1994).

Our results also demonstrate that PB, which is capable of inducing some mammalian (Waxman, 1999), insect (Brun et al., 1996; Maitra et al., 1996; Dunkov et al., 1997; Stevens et al., 2000; Li et al., 2002a), and plant (Batard et al., 1998; Persans et al., 2001) P450s, has only a marginal ability to induce the P450(s) capable of bioactivating aflatoxin in fourth instars and some ability to induce P450s, possibly responsible for AFB1 detoxification, that allow larvae to survive and gain weight on diets containing aflatoxin. In humans, CYP3A4 and, to a lesser extent, CYP1A2 contribute to the transformation of AFB1 to less toxic hydroxylated AFM1 and AFQ1 derivatives (Ueng et al., 1995; Guengerich et al., 1998). Among candidate

P450s in *H. zea* that may be involved in these bioactivation processes are CYP6B8, which is induced by a range of plant allelochemicals and signaling compounds as well as PB (Li et al., 2000, 2002a,b), CYP6B9 and CYP6B27, which are induced by plant allelochemicals and signaling molecules (Li et al., 2002a,b), and CYP321A1, which at present is known to be induced only by xanthotoxin (Sasabe et al., 2004). Of these, CYP6B8 and CYP321A1 are both capable of metabolizing a wide range of toxic allelochemicals and insecticides (Li et al., 2004; Sasabe et al., 2004).

Bioactivation of aflatoxins by P450s has been demonstrated as a necessary step in bringing about most of their toxic effects in humans and other animals (Eaton et al., 1994). P450s in corn earworm appear to be involved in both bioactivation and detoxification of AFB1. In that these P450s are induced in response to exposure to plant allelochemicals, bioactivated mycotoxins such as aflatoxins, which co-occur with plant allelochemicals that are detoxified by P450s, present a distinct toxicological challenge to *H. zea*. In view of the fact that insect damage predisposes plants to fungal infection, and that mycotoxins other than aflatoxins depend on P450-mediated metabolism for their toxic effects (e.g., ochratoxin A, Obrecht-Pflumio et al., 1999), bioactivation may account at least in part for negative effects of phytopathogens on herbivorous insects documented in many plant–insect interactions (Hatcher, 1995).

Acknowledgments This research was supported by US Department of Agriculture Grant 01-35302-10884 to M.A.S. and M.R.B., by NIH1GM071826 to M.A.S., and by China Natural Science Foundation Grants (30270230, 30370246), the National 973 project of China (2006CB100200), Program for New Century Excellent Talents in University in China, and Guangdong Natural Science Foundation (039254, 04105977) to R.S.Z. We thank Dr. Arthur Zangerl for technical assistance, Allen Lawrance for help with insect rearing, and Terry Harrison for describing the pupal deformities.

Abstract Allelopathy has been implicated as a factor contributing toward failure of black spruce (*Picea mariana*) regeneration in *Kalmia angustifolia*-dominated sites in eastern Canada. Several phenolic acids of *Kalmia* origin inhibit primary root growth of black spruce. We tested the hypothesis that some well-adapted conifer ectomycorrhizae can degrade and detoxify water-soluble phenolic compounds produced by *Kalmia* and use the degraded products as a carbon source to stimulate growth. We found that hyphal growth of *Paxillus involutus*, a common ectomycorrhizal fungus of black spruce, was stimulated by water leachates of *Kalmia* leaf and litter. An equimolar mixture of three phenolic acids (ferulic, *o*-coumaric, and *o*-hydroxyphenylacetic acid), commonly found in *Kalmia*, had no negative effects on fungal growth at 1 mM concentration. The *o*-hydroxyphenylacetic (*o*-HPA) acid, which is known to be toxic to black spruce, was found to stimulate the growth of *Laccaria laccata*, *L. bicolor*, and *P. involutus* (isolates 211804 and 196554) by 38.4, 29.3, 25.0, and 18.9%, respectively, at 1 mM. Pure ferulic, *o*-coumaric, and *o*-HPA acids were degraded by 100, 98, and 79.5%, respectively, within 10 d in the presence of *P. involutus* 211804. However, *L. laccata* could not tolerate high concentrations of the *Kalmia* leachates. *P. involutus* and *L. bicolor* used *o*-HPA acid as a carbon source when cultured in noncarbon nutrient medium. The 0.5 and 0.2 mM *o*-HPA acid inhibited the root growth of black spruce. However, after solutions had been exposed to a culture of *P. involutus*, they had no significant effect on seedling growth of black spruce. We concluded that some ectomycorrhizal fungi, such as *P. involutus* and *L. bicolor*, are able to degrade *Kalmia* phenolics. Our findings point to

a mechanism by which ectomycorrhizal species can control species interactions in higher plants by changing the rhizosphere chemistry.

Keywords Ectomycorrhizal fungi · Phenolic compounds · Detoxification · *Picea mariana* · *Kalmia angustifolia*

Introduction

Naturally regenerating and planted conifers in nutrient-poor boreal forests of eastern Canada often suffer from growth inhibition due to ericaceous understory shrubs (Mallik, 1987, 2001; Mallik and Newton, 1988; Thiffault et al., 2004). Following clear cutting and fire, sheep laurel (*Kalmia angustifolia* L. var. *angustifolia*, hereafter referred to as *Kalmia*), a common ericaceous understory plant in eastern Canada, can seriously hinder conifer regeneration, especially black spruce [*Picea mariana* (Mill.)]. One cause has been attributed to allelopathic effects of *Kalmia* phenolics (Mallik, 1987; Thompson and Mallik, 1989; Zhu and Mallik, 1994). Phenolic acids are released into the soil as leaf and litter leachates, root exudates, or as decaying plant residues (Siqueira et al., 1991; Gallet and Pellissier, 1997). Several are reported to act as signal molecules, and some may influence signal transduction pathways in symbiotic systems (Lynn and Chang, 1990). Fries et al. (1997) reported that certain phenolic acids stimulate arbuscular mycorrhizal (AM) colonization, which may promote growth of host plants. The mechanism of conifer growth inhibition in the presence of ericaceous plants is complex and the role of *Kalmia* phenolics in black spruce growth inhibition is unclear (Wallstedt et al., 2002).

Reduced ectomycorrhizal (ECM) colonization of Norway spruce [*Picea abies* (L.) Karst] by *Cenococcum graniforme*, *L. laccata* (Pellissier 1993), and *Hebeloma crustuliniforme* (Souto et al., 2000) in the presence of *Vaccinium myrtillus* L. (hereafter referred to as *Vaccinium*) has been suggested as a cause of its regeneration failure in subalpine forests in Europe. Handley (1963) found few mycorrhizal fungi associated with Norway spruce root systems when grown in the presence of heather (*Calluna vulgaris* L.). Yamasaki et al. (1998) reported significantly lower stem height, root–shoot biomass, and reduced mycorrhization of black spruce grown near (<1 m) *Kalmia* than those grown away (>1 m) from *Kalmia* under field conditions. *Kalmia* leaf leachates have been found to be inhibitory to mycorrhizal formation and mycelial growth of some ectomycorrhizal fungi of black spruce (Mallik et al., 1998).

Ectomycorrhizal fungi often experience chemical stress from forest floor phenolics (Bending and Read, 1997). The role of phenolic acids in ectomycorrhizal associations is not well understood. Black spruce–*Kalmia* forests of eastern Canada and Norway spruce–*Vaccinium* forest of subalpine France and Fennoscandia produce large amounts of litter on the forest floor (Inderjit and Mallik, 1999; Berg and Dise, 2004). Ericaceous plants, such as *Kalmia* and *Vaccinium*, produce large amounts of phenolic acids, which may accumulate on the forest floor through leaching from leaves (Zhu and Mallik, 1994), litter, humus (Pellissier 1994), and possibly root exudates. Many of these phenolic acids inhibit primary root growth in black spruce (Zhu and Mallik, 1994), seed germination and seedling growth in

Norway spruce, and mycorrhizal fungal growth (Pellissier 1993). Several authors have reported inhibitory effects of ericaceous litter on growth and respiration of spruce mycorrhiza (Boufalis et al., 1994; Boufalis and Pellissier, 1994). Souto et al. (2000) showed that humus phenolics of *Vaccinium* were more toxic to the spruce mycorrhizal fungus, *H. crustuliniforme*, than to the ericoid (*Vaccinium*) mycorrhizal fungus, *Hymenoscyphus ericae*.

In ectomycorrhizal symbioses, plant roots and fungi function together as a unit. Formation of ECMs in plants often allows them to establish in habitats that neither symbiont may be able to occupy individually (Nehls et al., 2000). Ectomycorrhizae are able to alleviate toxic effects of heavy metal cations in host plants (Denny and Wilkin, 1987; Colpaert and Van Assche, 1993). They may have additional or related mechanisms to deal with phenolic allelochemicals on the forest floor. From a controlled experiment, Mallik et al. (1998) showed that the growth inhibitory effects of *Kalmia* leachate on black spruce could be overcome by inoculating black spruce with selected mycorrhizal fungi. Because mycorrhizal fungi are located at the interface between the soil-allelochemical reservoir and roots of the host plants, we hypothesized that if certain spruce ECM fungi can degrade *Kalmia* phenolics, and use the degraded product(s) as a carbon source, then these ectomycorrhizal fungi would be able to protect black spruce against *Kalmia* phenolics and enhance their growth.

The objectives of our study were (1) to identify certain ECM fungi that can withstand the toxicity of *Kalmia* leaf, litter, and humus leachates and their associated phenolic compounds, and (2) to test whether these ECM fungi can degrade and detoxify the phenolic acids of *Kalmia*.

Methods and Materials

Plant and Ectomycorrhizal Fungal Materials

Black spruce seeds were obtained from Hills Nursery, Thunder Bay, Canada. *P. involutus* (Batsch. Ex Fr.) Fr. 211804, 196554, and *L. laccata* (Scop.:Fr.) Cooke 211651 were obtained from the Canadian Collection of Fungal Cultures, Ottawa. *Pisolithus tinctorius* Coker and Couch 99132 was obtained from Prof. Mingqin Gong at the Research Institute of Tropical Forestry in Guangzhou, Forestry Academy of China. *Laccaria bicolor* (Maire) P.D. Orton 229559 was collected from Thunder Bay. *P. tinctorius* 99132 was used to compare responses of ECM fungi from ericaceous-dominated and nonericaceous-dominated areas.

Chemicals

Ferulic, *o*-coumaric, and *o*-hydroxyphenylacetic (*o*-HPA) acids were purchased from Sigma (St. Louis, MO, USA). Malt extract and granulated agar were bought from Becton Dickinson Co. All solvents used were analytical or HPLC grade.

Seed Surface Sterilization

Black spruce seeds were surface-sterilized with 1% NaClO₃ for 10 min and then rinsed with sterile water × 5 to remove surface borne pathogens. Sterilized seeds were dried with autoclaved filter paper and kept at 4°C for subsequent use.

ECM Fungal Cultures

Modified Melin–Norkrans' nutrient solution (MMN) was used for growing the ectomycorrhizal fungi (Marx, 1969). Petri dishes containing the MMN, *Kalmia* leachates, and phenolic acids were inoculated with 4-mm-diam agar plugs cut from the edge of 2-wk-old ectomycorrhizal fungal colonies. The inoculated plates were incubated at room temperature (20–25°C). Diameters of the fungal colonies were measured every 5 d. All experiments consisted of at least three replicates.

Kalmia Leachates

Kalmia fresh leaves (mature, 1-yr-old), litter (dry leaves on the ground), and humus (0–10 cm) were collected from 10 random locations in a *Kalmia*-dominated heath originating from a natural fire 25 yr ago near the village of Terra Nova just outside the boundary of Terra Nova National Park, Newfoundland. Composite samples of fresh leaves, litter, and humus were made by mixing the 10 samples. Coarse roots and branches were removed from the humus samples prior to mixing. Twenty g of fresh leaves and litter were soaked separately in 100-ml distilled water for 24 hr at room temperature (20–25°C). The concentrations obtained for leaf and litter leachates were 0.2 g FW equivalent of leaves or litter per ml of leachate. *Kalmia* humus leachate was obtained by draining 200 ml distilled water at a slow rate for 24 hr through 100 g fresh humus in a glass chromatography column (30 mm) at room temperature. The filtrate of humus leachate was adjusted to 100 ml, and its concentration was 1 g FW equivalent of humus per ml of leachate. The water leachates of leaves, litter, and humus were passed through Whatman No. 42 filter paper and then sterilized by passing through two layers of 0.45- μ m Millipore filters.

