

POTATO EXPRESSING BEETLE-SPECIFIC
Bacillus thuringiensis Cry3Aa TOXIN REDUCES
PERFORMANCE OF A MOTH

Abstract—Expression of the *Bacillus thuringiensis* beetle-specific toxin Cry3Aa, which renders a genetically modified potato cultivar resistant to the Colorado potato beetle *Leptinotarsa decemlineata*, exerts a deleterious effect on the polyphagous moth *Spodoptera littoralis*. The caterpillars of *S. littoralis* feed less and produce smaller pupae on the genetically modified cultivar (NewLeaf Superior) than on the parental nontransgenic cultivar (Superior). The conversion efficiencies of total dry matter, combustion heat, carbon, and nitrogen from leaves to insect biomass are similar on both cultivars. In spite of similar food utilization and a relatively small difference in the body mass at pupation, female adults that developed from caterpillars fed on NewLeaf Superior lay a mean of 309 eggs compared to a mean of 713 eggs deposited by females that developed from caterpillars fed on Superior. Because of this difference and a simultaneous reduction in fertility (egg hatchability) from 78 to 48%, a pair of adults that fed as larvae on NewLeaf Superior produces only 148 larvae, whereas a pair of adults that fed as larvae on Superior produces 556 larvae. We suggest that small amounts of Cry3Aa that accumulate in insect tissue and persist until the adult stage are responsible for the decline in reproduction.

Key Words—*Bacillus thuringiensis*, *Spodoptera littoralis*, *Leptinotarsa decemlineata*, genetically modified crops, Cry3Aa, Bt applications, insect digestion, pest population growth.

INTRODUCTION

The gram-positive soil bacterium *Bacillus thuringiensis* Berliner (Bt) produces an array of insecticidal toxins that are denoted with the Greek letters α , β , γ , and δ (Heimpel, 1967). The most important δ -toxins are known as Cry proteins in reference to their crystalline nature (Yamamoto, 2001). More than 150 Cry proteins are produced by different Bt strains (Schnepf et al., 1998), and each of them acts lethally on a certain range of insect species (Zalunin et al., 2004). For example, toxins of the Cry1A class are lethal for certain Lepidoptera, whereas those of the Cry3A and Cry11A classes are lethal for Coleoptera and Diptera, respectively. Toxin crystals formed during bacterial sporulation are dissolved when the spores germinate in the insect gut lumen; the toxin is activated following partial hydrolysis by insect digestive enzymes. Activated Cry proteins bind to receptors in the membrane of midgut cells and affect formation of pores for uncontrolled ion movement (Whalon and Wingerd, 2003). The pH gradient between gut lumen and hemolymph is disrupted, and the affected gut cells are lysed. The insect usually dies of starvation and septicemia rather than as a result of direct Bt toxicity.

The peptidic nature, high activity on specific target species, and relative safety to domestic animals and man make Cry toxins ideally suited for genetic modifications aimed at protecting agricultural crops against insect pests. Potato plants carrying the gene for the Cry3Aa toxin represented the first transgenic crop produced for commercial use (Perlak et al., 1993). This “Bt potato” proved fully resistant to the target pest, the Colorado potato beetle *Leptinotarsa decemlineata* (Say) (CPB) (Whalon and Wierenga, 1994; Arpaia et al., 2000; Reed et al., 2001). Field observations revealed that the predators of CPB and other beneficial insects were not affected (Riddick and Barbosa, 1998; Reed et al., 2001; Duan et al., 2004). However, laboratory studies with maize expressing Cry1Ab and fed to caterpillars showed that the toxin considerably enhanced larval mortality of the lacewing *Chrysoperla carnea* Stephens (Neuroptera: Chrysopidae), which had preyed on the caterpillars (Hilbeck et al., 1998a). Lethality of high toxin doses for *C. carnea* was confirmed by adding the toxin to a liquid diet of this predator (Hilbeck et al., 1998b).

The Bt maize cultivar MON810, which was reported to contain 7.9–10.3 ppm Cry1Ab in the leaves (Dutton et al., 2003), has been studied as a food source for the Egyptian armyworm *Spodoptera littoralis* (Boisd.) (Lepidoptera: Noctuidae) (EAW). No deviations from the controls were observed in the performance of EAW on the Bt maize (Hilbeck et al., 1998a), and in experiments with a semiartificial diet, the intoxication of EAW caterpillars was obtained only with a high concentration (100 ppm) of Cry1Ab (Hilbeck et al., 1999). An equally high concentration was needed to affect *C. carnea* when the toxin was administered to the artificial diet of this predator (Hilbeck et al., 1998b). These

data suggest that the lethality to *C. carnea* from prey fed on Bt maize is hardly a result of a massive accumulation of toxin. If this were the case, then the prey itself would be intoxicated. It is more likely that low toxin doses, which the caterpillars receive with their plant food, cause some subtle changes that are not manifested in an increased death rate of the caterpillars, but rather render these larvae less suitable as lacewing prey. A number of other studies have indicated that the interactions between Bt toxins and the nontarget insect species are complex and insufficiently understood (Scriber, 2004). In the present paper, we show that a low expression level of the beetle-specific toxin Cry3Aa in potato affects the physiology of EAW developing on the leaves. The effect is small and not easy to detect, but may alter long-term population dynamics of EAW.

METHODS AND MATERIALS

Potato Cultivation. Minitubers of the transgenic cultivar NewLeaf Superior, which carries a *Cry3Aa* Bt-toxin gene construct, and its parental, non-transgenic cultivar Superior, were obtained from Monsanto Co. (St. Louis, MO, USA). Subsequent potato generations were propagated as plant explants in agar cultures. Rooted explants were transferred to soil in 100-ml pots and later replanted to 10-l containers. Plants were grown in a greenhouse at 20°C and natural light from May to August; artificial illumination (16 hr/d) was used during the winter months.

Insect Handling. The stock culture of the EAW was derived from an Egyptian field population and maintained in the laboratory at 20–23°C and 16:8 hr (light/dark) photoperiod for 10–15 generations. The diet was *Manduca-Heliothis* Premix (Stonefly Industries Inc., Bryan, TX, USA), which is a mixture of wheat germ and agar. The four experiments described in this paper were conducted in July–August and October–November 2003, and in March–May and September–October 2004. Groups of five newly ecdysed caterpillars of the penultimate instar were transferred to potato leaves cut from nonflowering plants that were at least 20 cm tall. Each group received leaves (one per day) cut from the base to the top of a single plant. Unless stated otherwise, each experiment consisted of six groups of larvae. Food consumption, frass production, and insect body weight were measured daily. Newly emerged adults were collected, and groups of two to three males and two females were kept until death in paper cylinders (20 cm high, 10-cm diam) closed on both sides with a Petri dish. The adults were provided with tubes filled with water and diluted honey. Egg masses laid on the paper cylinder were cut out, and the numbers of hatched and unhatched eggs were counted.

Cry3Aa Quantification. The amounts of toxin in the potato leaves, the insect bodies, and the insect frass were measured with Bt-Cry3A ELISA PathoScreen

kit (Agdia Inc., Elkhart, IN, USA). One-gram aliquots of leaves and frass and 290- to 980-mg samples of pupae and adults were crushed in a mortar in 9 ml of extraction buffer provided with the kit. The homogenates were centrifuged at $15,000 \times g$ for 10 min, and 100- μ l aliquots of the supernatants were taken for enzyme-linked immunosorbent assay (ELISA), which was performed according to the manufacturer's instructions.

Food Conversion Analysis. In one experiment containing six groups of five insects on each potato cultivar, samples of the potato leaves, the insects, and their frass were dried, and the powdered dry matter was used for carbon and nitrogen quantification and for combustion calorimetry. Carbon and nitrogen were quantified with the elemental analyzer NC 2100 Soil Analyzer (Thermo-Quest, Milan, Italy). Energy content was measured by burning the samples in oxygen at 30 bars in an IKAC 700T calorimeter (IKA Werke, Janke & Kunkel, Stauffen, Germany). The efficiency of food utilization was evaluated and described according to Slansky and Scriber (1985) based on dry matter analysis from two experiments. The index M , called the metabolic loss ($M = I - F - B$, I = ingested food; F = frass; B = biomass), indicates how much of the digested food was not used for biomass accumulation. Approximate digestibility is the ratio on a percentage basis of digested to ingested food, i.e., $AD = [(I - F)/I] \times 100\%$. Gross growth efficiency or efficiency of ingested food conversion to biomass (ECI) indicates the ratio of body mass increase to the amount of ingested food, i.e., $ECI = (B/I) \times 100\%$. Net growth efficiency of the conversion of digested food to biomass represents the ratio of body mass increment to digested food, i.e., $ECD = [B/(I - F)] \times 100\%$.

Data Presentation and Analyses. Data are presented as mean \pm standard error. Comparisons of the growth and food utilization parameters on the Bt and non-Bt potatoes were performed with a t -test ($\alpha = 0.05$). Female fecundity and fertility were examined in three independent experiments and were analyzed by two-way analysis of variance (ANOVA); correlation of these parameters with the pupal body weight was examined with two-way analysis of covariance (ANCOVA). These analyses were conducted using Statistica 6 (StatSoft Inc., Tulsa, OK; <http://www.statsoft.com>).

RESULTS

Larval Growth Rate and Cry3Aa Turnover. Transfer of EAW caterpillars from the Premix diet to potato leaves caused a reduction of their growth rate. The insects retained on Premix reached a maximal larval body weight around 700 mg (data not shown), whereas those transferred to the potato leaves of either cultivar reached a weight of about 500 mg (Figure 1). The total duration of the penultimate and last larval instars was 11 d on both cultivars. Larval

mortality averaged 1.4% on both cultivars, whereas pupal mortality was 2.2% on the Superior and 4.4% on NewLeaf Superior. The growth of larvae varied among the four experiments, but invariably they grew bigger on Superior than on NewLeaf Superior. In one experiment (Figure 1), the insects feeding on Superior reached a pupal weight of 227 ± 4.9 mg, and those grown on NewLeaf Superior reached a pupal weight of 205 ± 6.5 mg. These two values are significantly different ($P = 0.02$).

The uptake of Cry3Aa was examined in another experiment in which the insects reached a mean pupal weight of 282 ± 9.8 mg on the Superior and 258 ± 8.2 mg on the NewLeaf Superior leaves ($P = 0.015$). In this experiment, the larvae consumed 3856 ± 97 mg Superior and 3307 ± 94 mg NewLeaf Superior leaves per specimen ($P = 0.01$). Given a mean Cry3Aa leaf content of 1.43 ng/g, each caterpillar reared on NewLeaf Superior ingested nearly 5 μ g of the toxin (Table 1). About 1.5 μ g was discarded with the feces, and most of the remainder was apparently degraded to the extent that it could not be detected with our ELISA. However, between 10 and 60 ng detectable Cry3Aa was retained in each female pupa, and approximately 1% of this amount remained in female adults analyzed in the middle of their ovipositional period. No toxin was detected in male pupae. The leaves of Superior contained no Cry3Aa, and the insects feeding on this cultivar were, therefore, not analyzed for the toxin.

Leaf Matter Conversion to Insect Biomass. EAW development on NewLeaf Superior was associated with slightly lower food consumption than it was

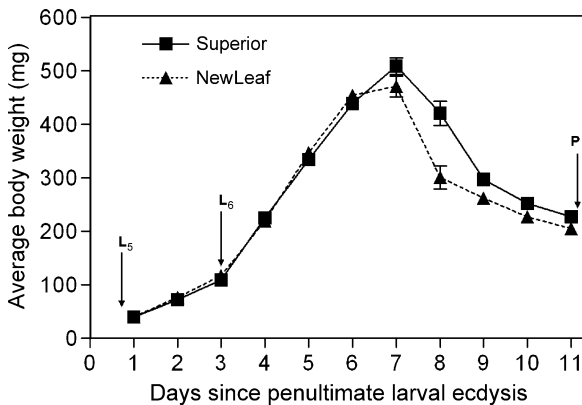

FIG. 1. Growth of *Spodoptera littoralis* from the beginning of the penultimate larval instar (day 1) until pupal ecdysis (day 11) on leaves of the potato cultivars Superior and NewLeaf Superior, respectively. Six groups of five larvae were followed on each potato cultivar (i.e., $N = 6$). Vertical lines represent standard errors. Arrows indicate approximate times (± 6 hr) of ecdyses to the fifth larval instar (L_5), sixth (last) larval instar (L_6), and pupa (P).

on Superior (Table 1), but it was not clear if this alone was responsible for the lower pupal weights attained by larvae grown on the NewLeaf Superior cultivar. Analysis of the conversion efficiency of food dry matter confirmed that caterpillars reared on the Superior cultivar consumed more leaf material ($P < 0.001$) and grew larger ($P = 0.007$) than those feeding on the NewLeaf Superior cultivar (Table 2). The mass of Superior leaves was assimilated more ($AD = 54$) than that of NewLeaf Superior ($AD = 48$), and this difference was marginally significant ($P = 0.051$). Surprisingly, most of the extra matter ingested by larvae from the Superior leaves dissipated as metabolic losses (cf. M values in Table 2). Higher metabolic costs on the nontransgenic potato might have been caused by the intake of a larger amount of food and possibly also by more efficient degradation of allelochemicals from this cultivar. The efficiencies of ingested (ECI) and digested (ECD) food to biomass were not significantly different between the two cultivars, suggesting that the difference in the amount of food consumed was the primary cause of the different growth rates.

Quantitative Analysis of the Dry Matter. Similar conversions of leaf dry matter to body biomass did not exclude differences in the availability and utilization of specific food components. This possibility was examined by analyzing

^aSample size (N) is given in brackets (a group of five insects was used for each growth parameter measured, and 1 g of plant or insect material was used for each Cry3Aa measurement). Results are presented as means ± standard errors. Because six attempts to detect Cry3Aa in the leaves of the Superior cultivar were all negative (n.d. = not detected), insects grown on this cultivar were not analyzed for the presence of Cry3Aa. No Cry3Aa was found in male pupae and adults. When appropriate, means from each cultivar were compared with a t -test ($\alpha = 0.05$).

^aSix groups of insects (*N*) were analyzed for all parameters. Each group included five insects, but the data (means ± standard errors) are expressed per specimen.

B, body mass increment between penultimate instar larva and newly ecdysed pupa; *I*, mass of food consumed during the experiment; *F*, discarded frass and exuviae; *M*, metabolic loss; AD, approximate digestibility, i.e., ratio of digested to ingested food; ECI, conversion efficiency of ingested food to biomass, i.e., ratio of body mass increment to ingested food; ECD, conversion efficiency of digested food to biomass, i.e., ratio of body mass increment to digested food.

the carbon and nitrogen content and the combustion energy in larvae, leaves, frass, and pupae (Table 3). The penultimate instar larvae were analyzed for all parameters after feeding on the Premix diet and not comparatively against the two cultivars. The carbon content in leaf dry matter ranged from 36.5 to 40.2% in both cultivars; the means were not significantly different. The nitrogen content of leaves ranged from 5.21 to 5.97% in both cultivars; the means were not significantly different. The mean combustion heat values (energy content) in the leaves of each cultivar were also not significantly different. The variation in all three parameters was probably because, in large part, of the leaf age and the physiological status of the plant. Thus, the nutritional value of the Superior and the NewLeaf Superior potato leaves is virtually identical.

In the frass, the carbon content, nitrogen content, and combustion heat were not significantly different when compared across the two cultivars (Table 3). The carbon content of the frass was lower than that of the leaves, whereas the nitrogen content of the frass was about the same as that of the leaves. This suggests that the insects assimilated plant compounds containing nitrogen somewhat less efficiently than the non-nitrogenous organic materials. The combustion heat of the frass was only 85% of that of the leaves, irrespective of the cultivar.

As was the case with leaves and frass, the mean measures of carbon, nitrogen, and energy content from pupal dry matter were not significantly different between the two cultivars (Table 3). However, the carbon content was

Frass		13,500 ± 318 (9)	13,517 ± 195 (8)	$t = 0.05$; $P = 0.965$
Pupal body		25,105 ± 286 (9)	24,768 ± 184 (11)	$t = 1.06$; $P = 0.302$

^a Table entries are means ± standard errors (N in parentheses). Newly ecdysed penultimate instar larvae were assayed just prior to their transfer from the semiartificial diet to either of the potato cultivars; pupae were assayed just subsequent to ecdysis from last instar larvae. The carbon and nitrogen contents are given in dry matter percentage; the combustion heat in J/g dry matter.

higher, and the nitrogen content was lower in pupae when compared to newly ecdysed penultimate instar larvae. The combustion heat of pupae fell short of the value found in larvae at the beginning of the penultimate instar.

Mortality and Reproduction of EAW Grown on Potato Leaves. Caterpillars that fed continuously on the Premix diet perished only exceptionally and produced adults yielding 1077 ± 91 viable eggs per female. However, when the newly ecdysed penultimate instars were transferred from Premix to the potato leaves, 3.6% of insects reared on Superior and 5.8% of those reared on NewLeaf Superior perished prior to adult eclosion. Because the mortality varied greatly and the difference was relatively small, it was disregarded in our investigation of the fertility of emerged adults. The fecundity and fertility were measured in three experiments performed several months apart with different generations of EAW and their food plants. Evaluation of the results by two-way ANOVA revealed differences between the three experiments and significant dependence of the level of oviposition (fecundity) and the number of hatched eggs (fertility) on the type of cultivar (Table 4). Interaction between the two factors, cultivar and experiment, was not significant for fecundity but was significant ($F = 6.7$, $df = 2.23$, $P = 0.005$) for fertility. Addition of pupal weight as a continuous predictor in two-way ANCOVA calculations confirmed differences between the experiments and the dependence of female fecundity and fertility on the

^aEAW larvae of different generations (experiments I, II, and III, respectively) were transferred from the semiartificial diet to the potato leaves at the start of the penultimate instar. Emerged adults were grouped by two females and three males, and their reproduction was recorded until death (*N* per experiment is given in parentheses). Two-way ANOVA was used to evaluate the effect of potato cultivar and experiment on the pupal weight, fecundity, and fertility. Correlation between pupal weight and female reproductive characteristics was analyzed with ANCOVA.

potato cultivar. The effect of pupal weight on the reproductive potential was not significant.

Mean female fecundity calculated for all experiments combined was 713 ± 13 eggs on the Superior and 309 ± 8 eggs on the NewLeaf Superior cultivars. With mean egg hatchability of 78 and 48%, respectively, the insects grown on Superior produced 556 and those on NewLeaf Superior only 148 viable progeny per female.

DISCUSSION

The results presented in this report demonstrate that the potato cultivar NewLeaf Superior, which contains the *Cry3Aa* transgene, is a less suitable host

plant for EAW than the nontransgenic parental cultivar Superior. Insects feeding on the transgenic cultivar ingest less food, reach a smaller pupal weight, and yield fewer progeny than those on the nontransgenic cultivar. Lower food consumption accounts for reduced body mass increment, but our statistical analysis showed that smaller body size is not the cause of a nearly 74% reduction of the reproductive potential. The decrease in female fecundity and fertility is highly correlated with the potato cultivar and probably due to an unknown effect of Cry3Aa sequestered in the females. The insects assimilate part of Cry3Aa present in the potato leaves at 1.5 ng/g and accumulate up to 0.2 ng/g Cry3Aa in newly ecdysed female pupae. The major impact of dietary Cry3Aa on EAW, i.e., the fertility reduction, is manifested about 10 d after the termination of feeding when the body content of Cry3Aa is nearly undetectable. We have no explanation for the sex difference in Cry3Aa sequestration.

The reduction of energy content and the low nitrogen assimilation during food passage through the digestive tract indicate that the larvae preferentially utilize carbohydrates, and that some of the nitrogenous compounds present in potatoes are not digestible. The relative differences in carbon and nitrogen content between penultimate instar larvae and pupae are probably caused by the accumulation of fat and other reserves and possibly also by the secretion of thick cuticle in the pupae. The relatively lower combustion heat measured in the pupae might be explained by the accumulation of oxygen-rich sugars, including chitin, in the pupae.

The impact of Cry3Aa on EAW resembles the suppression of fertility caused in CPB by Cry3B expressed in potatoes (Arpaia et al., 2000). The beetles readily consumed the genetically modified plants, but laid virtually no eggs. Their sterility was traced to a low vitellogenin level in the hemolymph, but no explanation could be provided for this effect. The low mortality of CPB consuming Cry3B indicated that lethal disruption of the midgut wall, which is typical for the action of Cry toxins (Whalon and Wingerd, 2003), did not occur. It seems more likely that the toxin somehow penetrated into the hemolymph and deranged functions of the body organs involved in vitellogenin production.

The deleterious effect of Cry3Aa on EAW is surprising because the toxin is regarded as specific for Coleoptera (Knowles, 1994). Deml et al. (1999) observed that the presence of more than 10 ppm of a Cry3A preparation in the diet of several caterpillar species caused mortality, affected food utilization, and reduced larval growth considerably. Validity of these data, however, is undermined by the fact that CPB resisted this Cry3A preparation, indicating that it might have actually been a Cry version active primarily on Lepidoptera. Sublethal effects of various Bt treatments on the nontarget species have been described in several reports (reviewed by Scriber, 2004), but our study is the first in which expression of a presumably inactive toxin in a transgenic food plant is correlated with its sequestration in the affected insect herbivore.

Lepidopteran larvae presumably do not possess specific midgut receptors for Cry3Aa, but this does not fully exclude toxin interaction with the EAW cells. Several α -helices that form the first of the three domains of the Cry proteins are conserved between the moth- and the beetle-specific toxins (Li et al., 1991; Grochulski et al., 1995). Helix 5 from Cry3Aa was shown to insert readily in diverse planar lipid bilayers, to bind to the surface of midgut cells in the fall armyworm *Spodoptera frugiperda* (J.E. Smith), and to kill a cell line derived from the latter species (Gazit et al., 1994). Hence, a plausible explanation for the inhibitory Cry3Aa action on EAW is that the toxin binds to and hampers the digestive functions of midgut cells, thereby reducing food intake and larval body growth. The small toxin amounts that are sequestered may also interfere with some of the cells (trophocytes, follicle cells, fat body cells) intimately involved in the process of egg production. The interference probably occurs during the EAW pupal stage when much of the egg formation takes place.

We cannot exclude the hypothesis that Bt potatoes curb the growth and reproduction of EAW by a mechanism that is indirectly related to Cry3Aa expression. For example, transgene insertion could have modified the expression pattern of various endogenous genes and thereby altered the production of defensive substances such as proteinase inhibitors, alkaloids, etc. A deliberate suppression of the production of proteinase inhibitors in potatoes by means of molecular engineering enhanced the weight gain of the beet armyworm *Spodoptera exigua* (Hübner) by 52–63% and the fecundity by 73% (Ortego et al., 2001). A reverse, i.e., an elevated level of the inhibitors, would probably curb the development of EAW. However, it is unlikely that investment into the production of Cry3Aa in the genetically modified potato would be associated with increased output of other defense compounds. We conclude that Cry3Aa itself causes deterioration of the EAW performance on the NewLeaf Superior cultivar (Hussein et al., 2005). It remains to be examined if an interaction of Cry3Aa with other defense mechanisms contributes to this effect. Simultaneous administration of sublethal doses of a Cry toxin with a neem tree extract exhibited synergism (Trisyono and Whalon, 1999), and this might also occur between Cry3Aa and the solanine alkaloids present in the potato plants.

Whatever the mechanism of reduced EAW performance on the NewLeaf Superior potato, it appears that Cry toxins may exert subtle but potentially cumulative side effects on nontarget insects. The widespread adoption of Bt sprays and the rapidly expanding cultivation of Bt crops require refined ecosystem monitoring before their possible environmental impacts can be fully reconciled. Any pest management program bears a risk of negative environmental impacts that must be weighed against the benefits and compared with the alternative programs (Scriber, 2004). The effects of Bt sprays and of Cry expression in genetically modified plants on target pest species are not identical. For example, CPB adults resist topically applied Bt (i.e., foliar formulations)

containing Cry3Aa (Zehnder and Gelernter, 1989), but are readily eliminated on the transgenic potatoes expressing Cry3Aa (Perlak et al., 1993; Whalon and Wierenga, 1994). Thus, the results of the present study can be extrapolated to Bt sprays only with utmost caution. In fact, they accentuate the need for comparative environmental impact studies of diverse pest treatments.

Acknowledgments—Thanks are extended to Dr. P. Dědič of the Potato Research Institute, Havlíčkův Brod, and Dr. S. Rakouský of the University of South Bohemia, České Budějovice, for the *in vitro* cultures of potatoes. Statistical evaluations were carried out with the kind help of Dr. O. Nedvěd of the University of South Bohemia. The research was performed under the auspices of Institute Research Program Z50070508 and supported by grant 522/02/1507 from the Grant Agency of the Czech Republic.

Abstract—Cattle generally avoid grazing leafy spurge (LS; *Euphorbia esula*), whereas sheep and goats will often eat it. Understanding metabolism of toxic phytochemicals in LS by bovine rumen microflora may help explain why cattle often develop aversions to LS after initially eating it. Toxicity of LS compounds after *in vitro* fermentation with normal vs. antibiotic-modified bovine rumen digesta was evaluated at different lengths of fermentation. Levels of toxic and aversion-inducing ingenols were determined for fermented and nonfermented mixtures of LS and bovine rumen digesta, and the toxicity of an aversion-inducing extract of LS to rumen microbial species that are common in cattle, sheep, and goats was evaluated. Fermentation of LS with bovine digesta increased the toxicity of extracted compounds. Introduction of neomycin (an antibiotic that preferentially inhibits gram-negative bacteria) into the LS and bovine rumen digesta mixtures did not appear to affect toxicities regardless of fermentation length. Levels of ingenol were observed in LS and bovine digesta mixtures (both fermented and nonfermented) that were consistent with levels of ingenols reported for LS. Finally, a toxic extract of LS had little or no negative effect on the growth of several common species of rumen bacteria. The results indicate that LS is not generally toxic to the ruminal bacteria, but that microbial activity in the rumen may be responsible for enhancing LS toxicity to cattle.

Key Words—Cattle, ingenol, leafy spurge, ruminal fermentation, toxicity.

INTRODUCTION

Leafy spurge (LS; *Euphorbia esula* L.) is a problematic invasive plant species that was introduced in North America in the 19th century and now occurs in many areas of the western United States and Canada. Grazing of LS by sheep and goats is considered to be an important management tool, but many observations indicate that cattle eat little LS (Lym and Kirby, 1987; Hein and Miller, 1992). Cattle may initially graze the plant, but they appear to develop an aversion (Kronberg et al., 1993a). In contrast, sheep and goats can maintain good productivity with considerable daily intake of LS (Landgraf et al., 1984; Walker et al., 1994; Kirby et al., 1997).

One possible reason for differences in foraging behavior among ruminant species is differences in metabolism of phytochemicals by the host's ruminal microflora (Kronberg, 1999). Ruminal microbes have the capacity to detoxify some phytochemicals and increase toxicity of others (James et al., 1975; Carlson and Breeze, 1984; Pass et al., 1984; Craig et al., 1992; Duncan and Milne, 1992). Among ruminants, there are striking differences in tolerance of plant toxicants (Smith, 1992). If diet selection differences among ruminants are a result, in part, of differential rumen metabolism of phytochemicals (Kronberg, 1999), cattle may be reluctant to graze LS because their ruminal microbes do not metabolize toxic and aversive LS phytochemicals as do ruminal microbes in goats (Kronberg and Walker, 1993). Among potential toxicants in LS, ingenol and some of its esters occur in LS and are known to induce feed aversions in cattle (Halaweish et al., 2002). Moreover, antibacterial agents are known to modify ruminal fermentation (Russell and Strobel, 1988; Wachenheim et al., 1992) and could affect the ability of the ruminal microflora to metabolize compounds in LS to a less or more toxic form. This study had three objectives: (1) to determine if antibiotic addition to bovine rumen digesta would alter the ruminal microflora such that the toxicity of LS to ruminants was decreased or increased at different lengths of fermentation; (2) to quantify ingenol and its esters in fermented mixtures of LS and bovine ruminal digesta; and (3) to determine if an aversion-inducing extract of LS inhibited the growth of several common species of ruminal bacteria, thus indicating that LS could be inducing feeding aversions simply by inhibiting forage digestion.

METHODS AND MATERIALS

Leafy Spurge Collection and Preparation. Leafy spurge was collected in its flowering growth stage in July 2000 near Veblen, SD, USA (ca. 46°N, 97°W). Stems were cut within 4 cm of the ground, and this herbage was air dried and ground in a Wiley mill through a 1-mm screen. Air-dried alfalfa

(*Medicago sativa*) was also ground in a Wiley mill through a 1-mm screen. Air-dried LS was used rather than freeze-dried because the authors have found air-dried LS to be highly aversive to cattle in several feed aversion trials. Alfalfa was used as the control plant material because it is a forb like LS, but in contrast to LS, it is readily consumed by cattle.

Digesta Collection and Preparation of Fermentation Samples. For comparison of the effects of fermentation with normal or modified bovine digesta, ruminal digesta were collected from two ruminally cannulated yearling cattle fed with a diet of alfalfa and grass (mixed cool-season grass species) hay for at least 14 d prior to digesta collection. Whole digesta from the two individuals were combined to avoid the consequences of obtaining atypical digesta from one animal, and 75 ml of mixed digesta were added to 300 ml of buffer solution (Tilley and Terry, 1963) and 25 g of ground LS or alfalfa (control) in a 500-ml Erlenmeyer flask. The flasks were agitated, purged with CO₂, plugged with vented stoppers, and incubated at 39°C with periodic agitation. For the modified cattle digesta treatment, 0.5 mg of neomycin sulfate (an antibiotic that preferentially inhibits growth of gram-negative bacteria) were added to the buffer solution immediately before it was mixed with digesta and plant material to alter the population of microbes during fermentation. Because most conditioned food aversions develop from negative feedback received within 12 hr after ingestion of food (Kronberg et al., 1993b), metabolism of leafy spurge toxins was evaluated at 0, 6, and 12 hr. To stop the fermentation, samples were frozen quickly in thin layers (ca. 1 cm) in plastic bags.

Extraction of Fermentation Samples. Fermentation samples (400 ml each) were removed from the freezer 1–2 d prior to extraction. Samples were thawed at 4°C and extracted five times in a 2-l separatory funnel with 500 ml of petroleum ether (PE; manual shaking for 8 min each). PE extracts were filtered through Whatman 50 filter paper to remove any particles and were then concentrated by using a rotary evaporator at 45°C. Concentrated samples were pipetted into vials and refrigerated for use in the Brine Shrimp Lethality Tests.

Brine Shrimp Lethality Test. Potential toxicity of extracts to ruminants was estimated by using the Brine Shrimp Lethality Test, a general bioassay for toxic plant constituents (Meyer et al., 1982; Anderson et al., 1991). PE extracts of fermentations were completely dried under N₂ gas and were then redissolved in PE to a concentration of 1 mg ml⁻¹. Cytotoxic effects of the extract samples were evaluated at 50 µg of sample per milliliter of seawater. To obtain this concentration, 250 µl of sample were pipetted into each vial, and four vials (replicates) per sample were made. Samples were dried overnight in a hood. The next day, 20 µl of dimethyl sulfoxide (DMSO) were added to each vial to dissolve the samples. Two control vials were also used that contained only 20 µl of DMSO. Up to 50 µl of DMSO may be added per 5 ml of brine before DMSO toxicity affects the results (McLaughlin et al., 1991).

Seawater was prepared in an 18.9-l tank containing 152 g of sea salt (purchased locally) dissolved in 4 l of deionized water at room temperature (22–24°C). Shrimp eggs were added to one side of the tank (separated by a perforated dividing dam), and the tank was placed near a lamp to attract the shrimp. Shrimp eggs were allowed to hatch for approximately 48 hr after setup; hatchlings migrated toward the light and through the perforated dam, where they were collected.

Fermentation extract samples were vortexed, and seawater was added to a volume of 3 ml. Ten shrimp were added to each vial, and the final volume was brought to 5 ml. Vials were placed near a lamp for 48 hr, at which time the number of live shrimp in each vial were counted.

Two toxicity assays were conducted as described above. Assay 1 evaluated shrimp toxic response to LS or alfalfa fermented with bovine rumen digesta containing the antibiotic. Assay 2 evaluated the shrimp toxic response to LS fermented with normal bovine rumen digesta or the digesta containing the antibiotic.

Statistical Analysis. The general linear models procedure of SAS (1988) was used for statistical analysis. For each assay, the model statement included treatment, time of fermentation, and the interaction term as independent variables and the number of live shrimp in each vial as the dependent variable; vial was the experimental unit. Fischer's least significant difference procedure was used to separate treatment means. The threshold *P* value for significance was 0.05.

Isolation of Ingenol. LS was collected, dried, and ground as described above and was then extracted with methanol/water (9:1). The methanol extract was evaporated under reduced pressure to yield a concentrated aqueous sample, which was extracted with PE. The PE extract was removed, and the aqueous layer was freeze-dried and hydrolyzed with 0.5 M methanolic KOH for 2 hr at room temperature to hydrolyze esters, releasing ingenol and other alcohols. The hydrolyzed sample was neutralized to pH 7.0 with 1 M HCl. After neutralization, the sample was extracted with CH₂Cl₂ to yield an ingenol-rich fraction (Upadhyay et al., 1977), which was evaporated to dryness.

The 0- and 6-hr fermentation samples from bovine digesta not treated with antibiotic were analyzed. Because there were no significant differences between the 6- and 12-hr fermentation samples in the toxicity assays, we did not analyze the 12-hr sample. Each fermentation sample was hydrolyzed to yield an ingenol-rich fraction (0.8 and 0.9 g for 0- and 6-hr fermentation samples, respectively). The 0- and 6-hr fermentation samples from the antibiotic-treated rumen digesta were not hydrolyzed, so that we were able to detect potential differences with respect to types of ingenols in the fermentation samples.

Thin-Layer Chromatography/Solid Phase Extraction. For the nonfermented LS aqueous extract, normal-phase preparative thin-layer chromatography (TLC;

^b High-performance liquid chromatographic analysis confirmed the presence of ingenol in fraction 5. ACN = acetonitrile.

20 × 20 cm plate; 1000 pm) was used to detect ingenol by comparison with an ingenol standard. Sample was applied as a continuous band on preparative TLC plates; ingenol standard was applied as a reference. For this experiment, the ingenol-rich fraction from the CH₂Cl₂ extract (total extract for seven plates was 662 mg) was applied on seven preparative TLC plates. The plates were developed in a chamber containing hexane and isopropyl alcohol (2:1, v/v). They were analyzed and compared to the ingenol standard. The band corresponding to the ingenol standard was scraped off the plate, ground with mortar and pestle, extracted three times with CH₂Cl₂ and once with methanol, then filtered through Whatman 41 paper to remove silica material. This dried extract (2.0 mg) was dissolved in acetonitrile (1 ml) and processed through reversed-phase solid phase extraction (RP-SPE) to remove color and interfering material from samples prior to high-performance liquid chromatography (HPLC). A series of solvents was processed through SPE (Table 1). Each eluate from SPE was evaporated, redissolved in acetonitrile, and analyzed for ingenol by HPLC. Nonhydrolyzed samples were processed in the same manner via SPE. Hydrolyzed fermentation samples were not processed through SPE, but rather a guard column was used during the HPLC process to remove interfering materials.

High-Performance Liquid Chromatography. Each fraction eluted from SPE was analyzed (20 µl per injection) using a reversed-phase HPLC column (Econosil C18; 250 mm × 4.6 mm; 5 µm). The nonfermented aqueous extract of LS was used to optimize HPLC separation of ingenol, yielding the following chromatographic program with gradient elution: solvent A (acetonitrile) at 100% for 5 min, then decreased gradually to 60% in 45 min; solvent B (water) was increased from 0 to 40% in the 45-min gradient elution. Column effluent was monitored at 220–240 nm by using a photodiode array detector. Ingenol (Sigma, 1 mg in 1 ml of acetonitrile) was used as the standard. The nonhydrolyzed samples (0.5 mg each) were redissolved in 100 µl acetonitrile, and 15 µl were injected into the HPLC.

Standard Curve of Ingenol Concentration. A standard curve was generated using the solvent system described by Vogg et al. (1999) to determine if the concentration of ingenol esters was increased or decreased during exposure to rumen microbes. Four ingenol standard concentrations (0.0005–0.0375 mg ml⁻¹) were analyzed and used to construct a standard curve.

Determination of Ingenol Concentration in Samples. Ingenol in fermentation samples was determined by a known addition method. Five microliters of ingenol standard (1 mg ml⁻¹ acetonitrile) were dissolved in 95 µl of acetonitrile; Fifteen µl of this were injected into the HPLC to determine the peak area of ingenol. Next, 5 µl of ingenol standard (1 mg ml⁻¹) and 95 µl of each hydrolyzed sample (3 mg dissolved in 1 ml acetonitrile) were combined. Fifteen microliters of each combined sample (equivalent to 0.04275 mg of fermentation sample) were injected into the HPLC to determine how much of the peak area of ingenol was increased by ingenol in the hydrolyzed fermentation samples. Results from the sample enrichment technique produced average peak areas of ingenol standard alone and fermentation sample-enriched ingenol. The difference in peak areas was calculated to yield the peak area of ingenol in each fermentation sample. This value was then used in the equation generated by the standard curve to yield a value of milligram ingenol per injection (1 injection = 0.04275 mg of fermentation sample).

Effect of Leafy Spurge Extract on Growth of Pure Cultures of Ruminal Bacteria. The effect of an aversion-inducing LS extract on growth of six pure cultures of ruminal bacteria was tested in 96-well microtiter plates in an anaerobic glovebag (Weimer and Abrams, 2001). Six species were selected to represent bacteria capable of various ruminal catabolic activities, including the fermentations of cellulose (*Fibrobacter succinogenes*), hemicellulose (*Butyrivibrio fibrisolvens*), pectin (*Lachnospira multipara*), peptides (*Prevotella ruminicola*), starch (*Streptococcus bovis*), and soluble sugars (all five species plus *Selenomonas ruminantium*). The LS extract was dissolved to 0.1 mg ml⁻¹ in ethanol; the solution was transferred into the glovebag and then dispensed (30 ml) aseptically into wells of a microtiter plate. The covered plate was placed in an incubator (39°C) within the glovebag to accelerate evaporation of the solvent, which typically occurred within 2 hr. Plates were inoculated with diluted pure cultures of the ruminal bacterial species [300 µl per well of a mixture containing 5.4 ml of Modified Dehority Medium (Weimer and Abrams, 2001) supplemented with 0.5% (w/v) glucose or cellobiose + 0.1% (w/v) yeast extract, and 0.6 ml of an overnight culture of the ruminal species grown on the same medium]. Each strain was inoculated into eight wells that contained the dried LS extract and eight wells lacking LS extract, which served as controls. Additional controls were provided by wells that contained uninoculated culture media lacking LS extract to verify aseptic technique. The microtiter plate was incubated at 39°C in a Bio-Tek 808-IW plate reader contained within the glovebag.

The instrument shook the plates at maximum agitation for 30 sec prior to each reading of culture turbidity (A_{540}) at intervals of 15–30 min over a period of 16–18 hr, depending on the individual experiment. Methods for calculation of growth rates and for statistical comparisons have been described previously (Weimer and Abrams, 2001).

RESULTS AND DISCUSSION

Toxicity of Leafy Spurge after Fermentation with Normal or Modified Bovine Ruminal Digesta. In assay 1, LS was more toxic than alfalfa ($P < 0.001$; Figure 1), and its toxicity was increased by exposure to bovine ruminal microorganisms for 6 hr ($P < 0.001$) or 12 hr ($P = 0.008$). Observed toxicity was similar ($P = 0.20$) in 6- and 12-hr fermentations. These results indicate that microbial metabolism of chemicals in LS made them more toxic.

In the second assay, adding neomycin sulfate to the mixture did not affect the outcome ($P = 0.65$; Figure 2). LS toxicity increased following 6 hr of exposure to either untreated ($P < 0.001$) or antibiotic-treated bovine ruminal digesta ($P = 0.02$). The addition of neomycin sulfate to the mixtures was intended

FIG. 1. Number of live brine shrimp in response to extracts of leafy spurge or alfalfa fermented with modified cattle rumen digesta for 0, 6, or 12 hr (assay 1). Bars represent the SE of the means.

FIG. 2. Number of live brine shrimp in response to extracts of leafy spurge fermented with normal or modified cattle rumen digesta for 0, 6, or 12 hr (assay 2). Bars represent the SE of the means.

to suppress gram-negative bacteria. Assuming that gram-negative bacteria in the digesta were suppressed, this appeared to have no effect on rumen microbial interaction with toxins in leafy spurge. Neomycin blocks protein synthesis in sensitive bacteria, but over the short incubation times used, the bacteria present in the digesta may have already synthesized the proteins they used to metabolize or modify compounds in LS.

Compounds in LS appeared to become more toxic as time of exposure to ruminal microbes increased from 0 to 6 hr. Results from the second assay were consistent with the first in that microbial metabolism of LS compounds appeared to make them more toxic.

This increased toxicity may be caused by ruminal microbes converting compounds in LS into more toxic ones. The ability of ruminal microbes to detoxify or increase the toxicity of plant compounds is well known (James et al., 1975; Duncan and Milne, 1992; Smith, 1992; Wachenheim et al., 1992).

Ingenol Content in Leafy Spurge Following Fermentation with Bovine Rumen Digesta. Retention times from the ingenol standard and the non-fermented aqueous extract of LS were compared, and it was determined that Fraction 5 eluted from SPE contained parent ingenol. The standard curve developed with a HPLC Solvent System described by Vogg et al. (1999) generated a linear detector response with concentration that was used to quantify

ingenol in the hydrolyzed 0- and 6-hr fermentation samples. Results from the sample enrichment technique indicated that the 0-hr fermentation sample contained an average of 0.0024 mg of ingenol/mg sample injected (Figure 3); the 6-hr hydrolyzed fermentation sample contained 0.0011 mg of ingenol/mg sample injected (Figure 4). These values correlated to 0.0074 and 0.0038% ingenols in the original LS and cattle digesta mixture for the 0- and 6-hr fermentation samples, respectively, and they fall within the range of ingenol concentrations found in LS by others. Seip and Hecker (1982) found 0.0005% ingenols in LS, and Upadhyay et al. (1977) found 1.0% ingenols in leafy spurge. The lower concentration of ingenols in the 6-hr fermentation sample could be a result of several factors. Ruminal microbes may have converted ingenols into other toxic compounds, as evidenced by results from the toxicity assays. In each sample, there were peaks that eluted after ingenol, which indicates that these

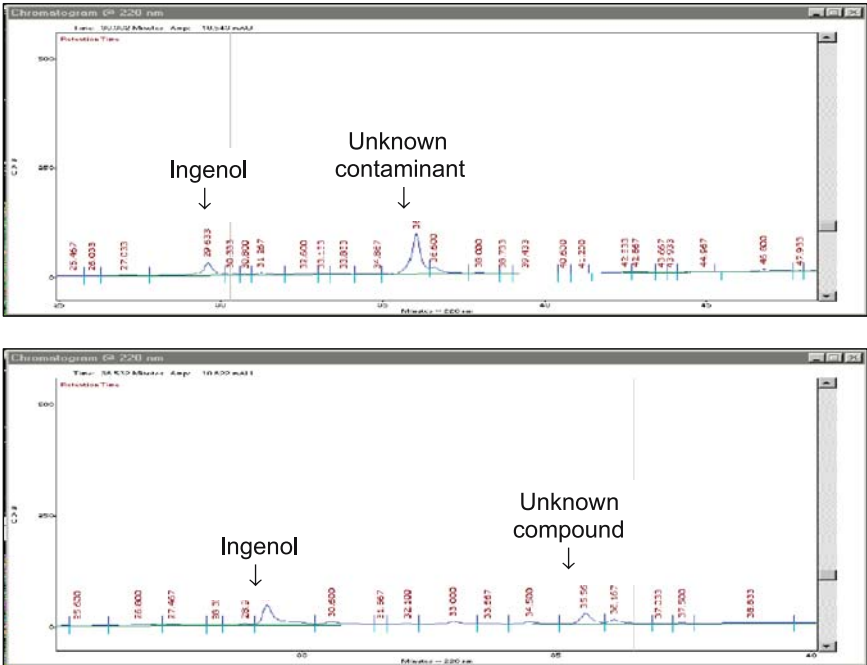

FIG. 3. High-performance liquid chromatogram (HPLC) of ingenol standard: solvent system II; 5 μ l dissolved in 95 μ l of acetonitrile; 15 μ l injected. Average peak area of ingenol = 696,783 AUP; retention time = 29.633 min (top). HPLC chromatogram of ingenol standard (5 μ l) + 0 hr hydrolyzed fermentation sample (95 μ l); 15 μ l injected; solvent system II. Average peak area of ingenol = 948,438 AUP; retention time = 29.300 min (bottom figure).

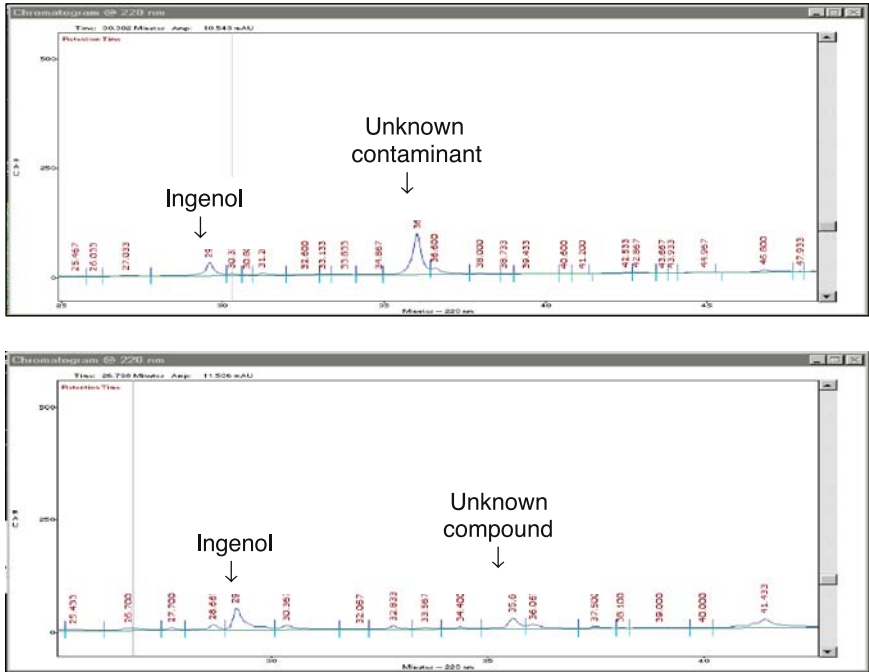

FIG. 4. HPLC chromatogram of ingenerol standard: solvent system II; 5 μ l dissolved in 95 μ l of acetonitrile; 15 μ l injected. Average peak area of ingenerol = 696,783 AUP; retention time = 29.633 min (top). HPLC chromatogram of ingenerol standard (5 μ l) + 6 hr hydrolyzed fermentation sample (95 μ l); 15 μ l injected; solvent system II. Average peak area of ingenerol = 893,311 AUP; retention time = 29.200 min (bottom figure).

unknown compounds are less polar than ingenerol. Rumen microbes may have transformed ingenerol into less polar derivatives. Less polar compounds cross cell membranes easier, and this may explain the higher toxicity of extracts of the fermented mixtures. Alternatively, there may be other toxic compounds in leafy spurge that occur at low levels and are less polar than ingenerols.

For the fermentation samples that were not hydrolyzed, ingenerol esters present in both the 0- and 6-hr samples showed similar retention times (Figure 5). In each of these samples (from SPE Fraction 5), there were two significant esters present. These esters can passively diffuse through hydrophobic mammalian membranes and enter cells where their toxicity would alter cellular activities (Campbell, 1999). Hasler et al. (1992) demonstrated that ingenerol esters activated protein kinase C and were biologically active in cell development, cell-to-cell communication, epidermal growth-factor binding, arachidonic acid metabolite release, and ornithine decarboxylase activity.

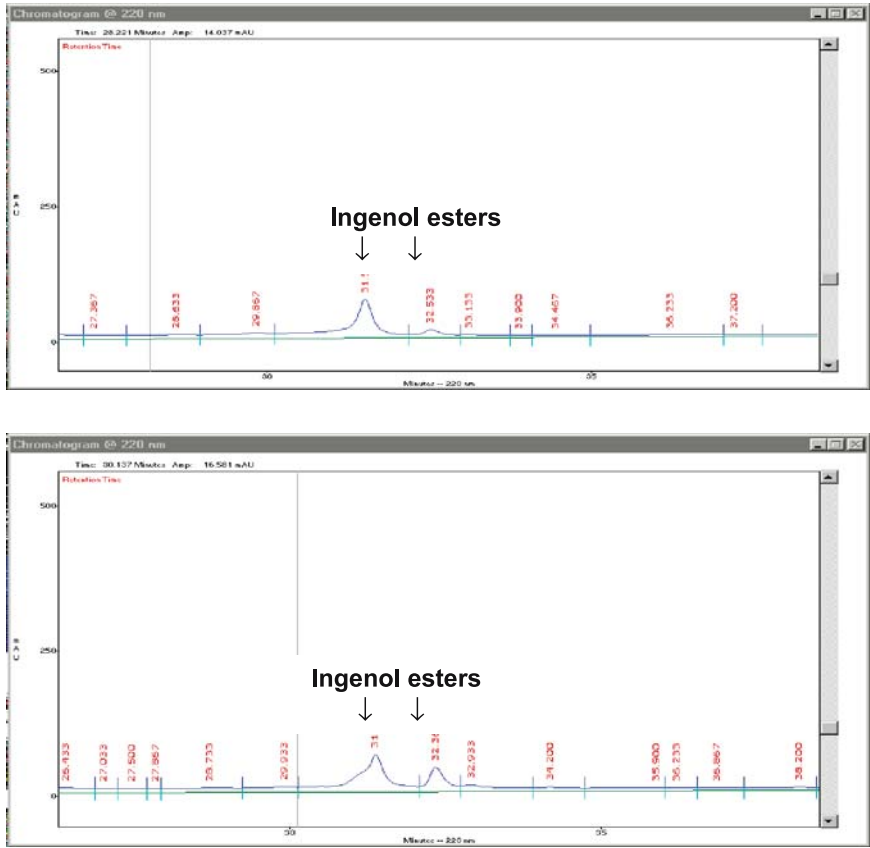

FIG. 5. HPLC chromatogram of 0-hr leafy spurge fermentation sample, nonhydrolyzed (from SPE fraction 5). Five milligrams dissolved in 100 μ l acetonitrile; 15 μ l injected; solvent system II. Ingenol ester 1 retention time = 31.533 min; ester 2 retention time = 32.533 min (top). HPLC chromatogram of 6-hr leafy spurge fermentation sample, nonhydrolyzed (from SPE fraction 5). Five milligrams dissolved in 100 μ l acetonitrile; 15 μ l injected; solvent system II. Ingenol ester 1 retention time = 31.400 min; ester 2 retention time = 32.367 min (bottom figure).

Effect of Leafy Spurge Extract on Growth of Pure Cultures of Ruminal Bacteria. The leafy spurge extract had a small inhibitory effect ($P < 0.05$) on the growth rate of only one of the six rumen bacterial strains tested (*Selenomonas ruminantium*; Table 2). The extract also altered ($P < 0.05$) maximum culture turbidity for this strain as well as for *Streptococcus bovis*, but not for the other four strains of rumen bacteria. It appears that LS does not contain compounds

that inhibit common species of bacteria known to be responsible for a wide array of fermentative activities in the rumen. Therefore, it appears unlikely that aversion-inducing compounds in LS are seriously inhibiting normal forage digestion in the rumen of cattle that could, thus, cause them to learn to avoid consuming additional LS. These results are consistent with those of Thomas et al. (1994) who concluded that leafy spurge had no negative effects on rumen digestion in sheep when it made up 50% of their diet.

In summary, fermentation of LS with bovine ruminal digesta generally increased the toxicity of extracted compounds to brine shrimp, a general model system for studies of animal toxicity. This indicates that interactions between LS toxins and rumen microbes are may be increasing the toxicity of these compounds to cattle. Introduction of a gram-negative antibiotic into the LS and cattle rumen digesta mixture did not increase or decrease toxicities of this mixture regardless of fermentation length. Levels of toxic ingenol that we observed in LS before or after exposure to bovine ruminal digesta were consistent with levels of ingenols others have reported for LS. Finally, an aversion-inducing extract of LS had little negative effect on several common species of rumen bacteria comprising a broad array of ruminal metabolic activities. This indicates that the mechanism of action of aversion-inducing compounds in LS is not inhibition of forage digestion by rumen microbes but rather is direct toxicity to cattle.

Acknowledgments—We thank Kristine Nichols, Douglas Ranynie, Igor Sergeev, and anonymous reviewers for their helpful comments on the manuscript and Kjersten Grong for help with the brine shrimp toxicity assays.

Abstract—Plants in the family Solanaceae possess numerous traits that are induced from damage from herbivores. Many of these also can be induced by exposing plants to the plant hormone jasmonic acid or its volatile ester methyl jasmonate. *Datura wrightii* (Solanaceae) is dimorphic for leaf trichome morphology in most southern California populations. Trichome phenotype is governed by a single gene, and the glandular trichome condition is dominant and under developmental control. This study addressed two major objectives. The first was to determine if mature plants with glandular or nonglandular trichomes responded differentially to methyl jasmonate. The second objective was to determine if exposure of seedlings to methyl jasmonate during the period of trichome differentiation altered either the phenotype or the density of trichomes that mature plants expressed. Methyl jasmonate induced from 200 to 800 µg/ml of proteinase inhibitor activity and increased the activity of polyphenol oxidase by more than threefold depending on the experiment. These increases did not differ significantly between plants expressing glandular or nonglandular trichomes. Methyl jasmonate exposure did not increase the activity of peroxidase or the concentration of scopolamine or hyoscyamine, the two major alkaloids of *Datura*. Exposure to methyl jasmonate during trichome differentiation did not affect either the final trichome phenotype or the density of either type of trichome, but did increase the production of acylsugars in glandular trichomes by 44%. Because trichome phenotype was not inducible, and because both trichome phenotypes showed similar increases in proteinase inhibitors and polyphenol oxidase activity, the methyl-jasmonate-inducible responses of *D. wrightii* are independent of trichome phenotype in *D. wrightii*.

Key Words—Acylsugars, alkaloids, chemical defense, *Datura wrightii*, methyl jasmonate, inducible traits, polyphenol oxidase, proteinase inhibitors, trichomes.

INTRODUCTION

Plants possess numerous traits that reduce damage by herbivores and subsequent losses in fitness caused by herbivory. These defensive traits may be expressed constitutively or induced following herbivory. Responses induced after damage by herbivores are becoming more widely documented and include changes in plant nutritional quality, the induction of defensive proteins and other allelochemicals, and the release of complex blends of volatile compounds (reviewed by Karban and Baldwin, 1997; Walling, 2000). Many induced responses are mediated by the jasmonic acid (JA) signaling pathway, and, in many cases, responses can be induced simply by exposing plants to JA or its methyl ester (MeJA) in the absence of damage by herbivores (Baldwin, 1996; Thaler et al., 1996). Induced responses have been extensively studied in solanaceous crops, such as tomato, potato, and tobacco, and often include the production of proteinase inhibitors (Pins), polyphenol oxidase (PPO), and sometimes alkaloids (Farmer and Ryan, 1990; Baldwin, 1996; Thaler et al., 1996; Constabel and Ryan, 1998).

In crucifers, one of the responses induced by herbivory can be an increase in leaf trichome density (Agrawal, 1999; Traw and Dawson, 2002), and trichome density in *Arabidopsis thaliana* can also be induced by exposure to MeJA (Traw and Bergelson, 2003). More recently, a JA-insensitive (*jai1*) mutant of tomato (Li et al., 2001, 2004), which is deficient in the accumulation of PPO and Pins compared to wild type when exposed to MeJA, was found that exhibits altered trichome development on fruit and leaves (Li et al., 2001). Whereas wild-type tomato produces two types of glandular trichomes on fruit prior to ripening, the developing fruits of *jai1* plants are devoid of glandular trichomes (Li et al., 2004). Moreover, the densities of four-lobed glandular trichomes on *jai1* leaves are only 25–35% that of wild-type plants. In another study, exposing young tomato plants to MeJA increased the densities of four-lobed glandular trichomes by up to ninefold (Boughton et al., 2005). Collectively, these data suggest that increases in trichome density can be mediated by exposure to MeJA in some plant species.

In southern California, the native perennial species *Datura wrightii* Regel (Solanaceae) expresses two distinct trichome phenotypes in most populations (van Dam et al., 1999; Hare and Elle, 2001). Some plants are densely covered with short, nonglandular trichomes, whereas others are less-densely covered with two types of uniseriate, multicellular glandular trichomes. These trichome types correspond to the type V nonglandular trichomes and types I and IV glandular trichomes of tomato described by Luckwill (1943). Both phenotypes also produce a small number of four-lobed glandular (type VI) trichomes as well (van Dam et al., 1999). Glandular trichomes secrete glucose esterified with several aliphatic acids (van Dam and Hare, 1998a), which makes

the plants feel sticky. Plants with nonglandular trichomes are velvety to the touch (van Dam et al., 1999). Trichome phenotype is controlled by a single Mendelian gene, and the sticky condition is dominant (van Dam et al., 1999). All seedlings produce glandular trichomes when young, but homozygous recessive plants produce leaves with a progressively greater ratio of nonglandular to glandular trichomes over a period of approximately 10 wk, after which homozygous recessive plants produce leaves that are essentially covered by nonglandular trichomes. Heterozygous and homozygous dominant plants continue to produce leaves with nearly 100% glandular trichomes throughout their lives (van Dam et al., 1999). At least 10 insect species attack *D. wrightii*, and they are differentially affected by glandular trichomes (van Dam and Hare, 1998a,b; Elle et al., 1999; Elle and Hare, 2000; Hare and Elle, 2002). A group of herbivores including flea beetles, hornworms, leafhoppers, and whiteflies preferentially attack velvety plants, whereas a mirid bug, *Tupiocoris notatus*, preferentially attacks sticky plants. The chrysomelid beetle *Lema daturaphila*, however, attacks both plants (Elle et al., 1999; Hare and Elle, 2002).

Although *Datura* spp. are notorious for their high constitutive levels of the alkaloids, scopolamine, and hyoscyamine (e.g., Parr et al., 1990), relatively little is known about the inducible responses of *Datura*. In the annual species *Datura stramonium*, proteinase inhibitor 1 (Pin1) activity was induced in detached leaves (Gurusiddaiah et al., 1972), but alkaloids were not induced in intact plants by damage by flea beetles (Shonle and Bergelson, 2000). Undamaged sticky and velvety phenotypes of *D. wrightii* do not differ in concentrations of water, total nitrogen, soluble sugars, total phenolics, or total alkaloids (van Dam and Hare, 1998a). There is no information available, however, about which plant traits may be inducible in *D. wrightii*, or if the two trichome phenotypes might be differentially inducible.

Here, the nature and magnitude of inducible traits in *D. wrightii* was investigated. First, we determined if short-term exposure to MeJA induced the accumulation of defensive proteins and alkaloids, and if defensive proteins or alkaloids were differentially induced in the two adult trichome phenotypes. This helps us understand the breadth of induced responses of *D. wrightii* relative to other solanaceous species, and whether or not induced responses are more important to one trichome phenotype or the other. Additionally, we determined if long-term exposure to MeJA during the period of trichome differentiation altered the ultimate adult trichome phenotype, the densities of either glandular or nonglandular trichomes, or the concentration of acylsugars that are produced by glandular trichomes. These results help us understand to what extent adult trichome type or density are themselves induced or modified by herbivore damage that occurs during the seedling or juvenile plant stages.