Experiment 1: Effects of *Kalmia* Water Leachates on ECM Fungi

We measured the growth responses of two fungal isolates, *P. involutus* 211804 and *L. laccata* 211651, to three concentrations of leaf and litter leachates and two concentrations of humus leachate. The 0.1 g FW/ml leachate was prepared by adding 50 ml original leachate (0.2 g FW/ml) into 50 ml autoclaved MMN medium containing 1.5 g agar at 50–60°C. The 0.05 g FW/ml leachate was prepared by adding 25 ml original leachate and 25 ml sterilized water into 50 ml autoclaved MMN agar medium. The 0.01 g FW/ml leachate was prepared by adding 5 ml original leachate and 45 ml sterilized water into 50 ml autoclaved MMN medium. Concentrations of 0.25 and 0.05 g FW/ml of humus leachate were used. The original leachates of humus (25 ml, 1 g FW/ml) and 25 ml sterilized water were mixed with 50 ml autoclaved MMN medium containing 1.5 g agar at 50–60°C to obtain 0.25 FW/ml of humus leachate. The 0.05 g FW/ml humus leachate was prepared by adding 5 ml original leachate and 45 ml sterilized water into 50 ml autoclaved MMN agar medium. The control was made from half-strength MMN medium. The medium was poured into 9-cm-diam Petri dishes (20 ml medium in each dish). A disk of inoculum (diam 4 mm) from each of the five ECM fungi was cut from the edge of a 2- to 3-wk-old colony and inoculated in a Petri dish. After they were cultured for 28 d at 20–25°C, diameters of the fungal colonies were measured.

Experiment 2: Effect of Pure Phenolics on ECM Fungi

o-HPA, ferulic, and *o*-coumaric acids were the major phenolic acids in *Kalmia* leaf leachates (Zhu and Mallik, 1994) and humus (Mallik, unpublished data). Therefore, we measured the responses of five ECM fungal isolates, *P. involutus* (211804, 196554), *L. laccata* 211651, *P. tinctorius* 99132, and *L. bicolor* 229559 to these compounds. *o*-HPA acid was directly dissolved in sterile water to obtain a 2-mM solution. Ferulic and *o*-coumaric acids were dissolved in sterile hot water (80°C). Phenolic solutions were sterilized by passing through two layers of 0.45- μ m Millipore filters. Equivalent volumes of a 2-mM phenolic solution and a double concentration MMN agar were mixed to obtain a medium with 1 mM phenolic acid and full-strength MMN. The equimolar mixture of the three phenolic acids was obtained by mixing equivalent volumes of their respective 1 mM media for a final concentration of 0.33 mM for each acid. The control consisted of only MMN medium. Petri dishes containing the above-mentioned media were inoculated with the ectomycorrhizal fungi employed in Experiment 1, with four replicates for each treatment. The inoculated plates were incubated at 20–25°C and the diameters of the fungal colonies measured after 20 d.

Experiment 3: Phenolic Acids as Carbon Source for ECM Fungi

In this experiment, we investigated whether *P. involutus* 211804 and *L. bicolor* 229559 could grow with *o*-HPA acid as the only source of carbon. To prepare fungal inocula, *P. involutus* 211804 and *L. bicolor* were cultured on MMN agar for 16–20 d. Mycelial disks (diam 10 mm) were cut from the edges of fungal colonies and transferred to dishes containing water agar. Large-diameter inocula (10 mm as opposed to standard 4 mm) were used to provide nutrition for fungal growth. Water agar was used to exclude the possible nutrient effect of inoculated plugs on noncarbon nutrient experiment. These fungi were cultured in water agar for 22 d. After 22 d, a plug of inoculum (diam 4 mm) cut from the colony edge on water agar was inoculated on the noncarbon MMN medium (MMN agar medium without sucrose and malt extracts) without *o*-HPA acid (control) and noncarbon MMN medium with 1 mM *o*-HPA acid. There were four dishes for each fungus and treatment combination. The experiment was conducted at room temperature (20–25°C). Diameters of the fungal colonies were measured after 25 d.

Biomass Assay in Liquid Media

Because mycelial biomass in the noncarbon medium was very small, half strength of MMN liquid medium was used to culture *P. involutus* 211804 and *L. bicolor*. Each Petri dish (9 cm) contained 12 ml liquid medium with or without 1 mM *o*-HPA acid, prepared as described above. There were 10 dishes for each treatment. After autoclaving, a U-shaped glass rod (diam 2 mm) wrapped with a piece of 4 \times 4 cm unbleached paper towel was added to each dish and was inoculated with two plugs (diam 4 mm) of *P. involutus* 211804 inocula on the surface of the unbleached paper. The glass rod and unbleached paper towel facilitated the culturing of the ECM fungi in liquid media and subsequent collection of mycelia. Five ml of sterile water were added after 15 d. After 30 d culture, the mycelia were harvested from the unbleached paper. Ten dishes were divided into five groups, and mycelia from two dishes were combined, dried at 60°C for 24 hr, and weighed to ± 0.1 mg.

Experiment 4: Phenolic Reduction by ECM Fungi in Pure Culture

We tested whether *P. involutus* 211804 could metabolize phenolics. *P. involutus* 211804 was cultured on MMN agar medium. The Petri dish was inoculated at the center with one piece of 4 mm mycelial plug. Cultures were maintained at 20–23°C for 20 d. Then two U-shaped glass rods (diam 2 mm) were placed on the surface of the medium. Acetone solutions of the phenolic compounds (10 mM, 200 µl) were spotted on a piece of Whatman No. 3 filter paper (diam 12 mm). When the acetone had completely evaporated, 200 µl sterile water were added to the filter paper. Filter papers were placed over each rod. Each treatment consisted of three replicates. The filter papers were taken out 10 d later and they were soaked in 5 ml methanol for 24 hr. The methanol extracts were concentrated to 2.5 ml at 40°C under reduced pressure and passed through Whatman No. 1 filter paper. Phenolic compounds in the filtrates were analyzed by using a Varian Prostar HPLC equipped with a Chrompak column (250 × 4.6 mm) and PDA detector (Model 330) monitoring the absorbance of the elution at 280 nm. The solvent system was as follows: 0–9 min, 10% methanol and 90% water containing 2.5% formic acid; 9–20 min, 40% methanol and 60% water containing 2.5% formic acid; 20–25 min, 60% methanol and 40% water containing 2.5% formic acid; 25 min, 100% methanol. Flow rate was 1.5 ml/min, and temperature was 32°C. Pure compounds were used as standards, and phenolic acids were identified by comparison of retention times and UV spectrum.

Experiment 5: Detoxification Bioassay

We investigated whether inoculation of spruce seedlings with ECM fungus reduced the phytotoxicity of *o*-HPA acid. Because *o*-HPA acid was the most toxic phenolic acid in *Kalmia* leaf leachates affecting black spruce seedlings (Zhu and Mallik, 1994), it was used to conduct further detoxification studies. Since full-strength MMN medium itself inhibits seedling growth of black spruce, all media used were half-strength MMN. *P. involutus* 211804 was cultured in MMN liquid medium (half strength) containing 0.2 and 0.5 mM *o*-HPA acid. Each Petri dish (10 cm) contained 15 ml liquid medium. *P. involutus* 211804 was inoculated and cultured as described in Experiment 4. Noninoculated culture was used as the control. Plates were incubated at room temperature (20–23°C). Five ml sterile water were added after 15 d. The culture solution was decanted from the dishes after 30 d and passed through Whatman No. 42 filter paper. Filtrates were adjusted with sterile water to initial volume and used for the phytotoxicity test with black spruce seedlings. Each dish contained 20 surface-sterilized black spruce seeds placed on a piece of Whatman 3 filter paper to which 5 ml culture solution were added. The half-strength MMN medium was used as negative control, and half-strength MMN medium with 0.2 and 0.5 mM *o*-HPA acid were used as positive controls. The bioassay was conducted at 20–25°C with a 16-hr photoperiod. Two ml sterile water were added to each Petri dish during incubation. The lengths of black spruce primary root and shoot were measured after 15 d.

Experiment 6: Phenolic Degradation by Inoculated Black Spruce

Black spruce seedlings were inoculated with *P. involutus* 211804 following the method described by Marx and Kenney (1982) with some modifications to

determine whether the ECM inoculated seedlings are able to degrade *o*-coumaric, ferulic, and *o*-HPA acids and enhance the root–shoot growth of black spruce.

ECM Inoculum Preparation

Vermiculite (approximately 600 ml) and MMN liquid medium (300 ml) were added to 1-l glass jars. The jar lids had holes tightly plugged with cotton. After autoclaving for 30 min, each jar was inoculated with 10 mycelial disks. After 45 d incubation, the inoculum was wrapped with four layers of cheesecloth and irrigated with tap water for 5 min to remove any remaining nutrient. This material was used for black spruce seedling inoculation for the following experiment.

Seedling Inoculation

Autoclaved (121°C for 30 min) vermiculite and peat/moss mixture (1:1) was added to multipots (120 ml/cell) for seedling culture. Pregerminated black spruce seedlings (5 d) developed from surface-sterilized seeds were sown in multipots and kept in a growth incubator maintained at 26°C with a 16-hr photoperiod, 150 Md/m²/s PAR and 60% relative humidity. Seedlings were watered daily and fertilized once a week with 20–20–20 NPK. After 60 d incubation, the seedlings were removed to new, larger multipots (250 ml/cell) that were filled with the mycorrhizal fungal inocula and vermiculite/peat moss mixture at the ratio 1:15. Each cell contained one seedling. Inoculated seedlings were grown in the same incubator and under the same environmental conditions as in the other experiments. The roots of inoculated seedlings were surrounded by dense mycelia after 135 d inoculation. Noninoculated (control) seedlings were prepared and grown in the same manner without inoculation. No mycorrhizal infection was found in control seedlings. At this point, 30 ml of 1 mM phenolic acid solution were added to each cell. There were six seedlings per treatment. Five d later, the growing media (peat/vermiculite mixture) of seedlings were extracted with 300 ml distilled water × 3. The water extracts were pooled and partitioned against hexane × 3 to remove lipids, then extracted with ethylacetate × 3. Ethylacetate extracts were combined and concentrated to dry form at 40°C under reduced pressure, and then dissolved with 5 ml methanol/ethyl acetate (4:1). The phenolic acids were analyzed with HPLC.

Statistical Analysis

All data were normally distributed. One-way analysis of variance (ANOVA) was used, and treatment differences among means were tested at $P = 0.01$ with Duncan's multiple range test.

Results

Experiment 1: ECM Fungal Response to *Kalmia* Leachates

Growth response of the ECM fungi to *Kalmia* leachates depended on the type of leachate (leaf, litter, or humus), its concentration, and the species of ECM fungus. Higher concentrations of leaf leachates and lower concentrations of litter leachates

had stimulatory effects on *P. involutus*. The 0.1 and 0.05 g FW/ml leaf leachates significantly stimulated the growth of *P. involutus* by increasing the colony diameter of the fungus by 101.0 and 60.1%, respectively (Table 1). However, these two concentrations inhibited *L. laccata*, whose colony diameters were 12.6 and 11.4% smaller with 0.1 and 0.05 g FW/ml leaf leachates, respectively, relative to controls. The 0.1 g FW/ml litter leachate had no effect on colony diameter of *P. involutus*. However, the 0.05 and 0.01 g FW/ml litter leachates stimulated colony diameter by 72.6 and 49.0%, respectively. The 0.1 and 0.05 g FW/ml litter leachate had little effect on colony diameter of *L. laccata*, but with 0.01 g FW/ml litter leachate, there was a increase of 8% compared to control. The 0.25 and 0.05 g FW/ml humus leachate had no effects on colony diameter of either *P. involutus* or *L. laccata* (Table 1).

Experiment 2: ECM Response to Pure Phenolic Acids

The response of fungal isolates to pure phenolic acids also differed depending on the type of phenolic acid and its concentration. *P. involutus* 211804 was the most tolerant fungal isolate to the three phenolic acids and their equimolar mixture (Fig. 1). Indeed, the colony diameter of this isolate was increased by 25% in the presence of 1.0 mM *o*-HPA acid, and the mixture of the three phenolic acids did not inhibit growth at either concentration. However, *P. involutus* 211804 was inhibited by ferulic acid at 1 mM. Both the 1.0 and 0.1 mM phenolic mixtures inhibited colony diameter of *P. involutus* 199554 and *L. laccata* 211651. Colony diameter of *L. bicolor* 229559 was reduced by 41.7% on a 1 mM phenolic mixture, but it was increased (by 17.8%) in the presence of the 0.1 mM mixture. Colony diameter of both *L. bicolor* and *L. laccata* was increased by 1.0 mM *o*-HPA acid. Colony diameter of *L. laccata* was also increased by 0.1 mM *o*-HPA acid. *P. tinctorius* was the most sensitive of the fungal isolates to the phenolic mixture at 1.0 mM, and its colony diameter was inhibited by 80.5% on the 1.0 mM mixture.

With respect to the effect of individual phenolic compounds on the mycorrhizal fungi, ferulic acid was the most toxic, strongly inhibiting growth of all tested ECM fungi at 1 mM. The decrease in colony diameter of *P. involutus* 211804, 199554, and

Values are mean \pm standard error ($N = 4$). Significant differences ($P < 0.01$) among treatments in each group are indicated by different letters

P. tinctorius was 95.0, 72.5, and 92.5%, respectively (Fig. 1). The compound also inhibited growth of *P. involutus* 199554 and *P. tinctorius* 99132 at 0.1 mM, but it stimulated the growth of *L. laccata* at this concentration. The *o*-HPA acid stimulated the colony diameter of *L. laccata*, *L. bicolor*, and the two isolates of *P. involutus* by 38.4, 29.3, 25.0, and 18.9%, respectively, at 1.0 mM; it also stimu-

Fig. 2 Effects of 1 mM *o*-hydroxyphenylacetic acid on (a) colony diameter and (b) mycelial dry biomass of *P. involutus* 211804 and *L. bicolor* 229559 in carbon-free liquid MMN medium. lated the colony growth of *P. involutus* 199554 and *L. laccata* at 0.1 mM. It did not stimulate colony growth of *P. tinctorius*. Coumaric acid inhibited the colony growth of ECM fungi except *P. involutus* 211804 at 1 mM. At 0.1 mM, coumaric acid did not inhibit any fungus, and stimulated the growth of *P. involutus* 199554 (Fig. 1).

Experiment 3: Phenolic Acids as Carbon Source for ECM Fungi

When *P. involutus* 211804 was cultured on noncarbon MMN agar medium, its colony diameter increased by 41.7% in the presence of 1 mM *o*-HPA acid (Fig. 2a). The hyphal density of the fungus in the medium with *o*-HPA acid was much higher than that of the control. Control plates had little mycelia. *L. bicolor* did not grow at all on the noncarbon MMN medium, but did in the presence of 1 mM *o*-HPA acid. *L. laccata* did not grow either on control or *o*-HPA acid medium.

The mycelial biomass of *P. involutus* 211804 and *L. bicolor* was increased by 20.1 and 33.9%, respectively when the two fungi were cultured separately in MMN liquid medium containing 1 mM *o*-HPA acid (Fig. 2b).

Experiment 4: Phenolic Degradation by ECM Fungus in Pure Culture

The concentrations of all three phenolic compounds, ferulic, coumaric, and *o*-HPA acids were reduced in the presence of *P. involutus* 211804 in pure culture. While the recovery of coumaric and *o*-HPA acids was reduced by 97.9 and 79.5%, respectively, we could not detect any ferulic acid following exposure to the fungal culture on the medium (Fig. 3).

Fig. 3 Concentrations of *o*-coumaric, *o*-hydroxyphenylacetic, and ferulic acids in filter paper extract without (control) or with *P. involutus* 211804 culture. Values are mean \pm standard error ($N = 4$). Significant differences ($P < 0.01$) among treatments in each group are indicated by different letters above bars

Values are mean \pm standard error ($N = 3$). Significant differences ($P < 0.01$) among treatments in each group are indicated by different letters above bars

Experiment 5: Detoxification of *o*-HPA acid by ECM Fungi

Root growth of black spruce seedlings was inhibited by 82.0 and 63.9%, respectively, in the presence of *o*-HPA acid at 0.5 and 0.2 mM (Fig. 4a). However, no significant effect of *o*-HPA acid on root and shoot length was found when seedlings were grown with *P. involutus* 211804 culture broths (Fig. 4a,b).

Experiment 6: Phenolic Degradation by Inoculated Black Spruce

The concentrations of phenolic acids in peat/vermiculite mixture with mycorrhiza inoculated black spruce were much lower than those containing noninoculated black spruce (Fig. 5). Five d after adding *o*-HPA acid to the growing medium containing the ECM inoculated black spruce, less than 3% of the compound was recovered. Similarly, the recovery of *o*-coumaric acid and ferulic acid was only 13.3 and 10.4%, respectively, in the peat–vermiculite mixture that had *P. involutus* 211804-inoculated black spruce.

Discussion

Our results show that the different ECM fungal isolates had differential growth response to *Kalmia* leachates and phenolic compounds. *L. laccata* was less resistant than *P. involutus*. The growth of *P. involutus* 211804 was significantly stimulated by leaf and litter leachates even in the presence of full-strength leaf leachate (0.1 g FW/ml). This growth enhancement may be caused either by additional nutrients in the leaf and litter leachate and/or the degradation products of *Kalmia* phenolics in the

leachate that the ECM fungi can use as a carbon source. Earlier, Mallik and Zhu (1995) reported that growth of one isolate of *P. involutus* (NF4) was stimulated in the presence of *Kalmia* leaf leachate. Coté and Thibault (1988) found an isolate of *P. involutus* (0077) to be more sensitive to leaf leachate toxicity of raspberry (*Rubus idaeus*) compared to other ECM fungi. In this study, water leachate of *Kalmia* humus showed no significant effect on colony diameter of *P. involutus* and *L. laccata*. Phenolic profiles of leaf and litter leachates were different from that of humus. It is possible that by the time leaf and litter were decomposed into humus, many of the influential alleochemicals were degraded by microorganisms. It is also possible that degradation and use of humus phenolics is more difficult for ECM fungi than those of leaf and litter.

Because different isolates of the same species of ECM fungus responded differently to a particular phenolic acid, our results suggest that coadaptation may influence ECM fungal tolerances to phenolics. *P. tinctorius* was the most sensitive fungus to the phenolic mixture; its colony diameter was inhibited by 80.5% in the presence of 1.0 mM mixture. This isolate was collected from the subtropical region of Guangdong, South China, whereas the other four fungal isolates were collected from boreal forests of Canada. In South China, we know of no report of high concentrations of phenolic acids in soils, presumably because of high precipitation, high litter quality, rapid decomposition, and little organic matter accumulation. Therefore, this isolate may not have mechanisms to deal with high concentrations of phenolic compounds, whereas the fungi collected from Canada may possess this adaptation (Callaway and Ridenour, 2004; Vivanco et al., 2004).

In the noncarbon growing medium, both *P. involutus* and *L. bicolor* grew significantly better with respect to colony diameter and mycelial biomass in the presence of *o*-HPA acid than those without the phenolic acid (Fig. 2). Since *o*-HPA acid was the only carbon source in the medium, we conclude that the fungus must have used *o*-HPA acid as a carbon source to increase its biomass. Our phenol reduction experiment (Experiment 4) conducted with three pure phenolic acids confirmed the idea that *P. involutus* is able to reduce or oxidize phenolic acids quite easily within a short time (Fig. 3). However, high concentration (1 mM in the media) of ferulic acid inhibits the growth of *P. involutus* (Fig. 1b).

After *P. involutus* 211804 was cultured in 0.5 and 0.2 mM *o*-HPA, its phytotoxicity disappeared (Fig. 4). *o*-HPA acid, at 0.2 mM, was toxic to black spruce seedlings in the absence of *P. involutus*, but the 0.5 mM *o*-HPA acid solution became nontoxic in the presence of the fungal culture. From this result, we conclude that the concentration of 0.5 mM *o*-HPA acid was reduced to less than 0.2 mM, as a result of fungal culture. In other words, *P. involutus* detoxified the 0.5 mM *o*-HPA acid to a level lower than 0.2 mM, and allowed the seedlings to grow. Zhu and Mallik (1994) have shown that black spruce seedlings can grow in the presence of ferulic and coumaric acids but cannot tolerate high concentrations of *o*-HPA acid. From this study, we suggest that the symbiotic ECM fungi of black spruce can not only tolerate high concentrations of *o*-HPA, but can also degrade the compound and use it as a carbon source.

Most of the added phenolic acids in the peat/vermiculite mixture containing *P. involutus* inoculated black spruce disappeared within 5 d, whereas substantial amounts of the added acids were recovered from the growing medium of the noninoculated (control) seedlings. We suggest that the *P. involutus*-inoculated

seedlings are able to degrade *Kalmia* phenolics in the potting medium. However, the incomplete recovery of *o*-coumaric and ferulic acid in the uninoculated (control) medium suggests that preinoculation of black spruce seedlings with suitable ectomycorrhizal fungi may promote conifer regeneration in *Kalmia* dominated sites.

The problem of *Kalmia*-induced growth inhibition in black spruce is complex and the relationship between *Kalmia* phenolics and mycorrhizae is still unclear (Wallstedt et al., 2002). From a field study that showed poor growth, foliar N and P concentrations and mycorrhization of black spruce seedlings growing closer to *Kalmia* than those growing away, Yamasaki et al. (1998) concluded that *Kalmia* limits the growth of black spruce in ways other than direct nutrient competition. They suggested that since mycorrhizae and plant nutrition are closely related, fewer mycorrhizal short roots in black spruce growing near *Kalmia* means less nutrient acquisition due to poor mycorrhizal symbiosis, thus resulting into poorer growth in these seedlings. Another cause of poor growth was attributed to the susceptibility of black spruce near *Kalmia* to a potential pathogenic fungus, *Phialocephala dimorphospora*. Yamasaki et al. (1998) suspect that higher amount of mycorrhizal short roots in seedlings growing away from *Kalmia* may have protected them from the pathogenic fungus and consequently allowed better growth. One could also suspect long-term dominance of *Kalmia* in the absence of an appropriate host (in this case, black spruce) that the beneficial ECM would be reduced in soil inoculum. Our previous laboratory studies have shown that out of 51 fungal isolates tested, the growth of 41 isolates was reduced in the presence of *Kalmia* leaf leachate in liquid MMN agar. Yamasaki et al. (1998) suspect that *Kalmia* compounds could affect the survival of fungal inoculum in soil or the fungal symbionts in black spruce roots. Robinson (1972) proposed a similar hypothesis in explaining the growth inhibition of Sitka spruce [*Picea sitchensis* (Bong.) Carriere] seedlings in the presence of another heath-forming ericaceous shrub, *C. vulgaris*. Response of ECM to ericaceous compounds can be negative, positive, or neutral depending on the species and strains of the ECM (Mallik and Zhu, 1995). In this study, we found that certain black spruce ECM (particularly *P. involutus*) can respond positively to *Kalmia* phenolics with increased biomass. This, in turn, enhances seedling growth under laboratory and greenhouse conditions. Given the fact that biophysical conditions in the field can be very different from those in the controlled laboratory and greenhouse, the logical next step of this research is to test if black spruce seedlings preinoculated with *P. involutus* out planted in *Kalmia* dominated sites can overcome the growth inhibition by maintaining the symbiotic relationship.

We can draw several conclusions from this study. First, our results prove that certain ECM fungi can not only offer protection to host plants against phenolic allelochemicals released from neighboring plants, but they can also use them as a carbon source. This, in turn, can benefit the host plant. Our findings have important ecological significance in the sense that they point to a mechanism by which ectomycorrhizal fungal species can control species interactions in higher plants by changing the rhizosphere chemistry. Second, the ability of ECM fungi to degrade and detoxify phenolic allelochemicals is not only species-specific, but also specific to different strains of the same fungal species. Third, tree seedlings preinoculated with beneficial ECM fungi can degrade plant phenolics in peat/vermiculite mixture. This offers some hope toward overcoming phenolic-induced conifer growth inhibition in

ericaceous-dominated sites by outplanting tree seedlings preinoculated with carefully selected beneficial ECM fungi.