METHODS AND MATERIALS

Experimental Plants. “Velvety” plants possess the homozygous recessive genotype and express the nonglandular trichome phenotype, whereas “sticky” plants possess the heterozygous genotype and express the glandular trichome phenotype. Seedlings from 7 randomly selected lines originating from crosses between a randomly selected velvety pollen donor and a heterozygous sticky pollen acceptor from 4 local populations were used. These lines were backcrossed to the velvety pollen donor for two generations. Because the sticky phenotype is inherited as a dominant Mendelian character, the expected ratio of adult heterozygous sticky to homozygous recessive velvety offspring from these backcrosses is 1:1.

Batches of seeds were germinated in the fall of 2004 and winter of 2005 in a heated greenhouse equipped with four 1000-W high-pressure sodium lamps. Greenhouse temperatures ranged between 15 and 35°C, and the lamps were used to extend the photoperiod to 16 hr. The greenhouse also was equipped with a “pad and fan” cooling system that permitted a constant cross-flow of air entering the greenhouse on one side and exiting through an exhaust fan on the opposite side; the exhaust fan was constantly in operation during all experiments. Plants were placed onto the two center benches of the greenhouse with control plants placed 1 m upwind of treated plants to avoid inadvertent contamination with MeJA vapors.

Methyl Jasmonate Application. There are several ways to treat plants with MeJA or JA ranging from dipping leaves in dilute MeJA solutions (Spoel et al., 2003), spotting MeJA on leaf surfaces (Penninckx et al., 1998), enclosing plants in chambers and allowing MeJA to be taken up through the transpiration stream (Gu et al., 1996) to applying MeJA in lanolin to leaf surfaces (Kessler and Baldwin, 2001). We chose the lanolin–MeJA treatments that were previously used in field experiments with *Nicotiana* sp. (Kessler and Baldwin, 2001). This technique has proven its effectiveness, easily allows for renewed applications, and does not require detachment of leaves or the use of chambers for the long-term studies that we anticipated (see below). A 20-ml quantity of lanolin (Sigma, St. Louis, MO, USA) was heated to 60°C. The liquefied lanolin was poured into a wide-mouth jar, 200 μ l of MeJA (Bedoukian Research, Inc.) were added, and the mixture was rapidly stirred. The jar was sealed, and the mixture was allowed to solidify. Approximately 20 μ l of this mixture were applied to the stem or abaxial surface of the midrib of a leaf of treated plants by using a dissecting needle; a similar quantity of lanolin was applied to control plants. Only one application was made to plants during the short-term experiments, whereas applications were made three times per wk in the long-term treatments.

Experimental Designs. We carried out a preliminary experiment with 3 groups of 5 seedlings randomized over families that had produced four true

leaves. These seedlings were approximately 3-wk-old and of both genotypes, and all were still producing glandular trichomes at the time of treatment. The treated group of 5 plants was placed on the downwind side of the center aisle of the greenhouse and treated with MeJA in lanolin. One control group of 5 was placed 1 m away on the upwind side of the center aisle of the greenhouse and treated with lanolin only. A second control group of 5 plants was moved to a separate greenhouse with similar growing conditions and treated with lanolin only. Plants were maintained in these greenhouses for 10 d, and treatments were renewed every other day. All plants were assayed for Pin activity on day 11 to determine if the MeJA/lanolin treatments could induce Pins, and if control plants, when housed 1 m upwind of treated plants in the same greenhouse as treated plants, remained uninduced.

We carried out two short-term experiments using plants approximately 11-wk-old that had just completed their trichome differentiation. This was done to determine if the conditions that induced a direct gene product, such as Pins, might also increase the concentration of two other defensive proteins, PPO and peroxidase (POD), in one experiment or alkaloids in the other. Eight plants of each trichome phenotype, matched for size and randomized over families, were randomly assigned to “control” and “treated” treatments. Control plants were placed on the upwind side of the greenhouse, and treated plants on the downwind side, 1 m away. A 20- μ l quantity of either lanolin or MeJA/lanolin was applied to the midrib of one leaf per plant as above. After 72 hr, we assessed Pin, PPO, and POD activities or Pin activity and alkaloid content. Assays were performed on the treated leaf and the next youngest leaf for each of the 16 plants by using methods described below.

We completed a long-term experiment by using a total of 99 seedlings from the seven backcross families to determine whether long-term exposure to MeJA affected trichome phenotype or final density. The transition from glandular to nonglandular trichomes occurs over approximately 10 wk (van Dam et al., 1999), and it is uncertain when the developmental transition is initiated. Accordingly, we chose a long-term persistent exposure to MeJA to ensure that the experimental treatment encompassed the developmental transition, and we treated plants with MeJA/lanolin or lanolin alone throughout the period of trichome differentiation. There were no additional observable effects of these long-term MeJA treatments on plant growth or development other than those described below.

Seedlings from different families were randomly assigned to treatments. Fifty-one seedlings were assigned to the “control” treatment and placed on the upwind side of the greenhouse, and 48 were assigned to the “treated” treatment and placed on the downwind side 1 m away. Beginning on January 21, 2005, plants were treated with lanolin or MeJA/lanolin by applying a 20- μ l quantity to the main stem below the growing tip. Plants were approximately 3-wk-old at

this time, and all were still producing glandular trichomes. Treatments were renewed three times a wk for a total of 9 wk. Trichome phenotype was assessed every 2 wk by examining the newest leaf with a hand lens. Five randomly selected plants from treated and control groups also were assayed for Pin production at this time to verify the efficacy of MeJA treatments relative to control plants. The experiment was terminated on March 28, when glandular to nonglandular differentiation of control plants was complete (see Results). At this time, an additional 20 randomly selected plants, five velvety and five sticky, each from the treated and control groups, were assayed for Pin, PPO, and POD activities and total alkaloid content. All chemical assays were performed on tissue from the same leaf per plant.

Defensive Proteins. Pin activity was assayed semiquantitatively by using a radial diffusion assay (Ryan, 1967). Freshly harvested leaf tissue (100 mg) was ground in 100 μ l 10 mM phosphate buffer (pH 7.2) in microcentrifuge tubes with a pestle. Debris was removed by two consecutive centrifugations at 18,000 $\times g$ for 5 min each, and the soluble proteins were recovered. Agar plates with Pin1 antiserum (provided by Dr. Clarence Ryan, Washington State University) were prepared, and leaf soluble protein samples and Pin1 standards (0.5, 1.0, and 2.0 μ g, also provided by Dr. C. Ryan) were added to wells and allowed to absorb into the agar; plates were inverted and incubated at room temperature for 20 hr. Plates were flooded with 7.5% acetic acid for 10 min to visualize immunoprecipitin rings and subsequently rinsed in water. The diameters of the rings were measured and used to determine Pin1 quantities. Pin1 quantities are proportional to ring diameters and are reported in units of μ g/ml of leaf extract as per Green and Ryan (1972).

PPO and POD were analyzed using methods based on those of Stout et al. (1998) and Thaler et al. (1996). Chemicals were purchased from Sigma. Two or three 1.0-cm diam. leaf disks were punched from a leaf with a cork borer, excluding the midrib, and weighed to provide leaf tissue weighing between 100 and 150 mg (fresh wt.). The leaf tissue was placed into 1.0 ml 0.1 M potassium phosphate buffer (pH 7.0; 4°C) with 7% (w/v) insoluble polyvinylpyrrolidone. The tissue was homogenized in a motorized ground-glass tissue homogenizer. The slurry was transferred to a 1.5-ml microcentrifuge tube, 0.3 ml of 10% Triton X-100 was added, and the mixture was vortexed. The extracts were centrifuged for 5 min at 5000 $\times g$ at 10°C, and the supernatant was removed and used immediately for enzyme assays without further purification. PPO activity was assessed by determining the rate at which the extract would polymerize caffeic acid, and the rate of polymerization was monitored at 470 nm for 30 sec. POD activity was assessed similarly at 470 nm by monitoring the rate that guaiacol was oxidized by H₂O₂ in the presence of POD. The activities of both enzymes are reported as the change in absorbance per minute per gram (fresh wt.) of leaf tissue (Thaler et al., 1996).

Alkaloids. The quantities of scopolamine and hyoscyamine in samples of lyophilized leaf tissue were determined by high-performance liquid chromatography by using methods described by Fliniaux et al. (1993) as implemented by van Dam and Hare (1998a) with anisodine hydrobromide (Sigma) as an internal standard. Calibration curves were made by using commercially available scopolamine and hyoscyamine (Sigma). Only total alkaloids (mg/g dry wt) are reported to simplify data presentation. The ratio of scopolamine/hyoscyamine averaged 16:1 and never differed between MeJA treatments or trichome types (data not shown).

Trichomes and Acylsugars. The densities of all trichomes for all surviving plants in the long-term experiment were determined microscopically with techniques described previously (van Dam et al., 1999). Briefly, the density of glandular (types I and IV combined), nonglandular (type V), and four-lobed (type VI) trichomes were counted in a 3-mm² area along the abaxial midrib at 25× magnification. In previous studies, midrib densities predicted trichome densities on the leaf surface (van Dam et al., 1999), but trichomes are more easily counted on the midrib. To avoid losing any acylsugars during counting of glandular trichomes, a piece of aluminum foil was placed below the leaf on the microscope stage. After trichomes were counted, the leaf was wrapped in foil and placed into a refrigerator (4°C). For leaves with nonglandular trichomes, leaf area was determined with a leaf area meter (Li-Cor 3000, Li-Cor Corp., Lincoln, NE, USA), and the leaf was discarded. Leaves with glandular trichomes were extracted with CHCl₃ to remove the acylsugars (see below) before leaf area was determined.

The quantities of acylsugars produced by leaves with glandular trichomes were determined by extraction of both surfaces of the leaves, saponifying the acylsugars to glucose and aliphatic acids, then quantifying the liberated glucose spectrophotometrically (Hare, 2005). Aluminum foil that was used to wrap and store the leaf also was extracted to recover any acylsugars that might have been transferred to the foil during trichome counting and leaf storage. The millimoles of glucose liberated equals the millimoles of acylsugars extracted because each acylsugar molecule in *D. wrightii* is composed of a glucose molecule esterified with one or more C₆–C₉ acids (van Dam and Hare, 1998a). Acylsugars are reported as micromoles per square centimeter of leaf surface.

Statistical Analyses. For the short-term experiments, the data were analyzed by a two-factor analysis of variance (ANOVA) using PROC GLM of SAS/STAT[®], version 8.0 (SAS Institute, 2000), when sample sizes were equal among treatments and PROC MIXED of SAS when sample sizes were unequal. The effects of treatment, trichome phenotype, and treatment × phenotype interaction were tested over the variation among plants within

treatment \times phenotype combinations. Alkaloid concentration was transformed by using the square root transformation to ensure that the residuals were normally distributed, but Pin, PPO, and POD activities required no transformation.

In the long-term experiment, the frequencies of sticky and velvety plants in the treated and control groups were compared by using a replicated goodness-of-fit G test (Sokal and Rohlf, 1995) to compare the frequencies of the two groups and to compare the observed frequencies of each group to the expected frequency of a 1:1 ratio of sticky to velvety plants in these backcross progenies. The chemical concentrations of leaves and densities of four-lobed trichomes were compared by using a multiway mixed model ANOVA using PROC MIXED. Treatment and type were fixed effects, and the effect of family and all interactions that included the effect of family were random effects. Random effects that were not statistically significant were sequentially deleted, and the analysis was repeated to yield the final reduced model. The densities of glandular and nonglandular trichomes were analyzed separately by trichome phenotype. The MeJA treatment was a fixed effect, whereas the family and the family \times treatment interaction were random effects. Leaf area was also included as a potential covariate in these analyses. Non-significant effects were sequentially deleted from the full model to yield the final reduced model.

RESULTS

Preliminary Experiment. Treatment with MeJA/lanolin induced *D. wrightii* to produce a mean of 375 μg (± 85 SE, $N = 5$) of Pin activity per milliliter of leaf extract. None of the control plants treated only with lanolin, either in the same or separate greenhouse, produced Pins. On the basis of these results, we concluded that applying MeJA/lanolin to the leaves of plants was an effective way to induce plant defense responses, and that plants 1 m upwind of treated plants in the same greenhouse were not contaminated by exposure to MeJA. Therefore, we used the induction of Pins as a marker for the efficacy of the induction treatment and tested for MeJA-induced changes in the other traits in all subsequent experiments only in plants where MeJA also induced Pin activity.

Defensive Proteins. There was some variability in the induction of Pins in the short-term experiments. In the experiment to investigate the induction of PPO and POD, three of the eight plants exposed to MeJA failed to produce Pins. Leaves from sticky plants in which Pins were induced, produced an average of 791.6 ± 240.4 μg of Pin activity per milliliter of leaf extract (least-squares mean \pm SE, $df = 5$), whereas induced velvety leaves pro-

duced an average of 560.8 ± 169.5 $\mu\text{g/ml}$ of Pin activity (least-squares mean \pm SE, $df = 5$). There was no significant difference in Pin activity between sticky and velvety leaves of induced plants ($F_{1,5} = 0.83$, $P = 0.40$). PPO activity increased overall by nearly twofold in leaves induced to produce Pins ($F_{1,10} = 8.73$, $P = 0.014$; Figure 1A) but did not differ between sticky and velvety leaves ($F_{1,10} = 0.00$, $P = 0.99$), nor because of the induction \times leaf-type interaction ($F_{1,10} = 1.35$, $P = 0.27$). Unlike PPO activity, POD activity was independent of the induction of Pin activity ($F_{1,10} = 3.81$, $P = 0.08$; Figure 1B). POD activity also did not vary between sticky and velvety leaves ($F_{1,10} = 0.01$, $P = 0.94$), nor because of the induction \times leaf-type interaction ($F_{1,10} = 2.95$, $P = 0.12$).

At the end of the long-term experiment, Pin activity was consistently expressed in all sampled MeJA-treated plants, but was never expressed in the controls. Pin activity averaged 250 ± 88 $\mu\text{g/ml}$ in induced sticky plants (least-squares mean \pm SE, $df = 5$) and 225 ± 83 $\mu\text{g/ml}$ in induced velvety plants (least-squares mean \pm SE, $df = 5$), and Pin activity did not differ between leaf phenotypes ($F_{1,8} = 0.04$, $P = 0.84$). Exposure to MeJA increased PPO activity more than threefold in the long-term study ($F_{1,16} = 145.18$, $P < 0.001$; Figure 2A), but MeJA did not increase POD activity ($F_{1,16} = 0.16$, $P = 0.70$; Figure 2B). In neither case did PPO or POD activities differ between leaf phenotypes ($P \geq 0.17$) nor because of the treatment \times type interaction ($P \geq 0.60$) in the long-term experiment.

Alkaloids. There was also some variability in the induction of Pins by MeJA in this short-term experiment as in the first. One treated plant of eight failed to express Pins, but a low level of Pin activity was detected in three of the eight control plants. Leaves from sticky plants in which Pins were induced produced an average of 243.28 ± 129.8 $\mu\text{g/ml}$ of Pin activity (least-squares mean \pm SE, $df = 10$), and leaves from induced velvety plants produced 372.8 ± 117.5 $\mu\text{g/ml}$ of activity (least-squares mean \pm SE, $df = 10$). Pin activity also did not differ between leaf phenotypes in this experiment ($F_{1,10} = 1.44$, $P = 0.26$). Alkaloid concentration did not vary significantly between Pin-induced and -uninduced plants ($F_{1,10} = 0.00$, $P = 0.95$), between leaf types ($F_{1,10} = 1.99$, $P = 0.19$), nor because of the treatment \times leaf-type interaction ($F_{1,10} = 0.87$, $P = 0.37$; Figure 1C). MeJA also did not increase leaf alkaloid concentration in the long-term experiment ($F_{1,15} = 2.78$, $P = 0.12$; Figure 2C). In addition, as seen in the short-term studies, alkaloid concentrations did not differ between leaf phenotypes of differentiated plants ($F_{1,15} = 0.18$, $P = 0.68$) nor because of the treatment \times leaf-type interaction ($F_{1,15} = 0.05$, $P = 0.82$) after long-term exposure to MeJA.

Trichomes and Acylsugars. MeJA-treated plants expressed Pin activities averaging between 100 and 400 $\mu\text{g/ml}$ of leaf extract during trichome differentiation, depending on the sampling period (Figure 3A). None of

the control plants showed Pin activity except for one plant in the March 14 assay. Despite the effectiveness of thrice-weekly MeJA applications to induce Pin activity, MeJA had no effect on timing of trichome differentiation or final leaf phenotype. Trichome differentiation occurred over a period of 9 wk in this experiment, as is typically the case for *D. wrightii* (van Dam et al., 1999). After trichome differentiation completed, 55% of the control plants and 46% of the treated plants expressed the velvety phenotype (Figure 3B). These frequencies did not differ from each other ($G_1 = 0.815$, $P = 0.36$), nor did either differ from the expected value of 50% ($G_1 \leq 0.486$, $P \geq 0.49$).

The density of glandular trichomes on sticky plants did not differ between control and MeJA-treated plants ($F_{1,52} = 1.25$, $P = 0.27$; Figure 4A). Similarly, the densities of nonglandular trichomes on velvety plants did not differ between control and treated plants ($F_{1,47} = 0.23$, $P = 0.63$). Type VI trichomes comprised only a few percent of total trichomes (Figure 4B), and the densities of these trichomes also were similar in control and treated plants ($F_{1,99} = 0.02$, $P = 0.89$). In no case did the densities of any of the three types of trichomes differ among families or due to any interactions involving families (all $P \geq 0.65$), and in no case did the densities of any trichome type covary significantly with leaf area (all $P \geq 0.14$).

Although MeJA did not alter the densities of glandular trichomes nor prevent the differentiation of nonglandular trichomes, exposure to MeJA caused the glandular trichomes of sticky plants to produce about 44% more acylsugars per square centimeter of leaf area than control plants ($F_{1,46} = 4.43$, $P = 0.041$; Figure 4C). Acylsugar production did not differ, however, among families or due to the treatment \times family interaction (all $P \geq 0.95$).

DISCUSSION

The putative herbivore defenses of solanaceous species range from completely inducible to completely constitutive. The relative importance of constitutive and inducible traits may vary among solanaceous species and populations within species. The two best-studied solanaceous genera are *Lycopersicon*, including the cultivated tomato, and *Nicotiana*, including cultivated and wild

FIG. 1. Mean (+SE) polyphenol oxidase (PPO) and peroxidase (POD) activity [$\Delta\text{OD}_{470} \text{ g (fresh wt.)}^{-1} \text{ min}^{-1}$, A and B], and mean (+SE) alkaloid concentration (mg/g, dry wt., C) from induced or uninduced leaves after 72-hr exposure to MeJA.

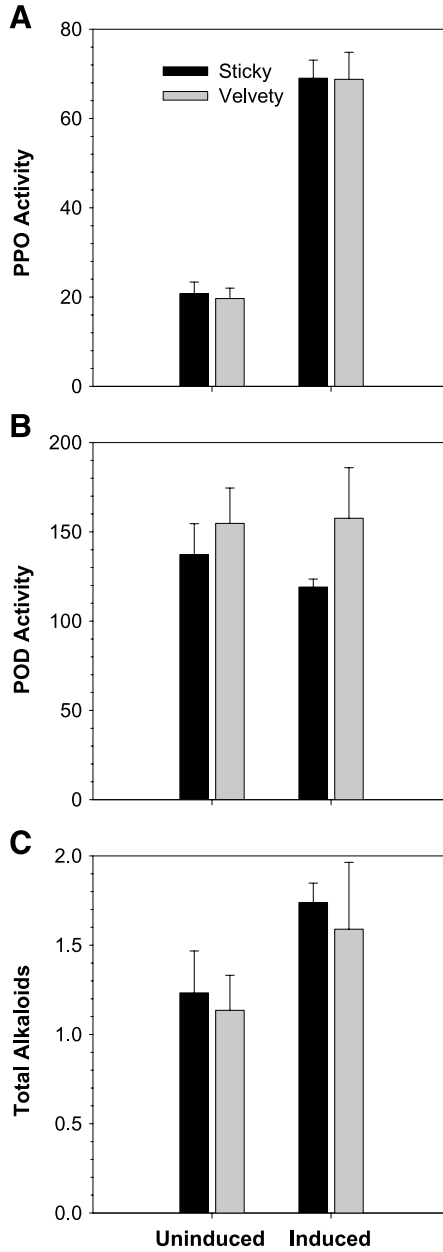

FIG. 2. Mean (+SE) PPO and POD activity [$\Delta\text{OD}_{470} \text{ g (fresh wt.)}^{-1} \text{ min}^{-1}$, A and B] and mean (+SE) alkaloid concentration (mg/g, dry wt., C) of sticky and velvety plans after 9 wk of exposure to MeJA.

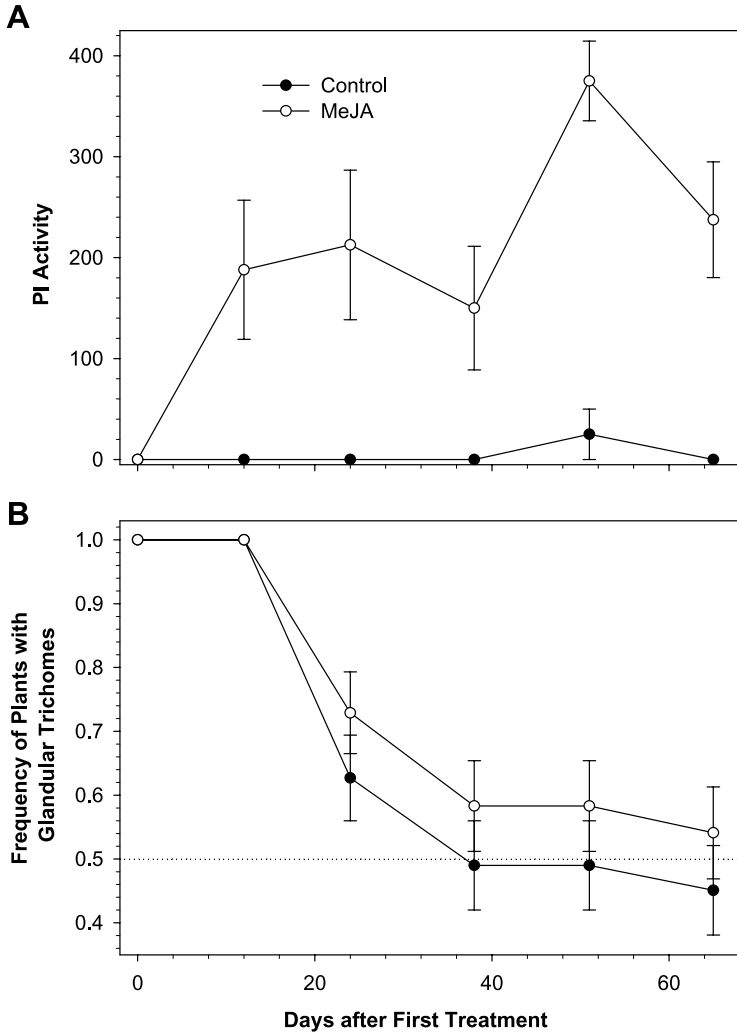

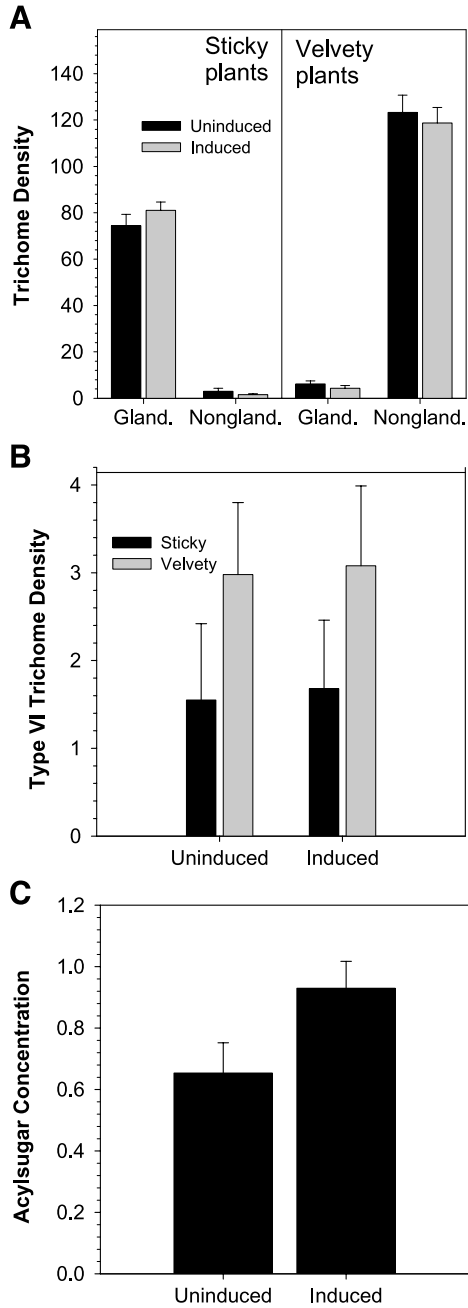

FIG. 3. Proteinase activity and trichome differentiation during 9 wk of exposure to MeJA. Mean (\pm SE) Pin activity ($\mu\text{g/ml}$ leaf extract) in treated and control plants (A) and frequency (\pm SE) of plants producing glandular trichomes (B). The dotted line in B shows the expected 1:1 frequency of sticky/velvety plants after trichome differentiation is completed.

tobacco species. In these genera, Pins are often expressed constitutively at low levels in leaves, but can be induced many fold by MeJA (Thaler et al., 1996; van Dam et al., 2001). PPO activity also is commonly expressed constitutively in many solanaceous species, but can be induced to higher levels by wounding

or exposure to MeJA. It is difficult to compare across studies because of the variation in magnitude of induced responses with variation in plant ontogeny, growing conditions, and experimental methodology (Constabel and Ryan, 1998; van Dam et al., 2001), but the observed Pin and PPO activities induced by MeJA in *D. wrightii* seem to compare favorably with those of other solanaceous species. The Pin activity of induced *D. wrightii* is similar to, or higher than, previous studies of tomato (202 $\mu\text{g/ml}$) and potato (336 $\mu\text{g/ml}$) in which the same radial diffusion assay was used (Green and Ryan, 1972). Similarly, although PPO activity of induced *D. wrightii* was lower than in tomato (Thaler et al., 1996), it was higher than in *Nicotiana tabacum*, *Solanum tuberosum*, *S. nigrum*, or *Capsicum annuum* (Constabel and Ryan, 1998). Thus, *D. wrightii* appears to share with other better-studied solanaceous species the ability to produce substantial quantities of Pins and PPO after exposure to MeJA.

Although the differences in POD levels approached statistical significance in the short-term experiments, neither the magnitude nor the pattern of difference was repeated in the long-term experiment. Others have noted inconsistency of induction of POD activity in response to MeJA in tomato and have suggested that POD induction may be mediated by signaling pathways other than those involving MeJA (e.g., Thaler et al., 1996). POD activity also was independent of MeJA exposure in *D. wrightii*.

The results of the short-term induction experiments were variable in that a single MeJA application failed to induce Pins in all plants, whereas multiple MeJA applications consistently induced Pins in the other two experiments. Multiple MeJA applications also induced a higher level of PPO activity than a single application. The variability in responsiveness to MeJA in the short-term experiments was observed in both genotypes and may be the result of differences in the number of MeJA applications or differences in age or developmental stage of plants at the initiation of each experiment (e.g., van Dam et al., 2001). A complete understanding of the causes of variable responses to MeJA observed in our short-term experiments would require a more extensive series of experiments.

In contrast to Pins and PPO, the concentrations of alkaloids in *D. wrightii* were not inducible. For this trait, *D. wrightii* differs from *Nicotiana* sp., in which alkaloid concentration is inducible (e.g., Baldwin, 1996). Our result for *D. wrightii* is similar to that of Shonle and Bergelson (2000), who found no

FIG. 4. Trichome densities of uninduced and MeJA-induced velvety and sticky plants, and acylsugar concentration of sticky plants. MeJA-induced plants were treated three times per week for 9 wk. (A) Mean (+SE) densities (no./mm²) of glandular (types I and IV) and nonglandular (type V) trichomes. (B) Mean (+SE) densities (no./mm²) of type VI lobed trichomes. (C) Mean (+SE) acylsugar concentration ($\mu\text{mol/cm}^2$).

increase in alkaloid concentration in response to feeding damage by flea beetles in either field- or greenhouse-grown *D. stramonium*. The little information available suggests that alkaloid profile and quantities may be a more constitutive characteristic of *Datura* spp. than *Nicotiana* spp.

Trichome phenotype and density also are more constitutive traits of *D. wrightii* genotypes than some tomato genotypes and cruciferous species, as long-term exposure to MeJA did not influence either trichome differentiation or final density. These results are in accord with previous qualitative observations. Neither the density nor the type of trichomes produced by *D. wrightii* on newer leaves distally on stems was visibly altered after insect damage of more proximal leaves on the same stem (Hare and Elle, 2002). In contrast to *D. wrightii*, tomato showed a transient increase in the density of type VI trichomes 7–21 d after exposure to MeJA (Boughton et al., 2005). Several annual crucifers also show a transient increase in trichome density on leaves initiated after older leaves on the same stem are damaged (e.g., Agrawal, 1999; Traw and Dawson, 2002). The different types of glandular trichomes in tomato and potato are apparently controlled by different genes (Lemke and Mutschler, 1984; Vallejo et al., 1994), and the developmental pathways leading to different types of trichomes also may vary in their sensitivity to MeJA. The absence of any trichome density response in *D. wrightii* was not because of inadequate MeJA treatments, as at least two MeJA-responsive gene products, notably Pin and PPO, accumulated substantially in the long-term MeJA studies.

This is, to our knowledge, the first example of acylsugar production being induced by MeJA. In previous studies with *D. wrightii*, the concentration of acylsugars on leaves of sticky plants not only varied seasonally, but also was reduced on leaves from irrigated compared to unirrigated plants (Hare, 2005). Acylsugar quantities also were independent of trichome density in *D. wrightii* (Forkner and Hare, 2000) and were only weakly correlated with trichome density in tomato (Blauth et al., 1998). Moreover, quantitative trait locus (QTL) analyses of acylsugar production and trichome densities in both potato and tomato indicate that although some QTLs are associated with both trichome density and acylsugar accumulation, other QTLs are associated with each independently (Bonierbale et al., 1994; Blauth et al., 1998). Although circumstantial, these independent lines of evidence suggest that type IV glandular trichomes do not simply secrete acylsugars passively, but that acylsugar production and secretion may be actively regulated within these trichomes.

It would not be surprising if different herbivores induced different traits and activated different groups of genes from those that are induced by MeJA alone (Stout et al., 1994; van de Ven et al., 2000; Traw and Dawson, 2002; Heidel and Baldwin, 2004). The present study provides a baseline to compare

and evaluate plant responses to damage by different herbivore species. Because of the known differences in susceptibility of Lepidoptera and Coleoptera to Pins and PPO (Murdock et al., 1987; Felton et al., 1992), the value of induced Pins and PPO may be higher when the herbivore community is dominated by lepidopterans than by coleopterans. In addition, because the structures of herbivore communities vary in space and time on *D. wrightii* (Elle and Hare, 2000; Hare and Elle, 2002), the realized benefit of these traits also is likely to vary spatially and temporally among and within *D. wrightii* populations.

Finally, because the expression of adult trichome phenotype by *D. wrightii* genotypes was not altered by exposure to MeJA, and because Pins and PPO were induced similarly in the two trichome genotypes, the induced responses that we examined probably have similar defensive roles within genotypes. Because of the similarities in responses across genotypes, induced responses probably contribute little to the variation in the frequencies of trichome genotypes among plant populations.

Acknowledgments—We thank W. Chang, K. Malloy, and C. Tiu for assistance in the greenhouse and with counting trichomes, F. Holzer for the Pin assays, and J. Narvaez for experimental advice. Abstract—Nectar of many bee flowers contains secondary compounds, which are considered toxic for honeybees on repeated exposure. Although many anecdotal reports indicate the toxicity of secondary compounds to bees, only a few studies have tested the extent of toxicity at different honeybee ages, especially at the larval stages. Honeybees encounter nicotine at trace concentrations (between 0.1 and 5 ppm) in floral nectar of a few *Nicotiana* spp. and in *Tilia cordata*. Adult honeybee workers tolerate these nicotine concentrations. In controlled nonchoice feeding experiments with caged bees, we investigated the effect of nicotine on hatching success and larval and forager survival. Naturally occurring concentrations of nectar–nicotine did not affect hatching success of larvae or their survival, but the latter was negatively affected by higher concentrations of nicotine (50 ppm). Concentrations of nicotine in fresh honey samples from the hives were 90% lower than the concentrations in the offered experimental sucrose solutions. Our results indicate that honeybees can cope with naturally occurring concentrations of nicotine, without notable mortality, even when consumed in large quantities for more than 3 weeks.

Key Words—Nectar, secondary compounds, nicotine, *Nicotiana* spp. honeybees, toxicity.

INTRODUCTION

Nectar of several plants contains secondary compounds (hereafter SC), which are suspected to be toxic to bees and other pollinators (Baker and Baker, 1975). The prevalence of SC in bee nectars has given rise to the hypothesis that bees are less susceptible to SC than are flower-inconstant butterflies (Baker and Baker, 1975). Conceivably, bees developed counteradaptations to SC (Rhoades and Bergdahl, 1981). Still, it is unclear whether bees consume SC deliberately or only for lack of alternative food sources. The actual concentrations of SC in nectar are known for only a few plants, yet, they are frequently reported to be toxic to honeybees (Adler, 2000). Detzel and Wink (1993) tested a wide array of nectar SC for their toxic (LD_{50}) effects on adult honeybees and found that most SC (particularly alkaloids) are highly toxic to bees across a wide range of concentrations.

Most reports on toxicity of SC to honeybees have not addressed the extent of toxicity in relation to the age of the bees. Toxic nectar may not affect forager bees but may still be toxic to brood or young nursing bees (Sharma et al., 1986). Conversely, anecdotal accounts indicate that SC may be fatal for foraging bees (Adler, 2000). Accordingly, it is important to test the age-related toxicity of SC on bees as they undergo clear-cut transitions in tasks and physiological plasticity with age (Smirle and Winston, 1988). The shift from the protected hive environment to the open field exposes honeybees to numerous challenges, such as pesticides and SC in nectar. The bees' ability to withstand exposure to such toxicants may be a critical factor determining colony foraging performance (Smirle and Winston, 1988). Plant SC and pesticides have been shown to induce detoxifying enzymes in honeybees (Terriere and Yu, 1974).

Nicotine is encountered by foraging honeybees in floral nectar of some *Nicotiana* species at concentrations between 0.1 and 5 ppm (Detzel and Wink, 1993; Tadmor-Melamed et al., 2004). Although birds and Lepidoptera are the typical pollinators of most *Nicotiana* species, honeybees also consume nectar of *N. tabacum* (Bhuiyan et al., 2002; Oddo et al., 2004) and possibly of *N. sylvestris* (Jakobsen et al., 1995) and *N. suaveolens* (Loughrin et al., 1991, 1993). Honeybees also actively collect nectar containing nicotine from *Tilia cordata* (Naef et al., 2004; the precise concentration is not known).

Detzel and Wink (1993) assessed the toxicity of nicotine in sucrose solutions for caged bees after an exposure of 48 hr. They found that nicotine was toxic to adult bees at LD_{50} concentration of 2000 ppm, a dosage that foragers probably never experience in nectar. Lower concentrations (<300 ppm) were tolerated for over a week without increased mortality (Detzel, 1990). Free-flying honeybees tolerated and even prefer nicotinated sucrose solutions at their naturally occurring concentration in nectar (Singaravelan et al., in press). Forager bees unload the collected (toxic) nectar to young workers in the hive,

who process and store it as honey, but they also feed it directly to young developing larvae. An effect can, therefore, be expected even in hive-bound adult bees and the developing brood. Developing larvae were more sensitive to such toxic constituents in the food than adult workers (Sharma et al., 1986; Miranda et al., 2003; Amir and Peveling, 2004), perhaps because of the low level of induced physiological specialization they have to manage. A remarkable increase was found in the activities of detoxification enzymes (glutathione *S*-transferases and the mixed-function oxidases) in forager bees. The detoxifying power proved positively correlated with workers' age (Smirle and Winston, 1988). Hence, because toxic nectar is also consumed by the developing brood (larvae), they should be more susceptible to it than adult worker bees.

Here, we investigated the effect of natural concentrations of nectar–nicotine on the hatching success of bee larvae and on survival of larvae and forager bees (*Apis mellifera ligustica*). Knowing the effect of nicotine at the colony level is essential for understanding the interactions between honeybees and nicotine-containing plants.

METHODS AND MATERIALS

Maintenance of Caged Hives. Minibeehives (400–2000 bees) of four-frame strength were obtained from an apicultural farm (Noga Reuven, Manoot, Israel). In the fall, experimental hives were randomly assigned to four nylon-meshed outdoor cages (3 × 3 m, allowing natural environments) erected at the Oranim Campus of the University of Haifa, Israel. Each beehive was introduced into a cage, and the bees were offered sucrose solution (20%) and pollen on Petri dish plates. In addition, pollen substitute (Bee-Pro^R) was provided *ad libitum* on plastic bowls placed inside the hives. To prevent ants from gaining access to test solutions, we applied tangle foot at the base of the table on which the solutions were provided. We routinely removed mites (*Varrora* spp.) and caterpillars of lesser wax moth (*Achroia grisella*) from the experimental colonies.

Experimental Procedure. The work schedule is shown in Table 1. To investigate the direct effect of nicotine, after 1 d of adjustment, the bees in each cage were fed exclusively with one of the following solutions: control (20% sucrose) or treated 20% sucrose laced with three concentrations of nicotine—0.5, 5, and 50 ppm. To trace the fate of individual eggs, after 10 d of bees' exposure to the test solutions, we mapped all frame cells on drawn sheets. We marked the cells of 15–30 new eggs randomly on two or three frames each day for 3 d using color dyes. We marked the cells of 75 (± 10 SD) new eggs in each colony. The developmental stage of each individual was classified as follows: “egg 1” to “egg 3” for 3 d in the egg stage; “L1d” through “L5d” for a 5-d larval period; and “CL” for capped larvae. We monitored the marked cells until

TABLE 1. WORK SCHEDULE WITH CAGED HIVES

Days	Tasks ^a
Day 1	Acclimatizing bees to the cage environment
Days 2–10	Exposure session
Days 11–14	Mapping, marking cells of new eggs
Days 15–17	Monitoring the cells for egg hatching
Days 18–26	Monitoring the cells for larval survival (capping)

^aNote that during the entire session, the hives were exposed to a single source of nectar.

the egg became a capped larva (usually about 9–10 d after the “egg 1” stage). Disappearances of eggs and larval death were noted regularly. To test the effect of nicotine concentrations on survival of forager bees, we numbered a minimum of 20–25 foragers in each colony in all replicates, and these were monitored for about 15 d. When our experiments were completed, we returned the hives to the apicultural farm. This setup was repeated four times (between August and November 2004), each time with new beehives that were randomly placed in the cages. In two cases, we terminated the experiment early, as the bees remained outside the hive. Therefore, the 5- and 50-ppm nicotine treatments had only three replicates.

Nicotine Concentration in Fresh Honey Samples. To determine the concentrations of nicotine in stored honey, we collected fresh honey samples from the combs with a blunt-tipped syringe. The samples were dried by a speed-vac (VR-Maxi, Heto, Allerød, Denmark) and kept at -20°C . Methanol (150 or 250 μl) was added to each of the dried samples, and after vortexing, the samples were centrifuged at 13,000 rpm for 5 min. Some 50 μl of the supernatant was derivatized, and the following solutions were sequentially added: 25 μl 4 M acetate buffer (pH 4.7); 10 μl 1.5 M potassium cyanide in water; 10 μl 0.4 M chloramine-T in water; 50 μl 50 mmol l^{-1} thiobarbituric acid in water/acetone (50:50, v/v). The contents were mixed and incubated for 5 min; the reaction was stopped by the addition of 10 μl 0.1 M sodium metabisulfite in water.

High-performance liquid chromatography (HPLC) analysis was performed exactly 3 min after the reaction had stopped. The HPLC configuration (HPLC, Beckmann system gold, Beckmann, Fullerton, CA, USA) for determination of nicotine consisted of an HPLC pump (Beckmann 125P) connected to a photodiode array detector (Beckmann 168; wavelength, 505 nm). The mobile phase—linear gradient was water/acetonitrile from 0 to 100% acetonitrile in 15 min (flow rate, 1 ml min^{-1}). The column used was Merck LiChroCART RP-18 (5 μm , 250 \times 4 mm; Merck, Darmstadt, Germany). The injection volume was 20 μl . The column was equilibrated for 3 min prior to each injection. Concentrations of nicotine were determined by calibration curves by using standards at concentrations between 0.3 and 50 $\text{ng } \mu\text{l}^{-1}$.

Data Analysis. The differences in the percentages of larval hatching and larval survival between the control and the different treatment groups and the differences in percent mortality among larval instars exposed to 50-ppm nicotine were analyzed with one-way analysis of variance on arcsine square-root-transformed data, followed by Tukey's multiple comparison mean separation test.

RESULTS

Foraging Activities and Survival of Forager Bees. Bees collected the test solutions until the end of the experiment except in the colonies exposed to 50-ppm nicotine; there, the bees reduced their usual flight activities as well as their food uptake after 15 d. We monitored the survival of foragers with minimal sample size (as it is already known that foragers tolerate nicotine up to 300 ppm without increased mortality; Detzel, 1990) for about 15 d and found that more than 80% of the bees survived (Table 2).

Hatching Success. Larvae hatched from about 70% of the eggs in all colonies. Exposures to nicotinated sucrose solutions did not affect the hatching success ($F_{3,10} = 2.858$, $P > 0.05$; Figure 1A). A slight nonsignificant reduction in hatching was found in the 50-ppm treatment (Figure 1A).

Larval Survival. Naturally occurring concentrations of nicotine (0.5 and 5 ppm) in nectar did not affect larval survival. About 70% of larvae survived. However, 50-ppm nicotine reduced larval survival 30% more than other concentrations ($F_{3,10} = 28.23$, $P < 0.001$; Figure 1B). Mortality rates differed significantly among larval instars ($F_{4,10} = 20.95$, $P < 0.001$) exposed to 50-ppm nicotine. High mortality occurred mainly in 3-d-old larvae (Tukey's multiple comparison, $P < 0.05$; Figure 2).

Concentrations of Nicotine in Fresh Honey Samples. On average, there was more than a 90% reduction in concentrations of nicotine in honey samples compared with the concentrations of the test solutions offered. The average concentration of nicotine traced in honey samples of colonies treated with 50-ppm nicotine was 3.23 ± 0.41 ppm (in wet mass; mean \pm SE; $N = 15$), whereas

TABLE 2. PERCENT SURVIVAL OF NUMBERED FORAGERS MONITORED IN DIFFERENT COLONIES (POOLED DATA)

Colonies	Foragers monitored	Foragers survived	Percentage
Control	79	68	86.1
0.5 ppm	84	72	85.7
5 ppm	63	51	80.9
50 ppm	58	49	84.5

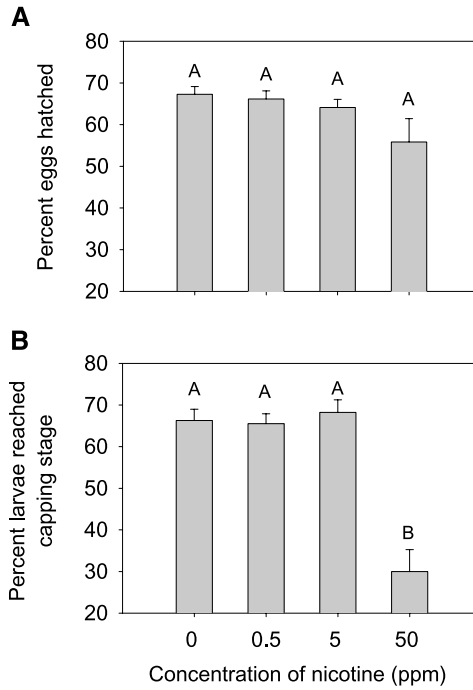

FIG. 1. Effect of nicotine consumption on honeybees. (A) Hatching success; (B) larval survival ($P < 0.05$, Tukey's multiple comparison). $N = 4$ hives with 0- and 0.5-ppm nicotine and $N = 3$ hives with 5- and 50-ppm nicotine. Values given as mean \pm SE. Bars followed by different letters are statistically significant.

FIG. 2. Percent mortality (mean \pm SE) of different larval instars in the colonies exposed to 50 ppm of nicotine.

concentrations in honey samples of colonies treated with 0.5- and 5-ppm nicotine were hardly detectable.

DISCUSSION

The results indicate that bees' consumption of nicotine in its naturally occurring concentrations in floral nectar does not adversely affect hatching success and larval survival, even in the absence of alternative nectar sources for more than 3 wk. However, the effect of nicotine was dose-dependent, and a higher concentration (50 ppm) significantly reduced larval survival (Figure 1). Adult forager honeybees proved unaffected at any of the tested nicotine concentrations. Previously, we found that free-flying bees tolerated and were even stimulated by naturally occurring concentrations of nicotine in artificial nectar (Singaravelan et al., 2005). Adult forager honeybees may escape the acute toxic effects of nicotine because they unload the collected nectar almost completely to receiver bees immediately upon returning to the hive (von Frisch, 1965). By contrast, nectarivorous sunbirds that consume naturally occurring concentrations of nicotine were adversely affected (Tadmor-Melamed et al., 2004). Unlike honeybees, birds immediately digest the consumed nectar (Tadmor-Melamed et al., 2004) and, hence, are more liable to suffer negative effects.

Baker and Baker (1975) suggested that the level of tolerance to SC in nectar by pollinators is related to their pollination efficiency. In our experiments, we used the European race of bees (*A. mellifera ligustica*), which may encounter nicotine naturally in nectar of *Nicotiana tabacum* (Detzel and Wink, 1993) and *T. cordata* (Naef et al., 2004). Although these plants are native to tropical America and Europe, respectively, they have been introduced and are cultivated in many areas, including Israel. General pollinators usually serve invasive plants in similar strategies that are used in their natural habitats (Richardson et al., 2000). Accordingly, interpreting the reciprocal adaptations of different flower visitors to tolerate nectar–nicotine in respective host plants is more complex and entails several lines of considerations. For just a few, this can be illustrated by the following questions: Is a particular pollinating species more tolerant or better adapted to nectar–nicotine concentrations in areas where it has coevolved with the host plant than in areas where it has not? If the host plant has an array of pollinating species in a given area, how does the ability of the different species to tolerate the nectar–nicotine level vary? Most nectar SC have proved toxic for honeybees across a wide range of concentrations (Detzel and Wink, 1993). Nicotine is toxic for adult workers at LD₅₀ concentration of 2000 ppm (Detzel and Wink, 1993). Detzel and Wink (1993) chose a high concentration range probably because bees also encounter the SC in pollen, in which their concentrations are many times higher than in nectar (Detzel

and Wink, 1993; Kretschmar and Baumann, 1999; London-Shafir et al., 2003). Because high concentrations of nicotine and other SC cause severe toxicity in forager bees, it has been suggested that they are not especially adapted to cope with them (Detzel and Wink, 1993). However, if the bees encounter SC only in nectar, it is reasonable to consider the toxic nature of SC only within the concentration range actually found in nectar. We focused on nicotine concentrations actually found in floral nectar of *Nicotiana* spp. because it is unknown whether the bees collect and consume the pollen of these plants. If they collect both nectar and pollen of a particular plant that contains SC, one has to consider the concentration ranges of SC of both. Pollen is vital for plant reproduction, so the higher concentrations of SC in pollen may reflect a differential allocation providing high protection from being consumed.

What factors may enable larvae to tolerate naturally occurring concentrations of nicotine? In nature, bees collect nectar from various plants, which may be mixed in the hive to reduce the concentrations of SC. In our experiment, they had no alternative nectar source, but only the experimental test solutions. We found a drastic reduction (>90%) in the concentration of nicotine in honey as compared with the consumed experimental solutions. This is consistent with previous observations on reduction in concentrations of SC, such as amygdalin (50% reduction) and caffeine (90% reduction) in honey (including fresh honey samples) compared with the nectar (Kretschmar and Baumann, 1999; London-Shafir et al., 2003). The actual mechanisms whereby bees reduce SC concentrations in honey are still unknown. Larvae are fed with honey containing reduced SC concentrations. Moreover, induction of detoxifying enzymes known in larval bees (Nielsen et al., 2000) should help to cope with SC toxicity.

In summary, our study demonstrates that naturally occurring concentrations of nicotine in nectar do not affect colony fitness of honeybees, even when such nectar has been consumed for nearly 3 wk and no alternative nectar was offered. However, higher concentrations of nicotine cause high larval mortality. Further studies are essential for clearer insights into the effect of SC in nectar and pollen on both adult honeybees and developing brood regarding their differential susceptibility and/or physiological resistance. In the future, it will be important to study what concentration spectra of different SC the bees encounter in both nectar and pollen and what concentration spectra of these SC they can handle at all developmental stages.

Acknowledgments—We thank Noga Reuven for her assistance in acquiring and maintaining the beehives. The devoted technical assistance of Yoni Gavish, Einat Shilo, Liz Margolis, Bentzy Carmona, and Noam Cohen is greatly appreciated. INTRODUCTION

Pseudocopulation or sexual mimicry is a remarkable and puzzling pollination strategy within the Orchidaceae. Flowers pollinated through pseudocopulation offer no floral reward to their pollinators and display sets of characters that prompt visitation and pollination by sexually excited male insects (mostly Hymenoptera; Kerr and Lopes, 1962; Van der Pijl and Dodson, 1966; Dressler, 1993; Ayasse et al., 2000). These flowers emit fragrances that mimic the sexual pheromones of virgin insect females (Borg-Karlson, 1990; Borg-Karlson and Tengö, 1986). Visual clues, such as coloration and floral indument of the labellum (median petal), reinforce the insect-like appearance of these flowers (Kullenberg, 1961; Van der Pijl and Dodson, 1966). In this pollination strategy, sexually excited male insects arrive at flowers and attempt copulation (normally with the median petal). As in most orchids, the pollen is packed into discrete units called pollinia. Additional flower secretions or structures hold the pollinia together. The pollinia and these secretions or structures form a complex pollen-dispersal unit or pollinarium (plural: pollinaria) (Singer and Koehler, 2004). During attempts by male insects to copulate with the flower, the pollinaria stick to the insects' body surface (Kullenberg, 1961; Van der Pijl and Dodson, 1966; Dressler, 1993). Insects laden with pollinaria then promote pollination during successive visits to other flowers by depositing the pollinia (or parts of them) on the surface of the floral stigma (Kullenberg, 1961; Van der Pijl and Dodson, 1966; Dressler, 1993).

Pollination through pseudocopulation has been particularly well documented in terrestrial orchids of the subfamily Orchidoideae from Europe, Africa, and Oceania (Kullenberg, 1961; Van der Pijl, 1995, 2001; Borg-Karlson, 1990; Borg-Karlson and Tengö, 1986; Schiestl et al., 2000; Ayasse et al., 2000, 2003). The pollination strategies of these taxa are closely associated with the biology of seasonal insects (Van der Cingel, 1995, 2001). The insects involved in pollination by pseudocopulation in orchids in the Old World are solitary bees and wasps. As a rule, these plants flower only when male insects are around, and, consequently, the males mistake the flowers for their respective female partners and promote pollination (Kullenberg, 1961; Van der Pijl and Dodson, 1966). When females finally emerge, males may be able to recognize "true females" and avoid the flowers (Van der Pijl and Dodson, 1966; but, see Ayasse et al., 2003). Consequently, pollination in these orchids is usually low (Neiland and Wilcock, 1998) and limited to a brief period of time prior to female emergence (Kullenberg, 1961; Van der Pijl and Dodson, 1966). Although a number of Neotropical orchid genera have been suggested as being pollinated by pseudocopulation (Van der Pijl and Dodson, 1966), these reports are preliminary and lack the details of literature on Afro-European or Australian taxa (Kullenberg, 1961; Borg-Karlson, 1990; Borg-Karlson and Tengö, 1986;

FIG. 1. (A) Flower of *Mormolyca ringens* (Orchidaceae: Maxillariinae) in frontal view. (B) *Scaptotrigona* drone attempting copulation with a flower of *M. ringens*.

Borg-Karlson, 1990; Van der Cingel, 1995; Ayasse et al., 2000, 2003; Schiestl et al., 2000; Van der Cingel, 2001). Recently, pollination through pseudocopulation has been reported for *Trigonidium obtusum* Lindl. and *Mormolyca ringens* (Lindl.) Schltr. (Figure 1A and B; both belonging to the subtribe Maxillariinae, sensu Whitten et al., 2000; Kerr and Lopes, 1962; Singer and Koehler, 2004; Singer, 2002; Singer et al., 2004). Interestingly, sexually excited drones of Meliponini pollinate both orchid species. In contrast to cases documented in the Old World, these bees are eusocial (i.e., there are castes, and there is division of labor in the hives). The hives are perennial and produce fertile individuals several times a year. In agreement, plants of *T. obtusum* and *M. ringens* produce flowers throughout most of the year (Singer, 2002; Singer et al., 2004). Gas chromatography–mass spectrometry (GC-MS) analysis of *T. obtusum* floral fragrance reveals that pentadecane is the main constituent (over 95%; Flach et al., 2004). In contrast, the fragrance of *M. ringens* contains 31 main components (Singer et al., 2004) and is visited and pollinated by *Scaptotrigona* and *Nannotrigona testaceicornis* (Apidae: Meliponini).

As part of our multidisciplinary studies on Maxillariinae orchids pollinated by pseudocopulation, we investigated the floral chemistry of *Mormolyca* and compared it with that of virgin queen bees, assuming that similar chemical components should be present in both organisms. Specifically, we wished to determine and compare the floral chemistry of *M. ringens* and the sex pheromone of virgin queens of *Scaptotrigona* sp. (Meliponini). *Scaptotrigona* is one of the two Meliponini genera recently reported to pollinate this orchid

(Singer et al., 2004; Figure 1A and B). There are around eight species of *Scaptotrigona* in Brazil (Silveira et al., 2002), but they vary in morphology and behavior and represent a taxonomically difficult group. Readers interested in the biology, taxonomic details, and phylogenetic affinities of *Scaptotrigona* bees are referred to Silveira et al. (2002).

METHODS AND MATERIALS

Plant Material. Fresh flowers were obtained from plants grown in the orchidarium of the Escola Superior de Agronomia Luiz de Queiroz, Universidade de São Paulo, Piracicaba, São Paulo State, Brazil. Voucher specimens (ESA 7247, ESA 16802, and ESA 1648) were deposited in the ESA and UEC herbaria. Insect voucher specimens were deposited in the Laboratório de Abelhas (Instituto de Biociências, Universidade de São Paulo, São Paulo State, Brazil).

Flower Extract. Pollinated ($N = 5$) and unpollinated ($N = 4$) flowers were extracted by immersion in bidistilled hexane (500 μ l) for 24 hr. The hexane was evaporated to 50 μ l under a nitrogen stream, and 1 μ l was analyzed by GC-MS.

Rearing Meliponini Queens. Young larvae were transferred to artificial cells (6.6-mm diam, 8.8 mm high), where the amount of food was controlled. To obtain complete success (100% of female larvae developing into queens), the amount of food necessary to develop a worker (35.4 mg) was tripled (106 mg).

Artificial cells and their caps were made from molded *Apis mellifera* L. wax. Food for larvae was harvested from 100 natural cells from a *Scaptotrigona* colony. Artificial cells were incubated at 28°C, with ca. 75% RH that was sustained by using a saturated KCl solution. Pupae were transferred to new cells to avoid fungal infection. Ten queens were reared and manually fed every 2 hr with a syrup of honey, pollen, and water. Only queens were reared. In addition, bees were kept in captivity until they were sacrificed and excludes the possibility that these bees were fertilized.

Extraction of Cuticular Waxes from Virgin Queens. The waxes of 10 virgin queens of *Scaptotrigona* sp. were extracted by washing their abdomens with bidistilled hexane (500 μ l). The solvent was reduced to 50 μ l under a nitrogen stream, and 1 μ l was analyzed by GC-MS.

Virgin Queens Cephalic Extract. The heads of 10 virgin queens of *Scaptotrigona* sp. were crushed and extracted with 200 μ l of bidistilled ethyl acetate. After 10 min, the solution was filtrated, and the solvent was evaporated to 50 μ l under a nitrogen stream, and 1 μ l was analyzed by GC-MS.

GC-MS Analysis. GC analysis was carried out using a Hewlett Packard 6890 apparatus fitted with an HP-5 fused silica capillary column (30 m \times 0.25 mm \times

0.25 μm). A sample volume of 1 μl was injected, and pressure programming was used to maintain a constant flow (1 ml/min) of the helium carrier gas. A Hewlett Packard 5973 mass spectrometer was used in the EI mode (ionization energy of 70 eV) and set to scan the mass range of 50–700 u at a rate of 2.94 scans/sec. The interface temperature was maintained at 280°C. The resulting data were processed using the Hewlett Packard Chemstation Software package. The temperature program was from 50 to 310°C at 4°C/min, plus 40 min at the final temperature. The injector temperature was 240°C.

Identification of Alkanes. Alkanes identification was confirmed by comparing mass spectra and retention times with those of standard alkanes and by using a Wiley275 database.

Derivatization of Alkenes. Extracts (0.3–0.5 mg) were solubilized in 50 μl of dimethyldisulfide and 10 μl of a 10% solution of iodine in ethyl ether. The reaction mixture was kept at 50°C for 12 hr, and the reaction was quenched with aqueous $\text{Na}_2\text{S}_2\text{O}_3$. The organic phase was extracted with hexane (0.5 ml) and evaporated to 50 μl under a nitrogen stream, and 1 μl of the solution was analyzed by GC-MS. The dimethyldisulfide adducts were identified, and the positions of the methylsulfide substituents were deduced from the fragmentation pattern.

Trans-Cinnamic Acid Methyl Ester. Cinnamic acid (1 mg) was treated with 200 μl of a diazomethane solution in ethyl ether at room temperature for 15 min. The solvent was evaporated and the product was analyzed by GC-MS and ^1H nuclear magnetic resonance (NMR). EIMS (70 eV): m/z (%) = 162 (M^+ , 50%), 147 (2%), 131 (100%), 103 (74%), 77 (36%), 51 (12%). ^1H NMR (300.067 MHz, CDCl_3): δ = 3.81 (s, 3H), 6.45 (d, 1H, J = 15.9 Hz), 7.38 (m, 3H), 7.53 (dd, 2H), 7.70 (d, 1H, J = 15.9 Hz).

Trans-Cinnamic Acid Ethyl Ester. Cinnamic acid (2 mg) in ethanol (200 μl) and sulfuric acid (10 μl) were heated to reflux for 12 hr. The reaction mixture was extracted with dichloromethane (2×1 ml) and washed with aqueous NaHCO_3 , after which the solvent was evaporated and the product was analyzed by GC-MS. EIMS (70 eV): m/z (%) = 176 (M^+ , 34%), 147 (20%), 131 (100%), 103 (44%), 77 (25%), 51 (10%). ^1H NMR (300.067 MHz, CDCl_3): δ = 1.34 (t, 3H), 4.26 (q, 2H), 6.44 (d, 1H, J = 16.2 Hz), 7.38 (m, 3H), 7.52 (dd, 2H), 7.69 (d, 1H, J = 16.1 Hz).