Abstract Numerous opisthobranchs are known to sequester chemical defenses from their prey and use them for their own defense. Information on feeding biology is critical for understanding the ecology and evolution of molluscs, yet information on feeding biology is still scarce for many groups. Gastropterid molluscs are often found on sponges, but there is controversy as to whether they are true sponge feeders. On Guam, we found the gastropterids *Sagaminopteron nigropunctatum* and *S. psychedelicum* on the sponge *Dysidea granulosa*. They seem to rely on contrasting defense strategies as *S. psychedelicum* has vivid colors, consistent with the warning coloration found in many chemically defended opisthobranchs, whereas *S. nigropunctatum* is highly cryptic on the sponge. *S. nigropunctatum* is avoided by the pufferfish *Canthigaster solandri* in aquarium assays. We analyzed the secondary metabolites of the two species and found that both share polybrominated diphenyl ethers (BDEs) with their host sponge *D. granulosa*. *S. psychedelicum* and *S. nigropunctatum* sequester the major BDE in the sponge and accumulate it in the mantle at approximately the same concentration as in the sponge (4.03 and 2.37%, respectively), and concentrate it in their parapodia at over twice the sponge concentration (7.97 and 10.10%, respectively). We also detected trace amounts in the mucus secretion of *S. psychedelicum*, and quantified significant amounts in the mucus (1.84%) and egg masses (2.22%) of *S. nigropunctatum*. Despite contrasting color patterns displayed by the two gastropterid species, they seem to share a similar

Introduction

Feeding biology plays a major role in the ecology and evolution of molluscs, particularly opisthobranchs (Kohn, 1983; Willan, 1984; Avila, 1995; Johnson and Willows, 1999). Many traits that drive the evolution of opisthobranchs, such as shell reduction or loss, have resulted from coevolution with diet organisms (Faulkner and Ghiselin, 1983; Cimino and Ghiselin, 1998, 1999; Cimino et al., 1999, 2001). Without shells, many opisthobranchs rely on other defense mechanisms. Camouflage or cryptic coloration is the most common strategy, with examples in a variety of organisms including opisthobranch mollusk. Since organisms must resemble their backgrounds (Endler, 1978), appropriate coloration is background-specific. Many opisthobranch molluscs are specialist predators, and cryptic species show evidence of a close association with their diets (Rudman, 1981; Morrow et al., 1992; Becerro et al., 2001, 2003). Aposematic or warning coloration is at the opposite extreme, and evolutionary theory postulates that aposematic coloration evolves in deterrent species because it is a more effective warning signal than the alternate cryptic coloration (Wallace, 1867; Poulton, 1890). In opisthobranch molluscs, warning coloration is based on the benefits provided by chemical defenses often sequestered from the opisthobranch food source (Faulkner and Ghiselin, 1983; Avila, 1995), and it seems associated with evolutionarily more derived, rather than more basal, taxa (Gosliner, 2001).

Despite the importance of feeding biology in the life history strategies of opisthobranchs, there is a lack of information on the feeding biology of many groups. Gastropterid molluscs are often found on sponges, which suggests they are sponge feeders. Despite the close association between gastropterids and sponges, it remains doubtful whether gastropterids actually feed on sponges since their radular teeth are similar to the closely related philinoid bubble shells, which feed on hard-shell prey (Hurst, 1965; Mikkelsen, 1996). Two sympatric gastropterid species of the genus *Sagaminopteron*, *S. nigropunctatum* and *S. psychedelicum*, show contrasting color patterns and are associated with the sponge *Dysidea granulosa* on which they are usually found. *S. nigropunctatum* displays cryptic coloration (Gosliner, 2001); it is well camouflaged with a pattern that is almost identical in color and texture to the sponge (Carlson and Hoff, 1973). In contrast, *S. psychedelicum* has a bright and remarkable color pattern that makes it obvious (Carlson and Hoff, 1974), which is consistent with an aposematic coloration (Gosliner, 2001). Both sagaminopteran species are associated with their host sponge and, in contrast to other gastropterids, neither is a spectacular swimmer, especially *S. nigropunctatum*, which seldom swims (Carlson and Hoff, 1973).

Many opisthobranchs feed on chemically defended prey (Faulkner, 1992; Avila, 1995). In a predator, the presence of secondary metabolites produced by its prey is considered evidence of a trophic relationship. Studies in chemical ecology show that

opisthobranchs sequester secondary metabolites from prey, accumulate, concentrate, and distribute them in their tissues, and use them for their own defense (Carté and Faulkner, 1983; Paul et al., 1990; Becerro et al., 2001, 2003). This strategy of sequestration, concentration, modification, and distribution of metabolites from the prey into the body of the predator is found widely in nudibranchs (Cimino and Ghiselin, 1999 and references therein), sacoglossans (Cimino and Ghiselin, 1998; Cimino et al., 1999; Becerro et al., 2001), notaspideans (Teeyapant et al., 1993; Ebel et al., 1999; Becerro et al., 2003), and sea hares (Johnson and Willows, 1999). *D. granulosa* is a chemically defended sponge that produces a number of polybrominated diphenyl ethers (Becerro and Paul, 2004). Given the close and consistent association of both gastropterid species with *D. granulosa* and the widespread occurrence of compound sequestration and biomagnification observed in specialist predators, we set forth the hypothesis that, if they are true specialist predators, both *S. nigropunctatum* and *S. psychedelicum* will share secondary chemistry with their host sponge *D. granulosa*. However, given the contrasting color patterns shown by the two species, they might differ in their defense strategies. Thus, we present two working hypotheses: (1) consistent with its warning coloration, *S. psychedelicum* will accumulate, concentrate, and distribute in its parapodia compounds sequestered from *D. granulosa*; and (2) the cryptic *S. nigropunctatum* will sequester sponge secondary metabolites in its digestive gland and will fail to concentrate and adequately distribute these metabolites in its tissues thus, relying on camouflage.

Methods and Materials

On Guam, *D. granulosa* (Bergquist 1965, n. sp., aff. *granulosa*; Kelly et al., 2003) (Family Dysideidae, Order Dictyoceratida) is a common shallow-water sponge mostly found on reef flats, where it can be abundant. *D. granulosa* is abundant up to a depth of 5–6 m in Gun Beach, a reef slope habitat with a series of 1- to 5-m-wide channels with vertical walls perpendicular to the shoreline and open to wave action and surge. On this location, *D. granulosa* has three polybrominated diphenyl ethers (BDEs) as major secondary metabolites (Becerro and Paul, 2004). On Gun Beach, the gastropterids *S. psychedelicum* and *S. nigropunctatum* are consistently found on *D. granulosa*, sometimes sharing the same specimen. Neither is highly abundant, and because of their small size (smaller than 0.5 cm in our study site), they are difficult to observe.

Chemical Analysis

We collected five specimens of *S. psychedelicum*, nine specimens of *S. nigropunctatum*, and 10 egg masses of *S. nigropunctatum*. We found no egg masses of *S. psychedelicum* at the time of collection. All samples were collected by scuba diving, and taken to the laboratory where they were frozen at -20°C and stored until analyzed and used in experiments.

Frozen gastropterids were thawed and rinsed with distilled water to remove any secretion released by the animals. Gastropterids were dissected to separate parapodia and “tail,” digestive gland, and the remainder of the body. Because of the small size and in order to have enough material for chemical quantification, the same body parts from all specimens were pooled in preweighed vials and freeze-

dried. Eggs were rinsed in distilled water and freeze-dried. Samples were then extracted with 1:1 (v/v) DCM/MeOH. This extraction procedure differs slightly from that used by Becerro and Paul (2004) to extract BDEs from sponge samples, since we used DCM/MeOH instead of DCM as the extraction solvent. However, BDEs are exhaustively extracted by both solvent mixtures, and we did not find more polar secondary metabolites in the sponges or the gastropterids. The crude extract was redissolved in DCM and filtered through glass wool and a 1-cm, 60–200 mesh silica gel pipette column in preparation for gas chromatography.

We used gas chromatography/mass spectrometry (GC-MS) to quantify BDEs in the gastropterid body parts. For quantification by GC-MS, we dissolved crude extracts in DCM (2 ml/mg) containing naphthalene (50 $\mu\text{g/ml}$) as internal standard (IS). Quantification was done with a Hewlett-Packard 5890 Series II GC fitted with an HP-5 capillary column (5% phenyl methyl crosslinked silicon siloxane, 30 m long, 0.25 mm i.d., 0.25 μm film thickness) and coupled to a Hewlett-Packard 5972 MS. Gas chromatography was performed following methods of Becerro and Paul (2004). One μl of extract solution at a concentration of 0.5 mg/ml was injected. We quantified the % yield of compounds by comparing the ratio “area of compound divided by area of IS” in the samples to a calibration curve calculated with known concentrations of pure compounds. To calculate the % yield of BDEs per sample dry mass, we multiplied the yield of BDEs in the extract by the yield of crude extract in the sample $\times 100$.

We compared the concentration of compound **2** [3,5 dibromo-2-(2',4'-dibromophenoxy)phenol] in gastropterid body parts to the concentrations found by Becerro and Paul (2004) in the sponge ectosome and choanosome. Because we pooled the same gastropterid body parts from the same species, we have a single concentration value for each body part, i.e., we obtained an average value from our replicates but we lack variance data. To test whether our single values differ statistically from the replicated ectosome and choanosome data ($N = 10$, respectively), we used a *t*-test for a single specimen compared with the mean of a sample (previous arcsin transformation to meet parametric assumptions) as described by Sokal and Rohlf (1995).

Ecological Experiments

We ran two sets of experiments to investigate the relationship between the gastropterids and the sponge, and to assess whether gastropterids are defended against generalist predators. All experiments were run with *S. nigropunctatum* because we found no *S. psychedelicum* at the time of collection. We collected pieces of *D. granulosa* hosting *S. nigropunctatum* at Gun Beach. To reduce the likelihood of the animals discharging secretion, we collected the opisthobranchs by breaking off pieces of sponge rather than removing the animal from the sponge. The gastropterids and sponges were placed in large plastic bags with seawater and transported to the University of Guam Marine Laboratory in a cooler. In the laboratory, sponges were cleaned of epifauna and cut into equal sized pieces of ectosome and choanosome. Ectosome refers to the outer layer of sponge (about 2 mm in thickness), whereas choanosome refers to the gray interior. The ectosome contains abundant cyanobacteria that makes this zone a greenish-purple color. There also are bacterial and chemical differences between these two sponge parts (Becerro and Paul 2004). In the field, gastropterids are found on the surface of the sponge (ectosome), and we tested whether gastropterids show a preference for the

ectosome over the inner choanosome. Paired ectosome and choanosome sponge pieces were placed in watch glasses with single gastropterids ($N = 17$) and left until the animal chose one of the sponge pieces up to a maximum of 1 hr. We then scored the number of gastropterids present. Animals were left in the bowl for an additional hour and scored again. We used a *binomial distribution* ($P = Q = 0.5$) to test for significant preferences between ectosome and choanosome sponge pieces (two-tailed P values reported) at the two time intervals.

To test whether *S. nigropunctatum* was defended against generalist predatory fish, the same specimens used in the previous choice experiment were then offered to the sharpnose pufferfish *Canthigaster solandri* (Richardson, 1845). The pufferfish were kept in individual flowthrough aquaria (10 l) and maintained on artificial commercial catfish food pellets. We recorded whether *S. nigropunctatum* was eaten, tasted and rejected, or ignored by the fish. Immediately after this trial, we offered the same fish a piece of equally sized skinned octopus tentacle. Since we tested the same individual fish twice (first for treatment and then control tests), we used a McNemar test to check whether *S. nigropunctatum* inhibited feeding of the pufferfish compared to control food (Sokal and Rohlf, 1995).

Results

The extract of *D. granulosa* from Gun Beach has three major BDEs. The compound 3,5 dibromo-2-(2',4'-dibromo-phenoxy)phenol (hereafter referred to compound **2**, as in Becerro and Paul 2004) is the major metabolite in the extract and corresponds to a % yield per dry mass of sponge of 2.78 ± 0.27 (mean \pm SE) in the ectosome and 3.21 ± 0.67 in the choanosome (Becerro and Paul 2004). Other BDEs closely related to **2** that are found in lower concentrations in the sponge were not detected in the gastropterids (see Becerro and Paul, 2004 for a more comprehensive analysis of the chemical variation of the sponge *D. granulosa*).

Both *S. psychedelicum* and *S. nigropunctatum* share secondary chemistry with the sponge *D. granulosa*. We detected **2** in all body parts from both species, including the egg mass of *S. nigropunctatum* (Fig. 1). However, concentration of **2** between body parts and species differed quantitatively (Fig. 1, note lack of variance in body parts due to replicate pooling). Concentration of **2** sequestered in the digestive gland may depend on the amount of food in the gut and the actual concentration of compounds in the material ingested. *S. nigropunctatum* concentrates **2** in the parapodia or mantle's edge up to an average concentration of 10.10% per dry mass, which is a significant increase as compared to the concentration found in the sponge ectosome and choanosome ($P < 0.001$ and $P = 0.019$, respectively). *S. psychedelicum* also concentrates **2** in the parapodia up to an average concentration of 7.97%, which is a significant increase as compared to the ectosome ($P = 0.001$) and almost as much as the choanosome ($P = 0.055$). The body tissues of both gastropterid species and the egg masses and secretion of *S. nigropunctatum* had concentrations of **2** similar to those found in either the sponge ectosome or choanosome ($P > 0.05$ for all comparisons). Compound **2** was also present in the secretion of *S. psychedelicum* but below the quantification threshold.