Electrophysiology. *N. testaceicornis* male antennae ($N = 5$) were excised (pulled from the head) with forceps, and a few segments were cut off at the base and the tip (Bjostad, 1998). Each antenna was then fixed between two stainless-steel electrodes by pushing the base and tip into droplets of an electrically conductive gel (Spectra 360[®] electrode gel, Parker, Orange, NJ, USA) applied onto the metal electrodes.

Electroantennogram (EAG) recordings were carried out by using a Syntech EAG system (Hilversum, The Netherlands). An antenna was stimulated by

subjecting it to puffs (0.3 sec) of purified and humidified air (1.2 l/min) delivered through a Pasteur pipette, containing a filter paper strip (ca. 0.8 cm), impregnated with 5 μ l of test solution. Hexane and dichloromethane were used as control stimulus: crude floral extract and volatiles were captured by dynamic *headsapce*. Control stimulation was made before and after each test compound of each EAG experiment. Test compounds were applied randomly at intervals of 90 sec. The Syntech EAG software calculated the normalized values automatically. The mean normalized responses of the different compounds were submitted to ANOVA for statistical analysis and were compared by using Tukey's test ($P < 0.05$).

RESULTS AND DISCUSSION

Monitoring Mormolyca Floral Chemistry. While studying *M. ringens* floral chemistry, we observed that pollinated flowers attracted neither *Scaptotrigona* (Singer et al., 2004) nor *Nannotrigona*, the alternative pollinator. We assigned this phenomenon to floral chemistry changes in pollinated and unpollinated flowers.

Monitoring (Table 1, Figure 2) of the hexane extracts of unpollinated (Figure 2A) and pollinated (Figure 2B) flowers by GC-MS showed that the floral chemistry changed as soon as pollination occurred. The total relative abundance of alkene/alkane ratio for unpollinated flowers is 0.8, and in pollinated flowers, the ratio is lower (0.3). Additionally, the 9,17-octadecadienal and C-25 and C-27 alkenes were less abundant in pollinated flowers (1.60, 2.02, and 1.15%, respectively; Table 1) than in unpollinated flowers (7.88, 10.20, and 9.7% respectively; Table 1), and the males were no longer attracted to the pollinated flowers (Singer et al., 2004).

This analysis was repeated five times with different flowers, and the same results were always obtained. To determine the position of unsaturation, we derivatized the floral extract with dimethyldisulfide and iodine, as described by Buser et al. (1983). The fragmentation patterns of all the *bis*-methylsulfide derivatives in the total ion chromatogram were similar with major fragments at m/z 173 and at m/z 243 + n14, which was consistent with a homologous series of 9-alkenes ranging from C-23 to C-31, all of them possessing odd carbon numbers. The remaining constituents (peaks 1–6) were identified by coinjection with standards. Schiestl and Ayasse (2002) analyzed flower extracts of *Ophrys fusca* and *O. bilunulata* and detected alkenes ranging from C-25 to C-29, but with unsaturations at C-7, C-9, C-11, or C-12. In *M. ringens*, however, the double bond was always found at C-9.

Monitoring Scaptotrigona sp. Virgin Queens (bee) and M. ringens (Orchidaceae) Chemistry. The attraction of *Scaptotrigona* sp. and *Nannotrigona* males to *M. ringens* flowers and the induction of pseudocopulation suggested that the flowers had chemical compositions similar to virgin queen bees that were cultivated for investigation. This was based on the previous knowledge that in all Meliponini genera (except for *Melipona*), workers and queen castes are differentiated by a quantitative feeding system (Kerr, 1948). Thus, larvae ingesting moderate amounts of food will develop into workers, while larvae ingesting large amounts of food will develop into queens (Camargo, 1972b). Therefore, we used the technique of Camargo (1972a) and Menezes et al. (2004) to

TABLE 2. 2-ALKANOLS IDENTIFIED IN ACETATE CEPHALIC EXTRACTS OF VIRGIN QUEENS OF *Scaptotrigona* SP

Compound	Relative abundance (%)
Heptan-2-ol	28.3
Nonan-2-ol	25.6
Undecan-2-ol	19.1
Tridecan-2-ol	27.0

produce queens “in vitro.” We were more successful in rearing *Scaptotrigona* sp. than *N. testaceicornis*, thus, the chemistry from different *Scaptotrigona* sp. virgin queen’s (all originated from the same hive) bodies and heads ($N = 10$ individuals) was investigated. GC-MS analysis of the cephalic acetate extracts revealed the presence of a mixture of 2-alkanols (Table 2). A similar mixture of 2-alkanols was reported by Engels et al. (1997) in the volatile fraction of the cephalic secretions of receptive virgins of *S. postica*. These authors also demonstrated that the 2-alkanols acted as long-range attraction signals (Engels et al., 1997). Because we also detected the same 2-alkanol mixture, we concluded that the virgin queen bees we were dealing with were receptive to males.

In addition to an attractive, long-range “perfume,” virgin queen bees also require additional short-range chemical signals to prompt male sexual behavior (Schiestl et al., 2000). However, this additional short-range precopulatory signal has not yet been identified for *Scaptotrigona*. We hypothesized that the short-range attractive components were located on the abdominal surface. To examine this possibility, female bees ($N = 10$) were washed with hexane, and the extract was analyzed by GC-MS. This analysis revealed a homologous series of alkanes and alkenes. The latter showed an odd series C-23 to C-31 with unsaturation at position 9, identical to that seen in the *M. ringens* hexane extract, but in a slightly different alkane/alkene ratio.

Working with *Ophrys* (Orchidaceae) and *Andrena* bees, Schiestl and Ayasse (2002) have demonstrated that these two organisms have similar alkane/alkene constituents, not identical in abundance; the alkane/alkene mixture (present in both virgin bees and orchid labella) was demonstrated to be responsible for the pseudocopulatory behavior in the *Andrena* bees–*Ophrys* system (Schiestl et al., 2000). Extrapolating these results to the *Mormolyca* × *Scaptotrigona* system, we suggest that the homologous 9-alkane/alkene series present in the flowers and virgin queen bees may be responsible for the chemically induced copulatory activity in males.

Changes in Floral Chemistry. As indicated above, floral chemistry undergoes a compositional change following pollination (a decrease in the relative alkene/alkane abundance, assumed to be the short-range floral attractant), so that

the flower no longer attracts *Scaptotrigona* males. Although the relative floral alkene/alkane composition and abundance were similar in *M. ringens* and in *Scaptotrigona* sp. virgin queen bees, we were intrigued by the lack of similarity in the long-range attraction chemicals detected in the cephalic extracts of *Scaptotrigona* sp. (homologous series of 2-alkanols). A detailed examination of the floral hexane extract revealed no 2-alkanol. Because we considered that this negative result might reflect an inappropriate sampling method, we trapped the emitted volatiles of an unpollinated flower by using dynamic headspace methodology (Singer et al., 2004). At first, 2-alkanol was not detected, but a closer analysis of the total ion chromatogram for specific ions revealed the presence of 2-heptanol. We concluded that male attraction does not require large quantities of the active substance, and that, in this case, 2-heptanol may have been the active principle responsible for attracting *S. postica* males.

Based on these results, and on a similar phenomenon (Ayasse et al., 2000), we suggest that the 2-alkanols (specifically, 2-heptanol) act as long-range chemical signals, whereas homologous odd 9-alkene/alkane series act as short-range signals and induce copulation in *Scaptotrigona* sp. To confirm, *in vivo*, the pollinators' response to floral chemistry, we collected as many male bees as possible, all flying around the *M. ringens* flowers. However, many did not survive long enough to reach the analytical laboratory, and only the remaining specimens, i.e., *N. testaceicornis* drones, were investigated by electroantennography (EAG). Mean depolarization achieved by *N. testaceicornis* male antennae in response to the crude floral extracts and volatile components of *M. ringens* is

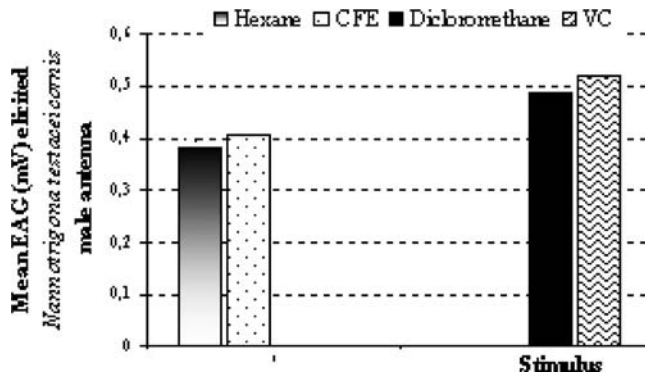

FIG. 3. Mean values (\pm SD, in mV) of electroantennography (EAG) responses of *Nannotrigona testaceicornis* male antenna to crude floral extracts (CFE) and volatile components (VC) of *M. ringens*. Mean values marked with the same letter are not significantly different at $P < 0.05$ based on Tukey's test ($N = 5$). Hexane, 100%; CFE, 1 mg/ml; dichloromethane, 100%; VC, not determined.

shown in Figure 3. Both extracts elicited EAG responses statistically different from controls. These results indicated that *N. testaceicornis* recognized the chemical components present in both extracts via antennae chemoreceptors and suggested that this bee uses *M. ringens* volatiles to find these specific flowers. EAG provided conclusive data on the selective antennae depolarization by the orchid floral constituents compared with the control (solvents).

SPECIES-SPECIFIC ANTENNAL RESPONSES TO TIBIAL FRAGRANCES BY MALE ORCHID BEES

THOMAS ELTZ,^{1,*} MANFRED AYASSE,² and KLAUS LUNAU¹

(Received June 21, 2005; revised August 11, 2005; accepted September 1, 2005)

Abstract—Male neotropical orchid bees (Euglossini) collect odoriferous substances from orchids and other sources and store them in tibial pouches, accumulating complex and species-specific bouquets. These fragrances are later exposed at display sites, presumably to attract females or conspecific males or both. We hypothesized that the necessity to detect and recognize specific fragrance bouquets has led to peripheral chemosensory specializations in different species of orchid bees. To test this, excised male antennae of four species of *Euglossa* were stimulated with complete tibial extracts of the same four species in a crosswise experiment. In the majority of the tested extracts, the amplitude of the electroantennogram (EAG) response was significantly different between species and always maximal in males of the extracted species. This effect did not appear to result from a given species' increased sensitivity toward certain attractive components: gas chromatography with electroantennographic detection (GC-EAD) of one extract of *Euglossa tridentata* evoked similar and generalized response patterns in all four species, encompassing a total of 34 peaks that elicited antennal responses. Therefore, the species effect in EAG responses to complete extracts likely resulted from species-specific interactions of compounds at the receptor level. Antennal specialization to conspecific bouquets adds additional strength to the argument that specificity is an important evolutionary aspect of euglossine tibial fragrances.

Key Words—Sensory specialization, olfaction, EAG, GC-EAD, odor bouquet, Euglossini.

INTRODUCTION

Male orchid bees are uniquely adapted for collecting and storing volatile chemicals, which they seek at flowering orchids, aroids, palms, and other plants, as well as at nonfloral sources such as rotting wood and feces (Vogel, 1966; Dressler, 1982). The fragrances are dissolved in lipoid labial gland secretions and are transferred to spacious cavities in the bees' hind tibiae. Here, complex mixtures of terpenoids and aromatics accumulate over weeks or months (Whitten et al., 1989; Eltz et al., 1999). Mounting evidence suggests that males release the substances during bouts of courtship display, for which they defend small territories around perch trees in the forest understory (Bembé 2004; Eltz et al., 2005a). On rare occasions, females visit these territories to mate, but it is unknown whether their attraction is mediated by the fragrances or indeed by any other chemical stimulus (Kimsey, 1980; Eltz et al., 2003).

Chemically, the tibial contents seem to be species-specific in a rather broad sense: males of *Euglossa* vary substantially in qualitative and quantitative aspects of their bouquets, but much less so within than between species. Notably, each species has a characteristic set of fragrance compounds (~6–15) that is shared with high probability even by individuals from distant and ecologically divergent localities (Eltz et al., 1999, 2005b). Field experiments suggest that this chemical profile is sufficient to promote specific long-range attraction. When hexane extracts of *Eulaema meriana* and *Eulaema bombiformis* hind legs were applied to filter paper and exposed at known male display sites in the forest understory, these extracts quickly and reliably attracted other males of the correct species (Zimmermann, Roubik and Eltz, submitted). Thus, it seems that fragrance perception is important to male euglossines in two rather different contexts. First, males must find remote fragrance sources, which emit mostly either single components (e.g., some nonfloral odors (Whitten et al., 1989, 1993; Eltz et al., 1999) or simple blends of 2 to 10 components (most euglossophilous orchids; Williams and Whitten, 1983; Gerlach and Schill, 1991). Second, fragrance perception is important in the context of territorial behavior, where males encounter the much more complex blends previously accumulated by their peers. In either context, one might expect strong selection pressures leading to sensory specialization in favor of certain odor qualities and divergent sensory tuning in different species of bees.

Here, we used electroantennography (EAG) to quantify antennal responses to conspecific and heterospecific tibial extracts in four species of *Euglossa*. EAG records the sums of receptor potentials from the entirety of olfactory neurons located in the antenna, and the amplitude of the recorded signal is assumed to reflect the strength of stimulation evoked by an odor. The method has previously been used to investigate odor detection in a wide variety of insects (Roelofs, 1984; Schiestl and Marion-Poll, 2002), including orchid bees (Schiestl and Roubik, 2003). In addition to recording EAG responses to

complete extracts, we used gas chromatography coupled with electroantennographic detection (GC-EAD) to screen tibial extract components for their ability to elicit responses from antennae of male bees.

METHODS AND MATERIALS

Bees. Males of *Euglossa imperialis* (imp), *E. cognata* (cog), *E. mixta* (mix), and *E. tridentata* (trid) were captured during the first 2 wk of March 2005 in forests of the Barro Colorado National Monument, Panama. Individuals were captured upon arrival at screened 1,8-cineole (imp, cog, trid), methyl salicylate (imp, cog, mix), *p*-dimethoxybenzene (cog, trid, mix), and skatole (mix) baits, and were later transferred to Düsseldorf, Germany, in individual vials. The bees were introduced into 50 × 50 × 60 cm mesh cages placed in a greenhouse (25–30°C, 70–90% relative humidity) where they learned to drink honey-water from artificial flowers. Individuals were subjected to EAG (Düsseldorf) and GC-EAD (Ulm) over the course of 4 wk.

Test Extracts. Hexane extracts were prepared from males of all four species collected at the same time at the same Panamanian locality (see above). Individual heads and pairs of hind legs were extracted separately in 0.5 ml of p.a. grade hexane (Merck). Hind-leg extracts were screened by GC-MS for fragrance content, and three rich extracts of each species were selected as EAG stimuli. This screening for tibial content was necessary because many individual male *Euglossa* contain only tiny amounts of fragrances (Eltz et al., 1999). The selected extracts were likely derived from relatively old males that had accumulated substantial quantities. The hind-leg extracts contained a large quantity and variety of lower molecular weight (<300 Da) terpenoids and aromatics [the exogenous fragrances; see Eltz et al., (1999)], a range of long chain saturated and unsaturated hydrocarbons, alcohols, acids, acetates, diacetates, and esters (“lipids,” mostly products of the bees’ labial glands, added in the process of fragrance collection; Williams and Whitten, 1983), and a few high molecular weight compounds presumably derived from plant surfaces (e.g., triterpenoids) (see Appendix; Available online at www.springerlink.com; Search for DOI: 10.1007/s10886-006-9352-0). To test whether labial gland lipids alone stimulated antennae, we prepared and tested one head extract of each of the species. Head extracts contained roughly similar amounts of labial gland lipids as did the hind-leg extracts, but lacked fragrance compounds (see Appendix; Available online at www.springerlink.com; Search for DOI: 10.1007/s10886-006-9352-0).

EAG with Complete Extracts. Single antennae cut at the tip and at the third antennal segment were mounted between two glass pipettes filled with insect Ringer solution and connected to silver electrodes. All extracts were tested once on each antenna. During the test series, one stimulus was applied every 2 min, with the

individual extracts arranged in blocks of four (one of each species per block, randomized within-block sequence), interspersed by solvent blanks. For every stimulus, 5 μ l of the test solution were pipetted onto a fresh 2 \times 10 mm strip of filter paper. The solvent was allowed to evaporate before the strip was placed in a clean pipette tip. For stimulation, 200 μ l of air were puffed over the filter paper and injected into a purified and moistened air stream blowing over the antenna. EAG responses were amplified and recorded (in mV) using Syntech (Hilversum, The Netherlands) electrode holders, IDAC-232 acquisition controller, and EAG recording software. The amplitude of the negative baseline deflection was used as a measure of response. To analyze whether a species' response to an extract was greater than that elicited by the averaged hexane blanks, we calculated rank-based Wilcoxon matched-pairs tests for all extracts, separately in each species. We then standardized responses to extracts across antennae to control for variations in the size of bee and the quality of preparation. Single-factor ANOVA was calculated to test for the overall effect of the factor *species* on the response to a given extract.

GC-EAD Screening. The tibial extract *trid 3* was selected to screen for the electrophysiological effect of its single components. Antennal preparations were identical to those described above. GC-EAD was done with an HP 6890 gas chromatograph fitted with a DB-5 column (J&W Scientific, Folsom California, 30 m \times 0.25 mm I.D.). A variable outlet splitter (SGE) was used to divide the effluent 3:1, and the larger fraction was directed onto the bee antennae. Nitrogen was used as a makeup gas. Flame ionization detector and EAD signals were recorded with Syntech EAD recording software. For each run, 1 μ l of the extract was injected splitless, testing antennae of males of all four species. The GC oven was programmed from 50 to 300°C at 10°C/min. A peak was classified as "GC-EAD active" when it coincided with a negative EAD baseline deflection in all analyzed runs. Each antenna was tested only once, and all scored antennae originated from separate individuals.

RESULTS

EAG Responses to Complete Extracts. All tested hind-leg extracts elicited substantially larger antennal responses than did solvent blanks in each of the species [Wilcoxon matched-pairs tests: $P < 0.01$ in all 48 comparisons (12 extracts \times 4 species); Figure 1]. Irrespective of the perceiving species, the response level varied between extracts, with *E. tridentata* extracts eliciting relatively large and *E. imperialis* extracts relatively small responses (Figure 1). This variation corresponded to the overall concentration of fragrances in the different extracts (see Appendix; Available online at www.springerlink.com; Search for DOI: 10.1007/s10886-006-9352-0). In 9 of the 12 hind-leg extracts, there was a significant effect of the perceiving species on the magnitude of the

FIG. 1. Standardized electroantennogram response (mean and standard deviation) of males of four species of *Euglossa* to hind-leg extracts taken from males of the same four species captured in Central Panama. Three extracts of each species were tested (trid = *E. tridentata*, mix = *E. mixta*, imp = *E. imperialis*, cog = *E. cognata*). Significance levels of the factor “perceiving species” on response amplitude are given (single-factor analysis of variance: $N = 37$; ** $P < 0.01$; *** $P < 0.001$).

response (see Figure 1), with the correct (extracted) species showing the largest response in all cases. The species effect was particularly pronounced in the case of *E. tridentata* and *E. mixta*. Here, the extracted species showed a response that was roughly 20% larger than that of the other species.

In contrast to hind-leg extracts, the head extracts elicited only weak responses that were not significantly different from averaged solvent blanks in most comparisons (data not shown here). The following responses were marginally significant (Wilcoxon matched-pairs tests; $P < 0.05$): *E. cognata* to *E. tridentata*, *E. tridentata* to *E. tridentata*, and *E. imperialis* to *E. cognata*, *E. imperialis*, and *E. tridentata*.

GC-EAD Screening. The tibial extract *trid* 3 was selected to screen for physiologically active components. We analyzed a total of 17 GC-EAD runs: 5 with *E. tridentata*, 6 with *E. cognata*, 3 with *E. imperialis*, and 3 with *E. mixta* antennae. A total of 33 GC peaks elicited reproducible negative baseline deflections in all species, and 1 additional peak, an uncharacterized trace compound (28 in Figure 2), did so only in *E. tridentata*. Most of the dominant fragrance components elicited EAD responses, frequently causing strong negative deflections. Reproducible deflections also were caused by several minor fragrance components and by eicos-9-enyl-1,20-diacetate (34), the major component of *Euglossa* labial gland secretions. A few peaks were not active in spite of their relatively large size. These included the moderate peaks of α -pinene and β -pinene and the massive peak of (*E*)-nerolidol. The overall response pattern was similar between species, although some late eluting fragrance compounds seemed to cause somewhat larger responses in *E. tridentata* (29 and 30 in Figure 2).

DISCUSSION

Tibial fragrance bouquets of male *Euglossa* bees elicited larger EAG responses from conspecific than heterospecific antennae. This suggests that peripheral olfactory specialization has occurred in the different species of orchid bees, presumably because of different olfactory cues being important in their respective life cycles.

The various species of euglossine bees differ in the type of fragrances they prefer to collect. This is evident in the range of synthetic chemicals that can be used to lure males of different species during baiting assays (Ackerman, 1989). In a previous study, we tested a broad range of these pure compounds, but did not find a species-specific difference in the EAG responses, although the tested species had quite distinct chemical preferences on the behavioral level (Eltz and Lunau, 2005). These findings are broadly confirmed by the GC-EAD screening of extract components in the present investigation: response patterns to bait chemicals such as 1,8-cineole, eugenol, *p*-dimethoxybenzene, 2,3-epoxygeranyl acetate, or benzyl benzoate were surprisingly similar across species.

FIG. 2. Antennal responses of four male *Euglossa* spp. to components of a hind-leg extract of *E. tridentata* (*trid* 3 in Figure 1) eluting from the gas chromatograph. The flame ionization detector chromatogram is shown along with one representative electroantennographic detection (EAD) signal for each of the study species. Numbered peaks correspond to reproducible negative deflections of the baseline in all four species, except peak (28), which was active in *E. tridentata* only. Peaks (12) and (19) are marked but not numbered on the chromatogram because of limited space. (1) Limonene + 1,8-cineole; (2) (*E*)- β -ocimene; (3) ipsdienol; (4) *p*-dimethoxybenzene; (5) ?; (6) trace; (7) 2,3-epoxygeraniol; (8) eugenol; (9) (*E*)-methyl cinnamate; (10) β -elemene, ?; (11) trace; (12) (*E*)-caryophyllene; (13) (*E*)-isoeugenol; (14) 2,3-epoxygeranyl acetate; (15) (*E,E*)- α -farnesene; (16) β -bisabolene; (17) sesquiterpene alcohol; (18) *p*-methoxycinnamic alcohol; (19) methoxyeugenol; (20) (*E*)-farnesene epoxide; (21) (*E*)-methyl *p*-methoxycinnamate; (22) hedycaryol; (23) similar methoxyeugenol; (24) (*E*)-*p*-methoxycinnamyl acetate; (25) benzyl benzoate; (26) trace; (27) hexahydrofarnesyl acetone; (28) trace; (29) ?; (30) 3,7,11,15-tetramethyl-hexadeca-2,6,10,14-tetraen-1-ol, ?; (31) diterpene alcohol; (32) + (33) long-chain unsaturated acids; (34) eicos-9-enyl-1,20-diacetate; (35, not shown) long-chain acetate. *Peak of (*E*)-nerolidol, the only major component that did not elicit an EAD response. See text for further specifications.

Why should complete tibial bouquets elicit species-specifically different EAG responses if critical components do not? Natural fragrance cues encountered by male bees are in fact mixtures, either the tibial fragrances themselves (as exposed by displaying males) or the more simple blends of the floral sources from which they are derived. Detecting and discriminating among mixtures of odorants is certainly important to the bees and may be a challenging task given that more than 30 species of euglossines may coexist in neotropical forests. Antennal specializations to certain odorant combinations might facilitate fragrance resource partitioning among competing males of different species as well as benefit fragrance-based chemical communication within species (e.g., facilitate species recognition).

On the mechanistic level, species-specific differences in EAG responses to complete extracts could have accumulated from small species-specific differences in sensitivity to certain components. Each of these differences may have been too small to be detected when components were tested individually (as in Eltz and Lunau, 2005), but when combined in complex blends, they might produce a significant overall effect. Furthermore, with mixtures of odorants, antennal responses may also be influenced by how different components interact on the level of olfactory receptor neurons (Akers and Getz, 1993; Cromarty and Derby, 1997). Recent work on *Drosophila* suggests that individual receptor proteins can confer either excitatory or inhibitory effects on an olfactory neuron, depending on precisely which odorant is binding to them (Hallem et al., 2004). In the case of complex mixtures, a number of different odorants could bind simultaneously to any given neuron, with relative concentrations determining the outcome of the neuron-level response. If tested as mixtures, inhibitory effects of certain components may have substantial effects on the overall antennal response. For orchid bees, Schiestl and Roubik (2003) have argued that inhibitory interaction of compounds at the receptor level may be responsible for decreased EAG responses to certain synthetic fragrance mixtures. We hypothesize that species-specific inhibitory effects were responsible or at least contributed to differential responses to tibial bouquets. This view has interesting implications for the orchid–euglossine bee coevolution. Normally, a given euglossophilous orchid attracts only one or a few species of euglossine bees (Roubik and Hanson, 2004), although its scent may be dominated by a broadly attractive component. In such a case, selectivity appears to be achieved by minor modifying compounds that render a given bouquet unattractive to all but the pollinating species (Williams and Dodson, 1972). The inhibitory effects of these modifiers may already be operating at the antennal level. Future studies should attempt to imitate naturally occurring orchid fragrances by mixing synthetic components in the correct blends. Using stringent comparative EAG testing with pollinating and nonpollinating bees might help to elucidate the sensory basis of specialized orchid–bee interactions.

Acknowledgment—We thank the staff of the Botanical Gardens of Düsseldorf and Ulm for their hospitality and assistance with beekeeping. T.E. wishes to thank Anna Sramkova for providing first guidelines for GC-EAD, Yvonne Zimmermann for her help with catching bees, and R. Kaiser and H. Budzikiewicz for help with compound identification. Financial support from the Deutsche Forschungsgemeinschaft (EL 249/2-1) is gratefully acknowledged.

Abstract—Forty-nine secondary metabolites were isolated from aqueous and alcoholic extracts of the aquatic plant *Schoenoplectus lacustris*. All compounds were characterized based on spectroscopic data. Eleven free and glycosylated low-molecular polyphenols, 17 cinnamic acid and dihydrocinnamic acid derivatives, 11 flavonoids, and 10 C₁₃ *nor*-isoprenoids were identified. The structure of the new compound, 1-benzoyl-glycerol-2- α -L-arabinopyranoside, was elucidated by 2D NMR experiments (COSY, HSQC, HMBC, NOESY). To evaluate potential phytotoxic effects, all compounds were tested on the green alga *Selenastrum capricornutum*, a unicellular organism commonly used in tests of toxicity as a bioindicator of eutrophic sites. The most active compound was (–)-catechin, showing an inhibition similar to that of the algaecide CuSO₄.

Key Words—*Schoenoplectus lacustris*, polyphenols, cinnamic acids, dihydrocinnamic acids, flavonoids, C₁₃ *nor*-isoprenoids, (–)-catechin, phytotoxicity, antialgal, *Selenastrum capricornutum*.

INTRODUCTION

In aquatic systems, plants can release allelochemicals into the water, and complex interactions between phytoplankton and vascular plants have been in-

* To whom correspondence should be addressed. E-mail: antonio.fiorentino@unina2.it

vestigated. A number of plants possess inhibitory effects on populations of microalgae by releasing phytotoxic substances into the environment (Gross et al., 2003).

Early studies on interactions between aquatic plants and microalgae were conducted by Schreiter (1928), Hasler and Jones (1949), and Fitzgerald (1969). Later, experiments were designed to identify interactions between hydrophytes and microalgae (Kogan and Chinnova, 1972; Brammer, 1979; Godmaire and Planas, 1983).

Allelochemicals have been isolated from aquatic plants, and the ability of some natural products to inhibit *in vitro* development of microalgae has been reported by our research group in recent years (Cangiano et al., 2001; DellaGreca et al., 2001, 2003a, b).

In this research, we report on a phytochemical study of *Shoenoplectus lacustris* L. (Cyperaceae) and its effects on *Selenastrum capricornutum*, an algal species selected as a bioindicator of eutrophic sites for studies in aquatic environments (OECD, 1984; ISO, 1982). The effects of 49 low-molecular weight secondary metabolites on microalga *S. capricornutum* are reported.

METHODS AND MATERIALS

General Experimental Procedures. NMR spectra were recorded at 500 MHz for ^1H and 125 MHz for ^{13}C on a Varian spectrometer (Varian Inc., Palo Alto, CA, USA) in CDCl_3 or CD_3OD solutions at 25°C . Optical rotations were measured on a Perkin-Elmer 343 Polarimeter (Norwalk, CT, USA). CD spectra were obtained in MeOH solutions on a Jasco J-715 Spectrophotometer Polarimeter (Jasco, Great Dunmow, UK). Electronic impact mass spectra (EI-MS) were obtained with an HP 6890 instrument equipped with an MS 5973 N detector (SIS Instruments, Ringoes, NJ, USA). The HPLC apparatus (Shimadzu, Kyoto, Japan) consisted of a pump (Shimadzu LC-10AD), a refractive index detector (Shimadzu RID-10A), and a Shimadzu Chromatopac C-R6A recorder. Preparative HPLC was made by using a 250×10 mm i.d., $10 \mu\text{m}$, RP-18 Luna column (Phenomenex, Torrance, CA, USA) and SiO_2 (MAXSIL, 250×10 mm i.d., Phenomenex) columns. Analytical TLC was conducted on Merck Kieselgel 60 F_{254} or RP-8 F_{254} plates with 0.2-mm layer thickness (Merck, Darmstadt, Germany). Preparative TLC was performed on Merck Kieselgel 60 F_{254} plates, with 0.5 or 1 mm film thickness. Flash column chromatography (FCC) was carried out with Merck Kieselgel 60 (230–400 mesh) at medium pressure. Column chromatography (CC) was performed on Merck Kieselgel 60 (70–240 mesh), Baker Bond Phase C18 (0.040–0.063 mm), Fluka (Fluka, Buchs, Switzerland), Reversed phase silica gel 100 C8 (0.040–0.063 mm) or on Sephadex LH-20[®] (Pharmacia).

FIG. 1. Chemical constituents of *Schoenoplectus lacustris*.

Plant Material. Plants of *S. lacustris*, collected in the summer of 2002 from the Volturno River (Campania, Italy), were identified by Professor Assunta Esposito at the Second University of Naples (SUN). Voucher specimens (CE 31) were deposited at the Herbarium of the Dipartimento di Scienze della Vita of the SUN.

Extraction and Isolation. Fresh plants (12 kg) were extracted in 10% MeOH-H₂O over 3 d, in the dark at 4°C. After removal of the solution, plants

FIG. 1. Continued.

were extracted with MeOH for 5 d. After removal of methanol, the hydroalcoholic fraction was extracted first with methylene chloride and then with EtOAc. The two fractions were evaporated under reduced pressure to obtain crude residues (Scheme 1). Structures are provided in Figure 1. CH₂Cl₂ extract (13.3 g) was chromatographed on SiO₂ eluting with petroleum ether and EtOAc solutions to give seven fractions I–VII: Fraction I, eluted with petroleum ether, furnished compounds **6**, **7**, and **40**. Fraction II, eluted with petroleum ether–EtOAc (19:1), gave seven compounds: **5**, **13**, **14**, **4**, **8**, **23**, and **24**. Fraction III, eluted with petroleum ether–EtOAc (9:1), furnished three compounds: **1**, **17**, and **25**. Fraction IV, eluted with petroleum ether–EtOAc (4:1), gave six compounds: **2**, **20**, **22**, **27**, **28**, and **31**. Fraction V, eluted with petroleum ether–EtOAc (3:1), led to the isolation of **26**, **44**, **49**, and **45**. Fraction VI, eluted with petroleum ether–EtOAc (3:2), furnished compounds **38**, **41**, and **42**. Fraction VII, eluted with petroleum ether–EtOAc (1:1), gave isoprenoid **43**.

EtOAc extract (16.8 g) was chromatographed on SiO₂ eluting with CHCl₃ and EtOAc solutions to give six fractions VIII–XIII. Fraction VIII, eluted with CHCl₃, led to the isolation of **34** and **35**. Fraction IX, eluted with CHCl₃–EtOAc (19:1), gave flavone **36**. Fraction X, eluted with CHCl₃–EtOAc (9:1), furnished compound **32**. Fraction XI, eluted with CHCl₃–EtOAc (4:1), gave compounds **37** and **47**. Fraction XII, eluted with CHCl₃–EtOAc (3:2), led to the isolation of **21**, while fraction XIII, eluted with CHCl₃–EtOAc (1:4), gave compounds **42** and **46**.

MeOH extract (50.8 g) was dissolved in water and beaten with EtOAc to obtain an organic fraction and an aqueous one (Scheme 2). Structures are shown in Figure 1. The EtOAc fraction (30.4 g) was chromatographed by CC on Sephadex LH-20, eluting with hexane–CHCl₃–MeOH (1:1:1) to give five fractions, A–F. Fraction A furnished metabolites **12**, **21**, **29**, and **30**. Fraction B contained quercetin **33**. Fraction C consisted of compound **37**. Fraction D gave compounds **2** and **18**. Fraction E led to the isolation of **39** and **19**, whereas fraction F gave **3** and **35**.

The H₂O fraction (20.4 g) was chromatographed on Amberlite XAD-4 and eluted first with H₂O to eliminate sugars and proteins from the extract, then with MeOH–H₂O (1:1) and finally with MeOH. The eluate obtained with MeOH–H₂O (1:1) gave a fraction (G) that furnished compounds **15** and **16**. The eluate obtained with MeOH was chromatographed with H₂O and MeOH solutions to give five fractions H–L. Fraction H, eluted with H₂O–MeOH (17:3), gave compounds **10** and **48**. Fraction I, eluted with H₂O–MeOH (4:1), yielded glucoside **9**. Fraction J, eluted with H₂O–MeOH (4:1), gave compounds **11** and **36**. Fraction K, eluted with H₂O–MeOH (1:1), led to the isolation of glucoside **34**, whereas fraction L, eluted with H₂O–MeOH (1:3), gave rutinoid **35**.

Bioassay. The effects of the extracts and the isolated compounds were assessed on *S. capricornutum*, more recently renamed *Pseudokirchneriella*

FIG. 2. Antialgal activity of the extracts of *Schoenoplectus lacustris*.

subcapitata. The alga was provided in immobilized algal beads by MicroBio Test (Nazareth, Belgium). The antialgal test was performed by deimmobilizing algae from the matrix with ethylene-bis(oxyethylenenitrilo)tetracetic acid (EGTA). *S. capricornutum* was cultivated on Bold basal medium (BBM) (Nichols, 1973). Cell density was measured with an electronic particle dual threshold counter (Coulter Counter Z2, 100 μm capillary; Instrumentation Laboratory, Miami, FL, USA). When the culture reached exponential growth phase, 1 ml (1.0×10^4 cells/ml) was poured onto a Petri dish with 20 ml of BBM containing 1.5% agar. The plates were incubated in a growth chamber at 25°C under continuous illumination (8000 lx). After 24 hr, a green layer of algae was evident on the agar, and subsequently a known quantity (0.5, 1.0, 2.0, and 3.0 μmol) of each chemical, dissolved in acetone or ethanol, was poured onto paper disks (sterile banks, Difco Bacto Concentration Disks, 3 mm). Each treatment was repeated with four replicates. After evaporation of the solvent, disks were placed on each Petri dish inoculated 24 hr before. Positive controls, for tests on single compounds were prepared by inoculating 0.5, 1.0, 2.0, and 3.0 μmol of algaecide CuSO_4 in 10 μl of Milli-Q water on the disk. A solvent control using acetone or ethanol on each disk was also prepared and placed on plates after evaporation (2 hr). The same procedure, with acetone or ethanol as solvent, was used for the extracts, and three independent experiments were performed in four replicates. The plates were incubated in a growth chamber for 96 hr at 25°C under continuous illumination (8000 lx). Chemical inhibition was

calculated by measuring the diameter of the no-growth zone excluding the paper disk (3 mm). The values obtained represent the average of three experiments. Phytotoxicity was compared with that of algaecide CuSO_4 .

Data Analysis. The statistical significance of differences between groups was determined by Student's *t*-test, calculating mean values for growth inhibition. The significance level was set at $P < 0.05$.

RESULTS AND DISCUSSION

Aliquots of hydroalcoholic and methanolic extracts of *S. lacustris* were dried under reduced pressure, and the residues were tested on *S. capricornutum* to evaluate the anti-algal effects. A common algaecide, CuSO_4 , was used as positive control. This compound shows a median effective concentration (EC_{50}) in standard algal growth inhibition test (ISO 8692) equal to 0.045 mg/l with confidence interval at 95% ranging from 0.032 to 0.070. In this study, high concentrations of CuSO_4 were used because no information existed on the activity of the investigated extracts. Our results, reported in Figure 2, showed that the MeOH extract had a no-growth zone 66% greater than that of algaecide CuSO_4 at the maximum concentration tested, but became inactive below 40 mg/l. The aqueous extract was less active than the positive control at the highest concentrations but remained active up to 20 mg/l.

The hydroalcoholic fraction was extracted first with methylene chloride and then with EtOAc to obtain crude residues CH_2Cl_2 and EtOAc. The MeOH extract was dissolved in water and shaken with EtOAc to obtain an organic fraction and an aqueous one. Chromatographic processes of the fractions (Schemes 1 and 2) led to the identification of 49 compounds (Figure 1).

Compounds 1–4 were identified as 4-hydroxybenzaldehyde, benzoic acid, protocatechuic acid, and methyl benzoate, respectively. Compound 5 was identified as methyl 4-acetyloxy-3-methoxybenzoate. Its EI-MS spectrum showed the molecular peak at $m/z = 224$. The ^1H NMR spectrum showed three aromatic protons of a 1,2,4-trisubstituted benzene, two methoxyls at $\delta = 3.87$ and 3.84 and a methyl at $\delta = 2.20$. These data, together with NOE observed between this latter methyl and the aromatic doublet, allowed an acetoxy group to be localized at the C-4 carbon and a methoxyl at C-3 carbon with a methyl benzoate structure. In compounds 6 and 7, ^1H NMR evidenced the ABX spin system of the vinyl group. The differences in their collected spectral data could be justified by the 3,4-dihydroxystyrene structure for 6 and 4-hydroxy-3-methoxystyrene for 7. Compound 8 was identified as 1-(3,4-dihydroxyphenyl)ethane, and compound 9 as 4-hydroxy-3-methoxyphenyl-1- O - β -D-glucopyranoside. ^1H NMR showed three aromatic protons as two doublets at $\delta = 6.82$ ($J = 2.1$ Hz) and 6.79 ($J = 8.2$ Hz)

and a double doublet at $\delta = 6.58$. The spectrum also indicated a methyl singlet at $\delta = 3.82$, a doublet at $\delta = 4.75$, and six protons ranging from 3.75 to 3.30 ppm. GC analysis of the compounds, after hydrolysis, reduction, and acetylation, showed the sugar moiety to be glucose. The coupling constant (7.4 Hz) of the anomeric proton indicated a β configuration at C-1'. NOE, between the H-1' proton at $\delta = 4.75$ and the H-2 and H-6 protons localized the sugar at the C-1 carbon of the aromatic ring. Compound **10** was identified as benzyl-1-*O*- α -L-arabinopyranoside. EI-MS spectrum showed the molecular ion at $m/z = 240$, and ^1H NMR revealed signals of five aromatic protons as well as two diastereotopic protons as two doublets ($J = 11.4$ Hz) at $\delta = 4.25$ and 4.67. NMR data of the glycidic moiety revealed the presence of a pentose, identified as arabinose by GC analysis of the alditol acetate derivative. Compound **11** showed a molecular formula $\text{C}_{15}\text{H}_{20}\text{O}_8$, according to EI-MS spectrum, indicating a molecular ion peak at $m/z = 328$. The ^1H NMR spectrum revealed three aromatic signals as a doublet integrated for two protons at $\delta = 8.02$, a triplet at $\delta = 7.59$, and a triplet integrated for two protons at $\delta = 7.48$. These data suggested the presence of a benzoyl unit in the molecule. In the aliphatic region of the spectrum, there were also a doublet at $\delta = 4.92$, two double doublets at $\delta = 4.34$ and 4.44, as well as eight protons in the range 4.20–3.40 ppm. ^{13}C NMR showed a carboxyl carbon at $\delta = 167.1$ and four signals in the aromatic range, two of them due to the homotopic C-2'/C-6' and C-3'/C5' carbons of the benzoyl group. Eight carbons, five methines, and three methylenes were also evident in the spectrum. In the HMBC experiment, carboxyl carbon showed correlations with the H-2'/H-6' and H-3'/H-5' protons. The same carbon was also correlated with the protons at $\delta = 4.34$ and 4.44, which result correlated with the carbon at $\delta = 67.4$ in the HSQC experiment. This carbon was in turn correlated with the proton at $\delta = 4.18$ bonded to the carbon at $\delta = 70.3$, which showed heterocorrelations with the doublet at $\delta = 4.92$, due to an anomeric proton, and with two methylene protons at $\delta = 3.56$ and 3.92 bonded to the carbon at $\delta = 71.2$. The remaining ^1H and ^{13}C NMR signals were consistent with the presence of a pentose in the molecule. GC analysis of alditol derivative allowed the sugar moiety to be identified as L-arabinose.

Compounds **12–22** were identified as *p*-coumaric acid (**12**), caffeic acid (**17**), ferulic acid (**18**), and synapic acid (**21**), their corresponding methyl esters **13**, **19**, **20**, and **22**, 4-methoxycinnamic acid (**14**), and glucoside *p*-coumaryl-4-*O*- β -D-glucopyranoside (**15**) and glucoside *p*-coumaryl-1-*O*- β -D-glucopyranoside (**16**). Compounds **12**, **17**, **18**, and **21** were reported as allelochemicals by Li et al. (1993). These phenols inhibited lettuce seedling growth and seed germination. Compounds **19** and **20** were isolated from *Cestrum parqui* (D'Abrosca et al., 2004a), and their phytotoxicity assayed on the seeds of lettuce, tomato, and onion. The glucoside of *p*-coumaric acid (compounds **15** and **16**) were isolated from Riesling wine and play an important role as antioxidant components of this white wine (Baderschneider and Winterhalter, 2001).

FIG. 3. Antialgal activity of phenols on *Selenastrum capricornutum*. Values are presented as diameter of no-growth zone (mm) for Student's *t*-test. (a) $P < 0.01$, (b) $0.01 < P < 0.05$.

Compounds **23–28** were identified as phenyl propionic acid derivatives. 3-(4-Hydroxyphenyl)propionic acid (**23**) and 3-(4-hydroxy-3-methoxyphenyl)propionic acid (**26**) were reported from *C. parqui* (D'Abrosca et al., 2004a). Compounds **24**, **25**, **27**, and **28** were characterized as methyl 4-methoxydihydrocinnamate, methyl 4-hydroxydihydrocinnamate, methyl dihydroferulate, and methyl dihydrocaffeate, respectively.

Compounds **29–39** were identified as flavonoids. Compound **29** was identified as chrysoeriol, the aglycone of compounds isolated from *Potamogeton* spp. (Boutard et al., 1973; Roberts and Haynes, 1986; Les and Sheridan, 1990). Compound **30** was identified as tricetin, an allelopathic flavone released from rice seedlings (Kong et al., 2004). Compounds **31–33** were identified as luteolin, kaempferol, and quercetin, respectively. Glycosides **34–36** were isolated from *Sambucus nigra* (D'Abrosca et al., 2001). Compound **37** showed spectral data corresponding to catechin (Nahrstedt et al., 1987). It showed an $[\alpha]_D$ value (c, 0.16) -14.8 and a positive Cotton effect $\Delta\epsilon_{280\text{ nm}} +3.2$ nm, in accordance with the presence of (–)-catechin (Bais et al., 2003a). Calcones **38** and **39** were identified on the basis of their spectral data. $^1\text{H NMR}$ of **38** showed two protons as doublet of a *trans* double bond at $\delta = 6.27$ and 7.59 , an α,β unsaturated carbonyl group and four doublets of two aromatic system at $\delta = 7.44$, 7.16 , 6.80 , and 6.73 . EI-MS spectrum confirmed the proposed structure showing the molecular ion at $m/z = 240$ and fragments at $m/z = 147$ $[\text{CO}-\text{CH}-\text{CH}-\text{C}_6\text{H}_4\text{OH}]^+$, 119 $[\text{CH}-\text{CH}-\text{C}_6\text{H}_4\text{OH}]^+$, 121 $[\text{CO}-\text{C}_6\text{H}_4\text{OH}]^+$, and 93

FIG. 4. Antialgal activity of cinnamic acids derivatives on *S. capricornutum*. Values are presented as diameter of no-growth zone (mm) for Student's *t*-test. (a) $P < 0.01$, (b) $0.01 < P < 0.05$.

FIG. 5. Antialgal activity of dihydrocinnamic acids derivatives on *S. capricornutum*. Values are presented as diameter of no-growth zone (mm) for Student's *t*-test. (a) $P < 0.01$, (b) $0.01 < P < 0.05$.

FIG. 6. Antialgal activity of flavonoids on *S. capricornutum*. Values are presented as diameter of no-growth zone (mm) for Student's *t*-test. (a) $P < 0.01$, (b) $0.01 < P < 0.05$.

$[\text{C}_6\text{H}_4\text{OH}]^+$. ^1H NMR of compound **39** showed two doublets of the *trans* double bond at $\delta = 7.32$ and 6.33 , two methoxyl groups as a singlet at $\delta = 3.88$, and two 1,2,4-trisubstituted aromatic rings at $\delta = 7.58$ (d, $J = 2.0$ Hz), 7.48 (dd, $J = 8.5$ and 2.0 Hz), 7.11 (d, $J = 2.0$ Hz), 6.97 (dd, $J = 8.5$ and 2.0 Hz), 6.76 (d, $J = 8.5$ Hz), and 6.74 (d, $J = 8.5$ Hz). EI-MS spectrum showed the molecular ion at $m/z = 300$ and fragments at $m/z = 177$ $[\text{CO}-\text{CH}-\text{CH}-\text{C}_6\text{H}_3(\text{OCH}_3)\text{OH}]^+$, 149 $[\text{CH}-\text{CH}-\text{C}_6\text{H}_3(\text{OCH}_3)\text{OH}]^+$, 151 $[\text{CO}-\text{C}_6\text{H}_3(\text{OCH}_3)\text{OH}]^+$, and 123 $[\text{C}_6\text{H}_3(\text{OCH}_3)\text{OH}]^+$.

Compounds **40–49** were identified as C_{13} *nor*-isoprenoids. Compounds **40–42** and **44–45** were isolated and characterized from *C. parqui* (D'Abrosca et al., 2004b), whereas compounds **46**, **47**, and **49** were isolated from *Chenopodium album* (DellaGreca et al., 2004). Compound **43** was identified as the aglycone of some glucoside isolated from *Acanthus ebracteatus* (Kanchanapoom et al., 2001).

All compounds were tested on the green alga *S. capricornutum* to assay their antialgal effect. This organism is commonly present in aquatic systems and has been selected as bioindicator of the eutrophic sites. The test was conducted on agar using a modified antibiotic assay method. The phytotoxicity results are summarized in Figures 3–6, where only the active compounds are reported.

The results of the active low-molecular phenols **1–11**, which are reported in Figure 2, show a correspondence between dose and activity. The antialgal effect for compounds **1–3** increased with their polarity. The most active was protocatechuic acid **3**. The activity should be correlated with the hydrophilicity and/or acidity: the antialgal effect of the methyl ester of **1** (compound **4**) was

about 50% of the activity of the corresponding acid. Compound **5**, which has all its hydroxyl groups derivatized, was less phytotoxic in respect to the more polar compounds **1–3**. Compound **8** only showed a moderate antialgal effect for the highest doses used (2 and 3 μmol).

Figure 3 reports the results of the cinnamic acid derivatives. The most active compound was methyl ferulate **20**. For ferulic and synapic acids, esterification of the carboxyl group increased activity (**18** vs. **20** and **21** vs. **22**). *p*-Coumaric acid and its methyl derivative **13** showed a similar toxicity, whereas methyl caffeate was over 50% less active than caffeic acid (**19** vs. **17**). The most active of the dihydrocinnamic acid derivatives (Figure 4) was 3-(4-hydroxyphenyl)propionic acid (**23**); the introduction of another hydroxylated function in the molecule reduced activity (cf. **26** and **28**). Methylation also made the molecule less active with the carboxymethyl group in compound **25**, and with the carboxy and methoxy groups in compound **24**. Hydrogenation of the double bond of cinnamic acid increased correspondence between dose and activity and had a slow effect on toxicity (**12** vs. **23** and **18** vs. **26**). Hydrogenation of methyl ester **20** reduced the activity considerably, whereas methyl dihydroferulate **27** was less phytotoxic in respect to methyl ferulate **19**.

Results of bioassay with the flavonoids are reported in Figure 5. The presence of the catechol ring made the compound especially active (**31**, **33**, **34**, **36**, **37**). Glycosylation had little effect on activity, and the presence of the hydrophobic groups (methoxyls) decreased activity. The most active compound was (–)-catechin **37**, showing a no-growth zone similar to that of algacide CuSO_4 . C_{13} *nor*-isoprenoids were inactive at all quantities tested. Only **42**, **44**, and **45** metabolites showed slight no-growth zones of 3.0-, 4.2-, and 2.5-mm diameters, respectively, with 3.0 μmol of chemicals.

Among the constituents of *S. lacustris*, (–)-catechin **37** was the most active compound. The no-growth zone showed diameters similar to those of CuSO_4 , with an anomalous brown coloration probably as result of a photooxidation reaction that caused blocking of photosystem activity. The production of the reactive species (i.e., singlet oxygen) and the absence of photoprotection could cause the degradation of the photosynthetic pigments. The toxicity of (–)-catechin seemed to inhibit the photorespiration phenomenon. These results were in accordance with Bais et al. (2003b), showing that allelopathic effects of the weed *Centaurea maculosa* are attributable to a racemic mixture of (\pm)-catechin. They demonstrated that phytotoxic activity was due to (–)-catechin, whereas (+)-catechin had an antibiotic activity (Bais et al., 2002).

The natural abundance of *S. lacustris* along our rivers could optimize its use. In fact, the chemical characterization of the algal inhibitory component of the plant could provide a reliable method for controlling algal growth in eutrophic sites. Among the isolated metabolites, low-molecular phenolic compounds are toxic to algae and show a superior inhibitory activity on algal growth.

(Received June 25, 2005; revised September 23, 2005; accepted October 1, 2005)

Abstract—Sponges of the genus *Aplysina* accumulate brominated isoxazoline alkaloids in concentrations that sometimes exceed 10% of their dry weight. We previously reported a decrease in concentrations of these compounds and a concomitant increase in concentrations of the monocyclic nitrogenous compounds aeroplysinin-1 and dienone in *Aplysina aerophoba* following injury of the sponge tissue. Further investigations indicated a wound-induced enzymatic cleavage of the former compounds into the latter, and demonstrated that these reactions also occur in other *Aplysina* sponges. A recent study on Caribbean *Aplysina* species, however, introduced doubt regarding the presence of a wound-induced bioconversion in sponges of this genus. This discrepancy motivated us to reinvestigate carefully the fate of brominated alkaloids in *A. aerophoba* and in other *Aplysina* sponges following mechanical injury. As a result of this study we conclude that (1) tissue damage induces a bioconversion of isoxazoline alkaloids into aeroplysinin-1 and dienone in *Aplysina* sponges, (2) this reaction is likely catalyzed by enzymes, and (3) it may be ecologically relevant as the bioconversion products possibly protect the wounded sponge tissue from invasion of bacterial pathogens.

Key Words—Wound-induced bioconversion, chemical defense, biotransformation, brominated alkaloids, enzymatic cleavage, marine sponge.

they are exposed to, they follow different strategies. In cases of predictable or constant stress factors, constitutive defense mechanisms (e.g., shells and stings or the constitutive accumulation of protective metabolites) have usually evolved (Hay and Fenical, 1988). However, if the disturbing impacts display a high spatial or temporal variability, facultative defense mechanisms have often developed instead (Adler and Harvell, 1990; Harvell, 1990). The latter can be divided into two different forms: induced defenses and activated defenses.

“Induced defenses” such as induced defense metabolite biosynthesis (Havel, 1986; Roda and Baldwin, 2003) or induced morphological changes (Steneck and Adey, 1976; Lewis et al., 1987; Lurling, 2003) are slow. Inducing factors include predation or attack by harmful microorganisms. After the initial attack, the priorities of resource allocation in the attacked organism may be shifted from growth to defense. Sometimes it takes weeks until a protective effect occurs (Hammerstrom et al., 1998; Taylor et al., 2002). Thus, this type of mechanism can not be expected to provide immediate protection, but rather prepares the harmed organism for future attacks.

A faster response to stress factors is the attack-induced transformation of inactive precursor compounds stored in the tissue of the attacked organism, thereby yielding transformation products that exhibit a pronounced defensive activity. Paul and van Alstyne (1992) described this phenomenon as “activated defense” to distinguish it from the slower “induced defense.” Such mechanisms are fast (often occurring within seconds after wounding) in order to facilitate immediate protection against the affecting organism. These reactions are usually catalyzed by enzymes that convert inactive storage compounds into defensive products (Paul and van Alstyne, 1992; Hickel et al., 1996).

In the terrestrial environment, activated defense reactions involving enzymatic transformations of inactive precursors are frequently found in plants. Examples include cyanogenic glycosides that are transformed into highly toxic HCN (Conn, 1979; Wajant and Effenberger, 1996; Gleadow and Woodrow, 2002), or as in Brassicaceae and related plants, glucosinolates that are cleaved to form thiocyanates, isothiocyanate, or isonitriles (Stoewsand, 1995; Fahey et al., 2001). In all reported examples, the respective precursors are physically separated by compartmentalization from the biotransformation enzymes. Upon mechanical damage, the compartments are destroyed, which facilitates the formation of the protective substances as the enzymes and substrates make contact.

In the marine environment, examples of activated chemical defense mechanisms are also found. In green algae, *Halimeda*, tissue damage leads to the transformation of the diterpene halimeditetraacetate to the aldehyde halimedatrial, which is a more potent toxin compared to the precursor (Paul and van Alstyne, 1992). The green alga *Caulerpa taxifolia* accumulates caulerpenyne. After wounding of the algal tissue, it is deacetylated forming a

group of aldehydes, mainly oxytoxins 1 and 2 (Jung and Pohnert, 2001). Presumably, the transformation products are more potent defensive compounds than the precursor. It has been suggested that the rapid biotransformation of caulerpenyne is catalyzed by an esterase (Jung et al., 2002). A third example is the cleavage of dimethylsulfonylpropionate (DMSP) to acrylic acid and dimethylsulfide (DMS) by the enzyme DMSP lyase that was recently observed in macroalgae (van Alstyne et al., 2001; van Alstyne and Houser, 2003). This reaction was previously described in unicellular phytoplankton (Wolfe and Steinke, 1996; Wolfe et al., 1997).

Numerous marine invertebrates face ecological situations that are similar to those in marine or terrestrial plants. Ascidians, sponges, corals, and bryozoans are sessile and unable to protect themselves actively by flight or attack. They have evolved defense mechanisms similar to those of plants. Marine sponges have been particularly well investigated with regard to putative defense metabolites. Within the last 30 yr, over 4000 secondary metabolites have been isolated and described, many of which are biologically active (MarinLit, 2003). In various cases, these metabolites protect invertebrates against predators, competitors for settlement space, or against microbial pathogens (Green, 1977; Bakus et al., 1986; Becerro et al., 1997; McClintock et al., 1997; Thacker et al., 1998; Engel et al., 2002).

Induced chemical defense reactions have also been reported for sponges. Recent examples are *Suberites domuncula* and *Agelas conifera*. In *S. domuncula*, the level of two lyso-PAF (platelet-activating factor) congeners is increased upon exposure to an endotoxin derived from the outer cell wall of gram-negative bacteria (Müller et al. 2004). Lyso-PAF and analogues possess strong antimicrobial activity (Steel et al., 2002) and inhibit the growth of phytopathogenic fungi (Tanaka et al., 1997). In *A. conifera*, the concentrations of the antimicrobial and feeding-deterrent compounds sceptrin and oroidin increase 3- to 4-fold within 0.5–6 d following wounding of the sponge tissue (Richelle-Maurer et al., 2003).

An example for an activated chemical defense mechanism in sponges has been reported for *Aplysina aerophoba*. This sponge, like other *Aplysina* species, accumulates brominated isoxazoline alkaloids in concentrations of up to 10% dry weight (Albrizio et al., 1994; Aiello et al., 1995; Ciminiello et al., 1994a,b, 1995, 1996a,b, 1997, 1999, 2000; Thoms et al., 2003a). X-ray microanalysis revealed that these brominated metabolites are mainly stored in specialized sponge cells called spherulous cells (Turon et al., 2000). Teeyapant and Proksch (1993) reported the cleavage of these isoxazoline alkaloids in tissue of *A. aerophoba* when freeze-dried sponge material was extracted with water or with aqueous MeOH. During this reaction, the monocyclic nitrogenous compounds aeroplysinin-1 (**5**) and dienone (**6**) were formed (Figure 1). By extraction of freeze-dried tissue with 100% MeOH, however, only putative isoxazoline

FIG. 1. Wound-induced bioconversion of the brominated isoxazoline alkaloids aerophobin-2 (1), aplysinamisin-1 (2), and isofistularin-3 (3) to aeroplysinin-1 (5) and the dienone (6) in tissue of *Aplysina aerophoba*. When isofistularin-3 (3) is used as a substrate for the reaction, the bisoxazolidinone derivative (4) is recovered as a further product.

precursors, such as isofistularin-3 (**3**) or aerophobin-2 (**1**), were recovered. Subsequently, Ebel et al. (1997) reported that the bioconversion of the isoxazoline precursors into aeroplysinin-1 (**5**) and dienone (**6**) also takes place when fresh sponge tissue is crushed mechanically in the presence of seawater. Additional experiments with cell-free extracts from *A. aerophoba* and from six other *Aplysina* species collected in the Caribbean and in the Mediterranean Sea revealed that all *Aplysina* species had the capability to cleave isoxazoline alkaloids, thereby generating aeroplysinin-1 (**5**) (Ebel et al., 1997). This led to the conclusion that the observed cleavage of the isoxazoline precursors is catalyzed by enzymes present in *Aplysina* sponges. It was concluded that the cleavage reactions consist of at least two different steps: in a first step, degradation of the isoxazoline alkaloids gives rise to the β -hydroxynitrile aeroplysinin-1 (**5**), while in a second, this intermediate is converted into the dienone (**6**) via enolether hydrolysis and partial hydrolysis of the nitrile group (Teeyapant and Proksch, 1993; Goldenstein et al., 2000).

Bioactivity studies revealed that bioconversion of the isoxazoline alkaloids in *Aplysina* sponges is paralleled by an increase in antibiotic and cytotoxic activity (Teeyapant et al., 1993; Weiss et al., 1996). In contrast, feeding deterrent activity of the bioconversion products against the Mediterranean fish species *Blennius sphinx* is significantly weaker than observed for their isoxazoline precursors (Thoms et al., 2004).

Recently, Puyana et al. (2003) investigated the Caribbean sponges *A. insularis* and *A. archeri* with regard to a possible biotransformation of isoxazoline alkaloids following mechanical injury, which was simulated by stabbing the sponges with a scalpel. In this study, the authors came to the conclusion, that a conversion of the isoxazoline alkaloids into aeroplysinin-1 (**5**) and dienone (**6**) as reported for *A. aerophoba* was not apparent in the Caribbean *Aplysina* species, and they assumed that past observations of biotransformation reactions within the genus *Aplysina* were the results of either differential tissue extraction efficiency, hydrolysis from insoluble precursors, or a heterogeneous distribution of metabolites in sponge tissue. These contradictory results motivated us to reinvestigate the fate of brominated alkaloids in *Aplysina* sponges following mechanical injury.