In laboratory choice experiments, *S. nigropunctatum* significantly selected the outer ectosome of *D. granulosa* over the interior choanosome. At the initial choice, 12 out of 17 molluscs selected the ectosome over the choanosome (binomial test,

Fig. 1 Concentration (as % dry mass) of compound 2 (3,5-dibromo-2-(2',4'-dibromo-phenoxy)phenol) found in several tissues of the gastropterid *Sagaminopteron nigropunctatum* and *S. psychedelicum*. Note lack of error bars in gastropterid body parts due to replicate pooling. Mean (± 1 SE) percent of compound 2 in the ectosome and choanosome ($N = 10$) of the sponge *Dysidea granulosa* is shown for comparison. Sponge data from Becerro and Paul (2004). Letters “e” or “c” above bars denote significant differences between the bar value and the ectosome or choanosome data, respectively ($P < 0.05$)

$P = 0.047$). After 1 hr, three of the five specimens that chose pieces of choanosome had moved away and were observed on the ectosome ($N = 1$) or crawling on the aquarium ($N = 2$) (binomial test, $P = 0.018$). Individuals that chose a piece of ectosome remained on it until the end of the experiment.

In feeding assay experiments, *S. nigropunctatum* deterred feeding of the pufferfish *C. solandri* (McNemar $G = 4.159$, $P < 0.05$); eight out of 10 pufferfish tasted and rejected the gastropterid in the laboratory, three of which consumed the control food. No fish fed on the gastropterid and rejected control food.

Discussion

Cephalaspideans are a polyphyletic group of opisthobranch molluscs that consume a variety of diets such as polychaetes, molluscs, urchins, or foraminifera (Mikkelsen, 1996). There is some controversy about gastropterid feeding habits and whether or not they are true sponge feeders, with indirect evidence either supporting or casting doubts on this hypothesis (see below). The hypothesis that gastropterid are sponge feeders is mostly based on the close association between gastropterids and sponges, including the close association between *S. psychedelicum* and *S. nigropunctatum* and their host sponge *D. granulosa* investigated in this study (*Dysidea* cf. *reticulata* in Carlson and Hoff, 1973, 1974). Yet, a close association may not necessarily involve a trophic relationship. Nudibranch species of the genus *Trapania* are associated with sponges, which were assumed to be their food source. However, there is some evidence that *Trapania* species seem to feed on entoprocts that grow on top of the sponges rather than feeding on the sponges themselves (<http://www.seaslugforum.net/display.cfm?id=3767>).

Anatomical data argue against *Sagaminopteron* species as sponge feeders. Gastropterid radular teeth are similar to those of their relatives, none of which

feed on sponges but instead on hard-shell prey such as the polychaete *Pectinaria*, small clams, snails, sea urchins, and foraminiferans (Hurst, 1965; Burn and Bell, 1974a,b; Shonman and Nybakken, 1978). Accordingly, it is reasonable to hypothesize that *S. nigropunctatum* and *S. psychedelicum* feed on food sources they encounter while crawling on the sponge surface. For example, aeolid nudibranchs typically feed on cnidarians, but species of the genus *Calma* have a modified radular structure (a species-level character) to feed efficiently on fish egg masses (Calado and Ugorri, 2002). Alternatively, gastropterids could feed on sponges without evolving a modified radula. Sacoglossans are considered highly specialized herbivores that feed on green algae (Williams and Walker, 1999), but some species of the genera *Favorinus*, *Stiliger*, and *Olea* are oophagous rather than herbivorous (Thompson and Brown, 1984)—yet they show no radular adaptations that reflect their change of diet. Likewise, polyceratid nudibranchs typically feed on bryozoans, but species of the genera *Roboastra* and *Nembrotha* feed on nudibranchs and ascidians, respectively (Carté and Faulkner, 1986; Paul et al., 1990; Megina and Cervera, 2003), and show no radular modifications to do so.

Our study shows that *S. nigropunctatum*, *S. psychedelicum*, and their host sponge *D. granulosa* share secondary chemistry, which supports the hypothesis that gastropterids are sponge feeders. Pawlik et al. (1988) showed that the Spanish dancer nudibranch *Hexabranchus sanguineus* sequesters its chemical defense from its food sponge *Halichondria* sp., and distributes and concentrates the chemical defenses in the mantle, mucus secretion, and the egg masses. The gastropterids *S. psychedelicum* and *S. nigropunctatum* seem to share the same strategy, even though they are a fraction of the size. Both species sequester, distribute, and accumulate sponge BDEs in their parapodia, a strategy similar to that found not only in *H. sanguineus* but in many other opisthobranch molluscs that feed on chemically defended prey (Pawlik et al., 1988; Faulkner, 1992; Avila, 1995; Avila and Paul, 1997). Thus, compound **2** (3,5-dibromo-2-(2',4'-dibromo-phenoxy)phenol), the major BDE in *D. granulosa*, is present in the mantle of the gastropterids at over twice the concentration found in the sponge, and additionally is present in the digestive glands. When disturbed, both gastropterids discharge a mucus secretion that include **2**, which suggests BDEs contribute to predator deterrence. Also, *S. nigropunctatum* transfers **2** to egg masses, where it could help prevent predation or fouling by bacteria, fungi, or other benthic organisms (Matsunaga et al., 1986). BDEs have a variety of biological activities (Sharma and Vig, 1972; Fu et al., 1995; Handayani et al., 1997) including defense against predators (Duffy and Paul, 1992; Pennings et al., 1994). Compound **2** deters a variety of predators including pufferfish *C. solandri*, xanthid crabs *Leptodius* spp., and the sea hare *Stylocheilus longicauda* (Duffy and Paul, 1992; Pennings and Paul, 1993; Pennings et al., 1994) even at concentrations below those found here. The pufferfish *C. solandri* tasted and rejected specimens of *S. nigropunctatum* in the laboratory suggesting that it is defended against them.

Coral reefs are among the ecosystems with the highest levels of predation (Carpenter, 1986) including generalist fish predators that use visual cues to obtain food (Lowe-McConnell, 1987). *S. nigropunctatum* is highly cryptic on *D. granulosa* since the gastropterid mimics both the color and texture of the sponge. Egg masses and some orange parts on the head shield and siphon of *S. nigropunctatum* are the only indications of its presence. *S. nigropunctatum* also mimics *D. granulosa* chemically by incorporating the sponge major metabolite in its tissues. Consequently, predators may overlook *S. nigropunctatum* in the field as a result of visual and

chemical camouflage. When cryptic coloration fails, chemical defenses may help the gastropterid overcome predators.

In contrast, *S. psychedelicum* has a conspicuous color pattern, which suggests a true aposematic coloration (Edmunds, 1991; Gosliner, 2001). Being conspicuously advertised is just one of the four criteria needed to fit the definition of aposematic coloration (Edmunds, 1991). It is also necessary to know whether or not (1) the organism deters predators, (2) predators avoid attacking a potential prey because of its colors, and (3) the aposematic color pattern is more effective than being cryptic (Edmunds, 1991). Although not tested, it is reasonable to think that *S. psychedelicum* is also chemically defended against predators, because it shares the same chemical as *S. nigropunctatum* at concentrations above those known to deter potential consumers. Despite the high numbers of generalist predators sharing habitat with the gastropterid, we have seen no sign of predation on this species in the field. Whether or not the striking color pattern of *S. psychedelicum* is more effective than the alternative cryptic coloration found in *S. nigropunctatum* is unknown, but these gastropterids may be an excellent system to understand better the role that color patterns and chemistry play in predation.

Our data also show that *S. nigropunctatum* significantly prefers the ectosome of *D. granulosa* over the interior choanosome. Some species of the genus *Dysidea* are known to contain large number of cyanobacteria. The cyanobacteria *Oscillatoria spongeliae* may represent up to 50% of the tissue volume of *D. herbacea* and is thought to be responsible for the production of BDEs in the sponge (Unson et al., 1994; Faulkner et al., 2000). *D. herbacea* and *D. granulosa* have genetically distinct populations of *O. spongeliae* (Thacker and Starnes, 2003), which are restricted to the ectosome of *D. granulosa* (Becerro and Paul, 2004). Cyanobacteria might also be responsible for the production of the BDEs in *D. granulosa* (although see Elyakov et al., 1991; Voinov et al., 1991). Whether they are behind the preference of *S. nigropunctatum* for the ectosome as described for the opisthobranch *Tylodina perversa* (Becerro et al., 2003) is unknown. The possibility that other chemical or structural differences between the ectosome and choanosome of the sponge or other microorganisms associated with the sponge may be responsible for the selection by the gastropterid cannot be completely ruled out. The use of standard methods in chemical ecology along with appropriate experimentation may provide new light on the feeding biology of opisthobranch molluscs and help us understand the role that color patterns and chemical defenses play in their biology, ecology, and evolution.

Acknowledgments This study was supported by a grant from the Guam Shell Club to J.A.S. and NIH grants GM38624 and GM44796 to V.J.P. Raphael Ritson-Williams, Lucas Cervera, and two anonymous reviewers made useful comments on earlier versions of this manuscript. Lee-Ann Hayek provided advice on statistical analyses. This is contribution no. 575 of the University of Guam Marine Laboratory and contribution no. 615 of the Smithsonian Marine Station at Fort Pierce.

Abstract Mussels *Perna viridis* and *Brachidontes variabilis* were exposed to chemical cues from the predatory crab *Thalamita danae* maintained on different diets, and byssal thread production of the mussels was studied. *P. viridis* produced the highest number as well as the thickest and longest byssal threads when they were exposed to crabs maintained on a diet of *P. viridis* as compared with those exposed to crabs maintained on a diet of the top shell *Monodonta labio*, the rock oyster *Saccostrea cucullata*, or crabs that were starved. For *B. variabilis*, results were similar, in that a diet containing *B. variabilis* elicited the greatest response as compared with other treatments. This indicates that the mussels were able to discriminate chemical cues released from predators maintained on different diets, and respond accordingly to the level of predation risk. By increasing the strength of byssal attachment as a defensive trait, the chance of being dislodged and consumed by crabs is reduced. As energy cost involved in the induction of an antipredatory response is considerable, this defensive trait seems to be an advantage to the mussels in enhancing efficiency. The short response time in byssal thread production allows the mussels to increase resistance against predation by crabs at the time when predation pressure is the highest in a tidal cycle.

Introduction

Under predation risks, prey may be induced to develop physiological, morphological, or behavioral antipredatory responses so as to increase resistance to predation

(Vermeij, 1987). Such responses are widely documented in various kinds of aquatic invertebrates, including protozoans (Wicklow, 1988), cnidarians (Grosberg, 1988), flatworms (Wisenden and Millard, 2001), gastropods (Appleton and Palmer, 1988; Trussell, 1996), bivalves (Leonard et al., 1999; Cheung et al., 2004a,b), sea urchins (Hagen et al., 2002), and ascidians (Pisut and Pawlik, 2002). The induction of an antipredatory response, however, may incur a cost in energy reserve, which could otherwise be utilized for other functions such as foraging and reproduction (Sih, 1980). Therefore, a capability to identify reliable information cues associated with predation risk is crucial to the induction of antipredatory responses, which in turn reduces the risk of injury or mortality and optimizes energy utilization. These informational cues can be visual, tactile, or chemical.

Chemical cues involved in the assessment of predation risks by aquatic animals have received increasing attention in recent years. These cues may originate and be released from predators *per se* (see review by Kats and Dill, 1998) or from prey animals when they detect or are attacked by predators (see review by Chivers and Smith, 1998). It is maladaptive, however, for the predator to release cues that could be identified by the prey, as this would cause the prey to elicit antipredatory responses (Hagen et al., 2002). An increasing number of findings from recent research have indicated that antipredatory responses are elicited by cues released from consumed conspecific or heterospecific prey through the predator (predator-labeling effect), but not from the predator *per se*. The predator may thus be undetectable by the prey when the diet of the predator does not include conspecific or heterospecific prey. Such predator-labeling effects occur in a number of aquatic animals including sea anemones (Howe and Harris, 1978), gastropods (Jacobsen and Stabell, 2004), sea urchins (Hagen et al., 2002), insects (Chivers et al., 1996), amphibians (Wilson and Lefcort, 1993), and fish (Mathis and Smith, 1993).

Antipredatory responses have been reported for mussels exposed to chemical cues of predators and damaged conspecifics. These responses include increase in shell thickness in the presence of the scent of crabs and whelks (Leonard et al., 1999; Smith and Jennings, 2000; Cheung et al., 2004a), size of the adductor muscle in the presence of the scent of starfish (Reimer and Harms, 2001), and the number of byssal threads and the strength of byssal attachment in the presence of the scent of crabs and starfish (Côtè, 1995; Leonard et al., 1999; Reimer and Harms, 2001; Cheung et al., 2004b).

Mussels form the major diet of crabs (Seed, 1993). To consume mussels, crabs have to cut the byssal threads before dislodging the mussels from their surroundings and cracking them open (Elner, 1978). An increase in the strength of byssal attachment, therefore, may serve as an effective defensive tactic against crab predation. In a laboratory experiment, Côtè (1995) showed that *Mytilus edulis* produced more and thicker byssal threads upon exposure to the scent of crabs. Leonard et al. (1999) transplanted the same species from a site with low crab predation pressure to another where crab predation was dominant and found that mussels produced 72% more byssal threads and the attachment strength was increased by 87%.

Mussels *Perna viridis* and *Brachindontes variabilis* are widely distributed throughout the Indo-Pacific, typically occurring on protected shores (Lee and Morton, 1985). Although both mussels are commonly found in sheltered harbors in Hong Kong, their distribution is different. *P. viridis* ranges from the lower intertidal zone downwards to depths of around 10 m, whereas *B. variabilis* occurs principally

in the midhigh zone, often nestling in crevices or among the encrusting shells of the rock oyster *Saccostrea cucullata*. Both mussel species form the major diet of the swimming crab *Thalamita danae*, which moves into the intertidal zone with each flood tide to feed rapaciously on small mussels (<15 mm shell length). In an analysis of the stomach contents of *T. danae*, more than 14 prey species were found, with *P. viridis* and *B. variabilis* being the most common prey (53.9% and 42.3% of the stomachs contained *P. viridis* and *B. variabilis*, respectively). Other prey items included the rock oyster *S. cucullata* and top shell *Monodonta labio*, which were present in 15.4% and 11.5% of the stomachs, respectively (Seed, 1990).

Our previous study showed that *P. viridis* is responsive to chemical cues of damaged conspecifics and predators, including the swimming crab *T. danae* and muricid gastropod *Thais clavigera*. *P. viridis* produced more byssal threads, which were also longer and thicker compared to the control mussels without being exposed to these cues (Cheung et al., 2004b). The design of that experiment, however, could not differentiate whether cues from the predators *per se* or cues from consumed conspecific and heterospecific prey through the predator; i.e., a predator-labeling effect induced the byssus production. To address this question, the present study thus used cues generated from the predator *T. danae* feeding on a diet of mussels or other prey items, and compared their effects on byssus production in *P. viridis* and *B. variabilis* in an attempt to test the presence of a predator-labeling effect in mussels. This is the first time that an antipredatory response has been reported for *B. variabilis*.

Methods and Materials

Perna viridis (shell length: 10–15 mm) were collected from a pier at Sham Pui Chau, and *B. variabilis* (shell length: 10–15 mm) were collected from a boulder shore at Ting Kok. Both sites are located in the inner Tolo Harbour, Hong Kong (22°20'N; 114°10'E), and are 5 km apart; both sites experience similar hydrography. Although these two mussels occurred at both sites, their numbers were different, with a high density of *P. viridis* found at Sham Pui Chau, and *B. variabilis* at Ting Kok. Upon return to the laboratory, the mussels were cleaned of epibionts and detached carefully from clumps by cutting the byssal threads with scissors (avoiding damage to the pedal apparatus, which could impair byssal thread secretion). Each species was maintained in separate fiber glass tanks (500 l) equipped with a filtering system and air supply. Mussels were fed with the green alga *Dunaliella tertiolecta* once every 2 d. Seawater at a salinity of 32‰ was maintained by a thermostatic heater at 28°C, which is the average summer seawater temperature in Hong Kong (Environmental Protection Department, 2004). Mussels were allowed to acclimate to laboratory conditions for 1 wk prior to experimentation. Intermolt male crabs *T. danae* (carapace width: 60–70 mm) used to induce byssal thread production in mussels were collected from the field and acclimated for 1 wk in a 500-l fiber glass tank under the same laboratory conditions as the mussels. Crabs were fed with shrimp meat once every 2 d. Only males were used to avoid potential bias that might be introduced through sexual differences in predatory morphology. Other than the two mussel species, prey used to feed the crabs in the experiment also included the rock oyster *S. cucullata* and top shell *M. labio* collected from Sham Pui Chau. All prey types, including mussels, were frozen after transportation to the laboratory.

Experimental Set-up

Four treatments were prepared for each mussel species, and four aquaria were assigned for each treatment as replicates. An individual of *T. danae* was put into each aquarium as a stimulus source, and each aquarium also contained eight experimental mussels (shell length: 10–15 mm). Each experimental mussel was kept in a separate perforated plastic vial (4 cm diam, 6 cm high) and identified by a numbered plastic tag on the shell. Shell length of each individual was measured by vernier calipers to the nearest 0.1 mm. To prevent physical contact between the mussels and crab, but allowing scent from the crab to enter the vials, the crab in the aquarium was separated from the vials by a plastic mesh.

For the study of byssal thread production in *P. viridis*, *T. danae* in the first treatment (Treatment PV) were fed on *P. viridis*, whereas those in the second and third treatments were fed on the rock oyster *S. cucullata* (Treatment SC) and top shell *M. labio* (Treatment ML), respectively. *T. danae* in the fourth treatment were starved and served as controls (Treatment C). Treatment groups in *B. variabilis* were similar except that *P. viridis* offered as food to crabs in the treatment PV was replaced by *B. variabilis* and labeled as Treatment BV. All prey items were defrosted before being fed to crabs.

Except for the controls, crabs in the other three treatments were offered either one of the three prey types once every 2 d over 1 wk before the start of the experiment. The amount of prey offered was standardized to 10 g wet weight per meal. To avoid chemical cues released from the prey that might affect the results, crabs were taken out and fed in another aquarium and were put back into the experimental aquaria after feeding. The same procedure was applied to the starved crabs (Treatment C), so as to standardize the effect of manipulation. No food was offered to the crabs 24 hr before commencement of the experiment nor throughout the 48-hr experimental period.

Fig. 1 Cumulative production of byssal threads (\pm SD) of *Perna viridis* as a function of time. PV: *Perna viridis* diet; SC: *Saccostrea cucullata* diet; ML: *Monodonta labio* diet; C: control

Byssus Production

The method developed by Côté (1995) was adopted with modifications. The number of byssal threads produced by each mussel was counted every 30 min for 6 hr. Further counts were taken 24 and 48 hr after the onset of the experiment. During the experiment, some mussels shed their byssal threads to release themselves and move to other attachment sites. The number of shed byssal threads was noted but not included in the byssal counts, as only the number of functional byssal threads was relevant to this study.

At the end of the experiment, all experimental mussels were detached from the vials by cutting the threads as near as possible to the point of insertion between the valves. Lengths and diameters of 5 threads were measured for each of 4 mussels chosen randomly from each aquarium. As there were 4 aquaria assigned to each

^a Mean and SD are calculated using pooled data from all the replicates of the four aquaria.

*Treatment groups not underlined by the same lines are significantly different ($P < 0.05$).

treatment, 80 byssal threads were measured for each treatment. Byssal thread length was measured by using vernier calipers to the nearest 0.1 mm, and diameter was measured under a dissecting microscope equipped with an ocular micrometer at 1–1.5 mm from the adhesive disk. The volume of the byssal threads was computed from the length and diameter of the threads, assuming that the byssal thread was cylindrical. The above procedure was used for both studied species.

Statistical Analyses

Data obtained for mussels in an aquarium were pooled, and individual aquaria of the same treatment were considered as replicates (i.e., $N = 4$). Treatment and replicate effects on byssus production, and the length and diameter of individual byssal threads were analyzed with nested ANOVA followed by the Tukey multiple comparison procedure, with individual aquaria assigned as a random factor nested within the four treatments. Normality of the data was checked by using the Kolmogorov–Smirnov test, and homogeneity of variances by Bartlett's test. All statistical tests were performed by using the statistical software Minitab Release 14.

Results

Inducible Byssal Thread Production in *P. viridis*

All mussels steadily secreted byssal threads in the perforated plastic vials within 48 hr (Fig. 1). The mean number of threads produced at the end of the experiment varied from 7.03 (C) to 13.59 ind⁻¹ (PV) (Table 1). PV produced the highest

Fig. 2 Cumulative production of byssal threads (\pm SD) of *B. variabilis* as a function of time. BV: *Brachidontes variabilis* diet; SC: *Saccostrea cucullata* diet; ML: *Monodonta labio* diet; C: control

number of threads and was different from the other three treatments ($P < 0.001$), whereas ML and SC also produced more byssal threads than the control (C).

The mean length of threads ranged from 7.45 mm (C) to 10.93 mm (PV), in which PV produced significantly longer threads ($P < 0.001$) than the other three treatments (Table 1). Although the mean byssal length of ML was higher than that of C ($P < 0.05$), no significant difference was found between SC and C.

The mean diameter of threads varied from 0.114 mm (C) to 0.171 mm (PV), with PV producing thicker threads ($P < 0.001$) than the other three treatments (Table 1). The mean diameter of threads of SC was higher than that of C ($P < 0.05$); however, no significant difference was found between ML and C.

Cumulative byssal thread length (no. of byssal threads \times mean length of a thread) and cumulative thread volume (no. of byssal threads \times mean volume of a single thread) were highest for PV and significantly different from the other three

treatments ($P < 0.001$). The values for SC and ML were also significantly higher than those for C ($P < 0.05$).

Inducible Byssal Thread Production in *B. variabilis*

Byssal thread production increased with time for all treatment groups within 48 hr (Fig. 2). The rate of thread production among different treatments was similar in the first 2 hr, but the difference between BV and other treatment groups increased with time. The mean number of threads produced at the end of the experiment varied from 5.69 to 7.63 ind⁻¹, with more threads being produced by BV than the other treatments ($P < 0.001$) as tested by nested ANOVA (Table 2).

The mean length of threads ranged from 5.28 mm (ML) to 8.47 mm (BV), and the mean diameter of threads varied from 0.101 mm (ML) to 0.114 mm (BV) (Table 2), in which BV produced longer ($P < 0.001$) and thicker ($P < 0.05$) threads than the other treatments.

Cumulative byssal thread length (no. of threads \times mean length of a thread) and cumulative thread volume (no. of threads \times mean volume of a single byssus) were also highest for BV and significantly different from the other treatments ($P < 0.001$).

Discussion

Perna viridis exposed to chemical cues from crabs maintained on a *P. viridis* diet produced more byssal threads than those exposed to chemical cues from crabs maintained on other prey diets or from starved crabs. The threads produced by the former group were also the longest, thickest, and of the highest volume among all treatments. Chemical cues produced by starved crabs elicited weaker response in *P. viridis* than those produced by crabs maintained on the rock oyster or top shell diet. Similar responses were observed in *B. variabilis* with greatest response being elicited by crabs maintained on a *B. variabilis* diet. However, no significant difference was observed in thread production between *B. variabilis* exposed to chemical cues from crabs maintained on the rock oyster or top shell diet, and those exposed to starved crabs. Since control crabs were not feeding during the experiment, differences in the degree of the response among treatments indicated that the crabs were labeled by their diets and could be differentiated by the mussels. To our knowledge, this is the first time the presence of a diet-related, predator-labeling effect on byssal thread production in mussels has been reported. As crabs are able to cut byssal threads by using their claws and dislodge individuals from a mussel bed, mussels with firmer attachment are less likely to be removed, leading to less predation by crabs, and hence, reduction in mortality (Lin, 1991; Hughes and Seed, 1995). As tensile stress increases with byssal thread length (Price, 1981), longer threads also help increase the resistance of the mussels being dislodged from the substratum. Predator-labeling effects on antipredatory responses have been reported in a number of aquatic animals (Howe and Harris, 1978; Mathis and Smith, 1993; Wilson and Lefcort, 1993; Chivers et al., 1996; Hagen et al., 2002; Jacobsen and Stabell, 2004). For example, avoidance response in the gastropod *Tegula funebralis* was more pronounced when they were exposed to crabs previously maintained on a *Tegula* diet than in crabs maintained on other diets (Jacobsen and Stabell, 2004). A stronger behavioral response was also elicited in the green sea urchin *Strongylocentrotus droebachiensis*

when animals were exposed to a sea urchin diet with seawater preconditioned by the predator (the Atlantic wolffish *Anarhichas lupus*) as compared to urchins maintained on a mussel diet or without food (Hagen et al., 2002). As suggested by Jacobsen and Stabell (2004), the chemical labels released by crustaceans may be emitted through excretion of urine, which serves the function of compensating short-term internal volume changes due to ingestion (Mantel and Farmer, 1983; Cheng and Chang, 1991). Elevated urine production has been observed in crabs exposed to prey extract, indicating that urine production is also associated with triggering of feeding responses (Jacobsen and Stabell, 2004).