METHODS AND MATERIALS

Sponges of the genus *Aplysina* (Demospongiae, Verongiida, Aplysinidae) frequently occur in the Mediterranean as well as in the Caribbean Sea. From both geographical regions, two representatives each were obtained. Specimens of the sponge *A. aerophoba* were collected by scuba diving and snorkeling at

depths between 3 and 10 m at Banyuls-sur-mer, France, in April 2002 and at Rovinj, Croatia, in August 2003. *A. cavernicola* was collected in May 2001 at Elba, Italy, whereas *A. fistularis* and *A. archeri* were from previous collections in the Bahamas in 1995. The Mediterranean sponge *Crambe crambe* (Demospongiae, Poecilosclerida, Myxillidae) was collected off the coast of Rovinj, Croatia, in August 2003. All sponges were carefully detached from the substratum with a knife to avoid tissue damage.

During sampling, specimens were kept submerged in ziplock bags filled with seawater for transport to the laboratory. All experiments with fresh, living sponge tissue were performed with *A. aerophoba* collected at Rovinj, Croatia. These specimens were directly used. For experiments involving lyophilized tissue, specimens were flash frozen and kept at temperatures below -80°C until freeze-drying and homogenization of the lyophilized tissue.

Wounding Intensity Series. Six tissue slices, each comprising a volume of 8 ml (thickness, 1 cm) were cut from one *A. aerophoba* individual with a scalpel. After the respective treatments, all samples were placed in 15-ml cryo tubes and flash frozen in liquid nitrogen.

Sample “t₀” was flash frozen after it was excised from the living sponge. Sample “b” was repeatedly stabbed with a scalpel over its entire surface for a total of 15 sec. After an additional period of 4 min and 45 sec, during which no further treatment was applied, the sample was flash frozen. Sample “c” was ground in a mortar for 15 sec instead. After an additional 4 min and 45 sec (no further treatment), it was flash frozen. Sample “d” was ground for a total of 5 min and immediately flash frozen. Sample “e” was treated like sample “d” with the exception that 1.5 ml EtOH were immediately added to the fresh tissue prior to grinding.

The same series of treatments was repeated four times, each time with samples that had been cut from a different *A. aerophoba* individual. Additional slices of two *A. aerophoba* individuals (samples “a”) were placed in a mortar without further treatment for 5 min followed by flash freezing.

Prior to HPLC analysis, all samples were lyophilized, ground to a fine powder, and exhaustively extracted with MeOH. Extracts were then injected into an HPLC system coupled to a photodiode array detector (Dionex, Germany). Routine detection was at 254 and 280 nm. The separation column (125 × 4 mm i.d.) was prefilled with Eurosphere C-18 (5 μm) (Knauer, Germany). Compounds were identified by their online UV spectra and by direct comparison with previously isolated standards (Ebel et al., 1997). Identification of compounds in extracts was further verified by LC-MS analysis using a diode array equipped HPLC system (Agilent 1100 Series; Agilent Technologies, Waldbronn, Germany) coupled to an electrospray ionization (ESI) Mass Spectrometer (LC-Q Deca; Finnigan, Bremen, Germany). Separation was achieved using a Knauer Eurospher C-18 column (5 μm, 2 mm diam × 250 mm long).

The amount of each individual compound in the samples was calculated from the detector response in HPLC-UV and the compound-specific molar extinction coefficients. Based on these data, proportions of the respective brominated alkaloids in the samples were expressed as percentage of the total content of brominated alkaloids (set at 100%) present in 1 g lyophilized sponge tissue.

A control experiment was performed with fresh tissue of the sponge *C. crambe* that had been collected at Rovinj. Three samples of the sponge tissue were spiked with one of the *A. aerophoba* metabolites aeroplysinin-1 (**5**), aerophobin-2 (**1**), or isofistularin-3 (**3**), each at concentrations within the range of their natural abundance in *A. aerophoba* (aeroplysinin-1 as found in damaged sponge tissue). To a fourth *C. crambe* tissue piece, no *A. aerophoba* metabolites were added. Samples were ground for 5 min and subsequently flash frozen. After lyophilization, samples were extracted and analyzed as described above.

Time Course Experiment Fresh tissue slices of *A. aerophoba* of the same volume as described in the experiment above (8 ml) were ground for 15 sec in a mortar. Over a total period of 165 sec, measured from the onset of grinding, aliquots were collected from the ground material and immediately frozen in liquid nitrogen. Following lyophilization, they were extracted and analyzed using HPLC-UV and LC-MS under the conditions described above. All samples comprising one time series resulted from one *A. aerophoba* individual. The four parallel experiments were performed with one individual each.

Experiments with Lyophilized Animal Tissue Experiments were performed with tissue of the two Mediterranean sponges, *A. aerophoba* and *A. cavernicola*, and the Caribbean sponges *A. fistularis* and *A. archeri*. For each species, lyophilized tissue from three different individuals was used. Tissue was ground and homogenized. Subsequently, two portions of 100 mg were sampled. One of these was used for exhaustive extraction with MeOH. The other was mixed with 600 μ l seawater, kept therein overnight, and was subsequently lyophilized again. After extraction with MeOH, all samples were analyzed as described above to determine the molar concentrations of the brominated alkaloids.

Additionally, lyophilized and ground tissue of *A. archeri* was spiked with aerophobin-2 (**1**) isolated from *A. aerophoba* in a concentration found naturally in the latter. The mixture was incubated in 600 μ l seawater and subsequently lyophilized, extracted, and analyzed as described above.

Control experiments were performed with lyophilized and ground tissue of the marine opisthobranch *Tyrodina perversa* and the sponge *C. crambe*. Mantle tissue of *T. perversa* naturally contains *Aplysina* alkaloids (Ebel et al., 1999; Thoms et al., 2003b). The opisthobranch tissue was incubated in seawater, lyophilized again, and subsequently extracted and analyzed as described for the lyophilized *Aplysina* sponge samples. Tissue of the sponge *C. crambe* was treated likewise, but prior to incubation in seawater was mixed with aerophobin-2 (**1**) and isofistularin-3 (**3**) in concentrations as found in *A. aerophoba*.

Data Analyses. Data of the wounding intensity series and the time course experiment were analyzed by randomized block analysis of variance, and multiple comparisons were made with the Tukey–Kramer test for unequal sample sizes (Zar, 1999). Percentage data were arcsine-transformed prior to statistical analyses. In case of missing data in the randomized block design, data were estimated iteratively, and the bias in the group sum of squares (group SS) as well as the total degrees of freedom (*df*) was corrected according to Li (1964) and Glen and Kramer (1958).

For analysis of variations in the relative concentration of bioconversion products in lyophilized *Aplysina* sponge tissue upon treatment with seawater, the percentage data were arcsine-transformed and subsequently analyzed using a two-tailed paired *t*-test (Zar, 1999).

RESULTS

Constitutive Alkaloid Patterns in Intact A. aerophoba Individuals Obtained from Croatia and France. The isoxazoline alkaloids aerophobin-2 (**1**) and isofistularin-3 (**3**) were the dominant compounds in individuals collected at Rovinj, Croatia (Table 1A). Aeroplysinin-1 (**5**) was present only at lower concentrations. Other isoxazoline alkaloids that are known for *A. aerophoba* (e.g., purealidines and aerophobin-1) were detected but not quantified, as they occurred only in negligible concentrations. Dienone (**6**) and aplysinamisin-1 (**2**) were not detected. In contrast, in individuals of *A. aerophoba* collected at the French coast at Banyuls, aplysinamisin-1 (**2**) was dominant, followed by aerophobin-2 (**1**) and isofistularin-3 (**3**) (Table 1B). Neither aeroplysinin-1 (**5**) nor dienone (**6**) was detected in these sponges. The sponge zochrome uranidine

was abundantly present in all analyzed sponge individuals, but due to its instability upon contact with air it could not be reliably quantified.

The overall concentration of brominated alkaloids was considerably lower in the *A. aerophoba* samples from France (Table 1B) than in the specimens from Croatia (Table 1A). Consistent with previous studies on other *Aplysina* species (Puyana et al., 2003), the absolute amounts of the various alkaloids detected in individuals of *A. aerophoba* (expressed as micromoles per gram dried tissue or as micromoles per ml volume of sponge tissue) varied considerably, whereas the relative proportions (in % compared to the total amount of alkaloids that was set at 100%) of the individual alkaloids turned out to be remarkably consistent for sponge specimens collected in France as well as in Croatia (Table 1A, B).

Wounding Intensity Series. The intensity of artificial damage to tissue taken from freshly collected *A. aerophoba* individuals was gradually increased by applying different methods of tissue destruction (stabbing with scalpel, grinding in mortar, addition of organic solvent plus grinding). This approach revealed an unequivocal correlation between increase in tissue destruction (wounding intensity), gradual disappearance of isoxazoline alkaloids, and concomitant increase in aeropylsinin-1 (5) content in injured vs. intact *A. aerophoba* tissue (Figure 2 and Table 2).

The possible effect of air exposure (without accessory wounding) on the metabolite pattern in tissue slices was tested (samples "a" in Figure 2 and Table 2). For this purpose, freshly cut slices of *A. aerophoba* were kept exposed to air in a mortar for 5 min before they were flash frozen. The brominated alkaloid composition in this tissue remained largely unchanged by this treatment, when compared to controls ("t₀" samples) that were flash frozen immediately after having been cut from the living sponge.

FIG. 2. Variations in the relative concentration of aeroplysinin-1 (**5**) in *A. aerophoba* tissue upon different intensities of wounding. Aeroplysinin-1 proportion is given in percent relative to the total brominated alkaloid content (set at 100%) in the sponge. For explanation of t_0 , a, b, c, d, and e, refer to Table 2. Data were arcsine-transformed prior to statistical analysis. Randomized block analysis of variance: $F = 21.13$, $P < 0.001$. Tukey–Kramer multiple comparisons (significant differences are indicated, only): $d \neq t_0$, $d \neq a$, $d \neq b$, $e \neq t_0$, $e \neq a$, $e \neq b$, $e \neq c$.

Stabbing of the sponge tissue with a scalpel over a period of 15 sec followed by subsequent exposure to air for 4 min 45 sec similarly had no apparent effect on the alkaloid pattern (samples *b*). However, the pronounced increase in tissue destruction caused by grinding the tissue in a mortar for 15 sec substantially changed the metabolite composition (samples *c*). By this treatment, a heterogeneous mixture of different-sized tissue pieces was obtained. As a result, aeroplysinin-1 (**5**) abundance in the sponge tissue increased more than 3-fold when compared to samples “a” or “b” (Table 2), whereas the concentrations of aerophobin-2 (**1**) and isofistularin-3 (**3**) decreased markedly.

When the grinding time of the sponge tissue was extended to 5 min (sample “d”), the tissue was more effectively crushed than observed for sample “c,” yielding a rather homogenous mixture of cellular debris. This resulted in a pronounced increase in the abundance of aeroplysinin-1 (**5**) (compared, for example, to sample “c”), which now accounted for almost two-thirds of all brominated alkaloids detected (Figure 2). In sample “e,” which had been subjected to grinding for 5 min in the presence of 16% EtOH (v/v), aeroplysinin-1 accounted for almost 90% of all brominated metabolites (Figure 2). In samples “c,” “d,” and “e,” the rise in concentration of aeroplysinin-1 was

t₀ Controls that were immediately flash frozen.

a Controls that were kept exposed to air for 5 min before flash freezing.

b Tissue pieces that were stabbed over 15 sec with a scalpel and were then subsequently left untreated for another 4 min 45 sec before flash freezing.

c Tissue pieces that were ground over 15 sec and were subsequently left untreated for another 4 min 45 sec before flash freezing.

d Tissue pieces that were ground over 5 min.

e Tissue pieces that were ground over 5 min after 16% (v/v) EtOH had been added.

Randomized block analysis of variance: aerophobin-2: $F = 24.68, P < 0.001$; isofistularin-3: $F = 15.21, P < 0.001$; aerophysinin-1: $F = 7.98, P < 0.001$.

Tukey-Kramer multiple comparisons (significant differences are indicated, only): aerophobin-2: c ≠ t₀, c ≠ b, d ≠ t₀, d ≠ a, d ≠ b, e ≠ t₀, e ≠ a, e ≠ b; isofistularin-3: c ≠ t₀, c ≠ b, d ≠ t₀, d ≠ b, e ≠ t₀, e ≠ a, e ≠ b, e ≠ c.

paralleled by an equally impressive decrease in the concentrations of isofistularin-3 (**3**) or of aerophobin-2 (**1**) (Table 2). Dienone (**6**) was not detected in any of the samples.

A control experiment was performed with the Mediterranean sponge *C. crambe* that contains no brominated alkaloids. Aeroplysinin-1 (**5**), aerophobin-2 (**1**), and isofistularin-3 (**3**) isolated from *A. aerophoba* were added to fresh tissue of *C. crambe*. The concentrations remained unchanged (recovery rates of 97–98%) after they were ground with *C. crambe* tissue over 5 min (similar treatment to sample “d” in the experiment with *A. aerophoba*; Table 2) (Figure 3). Neither aeroplysinin-1 (**5**) nor dienone (**6**) was detected in the ground samples that had been mixed with aerophobin-2 (**1**) and isofistularin-3 (**3**). In the ground sample that had been mixed with aeroplysinin-1 (**5**), no dienone (**6**) was detected. The metabolite composition of *C. crambe* also remained unaffected by the treatment.

Time Course Experiment. Grinding of fresh *A. aerophoba* tissue for 15 sec and subsequent collection of samples at set time intervals revealed a gradual and time-dependent increase in the relative proportions of aeroplysinin-1 (**5**) from

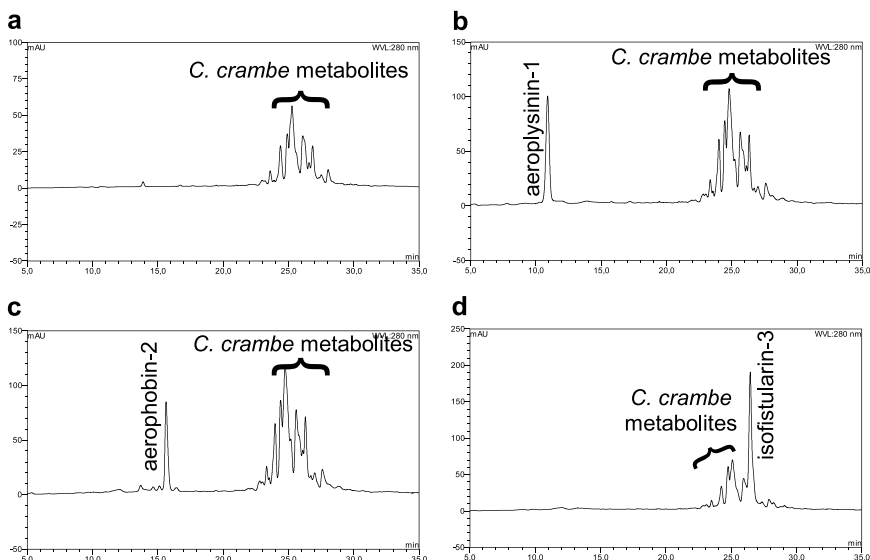

FIG. 3. Comparative HPLC analysis of crude extracts from ground fresh *Crambe crambe* tissue spiked with *A. aerophoba* metabolites (grinding time: 5 min). (a) *C. crambe* tissue without *A. aerophoba* metabolites added. (b) *C. crambe* tissue + aeroplysinin-1 (**5**). (c) *C. crambe* tissue + aerophobin-2 (**1**). (d) *C. crambe* tissue + isofistularin-3 (**3**). Recovery rates for *A. aerophoba* metabolites after grinding: 97–98%.

FIG. 4. Variations in the relative concentrations of aerophobin-2 (1), isofistularin-3 (3), and aeropylsinin-1 (5) in *A. aerophoba* tissue after 15 sec of grinding over a 165-sec time course. Proportions of the respective alkaloids are given in percent relative to the total brominated alkaloid content (set at 100%) in the sponge. Data were arcsine-transformed prior to statistical analysis. Randomized block analysis of variance: aeropylsinin-1: $F = 10.75$, $P < 0.001$; aerophobin-2 and isofistularin-3: no statistically significant differences. Tukey–Kramer multiple comparisons for aeropylsinin-1 (significant differences are indicated only): $0 \neq 20$ sec, $0 \neq 45$ sec, $0 \neq 75$ sec, $0 \neq 105$ sec, $0 \neq 135$ sec, $0 \neq 165$ sec.

$4.5 \pm 2.0\%$ in undamaged controls (t_0) to $25.0 \pm 4.8\%$ in samples taken after 45 sec (Figure 4). Thereafter, the aeropylsinin-1 concentrations remained largely unchanged until the observation was terminated after 165 sec.

Experiments with Lyophilized Animal Tissue. In lyophilized tissue of intact *Aplysina* sponges from the Mediterranean Sea (*A. aerophoba* and *A. cavernicola*) and from the Caribbean Sea (*A. fistularis* and *A. archeri*), brominated isoxazoline alkaloids consistently dominated over aeropylsinin-1 (5) or dienone (6) (Tables 1A, B, and 3) even though the alkaloid concentrations showed considerable inter- and intraspecific variation. Following incubation of lyophilized tissue in seawater, the concentrations declined in a pronounced manner, whereas the concentrations of both aeropylsinin-1 (5) and the dienone (6) increased sharply (Table 3, Figure 5). This phenomenon was consistent for all analyzed samples.

A second experiment was performed with lyophilized tissue of *A. archeri*. This sponge contains large amounts of various isoxazoline alkaloids (Table 3). Aerophobin-2 (1), however, which is a major alkaloid in *A. aerophoba*, was not detected in the specimens of *A. archeri* available for this study. Powdered

Quantities are expressed in μmol of compound per gram dry weight of sponge tissue.

Isoxazol. = pooled content of all detected isoxazoline alkaloids in the tissue; aerophys-1 = aeropylinin-1 (5) content; n.d. = not detected in the sample by HPLC-UV.

FIG. 5. Variations in the relative concentration of the postulated bioconversion products in ground lyophilized tissue of various *Aplysina* species upon treatment with seawater. The concentrations of bioconversion products aeropylsinin-1 (5) and dienone (6) are pooled. Their proportion is given in percent relative to the total brominated alkaloid content (set at 100%) in the respective sponge. Data were arcsine-transformed prior to statistical analysis. no sw = before treatment with seawater; sw = after treatment with seawater.

lyophilized tissue of *A. archeri* was spiked with aerophobin-2 (1) and subsequently incubated in seawater. Extraction and chromatographic analysis of the sample revealed that the added aerophobin-2, as well as the native isoxazoline alkaloids originally present in *A. archeri*, completely disappeared, whereas dienone (6) showed a considerable increase when compared to a parallel sample that had been lyophilized and extracted without seawater (Figure 6). In contrast, concentrations of the isoxazoline alkaloids aerophobin-2 (1) and isofistularin-3 (3) added to lyophilized and ground tissue of the sponge *C. crambe* remained unchanged, and neither aeropylsinin-1 (5) nor dienone (6) occurred after the tissue had been incubated in seawater [resulting HPLC chromatograms were similar to those shown for the experiments with fresh tissue of *C. crambe* (Figure 3) and, therefore, are not shown separately]. Similarly, in mantle tissue of the marine opisthobranch *T. perversa*, the

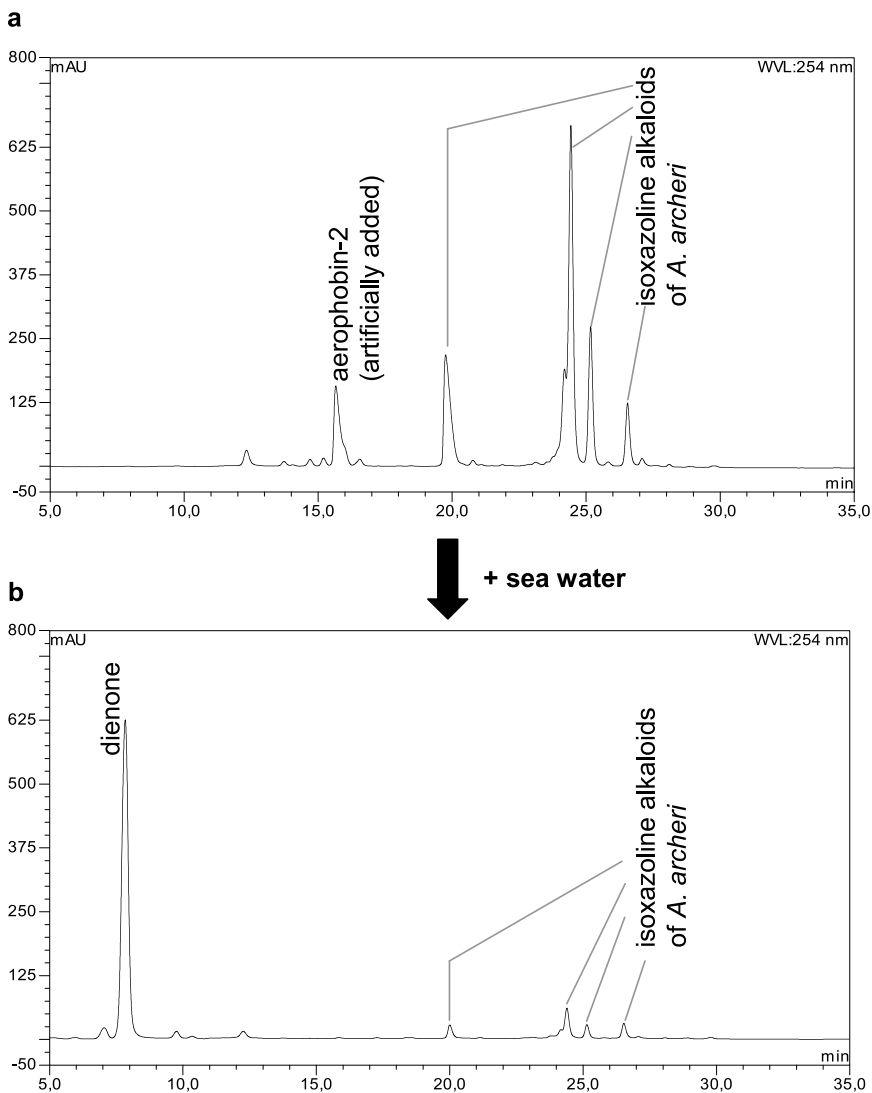

FIG. 6. Comparative HPLC analysis of ground lyophilized tissue of *Aplysina archeri* spiked with aerophobin-2 (**1**) before (a) and after (b) treatment with seawater. The signal intensity axis in both chromatograms is uniformly scaled to facilitate direct comparison.

concentrations of naturally occurring isoxazoline alkaloids remained unchanged, and neither aeroplysinin-1 nor dienone was detected after incubation of the lyophilized and ground material in seawater (data not shown).

DISCUSSION

Comparison of *A. aerophoba* individuals collected at Banyuls-sur-mer with those collected at Rovinj revealed considerable qualitative and quantitative differences in alkaloid patterns (Table 1A, B). The isoxazoline alkaloid aplysinamisin-1 (**2**) that consistently dominated the alkaloid pattern of the sponges from the French Mediterranean coast was not detected in sponges from Croatia. In sponges collected at Rovinj, we detected minor amounts of aeroplysinin-1 (**5**), which, in turn, were not found in individuals from Banyuls (Table 1A, B).

Within 10 specimens of *A. aerophoba* collected along a transect spanning several kilometers at Rovinj, the qualitative composition of the alkaloid patterns turned out to be remarkably similar (Table 1A). However, the absolute contents of brominated alkaloid showed a pronounced variability. Even different tissue samples within a single individual had considerable differences in total brominated alkaloid content. Pronounced variability of secondary metabolite concentrations is a commonly observed phenomenon in Porifera (e.g., Becerro et al., 1995; Betancourt-Lozano et al., 1998; Page et al., 2005), and in regard to the distinct natural variability of the alkaloid pattern in sponges of the genus *Aplysina*, our observations are in accordance with those of Puyana et al. (2003).

This natural variability in *Aplysina* sponges complicates investigations on artificially induced changes in the alkaloid profile, as large standard deviations resulting from replicates with erratic values are likely to obscure possible changes. For our experiments on the injury-induced bioconversion, we, therefore, selected the sponges from Rovinj that showed similarity in relative compositions of their alkaloids. By comparison before and after an experimental treatment (next to the comparison of the absolute values), we circumvented the problem of the vast standard deviations arising when absolute values are compared. We also complimented the experiments involving fresh tissue of *A. aerophoba* with experiments employing lyophilized sponge material. We had determined in our earlier studies (Teeyapant and Proksch, 1993) that the latter has the advantage of being amenable to grinding and homogenization prior to experimental treatment without inducing changes in the alkaloid pattern. Hereby, identical starting material is provided for all samples of an experiment, and even absolute values of the metabolite contents can be compared.

We caused injuries of different intensities to fresh, living tissue of *A. aerophoba* individuals (Table 2, Figure 2). In all samples, the reaction time, i.e.,

the period of time between the onset of the wounding and the flash freezing of the sample, was kept constant at 5 min. Thus, the only variable parameter was the intensity of wounding. In tissue samples that were only damaged to the degree necessary for removal of the sample from the whole sponge (samples "a"), the isoxazoline alkaloid (**1** and **3**) proportion relative to the total brominated alkaloid content amounted to $93.2 \pm 0.1\%$ (Figure 2). Alkaloid proportions in these samples were almost identical to samples that were immediately flash frozen after being cut from the sponge (samples "t₀"). Also, wounding by stabbing with a scalpel (samples "b") did not cause any observable changes in the alkaloid patterns. However, grinding the tissue over 15 sec lowered the isoxazoline alkaloid (**1+3**) proportion to $66.9 \pm 11.9\%$, whereas proportions of aeroplysinin-1 (**5**) increased (samples "c"). By grinding for 5 min, the sponge tissue was more finely homogenized, causing a decrease in the isoxazoline alkaloid proportion to $32.7 \pm 12.0\%$ (samples "d"). Addition of EtOH before 5 min grinding resulted in an isoxazoline alkaloid proportion of merely $9.6 \pm 7.5\%$ (samples "e"). The absolute content of the alkaloids (**1 + 3**) consequently decreased from an original value of $183.3 \pm 49 \mu\text{mol g}^{-1}$ dry weight in the samples "t₀" to $8.8 \pm 5.0 \mu\text{mol g}^{-1}$ in samples "e" (Table 2). At the same time, the aeroplysinin-1 (**5**) content increased from 11.8 ± 9.2 to $107.6 \pm 54.4 \mu\text{mol g}^{-1}$ dry weight sponge tissue. Thus, this experiment revealed a clear relationship between intensity of injury, decline of isoxazoline alkaloids (**1 + 3**), and rise of aeroplysinin-1 (**5**).

A time course experiment conducted for an aliquot of sample "c" that ran over a total of 165 sec (15 sec grinding followed by an additional exposure of the treated tissue for 150 sec) demonstrated the time-dependent increase in aeroplysinin-1 (**5**) (Figure 4). The injury-induced reactions take place within less than 1 min after wounding.

The capability of converting isoxazoline alkaloids to aeroplysinin-1 (**5**) and to the dienone (**6**), which possibly arises from the former by enolether hydrolysis and by partial hydrolysis of the nitrile group thereby giving rise to the amide function, can also be demonstrated for other *Aplysina* sponges such as *A. cavernicola*, *A. fistularis*, and *A. archeri*. From the latter three, only freeze-dried material was available. To obtain comparable results for the different sponges tested, *A. aerophoba* tissue was also lyophilized. Lyophilized and ground material of each *Aplysina* sponge analyzed was divided into two aliquots. One cohort was extracted with MeOH, the other aliquot was incubated in seawater, again lyophilized and subsequently extracted with MeOH. HPLC analysis revealed clear differences in alkaloid profiles between the two treatments (Table 3). Isoxazoline alkaloids dominated in all sponges that had been directly extracted after lyophilization, whereas samples that had been incubated in seawater showed decreased levels and dramatic increases in amounts of aeroplysinin-1 (**5**) and/or dienone (**6**). Exogenously added

aerophobin-2 (**1**), which was not among the brominated isoxazoline alkaloids detected in *A. archeri*, was similarly metabolized by lyophilized powder of this sponge when incubated in seawater (Figure 6). The possibility that the cleavage of the isoxazoline alkaloids is mediated by seawater alone can be excluded as it does not occur in the absence of *Aplysina* sponge tissue (or crude protein extract of these sponges) as demonstrated in our controls with tissue of *C. crambe* and *T. perversa* (Figure 3).

In contrast to compounds such as aerophobin-1 (**1**), alkaloid precursors consisting of two isoxazoline moieties (e.g., isofistularin-3 (**3**) in *A. aerophoba* and aerotionin in *A. cavernicola* and in the Caribbean *Aplysina* species) give rise to two molecules of aeroplysinin-1 upon enzymatic cleavage. This may explain the observation that the total molar concentrations of alkaloids (isoxazoline precursors + generated bioconversion products) in samples treated with seawater in some cases exceed the molar concentrations of precursors in the untreated samples (Table 3). The fact that the dienone (**6**) was also observed for *A. aerophoba* (Table 3) in experiments using lyophilized sponge tissue, whereas it had not been detected for the same sponge in the wounding intensity experiment (Table 2), can probably be explained by the different incubation times used in the experiments (overnight vs. 5 min in case of living tissue).

All experiments unequivocally suggest a wound-induced conversion of brominated isoxazoline alkaloids to aeroplysinin-1 (**5**), which may react further yielding the dienone (**6**). These results are in line with our earlier studies (Teeyapant and Proksch, 1993; Ebel et al., 1997), but are in contrast to the observations and conclusions made by Puyana et al. (2003) in their recent study. Puyana et al. (2003) suggest that our reports on the bioconversion phenomenon were the result of either (1) differential tissue extraction efficiency, (2) formation of aeroplysinin-1 (**5**) and/or dienone (**6**) upon contact of the fresh, wet sponge tissue with organic solvents as artifacts from otherwise insoluble precursors (other than the isoxazoline alkaloids), or (3) heterogeneous distribution of the putative bioconversion products in sponges. Based on these new results and on those from previous studies (Teeyapant and Proksch, 1993; Ebel et al., 1997), we believe that the arguments raised by Puyana et al. (2003) are insufficient to explain the observed phenomenon. We comment on them point by point:

- (1) *Differential tissue extraction efficiency*: Upon artificial wounding of living tissue of *A. aerophoba*, an obvious correlation between wounding intensity, decrease in brominated isoxazoline alkaloids (**1** and **3**), and a concomitant rise of aeroplysinin-1 (**5**) became obvious (Table 2, Figure 2). Different extraction efficiencies as an explanation for this phenomenon are unlikely as all tissue samples had been treated the same way (5 min of exposure followed by flash freezing, lyophilization, and extraction). The only

parameter in which the samples differed was the degree of tissue damage inflicted. While in the aforementioned experiment wounding intensity varied, this parameter was identical for all samples of the time course experiment (Figure 4). Nevertheless, we observed a steady increase the aeroplysinin-1 (5) concentration paralleled by a decrease in isoxazoline alkaloids that was positively correlated with the time between wounding and flash freezing of the damaged tissue.

- (2) *Formation of aeroplysinin-1 (5) and/or dienone (6) upon contact of the fresh, wet sponge tissue with organic solvents as artifacts from otherwise insoluble precursors:* Aeroplysinin-1 (5) is indeed accumulated when living tissue of *A. aerophoba* contacts organic solvents as shown, for example, for sample “e” (Table 2), where living tissue of *A. aerophoba* was treated with diluted EtOH. Except for sample “e,” however, all other samples of living *A. aerophoba* tissue analyzed in this study had been lyophilized prior to exposure to organic solvents. Nevertheless, in all of these samples, aeroplysinin-1 (5) occurred at high concentrations when the respective tissue had been damaged in a substantial manner prior to extraction (Table 2 and Figure 4). At the same time, isoxazoline alkaloid concentrations decreased significantly. Thus, the formation of artifacts upon organic solvent exposition of wet sponge tissue can be ruled out as a plausible explanation for the observed changes in the alkaloid pattern.
- (3) *Heterogeneous distribution of the putative bioconversion products in sponge tissue:* As described in Table 1A and B, alkaloid patterns as well as alkaloid concentrations in different specimens of *A. aerophoba* are subject to intraspecific and even intraindividual variation. Within a given sponge population, these differences are, however, mostly quantitative and not qualitative. For example, all specimens of *A. aerophoba* collected in Rovinj (Croatia) exhibited remarkably homogenous alkaloid profiles and differed only in regard to total alkaloid concentrations (expressed as $\mu\text{mol/g}$ dried tissue or as $\mu\text{mol/ml}$ volume of sponge tissue). The observed changes (reproducible decrease in isoxazoline alkaloids paralleled by a concomitant increase in aeroplysinin-1) we encountered during our experiments, therefore, can not be ascribed to lack of homogeneity of the sponge samples used.

While experiments with lyophilized sponge tissue provide only limited information for processes taking place under *in situ* conditions in living tissue, these experiments have the advantage of providing homogenous material in regard to alkaloid patterns and concentrations. Therefore, differences in alkaloid concentrations of control samples vs. treated samples can not be attributed to nonhomogeneous sponge tissue in experiments using lyophilized material (Table 3, Figure 5 and 6).

The only plausible explanation for the observed changes in the alkaloid patterns of *Aplysina* species is the effect of wounding itself, which results in a breakdown of cellular compartmentalization. We assume that the spherulous cells containing the isoxazoline alkaloids are broken down by mechanical damage. This results in the activation of the bioconversion of isoxazoline alkaloids yielding aeropylsinin-1 (**5**), which may further react to the dienone (**6**). This process would be similar to other known wound-induced bioconversion reactions (e.g., cleavage of cyanogenic glycosides or glucosinolates) in the plant and animal kingdom (Conn, 1979; Paul and van Alstyne, 1992; Wajant and Effenberger, 1996).

The hypothesis that aeropylsinin-1 (**5**) and dienone (**6**) arise from a cleavage of isoxazoline alkaloids is corroborated by a series of further observations: (1) after damaging tissue of *Aplysina* sponges, we never observed an increase in the concentration of the postulated bioconversion products aeropylsinin-1 (**5**) and dienone (**6**) without a concomitant decrease in the concentrations of the isoxazoline alkaloids; (2) the structures of the postulated bioconversion products (**5** + **6**) are directly deducible from the structures of the brominated isoxazoline alkaloids (**1**–**3**) (Figure 1); (3) the bisoxazolidinone derivative (**4**) would be expected as a byproduct of the proposed cleavage of isofistularin-3 (**3**) into aeropylsinin-1 (**5**). When performing *in vitro* assays on the bioconversion of isofistularin-3 using a cell-free extract of *A. aerophoba*, we detected the formation of the bisoxazolidinone derivative (**4**) next to aeropylsinin-1 (**5**) and dienone (**6**) (Ebel et al., 1997).

The fact that Puyana et al. (2003) failed to detect alkaloid conversions is probably attributable to insufficient wounding of the sponges, as a mere stabbing of sponge tissue with a scalpel was insufficient to provoke a measurable conversion of isoxazoline alkaloids in our study as well (Table 2). More severe tissue damage as can be achieved by grinding are necessary (Table 2), as otherwise small changes in the alkaloid composition that will occur only in injured cells are likely to be masked by the unchanged alkaloid profiles remaining in the intact cells that will by far outnumber the former.

Activated chemical defense mechanisms, i.e., rapid conversions of inactive precursor compounds into ecologically active products (reviewed in Havel, 1986; Adler and Harvell, 1990; Paul and Puglisi, 2004), are typically catalyzed by enzymes that are usually separated from their substrates (precursors) by compartmentalization. Upon tissue damage, these compartments are disrupted, facilitating the contact between substrates and the enzymes, which in turn induces the bioconversion. In many cases, the compounds emanating from such reactions arise from cleavage of the precursors. Compartmentalization is also observed in the mesohyl tissue of sponges of the genus *Aplysina*: the brominated isoxazoline alkaloids are mainly stored in specialized cells, the so-

called spherulous cells, in the sponge tissue (Thompson et al., 1983; Turon et al., 2000).

The bioconversion reactions that are observed for living as well as for lyophilized tissue of *Aplysina* species appear to be specific for these sponges, as other marine invertebrates, the sponge *C. crambe* and the opisthobranch *T. perversa*, were unable to convert isoxazoline alkaloids. This is of special interest with regard to *T. perversa*, as this gastropod sequesters isoxazoline alkaloids from its prey *A. aerophoba* (Ebel et al., 1999; Thoms et al., 2003b). In contrast to *C. crambe*, the tissue of this gastropod “naturally” contains brominated isoxazoline alkaloids. However, after grinding and incubating lyophilized tissue of *T. perversa*, we observed no changes in alkaloid profiles or concentrations. Neither aeroplysinin-1 nor dienone was detected, indicating that no biotransformation reactions had occurred.

Earlier experiments with cell-free protein extracts from various sponges revealed that only extracts from the sponges *A. aerophoba*, *A. cavernicola* (both from the Mediterranean Sea), *A. archeri*, *A. cauliformis*, *A. fistularis*, *A. fulva*, and *A. lacunosa* (all from the Caribbean) were able to cleave isoxazoline alkaloids into aeroplysinin-1 and dienone. In cell-free protein extracts from other sponges, *Stelletta globostellata* (order Astrophorida), *Axinella carteri* (order Halichondrida), and *Theonella swinhoei* (order Lithistida) that do not accumulate brominated isoxazoline alkaloids, the concentrations of added isofistularin-3 or aerophobin-2 remained unchanged, and no aeroplysinin-1 or dienone occurred under otherwise identical conditions (Ebel et al., 1997). Alkaloid biotransformation by cell-free protein extracts from *Aplysina* sponges may be inhibited by addition of trichloric acid as well as by boiling (Ebel et al., 1997; Fendert, 2000). Substrate specificity studies that were carried out *in vitro* with naturally occurring isoxazoline alkaloids and with synthetic analogues indicated that the postulated alkaloid splitting enzyme(s) are specific for substrates containing spirocyclohexadienisoaxazoline moieties and acyl amide chains (Fendert, 2000; Goldenstein et al., 2000). Unfortunately, attempts to isolate the responsible enzyme(s) from this crude extract have been unsuccessful due to activity loss during purification (Ebel, 1998). Thus, while a final proof for the enzymatic nature of the bioconversion [e.g., the purification and detailed characterization of the responsible enzyme(s)] is still lacking, our observations point toward an involvement of enzymes in the bioconversion reactions.

The question remains whether the alkaloid conversion is ecologically advantageous for *Aplysina* sponges and can be considered an example of an activated chemical defense. Choice feeding experiments with the Mediterranean fish *B. sphinx* revealed that aeroplysinin-1 (**5**), as well as dienone (**6**), possesses considerably lower feeding deterrent properties against test fishes than their precursors (e.g., aerophobin-2 or isofistularin-3) when tested at their natural concentrations (Thoms et al., 2004). Even if in the course of the bioconversion

the feeding deterrent properties intensified, this could hardly be considered an activated protection against predatory fishes. First, the bioconversion rate (45 sec to 1 min; Figure 4 and Ebel et al., 1997) would probably be too slow to deter the predators in time, before serious wounding was caused. Second, the bioconversion products would presumably only arise at the surface of the sponge tissue piece bitten off, as only here does a decompartmentalization of the spherulous cells occur. The arising bioconversion product concentration would probably be too low to have a noteworthy effect on predators. It appears unlikely that the wound-induced bioconversion of alkaloids in *Aplysina* species will increase the fitness of sponges toward fish predators.

The situation is different, however, when a defense against microbial pathogens is considered. In this case, it might possibly be sufficient if the bioconversion products were formed only in injured cells, as penetration of pathogenic microorganisms is likely to occur through wounded tissue. It is difficult to determine the actual metabolite concentration in the thin surface layer covering the wounded tissue, because it is virtually impossible to harvest and analyze only wounded cells without adherent healthy tissue that will mask the results of a chemical analysis due to the “static” alkaloid profile that will remain unchanged. The only reasonable approximation for the concentrations of aeropylsinin-1 (**5**) and the dienone (**6**) that arise locally in wounded surface tissue are the amounts of bioconversion products that are formed in finely macerated sponge tissue. We determined the concentration of aeropylsinin-1 (**5**) in tissue of *A. aerophoba* after 5 min of grinding to amount to $4400 \pm 2036 \mu\text{g ml}^{-1}$ sponge tissue (Table 2). Teeyapant et al. (1993) determined the Minimum Inhibitory Concentrations (MIC) of aeropylsinin-1 and dienone against *Bacillus subtilis*, *Staphylococcus aureus*, and *Escherichia coli* to range between 12.5 and $50 \mu\text{g ml}^{-1}$ depending on the bacterial species tested. Kelly et al. (2003) were able to show that seawater bacteria attachment to agar blocks treated with aeropylsinin-1 at a concentration of $1000 \mu\text{g ml}^{-1}$ was reduced to $1.4 \pm 0.1\%$ compared to untreated controls. Dienone at a concentration of $250 \mu\text{g ml}^{-1}$ reduced bacterial attachment to $4.1 \pm 0.1\%$. An amount of $5 \mu\text{g}$ aeropylsinin-1 showed activity against two out of six marine bacteria species tested in an agar diffusion assay (Weiss et al., 1996). Dienone at the same concentration inhibited the growth of five of six species in this experiment. One hundred μg of aeropylsinin-1 as well as $100 \mu\text{g}$ dienone were active against all eight marine bacteria species tested. Debitus et al. (1998) found activity for both compounds when they tested $10 \mu\text{g}$ of them against *S. aureus* and *Vibrio anguillarum* in agar diffusion assays. They proposed dienone (**6**) for use as an antibiotic in mariculture, as their investigation revealed that it rivals chloramphenicol with regard to decreasing mortality of scallop (*Pecten maximus*) larvae in culture. Thus, the concentrations of the bioconversion products arising in ground fresh *A. aerophoba* tissue exceed concentrations that have proven effective against

bacterial invasion, suggesting that the generation of aeroplysinin-1 (**5**) and subsequently of the dienone (**6**) at the site of wounding might protect injured sponge tissue against pathogenic bacteria. Consequently, in the course of the wound-induced bioconversion, the antipredatory isoxazoline alkaloids stored constitutively in tissue of *Aplysina* sponges are cleaved into compounds with pronounced antimicrobial activity. This process seems to correlate with the change in needs of the sponges after their tissue has been wounded and reveals the multiple ecological functions that marine natural products can possess.

Acknowledgment—We acknowledge Prof. Werner E.G. Müller, Prof. Renato Batel, and the staff of the Ruder Boscosvic Center for Marine Research for assistance during organization of sample collections and laboratory work at Rovinj, Croatia. We also thank Sabine Borstel for help in isolating the sponge metabolites and Arno Kunze for samples from Caribbean *Aplysina* sponges. Carsten Thoms acknowledges support with a Fedodor Lynen Fellowship from the Alexander von Humboldt Foundation, Bonn. This work was supported by the Bundesministerium für Bildung und Forschung (project: Center of Excellence BIOTECmarin). Finally, we thank two anonymous referees who helped to improve this manuscript.

Abstract—During its natural life cycle, the yellow dog tick, *Haemaphysalis leachi*, has three hosts, and it has to spend enough time on each of them to complete a blood meal. When irritated, the females of this tick species produce a cuticular secretion that contains a dog-repelling allomone. This improves the tick's chances of survival by deterring the dog from biting the tick off its body. Employing response-guided isolation techniques in conjunction with gas chromatography-mass spectrometry, the defensive allomone of *H. leachi* was found to consist of the six homologous aliphatic aldehydes from hexanal to undecanal. A mixture of synthetic versions of these six aldehydes in quantities corresponding to those secreted by one tick elicited strong aversion reactions in the majority of dogs of various breeds.

Key Words—Dog repellent, *Haemaphysalis leachi*, cuticular secretion, preparative GC, GC-MS, bioassay, sampling techniques.

INTRODUCTION

The yellow dog tick, *Haemaphysalis leachi*, is endemic to Southern Africa, Asia, and Australia, where it is a vector of *Rickettsia conori*, *R. rickettsii*, and *Coxiella burnetii*, which are responsible for tick bite fever, Rocky Mountain spotted fever, and Q fever, respectively, in humans (Howell et al., 1978). This tick is also the only known vector of *Babesia canis*, the bacterium responsible

* To whom correspondence should be addressed. E-mail: LECUS@sun.ac.za

for biliary fever in dogs (Van Heerden et al., 1995). *H. leachi* is a tick where the female requires taking a blood meal from three hosts to complete the life cycle. Molting takes place on the ground because the female tick cannot cling to its host when she molts. Engorged female *H. leachi* have soft bodies that are completely unprotected from attack by their hosts. This is an especially significant handicap if the host is a dog that can use its teeth with considerable dexterity to remove the small parasites from its body. However, dogs do not attempt to remove female *H. leachi* from their bodies with their teeth (Oelofsen, unpublished data). Instead, when they are presented with *H. leachi* or with an extract of its cuticular secretion, dogs exhibit behaviors suggesting disgust (e.g., looking at the owner or handler in a reproachful way, turning the head away, straining at the leash, running away, hiding behind or under something) or even nausea (e.g., salivating copiously) (Oelofsen, unpublished data).

We hypothesize that a dog-detering allomone in the cuticular secretion of the tick elicits aversion in dogs and this probably constitutes a defensive mechanism used by the tick to prevent the host from removing the tick from its body during its blood meal. Even when engorged, the male dog tick has an average body mass of only about 2% of that of an engorged female. It would be difficult for a dog to find and remove these small animals. Therefore, the male probably does not produce a dog repellent. The female, on the other hand, is much more vulnerable and the secretion of a repellent would enable her to complete a blood meal on each of her three hosts (Arthur, 1962). In this article, we report the identification of the constituents of the cuticular dog-repelling allomone of the female yellow dog tick.

METHODS AND MATERIALS

General. Dichloromethane (Merck, Suprasolv Grade) was used for all extractions and as the solvent in which preparatively isolated fractions were collected. For the cleaning of syringes and glassware, dichloromethane (Riedel de Haën, pesticide analysis grade) was used. Synthetic chemicals were purchased from Aldrich (St. Louis, MO, USA).

Sample Preparation

Collection and Handling of Ticks. Live, engorged female *H. leachi* were collected by local dog pound personnel and veterinarians. To stimulate the female *H. leachi* to produce the cuticular exudates, we touched the tick with the tip of a soft artist's brush. This promoted the secretion of a varying number of less than about 50 tiny, barely visible droplets of liquid through pores in the integument of the engorged female. The production of the cuticular exudate can

also be stimulated by methods such as prodding the female *H. leachi* with a glass rod or pinching it with a pair of tweezers, but such methods can perforate the animal's integument.

Solvent Rinse of Cuticle. Female ticks were lightly held with a pair of tweezers and irritated as described above. Each irritated female tick was rinsed with about 1 ml dichloromethane. The combined rinses were stored at -18°C until analyzed or used for bioassays. For gas chromatography with flame ionization detection (GC-FID) and gas chromatography with mass spectrometric detection (GC-MS), the dichloromethane rinses of 10 ticks were combined and concentrated at room temperature (22°C) to a volume of about 10 μl by slow evaporation of the solvent in a static nitrogen gas atmosphere (Reiter et al., 2003). Samples were analyzed by injecting 2.5 μl of the concentrated extract in splitless mode, allowing for a splitless period of 150 sec.

Volatile Collection: Solid Phase Microextraction. The effluvium of 10 irritated, engorged ticks in a 25-ml glass bottle was sampled by solid phase microextraction (SPME; 100 μm polydimethylsiloxane fiber) for 5 hr at room temperature (Arthur and Pawliszyn, 1990). For GC-MS analysis, the sorbed volatiles were thermally desorbed for 150 sec at 220°C in the instrument's inlet. In this and all following experiments, volatiles trapped in a solventless manner were immediately analyzed after sample collection.

Volatile Collection: Adsorption on Activated Charcoal. The tip of a length of fused silica tubing (100 \times 0.7 mm o.d.) was coated to a length of 15 mm with polyimide monomer and carefully dusted with activated charcoal (particle size, 38–48 μm) of the type used in cigarette filters. The polyimide was cured overnight at 290°C to give a probe coated with a stable monoparticulate layer of activated charcoal. Sample enrichment by adsorption on the activated charcoal and GC-MS analysis of the enriched volatiles were performed as described above for SPME. In this technique, the septum was replaced by a septum carrying the probe (Burger et al., unpublished data). The carrier gas was turned off during the installation of the probe in the instrument's injector to avoid premature desorption of the collected volatiles.

Volatile Collection: Sorption in an Open Tubular Trap. The volatile organic constituents of the effluvium of irritated females were also collected on a phase-coated open tubular trap and analyzed according to the method described by Burger et al. (1995). Using helium as carrier gas, the effluvium of 10 irritated, engorged females was purged from a 50-ml screw-capped glass bottle with a Teflon-faced septum at 22°C , and the volatile organic compounds were trapped on the capillary trap (90 \times 0.3 mm) coated with 15 μm of the apolar phase PS-255 (Burger et al., 1991). The capillary trap was connected to the column using shrinkable Teflon (PTFE) tubing and inserted into the injector where the trapped material was thermally desorbed, transported to the column by the carrier gas, and analyzed by GC-MS.

Volatile Collection: Cryoprecipitation in Uncoated Capillary Trap. The previous experiment was repeated with an uncoated capillary trap. In this experiment, volatiles were immobilized from the effluvium of 10 irritated, engorged females in an uncoated capillary cooled with dry ice. The experiment was also repeated with liquid nitrogen as a cooling medium and helium as a purge gas. Desorption and analysis were performed according to the procedure used for the phase-coated trap described above.

Solventless Sampling. Attempts at collecting droplets of the secretion in capillary tubes were not successful. The following method was, therefore, used to collect material for solventless sample introduction. A strip (25 × 4.5 mm) of glass fiber filter paper (Whatman, Glass Microfibre Filter, Cat. 1820 090) was partly inserted into the 4-mm i.d. glass inlet liner of the GC-MS instrument. Two engorged females were irritated with the part of the filter strip protruding from the liner and the cuticular secretion absorbed by the filter paper. The strip of filter paper was fully inserted into the liner, and the liner was installed in the injector (220°C) of the instrument for splitless desorption (150 sec) at 220°C and GC-MS analysis of the desorbed volatiles.

Sample Analysis, Fractionation, and Bioassay

Chemical Analysis. Analytical and preparative GC separations were done with a Carlo Erba 4200 GC, equipped with a FID and split/splitless injector operated at 280 and 220°C, respectively, and a 40 m × 0.25 mm glass column coated with 0.25 μm of the stationary phase PS-089 (DB-5 equivalent). Hydrogen was used as carrier gas at a linear velocity of 50 cm/sec. The column was temperature programmed from 30 to 250°C at 2.0°C/min. Low-resolution electron impact mass spectrometry (LR-EIMS) was performed on a Carlo Erba QMD 1000 GC-MS system, using the same gas chromatographic parameters. Helium was used as carrier gas at a linear velocity of 32.25 cm/sec. The line-of-sight interface was kept at 250°C and the ion source temperature was set at 180°C. Mass spectra were recorded at 70 eV.

Sample Fractionation. A four-way effluent splitter was used to isolate fractions of the collected cuticular secretion of the tick. This splitter made provision for the introduction of make-up gas as well as splitting of the column effluent in a 1:3 ratio with 25% of the effluent directed to the detector. Uncoated, deactivated fused silica capillary tubing was used to connect the effluent splitter to the make-up gas supply, detector, and fraction collection port. The fraction collection outlet line was heated to its tip by an aluminum block thermostatted at 250°C. Fractions were collected manually by passing the effluent gas through 150 μl of dichloromethane in 1-ml conical vials. To avoid cross-contamination of fractions, each fraction was collected with a fresh glass

exit tip that was connected in a press-fit manner to the heated fused silica transfer line from the effluent splitter.

During the first fractionation series of the crude extract from the solvent rinse of the cuticle, 11 fractions were collected over 5-min retention time windows and then bioassayed. To keep the number of bioassay fractions within reasonable limits, the next fractionation was started at a retention time offset of 2.5 min. From this second fractionation series, 11 fractions were bioassayed. During additional series of fractionations, fractions were collected over smaller windows and only in those overlapping windows where activity had been detected in both of the initial fractionations, and then over incrementally smaller windows, which eventually corresponded to about the average width of peaks in the gas chromatogram. A total of about 80 fractions were collected.

Sample Bioassays. Only a limited number of appropriate dogs were available to us for the behavioral assays. Dogs from an animal health facility were not used for the behavioral assays because their craving for attention appeared to override the repellency of test samples. Similarly, untrained, young dogs were not used because they tended to run around uncontrollably. Instead, dogs that had undergone obedience training were used for the assays because they remained still when confronted with test samples. The limited availability of dogs for bioassay thus precluded replicated data collection and statistical analysis of the behavioral responses.

Aliquots (0.5 ml) of the crude unconcentrated solution of the cuticular secretion or of fractions were pipetted onto strips of filter paper (35 × 5 mm; Schleicher & Schüll GmbH, Dassel, Germany) and the solvent was allowed to evaporate for 5 min at 22°C. Controls were prepared by treating strips of filter paper in a similar manner with dichloromethane. The filter paper strips with the crude cuticular secretion, the fractions, or the controls, were handled with dressing forceps at all times and were placed individually in screw-capped glass vials with Teflon-faced septa and transported at the current daytime temperature to the sites where the bioassays were conducted. Bioassays were performed as soon as possible after the preparation of the test paper strips, normally with a delay of between 30 min and 3 hr, depending on whether bioassays were done locally or in neighboring towns. The samples were kept in the dark, but were not cooled to avoid the sublimation of the collected material from the paper strips onto the walls of the glass vials.

The vials with partly protruding paper strips were presented to the dogs by hand, and a distance of about 3 cm was maintained between each paper strip and the nose of the test animal. If a test strip came into contact with a dog's nose, it was discarded. With the exception of a few dogs (Table 1), the bioassays were the first encounters between each dog and the presenter of the test sample. In all cases, the bioassays were conducted in the presence of the dog's owner. The

situations in which the bioassays were done, whether at the home of the dog or after an obedience training session, and the handling of dogs just prior to bioassays, varied from dog to dog and was beyond our control.

In most cases, the assay dogs paid immediate attention to the test samples and would advance toward the sample, so that the 3-cm test distance could be established and the behavioral response could be described and recorded. In these instances, the test animal sometimes even attempted to lick the sample. In other cases, assay dogs remained uninterested when presented with samples, and the sample had to be brought within the 3-cm range by the presenter. Test animals sometimes turned their heads away from the samples, making it difficult to maintain the 3-cm test distance.

A solution of the synthetic aldehydes hexanal, heptanal, octanal, nonanal, decanal, and undecanal was prepared by dissolving these compounds in 1 ml dichloromethane in the quantitative ratio in which they are secreted by female *H. leachi*. Test filter paper strips were prepared by transferring 2.5 μl of this solution, equivalent to the quantities of the aldehydes present in the secretion of one female tick, to each of the paper strips. Assays were done by presenting 30 dogs, individually, first with a solvent control and then with an aldehyde-treated paper strip. The behavioral responses of the dogs to the controls and aldehydes were observed (e.g., degree of movement away from the stimulus, extent of salivation, movement of the head, etc.) and recorded.

RESULTS AND DISCUSSION

The cuticular secretion of female *H. leachi* was expected to contain some heavy lipid material that would not be amenable to gas chromatographic analysis. To avoid possible contamination of the capillary GC column with heavy material, methods were initially investigated for the enrichment of the volatile organic compounds directly from the effluvium of irritated female ticks. Sample enrichment by SPME, adsorption on activated charcoal, trapping in open tubular traps, and cryotrapping in capillary tubes with dry ice and liquid nitrogen as cooling media all produced poor results. With the exception of a considerable quantity of hexadecanoic acid trapped on activated charcoal, only a few peaks of compounds present in extremely low quantities were visible in the total ion chromatograms (TICs) of the material trapped with these sample enrichment methods. Some of the peaks could be attributed to thermal degradation of the stationary phase of the column. Other small peaks appeared at different retention times in the different TICs, and it was concluded that these compounds were either artifacts of unknown origin or, more likely, they

resulted from differences in selectivity toward compounds with different boiling points and polarities by the enrichment methods.

The collection of the cuticular secretion by absorption on a piece of glass fiber filter paper followed by insertion of the paper strip into a glass injector liner and introduction of the liner into the injector of the GC-MS, yielded a satisfactory TIC and mass spectra with ions of high abundance. TICs obtained by this procedure were used for identification of the components of the cuticular secretion. However, this technique could potentially overload the column with heavy lipid material and shorten its lifetime. This method also makes it difficult to control the quantity of material introduced into the injector and to obtain chromatograms with reproducible retention times, essential for the accurate and reproducible collection of fractions in preparative GC. Therefore, a more conventional method was employed for the collection of material for some GC procedures: irritated females were rinsed with dichloromethane and aliquots of the resulting extract were used for analytical and preparative work. Analysis of this extract by GC-MS showed that organic acids and aldehydes ranging in length from C₃ to C₁₁, as well as many other compounds that could not be characterized, were present in the extract (Figure 1).

We approached the fractionation of this extract by considering that there are at least two possible methods to locate the active constituent(s) in a crude extract. Following a conventional response-guided strategy, fractions can be collected, a certain percentage of each fraction bioassayed, and the rest of each fraction subjected to further fractionation and bioassay. This procedure can be

FIG. 1. Total ion chromatogram (TIC) of volatile organic compounds in rinses of engorged, irritated female yellow dog ticks. First 60 min of the chromatogram are displayed. 1 = Propanoic acid; 2 = hexanal; 3 = heptanal; 4 = hexanoic acid; 5 = octanal; 6 = nonanal; 7 = heptanoic acid; 8 = octanoic acid; 9 = decanal; 10 = nonanoic acid; 11 = undecanal. Analytical parameters are given in the text.

repeated until a fraction containing only one active constituent has been isolated. If, as in the present case, the active constituent(s) is present in such a low concentration in the starting extract that a large percentage has to be sacrificed for chemical detection, the consumption of material can be so high that insufficient material will eventually be available to continue with further fractionation steps. We used a second procedure in which preparative separations were all conducted on the original extract. In the first fractionation series, fractions were collected over relatively wide consecutive retention-time segments (windows) of 5 min and assayed for their repellent activity. In the following fractionation of a fresh aliquot of the original extract, fraction collection was initiated at a retention-time offset of 2.5 min, after which smaller fractions (1-min windows) were collected only in those windows that contained active material in the initial fractionation. The fractionation was repeated using incrementally smaller retention time windows, which eventually corresponded to about the width of the peaks in the gas chromatogram. In this approach, each fractionation is done with the original extract, and only one fractionation step had to be repeated to get back on track when bioassays gave inconclusive results. In one of the final fractionations, all the material collected during "inactive" time windows was pooled and bioassayed. This material did not show any activity, supplying corroborating evidence that all the active constituents had been correctly identified from the crude extract. In total, we conducted 10 series of iterative fractionations on the crude extract.

We experienced some technical limitations during the final stages of the fractionation procedure. The thin fused-silica transfer line had to be heated right up to its tip to prevent the condensation of the eluting constituents in a cold spot, and it was difficult to successfully couple the equally thin collection capillary, with its tip already in dichloromethane, to the transfer line at exactly the right moment for sample collection. The collection of material in very narrow windows was also complicated by the change of linear flow rates through the different components of the temperature-programmed preparative system, resulting in an increasing time lag between detection of a component and its arrival at the sample collection point. The minor constituents of the fractions were, therefore, collected in small quantities and low purities.

Approximately 100 samples of the crude cuticular secretion and the isolated fractions were bioassayed. We began the bioassay procedure by assessing the effect of the crude cuticular extract on four test animals: a docile Labrador, two well-behaved Corgis, and a Fox terrier. When we attempted to repeat the bioassays a few days later, the dogs refused to come near the presenter. The Corgis avoided this person for several weeks afterwards. Thus, we concluded that it would not be possible to use the same dog twice in this behavioral assay. Samples of the crude extract and the fractions were assayed only until the first clear indication of repellent activity had been obtained (data

not shown). In most cases, only one or two dogs were necessary to confirm the presence of activity in an extract or a fraction of the cuticular secretion, and these responses were compared to a previous assessment of the response to the solvent control by the same animal. The responses of the dogs to some of the fractions were also rather subtle. They were mostly reluctant to sniff at a specific test strip for a second time and/or they avoided eye contact with the presenter. The relatively indefinite results were interpreted as an indication that the defensive secretion contains several active constituents eliciting slightly different responses in the dogs, and that all of the active constituents have to be present in test samples to elicit the full aversive response.

We did not detect any behavioral activity in the major constituents of the cuticular secretion of female *H. leachi* (the later eluting peaks in Figure 1 and in the part of the TIC not shown). Upon fractionation, we found activity in several fractions collected over retention time windows that did not contain particularly prominent peaks. Comparative GC-MS analysis of the whole extract and the active fractions revealed the presence of an aldehyde in all of the active fractions. These aldehydes were tentatively identified as unbranched aldehydes. Because it is difficult to differentiate between the mass spectra of long-chain unbranched, iso- and anteiso-branched aldehydes, the active constituents were identified by GC-MS as the unbranched isomers by coelution with authentic unbranched synthetic compounds. On average, females secreted the aldehydes in the following approximate quantities (in ng/female): hexanal (0.1), heptanal (9.0), octanal (7.5), nonanal (43.0), decanal (34.0), undecanal (5.0). The shorter chain aldehydes eluted as broadened peaks due to the splitless sample introduction method (Figure 1). Partial coelution with some of the carboxylic acids also affected this analysis. Although these aldehydes have not been previously identified as constituents of arachnid defensive secretions, they are common constituents of insect defensive secretions (Dettner and Reissenweber, 1991; Dettner, 1993; Farine et al., 1993).

Synthetic versions of the six aldehydes were mixed for bioassays in a 1-ml solution of dichloromethane in the quantities noted above. The solvent control and this mixture were presented (in that order) to each of 30 dogs. In these assays, all dogs sniffed or inspected the solvent controls, but showed no negative behavioral responses (Table 1). Of the 30 dogs used in bioassays, four individuals exhibited no behavioral response differences to the solvent control and the synthetic mixture. However, 26 individuals displayed some type of aversion reaction to the synthetic mixture ranging from salivation (6 of 30 dogs) to turning the head away and avoiding eye contact with the presenter (15 of 30 dogs) to running away from the presenter with or without a return (7 of 30 dogs). In some cases, multiple behavioral responses were elicited from the same animal (e.g., salivation and turning of the head). One dog showed no aversive response to the test strip and attempted to chew on it; another dog

barked at the test strip and then tried to attack the presenter. Two dogs were reassayed 8 weeks later and both responded aversively again to the test strip. Since both ran away when they saw the presenter, even 8 weeks after the first test had been done, it was clear again that we could only assay each dog once.

The synthetic aldehyde mixture elicited the same range of aversive behaviors that we observed in the pilot study of the crude extract of the solvent rinse of the cuticle of *H. leachi*. However, because of the limited number of test animals available to us, we were not able to directly compare (i.e., in the same experiment) the behavioral response to the synthetic aldehyde mixture with the behavioral response to the crude extract of the solvent rinse of the cuticle of *H. leachi*. We note that the behavioral portion of this study is limited by the inherent difficulties of obtaining a sufficient number of test animals and by the differences in the behavioral experiences, personalities, and status of the test animals at the time of the assay. Under these circumstances, a statistical evaluation of the results of the bioassays was not feasible. Thus, we have presented the data in raw form (Table 1).

We observed that many different compounds inconsistently appeared in rinses collected from individual female *H. leachi* and in material obtained by batchwise rinsing of female *H. leachi*. Perhaps impurities picked up by ticks from their hosts and/or the environment could be responsible for the complexity of the extracted cuticular material. Propanoic acid and some of the other unbranched carboxylic acids from C₅ to C₁₅ were present in many of the rinses but, again, there was no consistent pattern. Some of these acids could have been picked up from the bodies of their hosts, but it is also possible that the C₆ to C₁₂ acids were formed by autoxidation of aldehydes previously secreted by irritated females.

We recognize that there are other possible interpretations of the results of the bioassays. The various reactions of dogs in our behavioral assays suggest that a dog's reaction may be influenced by its previous experiences with female *H. leachi*. Well-kept dogs or dogs from urban areas that have not had the unpleasant experience associated with tick infestation might, therefore, respond less aggressively to test substances than dogs from the outlying parts of town where they might be more prone to tick infestation. It is possible that the dogs are not inherently deterred by the smell of these aldehydes, which are not uncommon in nature, but rather that they associate it with the nasty taste and/or burning sensation caused by contact of the mammalian mucous membrane with the short-chain aldehydes. In addition, some of these aldehydes occur in rancid food where they are formed by autoxidation of unsaturated oils and fats. Thus, it is possible that the dogs used in the bioassays could have unpleasant memories of rancid food, which would explain the signs of nausea and excessive salivation displayed by some of the dogs in reaction to the mixture of aldehydes in bioassays. Finally, extracts of the cuticular exudate of female *H. leachi*

consistently contained several compounds in the higher mass range (not shown in Figure 1). These compounds apparently belong to different homologous series. Their mass spectra, which are not represented in any of the large libraries of spectra, could not be interpreted so far. These compounds could be the real poisonous defensive constituents of the secretion, whereas the aldehydes might constitute an aposematic odor associated by learning with the truly toxic material. These aspects might be investigated in future studies of this system.

Acknowledgments—The authors thank Dr. M. E. Potgieter, veterinary surgeon, for the collection of ticks. The research was supported by Stellenbosch University and the National Research Foundation, Pretoria, South Africa.

Abstract—Previous studies have shown that some mammals are able to neutralize venom from snake predators. California ground squirrels (*Spermophilus beecheyi*) show variation among populations in their ability to bind venom and minimize damage from northern Pacific rattlesnakes (*Crotalus oreganus*), but the venom toxins targeted by resistance have not been investigated. Four California ground squirrel populations, selected for differences in local density or type of rattlesnake predators, were assayed for their ability to neutralize digestive and hemostatic effects of venom from three rattlesnake species. In Douglas ground squirrels (*S. b. douglasii*), we found that animals from a location where snakes are common showed greater inhibition of venom metalloprotease and hemolytic activity than animals from a location where snakes are rare. Effects on general proteolysis were not different. Douglas ground squirrels also reduced the metalloprotease activity of venom from sympatric northern Pacific rattlesnakes (*C. o. oreganus*) more than the activity of venom from allopatric western diamondback rattlesnakes (*C. atrox*), but enhanced the fibrinolysis of sympatric venom almost 1.8 times above baseline levels. Two Beechey ground squirrel (*S. b. beecheyi*) populations had similar inhibition of venoms from northern and southern Pacific rattlesnakes (*C. o. helleri*), despite differences between the populations in the locally prevalent predator. However, the venom toxins inhibited by Beechey squirrels varied among venom from Pacific rattlesnake subspecies, and between these venoms and venom from allopatric western diamondback rattlesnakes. Blood plasma from Beechey squirrels showed highest inhibition of metalloprotease activity of northern Pacific rattlesnake venom, general proteolytic activity and hemolysis of southern Pacific rattlesnake venom, and

hemolysis by allopatric western diamondback venom. These results reveal previously cryptic variation in venom activity against resistant prey that suggests reciprocal adaptation at the molecular level.

Key Words—*Spermophilus beecheyi*, *Crotalus oreganus*, *Crotalus atrox*, venom, natural resistance, coevolution, predator–prey.

INTRODUCTION

Some species of mammals are known to be resistant to the venom of the viperid snakes that hunt them (Thwin and Gopalakrishnakone, 1998; Pérez and Sánchez, 1999). Viper venoms contain toxins with a variety of effects (Meier and Stocker, 1995), including metalloproteases that break down the lining of blood vessels and extracellular matrix (Gutiérrez and Rucavado, 2000). Other venom components disrupt the normal processes of coagulation and induce hemolysis (Markland, 1998; Braud et al., 2000). In susceptible prey (and humans), venoms can lead to extensive hemorrhage, edema, tissue necrosis, and death (Russell, 1980; Ownby, 1982). Even if the prey successfully evades ingestion by a viperid predator, venom-induced shock and the digestive effects of toxins pose a serious threat. To maintain the ability to survive and reproduce in an environment that holds challenges from predators, competitors, and conspecifics, mammals must minimize hemorrhage, tissue destruction, and disruptions to hemostasis that follow envenomation.

The interactions of California ground squirrels (*Spermophilus beecheyi*) and northern Pacific rattlesnakes (*Crotalus oreganus oreganus*) may be the most intensively studied examples of the relationship between rattlesnakes and preferred prey. Ground squirrels are an important food resource for rattlesnakes throughout California (Linsdale, 1946; Fitch, 1948). Fitch (1949) estimated that *S. beecheyi* make up to 69% (by weight) of the diet for adult northern Pacific rattlesnakes (*C. o. oreganus*) at one site in the foothills of the Sierra Nevada. Field observations reveal that northern Pacific rattlesnakes are common near burrow systems during the reproductive season and periods of pup emergence. They are responsible for approximately 40% of pup and juvenile mortality in ground squirrel colonies (Linsdale, 1946; Fitch, 1949; personal observation). Sympatry between California ground squirrels and Pacific rattlesnakes is indicated in late Pleistocene fossil assemblages (Miller, 1912; Stock, 1918; Brattstrom, 1953). Elsewhere in the United States, middle Miocene fossil deposits indicate longer sympatry between rattlesnakes and the *Otospermophilus* ancestor of modern sciurids (Black, 1963; Holman, 1979). Therefore, the intensity of this predator–prey relationship is probably not a recent phenomenon, and represents an important biotic interaction for both ground squirrels and rattlesnakes.

It is not surprising, therefore, that *S. beecheyi* exhibits a variety of strategies to deter rattlesnake predation. Beyond a primary defense of vigilance, these squirrels will aggressively confront snake predators detected near their burrows (Owings and Coss, 1977; Coss and Owings, 1989; Rowe and Owings, 1990, 1996; Swaisgood et al., 1999). However, active harassment requiring close approach to rattlesnakes exposes squirrels to the risk of envenomation. To protect against this risk, California ground squirrels possess innate blood plasma factors that allow them to survive envenomation by northern Pacific rattlesnakes (Poran et al., 1987; Poran and Coss, 1990). Serum-venom binding in radioimmunoassays (RIA) has been used extensively to characterize variation in resistance among *S. beecheyi* populations (Poran et al., 1987; Coss et al., 1993). Unfortunately, RIA binding levels provide only indirect information about functional differences in venom neutralization among *S. beecheyi* populations. Although the RIA binding of pooled sera from squirrel populations correlates highly with the same sera used to protect envenomated mice in approximate LD₅₀ tests (Poran et al., 1987), this method does not reveal the underlying biochemical dynamics of toxicity and resistance. Enzyme-inhibitor binding, such as that described for the resistance of opossum to rattlesnake venom (Catanese and Kress, 1993), is indistinguishable from a variety of other protein-protein interactions that result in high binding levels (Mishell and Shiigi, 1980).

Experimental Questions. Adult northern Pacific rattlesnakes (*C. o. oreganus*) possess venoms with multiple proteolytic and hemolytic venom toxins that ground squirrel prey must defend against (Mackessy, 1988, 1993, 1996). Biardi et al. (2000) showed that plasma from California ground squirrels can reduce the activity of venom proteases on hide powder azure and gelatin. However, this study did not specifically measure the activity of venom metalloproteases or toxins affecting clotting and hemolysis.

A more detailed understanding of the biochemical basis of resistance is essential when attempting to clarify the relationship between RIA binding levels and functional resistance to venom. For example, previous research has revealed conflicting evidence about resistance in two populations of Douglas ground squirrels (*S. b. douglasii*) that vary in local rattlesnake density. One location (Winters, Yolo County, CA) is in oak woodland habitat in the foothills on the west side of the Sacramento Valley where rattlesnakes are common. This site also holds a winter hibernacula for rattlesnakes (W. Hamilton, personal communication). As expected, squirrels from this location show high RIA binding levels (Coss et al., 1993). A nearby site (Davis, Solano Co., CA) is on the floor of the valley less than 20 km to the east where rattlesnakes are rare (Poran et al., 1987). RIA binding levels in Davis squirrels are 59% lower, which Coss et al. (1993) interpreted as a decline in resistance that correlated with colonization of this rattlesnake-rare habitat when the populations diverged about 8.6 ± 5.9 thousand years ago. However, Biardi et al. (2000) showed that plasma samples

from these two populations are indistinguishable in their capacity to inhibit proteolytic activity of northern Pacific rattlesnake venom.

One interpretation of this discrepancy is that the correlation between RIA and approximate LD₅₀ dose, determined using squirrels from sites where snakes are common (Poran et al., 1987), may not be an informative measure of resistance in squirrel populations where encounters with rattlesnakes are rare. An alternative interpretation is that reduced inhibition of other venom toxins is responsible for lower binding in the Davis population. One goal of this study was to use three additional measures of venom activity (metalloprotease activity, fibrinolysis, and hemolysis) in order to determine whether decreased RIA binding reflects venom resistance or nonfunctional binding interactions.

Additional measures of venom biochemical activity also provide more detailed information on how ground squirrel plasma defenses deal with venoms from different rattlesnake lineages. Other mammal species seem to be broadly resistant to toxins from a variety of venom (e.g., Huang and Pérez, 1980; Soto et al., 1988; Tomihara et al., 1990). However, northern Pacific rattlesnakes (*C. o. oregonus*) are the only pit vipers sympatric with ground squirrels in northern and central California (Klauber, 1972). Folsom Lake in the foothills of the Sierra Nevada east of Sacramento lies within the core of this range, and has a high density of northern Pacific rattlesnakes (Poran et al., 1987). Ground squirrels (*S. b. beecheyi*) from this site show high resistance when measured by experimental envenomation, *in vivo* protection of venom-challenged mice (Poran et al., 1987), and RIA binding levels (Poran and Coss, 1990). Squirrels in the Santa Ynez Valley inhabit a snake-rich location southwest of the Central Valley within the zone of intergradation between northern (*C. o. oregonus*) and southern Pacific (*C. o. helleri*) rattlesnakes (Klauber, 1972). Squirrels from these two regions show differences in allozyme frequencies (Goldthwaite, 1989), reflecting divergence during the late Pleistocene (Coss and Goldthwaite, 1995; Coss, 1999). They have also been subject to predation from simultaneously diverging lineages of Pacific rattlesnake predators (Pook et al., 2000; Ashton and de Queiroz, 2001; Douglass et al., 2002).

Mackessy (1988) found no significant differences between venoms from northern and southern Pacific rattlesnake venoms collected from Santa Barbara, San Luis Obispo, and Ventura Counties across several assays of enzymatic activity and toxicity (to lizards). Similarly, Bee et al. (2001) detected only minor differences in metalloprotease activity between these two venoms. However, genetic divergence and geographic separation in squirrel populations suggests the opportunity for coevolutionary change (Thompson, 1994, 1997; Nuismer et al., 1999; Gomulkiewicz et al., 2000) that may affect the ability of plasma defenses to deal with venom from these two subspecies.

In other words, we expect plasma defenses in squirrels from Folsom Lake to be more effective against northern Pacific rattlesnake venom. Conversely, plasma

defenses in squirrels from the Santa Ynez valley should be more effective against southern Pacific rattlesnake venom. Finally, venom from western diamondback rattlesnakes (*C. atrox*) constitutes a novel challenge to plasma defenses of squirrels in both of these locations. This venom also shows proteolytic, hemorrhagic, and hemolytic activity (Soto et al., 1988), but western diamondback rattlesnakes are a lower Sonoran species restricted to the deserts of the southeastern part of California (Klauber, 1972). We know that California ground squirrel plasma inhibits *C. o. oregonus* proteolytic activity more than *C. atrox* activity (Biardi et al., 2000), and we expect a similar result when measuring the effects on other venom toxins. Therefore, a second goal of this study was to assess the specificity of plasma defenses by challenging them with venom from sympatric and allopatric predators.

METHODS AND MATERIALS

Blood Collection and Storage. We collected blood samples from ground squirrels in four locations that varied in the density or identity of rattlesnake predators. The method of determining local snake density (\approx predation intensity) is described in Poran et al. (1987), supplemented by information on rattlesnake distributions prior to extensive human disturbance of the Central Valley (Grinnell and Camp, 1917; Nussbaum et al., 1983).

Two populations of Douglas squirrels (*S. b. douglasii*) were sampled: Winters (Yolo Co.) is in the Coast Range foothills and has a high density of northern Pacific rattlesnake predators (*C. o. oregonus*); the Davis site (Yolo Co.) is on the floor of the Sacramento valley where rattlesnakes are rare (only two *C. o. oregonus* reported during the last 25 yr). Two populations of Beechey squirrels (*S. b. beecheyi*) were sampled: Folsom Lake State Recreation Area (El Dorado Co.) has a high density of northern Pacific rattlesnakes (*C. o. oregonus*); Sedgwick Natural History Reserve (Santa Barbara Co.) in the Santa Ynez valley also has a high density of rattlesnakes, and lies within the range of southern Pacific rattlesnakes (*C. o. helleri*). The number of individuals collected at each location is as follows: Davis = 11; Winters = 16; Folsom Lake = 10; and Sedgwick Reserve = 9.

Squirrels were live-trapped and anesthetized with ketamine-HCl (50 mg/kg, i.m.). Approximately 3 ml blood were collected from individual adults via cardiac puncture and stored in additive-free Vacutainer blood collection vials (Becton Dickinson, Irvine, CA, USA). Squirrels were released at the site of capture following their recovery from anesthesia. Samples were kept at 4°C overnight, then clots were removed and discarded. The supernatant was centrifuged at $3000 \times g$ for 10 min at 4°C to separate any remaining erythrocytes, then stored at -70°C until used.

Venom Source and Preparation. Lyophilized venoms were purchased from Sigma (St. Louis, MO, USA). Although venoms were not collected from the same sites as squirrel plasma samples, venoms from Pacific rattlesnakes were obtained from regions within the geographic range of California ground squirrels (Hall, 1981). According to the supplier, northern Pacific rattlesnake (*C. o. oreganus*) venom was obtained from multiple snakes originating in northern California and Oregon. Venom from southern Pacific rattlesnakes (*C. o. helleri*) was obtained from snakes originating in southern California. Information on the site(s) of origin for western diamondback (*C. atrox*) venom was unavailable. Venoms were reconstituted at a concentration of 10 mg/ml in a buffer containing 20 mM Tris-HCl + 1 mM CaCl₂, pH 8.0, and stored at -20°C until used.

Assays of Venom Toxicity. Four assays examined the effects of ground squirrel plasma in inhibiting the proteolytic, collagen hydrolysis, hemolytic, and fibrinolytic activity of rattlesnake venom. Agarose-gelatin plates were prepared according to the method described by Palmer (1993) and used as a measure of total venom proteolytic activity. A template was used to punch equally spaced 3-mm-diam. wells in the surface of the gel, and wells were loaded with 20 µl assay mixture. The gel was then incubated at 37°C for 24 hr in a humidified chamber. Following incubation, unhydrolyzed gelatin was precipitated in a saturated ammonium sulfate solution at 70°C for 10 min, and the area of hydrolysis was calculated from the product of two perpendicular diameters across the clear lysis zone.

Snake venom metalloprotease activity was quantified using Azocoll (Sigma) as a collagen substrate to model the effects on mammalian connective tissue and extracellular matrix. One-ml aliquots of 1% Azocoll (w/v) solution in 20 mM Tris-HCl, pH 8.0, were prepared in a microcentrifuge tube. Assay mixture (20 µl) was added, and the reaction mix was incubated at 37°C for 2 hr with occasional agitation. Following incubation, the tubes were centrifuged for 2 min at 16,000 × g to pellet unreacted substrate. The absorbance of the supernatant was determined at 520 nm using a Shimadzu UV160 spectrophotometer.

BBL Stacker plates (Carolina Biological Supply) containing 5% defibrinated sheep's blood in Columbia agar were used to assay for hemolytic activity. Wells (3 mm diam.) were punched in the substrate in a grid pattern. Assay mixtures (20 µl) were loaded into each well, then the plate was sealed with Parafilm and incubated at 37°C for 24 hr. The area of hemolysis, defined as the transparent zone around the well cleared of red blood cells, was calculated from two perpendicular measurements of well diameter.

Fibrin agarose plates prepared by a modification of the method described by Astrup and Müllertz (1952) were used to measure venom fibrinolytic activity. Bovine fibrinogen was dissolved in Tris-HCl, pH 8.0, to a concentration of 1 mg/ml using a sonicator bath. Ten ml of fibrinogen solution were placed in a 100 × 15 ml Petri dish and clotted by the addition of 100 µl thrombin (100 units/ml). Clot formation was completed within 30 min, as determined by the

opacity of the fibrinogen solution. Assay mixtures (20 μ l) were applied to the surface of the clot, and the plate was incubated at 37°C for 24 hr in a humidified chamber. Following incubation, the area of hydrolysis was calculated from the product of two perpendicular diameters across the liquefied lysis zone.

Relative Activity Scores and Statistical Analyses. Plasma samples from individual squirrels were screened against relevant venoms, and individual scores were recorded for each of the four assays as the mean of at least three replicates. Assay mixtures used in each of the four methods consisted of a venom-only treatment (10 μ l venom + 10 μ l buffer) and a venom + plasma treatment (10 μ l venom + 5 μ l plasma + 5 μ l buffer), as well as negative controls [(buffer only) and (plasma only)]. The difference in activity between venom-only and venom + plasma treatments was expressed as a ratio:

$$\text{Relative activity} = \frac{\text{activity of [venom + plasma]}}{\text{activity of [venom only]}}$$

This allows for testing qualitative differences in the outcome of interactions between venom toxins and plasma defensive factors across the four assays. It simultaneously adjusts for differences in scaling due to differences among venoms in baseline activity on these assays (Soto et al., 1988).

Since relative activity scores are proportions, they were subject to arcsine transformation prior to statistical analysis to yield measures that followed an approximately normal distribution (Zar, 1984). Data were analyzed using a one-factor between-subjects (populations), two-factor within-subjects (assay type, venom type) repeated-measures ANOVA. Specific comparisons of population and venom effects were tested with planned contrasts of the relevant group means.

RESULTS

Plasma Defenses in Douglas Ground Squirrels (S. b. douglasii). Effects of Douglas ground squirrel plasma on venom activity are shown in Figure 1. The two populations differed in their ability to inhibit venom from the northern Pacific rattlesnake ($F_{3,18} = 18.96$, $P < 0.001$). This was primarily due to higher inhibition by animals from Winters (where snakes are common) in the collagenase assay ($F_{1,20} = 56.97$, $P < 0.001$). Winters animals were also slightly more effective at reducing venom hemolytic activity ($F_{1,20} = 7.25$, $P = 0.014$), although the mean difference was quite small—a change in relative activity of only 2.4% of baseline venom activity. There were no significant differences between plasma samples from Davis and Winters squirrels in their effects on general proteolytic activity of northern Pacific rattlesnake venom. The two populations also did not differ in

their effect on fibrinolysis. In this case, relative activity increased to almost 1.8 times that of venom-only treatments (Figure 1a, b).

There were also differences in the effects of plasma samples on sympatric and allopatric venoms. Winters animals reduced proteolysis ($F_{1,25} = 17.21$, $P = 0.003$) and collagen hydrolysis ($F_{1,20} = 115.45$, $P < 0.001$) of northern Pacific rattlesnake venom more than western diamondback venom. Plasma samples from Davis animals were also more effective at reducing proteolytic activity of *C. o. oregonus* venom ($F_{1,25} = 6.44$, $P = 0.018$), but showed no difference in their effect on collagen hydrolysis by the two venoms ($F_{1,26} = 0.67$, $P > 0.05$).

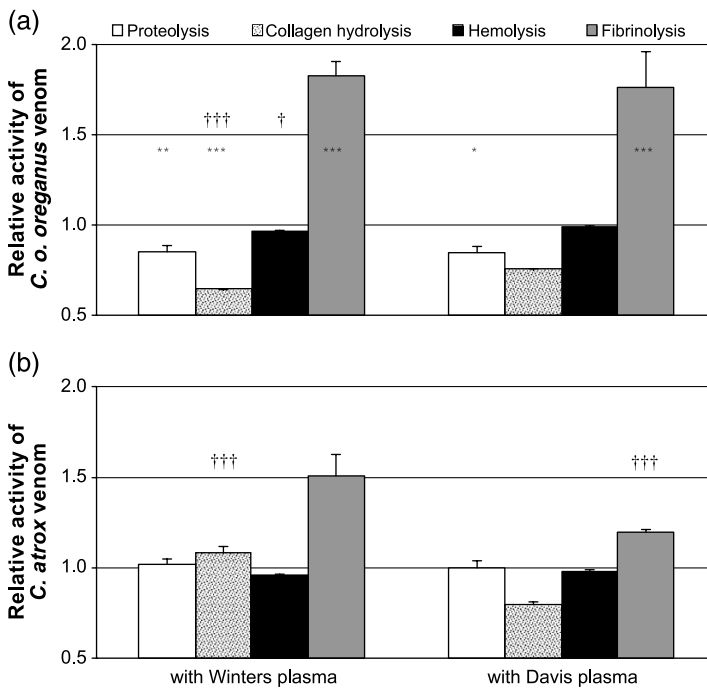

FIG. 1. Activity (mean \pm SE) of rattlesnake venoms incubated with plasma samples from two populations of Douglas ground squirrels (*S. b. douglasii*) that vary in local density of northern Pacific rattlesnakes (*C. o. oregonus*). Winters is a location where rattlesnakes are common, while Davis is a site where snakes are rare. Western diamondback rattlesnakes (*C. atrox*) are allopatric with both populations of squirrels. Activity is expressed relative to venom controls as described in Methods and Materials. Daggers indicate significant differences between the two squirrel populations ($\dagger P < 0.05$, $\dagger\dagger\dagger P < 0.001$). Asterisks indicate significant differences between the two venoms ($*P < 0.05$, $**P < 0.01$, $***P < 0.001$).

Plasma was less effective against *C. o. oregonus* venom than against *C. atrox* venom in the fibrinolytic assay ($F_{1,20} = 16.12$, $P < 0.001$). There was no significant difference between venoms in the hemolytic assay ($F_{1,25} = 1.24$, $P > 0.05$).

Plasma Defenses in Beechey Ground Squirrels (S. b. beecheyi). There were no differences between plasma from Folsom Lake and Sedgwick in their effects on venom proteolysis, collagen hydrolysis, or hemolysis (all tests: $P > 0.05$) (Figure 2). While plasma from Sedgwick squirrels generally induced higher

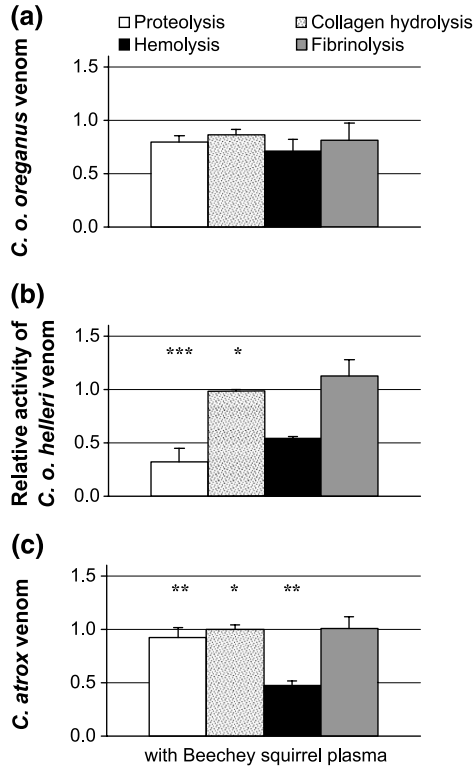

FIG. 2. Activity (Mean \pm SE) of rattlesnake venoms incubated with plasma samples from two populations of Beechey ground squirrels (*S. b. beecheyi*) that are subject to predation by Pacific rattlesnakes. Folsom Lake is a site where northern Pacific rattlesnakes (*C. o. oregonus*) are common, while the Sedgwick Reserve is a site within the zone of intergradation between northern and southern Pacific (*C. o. helleri*) rattlesnakes. Western diamondback rattlesnakes (*C. atrox*) are allopatric with both populations of squirrels. Activity is expressed relative to venom controls as described in Methods and Materials. Asterisks indicate significant differences from the effect on *C. o. oregonus* venom (* $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$).

relative activity in the fibrinolysis assays than Folsom plasma samples, this difference also was not statistically significant ($F_{1,10} = 1.43$, $P > 0.05$). Consequently, data from the two Beechey populations were combined for analysis of the effects of plasma defenses across different venoms.

Beechey squirrel plasma varied in effectiveness against general proteolytic activity of the three venoms ($F_{2,32} = 19.8$, $P < 0.001$)—Southern Pacific rattlesnake (*C. o. helleri*) venom was inhibited more than northern Pacific rattlesnake venom ($F_{1,16} = 11.09$, $P = 0.004$), which in turn was inhibited more than western diamondback venom ($F_{1,16} = 18.24$, $P < 0.001$). In contrast, Beechey plasma samples reduced northern Pacific rattlesnake metalloprotease activity more than southern Pacific ($F_{1,17} = 5.843$, $P = 0.032$) or western diamondback ($F_{1,17} = 5.536$, $P = 0.031$) venom. Hemolytic activity of western diamondback venom was reduced more than that of the two Pacific rattlesnake venoms ($F_{2,10} = 8.03$, $P = 0.008$). There were no significant differences in the way Beechey plasma samples affected fibrinolysis by the three venoms.

DISCUSSION

Although California ground squirrel sera-to-venom binding level in RIAs correlates highly with approximate LD_{50} in mice, this method does not directly measure the ability of prey sera to inhibit specific venom toxins. We observed distinct differences in the capacity of plasma proteins from California ground squirrels to affect the proteolytic and hemolytic activities of rattlesnake venoms. The protease, metalloprotease, and hemolytic activity of all three venoms were reduced in the presence of prey plasma from one or more ground squirrel populations. However, Douglas squirrels are unable to decrease venom fibrinolysis. In fact, fibrinolytic activity of northern Pacific rattlesnake venom is almost twice as high when incubated with plasma from Douglas squirrels (Figure 1a) than when assayed alone (relative activity = 1.0) or against Beechey squirrel plasma (Figure 2a). Fibrinolysis may result from plasmin-like activity of venom toxins or from activation of endogenous serum components (Hofmann and Bon, 1987; Braud et al., 2000). Increased activity of venom when incubated with serum suggests that venom not only maintains effectiveness in the face of prey defenses, but can also capitalize on the biochemical properties of prey tissues. RIA binding levels, therefore, may represent a multitude of interactions between venom and prey tissues that simultaneously reduce and enhance the toxic activities of venom. Radioimmunoassays have been valuable in screening for population differences in venom resistance in California ground squirrels (Poran et al., 1987; Poran and Coss, 1990; Coss et al., 1993). However, assays of venom + plasma interactions clarify the functional basis of differences in

binding levels, and will be more valuable in understanding the consequences of variation in prey defenses.

In contrast to enhanced fibrinolytic activity in the presence of Douglas blood plasma, samples from all four populations significantly reduced the metalloprotease activity of northern Pacific rattlesnake (*C. o. oreganus*) venom (Figures 1a and 2a). This is consistent with our understanding of antihemorrhagic factors identified in other mammalian prey of viperid snakes, which have been identified as snake venom metalloprotease inhibitors (SVMPI) (Pérez and Sánchez, 1999). The ability to inhibit hemorrhagic toxins appears to be a convergent response to envenomation, perhaps because the major threat of viper venoms, hemorrhage *in rhexis*, is thought to result from hydrolysis of collagen-rich connective tissue lining the capillary endothelium (Baramova et al., 1989; Tu, 1991). Minimizing the ability of venom toxins to rupture blood vessels can have a cascade of multiple subsequent protective benefits, including reduced access of other venom toxins to target tissues, reduced edema, and continued circulation of blood to regions near the bite, enhancing tissue repair and minimizing necrosis (Gutiérrez and Rucavado, 2000; Anai et al., 2002). However, it is surprising that the metalloprotease activity of southern Pacific and western diamondback venoms was relatively unaffected, since defenses specialized to one or a few venoms seems to be rare. For example, Soto et al. (1988) showed that sera from opossum (*D. virginiana*) and woodrats (*N. micropus*) were effective at preventing hemorrhage by all 47 species of snakes they examined. California ground squirrels encounter only a single rattlesnake species (*C. o. oreganus*) from central California northward to British Columbia. We suspect that coevolution may have favored plasma defenses in populations from the Central Valley that are especially effective against venom from this species.

Generalized resistance to venom metalloproteases is similar to the pattern observed in animals from the Davis site, where rattlesnakes are rare (cf. Figure 1a, b). Compared to the nearby Winters population, plasma factors were not as effective against the local rattlesnake predator (*C. o. oreganus*), but maintained some effectiveness against western diamondback (*C. atrox*) venom. Antihemorrhagic proteins isolated from other mammals show homology to proteins in the immunoglobulin supergene family (Perales and Domont, 2002), which includes plasma serpins and other protease and metalloprotease inhibitors. Catanese and Kress (1993) identified differences in the amino acid sequence of oprin (the antihemorrhagic factor from *Didelphis virginiana*) that distinguish it from other mammalian α_1 -proteinase inhibitors. Presumably because of these differences, oprin can bind and inhibit venom metalloproteases while these toxins rapidly hydrolyze human α_1 -proteinase. We suspect that consistent selection from northern Pacific rattlesnake toxins in the Winters, Folsom Lake, and Sedgwick Reserve animals has favored sequence changes in ground squirrel SVMPI that

maximize effectiveness against this venom. Since venom metalloproteases are also subject to selection favoring escape from inhibition by prey defenses, reciprocal changes may have led to SVMP and SVMPI variants unique to these species. Reactive center sequences in plasma serpins are hypervariable and affect protease recognition and inhibition effectiveness (Hill and Hastie, 1987; Goodwin et al., 1996). It will be interesting to see whether Davis individuals, and squirrels from other sites where snakes are rare or absent, possess plasma factors with a reactive site sequence similar to the precursor of SVMPIs in this species. Such sequences may confer some level of protection against xenologous metalloproteases, including those from a variety of snake venoms, but may not represent a form optimized to inhibit SVMP from the lone sympatric species, northern Pacific rattlesnakes.

The contrast between squirrel blood plasma effects on metalloprotease and fibrinolytic activity may reflect alternative solutions to venom toxicity by rattlesnakes and ground squirrels. Although ground squirrel plasma factors can reduce the activity of venom metalloproteases, rattlesnakes may still benefit by immobilizing prey as they disrupt hemostasis. Elevated fibrinolytic activity of *C. o. oregonus* venom may aid snakes in subduing prey by the induction of hypotensive shock if internal bleeding after envenomation is prolonged (Mackessy, 1993; Mackessy et al., 2003). This would increase the likelihood of obtaining a valuable meal, as long as sufficient SVMP activity is maintained to facilitate the rupture of prey viscera after ingestion (Thomas and Pough, 1979).

From the squirrel's perspective, avoidance of tissue damage from digestive venom toxins may be the crucial task of plasma defenses since behavioral defenses may buffer against the risk posed by venom-induced shock. Poststrike trailing by *C. oregonus* depends on a chemosensory profile of individual prey items developed from cues obtained during the strike and subsequent envenomation (Kardong and Smith, 2002). Chemosensory searching by vipers using this profile may last hours, and perhaps days after envenomation (see Diller, 1990), and may depend in part on tissue damage in prey after envenomation (Greenbaum et al., 2003). It is possible that inhibition of venom proteolytic activity may play a role in disrupting a snake's ability to search for prey. Certainly, recruitment of other colony members to mob rattlesnakes (Owings and Coss, 1977; Hersek and Owings, 1993) may minimize the opportunity for snakes to trail and ingest envenomated squirrels, even if they are temporarily immobilized by shock. In this case, the digestive effects of metalloproteases may pose a greater threat to squirrel fitness due to the potential for lasting damage to tissues. Studies of venom resistance in the rock squirrel, *Spermophilus variegatus*, a closely related species that also shows aggressive confrontation of rattlesnake predators (Owings et al., 2001), also indicate that metalloprotease inhibition is of primary importance (Biardi, 2000).

Our measures of venom activity also revealed significant differences between Pacific rattlesnake venoms when preying on the Beechey subspecies of California ground squirrels (*S. b. beecheyi*). We expected to find differences between squirrels from the Folsom and Sedgwick sites, but were unable to distinguish between them using any of the four assays of resistance. Instead, we observed striking differences between venoms. Northern Pacific rattlesnake venom maintained greater activity in the general proteolytic and hemolytic assays, whereas southern Pacific rattlesnake venom maintained greater effectiveness in the metalloprotease and fibrinolysis assays (cf. Figure 2a,b). This was surprising because previous studies have not identified clear differences in activity between these venoms (Mackessy, 1988; Bee et al., 2001). However, our results show that these venoms pose distinctly different threats to ground squirrels inhabiting a site (like the Sedgwick Reserve) where they are likely to encounter both snake species.

The role of Douglas squirrel plasma in enhancing fibrinolytic activity, inhibition of venom metalloproteases by ground squirrel SVMPI, and the detection of differences in northern and southern Pacific rattlesnake venoms in the presence of Beechey squirrel plasma all highlight the adaptive context of venoms and resistance. Our assays of venom activity in the presence of resistance factors revealed variation that is not detected in assays of venoms alone, and reinforce the idea that the outcome of envenomation will depend on both predator and prey, and will, in turn, affect the evolution of both venom toxicity and resistance.

Detection of previously cryptic differences between *C. o. oregonus* and *C. o. helleri* venoms may reflect an arms race that has generated variation within and between predators and prey. Relationships among species over evolutionary time can foster reciprocal adaptation of traits crucial to their interaction (Futuyma and Slatkin, 1983). Because populations of California ground squirrels vary in their ability to neutralize venom toxins (Biardi, 2000; Biardi et al., 2000, this study), and because this variation has important implications for the fitness of both predators and prey, both theoretical (e.g., Thompson, 1994, 1997) and modeling (e.g., Gomulkiewicz et al., 2000) approaches to coevolution predict corresponding local variation in venom from northern Pacific rattlesnakes. There are no published studies describing population differences in venom for this species; unfortunately, our use of pooled venoms also does not allow us to detect differences at the population level.

However, population variation in venoms related to diet is not unknown. For example, Daltry et al. (1996a,b) demonstrated that population variation in venom composition of the Malayan pit viper (*Calloselasma rhodostoma*) is strongly influenced by diet. However, this study related variation to the relative representation of different prey categories (amphibians, reptiles, and “endotherms”) in the diet, making it unclear whether the effect is attributable

to basic structural and physiological differences among prey categories, or more specific defenses to venoms such as we observe in ground squirrels. The subsequent debate between Sasa (1999a,b) and Wüster et al. (1999) centering on neutral vs. adaptive explanations for variability in snake venoms highlighted the importance of studying venoms in their natural context. To date, however, studies designed to test coevolution of venomous snakes and their prey remain exceedingly rare (e.g., Heatwole and Powell, 1998; Jorge da Silva and Aird, 2001).

Research on snake venom chemistry has an extensive history, driven primarily by interest in the clinical treatment of snakebite and the characterization of toxins in a therapeutic and research context. However, approaches to understanding venoms in a natural context (Mackessy, 1988; Daltry et al., 1996a,b; Kordis and Gubensik, 2000; Creer et al., 2003; Mackessy et al., 2003), especially considering venom resistance (Poran et al., 1987; Poran and Coss, 1990; Coss et al., 1993; Heatwole and Poran, 1995; Chiszar et al., 1999; Biardi et al., 2000; Heatwole et al., 1999) are becoming increasingly common. Future studies that simultaneously evaluate local populations of snakes and prey are likely to provide additional surprising insights into toxicity and resistance that arise from the coevolutionary arms race at the molecular level.

Acknowledgments—This manuscript was greatly improved by the comments of two anonymous reviewers. J.E.B. was supported by a Floyd and Mary Schwall Dissertation Fellowship in Biomedical Research.

Abstract—Using male antenna as the sensing element, three electroantennographic detection (EAD)-active peaks were detected from pheromone gland extracts of the citrus leafminer, *Phyllocnistis citrella*. Based on gas chromatography (GC)-mass spectrometry and GC-infrared data, the semi-chemicals were tentatively identified as a novel pheromone, (Z,Z,E)-7,11,13-hexadecatrienal, a previously identified attractant, (Z,Z)-7,11-hexadecadienal, and (Z)-7-hexadecenal in a ratio of 30:10:1, respectively. Identification was confirmed with synthetic compounds, which gave retention times identical to those of the natural products on three capillary columns with polar and nonpolar phases. While traps baited only with the previously identified attractant alone did not catch any males in Brazil, binary and tertiary mixtures with the major constituents caught significantly more male moths than traps baited with five virgin females.

Key Words—(Z,Z,E)-7,11,13-Hexadecatrienal, (Z,Z)-7,11-hexadecadienal, (Z)-7-hexadecenal, Z7,Z11,E13-16Ald, Z7,Z11-16Ald, Z7-16Ald, Gracillariidae, Lepidoptera.

INTRODUCTION

Attractants for the citrus leafminer, *Phyllocnistis citrella* Stainton (Lepidoptera: Gracillariidae), are sorely needed not only for monitoring and controlling populations, but also for quarantine purposes as this serious pest of citrus is spreading rapidly. *P. citrella* was originally described in India (Stainton, 1856), but it is now established on five continents (Heppner, 1993). In the last decade, the citrus leafminer spread through Florida, Alabama, Louisiana, Texas, Brazil, and most Latin American countries (Heppner, 1999) and has reached California, Mexico, and Hawaii (Anonymous, 2004).

Field screenings of potential attractants for species in the Gelechiidae family led to the observation that Japanese populations of the citrus leafminer were captured in traps baited with (Z,Z)-7,11-hexadecadienal (Z7,Z11-16Ald) (Ando et al., 1985). However, subsequent field tests failed to catch males of *P. citrella* in traps baited with Z7,Z11-16Ald in China, Italy, Spain, USA, Turkey, and Brazil (reviewed in Sant'ana et al., 2003), although a related species, *P. wampella*, was captured with the same attractant in China (Du et al., 1989). These findings suggest there may be geographic variations in the pheromone system, prompting us to launch a collaborative project for the identification of the pheromone system of the citrus leafminer. In this work, we describe the isolation, identification, synthesis, and field evaluation of the sex pheromone of the Brazilian population of the citrus leafminer.

METHODS AND MATERIALS

Insects. Colonies, reared according to the protocol of Chagas and Parra (2000), were maintained at the Insect Biology Laboratory at Escola Superior de Agricultura Luiz de Queiroz (ESALQ), Universidade de São Paulo (USP) at $25 \pm 2^\circ\text{C}$, $65 \pm 10\%$ relative humidity, and a 14L:10D photoregime. Pupae were collected and held in individual glass vials (8×1 cm ID) containing a small piece of moistened filter paper. Adults were sexed using the criteria described by Jacas and Garrido (1996) and fed on a small drop of pure honey.

Pheromone Extraction and Isolation. Pheromone glands from groups of 200 2-d-old virgin females were excised during the last hour of the scotophase and the first hour of the photophase to coincide with the period of mating activity (Parra-Pedrazzoli et al., in press). The abdominal tips were immersed in hexane (200 μl) for ca. 1 hr. A total of 5000 gland-equivalent was pooled,

the extract was transferred to glass ampoules, which were sealed, and shipped to Davis. Crude extracts were subjected to flash column chromatography on silica gel (60–200 mesh; Fisher Scientific) by successively eluting with hexane–ether mixtures in the following order: 100:0 (hexane fraction), 99:1 (1% fraction), 98:2, 95:5, 90:10, 50:50, 0:100 (ether fraction). Aliquots of these fractions were shipped to Piracicaba, SP, Brazil for behavioral studies.

Electrophysiology. Gas chromatography-electroantennographic detection (GC-EAD) recordings were made with previously described methods and equipment (Cossé et al., 2005). The GC-EAD responses were amplified (500×) using an AC/DC UN-6 amplifier (Syntech) and analyzed on a computer equipped with an analog-to-digital conversion board (IDAC, Syntech) running GC-EAD software (Syntech). Samples were injected in splitless mode using a 6890 Series GC (Agilent Technologies, Palo Alto, CA, USA) fitted with a DB-1 column (J&W Scientific, Folsom, CA, USA; 15 m × 0.25 mm; 0.25 or 1.0 μm film thickness). GC-EAD sample analysis used temperature programs either from 50 to 280°C at 25°C/min (see Figure 1) or from 50 to 280°C in steps of 25°C/min to 180°C, 5°C/min until 215°C, and 25°C/min to 280°C (see Figure 4). Inlet temperatures were maintained at 280°C and GC-EAD effluent interface from postcolumn splitter was kept at 300°C.

Other Analytical Procedures. Gas chromatography-mass spectrometry (GC-MS) was performed either in EI or CI mode (methane) on a 5973 Network

FIG. 1. Simultaneously recorded gas chromatogram (FID) and electroantennographic detection (EAD) of a male *P. citrella* antenna responding to a hexane extract of female *P. citrella* ovipositors (approx. 8 FE). Insert shows an enlarged section with antennal activity indicated by asterisk (*).

mass selective detector linked to a 6890 Network GC system (Agilent Technologies, Palo Alto, CA, USA). Chromatographic separation was done on three different columns: HP-5MS (Agilent; 30 m × 0.25 mm; 0.25 μm), HP-INNOWAX (Agilent; 30 m × 0.25 mm; 0.25 μm), and DB-1 column (15 m × 0.25 mm; 1.0 μm), which were operated at 70°C for 1 min, increased to 250°C (or 290°C) at a rate of 10°C/min (or 5°C/min), and held at the final temperature for 10 min, i.e., 70(1)-10-250(10), 70(1)-5-250(10), or 70(1)-10-290(10). Vapor phase infrared (IR) spectroscopy was done on a Win GC/IR Pro (Varian, Randolph, MA, USA) with a GC interface and a Scimitar FTS 2000 linked to a 6890 Network GC system (Agilent). Chromatographic separation was obtained with an HP-5 column (Agilent; 30 m × 0.32 mm; 0.25 μm) operated at 100(1)-20-250(5). Hydrogenation and dimethyl disulfide (DMDS) derivatizations were performed as previously described by Leal et al. (1996, 2001).

Synthesis of (Z,Z)-7,11-Hexadecadienal (Figure 3). A solution of **4** (10.8 g, 57.8 mmol) in THF (100 ml) was added to a THF solution (50 ml) of dibromopropane **3** (11.7 g, 57.8 mmol) and Li₂CuCl₄ (0.203 g, 0.925 mmol) at 5°C. After stirring for 2 hr, the mixture was gradually raised to room temperature and kept overnight. The reaction mixture was poured into diluted HCl and extracted with ether. The organic layer was washed with water, saturated aqueous NaHCO₃, brine, dried (MgSO₄) (hereafter referred to as the “washing protocol”), concentrated, and distilled to give **5** (6.16 g, 26 mmol). A solution of **5** (6.16 g, 26 mmol) in THF (10 ml) was added to a THF solution (30 ml) of lithium acetylide–ethylenediamine complex (3.11 g, 33.8 mmol) and HMPA (5 ml) at 5°C. After stirring for 2 hr, the mixture was gradually raised to room temperature and kept overnight under the same conditions. The reaction mixture was poured into diluted HCl and extracted with ether. After treatment (washing protocol), the organic layer was concentrated and distilled to give **6** (4.26 g, 23.4 mmol). *n*-BuLi (1.6 mol/l solution in hexane, 14.6 ml, 23.4 mmol) was added to a THF solution (50 ml) of **6** (4.26 g, 23.4 mmol) at 5°C. After 30 min, **7** (4.47 g, 23.4 mmol) in 10 ml HMPA was added to the solution at 5°C. After refluxing for 8 hr, the reaction mixture was poured into diluted HCl and extracted with ether. After the washing protocol, the organic layer was concentrated and distilled to give **8** (3.41 g, 11.7 mmol). A mixture of **8** (3.41 g, 11.7 mmol), 5% Pd/BaSO₄ (0.17 g), and quinoline (1.7 g) in 30 ml of MeOH was stirred for 3 hr in an atmosphere of hydrogen. The reaction mixture was poured into diluted HCl and extracted with ether. Following the washing protocol, the organic layer was concentrated *in vacuo*. The residual material was chromatographed on silica gel column (hexane–ether, 9:1) to give **9** (3.07 g, 10.5 mmol). **9** (3.07 g, 10.5 mmol) was stirred with *p*-toluenesulfonic acid monohydrate (PTS, 100 mg, 0.53 mmol) in 30 ml of MeOH at 60°C. After stirring for 2 hr, the reaction mixture was poured into water and extracted with ether, treated with the washing protocol, and concentrated *in vacuo* to give **10**

(2.65 g, 9.41 mmol). **10** (2.65 g, 9.41 mmol) was added to 100 ml THF and diluted HCl solution at room temperature. After stirring for 1 hr, the reaction mixture was poured into water and extracted with ether. After the washing protocol, the organic layer was concentrated *in vacuo*. The residual material was chromatographed on silica gel column (hexane–ether, 9:1) to give **1** (2 g, 8.47 mmol, >98% purity). IR (ν_{\max} , film, cm^{-1}): 2927, 2858, 2715, 1728, 1654, 1458, 1099, 1011, 914. ^1H NMR (300 MHz, CDCl_3): δ 0.90 (3H, t, $J = 7.5$ Hz), 1.27–1.42 (8H, m), 1.64 (2H, quintet, $J = 7.5$ Hz), 2.00–2.09 (8H, 2 broad peaks), 2.43 (2H, dt, $J = 2.1$ Hz, $J = 7.2$ Hz), 5.31–5.43 (4H, m), 9.77 (1H, t, $J = 1.8$ Hz). ^{13}C NMR (75.4 MHz, CDCl_3) δ 14.0, 22.0, 22.4, 27.0 (2C), 27.4 (2C), 28.8, 29.4, 31.9, 43.9, 129.1, 129.6, 129.8, 130.4, 202.8. GC-MS: m/z 236, 218, 175, 161, 147, 137, 123, 121, 109, 95, 93, 81, 69, 67, 55 (100%), 41.

Synthesis of (Z,Z,E)-7,11,13-Hexadecatrienal (Figure 6). **5** (2.37 g, 10 mmol) and NaI (2.98 g, 20 mmol) were added into acetone (50 ml) at room temperature. After the solution was refluxed for 2 hr, the reaction mixture was poured into water and extracted with ether. The organic layer was washed (see washing protocol) and concentrated *in vacuo*. The residual material was chromatographed on silica gel column (hexane–ether, 9:1) to give **11** (2.52 g, 8.91 mmol). *n*-BuLi (1.6 mol/l solution in hexane, 8.4 ml, 13.4 mmol) was added into THF solution (30 ml) of **12** (5-chloro-1-pentyne 1.37 g, 13.4 mmol) at 5°C. After 30 min, **11** (2.52 g, 8.91 mmol) in HMPA (5 ml) was added into the solution at 5°C. After the solution was refluxed for 2 hr, the reaction mixture was poured into diluted HCl and extracted with ether. Following the washing protocol, the organic layer was concentrated and distilled to give **13** (1.84 g, 7.13 mmol). **13** (1.84 g, 7.13 mmol) was stirred with CH_3COOK (1.37 g, 14 mmol) in HMPA (30 ml) at 60°C. After stirring for 2 hr, the reaction mixture was poured into diluted HCl and extracted with ether. The organic layer was washed (see washing protocol) and concentrated *in vacuo* to give **14** (1.62 g, 5.7 mmol). A mixture of **14** (1.62 g, 5.7 mmol), 5% Pd/BaSO₄ (0.081 g), and quinoline (0.81 g) in MeOH (10 ml) was stirred for 1 hr in an atmosphere of hydrogen. The reaction mixture was poured into diluted HCl and extracted with ether. The organic layer was washed (see washing protocol) and concentrated *in vacuo*. The residual material was chromatographed on silica gel column (hexane–ether, 9:1) to give **15** (1.45 g, 5.13 mmol). A solution of **15** (1.45 g, 5.13 mmol) in MeOH (5 ml) was added into MeOH solution (20 ml) of KOH (0.56 g, 10 mmol) and water (2 ml) at 5°C. After stirring for 1 hr, the reaction mixture was poured into water and extracted with ether. After treatment with the washing protocol, the organic layer was concentrated *in vacuo*. The residual material was chromatographed on silica gel column (hexane–ether, 5:5) to give **16** (1.1 g, 4.62 mmol). Pyridinium dichlorochromate (PDC) was added into CH_2Cl_2 solution of **16** (370 mg, 1.54 mmol) at 5°C. After stirring for 2 hr, the temperature was gradually raised to room temperature and maintained overnight

under the same conditions. The reaction mixture was chromatographed on silica gel column by ether and concentrated *in vacuo* to give **17** (294 mg, 1.23 mmol). *n*-BuLi (1.6 mol/l solution in hexane, 1.6 ml, 2.46 mmol) was added to a THF solution (20 ml) of **18** (1.01 g, 2.46 mmol) at -20°C . After stirring for 30 min, the temperature was gradually raised to room temperature. After 1 hr at room temperature, the solution was cooled to -100°C . **17** (294 mg, 1.23 mmol) in THF (2 ml) was added to the solution at -100°C . After stirring for 2 hr, the reaction mixture was poured into water and extracted with hexane. The organic layer was washed (see washing protocol) and concentrated *in vacuo*. The residual material was chromatographed on silica gel column (hexane–ether, 95:5) to give **19** (288 mg, 0.987 mmol). **19** (288 mg, 0.987 mmol) was stirred with PTS (9.6 mg, 0.05 mmol) in MeOH (30 ml) at 60°C . After stirring for 2 hr, the reaction mixture was poured into water and extracted with ether. Following the washing protocol, the organic layer was concentrated *in vacuo* to give **20** (249 mg, 0.888 mmol). **20** (249 mg, 0.888 mmol) was added to 10 ml THF and diluted HCl solution at room temperature. After stirring for 1 hr, the reaction mixture was poured into water and extracted with ether. The organic layer was washed (see washing protocol) and concentrated *in vacuo*. (7*Z*,11*E*,13*E*)-7,11,13-hexadecatrienal was removed as a Diels–Alder adduct with tetracyanoethylene. The residual material was chromatographed on silica gel column (hexane–ether, 9:1) to give **2** (110 mg, 0.47 mmol, >96% purity). IR (ν_{max} , film, cm^{-1}): 2927, 2854, 2715, 1728, 1651, 1458, 1076, 983. ^1H NMR (300 MHz, CDCl_3) δ : 1.02 (3H, t, $J = 7.5$ Hz), 1.31–1.41 (4H, m), 1.57–1.66 (2H, m), 2.00–2.26 (8H, m), 2.42 (2H, dt, $J = 1.8$ and 7.5 Hz), 5.26–5.43 (3H, m), 5.71 (1H, dt, $J = 6.6$ and 15.0 Hz), 5.96 (1H, t, $J = 11.1$ Hz), 6.29 (1H, ddt, $J = 1.5$, 11.1 and 15.0 Hz), 9.76 (1H, t, $J = 1.8$ Hz). ^{13}C NMR (75.4 MHz, CDCl_3) δ : 13.6, 22.0, 25.9, 27.0, 27.3, 27.8, 28.8, 29.4, 43.9, 124.6, 129.0, 129.2, 129.3, 130.0, 136.5, 202.8. GC-MS: m/z 234, 205, 173, 149, 135, 121, 107, 95 (100%), 79, 67, 55, 41.

(*Z*)-7- and (*Z*)-11-Hexadecenal were purchased from a commercial source (Shin-Etsu Chemical Co. Ltd., Tokyo, Japan).

Formulation and Field Evaluation. Hexane solutions of the synthetic pheromone constituents were shipped to Brazil and maintained at -80°C until use. Several hours before field experiments (August 3, 2004 to April 23, 2005), test blends were incorporated into rubber septa (Aldrich) at two different dosages (50 and 500 μg per septum) in the triene/diene/monoene ratio of 30:10:1. The lures were placed into delta traps, which were hung in a citrus orchard (Fazenda Quatrimãs, Botucatu, SP, Brazil) at a height of 1.6 m and with intertrap distance of 30 m. Pheromone traps were set in randomized blocks

FIG. 2. GC-MS data for peaks A, B, and C obtained from virgin female *P. citrella* pheromone glands.

(four replicated per block) along with control (empty traps) and those baited with five 2-d-old virgin females. Each set of experiments was conducted in two different locations with at least three temporal replicates. After daily inspection, virgin females were replaced, and traps were rotated to rerandomize the experimental block. Capture data were transformed to $\sqrt{(x + 0.5)}$ and analyzed by ANOVA (Tukey's test, 5%).

RESULTS AND DISCUSSION

Male attraction to female gland extracts was demonstrated in indoor bioassays conducted from 1 hr before to 1 hr after the onset of photophase (data not shown), coinciding with the peak of mating activity (Parra-Pedrazzoli et al., in press). After flash chromatography of the crude extract, behavioral activity was recovered in the 2% fraction, which was also EAD-active. Three EAD-active peaks (A, B, and C) were detected (Figure 1), with residual EAD activity of the peak C being also detected in a subsequent fraction (5%). This elution pattern suggests that the three compounds had the same functional group. Although not clearly identified in GC-MS analysis in the electron impact mode (Figure 2), CI-MS indicated that the molecular weights of A, B, and C were 236, 238, and 234, respectively. Based on the retention times of saturated hydrocarbon standards [GC-MS, HP-5MS, 70(1)-10-250(10); C₁₇, 13.11; C₁₈, 14.19; C₁₉, 15.21 min], we hypothesized that the three compounds were hexadecadienal, hexadecenal, and hexadecatrienal, respectively. To compare the EAD-active compounds with the previously identified attractant, we prepared a sample of (*Z,Z*)-7,11-hexadecadienal (**1**) in 14.7% overall yield, starting from dibromopropane (Figure 3). Synthetic *Z*7,*Z*11-16Ald was indistinguishable from peak A in the MS profile and gave identical retention times in polar and nonpolar capillary columns (HP-5MS, DB-1, and HP-INNOWAX). The *Z,Z* stereochemistry of the natural 7,11-hexadecadienal was further supported by GC-FTIR, which showed a characteristic *cis* C–H stretching band (medium intensity) at 3012 cm⁻¹ (Leal, 1998). Next, we tested whether the monoene B was biosynthetically related to the diene A. MS from both (*Z*)-7- and (*Z*)-11-hexadecenal were similar to that of the natural product. The retention times of (*Z*)-7-hexadecenal and B in three capillary columns were identical, but that of (*Z*)-11-hexadecenal differed (e.g., HP-5MS, 70(1)-10-250(5); Z11-16Ald, 14.27 min; B, 14.16 min). Given the small amount of sample available, it was not possible to determine analytically (GC-IR) the stereochemistry of the double bond. However, the retention time of the (*E*)-isomer differed from that of the natural product (e.g., HP-5MS, 70(1)-10-250(5); E7-16Ald, 14.21 min; natural product, 14.16 min). In addition, GC-EAD analysis further confirmed that peak B was indeed (*Z*)-7-hexadecenal (Figure 4).