Energy cost involved in the induction of antipredatory responses can be considerable (Covich et al., 1994). Rawlings (1994) found that the rocky shore gastropod *Nucella emarginata* showed dramatic reduction in reproductive activity due to heightened metabolic rate induced by exposure of snails to increased predation risks. Byssal threads constitute a significant component of total production by mussels, accounting for 3–10% of annual production in *P. viridis* (Shafee, 1979; Cheung, 1991) and up to 15% of total body energy in the ribbed mussel *Aulacomya ater* (Griffiths and King, 1979). After exposure to the scent of predators and damaged conspecifics for 48 hr, *P. viridis* has been shown to produce between 1.3 and 7.6 times more byssal threads as compared with controls (Cheung et al., 2004b). With the ability to discriminate between levels of predation risk via chemical labels, prey can respond according to the level of the risk and, hence, maximize the efficiency of energy utilization.

Crabs maintained on either one of the diets elicited a greater response in *P. viridis* than starved crabs. There are two possible explanations. The first is the addition effect of different sources of chemical cues. There were two sources of cues released from crabs maintained on a diet, one from the prey consumed and another from the crabs *per se* without considering that the prey cues may be chemically altered during passage through the predator (Jacobsen and Stabell, 2004). In contrast, only chemical cues were released from starved crabs. Second, such differences might be attributed to *P. viridis* detecting an elevated risk associated with the consumption of heterospecifics by the crabs. The design of the experiment, however, did not allow us to judge which explanation is more feasible because all prey types used form part of the diet of crabs in the field, although the preference varies with species. Nevertheless, the results for *B. variabilis* indicate that the addition effect of chemical cues may not be significant, at least in this species, because the same degree of response in byssal thread production was obtained for the starved crab group as for treatments with the top shell or rock oyster diet. An analysis of the stomach contents of a natural population of *T. danae* showed that 53.9% and 42.3% of the stomachs contained *P. viridis* and *B. variabilis*, respectively. In contrast, only 15.4% and 11.5% contained rock oysters and top shells, respectively (Seed, 1990). The predation risk associated with chemical cues from these less-preferred prey, therefore, is much lower compared to chemical cues from conspecifics.

The present study demonstrates that byssal thread production as an antipredatory response is most reactive in the first 5 hr of exposure to predator cues, with the response slowing after this period. This is consistent with other studies on mussels including *M. edulis* (Côté, 1995) and *P. viridis* (Cheung et al., 2004b). Such a time-dependent response, however, can not be correlated with the release rate of chemical cues associated with diet, which may decrease with time as digestion of

prey is completed. The same observation was found for mussels receiving chemical cues from starved crabs. Additionally, the mussels from all treatments were maintained in a closed system in which the crabs and seawater were not renewed during the experiment. Chemical cues from crabs are thus expected to accumulate throughout the experiment instead of deteriorating with time, unless degradation is faster than accumulation of cues.

Juveniles (<15 mm) of *P. viridis* and *B. variabilis* are the prey most preferred by *T. danae* on Hong Kong sheltered rocky shores. These crabs live in subtidal waters and move with each flood tide into the intertidal zone to feed (Seed, 1990). More and thicker byssal threads increase the time and difficulty for crabs to dislodge the mussels from the surrounding bed before they can be cracked and opened (Elner, 1978). As feeding time of crabs is constrained by duration of the flood tide, which only lasts for several hours in locations with semidiurnal tidal conditions such as Hong Kong (Morton and Morton, 1983), a short response time to chemical cues from predators is critical to the survival of the mussels. It allows an increase in the resistance to predation at a time when predation risk is the highest. This is adaptive for survival in terms of energy conservation because, when predation risk becomes less threatening when the tide recedes, species can divert less energy to byssus production so that more energy is conserved for other life processes such as reproduction.

In summary, mussels were able to discriminate chemical cues released from predators maintained on different diets and respond accordingly to the level of predation risk. Those maintained on a diet of conspecific mussels produced the largest number of byssal threads that were also the longest and thickest. The ability to discriminate between levels of predation risk by diet-dependent chemical cues from predators allows mussels to respond according to the level of the risk and, hence, to maximize efficiency of energy utilization. The short response time in byssal thread production enhances the mussel's ability to react appropriately against predation when the intensity changes with the tides.

Abstract Methyl eugenol (ME) is a natural phenylpropanoid highly attractive to oriental fruit fly *Bactrocera dorsalis* (Hendel) males. The flies eagerly feed on ME and produce hydroxylated metabolites with both pheromonal and allomonal functions. Side-chain metabolic activation of ME has long been recognized as a primary reason for hepatocarcinogenicity of this compound on rodents. In an attempt to develop a safer alternative to ME for fruit fly management, we developed a fluorine analog 1,2-dimethoxy-4-(3-fluoro-2-propenyl)benzene (I), which, in earlier field tests, was as active to the oriental fruit fly as ME. Now we report that *B. dorsalis* males are not only attracted to, but also eagerly consume (up to ~1 mg/insect) compound I, thus recognizing this fluorinated benzene as a close kin of the natural ME. The flies metabolized the fluorine analog I in a similar fashion producing mostly two hydroxylated products, 2-(3-fluoro-2-propenyl)-4,5-dimethoxyphenol (II) and (*E*)-coniferyl alcohol (III), which they stored in rectal glands. However, the introduction of the fluorine atom at the terminal carbon atom of the double bond favors the ring hydroxylation over a side-chain metabolic oxidation pathway, by which coniferyl alcohol is produced. It also appears that fluorination overall impedes the metabolism: at high feed rate (10 μ l per 10 males), the flies consumed in total more fluorine analog I than ME but were unable to metabolize it as efficiently as ME.

Introduction

The oriental fruit fly *Bactrocera dorsalis* (Hendel) is a wide-spread pest of a broad range of tropical, subtropical, and temperate host plants (US Department of Agriculture, 1983; White and Elson-Harris, 1992). Males of *B. dorsalis* are strongly attracted to and compulsively fed on methyl eugenol (ME) (Steiner, 1952), a commonly occurring plant phenylpropanoid (Metcalf, 1990). ME is also a common component of spices and is being used as food-flavoring agent at low concentrations (Hall and Oser, 1965). The use of ME in traps and killing stations assures successful detection, control, and eradication of the oriental fruit fly populations worldwide (Steiner et al., 1965; Koyama et al., 1984). The attraction to and consumption of ME by *B. dorsalis* and sibling species of the *dorsalis* complex, *B. papayae* and *B. carambolae*, have an ecological significance in the fly's communication system. It has been demonstrated that mature males after feeding on ME produced metabolites, mostly 2-(2-propenyl)-4,5-dimethoxyphenol (IV) and (*E*)-coniferyl alcohol (III), that display pheromonal and allomonal properties (Nishida et al., 1988a,b; Tan and Nishida, 1996). In addition, ME-acquired males have an earlier onset of courtship and are sexually more competitive than ME-deprived males (Tan and Nishida, 1996, 1998; Shelly, 2000).

Posing a potential problem to the continued use of ME in area-wide pest management programs are reports indicating that it causes hepatic tumors in mice (Miller et al., 1983), induces intrachromosomal recombination in a yeast assay (Schiestl et al., 1989), and elicits an abnormal response in a bacterial DNA repair test (Sekizawa and Shibamoto, 1982). The National Toxicology Program (NTP), US Department of Health and Human Services, evaluated ME and found that given orally to rats, it induced liver and stomach tumors in both sexes and kidney, mammary gland, and skin tumors in males (NTP, 1998). Recently, NTP listed ME as reasonably anticipated to become a human carcinogen based on sufficient evidence of its carcinogenicity in experimental animals (NTP, 2002). In 2001, the Expert Panel of the Flavor and Extract Manufacturers' Association performed a comprehensive review of all data relevant to safety evaluation of ME and concluded that daily intake of threshold doses that were carcinogenic in rodents was much higher than anticipated in human dietary intake. Hence, its potential to induce hepatotoxicity and carcinogenicity through dietary intake was expected to be negligible (Smith et al., 2002).

Since early warnings about the carcinogenicity of ME, a number of compounds have been evaluated as attractants for *B. dorsalis* (Mitchell et al., 1985; Khrimian et al., 1993, 1994; Liquido et al., 1998). In 1994, we discovered a fluorine analog, (*E*)-1,2-dimethoxy-4-(3-fluoro-2-propenyl)benzene (*I-E*), which in short field tests was as attractive as and more persistent than ME and, remarkably, was about twice as active as the *Z* isomer (Khrimian et al., 1994; Liquido et al., 1998). Metabolic activation of ME and production of 1'-hydroxy metabolite through enzymatic side-chain hydroxylation has been demonstrated as primarily responsible for hepatotox-

icity and carcinogenicity of ME (Smith et al., 2002). Earlier, we speculated that introduction of fluorine into the allylic group of ME might enhance its metabolic stability (Khrimian et al., 1994). Whether or not that was the case, the fluorine analog I showed reduced toxicity and reduced recombinogenicity in the yeast deletion assay compared to ME (Brennan et al., 1996). From the time NTP updated the list of carcinogens (NTP, 2002), we started to more vigorously pursue studies on fluoroanalog I as an alternative to ME for detection and control of oriental fruit fly. Here, we report on feeding behavior and metabolism of 1,2-dimethoxy-4-(3-fluoro-2-propenyl)benzene in *B. dorsalis* as well as its new, economical synthesis.

Methods and Materials

Insects

Laboratory-reared oriental fruit flies (strain: Punador initiated in 1988–1989 and monitored by mating and survival tests) were obtained from the USDA-ARS-PBARC rearing facility in Honolulu, HI, USA. Pupae (60 ml) were placed in a screened aluminum cage (30 × 30 × 30 cm) and allowed to emerge. Flies were given water, sugar, and hydrolyzed yeast protein and held in a room at 25–26°C, 50–70% rh, and a 12:12-hr light/dark cycle.

Chemicals

All reagents and solvents were purchased from Aldrich Chemical Co. unless otherwise specified. Tetrahydrofuran (THF) was distilled from sodium benzophenone ketyl. Methylene chloride was distilled from calcium hydride. Coniferyl alcohol was prepared from ferulic acid (Quideau and Ralph, 1992), 2-(2-propenyl)-4,5-dimethoxyphenol (IV) was synthesized from 3,4-dimethoxyphenol (Benbow and Katoch-Rouse, 2001), and 3,4-dimethoxyphenylacetaldehyde was made from veratraldehyde (Ban and Oishi, 1958). Specific caution is necessary because osmium tetroxide is highly toxic and benzene is a carcinogen.

1,2-Dimethoxy-4-(3,3-difluoro-2-propenyl)benzene (V)

A 1-l three-neck flask equipped with a mechanical stirrer, dropping funnel, thermometer, and N₂ inlet was flashed with N₂ and loaded with hexamethylphosphorous triamide ([(CH₃)₂N]₃P, 70 ml, 0.387 mol). A solution dibromodifluoromethane (18 ml, 0.197 mol) in dry THF (350 ml) was added dropwise at 0°C under N₂ atmosphere. A thick white paste was formed close to the end of addition. The mixture was warmed to room temperature (RT) and stirred for another 30 min. A solution of 3,4-dimethoxyphenylacetaldehyde (17.4 g, 0.097 mol) in dry THF (80 ml) was added slowly at 25°C, whereupon the temperature was maintained at 25–30°C by cooling in a water bath. The yellowish suspension was stirred 1 hr at RT (or until TLC showed the completion of reaction), poured into the ice water (~600 ml), and extracted with hexane/ether, 1:1 (4 × 200 ml). The organic layer was washed with water (2 × 100 ml), dried (Na₂SO₄), and evaporated. The remainder was distilled in vacuum to furnish 18.03 g (87%) V of 98% purity. ¹H NMR: 3.27 (br. d, J = 8.0 Hz,

CH₂), 3.85 and 3.87 (both s, CH₃O), 4.37 (dtd, $J_{\text{HF-trans}} = 25.0$, $J_{\text{HF-cis}} = 2.0$ Hz, CH₂CH=C), 6.65–6.85 (m, arom, 3H). GC-MS (EI): 214 (M⁺, 100%), 199 (12), 183 (31), 77 (19). Anal. found: C 61.54; H 5.61. C₁₁H₁₂F₂O₂ requires C 61.67 and H 5.66.