FIG. 3. Synthetic route for (Z,Z)-7,11-hexadecadienal.

Hydrogenation of a fraction containing peaks A, B, and C (50 gland-equivalent) generated the saturated 16Ald, thus suggesting that peak C was a related aldehyde with three unsaturations. Attempts to determine the positions of the double bonds by DMDS were unrewarding. With a large sample pooled

FIG. 4. Simultaneously recorded gas chromatogram (FID) and electroantennographic detection (EAD) of a male *P. citrella* antenna responding to synthetic (Z,Z)-7,11-hexadecadienal (A) and (Z)-7-hexadecenal (B). Asterisk (*) denotes antennal activity.

FIG. 5. GC-IR data for the natural (top) and synthetic (bottom) (*Z,Z,E*)-7,11,13-hexadecatrienal. Arrow and arrowhead indicate a = CH stretching and a CH bending of *cis* and conjugated *trans* configuration, respectively.

from ca. 2500 females-equivalent, we obtained a GC-IR trace (Figure 5). A band of medium intensity at ca. 3018 cm^{-1} suggests that C had two double bonds in *cis*-configuration as observed in A (data not shown), whereas a weak band at ca. 980 cm^{-1} indicated one conjugated double bond in the *trans*-configuration. Note also the carbonyl band at 1742 cm^{-1} , which is typical of aldehydes (Leal, 1998). In conjugated *Z,E*-dienes, the “*trans* band” ($940\text{--}990\text{ cm}^{-1}$) normally appears as a doublet, whereas a single band is characteristic of *E,E*-dienes (Leal, 1998). Given the limited amount of sample and consequently

FIG. 6. Synthetic route for (Z,Z,E)-7,11,13-hexadecatrienal.

the poor resolution of small bands, it was not clear whether the *trans* band was a single or double peak. However, the medium intensity of the CH stretching band (Figure 5) suggests the occurrence of two double bonds in *cis* configuration, implying that the conjugated diene was in configuration *Z,E*. Considering that *P. citrella* biosynthesizes (*Z*)-7-hexadecenal, it is reasonable to assume that (*Z,Z*)-7,11-hexadecadienal is produced by the sequential action of a $\Delta 11$ desaturase on the 7-monoene (Jurenka, 2004). Similarly, the triene could be produced by the action of another desaturase on a 7,11-diene substrate. Given the conjugation in C, it could be produced by a $\Delta 5$, $\Delta 9$, or $\Delta 13$ desaturase. Based on the GC-IR data, we ruled out 7,9,11-hexadecatrienal, because an *E9* configuration flanked by (and conjugated to) two *Z*-double bonds would give a different ratio of the *cis/trans* bands, and probably shift the *trans* band. An examination of The Pherolist (Witzgall et al., 2004) indicated that, albeit common in pheromones with a shorter skeleton, it is unusual to have a double bond at position 5 in multiple unsaturated C-16 pheromones. It could be that $\Delta 5$ desaturases have a preference for C12 substrates, as demonstrated for the biosynthesis of (*E,Z*)-5,7-dodecadien-1-yl acetate (Ono et al., 2001). We then

FIG. 7. Catches of male *P. citrella* in delta traps baited with five virgin females (VF), a binary mixture (triene + diene, 3:1), and a tertiary mixture (triene + diene + monoene, 30:10:1) at low (50 μg) and high (500 μg) doses. Experiments were run in randomized blocks for 3 d, with no catches in empty (control) traps. Bi-L: binary mixture, low dose; Bi-H: binary mixture, high dose; T-L: tertiary mixture, low dose; T-H: tertiary mixture, high dose. Treatments with the same letter are not significantly different (Tukey's test, 5%). Means of captures are untransformed, and error bars show 0.5 SE.

reasoned that C would be (*Z,Z,E*)-7,11,13-hexadecatrienal. A sample of authentic (*Z,Z,E*)-7,11,13-hexadecatrienal (**2**) was synthesized from **5** in 9% overall yield (Figure 6). MS and IR data (Figure 5) of the synthetic and natural products matched perfectly. Next, we compared the retention times of synthetic *Z7,Z11,E13*-16Ald and C in three different capillary columns. Both synthetic and natural products gave the same retention times in polar and nonpolar columns even when more shallow temperature programs were used [e.g., C and *Z7,Z11,E13*-16Ald appeared at 41.02 min in HP-INNOWAX with a ramp of 2.5°C/min, i.e., 70(1)-2.5-250(10)]. In summary, we identified three physiologically active compounds from the pheromone gland of *P. citrella*, namely, (*Z,Z*)-7,11-hexadecadienal, (*Z*)-7-hexadecenal, and (*Z,Z,E*)-7,11,13-hexadecatrienal, corresponding to peaks A, B, and C (Figure 1). These compounds appeared in crude extracts and a 2% fraction in the approximate ratio of 30:10:1, respectively.

In preliminary indoor Y-olfactometer bioassays, reported elsewhere (Parra-Pedrazzoli et al., in press), males responded to synthetic mixtures of the three compounds (but not to single constituents). They not only were attracted to the side-arm with pheromone, but also displayed the same courtship behavior observed when males approach virgin females. In the field, there were no

catches in traps baited with Z7,Z11-16Ald alone or in combination with Z7-16Ald (10:1). However, traps baited with mixtures containing the major constituent, Z7,Z11,E13-16Ald, caught significantly more males than virgin female-baited traps (Figure 7). These experiments indicate that mixtures of Z7,Z11,E13-16Ald and Z7,Z11-16Ald are attractants to males. However, the function of the minor EAD-active Z7-16Ald was not clear. One possibility is that the monoene is a behavioral antagonist to other species. However, as *P. citrella* is an exotic species in Brazil, this hypothesis must await field tests in the native habitat of *P. citrella*.

Activity of the pheromone samples, formulated in rubber septa with BHT, decreased dramatically over a 3-d period so experiments were run only in 3-d intervals before renewing the lures. We did not observe a significant difference in catches by traps loaded with low (50 µg) and high (500 µg) doses of pheromone. These results suggest that a long-lasting, low-releasing pheromone dispenser can be designed to monitor populations of the citrus leafminer.

Acknowledgments—A.L.P.-P. was supported by scholarships from Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) and the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) in Brazil and the USA, respectively. This research was support in part by a gift from Fuji Flavor Co. Ltd. Work in Brazil was supported by FAPESP and FUNDECITRUS. (Received June 9, 2005; revised August 11, 2005; accepted October 3, 2005)

Abstract—The citrus leafminer is an important vector of citrus canker in many of the major citrus production areas of the world. (7Z,11Z)-Hexadecadienal was reported as a sex attractant for this insect in the 1980s, based on trap catches during pheromone screening trials in Japan. However, attempts to reproduce this work in other areas of the world have not been successful. We report here that (7Z,11Z)-hexadecadienal is only one component of the pheromone, with the other critical component being the analogous trienal, (7Z,11Z,13E)-hexadecatrienal. Both compounds were identified in the effluvia from live female moths by coupled gas chromatography (GC)-electroantennography using nonpolar and polar GC columns, and the identifications were confirmed by comparisons of mass spectra with those of authentic standards. Stereoisomers of the two compounds, and a number of analogs, were synthesized to confirm the identifications. In field trials, neither compound alone was attractive to male moths, but blends of the two were highly attractive, with thousands of insects being caught per trial. Addition of the isomeric (7Z,11Z,13Z)-hexadecatrienal inhibited attraction to the two-component blend.

Key Words—Sex pheromone, (7Z,11Z)-hexadecadienal, (7Z,11Z,13E)-hexadecatrienal, 5,7,11-hexadecatrienal, citrus leafminer, (7Z,11Z,13Z)-hexadecatrienal.

INTRODUCTION

The citrus leafminer (CLM), *Phyllocnistis citrella* Stainton (Lepidoptera: Gracillariidae), is a pest in most of the citrus-growing regions of the world (Heppner, 1993). It attacks all varieties of citrus and some related plant species, with grapefruit, tangerine, and pumello being among the most susceptible hosts (Legaspi and French, 2003). Although mature trees can tolerate some damage, growth of young trees in nurseries and newly planted orchards is reduced. Damage is caused by the larvae forming serpentine mines in the leaves, in which they are well protected from insecticide sprays, making them difficult to control. Even more important than direct damage is the potential for the adult moths to vector the highly contagious and lethal citrus canker bacterium, *Xanthomonas axonopodis* pv *citri*, where this pathogen occurs (Ando et al., 1985). The importance of this highly contagious disease to growers is reflected in the control program in Florida, USA, which calls for the destruction of all exposed citrus trees within 1900 ft of an infected one (Florida Department of Agriculture and Consumer Services, <http://www.doacs.state.fl.us/pi/canker/cankerflorida.pdf>).

There are currently no good methods for early detection and sampling of this insect to track the continued spread through California and other citrus-growing regions in the United States. Often, the first signs of its presence are the characteristic mines in the leaves, by which time the infestation may be well established. Although (7Z,11Z)-hexadecadienal (7Z,11Z-16:Ald) was reported as a sex attractant for this insect from screening trials 20 yr ago (Ando et al., 1985), in subsequent trials in other parts of the world, including China, Spain, Florida, and Italy (Jacas and Peña, 2002), this compound was not effective. Due to the threat of CLM to the California citrus industry, we undertook an investigation of its pheromone chemistry, and report that the pheromone of California populations consists of at least two components, the previously identified (7Z,11Z)-hexadecadienal, and the corresponding (7Z,11Z,13E)-hexadecatrienal (7Z,11Z,13E-16:Ald).

METHODS AND MATERIALS

Insects. Insects were obtained by collecting branches with infested leaves from lemon orchards in the Coachella Valley, Riverside Co., CA, USA and from Escondido, San Diego Co., CA. Branches with larvae were kept in humidified, vented plastic boxes [32 × 17 × 9 cm (*L* × *W* × *H*), with four 18-mm vents covered with fine brass screening, or for larger quantities, 40 × 30 × 14 cm with four 38-mm screen-covered vents) until the insects pupated. Pupae were removed from cocoons and transferred, using a damp camel-hair brush if necessary, into a Petri dish lined with a damp filter paper. The sex of pupae was

determined by examining the terminal abdominal segments (Garrido and Jacas, 1996). Pupae were then transferred to individual 1-dram glass shell vials (45×15 mm, $L \times \text{diam.}$) with a small disk of filter paper to prevent them from becoming trapped in condensation on the glass. The vials, closed with a plastic cap with a pinhole for ventilation, were held in groups in a vented, humidified plastic box. Vials were checked daily for adult emergence. Adults were fed a sugar-water solution (10 g sugar in 100 ml deionized water) absorbed on 2- to 3-mm cubes of cellulose sponge (ca. 10–20 $\mu\text{l}/\text{cube}$). Male moths were used for coupled gas chromatography-electroantennogram detection (GC-EAD) studies, and females were used for pheromone sampling (see below).

Collection of Pheromone from Live Females. Pheromone was collected from female CLM by placing groups of 1–30 virgin females in aeration chambers for 1–4 nights, collecting the emitted pheromone on solid phase microextraction (SPME) fibers. The aeration chambers were constructed from Swagelok[®] fittings (two 1/8 to 1/2 in. unions and one 1/2 to 1/2 in. union) connected to central 12-mm OD glass tubes (6.5 cm long). Activated-charcoal purified medical air was humidified by passage through a $\sim 5 \times 1$ cm ($L \times \text{diam.}$) wad of Soxhlet-extracted glass wool wetted with 1 ml of MilliQ[®] purified water, then it was passed through a 5×1 cm ($L \times \text{diam.}$) bed of 50–200 mesh activated charcoal, and finally into the aeration chamber through a steel frit, at a flow rate of ~ 8 –10 ml/min. An SPME fiber (100 μm polydimethylsiloxane coating, SPME portable field sampler; Supelco Inc., Bellefonte, PA, USA) was inserted into the 1-mm-diam. Teflon outlet tube at the downwind end of the chamber for collection of volatiles. Insects were added to the chamber prior to assembly, and were provided with sugar-water on a cellulose sponge cube during aerations. When there were >3 females, a 1×9 cm piece of clean, fine brass screening was provided as a perching substrate. Aerations were conducted in the laboratory with natural daylight, augmented with room fluorescent lighting during the day. Room temperatures varied from 20 to 25°C and were not precisely controlled.

Coupled Gas Chromatography-Electroantennography. Female-produced volatiles collected by SPME and synthetic standards were analyzed by GC-EAD on Hewlett-Packard 5890 series II gas chromatographs, with the first fitted with a DB-5 column (30 m \times 0.25 mm ID, 0.25 μm film, 100°C/1 min, 10°/min to 275°C for 15 min; J&W Scientific, Folsom, CA, USA) and the second with a DB-WAX column (30 m \times 0.25 mm ID, 0.25 μm film, 100°C/1 min, 10°/min to 240°). Loaded SPME fibers were desorbed in the injection port for 1 min prior to starting the GC. Helium was used as the carrier and makeup gas, and all injections were made splitless. The column effluent was split equally with a glass X-cross with one branch going to the flame ionization detector (FID), another to the EAG detector (EAD), and the final branch providing helium makeup gas (3 ml/min). The EAD branch passed through a heated conduit

(250°C) and into the side of a 15-mm ID glass tube swept with humidified medical air (770 ml/min), with the air flow directed over the antennal preparation. Signals were recorded on either matched HP 3394 integrators or with SRI model 202 PeakSimple chromatography data system running on a personal computer with PeakSimple v. 2.83 software (SRI Instruments, Torrance, CA, USA).

Males (1–2 d old) used in GC-EAD analyses were not chilled or anesthetized prior to use. Males were held with fine forceps, the head removed with a scalpel, and the antennal tips cut off. The head was mounted on the ground electrode and both cut antennal tips were placed in contact with the saline-filled glass recording electrode.

Field Trials. In all trials, moths were counted under a stereomicroscope to ensure correct identification (based on distinctive wing patterns) because of the insects' small size (less than 3 mm) and the large numbers trapped. Moths were readily identified from their distinctive wing patterns. Voucher specimens, UCRC 92975-92982 (pinned) and 92983 (specimens in alcohol), have been deposited in the UC Riverside Entomology Museum.

Lures consisted of 11-mm gray rubber septa (West Pharmaceutical Services Co., Lionville, PA, USA) individually labeled with a treatment number and loaded with heptane solutions (75 or 100 μ l) of test blends. Field trials were conducted in September 2004, in a heavily infested lemon orchard in Escondido, CA. Green Delta traps were used [Pherocon IIID traps (Trécé Inc., Salinas, CA, USA) or Intercept D traps (IPM Tech Inc., Portland, OR, USA)]. In the first two trials, testing blend ratio and total dose, respectively, five replicate blocks containing a complete set of treatments (including a solvent control) were spaced four to seven rows apart. Treatments were randomly placed within the rows, four trees in from the end and on every other tree within a row. Traps were positioned just inside the canopy, 1.5–2 m above ground. Counts were taken 1–2 d after initial setup, and then the traps were re-randomized, with a second count made 2 d later. Traps with more than 10 moths were changed by transferring the rubber septum to a new trap, and the moths in the old trap counted. In the first trial, testing blend ratios, trap catches from the two counts were summed prior to transformation ($\sqrt{x + 0.5}$), and then subjected to two-way analysis of variance using SigmaStat v. 1.0 (Jandel Scientific, San Rafael, CA, USA). Significantly different treatment means were distinguished using the Student–Neuman–Keuls test (SNK, $\alpha = 0.05$). In the second trial, testing dose response, data could not be normalized by transformation, and so the data were analyzed by Friedman's two-way nonparametric ANOVA on the untransformed data, followed by Bonferroni's tests for separation of means ($\alpha = 0.05$).

A final trial testing the effects of 7Z,11Z,13Z-16:Ald as a possible synergist or antagonist was carried out on June 7–8 2005, using a standard blend of

7Z,11Z,13E-16Ald and 7Z,11Z-16:Ald (100:33 μg) augmented with 0 to 100 μg 7Z,11Z,13Z-16:Ald. The experiment was set up in the same orchard as used previously. After $\log_{10}(x + 1)$ transformation to normalize the data, the transformed counts were analyzed by two-way ANOVA followed by SNK tests ($\alpha = 0.05$).

Synthesis of Pheromones and Related Compounds. Tetrahydrofuran (THF) was distilled from sodium/benzophenone under argon atmosphere. ^1H and ^{13}C NMR spectra were recorded with a Varian INOVA-400 (400 and 100 MHz, respectively) spectrometer, as CDCl_3 solutions. Chemical shifts are expressed in ppm relative to CDCl_3 (7.26 and 77.23 ppm for ^1H and ^{13}C NMR, respectively). Mass spectra were obtained with an HP 5890 GC equipped with a DB5-MS column (25 m \times 0.20 mm ID \times 0.33 μm film; J&W Scientific, Folsom, CA, USA), interfaced to an HP 5970 mass selective detector, in EI mode (70 eV) with helium carrier gas. Products were purified by flash or vacuum flash chromatography using silica gel (230–400 mesh; EM Science, Gibbstown, NJ, USA). Reactions with air- or water-sensitive reagents were carried out in dried glassware under argon atmosphere. Worked up reaction mixtures were dried over anhydrous Na_2SO_4 and concentrated by rotary evaporation under reduced pressure.

The syntheses of the 5,7,11-hexadecatrienal isomers (Schemes 1 and 2), and the previously known (7Z,11Z)-hexadecadienal (Scheme 5) are described in detail in the online supplement to this manuscript (Electronic Supplementary Material is available for this article at <http://dx.doi.org/10.1007/s10886-006-9359-6> and is accessible for authorized users).

Short, Nonstereospecific Preparation of 7,11,13-Hexadecatrienal Isomers. (Z)-11-Acetoxyundec-4-enal (**28**). (Scheme 3) A solution of KMnO_4 (1.70 g, 10.7 mmol) in water (12.7 ml) was added dropwise to a stirred solution of (7Z,11E/Z)-hexadecadienyl acetate **25** (3.00 g, 10.7 mmol; Shin-Etsu Chemical Co., Tokyo, Japan) in ethanol (35 ml) at 0°C over 2.5 hr, and the resulting mixture was stirred at ambient temperature for 2 hr. The mixture was then filtered through a pad of Celite and the filtrate was concentrated. The residue was taken up in Et_2O (100 ml), washed with brine, dried, and concentrated. The crude product was filtered through a plug of silica gel (hexane/EtOAc, 9:1) giving 0.71 g of diols **26** and **27**. The diols (0.61 g, 1.94 mmol) were added to a solution of NaIO_4 (1.45 g, 6.8 mmol) in a mixture of THF/acetone/water (8:4:13–20 ml) and stirred for 4 hr at 0°C , then diluted with ethyl acetate (50 ml), washed with water and brine, dried, and concentrated. Purification by vacuum flash chromatography (hexane/EtOAc, 95:5 as eluent) afforded 0.21 g of aldehyde **28** (10.1% yield over two steps). MS: 226 (M^+ , trace), 148 (6), 122 (14), 109 (3), 95 (11), 93 (14), 84 (19), 81 (27), 80 (17), 79 (19), 69 (13), 68 (28), 67 (51), 55 (35), 54 (20), 43 (100), 41 (56).

(7Z,11E/Z,13Z)-Hexadecatrienyl Acetate (**31**). LDA (1.5 M in cyclohexane, 0.44 ml, 0.66 mmol) was added dropwise to a suspension of (Z)-2-pentenyl

SCHEME 1. Synthesis of (5,7,11Z)-hexadecatrienals.

triphenylphosphonium bromide **30** (0.273 g, 0.66 mmol) in THF (2.0 ml) at -10°C . The mixture was stirred for 2 hr and then cooled to -20°C , and (Z)-11-acetoxyundec-4-enal **28** (0.100 g, 0.44 mmol) dissolved in THF (1.0 ml) was added dropwise. The resulting mixture was warmed to room temperature and stirred overnight, then quenched with water and poured into saturated aqueous

SCHEME 2. Synthesis of (5Z,7Z,11Z)-hexadecadienal **24**.

NH_4Cl solution. The organic layer was separated and the aqueous phase extracted with Et_2O ($3 \times 10 \text{ ml}$). The combined organic layers were washed with brine, dried, and concentrated. The residue was purified by flash chromatography (hexane/ethyl acetate, 95:5) affording (7Z,11E/Z,13Z)-hexadecatrienyl

SCHEME 3. Synthesis of (7Z,11,13)-hexadecatrienals.

acetate **31** (0.052 g) in 42.3% yield, in a 49:51 ratio of geometric isomers. MS: 7Z,11E,13Z (minor) isomer: 278 (M^+ , 10), 207 (1), 149 (3), 135 (8), 119 (5), 95 (100), 81 (16), 79 (23), 67 (48), 55 (21), 43 (51), 41 (30). MS: 7Z,11Z,13Z (major) isomer: 278 (M^+ , 8), 149 (2), 135 (7), 121 (7), 95 (100), 81 (17), 79 (24), 67 (58), 55 (24), 43 (54), 41 (31).

(7Z,11E/Z,13Z)-Hexadecatrien-1-ol (**32**). (7Z,11E/Z,13Z)-hexadecatrienyl acetate **31** (0.040 g, 0.14 mmol) was added to a solution of NaOH (6 M in water, 2 drops) in methanol (1.0 ml) and stirred for 4 hr at room temperature. After concentration, the residue was diluted with EtOAc, washed with water and brine, dried, and then concentrated. The residue was purified by flash chromatography (hexane/EtOAc, 5:1) affording (7Z,11E/Z,13Z)-hexadecatrien-1-ol **32** (0.030 g) in 88.2% yield. MS: 7Z,11E,13Z (minor) isomer: 236 (M^+ , 6), 163 (1), 149 (2), 135 (5), 121 (4), 95 (100), 81 (14), 79 (18), 67 (46), 55 (24), 41 (36). MS: 7Z,11Z,13Z (major) isomer: 236 (M^+ , 5), 149 (2), 135 (7), 121 (5), 95 (100), 81 (15), 79 (19), 67 (54), 55 (27), 41 (37).

(7Z,11E/Z,13Z)-Hexadecatrienal (**33**). (7Z,11E/Z,13Z)-Hexadecatrien-1-ol **32** (5.0 mg, 0.021 mmol) was oxidized with PCC and powdered 4 Å molecular sieve in CH_2Cl_2 as described above, yielding (7Z,11E/Z,13Z)-hexadecatrienal **33** in 56.6% yield (2.8 mg). MS: 7Z,11E,13Z (minor) isomer: 234 (M^+ , 3), 163 (1), 149 (2), 135 (5), 121 (2), 95 (100), 79 (16), 67 (50), 55 (25), 41 (36). MS: 7Z,11Z,13Z (major) isomer: 234 (M^+ , 3), 163 (1), 149 (1), 135 (3), 121 (1), 95 (100), 79 (13), 67 (44), 55 (21), 41 (34).

(7Z,11E/Z,13E)-Hexadecatrienyl acetate (**35**). In the same manner described for the preparation of (7Z,11E/Z,13Z)-hexadecatrienyl acetate **31**, the reaction of aldehyde **28** with the ylide from (*E*)-2-pentenyltriphenylphosphonium bromide **34** (0.273 g, 0.66 mmol) gave (7Z,11E/Z,13E)-hexadecatrienyl acetate **35** (0.071 g, 57.7% yield), in a 41:59 ratio of geometric isomers. MS: 7Z,11Z,13E (minor) isomer: 278 (M^+ , 7), 189 (1), 175 (1), 161 (2), 149 (2), 135 (5), 121 (4), 95 (100), 81 (13), 79 (22), 67 (47), 55 (23), 43 (47), 41 (29). MS: 7Z,11E,13E (major) isomer: 278 (M^+ , 7), 175 (1), 161 (1), 149 (1), 135 (4), 121 (3), 95 (100), 81 (10), 79 (13), 67 (40), 55 (18), 43 (40), 41 (23).

(7Z,11E/Z,13E)-Hexadecatrien-1-ol (**36**). (7Z,11E/Z,13E)-Hexadecatrienyl acetate **35** (0.060 g, 0.22 mmol) was hydrolyzed as described above for acetate **31**, giving (7Z,11E/Z,13E)-hexadecatrien-1-ol **36** (0.041 g, 80.6% yield). MS: 7Z,11Z,13E (minor) isomer: 236 (M^+ , 3), 207 (traces), 163 (1), 149 (2), 135 (4), 121 (3), 95 (100), 81 (10), 79 (16), 67 (45), 55 (24), 41 (34). MS: 7Z,11E,13E (major) isomer: 236 (M^+ , 4), 207 (traces), 149 (1), 135 (3), 121 (2), 95 (100), 81 (8), 79 (13), 67 (39), 55 (20), 41 (28).

(7Z,11E/Z,13E)-Hexadecatrienal (**37**). Alcohol **36** (5.0 mg, 0.021 mmol) was oxidized as described above for alcohol **32**, yielding (7Z,11E/Z,13E)-hexadecatrienal **37** (3.1 mg) in 62.7% yield. MS: 7Z,11Z,13E (minor) isomer: 234 (M^+ , 2), 149 (2), 135 (3), 121 (2), 95 (100), 79 (15), 67 (47), 55 (22), 41

 SCHEME 4. Synthesis of (7Z,11Z,13E)-hexadecatrienal **49**.

(32). MS: 7Z,11E,13E (major) isomer: 234 (M^+ , 3), 216 (traces), 149 (1), 135 (2), 121 (2), 95 (100), 79 (11), 67 (37), 55 (19), 41 (27).

Preparation of (7Z,11Z,13E)-Hexadecatrienal (**49**). 1-(*t*-Butyldimethylsilyloxy)-3-bromopropane (**39**). (Scheme 4) 4-(Dimethylamino)pyridine (70 mg, 0.57 mmol) and triethylamine (6.42 g, 63.4 mmol) were added dropwise to a -10°C , stirred mixture of 3-bromo-1-propanol **38** (8.00 g, 57.6 mmol) and *t*-butyl-dimethylsilyl chloride (9.11 g, 60.4 mmol) in CH_2Cl_2 (65 ml). After 1 hr, the mixture was warmed to room temperature and stirred for 16 hr. Water (50 ml) was added, and the mixture then was extracted three times with Et_2O (1 \times 80, 2 \times 50 ml). The combined organic phases were washed with 10%

 SCHEME 5. Synthesis of (7Z,11Z)-hexadecadienal **56**.

aqueous HCl (3 × 30 ml), saturated NaHCO₃ solution (2 × 50 ml), and brine, then dried and concentrated. The residue was Kugelrohr distilled (oven temp. 68–72°C, 10 mmHg) giving 13.66 g (93.7% yield) of bromide **39**. ¹H NMR: δ 0.07 (s, 6H), 0.90 (s, 9H), 1.93–2.00 (m, 2H), 3.51 (t, 2H, *J* = 6.4 Hz), 3.73 (t, 2H, *J* = 5.8 Hz). ¹³C NMR: δ -5.17, 18.51, 26.12, 30.89, 35.77, 60.64 ppm. MS: *m/z* 197 (M⁺ - 57, 48), 195 (45), 169 (61), 167 (60), 155 (5), 153 (6), 139 (100), 137 (97), 115 (65), 99 (7), 85 (8), 75 (23), 73 (28), 59 (27), 58 (16), 57 (24), 47 (19), 45 (31), 43 (20), 41 (43). The NMR spectrum matched literature values (Kerr et al., 1990).

1-(Tetrahydropyranyloxy)-oct-7-yne (41). Dihydropyran (16.00 g, 190.2 mmol) was added dropwise to a solution of 7-octyn-1-ol **40** (16.00 g, 126.8 mmol; prepared from 2-octyn-1-ol by the acetylene zipper reaction; Abrams and Shaw, 1988) and a few crystals of PTSA in CH₂Cl₂ (30 ml) at 0°C under argon. The reaction was allowed to warm to room temperature and stirred overnight. Most of the solvent was removed by rotary evaporation, the residue was diluted with hexane (150 ml), washed with saturated NaHCO₃ solution (2 × 50 ml) and brine, dried, and concentrated. The resulting oil was purified by vacuum flash chromatography (hexane, then hexane/ethyl acetate, 95:5) followed by Kugelrohr distillation (bp ~94–96°C, 1.0 mmHg) yielding 25.48 g (95.6%) of pure product. ¹H NMR: δ 1.32–1.48 (m, 4H), 1.48–1.65 (m, 8H), 1.67–1.75 (m, 1H), 1.78–1.88 (m, 1H), 1.93 (t, 1H, *J* = 2.7 Hz), 2.18 (td, 2H, *J* = 2.7 and 6.8 Hz), 3.38 (dt, 1H, *J* = 9.8 and 6.4 Hz), 3.46–3.53 (m, 1H), 3.73 (dt, 1H, *J* = 9.8 and 6.8 Hz), 3.83–3.90 (m, 1H), 4.57 (dd, 1H, *J* = 4.4 and 2.7 Hz). ¹³C NMR: δ 18.57, 19.92, 25.70, 25.99, 28.65, 28.79, 29.83, 31.00, 62.58, 67.75, 68.33, 84.90, 99.09 ppm. MS: *m/z* 209 (M⁺ - 1, 1), 125 (1), 109 (3), 101 (29), 85 (100), 67 (40), 55 (23), 43 (21), 41 (51).

1-(t-Butyldimethylsilyloxy)-11-(tetrahydropyranyloxy)-undec-4-yne (42). *n*-BuLi (1.6M in hexanes, 12.2 ml, 19.5 mmol) was added dropwise to a stirred solution of 1-(tetrahydropyranyloxy)-oct-7-yne **41** (3.90 g, 18.5 mmol) in dry THF (20 ml) at -40°C. The mixture was allowed to warm to -10°C and stirred for 4 hr. 1,3-Dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidinone (DMPU, 9.0 ml, 74.2 mmol) was added over 10 min, the resulting mixture was stirred for 1 hr, and then cooled to -40°C. A solution of 1-(*t*-butyldimethylsilyloxy)-3-bromopropane **39** (4.70 g, 18.5 mmol) in dry THF (10 ml) was added dropwise, and the mixture was allowed to warm to room temperature over ~4 hr and then stirred overnight. The reaction was quenched with saturated NH₄Cl solution (20 ml) and extracted with ethyl acetate (4 × 20 ml). The combined organic phases were washed with saturated NaHCO₃ solution and brine, dried, and concentrated. The residue was purified by vacuum flash chromatography (hexane/ethyl acetate, 95:5) affording 6.83 g of product contaminated with unreacted 1-(*t*-butyldimethylsilyloxy)-3-bromopropane **39**. This impure material was used directly in the next step. ¹H NMR: δ 0.05 (s, 6H), 0.89 (s, 9H), 1.33–

1.88 (m, 16H), 2.18 (tt, 2H, $J = 7.0$ and 2.3 Hz), 2.26 (tt, 2H, $J = 7.0$ and 2.3 Hz), 3.38 (dt, 1H, $J = 9.6$ and 6.6 Hz), 3.47–2.53 (m, 1H), 3.68 (t, 2H, $J = 6.0$ Hz), 3.73 (dt, 1H, $J = 9.6$ and 6.8 Hz), 3.77–3.87 (m, 1H), 4.57 (dd, 1H, $J = 4.3$ and 2.7 Hz). ^{13}C NMR: δ -5.12, 15.36, 18.57, 18.91, 19.90, 25.72, 26.04, 26.16, 28.93, 29.29, 29.88, 30.99, 32.36, 61.98, 62.54, 67.80, 79.90, 80.51, 99.06 ppm. MS: m/z 325 ($\text{M}^+ - 57$, 2), 241 (5), 165 (3), 159 (12), 93 (9), 85 (100), 81 (12), 79 (10), 75 (29), 73 (13), 67 (19), 57 (10), 55 (13), 43 (12), 41 (22).

11-(Tetrahydropyranyloxy)undec-4-yn-1-ol (43). A solution of tetrabutylammonium fluoride (1.0 M in THF, 21.4 ml, 21.4 mmol) was added to a solution of 1-(*t*-butyldimethylsilyloxy)-11-(tetrahydropyranyloxy)undec-4-yne **42** (6.82 g) in dry THF (35 ml), at room temperature. The mixture was stirred until the starting material had been consumed (1.5 hr), then diluted with Et_2O (50 ml) and washed with water. The organic phase was separated, and the aqueous layer was extracted with Et_2O (2×20 ml). The combined organic phases were washed with brine, dried, and concentrated. The residue was purified by vacuum flash chromatography (hexane/ EtOAc , 4:1) to yield 3.49 g of **43** (70.1% over two steps). ^1H NMR: δ 1.31–1.64 (m, 10H), 1.66–1.88 (m, 4H), 1.73 (quint, 2H, $J = 6.3$ Hz), 2.13 (tt, 2H, $J = 6.8$ and 2.5 Hz), 2.27 (tt, 2H, $J = 6.8$ and 2.5 Hz), 3.38 (dt, 1H, $J = 9.6$ and 6.6 Hz), 3.46–3.54 (m, 1H), 3.73 (dt, 1H, $J = 9.6$ and 6.8 Hz), 3.74 (t, 2H, $J = 6.0$ Hz), 3.82–3.90 (m, 1H), 4.57 (dd, 1H, $J = 4.5$ and 2.5 Hz). ^{13}C NMR: δ 15.64, 18.88, 19.88, 25.71, 25.95, 28.84, 29.15, 29.82, 30.98, 31.80, 62.24, 62.56, 67.76, 79.61, 81.22, 99.08 ppm. MS: m/z 268 (M^+ , trace), 195 (3), 183 (3), 167 (3), 125 (2), 111 (3), 101 (18), 85 (100), 81 (13), 79 (15), 67 (21), 57 (14), 55 (26), 43 (19), 41 (44). Anal. calculated for $\text{C}_{16}\text{H}_{28}\text{O}_3$: C, 71.60; H, 10.52. Found: C, 71.85; H, 10.59. The ^1H NMR spectrum was in agreement with that reported in the literature (Yadav et al. 1988).

(Z)-11-(Tetrahydropyranyloxy)undec-4-en-1-ol (44). Alkynol **43** (3.40 g, 12.67 mmol) was reduced to the corresponding alkenol with hydrogen and P2-nickel catalyst as described above. The crude product was purified by vacuum flash chromatography (hexane/ethyl acetate, 9:1), yielding 3.14 g of **44** (91.8% yield). ^1H NMR: δ 1.24–1.42 (m, 6H), 1.44–1.64 (m, 8H), 1.64–1.73 (m, 1H), 1.73–1.85 (m, 1H), 1.96–2.07 (m, 2H), 2.07–2.14 (m, 2H), 3.36 (dt, 1H, $J = 9.6$ and 6.6 Hz), 3.44–3.51 (m, 1H), 3.62 (dt, 2H, $J = 5.3$ and 6.4 Hz), 3.70 (dt, 1H, $J = 9.6$ and 6.8 Hz), 3.81–3.88 (m, 1H), 4.55 (dd, 1H, $J = 4.3$ and 2.7 Hz), 5.30–5.41 (m, 2H). ^{13}C NMR: δ 19.89, 23.81, 25.70, 26.31, 27.30, 29.28, 29.79, 29.90, 30.97, 32.86, 62.57, 62.76, 67.87, 99.06, 129.18, 130.85 ppm. MS: m/z 270 (M^+ , trace), 186 (1), 168 (1), 150 (1), 109 (3), 101 (4), 95 (7), 85 (100), 81 (11), 67 (19), 57 (10), 55 (17), 43 (12), 41 (28). The ^1H NMR spectrum was in agreement with that reported in the literature (Sharma et al. 1994).

(4Z)-1-Iodo-11-(tetrahydropyranyloxy)undec-4-ene (45). Iodine (2.91 g, 11.46 mmol) was added in small portions to a -40°C solution of Ph_3P (3.00 g,

11.46 mmol), imidazole (1.56 g, 22.92 mmol), and (*Z*)-11-(tetrahydropyranyloxy)undec-4-en-1-ol **44** (3.10 g, 11.46 mmol) in dry THF (18 ml). The resulting mixture was warmed to 0°C and stirred for 3 hr. The mixture was diluted with Et₂O (100 ml), washed successively with saturated sodium thiosulfate (100 ml), water (2 × 50 ml), and brine, then dried and concentrated. The residue was suspended in hexane to precipitate most of the Ph₃PO and filtered. After concentration, the crude product was purified by vacuum flash chromatography (hexane/ethyl acetate, 9:1) yielding 2.15 g of **45** (57.6% yield) as colorless oil and 0.201 g of unreacted starting material. ¹H NMR: δ 1.22–1.42 (m, 6H), 1.45–1.64 (m, 6H), 1.64–1.75 (m, 1H), 1.77–1.87 (m, 1H), 1.87 (quint, 2H, *J* = 7.0 Hz), 2.05 (q, 2H, *J* = 6.6 Hz), 2.13 (q, 2H, *J* = 7.2 Hz), 3.18 (t, 2H, *J* = 6.8 Hz), 3.37 (dt, 1H, *J* = 9.6 and 6.6 Hz), 3.46–3.52 (m, 1H), 3.72 (dt, 1H, *J* = 9.6 and 6.8 Hz), 3.82–3.90 (m, 1H), 4.57 (dd, 1H, *J* = 4.3 and 2.7 Hz), 5.28 (dtt, 1H, *J* = 10.7, 7.2 and 1.4 Hz), 5.42 (dtt, 1H, *J* = 10.7, 7.4 and 1.4 Hz). ¹³C NMR: δ 6.87, 19.93, 25.73, 26.37, 27.56, 28.14, 29.35, 29.88, 29.95, 31.02, 33.64, 62.57, 67.86, 99.07, 127.51, 131.92 ppm. MS: *m/z* 183 (1), 155 (4), 109 (4), 101 (4), 95 (10), 85 (100), 81 (13), 69 (8), 67 (17), 55 (18), 43 (9), 41 (27). Anal. calculated for C₁₆H₂₉O₂: C, 50.53; H, 7.69. Found: C, 50.64; H, 7.73.

(*Z*)-11-(Tetrahydropyranyloxy)undec-4-enyl triphenylphosphonium iodide (**46**). A solution of Ph₃P (1.66 g; 6.31 mmol) and (*Z*)-1-iodo-11-(tetrahydropyranyloxy)undec-4-ene **45** (2.40 g; 6.31 mmol) in toluene (7.0 ml) was refluxed for 2 d (GC analysis showed no remaining iodide), then poured with vigorous stirring into 50 ml hexane, to produce a viscous oil. The mixture was stirred for 1 hr, the solvent was replaced with fresh hexane (50 ml), and then stirred for an additional 1 hr. The solvent was removed and the remaining phosphonium salt **46** was pumped under high vacuum for 8 hr, then used without further purification.

(7*Z*,11*Z*,13*E*)-1-(Tetrahydropyranyloxy)-hexadecatriene (**47**). Lithium hexamethyldisilazide (LiHMDS, 1.0 M in THF, 4.50 ml, 4.5 mmol) was added to a solution of dry DMPU (2.56 g, 20.0 mmol) in THF (12 ml) at 0°C. The resulting mixture was stirred for 30 min, then cooled to -78°C. A solution of (*Z*)-11-(tetrahydropyranyloxy)undec-4-enyl triphenylphosphonium iodide **46** (3.21 g, 5.00 mmol) in THF (18.0 ml) was added dropwise. After stirring for 1 hr, (*E*)-2-pentenal (0.560 g, 6.50 mmol) in THF (2 ml) was added dropwise. The resulting mixture was stirred for 2 hr at -78°C, then warmed to room temperature and stirred an additional 2 hr. The mixture was diluted with hexane/Et₂O (3:1–50 ml) and washed with saturated NH₄Cl solution and brine, dried, and concentrated. Purification by vacuum flash chromatography (hexane/EtOAc, 95:5) afforded a 93:7 mixture of the (7*Z*,11*Z*,13*E*)- and (7*Z*,11*E*,13*E*)-trienes, respectively (0.664 g, 41.5% yield). (7*Z*,11*Z*,13*E*)-isomer: ¹H NMR: δ 1.01 (t, 3H, *J* = 7.6 Hz), 1.22–1.40 (m, 6H), 1.46–1.64 (m, 6H), 1.66–1.80 (m, 2H), 1.96–2.06 (m, 2H), 2.06–2.16 (m, 4H), 2.16–2.26 (m, 2H), 3.37 (dt, 1H, *J* = 9.6 and 6.6 Hz), 3.45–3.55 (m, 1H), 3.72 (dt, 1H, *J* = 9.6 and 6.8 Hz), 3.84–

3.90 (m, 1H), 4.56 (dd, 1H, $J = 4.3$ and 2.7 Hz), 5.30 (dt, 1H, $J = 10.7$ and 7.4 Hz), 5.32–5.42 (m, 2H), 5.70 (dt, 1H, $J = 15.2$ and 6.6 Hz), 5.95 (t, 1H, $J = 10.9$ Hz), 6.25–6.33 (m, 1H). ^{13}C NMR: δ 13.85, 19.92, 25.73, 26.11, 26.38, 27.45, 27.58, 28.07, 29.37, 29.88, 29.95, 31.01, 62.56, 67.87, 99.06, 124.85, 129.18, 129.21, 129.51, 130.69, 136.64 ppm. MS: m/z 320 (M^+ , 2), 302 (trace), 236 (1), 235 (1), 175 (1), 161 (1), 135 (2), 122 (3), 95 (35), 85 (100), 79 (15), 67 (29), 55 (20), 43 (11), 41 (30).

(7Z,11Z,13E)-Hexadecatrien-1-ol (**48**). The THP protecting group was removed from (7Z,11Z,13E)-1-(tetrahydropyranyloxy)-hexadecatriene **47** (0.650 g, 2.02 mmol) with PTSA in methanol, as described above. The crude product was purified by vacuum flash chromatography (hexane/ethyl acetate 5:1) followed by Kugelrohr distillation (oven temp. $\sim 112^\circ\text{C}$, 0.03 mmHg), yielding (7Z,11Z,13E)-hexadecatrien-1-ol (0.338 g, 70.8% yield). The isomeric purity of the product was increased to 97% by recrystallization from hexane at -20°C . ^1H NMR: δ 1.01 (t, 3H, $J = 7.4$ Hz), 1.26–1.42 (m, 6H), 1.52–1.60 (m, 2H), 1.98–2.06 (m, 2H), 2.06–2.16 (m, 4H), 2.18–2.26 (m, 2H), 3.63 (t, 2H, $J = 6.7$ Hz), 5.30 (dt, 1H, $J = 10.9$ and 7.4 Hz), 5.35–5.42 (m, 2H), 5.70 (dt, 1H, $J = 15.2$ and 6.6 Hz), 5.96 (t, 1H, $J = 10.9$ Hz), 6.29 (ddq, 1H, $J = 15.2$, 10.9 and 1.6 Hz). ^{13}C NMR: δ 13.84, 25.86, 26.11, 27.41, 27.58, 28.06, 29.28, 29.87, 32.97, 63.25, 124.84, 129.18, 129.28, 129.49, 130.61, 136.67 ppm. MS: m/z 236 (M^+ , 3), 163 (1), 149 (2), 135 (4), 121 (3), 107 (3), 96 (10), 95 (100), 93 (12), 81 (10), 79 (18), 67 (48), 55 (24), 53 (9), 41 (37). Anal. calculated for $\text{C}_{16}\text{H}_{28}\text{O}$: C, 81.29; H, 11.94. Found: C, 80.11; H, 12.06.

(7Z,11Z,13E)-Hexadecatrienal (**49**). (7Z,11Z,13E)-Hexadecatrien-1-ol **48** (18.0 mg, 0.076 mmol) was oxidized to the aldehyde with PCC and powdered 4 Å molecular sieve in CH_2Cl_2 as described above, and the crude product was flash chromatographed (pentane/ Et_2O 9:1) yielding (7Z,11Z,13E)-hexadecatrienal **49** in 77.4% yield (13.8 mg). ^1H NMR: δ 1.01 (t, 3H, $J = 7.4$ Hz), 1.34–1.42 (m, 4H), 1.63 (quint, 2H, $J = 7.4$ Hz), 2.00–2.06 (m, 2H), 2.06–2.17 (m, 4H), 2.18–2.26 (m, 2H), 2.42 (td, 2H, $J = 1.8$ and 7.4 Hz), 5.30 (dt, 1H, $J = 10.8$ and 7.4 Hz), 5.34–5.42 (m, 2H), 5.71 (dt, 1H, $J = 15.2$ and 6.6 Hz), 5.96 (t, 1H, $J = 10.9$ Hz), 6.29 (ddq, 1H, $J = 15.2$, 10.9 and 1.6 Hz), 9.76 (t, 1H, $J = 1.8$ Hz). ^{13}C NMR: δ 13.84, 22.21, 26.11, 27.25, 27.59, 28.02, 29.00, 29.62, 44.10, 124.82, 129.23, 129.42, 129.53, 130.27, 136.71, 203.04 ppm. MS: m/z 234 (M^+ , 2), 216 (trace), 187 (1), 173 (1), 149 (2), 135 (3), 121 (2), 107 (2), 95 (100), 93 (11), 79 (14), 67 (45), 55 (22), 41 (32).

Preparation of (7Z,11Z,13Z)-hexadecatrienal (**62**)(Scheme 6). 2-Pentynal (**58**). 2-Pentyn-1-ol **57** was oxidized with PCC, as described above. The crude product was flash chromatographed (pentane/ Et_2O , 9:1), and the solvent was distilled off using a Vigreux column, giving 2-pentynal **58** (0.832g) in a ca. 15% mixture with solvent. MS: m/z 82 (M^+ , 34), 81 ($\text{M}^+ - 1$, 57), 67 (1), 66 (7), 54 (57), 53 (100), 52 (12), 51 (32), 50 (40), 49 (17).

SCHEME 6. Synthesis of (7Z,11Z,13Z)-hexadecatrienal **62**.

(*Z*)-1-(Tetrahydropyranyloxy)-hexadec-7,13-diyne-11-ene (**59**). The title compound was prepared by a *Z*-selective Wittig between the anion of 11-(tetrahydropyranyloxy)-undec-4-ynyl triphenylphosphonium iodide **52** and 2-pentynal **58** in THF/DMPU as described above. After workup, purification by vacuum flash chromatography (hexane/EtOAc, 95:5) gave endiyne **59** in 57.7% yield. ^1H NMR: δ 1.161 (t, 3H, $J = 7.6$ Hz), 1.26–1.59 (m, 12H), 1.61–1.69 (m, 1H), 1.72–1.82 (m, 1H), 2.08–2.17 (m, 2H), 2.17–2.26 (m, 2H), 2.33 (dq, 2H, $J = 7.6$ and 2.2 Hz), 2.45 (q, 2H, $J = 7.2$ Hz), 3.32 (dt, 1H, $J = 9.6$ and 6.4 Hz), 3.40–3.47 (m, 1H), 3.67 (dt, 1H, $J = 9.6$ and 6.8 Hz), 3.76–3.84 (m, 1H), 4.51–4.59 (m, 1H), 5.37–5.48 (m, 1H), 5.83 (dt, 1H, $J = 10.8$ and 7.2 Hz). ^{13}C NMR: δ 13.43, 14.26, 18.64, 18.92, 19.90, 25.72, 26.03, 28.90, 29.24, 29.87, 29.88, 31.00, 62.54, 67.80, 76.62, 79.55, 80.90, 96.50, 99.07, 110.54, 140.69. MS: m/z 287 (1), 231 (1), 215 (2), 201 (1), 185 (3), 171 (3), 157 (9), 145 (13), 143 (16), 131 (13), 129 (21), 117 (16), 91 (39), 85 (100), 77 (40), 67 (22), 57 (19), 55 (21), 43 (18), 41 (47).

(*Z*,11*Z*,13*Z*)-1-(Tetrahydropyranyloxy)-hexadecatriene (**60**). A solution of cyclohexene (0.549 g, 6.68 mmol) in dry THF (2.0 ml) was added dropwise under argon to a solution of $\text{BH}_3\cdot\text{DMDS}$ (solution 2.0 M in THF, 1.67 ml, 3.34 mmol) in dry THF (5.0 ml) at -10°C . The resulting mixture was stirred for 3 hr between -10 and 0°C , then allowed to warm to room temperature and stirred for 1 hr. The resulting white slurry of dicyclohexylborane was recooled to -20°C and a solution of (*Z*)-1-(tetrahydropyranyloxy)-hexadec-7,13-diyne-11-ene **59** (0.264 g, 0.834 mmol) in dry THF (2.0 ml) was added dropwise over

20 min. The resulting mixture was slowly warmed to 0°C (ca. 2.5 hr) and then stirred for 4 hr. Glacial acetic acid (0.84 ml) was added dropwise, and the mixture was warmed to room temperature and stirred overnight. The solution was cooled to 0°C and treated with aqueous NaOH (20% by wt., 6.0 ml) followed by dropwise addition of hydrogen peroxide (30% by wt., 0.40 ml), keeping the temperature below 15°C. The mixture was warmed to room temperature and stirred for 1 hr, diluted with water (10 ml), and extracted with hexane (4 × 15 ml). The combined organic layers were washed with brine, dried, concentrated, and purified by vacuum flash chromatography on silica gel (hexane/EtOAc, 95:5) giving (7Z,11Z,13Z)-1-(tetrahydropyranyloxy)-hexadecatriene **60** (0.213 g) in 79.8% yield as a 92:8 mixture of the (7Z,11Z,13Z)- and (7Z,11E,13Z)-trienes, respectively. ¹H NMR: δ 0.98 (t, 3H, *J* = 7.6 Hz), 1.26–1.43 (m, 6H), 1.46–1.65 (m, 6H), 1.66–1.74 (m, 1H), 1.76–1.80 (m, 1H), 1.96–2.06 (m, 2H), 2.06–2.26 (m, 6H), 3.36 (dt, 1H, *J* = 9.6 and 6.6 Hz), 3.44–3.52 (m, 1H), 3.71 (dt, 1H, *J* = 9.6 and 6.8 Hz), 3.81–3.89 (m, 1H), 4.53–4.58 (m, 1H), 5.20–5.30 (m, 2H), 5.30–5.39 (m, 2H), 6.06–6.20 (m, 2H). ¹³C NMR: δ 14.40, 19.91, 21.01, 25.73, 26.37, 27.43, 27.47, 27.83, 29.34, 29.86, 29.94, 31.00, 62.54, 67.85, 99.05, 123.17, 124.03, 129.13, 130.71, 131.47, 134.09 ppm. MS: *m/z* 320 (M⁺, 2), 236 (1), 235 (1), 175 (1), 161 (1), 135 (2), 121 (3), 95 (38), 85 (100), 79 (12), 67 (33), 55 (20), 43 (11), 41 (32).

(7Z,11Z,13Z)-Hexadecatrien-1-ol (**61**). The THP protecting group was removed from (7Z,11Z,13Z)-1-(tetrahydropyranyloxy)-hexadecatriene **60** (0.163 g, 0.51 mmol) with PTSA in methanol as described above. The crude product was purified by vacuum flash chromatography (hexane/ethyl acetate, 9:1), yielding (7Z,11Z,13Z)-hexadecatrien-1-ol (0.096 g, 79.9% yield). The isomeric purity of the product was increased to 95% by chromatography over silica gel with 10% AgNO₃ (hexane/Et₂O, 9:1). ¹H NMR: δ 0.99 (t, 3H, *J* = 7.6 Hz), 1.28–1.42 (m, 6H), 1.50–1.62 (m, 2H), 1.98–2.06 (m, 2H), 2.07–2.26 (m, 6H), 3.62 (t, 2H, *J* = 6.6 Hz), 5.32–5.40 (m, 2H), 5.40–5.48 (m, 2H), 6.16–6.30 (m, 2H). ¹³C NMR: δ 14.40, 21.02, 25.85, 27.39, 27.47, 27.83, 29.26, 29.85, 32.98, 63.26, 123.16, 124.03, 129.21, 130.64, 131.47, 134.14 ppm. MS: *m/z* 236 (M⁺, 7), 207 (1), 163 (1), 149 (3), 135 (8), 121 (5), 107 (5), 96 (11), 95 (100), 93 (17), 81 (19), 79 (23), 67 (65), 55 (31), 53 (13), 41 (46).

(7Z,11Z,13Z)-Hexadecatrienal (**62**). (7Z,11Z,13Z)-Hexadecatrien-1-ol **61** (13.0 mg, 0.055 mmol) was oxidized to the aldehyde with PCC and powdered 4 Å molecular sieve in CH₂Cl₂ as described above, and the crude product was flash chromatographed (pentane/Et₂O, 9:1) affording (7Z,11Z,13Z)-hexadecatrienal **62** in 71.5% yield (9.2 mg). ¹H NMR: δ 0.99 (t, 3H, *J* = 7.6 Hz), 1.28–1.42 (m, 4H), 1.63 (quint, 2H, *J* = 7.4 Hz), 1.99–2.06 (m, 2H), 2.06–2.26 (m, 6H), 2.41 (td, 2H, *J* = 2.0 and 7.4 Hz), 5.34–5.39 (m, 2H), 5.39–5.49 (m, 2H), 6.16–6.30 (m, 2H), 9.76 (t, 1H, *J* = 2.0 Hz). ¹³C NMR: δ 14.40, 21.02, 22.20, 27.23, 27.48, 27.79, 28.99, 29.61, 44.09, 123.13, 124.08, 129.46, 130.30,

131.39, 134.19, 203.01. MS: m/z 234 (M^+ , 6), 219 (trace), 187 (1), 173 (1), 149 (2), 135 (6), 121 (3), 107 (3), 95 (100), 93 (15), 79 (20), 67 (59), 55 (28), 41 (43).

RESULTS

The amounts of the pheromone components collected by SPME from overnight aerations of 1–30 female moths were usually below the detection limit of GC and GC-MS. Therefore, identification of the active compounds was primarily guided by a combination of GC-EAD, using the retention behavior of the compounds on GC columns of different polarity, and the relative responses of male moth antennae to various standards with different functional groups. Male moth antennae responded consistently to two compounds in the effluvia from females. Sporadically, there was a third, much smaller response visible when extracts were analyzed on the DB-5 column (Figure 1, Table 1). The earliest response on both columns (for DB-5, Figure 1, peak 1) matched the retention time of synthetic 7Z,11Z-16:Ald, the previously reported sex attractant

FIG. 1. Coupled gas chromatography-electroantennogram detection traces showing responses from the GC and a male moth antenna to volatiles collected from two citrus leafminer females over 2 nights on a SPME fiber. GC responses with letters were also present in blank runs. Peak 1: (7Z,11Z)-hexadecadienal; peak 2: (7Z,11Z,13E)-hexadecatrienal; peak 3: tentatively identified as (7Z,11Z,13Z)-hexadecatrienal. Column: DB-5 (30 m \times 0.25 mm ID, 0.25 μ m film), 100°C/1 min, 10°C/min to 275°C.

TABLE 1. COMPARISON OF RETENTION INDICES ON DB-5 AND DB-WAX GC COLUMNS OF INSECT-PRODUCED COMPOUNDS ELICITING ANTENNAL RESPONSES IN GC-EAD EXPERIMENTS, AND OF SYNTHETIC STANDARDS

Compound	Retention indices	
	DB-5 ^a	DB-WAX ^a
<i>Insect-produced compounds</i>		
Leafminer first response	17.96	22.19
Leafminer second response	18.43	23.71
Leafminer third response	18.58	— ^b
<i>Synthetic standards</i>		
Z11-16:Ald	18.10	21.86
Z11,E13-16:Ald	18.56	23.35

7Z,11E,13E-16:Ald	18.56	23.97
7Z,11E,13Z-16:Ald	18.44	23.75

Matches are shown in boldface type.

^aGC conditions: DB-5 (30 m × 0.25 mm ID, 0.25 μm film, 100°C/1 min, 10°C/min–275°C/15 min); DB-WAX (30 m × 0.25 mm ID, 0.25 μm film, 100°C/1 min, 10°C/min–240°C/10 min). Because the final temperature was reached before the tetracosane standard eluted on DB-WAX, the retention indices on this column may differ slightly from true Kovat's indices.

^bThird response not seen on this column.

for this species (Ando et al., 1985). Furthermore, when challenged with synthetic standards of 7Z,11Z-16:Ald, male moth antennal responses were consistently stronger to the aldehyde than to the corresponding acetate or alcohol.

The second compound, which consistently elicited the largest antennal responses, eluted about 50 and 150 retention units later than 7Z,11Z-16:Ald from the DB-5 and DB-WAX columns, respectively (Table 1). Both retention time and antennal response data ruled out the possibility of the unknown being 7Z,11Z-16:OH or 7Z,11Z-16:Ac. Retention times on both the nonpolar and polar columns were markedly longer than those of 7Z,11Z-16:Ald, suggesting the presence of a conjugated diene or triene in the unknown. The presence of a conjugated triene (e.g., a 7,9,11-16:Ald) was ruled out by examination of retention time differences of standards available from other projects (10E,12E,14E-16:Ald, Chen and Millar, 2000; 9E,11Z,13Z-16:Ald, Millar

et al., 1996). On the DB-5 column, these standards eluted >100 retention units later than the unknown, whereas the difference was even greater on the DB-WAX column (208 and 179 retention units, respectively). Therefore, the most likely candidates for the unknown were the 5*E*/*Z*,7*Z*,11*Z*- or 7*Z*,11*Z*,13*E*/*Z*-16:Ald isomers. These isomers were synthesized, and only 7*Z*,11*Z*,13*E*-16:Ald matched the retention times of the unknown on both columns.

The identifications of both 7*Z*,11*Z*-16:Ald and 7*Z*,11*Z*,13*E*-16:Ald were subsequently confirmed from full-scan mass spectra of both compounds (Figure 2)

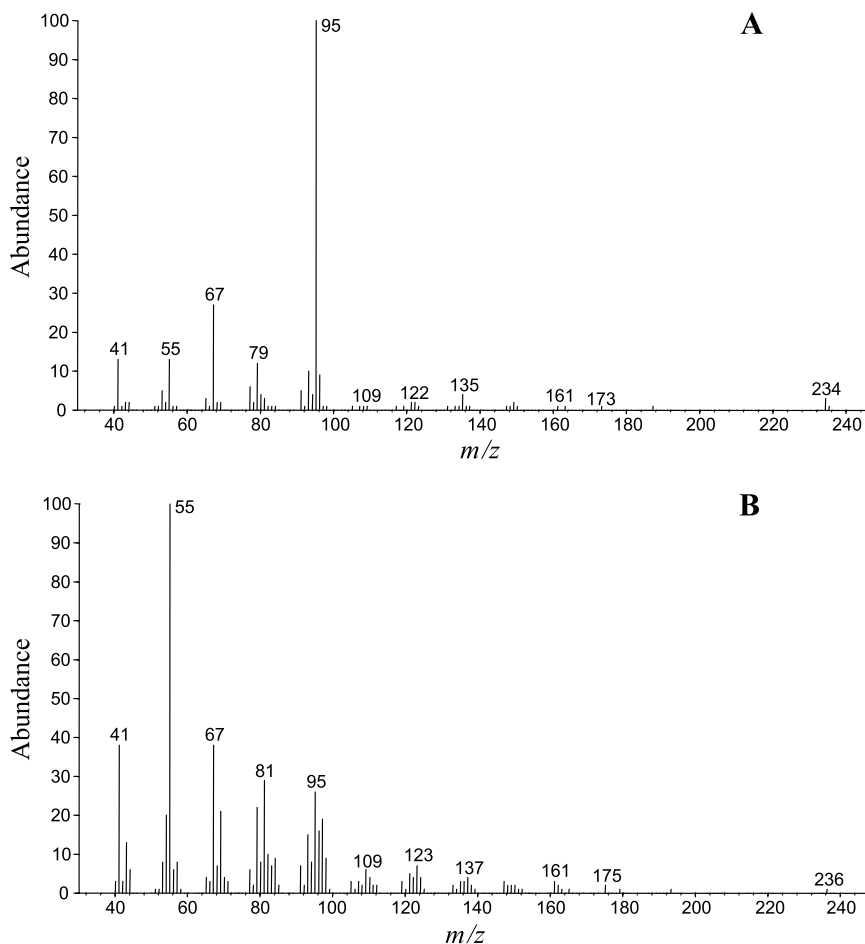

FIG. 2. EI mass spectra of (A) (7*Z*,11*Z*,13*E*)-hexadecatrienal and (B) (7*Z*,11*Z*)-hexadecadienal.

obtained from an SPME sample collected from two females aerated over five consecutive nights. In particular, the spectrum of 7Z,11Z,13E-16:Ald exhibits a diagnostic base peak at m/z 95, corresponding to a $C_7H_{11}^+$ ion arising from cleavage between allylic carbons 9 and 10, with the charge stabilized by the conjugated diene system. An analogous cleavage has been reported for 4,6,10-16:Ac isomers, which have a similar arrangement of double bonds (Beevor et al., 1986).

The third EAD response matched the retention time of 7Z,11Z,13Z-16:Ald on the DB-5 column. However, it was not seen on the DB-WAX column, nor was it possible to obtain a mass spectrum, and so the identity of this compound could not be confirmed.

Synthesis of the Pheromone Components and Analogs. The GC-EAD data indicated that the pheromone extracts contained 7Z,11Z-16:Ald, and we reasoned that the putative trienal, with a conjugated diene present, must either be a 5,7,11- or a 7,11,13-hexadecatrienal. Thus, we initially focused on short, nonstereoselective syntheses that would provide mixtures of isomers for comparisons of retention times with those of the insect-produced compound. These compounds enabled us to eliminate the 5,7,11-isomers, and confirmed that one of the 7,11,13-isomers matched the insect produced triene, so stereoselective syntheses were developed.

The syntheses of both pairs of (5E/Z,7E,11Z)-hexadecatrienals **11** and (5E/Z,7Z,11Z)-hexadecatrienals **16** started with the preparation of the key intermediate **4** (Scheme 1). Thus, (Z)-3-octen-1-ol **1** was transformed into its corresponding tosylate **2** (83% yield), which was then coupled with the terminal alkyne **3** followed by deprotection to give alcohol **4** in 31% yield in two steps. Enyne alcohol **4** was reduced to the corresponding (E)- and (Z)-allylic alcohols **7** and **12** by reaction with lithium aluminum hydride or P-2 Ni and H_2 , respectively. The alcohols were treated with PBr_3 to give bromides **8** and **13**. To introduce the third double bond into the alkyl chain, the bromides **8** and **13** were converted into the phosphonium salts **9** and **14**, followed by Wittig reactions of the corresponding ylides with protected hydroxyaldehyde **6**. Deprotection of the resulting trienes with PTSA in methanol gave (5E/Z,7E,11Z)-hexadecatrien-1-ol **10** (71% yield over two steps, 42:58 ratio of isomers) and (5E/Z,7Z,11Z)-hexadecatrien-1-ol **15** (75% yield, 55:45 ratio of isomers). Oxidation of alcohols **10** and **15** with PCC in dichloromethane gave the desired aldehydes **11** and **16** as pairs of isomers.

The synthesis of the (5E/Z,7Z,11Z)-hexadecatrienal mixture **16** gave an approximately 1:1 ratio of isomers. To determine the identities of the two isomers, one of which eluted very close to the insect-produced trienal, a stereospecific synthesis of the 5Z,7Z,11Z-isomer was carried out (Scheme 2). The key steps were the sequential alkylation of (Z)-1,2-dichloroethene **19** with the terminal alkyne **18** in the presence of CuI, $PdCl_2(PPh_3)_2$, and diisopropylamine, followed by a second alkylation of the resulting chloroenyne **20** with (Z)-3-octenyl magnesium bromide with $Fe(acac)_3$ catalysis and *N*-methylpyrrolidi-

none (NMP) as cosolvent (Cahiez and Avedissian, 1998). The latter coupling step was inefficient, returning mainly unreacted starting material, but it did furnish **21** in sufficient yield (13.5%) to proceed. Dienyne **21** was stereoselectively reduced to the corresponding triene **22** (76% yield) with dicyclohexylborane, in >99% isomeric purity by GC analysis. Removal of the THP group by acid catalysis in methanol gave trien-1-ol **23**, which was oxidized to (5*Z*, 7*Z*, 11*Z*)-hexadecatrienal **24** with PCC.

Although (5*Z*, 7*Z*, 11*Z*)-hexadecatrienal had retention times on both columns that were close to those of the insect-produced compound (Table 1), none of the four 5,7,11-isomers had retention times that exactly matched those of the insect-produced trienal on the two columns. Thus, we embarked on the syntheses of the other most likely isomers, the 7,11,13-trienals.

Initially, four of the eight possible geometric isomers of 7,11,13-hexadecatrienal were synthesized as two pairs of isomers, that is, (7*Z*, 11*E*/*Z*, 13*E*)-hexadecatrienal and (7*Z*, 11*E*/*Z*, 13*Z*)-hexadecatrienal, starting from commercially available (7*Z*, 11*E*/*Z*)-hexadecadienyl acetate **25** (pheromone of pink bollworm) (Scheme 3). Thus, oxidative cleavage of **25** gave aldehyde **28** (2 steps, 10.1% yield), which was reacted separately with the ylides generated from the phosphonium salts **30** and **34**. These reactions yielded the mixtures of trienes (7*Z*, 11*E*/*Z*, 13*Z*)-**31** and (7*Z*, 11*E*/*Z*, 13*E*)-**35** in 42 and 58% yield, respectively. After hydrolysis of the acetates, the corresponding alcohols **32** and **36** were oxidized with PCC, furnishing the desired mixtures of aldehydes **33** and **37**. With these mixtures in hand, the insect-produced trienal was identified as the 7*Z*, 11*Z*, 13*E*-16:Ald isomer. A more stereoselective route was developed to provide material for field trials, along with a parallel route to provide the diene component, 7*Z*, 11*Z*-16:Ald, in high isomeric purity as well.

The synthetic routes to 7*Z*, 11*Z*, 13*E*-16:Ald **49** and 7*Z*, 11*Z*-16:Ald **56** are shown in Schemes 4 and 5. The key step in both routes was a stereoselective Wittig reaction that placed a (*Z*) double bond in the 11 position of the desired compounds. The synthetic route to 7*Z*, 11*Z*, 13*E*-16:Ald **49** was based on a (C₈ + C₃) + C₅ approach. Thus, alkyne **41** (Waanders et al., 1987), prepared from 7-octyn-1-ol **40** by protection of the hydroxyl group as the tetrahydropyranyl (THP) ether, was deprotonated with BuLi, followed by addition of bromide **39** to give diprotected yne-diol **42**. Selective removal of the *t*-butyldimethylsilyl ether with tetrabutylammonium fluoride furnished monoprotected yne-diol **43** (Yadav et al., 1988) (70% over two steps). The alkyne was reduced by P-2 nickel-catalyzed reduction of **43** with H₂ (Brown and Ahuja, 1973) to produce **44** (Sharma et al., 1994) in 92% yield. Alcohol **44** was converted to the corresponding iodide **45** by reaction with iodine, triphenylphosphine, and imidazole (Gnädig et al., 2001) (58%), followed by reaction of **45** with triphenylphosphine to give the corresponding phosphonium salt. Wittig reaction of ylide **46** derived from this salt with (*E*)-2-pentenal in a THF–DMPU solvent

mixture, in a modification of the *Z*-selective olefination method of Labelle et al. (1990), afforded triene **47** as a 93:7 mixture of the 7*Z*,11*E*/*Z*,13*E*-trienes in 42% yield. The Labelle et al. (1990) method called for a THF–HMPA solvent mixture, whereas our results showed that DMPU was an effective and safer substitute for toxic and carcinogenic HMPA. Trienol **48** was obtained by removal of the THP protecting group with PTSA in methanol, and the isomeric purity of **48** was increased to 97:3 by recrystallization from hexane. Oxidation of **48** with pyridinium chlorochromate (PCC) then produced the desired aldehyde **49** in 77% yield.

The synthesis of 7*Z*,11*Z*-16:Ald was carried out by a modification of this route (Scheme 5). Thus, alkyne **41** was treated with BuLi followed by addition of 1-chloro-3-iodopropane to give chloride **50** (Sonnet, 1974) (64% yield). This was converted to the corresponding iodide **51** by refluxing with sodium iodide in acetone (95% yield). Reaction of **51** with triphenylphosphine gave the corresponding phosphonium salt **52**, which can be used as an intermediate for the syntheses of both the diene and the triene pheromone components. Wittig reaction of the ylide derived from **52** via treatment with lithium hexamethyldisilazide in THF–DMPU solvent gave the *Z* olefinic compound **53** (Yadav et al., 1988) in 65% yield as a 98.8*Z*:1.2*E* isomeric mixture. After removal of the THP group with PTSA in methanol, alcohol **54** (Yadav et al., 1988) was reduced with P-2 nickel and hydrogen, yielding dienol **55** in 71% yield. 7*Z*,11*Z*-16:Ald **56** was obtained by oxidation of **55** with PCC as before.

The synthetic route for the preparation of 7*Z*,11*Z*,13*Z*-16:Ald **62** is depicted in Scheme 6. Phosphonium salt **52**, previously used to prepare 7*Z*,11*Z*-16:Ald **56**, was deprotonated with lithium hexamethyldisilazide in THF–DMPU, and reacted with 2-pentynal to give protected endiynol **59** (58%), which was then stereoselectively reduced to the corresponding triene **60** with dicyclohexylborane (80%), yielding a 92:8 mixture of the (7*Z*,11*Z*,13*Z*)- and (7*Z*,11*E*,13*Z*)-trienes, respectively. After removal of the THP protecting group with PTSA in methanol (80%), the isomeric purity of trienol **61** was increased to 95:5 by chromatography on silica gel impregnated with 10% AgNO₃. Oxidation of **61** with PCC completed the synthesis, giving aldehyde **62** in 73% yield.

Field Trials. A preliminary, unreplicated field trial run for 1 d provided evidence that both 7*Z*,11*Z*-16:Ald and 7*Z*,11*Z*,13*E*-16:Ald were required for attraction of male moths, because traps baited with 100 μg of either component alone attracted no moths, whereas traps baited with 100:10, 100:50, or 100:100 μg ratios of 7*Z*,11*Z*,13*E*-16:Ald to 7*Z*,11*Z*-16:Ald caught 135, 192, and 146 moths, respectively. A subsequent, replicated field trial testing different blend ratios of the two components caught >13,000 moths, with a 3:1 ratio of the trienal and dienal being most attractive (Figure 3). A dose-response trial of the 3:1 ratio showed that trienal doses of 100–1000 μg were more attractive than lower doses of 1.0–33 μg/lure (Figure 4). Many thousands of moths were

FIG. 3. Citrus leafminer field trial to determine the optimum ratio of the trienal to the dienal, September 8–12, 2004. Each septum was loaded with 100 µg *Z7,Z11,E13-16:Ald* and variable amounts of *Z7,Z11-16:Ald*. Bars with different letters are significantly different (two-way ANOVA followed by Student–Neumann–Keuls test, $\alpha = 0.05$, $F = 180.4$, $df = 4, 24$, $P < 0.001$). Total moths trapped = 13,915. Solvent controls and the 1 µg dose of *Z7,Z11-16:Ald* each caught 1 moth, and were not included in the statistical analysis.

FIG. 4. Effect of pheromone dose on trap catches of citrus leafminer, October 15–22, 2004. The trienal/dienal ratio was fixed at 3:1. Bars with different letters are significantly different (two-way nonparametric ANOVA followed by Bonferroni's *t*-tests for means separation, $\alpha = 0.05$). For treatment, $F = 22.92$, $df = 6, 34$, $P < 0.001$; for block effect, $F = 0.0$, $df = 4, 34$, $P = 1.00$. Total number of moths trapped = 13,122. Control traps caught two moths, and were not included in the statistical analysis.

FIG. 5. Citrus leafminer blend ratio trial, June 2005. The trienal/dienal ratio was fixed at 100:33 µg, and variable amounts of 7Z,11Z,13Z-16:Ald were added to this base blend. Bars surmounted with different letters are significantly different (two-way ANOVA on $\log_{10}(x + 1)$ transformed data, followed by Student-Neumann-Keuls test, $\alpha = 0.05$). For treatment, $F = 44.0$, $df = 5, 29$, $P < 0.001$; for block, $F = 1.93$, $df = 4, 29$, $P = 0.14$. Total moths trapped = 617. Control traps caught no moths, and were not included in the statistical analysis.

caught, again indicating the effectiveness of the lure. The addition of increasing amounts of 7Z,11Z,13Z-16:Ald to the two component blend of 7Z,11Z,13E-16:Ald and 7Z,11Z-16:Ald (100:33) resulted in decreasing numbers of moths caught, indicating that this isomer was inhibitory at higher percentages of the blend (Figure 5).

DISCUSSION

Solvent extracts of pheromone glands were difficult to prepare because of the tiny size of these moths, and the pheromone components were not detected in these extracts by GC or GC-MS. In contrast, the SPME method of dynamic collection of pheromone from the effluvia from live female moths provided extracts in which the amounts of the pheromone components were detectable by GC and GC-MS, and these provided an accurate representation of the compounds released by the moths. However, even with overnight SPME collections made from groups of as many as 30 moths, and with the efficiency inherent in the desorption of the entire SPME sample directly into the injection port of the GC or GC-MS, we frequently could not detect the pheromone

components with either of these instruments. Thus, the preliminary identification of the two compounds was based solely on the combination of data from relative retention times on two GC columns of different polarities determined from EAD responses (Table 1), the relative sizes of antennal responses to different functional groups and double bond orientations, and latterly, the bioassay results. The sum total of these data presented a compelling case for the identification of the pheromone components. Confirmation of the pheromone structures was finally acquired after the field trials, when mass spectra of the two compounds were obtained from an SPME sample obtained from aeration of female moths for several sequential nights.

The analytical results and the field trials conclusively demonstrate that the citrus leafminer pheromone for California populations of this moth consists of two major synergistic components, with no attraction at all to either compound alone. This explains why researchers in several areas of the world had not been able to reproduce the results of Ando et al. (1985), who reported attraction of several hundred moths of a Japanese population of this species to 7Z,11Z-16:Ald as a single component. Furthermore, the marked difference between the attractiveness of 7Z,11Z-16:Ald between populations in Japan and other areas of the world suggests that the Japanese population may constitute a geographically distinct pheromone race, as has been reported for other lepidopteran species (e.g., turnip moth, *Agrotis segetum*, Tóth et al., 1992; moths in the genus *Hemileuca*, McElfresh and Millar, 2002).

The GC-EAD traces from the DB-5 column showed occasional weak antennal responses to another trace compound, tentatively identified as 7Z,11Z,13Z-16:Ald. However, addition of this isomer to the optimal two-component blend did not increase trap catches, and at higher doses, was actually inhibitory. Given that our field bioassays indicated that the two-component blend of 7Z,11Z,13E-16:Ald and 7Z,11Z-16:Ald was highly attractive to male moths, with many thousand moths being caught in each of the two bioassays in fall of 2004, it seems unlikely that this compound would be an important component of the pheromone blend.

To our knowledge, the citrus leafminer is the only lepidopteran species known to use 7Z,11Z-16:Ald, although the corresponding acetate has been reported as a sex attractant or sex pheromone component for one stathmopid, eight gelechiid, and one noctuid species (Witzgall et al., 2004). This is the first report of the trienal component, 7Z,11Z,13E-16:Ald, and to our knowledge, the 7Z,11Z,13E-16:X structural motif has not been reported before from any lepidopteran pheromone or other natural source. However, this may be a reflection of the few *Phyllocnistis* or related leafminer species' pheromones studied rather than a unique structural motif in nature.

In summary, this new pheromone blend will find immediate use in monitoring citrus leafminer populations, particularly in areas such as California

where the insect has been introduced fairly recently, and where it is still expanding its range.

Abstract—The coffee white stem borer, *Xylotrechus quadripes* Chevrolat (Coleoptera: Cerambycidae), is the foremost pest of arabica coffee in India, Sri Lanka, China, Vietnam, and Thailand. Previous work showed that female beetles were attracted to traps baited with male beetles. Analyses of volatiles from male *X. quadripes* of Indian origin by gas chromatography (GC) linked to electroantennographic (EAG) recording from a female beetle antenna showed three male-specific components comprising more than 90% of the volatiles, two of which elicited EAG responses. The major EAG-active component was produced at up to 2 $\mu\text{g hr}^{-1} \text{insect}^{-1}$ and was identified as (*S*)-2-hydroxy-3-decanone (**I**) by comparison of GC data, and mass (MS), infrared, and nuclear magnetic resonance (NMR) spectra with those of synthetic standards. The second component was identified as 3-hydroxy-2-decanone (**II**) produced in part by isomerization of **I** under the conditions of the GC analysis, although the NMR spectrum suggested it is naturally produced at up to 7% of **I**. The minor component that elicited an EAG response, present at 7% of the amount of **I**, was identified as (*S,S*)-2,3-dihydroxyoctane (**III**) from GC and MS data. 2-Hydroxy-3-octanone (0.2–0.5% of **I**), 2,3-decanedione (2% of **I**), 2-phenylethanol (3% of **I**), and octanoic acid (4% of **I**) were also identified in volatiles from male beetles. A general, stereospecific synthetic route to the enantiomers of 2-hydroxy-3-alkanones from the enantiomers of ethyl lactate was developed. The enantiomers of **III** were synthesized from (*E*)-2-octene by Sharpless asymmetric dihydroxylation. (*S*)-(**I**) was attractive to male *X. quadripes* in

laboratory bioassays, but addition of (*S,R,S*)-(III) at 10% of I reduced attractiveness. In field trials carried out in India with sticky, cross-vane traps, (*S*)- and (*R,S*)-(I) attracted male *X. quadripes* and addition of (*S,S*)-(III) at 10% of I reduced attractiveness. Significant numbers of female *Demonax balyi* Pascoe (Coleoptera: Cerambycidae) were sometimes caught in traps baited with (*S*)-(I) alone.

Key Words—*Xylotrechus quadripes*, coffee white stem borer, Coleoptera, Cerambycidae, male sex pheromone, (*S*)-2-hydroxy-3-decanone, 3-hydroxy-2-decanone, (*S,S*)-2,3-dihydroxyoctane, *Demonax balyi*.

INTRODUCTION

The coffee white stem borer, *Xylotrechus quadripes* Chevrolat (Coleoptera: Cerambycidae) is the foremost pest of arabica coffee in India, Sri Lanka, China, Vietnam, and Thailand (Le Pelley, 1968; Rhainds et al., 2002). In India, it is estimated that over 9 million trees have to be destroyed each year because of attack by *X. quadripes*, costing around \$40 m annually for replacement and loss of production.

The adults of *X. quadripes* have distinct flight periods, and the females lay eggs in crevices in the bark. The larvae tunnel into the trunk, blocking the tunnel with frass behind them to deter predators. The tunneling in the trunk and roots rapidly kills young plants of up to 7–8 yr old, whereas older plants may survive for a few seasons but eventually succumb. Current control measures include maintenance of good shade because the adults are more active in sunlight, but this can reduce photosynthesis and yield. Removal of loose bark or scrubbing the bark at the base of the tree discourages oviposition, and collar pruning of infested trees may be effective if the pest has not reached the roots. Benzene hexachloride applied to the trunk at critical times during the flight periods is still the only effective insecticide against young larvae of *X. quadripes*, but this has now been banned for agricultural use in India and many other countries. Once larvae have penetrated into the stem, trees should be removed and destroyed to prevent spread of infestation (Le Pelley, 1968; Sreedharan and Kumar, 2001; Rhainds et al., 2002).

Male *X. quadripes* were shown to attract female beetles in the field in India by Venkateshu et al. (1986). Production of a sex pheromone by males of a related species, the grape borer *X. pyrrhoderus*, was demonstrated by Iwabuchi (1982), and the chemical structures of the components were identified by Sakai et al. (1984). The same components were shown to be produced by the mulberry borer, *X. chinensis* (Iwabuchi et al., 1987; Kuwahara et al., 1987). Identification and synthesis of the male sex pheromone of *X. quadripes* could provide the basis for development of a monitoring system for this pest in order to determine its distribution, and to time control measures directed at young larvae more

effectively. Mass trapping with pheromone-baited traps could provide a method for control of this pest because it occurs at relatively low density and the pheromone attracts female beetles, thus directly affecting egg-laying.

We have reported the identification of (*S*)-2-hydroxy-3-decanone as the major component of the male sex pheromone of *X. quadripes* from India (Hall et al., 1998). This was confirmed by Rhains et al. (2001a), using insects from China, and those authors also reported the presence of 2,3-decanedione in volatiles from the male beetles. Here, we report in full the identification of the major component of the sex pheromone of male *X. quadripes* from India, identification of an alternative minor component, and laboratory and field bioassays of these components.

METHODS AND MATERIALS

Insects. *X. quadripes* adults were collected as they emerged from infested logs held in a netted room at the Central Coffee Research Institute (CCRI) under ambient temperature and humidity. Insects were collected several times during the morning emergence hours (Venkatesha et al., 1995) to ensure that they did not mate, and were sexed (Visitpanich, 1994) and maintained in separate tubes. These were hand-carried from India and separately maintained in an insectary at 70% RH with 12:12 h L/D light and 27:23°C temperature cycles.

Pheromone Collection. Volatiles were collected from 15 virgin male beetles held in a silanized, 2-liter round-bottomed flask containing a filter paper (15 cm diam; Whatman No. 52). Air was drawn into the flask through a filter of activated charcoal (10 × 2 cm; 10–18 mesh) at 2 l/min⁻¹, and volatiles were trapped on a filter of Porapak Q (50–80 mesh; 200 mg; Waters Corp., USA) packed between silanized glass wool plugs in a Pasteur pipette (i.d. 4 mm). The Porapak Q was purified by Soxhlet extraction with chloroform for 8 hr, and filters were rinsed well with dichloromethane before use. Volatiles from 15 virgin female beetles were collected similarly. Trapped volatiles were eluted from the filter after 24–72 hr with dichloromethane (3 × 0.5 ml) or alternatively with CDCl₃ (1 ml) or ether (1 ml) for nuclear magnetic resonance (NMR) analysis or microreduction, respectively. For the latter, a few grains of lithium aluminum hydride were added to the ether solution, and the mixture was shaken at intervals for 1 hr. Water (0.1 ml) was then carefully added and the mixture was shaken. The upper ether layer was removed, dried with magnesium sulfate and analyzed by GC.

A container wash was obtained by maintaining nine male beetles in a conical flask (250 ml) with a filter paper (7 cm diam; Whatman No. 52) for 48 hr and then removing the beetles and washing flask and filter paper with hexane (5 + 5 ml). A female beetle container wash was obtained similarly.

Whole-body washes were obtained by placing nine male or nine female beetles in hexane (2.5 ml) 3 hr after lights on. After 10 min, the solvent was removed, and the residue was rinsed with a further aliquot of hexane (1 ml).

Gas Chromatographic Analyses. Gas chromatographic (GC) analyses were carried out on Carlo Erba Mega instruments with fused silica columns (25 m \times 0.32 mm i.d.) coated with polar CP Wax 52CB (Carbowax 20M equivalent; Chrompack, London, UK) or nonpolar CP Sil 5CB (methyl silicone; Chrompack). Carrier gas was helium at 0.5 kg cm⁻² and oven temperature was programmed at 50°C for 2 min, then at 6°C min⁻¹ to 230°C. Injection was splitless or split (50:1) (200°C), and detection was by flame ionization detection (FID; 220°C). GC retention times are reported as retention indices (RI) relative to those of normal hydrocarbons.

Enantiomeric purity was determined by GC analysis on cyclodextrin GC columns (CP-Chirasil-DexCB, 25 m \times 0.32 mm i.d., Chrompack; or β -Cyclodextrin, 50 m \times 0.22 mm i.d., SGE, Milton Keynes, UK.). These were operated isothermally at 130 or 135°C, respectively, with helium carrier gas at 0.5 or 1.5 kg cm⁻², respectively, and injector and detector temperatures as described above.

Coupled Gas Chromatography-Mass Spectrometry. Gas chromatography-mass spectrometry (GC-MS) analyses were carried out on a fused silica column (25 m \times 0.2 mm i.d.; CP Wax 52CB) directly linked to a Finnigan ITD 700 ion trap detector (Thermoquest, Hemel Hempstead, Herts., UK) operated in EI or CI (*iso*-butane) mode. GC conditions were as described above.

Coupled Gas Chromatography-Electroantennography. Linked gas chromatography-electroantennography (GC-EAG) analyses were carried out as described by Cork et al. (1990) with effluent from the GC column split equally between the FID and a small glass reservoir in the column oven, the contents of which were expelled at 15-sec intervals with nitrogen (500 ml min⁻¹ for 3 sec) over an EAG preparation. In the GC analysis, we used a fused silica column (25 m \times 0.32 mm i.d.; CP Wax 52CB) programmed at 50°C for 2 min, then 20°C min⁻¹ to 100°C, and then 4°C min⁻¹ to 260°C. For EAG preparations, the head of the beetle was excised and impaled on the indifferent glass capillary electrode. The tip of one antenna was then inserted into the recording glass electrode and the preparation positioned so that the stimulus was directed at the terminal segments of the antenna. The electrodes contained 0.1 M aqueous KCl solution with 10% polyvinylpyrrolidone to reduce evaporation, and were inserted into stainless steel electrode holders (Syntech, Hilversum, The Netherlands) mounted on micromanipulators (Leica Microsystems, Wetzlar, Germany). Electrical contact was made with chloridized silver wires to the amplifier (UN-06, Syntech), and both EAG and GC signals were collected and processed with Turbochrom 4 software (Perkin Elmer, Beaconsfield, Bucks., UK).

Spectrometry. NMR spectra were recorded in CDCl_3 on a JEOL EX270 machine at 270 MHz for ^1H and 67.8 MHz for ^{13}C . Enantiomeric purity was determined after addition of the chiral cosolvent, (*R*)-(-)-2,2,2-trifluoro-1-(9-anthryl)ethanol (10 mg; Sigma-Aldrich, Gillingham, Dorset, UK). Infrared (IR) spectra were recorded as thin films with a Perkin Elmer 298 grating spectrophotometer (Perkin Elmer, Beaconsfield, Bucks., UK).

Synthetic Compounds. (*S*)-2-Hydroxy-3-decanone was synthesized from (*S*)-ethyl lactate by a short, general route (Figure 1). The *R* enantiomer was synthesized similarly from (*R*)-ethyl lactate. In initial experiments, (*S*)-ethyl lactate was protected as the benzyl ether by reaction with NaH in THF at room temperature followed by addition of benzyl bromide (65%; b.p. $82^\circ\text{C}/0.6$ mmHg). After hydrolysis to the acid (88%; b.p. $96^\circ\text{C}/0.75$ mmHg), reaction with heptyl lithium gave 2-benzyloxy-2-decanone (62%; b.p. $90^\circ\text{C}/0.2$ mmHg) (cf. Figure 1). The benzyl group was removed by catalytic hydrogenation over 10% palladium on charcoal in ethyl acetate (98%). Examination of the 2-hydroxy-3-decanone product by chiral GC (below) showed that the product was completely racemized. Analysis of the reaction intermediates by chiral GC showed that this racemization had occurred during the initial benzylation step. The (*R,S*)-2-hydroxy-3-decanone was used in some field trials as indicated.

Use of 2-tetrahydropyranyl or *tert*-butyl dimethylsilyl protecting groups gave 2-hydroxy-3-decanone without detectable racemization as shown in Figure 1. The former protecting group was preferred for large-scale synthesis, as described below.

Ethyl 2-(2-tetrahydropyranyloxy)propanoate. Freshly distilled 3,4-dihydro-2H-pyran (50.4 g, 0.6 mol) was added dropwise to a solution of (*S*)-ethyl lactate (59 g, 0.5 mol; Sigma-Aldrich, Gillingham, Dorset, UK) and a few crystals of *p*-toluenesulfonic acid (PTSA) in dry diethyl ether (250 ml) cooled to

FIG. 1. Synthesis of (*S*)-2-hydroxy-3-decanone. [R_1 = tetrahydropyranyl, R_2 = C_7H_{15} : (i) 2,3-dihydropyran/PTSA (92%); (ii) $\text{LiOH}\cdot\text{H}_2\text{O}/\text{EtOH}$ (100%); (iii) $\text{C}_7\text{H}_{15}\text{Li}/\text{ether}$ (90%); (iv) MeOH/PTSA (68%). R_1 = *tert*-butyldimethylsilyl, R_2 = C_7H_{15} : (v) tBDMSCl/imidazole/THF (93%), (ii) (94%), (iii) (57%), (vi) $\text{Bu}_4\text{NF}/\text{THF}$ (36%).

0°C under nitrogen. The reaction mixture was stirred for 4 hr at room temperature. Solid K_2CO_3 was added to the solution, and the mixture was extracted twice with saturated $NaHCO_3$ solution. The organic phase was dried over $MgSO_4$, filtered, and the solvent was removed on a rotary evaporator. The residue was distilled to give the product in 92% yield (92 g; b.p. 76–81°C/0.5 mmHg). 1H NMR: δ 1.27 (t, $J = 7.2$ Hz, 3H, CH_2CH_3), 1.45 (d, $J = 7.2$ Hz, 3H, $CHCH_3$), 1.55–1.80 (m, 6H, CH_2), 3.68 (m, 2H, $O-CH_2$), 4.16 (q, $J = 7.2$ Hz, 2H, CH_2CH_3), 4.20 (q, $J = 3.3$ Hz, 1H, CH_3CH-OH), 4.40 (d, $J = 6.9$ Hz, 1H, $O-CH-O$); MS: m/z (%) 200 (2), 184 (1), 157 (3), 144 (2), 130 (3), 119 (trace), 101 (10), 85 (100), 67 (5), 57 (5), 43 (10); GC analysis on the polar column showed the two diastereoisomers in a 68:32 ratio.

Lithium 2-(2-tetrahydropyranyloxy)propanoate. Lithium hydroxide monohydrate (4.6 g, 0.1 mol) was added to a stirred solution of ethyl 2-(2-tetrahydropyranyloxy)propanoate (20.2 g, 0.1 mol) in ethanol (50 ml) under nitrogen. After 4 hr of stirring, GC analysis showed no trace of the starting material. Ethanol was removed under reduced pressure and the residue was washed twice with petroleum ether (100 ml) to give lithium 2-(2-tetrahydropyranyloxy)propanoate as a white solid in 100% yield (18.0 g). 1H NMR: δ 1.40 (d, $J = 7.3$ Hz, 3H, $CHCH_3$), 1.65–1.80 (m, 6H, CH_2), 3.60 (m, 2H, $O-CH_2$), 4.20 (q, $J = 7.3$ Hz, 1H, $O-CHCH_3$), 4.40 (d, $J = 6.9$ Hz, 1H, $O-CH-O$).

2-(2-Tetrahydropyranyloxy)-3-decanone. Heptyl lithium was prepared from heptyl bromide (17.9 g, 0.1 mol) and lithium (1.75 g, 0.25 mol) in dry ether (100 ml) under argon. The heptyl lithium (95 ml, 66 mmol) was added dropwise to a mechanically stirred suspension of lithium 2-(2-tetrahydropyranyloxy)propanoate (10.8 g, 60 mmol) in dry ether (50 ml) under nitrogen and cooled in an ice bath. After stirring at room temperature overnight, the contents were poured onto ice and saturated NH_4Cl solution. The aqueous layer was extracted twice with ether and the extracts were washed with saturated NH_4Cl , dried with $MgSO_4$, and filtered through a pad of Florisil. The solvent was evaporated under reduced pressure to give the crude 2-(2-tetrahydropyranyloxy)-3-decanone (14.7 g; 95%). Kugelrohr distillation of an analytical sample gave the pure product as a colorless oil (90%), b.p. 98°C/0.06 mmHg; MS: m/z (%) 211 (2, $M-C_2H_4O$)⁺, 182 (2), 173 (5), 155 (3), 137 (2), 127 (5), 114 (3), 95 (trace), 85 (100), 67 (3), 57 (5), 41 (10); GC analysis on the polar column showed the two diastereoisomers in a 68:32 ratio.

(S)-2-Hydroxy-3-decanone. The crude 2-(2-tetrahydropyranyloxy)-3-decanone (14.7 g) was dissolved in methanol (120 ml), a few crystals of PTSA were added, and the solution was stirred at room temperature. GC analysis on the polar column indicated reaction was complete after 6 hr. A small amount of solid K_2CO_3 was added and most of the methanol was removed on a rotary evaporator under reduced pressure. The residue was dissolved in 1:1 diethyl ether/hexane, washed with saturated $NaHCO_3$ and dried over $MgSO_4$. After

removal of solvents under reduced pressure, the residue was distilled to give a main fraction in 68% yield (b.p. 57–60°C/0.04 mmHg; 7.0 g). IR (film): ν 3420 cm^{-1} (O–H), 1710 cm^{-1} (C=O); ^1H NMR: δ 0.88 (t, $J = 6.9$ Hz, 3H, CH_2CH_3), 1.27 (bm, 8H, CH_2), 1.38 (d, $J = 6.9$ Hz, 3H, CH_3CHOH), 1.61 (m, 2H, $\text{CH}_2\text{—CH}_2\text{—C=O}$), 2.41 (dt, $J = 16.8, 7.6$ Hz, 1H, $\text{CH}_2\text{—CH=CH—C=O}$), 2.52 (dt, $J = 16.8, 7.6$ Hz, 1H, $\text{CH}_2\text{—CH=CH—C=O}$), 3.55 (d, $J = 4.5$ Hz, 1H, CH—OH), 4.24 (dq, $J = 7.1, 4.5$ Hz, 1H, CH_3CHOH); ^{13}C NMR: δ 14.05, 19.86, 22.59, 23.63, 29.00, 29.18, 31.63, 37.54, 72.56, 212.72; MS: m/z (%) 173 ($\text{M} + 1$)⁺ (15), 155 (3), 137 (5), 127 (40), 57 (100), 45 (60), 29 (30).

By GC analysis on the polar GC column, all samples of 2-hydroxy-3-decanone contained 5–10% of the isomeric 3-hydroxy-2-decanone. GC analysis of the enantiomers on the 25-m cyclodextrin column at 130°C gave baseline separation (retention times R 23.7 min, S 24.0 min). Both synthetic enantiomers showed 98% enantiomeric excess (ee), similar to those of the starting ethyl lactates. A high level of enantiomeric purity was also indicated by the ^1H NMR spectrum of the S enantiomer in the presence of a chiral cosolvent using either the signals due to the $\text{CH}_3\text{—CH—OH}$ doublet or the $\text{CH}_3\text{—CH—OH}$ multiplet.

(S)-2-Hydroxy-3-octanone was synthesized similarly from (S)-ethyl lactate and 1-bromopentane in 62.5% yield (b.p. 110°C/15 mm). Spectroscopic data were identical with those of Mori and Otsuka (1985).

2,3-Dihydroxyoctane was first synthesized as a 40:60 mixture of the S,S and S,R diastereoisomers by reduction of (S)-2-hydroxy-3-octanone with lithium aluminum hydride in ether. The *erythro* S,R diastereoisomer was predicted to be the major product of this reduction, assuming coordination of the aluminum by the 2-hydroxy group, and this was confirmed by synthesis of the separate enantiomers (below). This diastereoisomeric mixture was used without further purification in laboratory bioassays.

(S,S)-2,3-Dihydroxyoctane was synthesized by reaction of (E)-2-octene (Sigma-Aldrich) with the Sharpless reagent “AD-mix- α ” (Sigma-Aldrich) in *tert*-butyl alcohol in the presence of methanesulfonamide (Sharpless et al., 1992). The product was obtained in 91% yield after chromatography and Kugelrohr distillation (b.p. 135°C/4 mmHg). Similar reaction of (E)-2-octene with the “AD-mix- β ” (Sigma-Aldrich) gave (R,R)-2,3-dihydroxyoctane in similar yield. Both compounds were completely free ($\leq 0.2\%$) of *erythro* diastereoisomers by GC analysis. ^1H NMR: δ 0.89 (t, $J = 6.6$ Hz, 3H, $\text{CH}_3\text{—CH}_2\text{—}$), 1.18 (d, $J = 6.3$ Hz, 3H, $\text{CH}_3\text{—CH(OH)—}$), 1.50–1.22 (m, 8H, $4 \times \text{CH}_2$), 2.47–2.41 (br m, 2H, $2 \times \text{OH}$), 3.48–3.46 (br m, 1H, CHOH), 3.58 (quint, $J = 6.3$, 1H, $\text{CH}_3\text{—CHOH}$); ^{13}C NMR: δ 14.0, 19.4, 22.6, 25.2, 31.8, 33.3, 70.8, 76.2. These data were identical with literature values (e.g., Mori and Otsuka, 1985).

Analyses of the synthetic 2,3-dihydroxyoctanes on the 50 m cyclodextrin GC column at 135°C showed good separation of the two enantiomers. The S,S enantiomer (retention time, 28.2 min) had an ee of only 83%, whereas that of

the *R,R* enantiomer (28.7 min) was 90%. The lower ee of the former was thought to be due to the prolonged reaction time (24 hr at 0°C and 17 hr at room temperature) compared with that used in the second reaction (15 hr at RT).

2,3-Decanedione was prepared in 50% yield by oxidation of (*S*)-2-hydroxy-3-decanone with pyridinium chlorochromate and sodium acetate in dichloromethane (Corey and Suggs, 1975) followed by flash chromatography and Kugelrohr distillation (b.p. 80°C/0.06 mm). ¹H NMR: δ 0.86 (t, $J = 7$ Hz, 3H, $\text{CH}_3\text{-CH}_2$), 1.27 (m, 8H, $4 \times \text{CH}_2$), 1.56 (quint, $J = 7$ Hz, 2H, $\text{CH}_2\text{-CH}_2\text{-CH}_2\text{-C=O}$), 2.31 (s, 3H, $\text{CH}_3\text{-C=O}$), 2.71 (t, $J = 7$ Hz, 2H, $\text{CH}_2\text{-C=O}$); ¹³C NMR: δ 14.0, 22.6, 23.1, 23.7, 29.0, 29.1, 31.6, 35.7, 197.7, 199.6; MS m/z (%) 127 (22), 109 (8), 83 (1), 81 (1), 67 (9), 58 (4), 57 (100), 55 (11), 43 (79), 42 (12), 41 (61) (c.f. slightly different data in Rhainds et al., 2001a).

Pheromone Dispensers. Controlled release dispensers for the synthetic pheromone were heat-sealed polyethylene vials (22 \times 8 \times 1.5 mm thick; Just Plastics Ltd., London, UK) or polyethylene sachets (2.5 cm \times 2.5 cm \times 120 μ thick) made from heat-sealed layflat tubing (Transatlantic Plastics, Southampton, UK) and contained 100 μ l (approximately 80 mg) or 200 μ l pheromone. Release rates from dispensers were measured by periodic weighing of duplicate dispensers maintained in a wind tunnel at 27°C and 8 km hr⁻¹ wind speed.

Bioassays. Bioassays were carried out in an insectary maintained at 27°C with 5000 lux lighting, between 10:00 and 12:00 hours coinciding with the period of maximum activity of the beetles in the field (Venkatesha et al., 1995). Two types of bioassay apparatus were used, both constructed of Plexiglas.

The "swastika" bioassay consisted of a central circular chamber (19 \times 5 cm high) with four equally spaced entry/exit openings in the side wall. The openings led to tubes (3.8 cm diam, total length 55 cm) with a right angle bend in the middle to give a swastika appearance. Plexiglas sample bottles (6 \times 4 cm) with fine mesh tops and bottoms were fixed to the distal ends of the tubes. Air was drawn into the apparatus through the arms and out through a tube attached to the center of the top of the central chamber at 20 l/min⁻¹. Initial studies were carried out at NRI with 25 male and 25 female insects so that insects were used as lures and/or test individuals more than once, but never on the same day. A single insect was placed at the center of the central chamber with appropriate treatments in the sidearms. Insect behavior was observed for 10 min: if an insect entered one of the sidearms this was scored, otherwise it was scored as remaining in the central chamber. The apparatus was rotated through 90° between each observation to avoid any possible effects due to uneven lighting or visual cues. Ten insects were tested in each experiment and data were analyzed by a χ^2 test assuming equal distribution of responding beetles between the arms as null hypothesis.

The tube bioassay utilized a Plexiglas tube (1 m \times 3.8 cm i.d.) with a Plexiglas sample bottle (6 cm \times 4 cm) with fine gauze top and bottom attached

at one end. The test source was put in the sample bottle and a single test beetle placed at the opposite end of the tube. Air was drawn in through the source bottle and out through the other end of the tube at 10 l min^{-1} . The tube was marked at 10-cm intervals, and the nearest approach to the source by the test insect during 10 min of observation was scored according to the interval mark crossed (i.e., 1.0 = reached source, 0.5 halfway, 0.0 = no upwind movement). Each lure was tested with 10 insects, the data were subjected to arcsin transformation before analysis of variance, and differences between means were tested for significance by Duncan's multiple range test (DMRT).

Field Trials. Field trials were carried out in estates round the Central Coffee Research Institute, Chikmagalur, Karnataka, the Coffee Research Sub-Station, Chettalli, Karnataka, and the Regional Coffee Research Station, Thandigudi, Tamil Nadu, India, during the two flight seasons, April–June and October–December, in 1997 and 1998. Traps were sticky delta traps (20×20 floor, 15-cm walls; Agrisense, Treforest, UK) or sticky white cross-vane traps (60×30 cm; Agrisense) fastened to wooden poles at a height of approximately 1.5 m. Treatments were tested in randomized complete blocks with 20 m between traps, and catches were recorded and discarded every 2–4 d. Total catches were ranked and analyzed by the nonparametric Kruskal–Wallis or Mann–Whitney *U* tests. Critical differences were calculated to test differences in catches for significance.

RESULTS

Pheromone Identification. GC analyses of volatiles from male *X. quadripes* beetles on a polar column showed two main components (A) and (B) representing up to 90% of the volatile material (Figure 2). These were produced at rates up to $2 \mu\text{g hr}^{-1} \text{ beetle}^{-1}$ of (A) measured over a 24-hr period and quantified by comparison of peak area with that of a 1-octen-3-ol standard. The two components cochromatographed on a nonpolar column, and retention indices (RI) are shown in Table 1. The same two components were observed in male container washes and male body washes, but they were not detected in volatiles collected from female beetles. In initial analyses, the ratio of (A)/(B) in volatile collections varied between 1:0.14 and 1:0.75, and different results could be obtained from the same sample, suggesting that (A) and (B) were interconverting under the conditions of the analyses.

In linked GC-EAG analyses of the male volatiles (Figure 2), an EAG response was elicited from antennae of female beetles by the major component (A) and also by a smaller peak (C) eluting after (B) on the polar GC column. GC-MS analyses in EI mode of components (A) and (B) showed the two

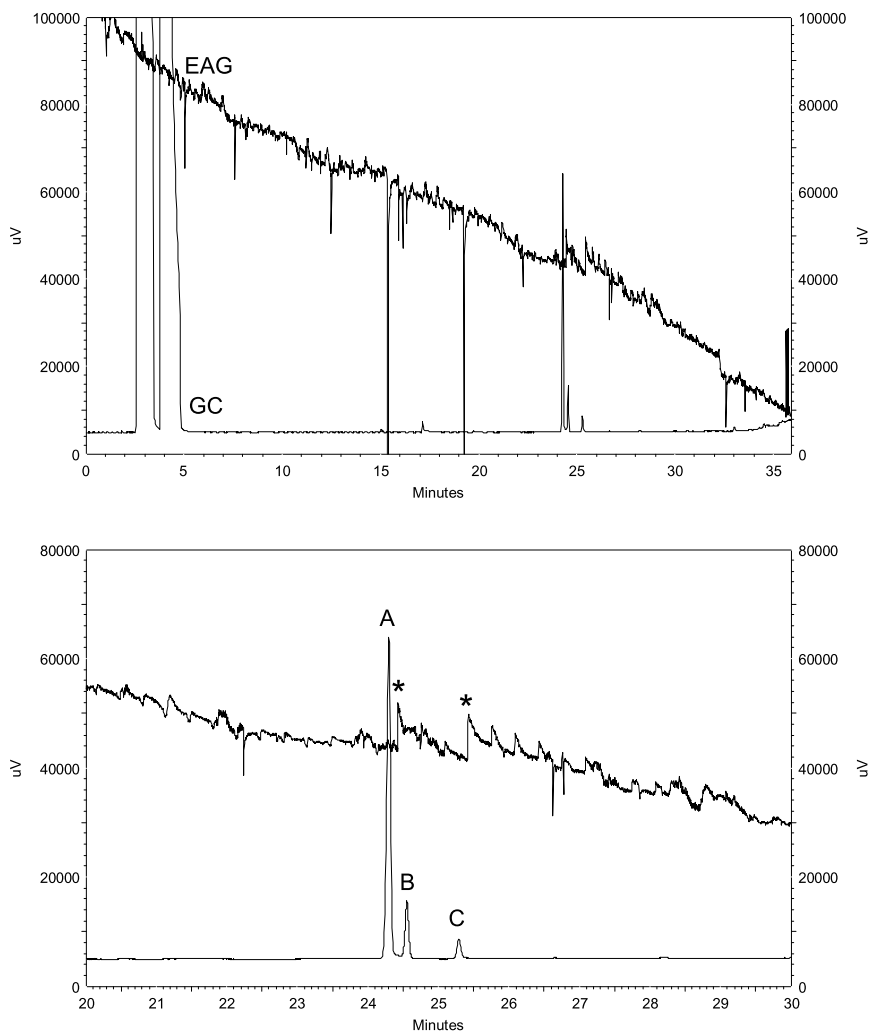

FIG. 2. Linked GC-EAG analysis of volatiles from male *X. quadripes* analyzed on polar CP Wax52CB column; lower traces are expansions of upper traces.

components had mass spectra (Figure 3) with highest mass ions at m/z 173. These indicated a possible molecular weight of 172 for both compounds, as the ion trap instrument used can give $M + 1$ ions due to self-induced chemical ionization, particularly at high concentrations. Molecular weight assignments were confirmed by CI (*iso*-butane) mass spectra, which both showed strong $M + 1$ ions at m/z 173. Comparison of the EI mass spectra with those reported

TABLE 1. GC RETENTION INDICES (RI) OF COMPONENTS IN VOLATILES FROM MALE *X. quadripes* AND SYNTHETIC COMPOUNDS

Compound	Retention index	
	CPSil5CB	CPWax52CB
Component A	1272	1848
Component B	1272	1862
Component C	1144	1902
(<i>S</i>)-2-Hydroxy-3-decanone (I)	1272	1848
3-Hydroxy-2-decanone (II)	1272	1862
2,3-Dihydroxydecane	1375, 1390	2105, 2144
(<i>S,S</i>)-2,3-Dihydroxyoctane (III)	1144	1902
(<i>S,R</i>)-2,3-Dihydroxyoctane	1155	1943
(<i>S,S</i>)-2,3-Diacetoxyoctane	1377	1823
(<i>S,R</i>)-2,3-Diacetoxyoctane	1366	1779
(<i>S</i>)-2-Hydroxy-3-octanone	1069	1631
3-Hydroxy-2-octanone	1069	1642
2,3-Decanedione	1161	1520

by Kuwahara et al. (1987) for 2-hydroxy-3-octanone and 3-hydroxy-2-octanone, pheromone components of *X. chinensis*, suggested that (A) and (B) might be the 10-carbon analogs, 2-hydroxy-3-decanone (**I**) for (A) and 3-hydroxy-2-decanone (**II**) for (B) (Figure 4). Thus, the spectrum of (A) has a prominent ion at m/z 127 ($M^+ - \text{CH}_3 - \text{CH} - \text{OH}$) and an ion at m/z 109 ($127 - \text{H}_2\text{O}$), corresponding to those in the spectrum of 2-hydroxy-3-octanone at m/z 99 and 81, respectively. The spectrum of (B) has ions at m/z 129 ($M^+ - \text{CH}_3 - \text{C} = \text{O}$) and 111 ($129 - \text{H}_2\text{O}$) corresponding to those at m/z 101 and 83 in the spectrum of 3-hydroxy-2-octanone.

Further evidence for these assignments was obtained from the IR spectrum of a volatile collection assayed at approx. 1.5 mg and evaporated onto a sodium chloride plate. The IR spectrum showed a broad hydroxyl absorption at 3400 cm^{-1} and a sharp carbonyl absorption at 1710 cm^{-1} . NMR spectra were obtained from a volatile collection eluted with CDCl_3 and assayed by GC at 0.5 mg of (A), the ratio of (A) to (B) being 1:0.14. The ^1H and ^{13}C spectra were consistent with those for 2-hydroxy-3-decanone (**I**) by comparison with corresponding data for 2-hydroxy-3-octanone reported by Bel-Rhlid et al. (1989) and Mori and Otsuka (1985), respectively. In the ^1H NMR spectrum, a singlet at δ 2.20 corresponding to the $\text{CH}_3 - \text{C} = \text{O}$ in isomer (**II**) (cf. Bel-Rhlid et al., 1989) integrated approximately 7% relative to the $\text{CH}_3 - \text{CH} - \text{OH}$ doublet at δ 1.38 for the major component (**I**). This suggested that **II** was indeed produced by the insect, although some isomerization of **I** to **II** also occurred during GC analysis.

A collection of volatiles from male beetles was eluted from the Porapak with ether and reduced with LiAlH_4 . GC analysis showed components (A) and

FIG. 3. EI mass spectra of component (A) (upper) and (B) (lower) in volatiles from male *X. quadripes*.

(B) had reacted to give two new components in 40:60 ratio at RI 2105 and 2144 on the polar GC column. The two components had identical mass spectra, which were analogous to that reported for 2,3-dihydroxyoctane by Kuwahara et al. (1987), with ions at m/z 129 and 111 compared with m/z 101 and 83 in the latter

FIG. 4. Proposed structures of components in volatiles from male *X. quadripes*, (*S*)-2-hydroxy-3-decanone (I), 3-hydroxy-2-decanone (II), and (*S,S*)-2,3-dihydroxyoctane (III).

compound. These two products were proposed to be two diastereoisomers of 2,3-dihydroxydecane (Table 1), and identical results were obtained on similar reduction of synthetic (*S*)-2-hydroxy-3-decanone (**I**).

The EI mass spectrum of component (C) is shown in Figure 5. The CI (*iso*-butane) spectrum showed a strong $M + 1$ ion indicating a molecular weight of 128. GC-EAG analyses were only carried out on a polar GC column, but component (C) could be detected in GC-MS analyses on a nonpolar column by its characteristic CI mass spectrum, and retention data are shown in Table 1. The mass spectra suggested that the structure of (C) was related to those of (A) and (B), although probably with a lower molecular weight. The retention data in terms of the differences between the relative retention indices on polar and nonpolar columns (Δ) showed that (C) ($\Delta = 758$) was significantly more polar

FIG. 5. EI mass spectrum of product of reduction of major component (A) in volatiles from male *X. quadripes* (upper) and spectrum of the minor component (C) in the volatiles (lower).

than either (A) ($\Delta = 570$) or (B) ($\Delta = 590$). Comparison of the EI mass spectrum with the literature mass spectrum of 2,3-dihydroxyoctane (Kuwahara et al., 1987) and the mass spectrum (Figure 5) and retention data (Table 1) for the product of reduction of major component (A) proposed as 2,3-dihydroxydecane, suggested that component (C) was 2,3-dihydroxyoctane (**III**) (Figure 4).

Synthesis and Configuration of Proposed Pheromone Components. The (*S*)- and (*R*)-enantiomers of 2-hydroxy-3-decanone were synthesized from (*S*)- and (*R*)-ethyl lactate, respectively (Figure 1). The synthetic 2-hydroxy-3-decanone had identical GC retention times, mass spectra, and ^1H and ^{13}C NMR spectra to the natural component (A) in volatiles collected from male *X. quadripes*. Comparison of retention times on a chiral GC column showed that the insect-produced compound cochromatographed with the *S* enantiomer (**I**) (Figure 6). Furthermore, in coupled GC-EAG analyses, the *S* enantiomer elicited a significant EAG response from the antenna of a female *X. quadripes* beetle, whereas the *R* enantiomer did not (data not shown).

The enantiomers of *threo* 2,3-dihydroxyoctane were each synthesized by Sharpless asymmetric dihydroxylation of (*E*)-2-octene. These *threo* enantiomers had identical mass spectra and retention times on polar and nonpolar GC columns to those of the minor component (C) in volatiles from male *X.*

FIG. 6. GC analysis of natural and synthetic enantiomers of 2-hydroxy-3-decanone on a chiral cyclodextrin GC column (25 m \times 0.32 mm i.d. at 130°C; i.s. = internal standard, decyl acetate).

quadripes, and none (<0.5%) of the *erythro* diastereoisomer could be detected. Mass spectra and GC retention times of the corresponding acetates were also identical to those of a minor component in a collection of volatiles from male *X. quadripes* after acetylation with acetic anhydride and pyridine (Table 1).

Analysis of the volatiles collected from male *X. quadripes* on the cyclodextrin GC column showed a peak at the retention time of (*S,S*)-2,3-dihydroxyoctane (**III**) (28.05 min), and addition of the synthetic compound confirmed cochromatography (Figure 7). The diastereoisomeric diols were not detected ((*S,R*)-2,3-dihydroxyoctane eluted at 31.11 min). Thus, the minor EAG-active component (C) in volatiles collected from male *X. quadripes* was confirmed as (*S,S*)-2,3-dihydroxyoctane (**III**) (Figure 4). The amount present assayed at 7.8% of the major component (**I**) on the nonpolar GC column, 7.0% on a polar column, and 2.6% on the cyclodextrin column. It was observed that these 2,3-diols chromatograph poorly on polar GC columns, and, moreover, that the *threo* diastereoisomers seem to chromatograph worse than the *erythro*, such that the former can be completely lost on an older column.

During this work, the corresponding eight-carbon analogue of the major pheromone component (**I**), i.e., (*S*)-2-hydroxy-3-octanone was found to be present at 0.2–0.5% of **I** in the volatiles collected from male *X. quadripes* by

FIG. 7. GC analyses of volatiles from male *X. quadripes* on a cyclodextrin GC column, alone and coinjected with synthetic (*S,S*)-2,3-dihydroxyoctane (**III**) (50 m \times 0.22 mm i.d. column at 135°C).

comparison of GC retention times and mass spectra with those of the synthetic material. Also, following the report of Rhainds et al. (2001a), 2,3-decanedione was synthesized, and reexamination of GC-MS results showed that this compound was present at 2% of the major component (**I**). The only other significant components detected were 2-phenylethanol (3% of **I**), octanoic acid (4% of **I**), and two unidentified components at RI 1894 and 2384, respectively, on the polar GC column (each approximately 1% of **I**) having mass spectra similar to that of 2,3-decanedione. No significant EAG responses from female *X. quadripes* were observed to these components in GC-EAG analyses of male volatile collections.

Pheromone Dispensers. Release of synthetic (*S*)-2-hydroxy-3-decanone (**I**) from both polyethylene vials and sachets was zero order under constant laboratory conditions. The release rate from the sachets was 0.32 mg hr^{-1} at 27°C , essentially commencing immediately after the sachets were made up and continuing at a constant level until the contents were exhausted. Release from the vials took 3 d to start, while the material permeated through the wall of the vial, but then remained constant at 0.018 mg hr^{-1} for the period of measurement (60 d).

Bioassays. Numerous attempts to develop a suitable bioassay were made during work in India in April and October 1997. A wind tunnel, pitfall bioassay, and simple observational cages were investigated, but no meaningful quantitative results were obtained, although mating behavior was observed in the cages (Venkatesha et al., 1995). Subsequently, satisfactory responses were obtained using swastika and tube bioassays measuring the responses of crawling beetles. Results with the swastika bioassay are shown in Figure 8. Female beetles were attracted to volatiles from male beetles but not to those from female beetles (Figure 8a, $\chi^2 = 14.56$, $df = 3$, $P < 0.01$; Figure 8c, $\chi^2 = 13.67$, $df = 3$, $P < 0.01$), whereas male beetles were not attracted to volatiles from males or females (Figure 8b, $\chi^2 = 0.33$, $df = 3$, $P > 0.05$). For the results shown in Figure 8d, only two arms were utilized, one with a polyethylene vial dispenser containing (*S*)-2-hydroxy-3-decanone (**I**) and the opposite arm with a vial containing a 10:1 mixture of (*S*)-2-hydroxy-3-decanone (**I**) and (*S,RS*)-2,3-dihydroxyoctane (diastereoisomers of **III**). Female beetles were attracted to **I** alone, but addition of **III** completely inhibited this attraction (Figure 8d, $\chi^2 = 8.00$, $df = 1$, $P < 0.01$).

These results were confirmed with the tube bioassay in which female *X. quadripes* beetles were tested against a blank control, a single male beetle, a vial containing (*S*)-2-hydroxy-3-decanone (**I**) alone, and a vial containing a 10:1 mixture of **I** and (*S,RS*)-2,3-dihydroxyoctane (**III**) as described above. Mean distances of attraction of the female beetles along the tube are shown in Figure 9 ($F = 7.13$, $df = 3,27$, $P = 0.001$). The male beetle or (*S*)-2-hydroxy-3-decanone (**I**) alone was equally attractive ($P > 0.05$) and more attractive ($P < 0.05$) than

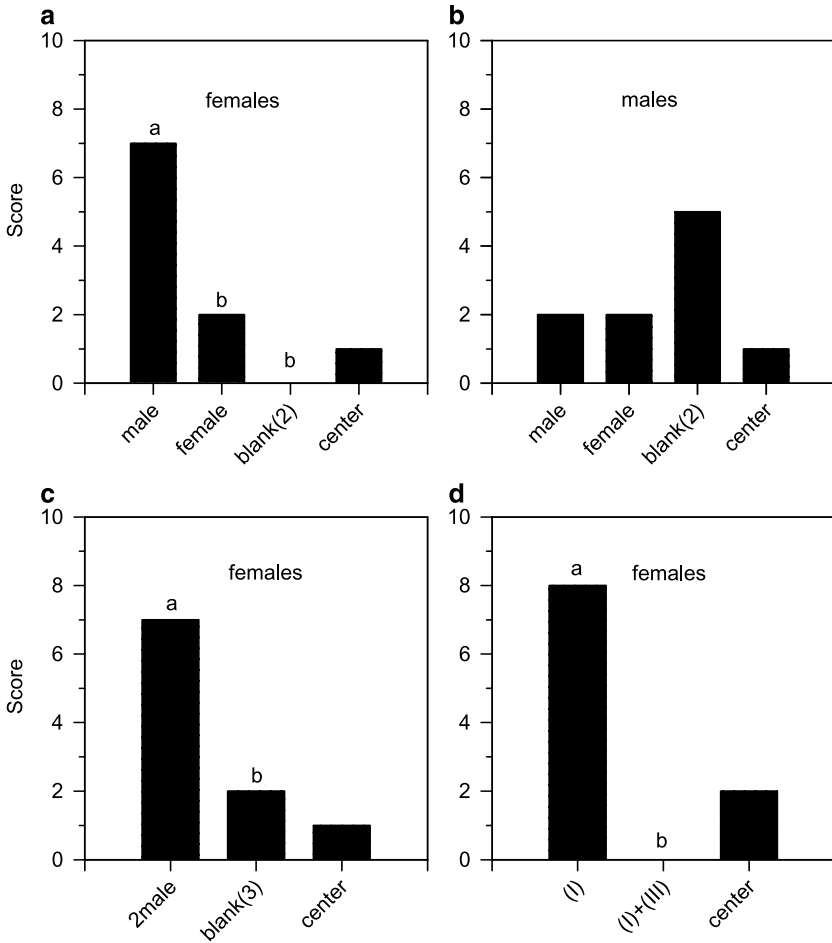

FIG. 8. Responses of female and male *X. quadripes* beetles in swastika bioassay to natural and synthetic sources of pheromone (each figure shows scores for 10 replicates; scores with different letters are significantly different, $P < 0.05$).

no lure or the 10:1 mixture of **I** and (*S,R,S*)-2,3-dihydroxyoctane (**III**). Mean levels of attraction of the latter two were not different ($P > 0.05$).