1,2-Dimethoxy-4-(3-fluoro-2-propenyl)benzene (I)

A solution of Red-Al[®] (48 ml, 70% w/w in toluene, $d = 1.036$, 3.4 M) was added slowly to a solution of V (17.00 g, 0.08 mol) in dry benzene (350 ml) at 0–5°C under N₂. Reaction mixture was warmed to 25°C and stirred for 20 hr or until GC indicated the completion of reduction. The mixture was poured into ice water and acidified with concentrated HCl. The organic layer was separated, and the aqueous was extracted with ether/hexane, 1:1 (2 × 100 ml). Combined organic extracts were washed with brine, dried, and distilled to give 14.50 g (92%) I (99% pure, *E/Z* 88:12); b.p. 55–56°C/0.05 mm Hg. ¹H NMR and MS spectra were identical to those described earlier (Khrimian et al., 1994).

2-(*tert*-Butyldimethylsilyloxy)-4,5-dimethoxyphenylacetaldehyde (VI)

Triethylamine (2.96 g, 29.25 mmol) followed by *tert*-butyldimethylsilyl triflate (6.19 g, 23.4 mmol) was added to a solution of IV (3.78 g, 19.50 mmol) in CH₂Cl₂ (40 ml) at 0°C. The mixture was allowed to warm to RT and was diluted after 2 hr with ether (150 ml) and washed with brine (3 × 30 ml). The organic layer was dried (Na₂SO₄), filtered, concentrated *in vacuo*, and purified by flash chromatography on SiO₂ (hexanes/ethyl acetate, 20/1 to 5/1) to yield a silyl ether of I (5.34 g, 89% yield, 99% pure). GC-MS (EI): 308 (M⁺, 93%), 251 (100), 223 (76), 220 (27), 177 (20), 73 (68). A solution of OsO₄ (508 mg, 2 mmol) in acetone (40 ml) was added to a solution of the silyl ether (3.08 g, 10 mmol) in ether (200 ml). The resulting dark-brown solution was stirred for 10 min prior to addition of water (200 ml). Finely powdered NaIO₄ (21.39 g, 0.1 mol) was added in five portions over a period of 5 hr. The mixture was stirred for additional 3 hr, diluted with ether (100 ml), and the layers were separated. The organic phase was washed with brine, dried (Na₂SO₄), and purified by flash chromatography on SiO₂ (hexane/ethyl acetate, 10:3) to yield VI as a brown oil (2.50 g, 81%) of 99% purity. GC-MS (EI): 310 (M⁺, 25%), 281 (21), 253 (100), 238 (37), 222 (74), 209 (16), 195 (30), 75 (49), 73 (75).

1-(*tert*-Butyldimethylsilyloxy)-4,5-dimethoxy-2-(3,3-difluoro-2-propenyl)benzene (VII)

CF₂Br₂ (1.52 ml, 16.65 mmol) was added to a solution of hexamethylphosphorous triamide (6.0 ml) in THF (30 ml) at 0°C. The mixture was stirred at RT for 1 hr, and a solution of aldehyde VI (2.53 g, 8.20 mmol) in THF (10 ml) was added. After stirring for 1.5 hr and workup described for the compound V, the crude mixture was chromatographed (hexane/ethyl acetate, 8:1) to furnish benzene VII (1.81 g, 64%) of 99% purity. ¹H NMR: 0.21 [s, 6H, Si(CH₃)₂], 1.00 (s, 9H), 3.21 (br. d, 2H, $J = 8.0$ Hz, CH₂), 3.80 and 3.82 (both s, CH₃O), 4.33 (dtd, $J_{\text{HF-trans}} = 25.0$, $J_{\text{HF-cis}} = 2.0$ Hz, CH₂CH=C), 6.38 (s, 1H, arom), 6.62 (s, 1H, arom). GC-MS (EI): 344 (M⁺, 51%), 243 (100), 77 (18), 73 (20). Anal. found: C 59.22; H 7.88. C₁₇H₂₂F₂O₃Si requires C 59.27 and H 7.61.

2-(3-Fluoro-2-propenyl)-4,5-dimethoxyphenol (II)

A solution of difluorobenzene **5** (1.758 g, 5.11 mmol) and Red-Al[®] (4.46 ml of 3.33 M in toluene, 14.85 mmol) in dry benzene (20 ml) was refluxed, and the reaction progress was monitored by GC. After about 48 hr, the mixture was taken into ice water, acidified with 20% HCl, and extracted with ether/hexane, 1:1. Combined organic extracts were washed with brine, dried, and concentrated. The remainder was treated at 0°C with a THF solution of tetrabutylammonium fluoride (3.0 ml, 1 M) and gradually warmed to RT to complete the removal of TBDMS protecting group. Water was added, and the products were extracted with ether, dried, and concentrated. Flash chromatography on SiO₂ with hexane/ethyl acetate, 1:1, afforded phenol II (0.960 g, 89%) with 87:13 ratio of *E* and *Z* isomers. M.p. 68–69°C. ¹H NMR: 3.18 (br. d, 2H, *J* = 7.2 Hz, CH₂-*E*), 3.37 (br. d, 2H, *J* = 7.2 Hz, CH₂-*Z*), 3.80 and 3.81 (both s, CH₃O), 4.70 (OH), 4.92 (dtd, *J*_{HF-trans} = 46.0, *J*_{HH-cis} = 4.2 Hz, CH₂CH-*Z*), 5.53 (ddt, *J*_{HF-cis} = 18.2, *J*_{HH-trans} = 11.0 Hz, CH₂CH-*E*), 6.41 and 6.61 (both s, arom, II-*E*), 6.43 and 6.64 (both s, arom, II-*Z*), 6.56 (br. dd, *J*_{HF} = 85.5, *J*_{HH-trans} = 11.0 Hz, CFH-*E*). GC-MS (EI) II-*E*: 212 (M⁺, 100%), 197 (21), 181 (9), 69 (27), 59 (19). *Z* isomer had almost identical mass spectrum. Anal. found: C 62.26; H 6.36. C₁₁H₁₃FO₃ requires C 62.26 and H 6.17.

Analytical Procedures

¹H NMR spectra were recorded at 300 MHz in CDCl₃ with TMS as an internal standard on a Bruker QE-300 spectrometer. Chemical shifts are reported in δ units. GC analyses were performed on a Shimadzu 17A gas chromatograph equipped with a flame ionization detector, an autosampler AOC-20s, and autoinjector AOC-20i. Hydrogen was used as carrier gas at 1.2 ml/min. RTX-1701 column (60 m × 0.25 mm, Restek Corporation) was used for routine analyses of synthesized and reference chemicals. HP-5 column (30 m × 0.25 mm × 0.25 μm film) was used for quantitative analyses of fly extracts in a splitless mode. Column temperature was maintained at 100°C for 2 min and then raised to 260°C at 10°C/min. Electron ionization (EI) mass spectra (70 eV) were obtained with an Agilent Technologies 5973 mass selective detector interfaced with 6890 N GC system equipped with a 30 m × 0.25 mm i.d. × 0.25 μm film HP-5MS column. Helium was used as the carrier gas at 1 ml/min. TLC analyses were conducted on Whatman AL SIL G/UV plates using hexane/ethyl acetate as a mobile phase. For visualization of spots, 20% ethanol solution of phosphomolybdic acid and/or UV light was used. Elemental analyses were conducted by Galbraith Laboratories (Knoxville, TN, USA).

Bioassay

In test no. 1, 50 laboratory-reared mature oriental fruit-fly males were evenly placed in five ~2-lb plastic containers (10/container) equipped with water inserts and screened covers. Flies in two containers were offered 10 μl ME (2 × 5 μl) on a slip of filter paper (25 × 5 mm) taped to a blank water pot. Twenty flies in two other cages were offered the fluorine analog I (10 μl/cage), and 10 males in the last cage were presented with a filter paper containing 10 μl water. The behavioral observations

(landing and feeding on the source) were recorded, and filter papers were removed after about 20 min. Water containers were replaced, and the flies were left overnight with a sugar cube on the cover. After 18 hr, the rectal glands of 10 flies each fed with ME and I as well as 10 control flies were dissected and placed in conical plastic vials with 20 μ l ethanol. The glands were crushed with a wire rod, sealed with parafilm, and centrifuged at \sim 4000 rpm for 10 min. Six hours later (or 24 hr into the test), the remaining 10 flies fed with ME and I were dissected. Three flies fed with fluorine analog I were dead at the time of second dissection. All 20 extracts were analyzed by GC-MS by splitless injection of 1- μ l solutions. The abdomens of 17 flies fed with I that were alive after 24 hr were separated from other body parts, placed in 20 μ l ethanol, crashed, and analyzed by TLC using hexane/ethyl acetate, 1:1. Then, the extracts were evaporated and flash-chromatographed on a short SiO₂ column (30 \times 5 mm) with hexane/ethyl acetate, 3:1. The fractions containing unmetabolized fluorine analog I were further combined, concentrated to ca. 1 ml, and quantified by GC using external standards of I. The remaining body parts (e.g., thorax, head, etc.) of 17 flies fed with I were combined, crashed, placed in ethanol (\sim 1 ml), and analyzed by TLC. Only contents of rectal glands of ME-fed flies were analyzed by GC-MS analogous to fluorine analog I-fed flies. A standard solution of coniferyl alcohol (20 ng/ μ l) was used to estimate the quantities of metabolites.

Test no. 2 was conducted analogously to test no. 1 with 10 flies presented with 10 μ l of ME, another 10 flies offered 10 μ l of fluorine analog I, and 10 flies offered water as control. The presentation time was 40 min. After 24 hr, rectal glands were dissected, placed in 100 μ l EtOH, treated as described above, and analyzed by GC with external standards of III, IV, and II. The other body parts for each fly, including abdomens, were individually placed in 20 μ l EtOH, analyzed by TLC, and then separately chromatographed on SiO₂ as described in test no. 1. The fractions containing starting ME and I were analyzed by GC using external standards.

In test no. 3, 10 flies were presented with 1.0 μ l (10 μ l of 10% v/v hexane solution) of ME and I, and 10 flies were offered water as a control. After 24 hr, rectal gland extracts were obtained in 220 μ l EtOH and analyzed by GC using standards of III, IV, and II. Abdomens were separated from other body parts, extracted with 200 μ l ether, evaporated to \sim 50 μ l, and analyzed by TLC. The abdomen extracts from FA-fed flies were further analyzed by GC. The other body parts were taken into 200 μ l ether, evaporated to about 50 μ l, and analyzed by TLC.

Data Analysis

Mean ratios were analyzed by using PROC GLM followed by a Tukey's test for mean separation. Significant differences were determined at the $P < 0.05$ level. Analysis was run on SAS version 8.2 (SAS Institute, 1990, Cary, NC, USA).

Results

Synthesis

Earlier, we synthesized both *E* and *Z* isomers of 1,2-dimethoxy-4-(3-fluoro-2-propenyl)benzene (I) utilizing Wittig reactions of 3,4-dimethoxyphenylacetaldehyde

with stabilized ylides (Khrimian et al., 1994). Although the methods proved satisfactory for small syntheses, we envisioned difficulties in scaling up, especially in the case of *I-E* isomer, the synthesis of which required expensive reagents and multiple chromatographic purifications. Now we report on a more efficient two-step synthesis of **I** in a total 80% yield from 3,4-dimethoxyphenylacetaldehyde (Scheme 1). Our new synthesis utilized a straightforward Wittig difluoroolefination with a subsequent selective reduction of intermediate difluoroolefin (Hayashi et al., 1979). Notably, both intermediate and final products were purified via distillation that renders the method amenable for scale-up. We obtained about the same ratio of *I-E* and *I-Z*, 88:12, as in our previous approach and plan to continue field studies with this material, which is now being manufactured by a contractor. The same synthetic strategy was utilized to make the principal metabolite **II** that is formed by feeding *B. dorsalis* males with fluorobenzene **I**. Synthetic allylphenol **IV**, which happened to be a key metabolite of oxidative biotransformation of ME in *B. dorsalis*, served as a starting material in the second synthesis (Scheme 1). A TBDMS protection of phenol **IV** with subsequent oxidative cleavage of the double bond following Benbow and Katoch-Rouse, 2001 furnished aldehyde **VI** in a 72% isolated yield. Difluoroolefination of **VI** with HPMT/CBr₂F₂ followed by selective reduction of **VII** with Red-Al[®] gave the mixture of *II-E* and *II-Z* in 87:13 ratio. GC retention times of the geometric isomers and respective mass spectra matched those isolated from *B. dorsalis*.

Feeding Behavior and Metabolism

In test no. 1, we noticed that eight to nine *B. dorsalis* males touched the filter paper impregnated with 10 μ l of **I** and started feeding on it. In case of ME, the number of flies that contacted the source was five to six, and no flies landed on filter paper treated with water. After about 20 min, the flies left the source in both treatments, and feeding was discontinued. By the time of dissection of first 10 individuals (18 hr), all flies in both treatments and in control were healthy, but