Field Trials. In a preliminary field test, the sachet dispensers were found to be inconvenient to use because the rapid release rate meant that the 100- μ l loading was exhausted within 7 d under field conditions. Polyethylene vial dispensers were used in all the experiments described here. In field tests during October–December 1997, delta and cross vane traps were compared directly.

FIG. 9. Attraction of female *X. quadripes* beetles in a tube bioassay to natural and synthetic sources of pheromone (mean distance in meters \pm SE for 10 replicates; means with different letters are significantly different ($P < 0.05$) after transformation of means to arcsin, ANOVA, and DMRT).

The racemic mixture and the separate *S* and *R* enantiomers of 2-hydroxy-3-decanone (**I**) were dispensed from polyethylene vial dispensers. No beetles were caught in the delta traps, and results with cross-vane traps are shown in Table 2. There were significant differences in catches of female *X. quadripes* by the different treatments (Kruskal–Wallis H statistic = 9.77, $df = 3$, $P = 0.02$). Catches were higher in traps baited with (*S*)-2-hydroxy-3-decanone (**I**) or the racemic *RS* mixture than in traps baited with the *R* enantiomer or in unbaited traps ($P < 0.05$). (*R*)-2-Hydroxy-3-decanone showed some attractiveness ($P < 0.05$), although the catches observed may have been due to the small amount of the *S* enantiomer (approximately 1%) present in the material used. Similar

numbers of male *X. quadripes* were caught in baited and unbaited traps. Small numbers of other, unidentified cerambycid beetles were also captured.

Field trials carried out during April–May 1998 compared catches in cross-vane traps baited with (S)-2-hydroxy-3-decanone (I) with those in unbaited traps. Combined results from sites in and around the Central Coffee Research Institute are shown in Table 3. Catches of female *X. quadripes* were higher in the baited than in the unbaited traps (Mann–Whitney $U = 9.00$, $P = 0.05$). Catches of male *X. quadripes* were low and numerically higher in the unbaited than the baited traps. During this time of the year, larger numbers of another cerambycid were caught at all sites in the baited traps (Mann–Whitney $U = 9.00$, $P = 0.05$), and these were identified as *Demonax balyi* Pascoe. Examination of the catch of 21 beetles from one trap showed 19 females and 2 males ($\chi^2 = 13.76$, $df = 1$, $P < 0.001$), the females being clearly distinguishable by their prominent ovipositor.

Trials held later in 1998 were set up to investigate the effect of adding 10% of the minor pheromone component, (S,S)-2,3-dihydroxyoctane (III) to the major component (I). Combined results from four sites in Karnataka and two in Tamil Nadu are shown in Table 4. More female beetles were caught in traps

TABLE 4. CATCHES^a OF *X. quadripes* BEETLES IN CROSS-VANE TRAPS BAITED WITH (S)-2-HYDROXY-3-DECANONE (I) OR A BLEND OF I WITH 10% (S,S)-2,3-DIHYDROXYOCTANE (III) AT SIX SITES IN INDIA (NOVEMBER 1998–JANUARY 1999)

Lure	No. trap days	Females		Males	
		Total	Mean/trap \pm SE	Total	Mean/trap \pm SE

I + III	758	6 b	0.50 \pm 0.26	1	0.08 \pm 0.08
Unbaited	758	1 b	0.08 \pm 0.08	0	0.08 \pm 0.08

^aCatches within a column followed by a different letter are significantly different ($P < 0.05$) by Kruskal–Wallis H test.

baited with the major pheromone component (**I**) alone than in traps baited with the blend or unbaited traps (Kruskal–Wallis H -statistic = 8.51, $df = 2$, $P = 0.01$). Catches of male beetles in traps baited with **I** or the blend were similar to those in unbaited traps (Kruskal–Wallis H -statistic = 0.82, $df = 2$, $P = 0.66$).

DISCUSSION

Pheromone Identification. As previously reported (Hall et al., 1998), the major component in volatiles from male *X. quadripes* beetles from India eliciting an EAG response from antennae of female beetles was (*S*)-2-hydroxy-3-decanone (**I**), and this was confirmed by Rhains et al. (2001a) using insects from China. However, in collections from Indian insects this compound represented up to 90% of the volatile materials and was produced at up to 2 $\mu\text{g hr}^{-1}$ beetle⁻¹, whereas the GC traces shown in Rhains et al. (2001a) contained at least six other peaks of similar size to the major component.

GC analysis with splitless or split injection of natural or synthetic 2-hydroxy-3-decanone produced variable amounts of the isomeric 3-hydroxy-2-decanone (**II**), although this did not elicit a response from female beetles in GC-EAG analyses. Rhains et al. (2001a) reported that this isomerization did not occur with cool, on-column injection and that this isomer is not produced by the male beetle. However, the ¹H NMR spectrum of crude material from the Indian insects showed a signal corresponding to this isomer integrating at approximately 7% of the major isomer, suggesting that 3-hydroxy-2-decanone was naturally produced or isomerized during the collection process.

Neither 2-hydroxy-3-decanone (**I**) nor 3-hydroxy-2-decanone (**II**) has previously been reported from insects although analogues are produced by other cerambycid species. The eight-carbon analogue of **I**, (*S*)-2-hydroxy-3-octanone, is produced by males of the grape borer, *X. pyrrhoderus* Bates (Iwabuchi, 1982; Sakai et al., 1984), and the mulberry borer, *X. chinensis* Chevrolat (Kuwahara et al., 1987; Iwabuchi et al., 1987). A six-carbon analogue of **II**, (*R*)-3-hydroxy-2-hexanone, is produced by the old house borer, *Hylotrupes bajulus* L. (Fettköther et al., 1995), *Pyrrhidium sanguineum* L. (Schröder et al., 1994), and *Anaglyptus subfasciatus* Pic. (Leal et al., 1995). The latter species also produces the eight-carbon analog, (*R*)-3-hydroxy-2-octanone (Leal et al., 1995).

The Indian insects were shown to produce a third component that caused at least as large an EAG response from females as the major component in GC-EAG analyses, although it was only present at approximately 7% of the major component. This was identified as (*S,S*)-2,3-dihydroxyoctane (**III**), found previously as the major component in volatiles from male *X. pyrrhoderus* (Iwabuchi, 1982; Sakai et al., 1984). This was not reported by Rhains et al.

(2001a), although it would have eluted before the major component in their analyses. These authors did find a second component present in relatively small amounts but highly EAG-active, and this was identified as 2,3-decanedione. This compound was present at approximately 2% of the major component (**I**) in volatiles from Indian insects. Small amounts [0.2–0.5% of the major component (**I**)] of 2-hydroxy-3-octanone were also detected, but neither of these two compounds elicited an EAG response from female *X. quadripes* in GC-EAG analyses.

Synthesis. At least three syntheses of (*S*)-2-hydroxy-3-octanone have been reported, but these were not suitable for large-scale production of 2-hydroxy-3-decanone (**I**), because of the unavailability of starting materials (Mori and Otsuka, 1985) or low yields (Bel-Rhlid et al., 1989). Sakai et al. (1984) reported the synthesis of 2-hydroxy-3-octanone from lactic acid without any details, but it was thought that this could provide a good route to **I** from readily available starting materials. Numerous attempts to react heptyl lithium with free (*S*)-lactic acid under a variety of conditions in a range of solvents failed to give any significant quantity of the desired product. However, protection of the hydroxyl group and hydrolysis of the ester followed by reaction with heptyl lithium in diethyl ether and deprotection gave the desired product (**I**).

Initially, it was considered that the deprotection step should be as mild as possible to avoid isomerization of **I** to **II**, and the benzyl protecting group was selected ($R_1 = \text{benzyl}$ in Figure 1). The reaction scheme proceeded well, the benzyl group being put on with sodium hydride and benzyl bromide in THF at room temperature and removed smoothly by hydrogenation over palladium on charcoal in ethanol. However, the product (**I**) was essentially racemic, and examination of intermediates by chiral GC showed that the starting (*S*)-ethyl lactate was optically pure but that conversion to the benzyl ether had caused racemization. However, use of the tetrahydropyranyl or *tert*-butyldimethylsilyl protecting groups gave (**I**) without any significant racemization, the former being favored because the reagents were cheaper and yields higher. A further useful modification of the procedure involved hydrolysis of the protected ester with one equivalent of lithium hydroxide in aqueous ethanol and isolation of the lithium salt. In the case of the tetrahydropyranyl-protected derivative, the lithium salt was a white amorphous solid, and this reacted with one equivalent of heptyl lithium rather than the two equivalents that would be required for the free acid.

Several multistep syntheses of (*S,S*)-2,3-dihydroxyoctane (**III**) have been reported (Mori and Otsuka, 1985; Bel-Rhlid et al., 1989; Chattopadhyay et al., 1990; Kang et al., 1990; Bonini and Righi, 1992; Takahata et al., 1994; Bonini et al., 1995; Paolucci et al., 1995), but a single-step synthesis applicable to both enantiomers was used in this work. Reaction of (*E*)-2-octene with the Sharpless reagents “AD-mix- α ” or “AD-mix- β ” in *tert*-butyl alcohol in the presence of

methanesulfonamide (Sharpless et al., 1992) gave (*S,S*)- or (*R,R*)-2,3-dihydroxyoctane (**III**), respectively, in 91% yield. Both compounds were completely free ($\leq 0.2\%$) of *erythro* diastereoisomers by GC analysis. Conducting the reaction at room temperature for 15 hr gave product with 90% ee, although this could probably be improved further. An analogous synthesis of the enantiomers of 2,3-dihydroxyhexane was recently described by Lacey et al. (2004).

Behavioral Bioassays. Attraction of female *X. quadripes* to male beetles or synthetic lures was demonstrated with crawling insects in swastika or tube bioassays in the laboratory. Attempts to carry out bioassays with a large wind tunnel, a similar swastika bioassay, or in cages under field conditions in India were less successful, although mating was observed as described by Venkatesha et al. (1995) and Rhainds et al. (2001a). These observations were consistent with those of Rhainds et al. (2001a), who were able to demonstrate weak attraction of female *X. quadripes* to natural or synthetic pheromone in a room or field cage but only by introducing large numbers of insects and after patient and detailed observations. These authors reported that mating on the ground was common, providing a possible explanation why bioassays with crawling beetles were more successful than those with flying beetles.

We also demonstrated the attraction of female *X. quadripes* beetles to synthetic lures in the field. The (*S*)- or racemic (*RS*)-2-hydroxy-3-decanone was attractive, but addition of (*S,RS*)- or (*S,S*)-2,3-dihydroxyoctane (**III**) at 10% of **I** reduced attractiveness in laboratory bioassays and field trapping trials, respectively. However, numbers trapped were extremely low. Rhainds et al. (2001a) essentially failed to trap any beetles in field tests using multifunnel or delta traps, although beetles were trapped in the funnel traps during the laboratory tests, presumably with much higher population densities. Rhainds et al. (2001a) suggested that our field trapping results (Hall et al., 1998) were attributable to higher population densities or favorable positioning of traps. Unfortunately, no independent estimations of population are available that can be compared with those of Rhainds et al. (2001a), but these were not thought to be particularly high, and traps were positioned at random. The most likely explanation for the difference in results is that we used much larger, sticky cross-vane traps, consistent with the mating behavior described by Venkatesha et al. (1995) and Rhainds et al. (2001a), in which females are attracted to the vicinity of males after which short range chemical or visual signals probably take over. Similar conclusions were reached by Morewood et al. (2002), who reported that cross-vane traps with a large silhouette were more effective than multifunnel traps for trapping cerambycid beetles.

Although small numbers of male insects were also trapped in these trials, numbers were not significantly different than those in unbaited traps. Thus, the pheromone of *X. quadripes* must be considered as a sex pheromone, similar to those in other *Xylotrechus* species (Iwabuchi, 1982; Iwabuchi et al., 1987).

Lacey et al. (2004) recently reported production of an aggregation pheromone by males of *Neoclytus acuminatus acuminatus*, a Cerambycid belonging to the same subfamily and tribe as *X. quadripes*—Cerambycinae and Clytini, respectively. Lacey et al. (2004) did not test the natural pheromone, but the synthetic pheromone attracted significant numbers of both females and males, generally more of the former than the latter.

Trials are in progress in India to determine whether pheromone traps can cause any reduction in damage by *X. quadripes*, but, as suggested by Rhainds et al. (2001a), the chances of success at a cost-effective density would not seem to be high unless the effectiveness of the traps can be improved. Because adult *X. quadripes* do not feed (Visitpanich, 1994; Venkatesha et al., 1995 and observations of the authors), addition of feeding attractants as used with *A. subfasciatus* (Nakamuta et al., 1997) is probably not an option. Addition of oviposition attractants described by Rhainds et al. (2001b) would not be expected to have much effect in coffee plantations where these odors must be in abundance. However, the field studies reported here were limited in that only a single blend of the two EAG-active components was tested, and the effects of other potential pheromone components such as the 2-hydroxy-3-octanone and 2,3-decanedione were not evaluated. Thus, possibilities exist for optimizing the pheromone blend, the pheromone release rate, and the trap design in relation to mating behavior.

Acknowledgments—This publication is an output from research projects (R6928 and 7246) funded by the United Kingdom's Department for International Development (DFID). However, DFID accepts no responsibility for any information provided or views expressed. *Demonax balyi* beetles were identified by the CABI Identification Service.

Abstract—Pheromone gland extracts of the Australian guava moth *Coscinoptycha improbana* (Lepidoptera: Carposinidae), contained four compounds that elicited responses from male moth antennae in gas chromatography-electroantennogram detection (GC-EAD) analyses. These were identified by GC-mass spectrometry as (Z)-7-tricosene (Z7-23Hy), (Z)-7-octadecen-11-one (Z7-11-one-18Hy), (Z)-7-nonadecen-11-one (Z7-11-one-19Hy), and (Z)-7-tricosen-11-one (Z7-11-one-23Hy) at a ratio of 65:23.5:1.5:10, respectively. Z7-23Hy, Z7-11-one-18Hy, and Z7-11-one-23Hy have not previously been reported as lepidopteran sex pheromone components. Z7-11-one-18Hy was active as a single component, and was synergized by Z7-11-one-23Hy but not Z7-11-one-19Hy, although the latter compound was weakly attractive as a single component. Addition of Z7-23Hy further increased attraction. The amount of the major pheromone component, Z7-11-one-18Hy in female pheromone gland extracts was estimated to be 16.4 ng/female ($N = 8$).

Phenological data gathered over a 12-mo period in 2002 and 2003 using the binary blend indicated that moths are active throughout the year. The pheromone has already been employed to monitor the spread of *C. improbana* in New Zealand and detect its presence in Queensland, Australia.

Key Words—Australian guava moth, *Coscinoptycha improbana*, carposiniidae, lepidoptera, (Z)-7-tricosene, (Z)-7-octadecen-11-one, (Z)-7-nonadecen-11-one, (Z)-7-tricosen-11-one, trapping trials, phenology.

INTRODUCTION

The Australian guava moth, *Coscinoptycha improbana* (Meyrick 1881), has recently invaded Northland, New Zealand, where it has rapidly developed significant pest status in several subtropical crops. The larvae are known to infest a range of fruits including mandarins and lemons (Rutaceae), plums, peach, nashi pears, and loquats (Rosaceae), guavas and feijoas (Myrtaceae), and macadamias (Proteaceae) (Jamieson et al., 2004). In its native Australia, the insect ranges from Eungella, Queensland, to Victoria and Tasmania, and also occurs on Norfolk Island (Common, 1990), but is not considered a significant pest. In New Zealand, *C. improbana* has been detected in commercial feijoa, macadamia, and plum orchards and is now a serious pest of macadamias and feijoas in Northland (Jamieson et al., 2004). Therefore, it was important to develop a system to monitor its phenology and likely rate of spread in New Zealand. The sex pheromone of *C. improbana* could be used for monitoring and possibly for pest management. The objective of this study was to characterize the pheromone of *C. improbana*.

Sex pheromones have been identified for only two carposinid moth species (El-Sayed, 2006). The pheromone of the peach fruit moth, *Carposina sasakii* (= *C. niponensis*), is either a mixture of (Z)-7-eicosen-11-one (Z7-11-one-20Hy) and (Z)-7-nonadecen-11-one (Z7-11-one-19Hy) (Tamaki et al., 1977; Honma et al., 1978) or the single component (Z)-7-eicosen-11-one (Z7-11-one-20Hy) (Shirasaki et al., 1979; Han et al., 2000). The pheromone of the New Zealand raspberry budmoth, *Heterocrossa rubophaga*, apparently consists of a single component, Z7-11-one-19Hy (Foster and Thomas, 2000). We report here the chemical identification of sex pheromone components for *C. improbana*, including the alkene (Z)-7-tricosene (Z7-23Hy) and three homologous mono-unsaturated ketones (Z)-7-octadecen-11-one (Z7-11-one-18Hy), Z7-11-one-19Hy, and (Z)-7-tricosen-11-one (Z7-11-one-23Hy).

METHODS AND MATERIALS

Insects. Ripening feijoa and macadamia infested with *C. improbana* larvae were collected from trees in Kaitaia and Mangonui in the Far North in April

2001 and from Kerikeri in 2002 and 2003. These were placed in 2-l containers on a layer of sawdust and kept at room temperature. Larvae emerged from the fruit and pupated in the sawdust. Pupae were shipped individually to quarantine facilities at Lincoln in sealed plastic containers (Lily[®] 35 ml portion cups with lids; Huhtamaki Henderson Limited, Auckland, N.Z.). Pupae were kept in the laboratory at room temperature in 6-cm plastic Petri dishes until emergence when they were sexed. Females had their pheromone glands excised and extracted, whereas males were used for coupled gas chromatography-electroantennogram analysis (GC-EAD). Male *C. improbana* have a raised tuft of silky white scales toward the base of the forewing (Hoare, 2001), which aided sex determination.

Pheromone Gland Extracts. All *C. improbana* gland extracts used for GC-EAD and GC-MS analysis were taken from 24- to 48-hr-old females at 1–2 hr into the scotophase. For quantitative analysis, the pheromone glands of eight females were extracted with a 50- μ l aliquot of *n*-hexane containing 50 ng of octadecane as an internal standard. This extract was held at 4°C for 12 hr before analysis.

Chemicals. Z7-11-One-18Hy, Z7-11-one-19Hy (both >97% isomerically pure), and Z7-11-one-23Hy (83% isomerically pure by gas chromatography) were purchased from Pherobank (Wageningen, The Netherlands). Z7-11-One-20Hy (97% isomerically pure) was provided by Shin-Etsu Chemical Co. Ltd. (Tokyo, Japan). Z7-23Hy and E7-23Hy (both >98% isomerically pure) were synthesized at HortResearch, Palmerston North (see below). (Z)-9-Tricosene (Z9-23Hy) (97%), octadecane (99%), and a straight chain hydrocarbon standard mixture for GC were purchased from Sigma-Aldrich.

Synthesis of (Z)-7-Tricosene (Z7-23Hy). *n*-Butyl lithium (4.7 ml, 7.5 mmol, 1.6 M in hexane) was added, under N₂, to a solution of 1-octyne (0.75 g, 6.8 mmol) in dry THF (50 ml) at –70°C. The solution was allowed to warm to 0°C, and bromopentadecane (2.0 g, 6.8 mmol) was added, followed by Bu₄NI (0.25 g, 0.68 mmol). The reaction was refluxed gently for 3 hr. Saturated aqueous NH₄Cl (30 ml) was added, and the organic phase was separated. The aqueous layer was extracted with diethyl ether (2 × 30 ml). After drying over MgSO₄, the solvent was removed under reduced pressure. The crude product was purified by using silica gel chromatography (petroleum ether) yielding 873 mg, (38%) of 7-tricosyne. This was reduced in MeOH (25 ml) using 10% palladium on charcoal (30 mg) and a balloon of H₂, for 24 hr at room temperature. After filtration, the product was purified by using silica gel chromatography (petroleum ether) yielding (Z)-7-tricosene as an oil (296 mg, 35%). ¹H NMR (CDCl₃, 400 MHz): δ 5.35 ppm (2H, m), 2.02 (4H, m), 1.26 (34H, m), 0.89 (6H, m) ppm. ¹³C NMR (CDCl₃, 125 MHz): δ 129.89, 129.88, 31.95, 31.81, 29.79, 29.76, 29.73 (6 carbons), 29.69 (2 carbons), 29.59, 29.39, 29.34, 29.02, 27.22, 22.72, 22.69, 14.13, 14.12 ppm.

Synthesis of (E)-7-Tricosene (E7-23Hy). Synthesis of (*E*)-7-tricosene was carried out using the Wittig reaction (Wittig and Schoellkopf, 1973). Hexadecylphosphonium bromide was prepared by refluxing bromohexadecane (10 g, 32.8 mmol) and triphenyl phosphine (7.87 g, 30 mmol) in benzene (45 ml) for 48 hr. The solvent was removed *in vacuo* to give a pale yellow oil that was refrigerated for 24 hr. The resulting solid was triturated with diethyl ether (2 × 50 ml) to give a white solid (8.8 g, 15.5 mmol, 52%). *n*-Butyl lithium (4.3 ml, 6.88 mmol, 1.6 M in hexane) was added to a suspension of hexadecylphosphonium bromide (3.6 g, 6.34 mmol) in diethyl ether (30 ml), and the resultant solution was stirred for 2 hr before adding heptanal (1.39 ml, 9.96 mmol) and refluxing 1 hr. The mixture was cooled to room temperature, filtered through celite, and rinsed with ether (2 × 50 ml). The filtrate was washed with water until the pH tested neutral, then dried over magnesium sulfate, and concentrated. The crude product was purified by column chromatography on silica gel (petroleum ether) to give a mixture of both isomers as a colorless oil (1.33 g, 4.43 mmol, 70%, 4:1 *Z/E*). The isomers were separated on silica gel impregnated with 30% silver nitrate eluting with 0.5% diethylether/petroleum ether, yielding each of the isomers in >98% isomeric purity. (*E*)-7-Tricosene ¹H NMR (CDCl₃, 400 MHz): δ 5.39 (2H, m), 1.97 (4H, m), 1.26 (34H, m), 0.89 (6H, m). ¹³C NMR (CDCl₃, 125 MHz): δ 130.30, 130.28, 32.32, 32.18, 30.16, 30.14, 30.10 (8 carbons), 30.06, 29.96, 29.77, 29.71, 29.39, 23.09, 23.06, 14.53, 14.52 ppm.

Gas Chromatography-Electroantennographic Detection. Pheromone gland extracts of *C. improbana* females were analyzed by GC-EAD using a Varian 3800 gas chromatograph with a splitless injector, coupled to an EAD Recording Unit (Syntech, Hilversum, The Netherlands). The injector and detector temperatures were 220 and 300°C, respectively. Samples were run on a ZB-5 (Phenomenex, Torrance, CA, USA) capillary column (30 m × 0.25 mm ID × 0.5 μm film) and a polar BPX70 (SGE, Victoria, AU) column (30 m × 0.25 mm ID × 0.25 μm film) provided with 1:1 split outlets with helium carrier gas (1 ml/min). The GC oven was programmed from 80°C/1 min to 240°C at 10°C/min and held for 15 min. An excised male *C. improbana* antenna was positioned between two glass electrodes, containing BE Ringer's solution with 10% polyvinylpyrrolidone (molecular weight = 360,000) (Sigma). Each glass electrode held a length of 1 mm silver wire to connect the preparation to the recording unit. The EAD exit port temperature was maintained at 200°C and the antennal preparation was placed in a charcoal filtered and humidified airstream (500 ml/min).

Gas Chromatography-Mass Spectrometry. Pheromone gland extracts were analyzed by GC-MS using three instruments. Initial analyses of gland extracts and comparison of these with synthetic compounds were carried out on a Hewlett-Packard (HP) 5890 GC, coupled to a VG-70SE magnetic sector mass spectrometer (VG Instruments, Manchester, UK). Later analyses were performed on an HP 5890 Series II Plus GC interfaced to an HP 5792

quadrupole mass spectrometer. Either an HP-Innowax column (30 m × 0.25 mm i.d. × 0.25 µm film) (Agilent, Palo Alto, CA, USA) or a BPX-70 column (30 m × 0.25 mm i.d. × 0.25 µm film) (SGE, Victoria, AU), was used in the first instrument (both columns, 80°C/2 min to 200°C at 20°C/min, then from 200 to 220°C at 10°C/min). The second instrument was fitted with a 30 m × 0.25 mm i.d. × 0.25 µm film ZB-Wax column (Phenomenex), and was used to compare retention times of *Z* and *E* isomers of the synthetic ketones with those of the natural pheromone components. Temperature programs of 80°C/2 min to 220°C at 5°C/min (for *Z7-11-one-18Hy* and *Z7-11-one-19Hy*) and 80°C/2 min to 230°C at 5°C/min (for *Z7-11-one-23Hy*) were used for this GC-MS. Both instruments were operated in EI mode (70 eV). Injections were splitless, using He carrier gas with a constant linear velocity of 30 cm/sec.

The third instrument (a Varian 3800 GC in splitless injection mode interfaced to a Varian 2200 MS with a VF-5ms column (30 m × 0.25 mm i.d. × 0.25 µm film) (Varian) was used for analyzing the adducts formed during dimethyldisulfide (DMDS) derivatizations of *Z7-23Hy* and *E7-23Hy* (both 10 ng in 20 µl *n*-hexane), and comparing their retention times and spectra with the adduct formed by DMDS derivatization of a 17 female pheromone gland extract of *C. improbana*. In addition, a 10 female pheromone gland extract of *C. improbana*, was compared with standards of *Z9-23Hy*, *Z7-23Hy*, and *E7-23Hy*. Injector 220°C, program 80°C/1 min to 200°C at 5°C/min and held for 3 min, then increased to 240°C at 2°C/min and held for 5 min. For the DMDS derivative analyses, the injector temperature was set at 220°C, and the GC oven was programmed from 100°C/1 min to 260°C at 10°C/min and held for 33 min.

Dimethyldisulfide Derivatizations. For DMDS derivatizations, we followed the procedure described by Buser et al. (1983) and Leonhardt and DeVilbiss (1985). Approximately 50 µl DMDS and 5 µl iodine solution (60 mg of I₂ in 1 ml of diethyl ether) were added to the solution of interest in a 1.8-ml glass vial, sealed with a Teflon-lined cap, and held at 40°C for 15 hr. The reaction was quenched with 50 µl 5% aqueous sodium thiosulfate, and the organic layer was dried with anhydrous sodium sulfate, and transferred to a clean 1.5-ml tapered-bottom vial, and blown down with a stream of argon to approximately 10 µl. A 1-µl aliquot [ca. 1.7 female equivalents (FE)] was immediately analyzed by GC-MS.

Isomerization of Synthetic Z7-11-one-18Hy. This was achieved by modifying the methods described by Ferreri et al. (2001) and Sgoutas and Kummerow (1969). Four µl of a 0.04 M solution of *Z7-11-one-18Hy* in *n*-heptane were added to 8 µl of 2-mercaptoethanol and 1 µl of azobisisobutyronitrile (AIBN) in a 2-ml vial flushed with N₂. This was capped and heated to 74°C for 48 hr, then diluted in 1 ml of *n*-heptane for GC-MS analysis.

Trapping Trials. Five trapping trials were carried out at Kerikeri (lat. 35.23°S, long. 173.95°E), Northland, NZ, during 2003 and 2004. Trial 1 was undertaken in

an organic macadamia orchard, whereas trials 2–5 were carried out in both a macadamia orchard and a feijoa orchard. In all trials, delta traps were attached to individual trees at a height of 1.5 m, with 10 m spacing between treatments and ca. 15 m spacing between replicates. Test compounds were loaded onto red rubber septa (Thomas Scientific Inc., Philadelphia, PA, USA), lures were replaced every 6 wk, and sticky trap inserts were replaced every week. Trap positions within each replicate were randomized weekly when trap catches were recorded. Pheromone blend ratios tested were based upon ratios found in pheromone gland extracts.

An initial trapping trial (April 10–June 20, 2003) tested Z7-11-one-18Hy and Z7-11-one-19Hy alone or in various combinations, including the 95:5 ratio present in pheromone gland extracts. Treatments were as follows: (1) a blank control, (2) 1000:0, (3) 990:10, (4) 950:50, (5) 900:100, (6) 500:500, and (7) 0:1000 μg loadings of Z7-11-one-18Hy and Z7-11-one-19Hy ($N = 5$).

A second trial (October 6–November 4, 2003, $N = 6$) tested the effects of addition of varying amounts of Z7-11-one-23Hy, to a 300- μg lure of Z7-11-one-18Hy and Z7-11-one-19Hy (95:5). Treatments were as follows: (1) a blank control, (2) 285:15:0, (3) 285:15:13.3, (4) 285:15:40, and (5) 285:15:120 μg loadings of Z7-11-one-18Hy, Z7-11-one-19Hy, and Z7-11-one-23Hy.

A third trial (November 14, 2003–January 9, 2004, $N = 6$) compared the best two-component lure from trial 1 (treatment 4) with various combinations of the three monounsaturated ketones. Treatments were as follows: (1) a blank trap as the control, (2) 950:50:0, (3) 670:40:290, (4) 700:0:300, (5) 0:120:880, and (6) 0:0:1000 μg loadings of Z7-11-one-18Hy, Z7-11-one-19Hy, and Z7-11-one-23Hy.

A fourth trial (February 11–May 7, 2004, $N = 6$) tested different doses of the best ternary blend (treatment 3 from trial 3). Treatments were as follows: (1) a blank control, (2) 20.1:1.2:8.7, (3) 67:4:29, (4) 201:12:87, (5) 670:40:290, and (6) 2010:120:870 μg doses of Z7-11-one-18Hy, Z7-11-one-19Hy, and Z7-11-one-23Hy.

A fifth trial (October 1–November 19, 2004, $N = 6$) tested the effect of addition of Z7-23Hy to the ternary blend. Treatments were as follows: (1) a blank control, (2) 670:40:290:0, (3) 950:50:0:0, (4) 250:0:0:750, and (5) 235:15:100:650 μg doses of Z7-11-one-18Hy, Z7-11-one-19Hy, Z7-11-one-23Hy, and Z7-23Hy.

Phenology. Three delta traps baited with septa loaded with 300 μg of a 95:5 ratio of Z7-11-one-18Hy and Z7-11-one-19Hy, were deployed in two macadamia orchards (HortResearch's orchard and Welch's organic orchard), from January 2002 to January 2003, to monitor the weekly catch of *C. improbana* male moths. Pheromone lures were replaced every 6 wk.

Statistics. All trapping data were analyzed by ANOVA (SAS Institute Inc., 1998). Residual plots were used to check the validity of the ANOVA assumptions. Square root transformations were undertaken when necessary. Means were compared by Fisher's Protected Least Significant Differences test (SAS Institute Inc., 1998).

RESULTS

Identification of Pheromone Components. GC-EAD analysis of *C. improbana* pheromone extracts (Figure 1) identified four compounds that repeatedly elicited responses from antennae of male moths. The greatest responses were elicited by compound **2**. Antennae of males also responded well to Z7-11-one-19Hy (the pheromone for *H. rubophaga*). This ketone had the same retention time as that of active compound **3** in the gland extracts on both ZB-5 and BPX-70 columns. Whereas male antennae gave a small response to Z7-11-one-20Hy (the major pheromone component for *C. sasakii*), no antennal response or peak was observed from gland extracts at the expected retention time for this compound. The ratio of compounds **1–4** in gland extracts was 65:23.5:1.5:10, respectively, with the amount of the major active compound **2** calculated to be 16.4 ng/female ($N = 8$).

FIG. 1. Male *C. improbana* antennal responses (EAD) to compounds in female moth pheromone gland extracts, eluting from a BPX-70 GC column (FID).

GC-MS analysis of a 2 FE aliquot of *C. improbana* pheromone gland extract showed several peaks for straight chain alkanes and alkenes including heneicosane, tricosane, and a tricosene (largest peak in total ion chromatogram; m/z (relative intensity) 322 (15, M^+), 294 (2), 125 (21), 111 (42), 97 (82), 83 (83), 69 (78), 55 (100), 43 (95), HP 5792 spectrometer, 70 eV), the latter corresponding to EAD-active compound **1**. Whereas the spectrum of compound **1** in the 10 FE extract was similar to that of Z9-23Hy, its retention time was longer on the VF-5ms column [Kováts retention indices (KI) of 2277 and 2270, respectively]. Analysis of a DMDS derivatized aliquot of the 17 FE extract on the VF-5ms column showed a large peak with a parent ion at m/z 416 and diagnostic ions at m/z 145 and 271 (base peak), indicating the addition of DMDS to a tricosene with a double bond at position 7. In addition, the retention time and spectrum of the tricosene in the 10 FE extract was identical with that of synthetic Z7-23Hy rather than E7-23Hy (KI = 2279 and 2284, respectively). Comparison of retention times of the adducts formed from DMDS-derivatized synthetic tricosenes, with those of the derivatized tricosene in the gland extract, corroborated that **1** was Z7-23Hy rather than E7-23Hy (KI = 2931 and 2935, respectively).

FIG. 2. Electron impact ionization mass spectrum (HP 5792 spectrometer at 70 eV) of Z7-11-one-18Hy, compound **2** in Figure 1.

There was also a major peak in the 2 FE gland extract with a mass spectrum containing a parent ion at m/z 266, and ions at m/z 195, 182, 167, 127, and 124 (Figure 2), which corresponded to EAD-active compound **2**. A relatively small peak corresponding to EAD-active compound **3** had a parent ion at m/z 280, and ions at m/z 141 (base peak) and 167, similar to the mass spectrum for *Z*7-11-one-19Hy reported by Foster and Thomas (2000) and Tamaki et al. (1977). Comparison with the synthetic standard of *Z*7-11-one-19Hy showed that they had identical mass spectra and retention times on HP-Innowax and BPX-70 columns.

A third major peak in the TIC of the 2 FE gland extract, with a retention time equivalent to EAD-active compound **4**, had mass spectral fragments at: m/z 336 (M^+), 197, 195, 182, 167, and 124 (Figure 3). Similarities in the spectra of **2**, **3**, and **4** suggested that they were homologous ketones, with differing chain lengths on the saturated side of the carbonyl group, i.e., Δ 7-11-one-18Hy for **2** and Δ 7-11-one-23Hy for **4**. This was confirmed by comparing the mass spectra of **2** and **4** with those of synthetic *Z*7-11-one-18Hy and *Z*7-11-one-23Hy, respectively, and with published data (Tamaki et al., 1977). The retention times of insect produced **2** and **4** and synthetic *Z*7-11-one-18Hy and *Z*7-11-one-23Hy were identical on the HP-Innowax (for **2**) or ZB-Wax (for **4**), and BPX-70 columns.

FIG. 3. Electron impact ionization mass spectrum (HP 5792 spectrometer at 70 eV) of *Z*7-11-one-23Hy, compound **4** in Figure 1.

To determine whether pheromone components **2–4** were *Z* or *E* isomers (or a mixture), the synthetic samples and gland extract were analyzed by GC-MS using a ZB-Wax column, with a slower temperature program. The *Z*7-11-one-19Hy standard contained approximately 3% of the *E* isomer (KI = 2367 and 2373, respectively), apparent as two peaks in the TIC and the selected ion chromatogram for *m/z* 141. Synthetic *Z*7-11-one-23Hy similarly contained 17% *E*7-11-one-23Hy (KI = 2765 and 2771, respectively). However, the synthetic *Z*7-11-one-18Hy was >99% pure, and any *E* isomer was poorly resolved from *Z*. Therefore, the sample was isomerized using 2-mercaptoethanol and AIBN to give a 2:1 mixture of *Z* and *E*7-11-one-18Hy (KI = 2261 and 2267, respectively). All three of the insect-produced ketones **2–4** had identical retention times to their respective synthetic *Z* isomers on the ZB-Wax column, with no peaks for *E* isomers apparent in the gland extract.

Field Trials. In all trapping trials, residual plots indicated that the analysis of variance assumptions were adequate. Results from trial 1 (Figure 4) established that *Z*7-11-one-18Hy alone was sufficient for attraction of male *C. improbana*, with a total of 84 moths trapped in treatment 2 during the course of the trial. The addition of 1% or 5% of *Z*7-11-one-19Hy did not enhance the trap

FIG. 4. Mean trap catches ($N = 5$) of *C. improbana* male moths with various ratios of *Z*7-11-one-18Hy and *Z*7-11-one-19Hy (1000 μg doses). Trial 1, macadamia orchard, Kerikeri, Northland, New Zealand, April 10–June 20, 2003. Treatments labeled with the same letter are not significantly different ($P > 0.05$).

catch. A 1:1 blend of *Z7-11-one-18Hy* and *Z7-11-one-19Hy* caught fewer moths, and *Z7-11-one-19Hy* alone trapped only a few moths ($N=5$).

In trial 2 (Figure 5), the addition of *Z7-11-one-23Hy* to a 300- μg lure of *Z7-11-one-18Hy* and *Z7-11-one-19Hy*, at a 95:5 ratio (corresponding to the ratio from gland extracts), increased trap catch in both the macadamia and feijoa orchards.

In trial 3 (Figure 6), no moths were trapped in traps baited with only *Z7-11-one-23Hy* (treatment 6), whereas one moth was attracted to the binary blend of *Z7-11-one-23Hy* and *Z7-11-one-19Hy* (treatment 5) in the macadamia orchard. The majority of moths at the macadamia orchard (316 out of 317 moths) and all the moths at the feijoa orchard (128 moths) were caught in traps baited with lures containing *Z7-11-one-18Hy* as one of the components, reinforcing the importance of this compound. The other blends in this trial (*Z7-11-one-18Hy*, *Z7-11-one-19Hy*, *Z7-11-one-23Hy* in ratios of 950:50:0, 670:40:290, and 700:0:300) were equivalent to each other (Figure 6).

In trial 4 (Figure 7), 300-, 1000-, and 3000- μg doses of the ternary ketone blend attracted equivalent numbers of moths in both orchards, whereas doses of 100 and 10 μg trapped fewer males.

FIG. 5. Mean trap catches ($N=6$) of *C. improbana* male moths with 300 μg doses of *Z7-11-one-18Hy* and *Z7-11-one-19Hy*, with and without *Z7-11-one-23Hy*. Trial 2, macadamia and feijoa orchards, Kerikeri, Northland, New Zealand, October 6–November 4, 2003. Treatments labeled with the same letter are not significantly different ($P > 0.05$).

FIG. 6. Mean trap catches ($N = 6$) of *C. improbana* male moths with various combinations of Z7-11-one-18Hy, Z7-11-one-19Hy, and Z7-11-one-23Hy (1000 μg doses). Trial 3, Macadamia and Feijoa Orchards, Kerikeri, Northland, New Zealand, November 14, 2003–January 9, 2004. Treatments labeled with the same letter are not significantly different ($P > 0.05$).

In trial 5 (Figure 8), addition of Z7-23Hy to Z7-11-one-18Hy (treatment 4) appeared to increase trap catch in one orchard but not the other. However, addition of Z7-23Hy to the ternary blend of ketones (treatment 5) increased the numbers of moths trapped in comparison to a higher dose of the ternary ketones blend (treatment 2).

Phenology. Phenological data gathered from January 2002 to January 2003, using the two-component lure of Z7-11-one-18Hy and Z7-11-one-19Hy at a ratio of 95:5, indicated that the adult moth was active throughout the year in an organic macadamia orchard (Figure 9). However, essentially no moths were caught from July to December at the research orchard in Kerikeri.

DISCUSSION

In this paper, we report the identification of four possible pheromone components for the Australian guava moth *C. improbana*. Z7-11-One-18Hy was active as a single component, and in appropriate ratios it was synergized by Z7-11-one-23Hy and Z7-23Hy. Z7-11-One-23Hy was not active alone. Z7-11-One-19Hy, although present in pheromone gland extracts, did not synergize the

FIG. 7. Mean trap catches ($N = 6$) of *C. improbana* male moths to different doses of Z7-11-one-18Hy, Z7-11-one-19Hy, and Z7-11-one-23Hy. Trial 4, macadamia and feijoa orchards, Kerikeri, Northland, New Zealand, February 11–May 7, 2004. Treatments labeled with the same letter are not significantly different ($P > 0.05$).

attraction, and was only slightly attractive as a single component. With the identification of Z7-11-one-18Hy from *C. improbana*, all three carposinids investigated to date have been found to use homologous unsaturated ketones as their sex pheromones, with the major component for each species differing in chain length by one carbon (El-Sayed, 2006). The attractive blends of all three species overlap to some extent. Furthermore, all three species have more than one active component present in the female pheromone gland, but the major component in all cases appears to be adequate for attraction.

Although Z7-11-one-18Hy had not been previously identified from moth pheromone gland extracts, Tamaki et al. (1977) found weak attraction of *C. sasakii* (*C. niponensis*) to synthetic Z7-11-one-18Hy. Removal of Z7-11-one-18Hy from the blend in our study decreased attraction for male guava moths, and it consistently produced the greatest response from male guava moth antennae in GC-EAD studies, indicating that it is the major pheromone component of *C. improbana*.

There was a relatively large amount of Z7-11-one-18Hy in *C. improbana* gland extracts (16.4 ng/female) compared to the major components for the two other carposinids with known pheromones. Foster and Thomas (2000) found an average of 2.5 ng Z7-11-one-19Hy/female in *H. rubophaga*, whereas Tamaki et

FIG. 8. Mean trap catches ($N = 6$) of *C. improbana* male moths to 1-mg doses of binary, ternary, and quaternary combinations of the four possible pheromone compounds identified from female pheromone gland extracts. Trial 5, macadamia and feijoa orchards, Kerikeri, Northland, New Zealand, October 1–November 19, 2004. Treatments labeled with the same letter are not significantly different ($P > 0.05$).

al. (1977) estimated the amount of Z7-11-one-20Hy in the gland extracts of 12,000 *C. sasakii* (*C. niponensis*) to be 18 μg (1.5 ng/female).

Both Z7-11-one-19Hy and Z7-11-one-23Hy alone attracted either few or no male *C. improbana* in our study. Han et al. (2000) found that addition of Z7-11-one-19Hy to Z7-11-one-20Hy had no effect or inhibited attraction of a Korean population of *C. sasakii*, whereas Tamaki et al. (1977) and Honma et al. (1978) reported synergism in a Japanese population of *C. sasakii* (*C. niponensis*) when ca. 5% of Z7-11-one-19Hy was added to a lure containing Z7-11-one-20Hy. However, Shirasaki et al. (1979) was not able to reproduce these results. Similarly, Foster and Thomas (2000) tentatively identified Z7-11-one-20Hy in a New Zealand population of *H. rubophaga* as a minor component, but addition of this compound to the major component (Z7-11-one-19Hy) did not increase trap catch at the ratio tested. In our study, addition of Z7-11-one-19Hy to Z7-11-one-18Hy at various ratios also did not enhance capture of male *C. improbana*.

Tamaki et al. (1977) isolated Z7-11-one-23Hy from female *C. sasakii* (*C. niponensis*) pheromone glands, but were not able to demonstrate any biological activity. In our study, addition of Z7-11-one-23Hy to the binary lure at a dose of

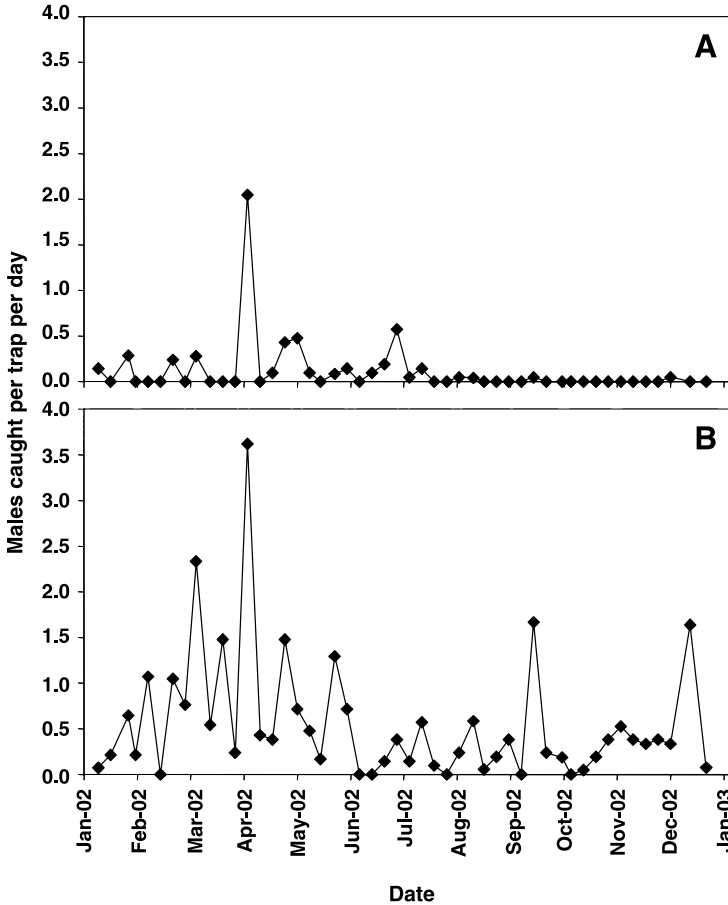

FIG. 9. Flight phenology of male *C. improbana* monitored with 300- μ g doses of a 95:5 blend of Z7-11-one-18Hy and Z7-11-one-19Hy deployed in delta traps from January 2002 to January 2003, in two macadamia orchards [(A) HortResearch Research Station and (B) Welch's organic macadamia orchard] in Kerikeri, Northland, New Zealand.

300 μ g increased the trap catch. However, in a subsequent trial with 1-mg doses, the ternary blend of ketones was no better than the binary blends of either Z7-11-one-18Hy and Z7-11-one-19Hy, or Z7-11-one-18Hy and Z7-11-one-23Hy.

Finally, addition of Z7-23Hy to Z7-11-one-18Hy alone marginally improved attraction, but it had a much larger effect when added to the ternary ketone blend. Whereas Z7-23Hy has previously been reported as a sex pheromone for the rove beetle *Aleochara curtala* (Peschke and Metzler,

1982), this is the first report of this compound as a sex pheromone component for a lepidopteran insect.

We have shown that the quaternary blend of Z7-23Hy, Z7-11-one-18Hy, Z7-11-one-19Hy, and Z7-11-one-23Hy at a ratio of 65:23.5:1.5:10, respectively, is an effective attractant for *C. improbana*, and we recommend the use of this lure for monitoring of *C. improbana*. The pheromone of *C. improbana* has already provided an effective tool for monitoring the phenology and range of this new arrival to New Zealand. Our trapping data, using a binary lure (Figure 9), indicate that the adult moth is active throughout the year. In 2003, 1-mg doses of the same binary lure were used to survey the guava moth's distribution in the Northland region (Jamieson et al., 2004). In addition, both the ternary ketone blend and the quaternary blend have been successfully used in Queensland, Australia, for detection of populations of *C. improbana* (J. Dymock, unpublished data).

Acknowledgments—We thank Stephen Foster for GC-MS analyses. Ashraf M. El-Sayed for review of this manuscript. Eileen Welch, N.H. and A. Le Page, and C.B. and E.J. Searles for the use of their orchards in Kerikeri, Northland, New Zealand, and Geoff Waite for checking traps at Maroochy and Woombye in Queensland, Australia. Shin-Etsu Chemical Co. Ltd. supplied synthetic Z7-11-one-20Hy. Funding was provided by the New Zealand Foundation for Research, Science, and Technology (FRST).

EFFECTIVENESS OF METAL–METAL
AND METAL–ORGANIC COMPOUND COMBINATIONS
AGAINST *Plutella xylostella*: IMPLICATIONS FOR PLANT
ELEMENTAL DEFENSE

Abstract—Plants that contain elevated foliar metal concentrations can be categorized as accumulators or, if the accumulation is extreme, hyperaccumulators. The defense hypothesis suggests that these plants may be defended against folivore attack, and recent research has indicated that metal concentrations at or below the accumulator range may be defensively effective. This experiment explored the toxicity of four metals hyperaccumulated by plants (Cd, Ni, Pb, and Zn) and asked if combinations of metals, or metals and organic chemicals, might broaden the defensive effectiveness of metals. Metals were used alone and in certain metal + metal (Zn plus Ni, Pb, or Cd) and metal + organic defensive chemical (Ni plus tannic acid, atropine, or nicotine) combinations. Artificial diet amended with these treatments was fed to larvae of the crucifer specialist herbivore *Plutella xylostella*. Combinations of metals and metals + organic chemicals significantly decreased survival and pupation rates, compared to single treatments, for at least some concentrations in every experiment. Effects of combinations were additive rather than synergistic or antagonistic. Because Zn enhanced the toxicity of other metals and Ni enhanced the toxicity of organic defensive chemicals, our findings suggest that the defensive effects of metals are more widespread among plants than previously believed. They also support the hypothesis that herbivore defense may have led to the evolution of metal hyperaccumulation by increasing the preexisting defensive effects of metals at accumulator levels in plants.

Key Words—Accumulation, alkaloids, cadmium, elemental defenses, hyperaccumulation, herbivory, lead, metal, nickel, zinc.

INTRODUCTION

Metals such as Ni, Zn, Pb, or Cd may reach high concentrations in soils because of geological processes (Reeves et al., 1981; Brooks, 1987) or industrial contamination (Reeves and Brooks, 1983; Baker and Brooks, 1989, 1994). Plants growing under natural conditions vary in tissue metal concentrations, and this variation can be used to classify them into three broad categories: normal, accumulator, and hyperaccumulator plants (Brooks et al., 1977; Baker, 1981; Baker et al., 2000; Reeves and Baker, 2000). These categories, summarized in Table 1, vary depending on the metal. In general, relatively small concentrations of Cd, Co, or Cr are unusual in plant tissues, whereas much larger concentrations of Mn or Zn are considered unusual. Other metals (Cu, Ni, and Pb) are elevated at levels between these extremes (Table 1).

Plants are defended by a variety of mechanisms, including organic chemicals (Gatehouse, 2002). Tannins, alkaloids, and glucosinolates are examples of organic defensive chemicals (Feeny, 1976; Rhoades and Cates, 1976; Schultz, 1988; Clausen et al., 1992; Agrawal, 2000). Certain elements, such as Si, F, Ni, Zn, Se, and Ca, also may have defensive functions for plants (McNaughton and Tarrants, 1983; Twigg and King, 1991; Boyd, 2004) or algae (Hay et al., 1994). Hyperaccumulated elements can defend against herbivores (Pollard and Baker, 1997; Boyd and Moar, 1999; Hanson et al., 2004) by reducing feeding (Pollard and Baker, 1997; Jhee et al., 1999; Hanson et al., 2004) or survival (Boyd and Martens, 1994; Boyd and Moar, 1999; Hanson et al., 2004). Termed “elemental defenses” by Martens and Boyd (1994), these

TABLE 1. NORMAL RANGE, MINIMUM ACCUMULATOR LEVEL, AND MINIMUM HYPERACCUMULATOR LEVEL FOR METALS OFTEN ACCUMULATED BY PLANTS^a

Metal	Normal range ($\mu\text{g g}^{-1}$)	Minimum accumulator level ($\mu\text{g g}^{-1}$)	Minimum hyperaccumulator level ($\mu\text{g g}^{-1}$)
Cd	0.1–3	20	100
Co	0.03–2	20	1000
Cr	0.2–5	50	1000
Cu	5–25	100	1000
Mn	20–400	2,000	10,000
Ni	1–10	100	1000
Pb	0.1–5	100	1000
Zn	20–400	2,000	10,000

^aNormal range, minimum accumulator level, and minimum hyperaccumulator level refer to tissue concentrations in field-collected plants and follow Reeves and Baker (2000). All values are expressed as $\mu\text{g metal g}^{-1}$ dry mass.

are based on elements taken from soil and sequestered rather than produced by metabolic pathways. Elemental defenses may be advantageous because they cannot be detoxified or degraded by herbivores (Martens and Boyd, 1994), unlike many organic chemicals (e.g., furanocoumarins, Weimin et al., 2003). They also may defend against specialist herbivores that have circumvented an organic chemical defense (e.g., Jhee et al., 2005).

Hyperaccumulator plants occur in many locations and on many soil types (Baker et al., 2000; Reeves and Baker, 2000; Macnair, 2003). Hyperaccumulators of Ni are typically found on ultramafic soils (Brooks et al., 1977; Reeves and Baker, 2000; Iturralde, 2004). Hyperaccumulators of Zn, Pb, and Cd are often found on Pb/Zn mineralized soils or metal polluted soils near mine sites or smelters (Reeves and Brooks, 1983; Baker et al., 2000). At least 418 hyperaccumulator taxa have been discovered, and most of these (318, or 76%) hyperaccumulate Ni (Reeves and Baker, 2000). Some species can hyperaccumulate multiple metals, such as Zn and Cd (Meerts and van Isacker, 1997; Escarré et al., 2000), Zn and Ni (Reeves and Baker, 1984, 2000), Zn and Pb (Meerts and van Isacker, 1997; Baker et al., 2000), Co and Cd (Reeves and Baker, 2000), or Co and Cu (Reeves and Baker, 2000).

Combinations of defensive chemicals can increase plant resistance in two ways. An additive effect of two chemicals can result in a larger combined effect on an herbivore. Compounds may also interact, so that their effects in combination differ from those predicted by adding their individual effects (Nelson and Kursar, 1999). Nelson and Kursar (1999) pointed out that interactions may increase toxicity of compounds in combination (synergism) or may decrease toxicity (antagonism). Most studies of synergism among plant defenses have focused on synergism between organic defenses (e.g., Dyer et al., 2003). Boyd (1998) suggested that multiple elemental defenses, or an elemental defense and an organic defense, may act together to provide greater herbivore resistance than each defense alone. Many Ni hyperaccumulating species belong to families (such as Lauraceae, Rutaceae, Verbenaceae, and Lamiaceae) that possess aromatic substances that may provide resistance to herbivores (Baker et al., 2000; Borhidi, 2001). Many other Ni hyperaccumulators belong to the Brassicaceae, known for production of glucosinolates (Louda and Mole, 1991), or the Rubiaceae, known for alkaloids (Borhidi, 2001). Thus, elemental and organic defenses co-occur in plant species, and together they may be more effective than each alone. Pioneering investigations of defensive effects of combinations of elemental and organic chemicals have been conducted for marine algae (e.g., Hay et al., 1994) but, to our knowledge, the possibility that combination effects contribute to the defensive ecology of metal accumulating or hyperaccumulating plants has yet to be formally addressed. Testing these questions is potentially significant for two reasons. First, combination effects may allow elemental defenses to contribute to plant fitness at concentrations

less than expected based on studies of the defensive effects of a metal alone. This could extend the defensive effects of metals to more plant species than otherwise expected. Second, combination effects (either additive effects or synergy) may have contributed to the evolution of metal accumulation and hyperaccumulation by plants (Boyd, 2004). In this scenario, a plant capable of taking up and tolerating elevated levels of a metal could derive a defensive benefit from that ability at a relatively low metal concentration in its tissues. Further stepwise increases in uptake and tolerance abilities could then be selected for in the population, as a result of differential damage from natural enemies, resulting in still greater levels of elemental defenses. By lowering the level of metal at which a defensive benefit first accrues to a plant, combination effects may help explain the evolution of metal accumulation, and later hyperaccumulation, by plants.

Recently, Coleman et al. (2005) used the diamondback moth (DBM), *Plutella xylostella*, to explore the boundaries of defensive effects of eight metals (Cd, Co, Cr, Cu, Mn, Ni, Pb, and Zn) often accumulated by plants (Reeves and Baker, 2000). They found that all metals were toxic to DBM larvae at hyperaccumulator levels. However, all also were toxic to larvae at accumulator concentrations. Five metals (Cd, Mn, Ni, Pb, and Zn) were toxic below accumulator levels, Cd and Pb were toxic near the concentration ranges of normal plants, and Zn was toxic at a concentration within the normal range. Their results indicated that single metals may be effective at concentrations far lower than previously hypothesized.

This study tests the hypothesis that combinations of metals, or combinations of metals and organic defense chemicals, have greater defensive effects than each compound alone. If this is the case, then defensive effects of metals in plants may be more extensive than previously proposed (Coleman et al., 2005). We used DBM as a bioassay herbivore because of its relative ease of colony maintenance and short generation time. We used Zn combined with Cd, Ni, and Pb to represent metals often found in combination in metal accumulator or hyperaccumulator plants. We also used several representative organic defensive compounds to test for combination effects with Ni. Nickel was chosen because it is the metal most often hyperaccumulated by plants (Reeves and Baker, 2000). Tannic acid was used to represent the “digestibility” reducing quantitative defense commonly found in apparent plants (Feeny, 1976; Rhoades and Cates, 1976; Behmer et al., 2002). Nicotine and atropine, both alkaloids, represented qualitative toxins that can defend against generalist herbivores (Feeny, 1976; Rhoades and Cates, 1976; Rhoades, 1979; Gómez et al., 2003). The toxic effects of both these alkaloids on herbivores have been well studied (e.g., Muller, 1998; Yildiz, 2004). Our experiments consisted of a series of artificial diet feeding trials using DBM larvae. In each trial, larvae were reared on one of four diet treatments: two treatments consisting of each chemical

added to diet separately, a third diet consisting of both chemicals in combination, and a fourth containing no added chemicals (control). Specifically, we asked the following questions:

- 1) Does a combination of two metals decrease survival or pupation of DBM larvae compared to each metal alone?
- 2) Does a combination of Ni and an organic chemical decrease larval survival or pupation compared to Ni alone or to the organic chemical alone?

METHODS AND MATERIALS

Experimental Colony. The diamondback moth, *P. xylostella* (L.) (Lepidoptera: Plutellidae), is an oligophagous herbivore of the Brassicaceae (Talekar and Shelton, 1993). This family contains a large percentage (about 25%) of the known hyperaccumulator species (Reeves and Baker, 2000). Although DBM has not been reported as attacking hyperaccumulators in the wild, surveys of herbivores on hyperaccumulator species are few (for exceptions, see Mesjasz-Przybyłowicz and Przybyłowicz, 2001; Wall and Boyd, 2002). The laboratory colony (Department of Entomology and Plant Pathology, Auburn University, Auburn, AL, USA) was maintained on an artificial DBM diet (BioServe, Frenchtown, NJ, USA). The diet's exact ingredients are proprietary information, but wheat germ and cabbage leaf powder are two of the main ingredients (Carpenter and Bloem, 2002). Colony maintenance procedures generally followed those of Harvey (2002). Eggs were collected on grooved aluminum foil sheets that had been coated with sterilized collard juice as an oviposition stimulant (Harvey, 2002). A 10% bleach solution was used to soak aluminum foil sheets of DBM eggs for 20 sec. Foil sheets were rinsed with deionized (DI) water for 1 min and allowed to dry. Dried egg sheets were cut into strips containing approximately 300–400 eggs per strip. Each strip was placed into a 250-ml paper cup (Solo, Twin Falls, ID, USA) with about 1 cm of congealed artificial diet covering its bottom. Cups were incubated at 37°C and approximately 30–50% humidity until eggs hatched and the instars first began to feed (~60 hr from egg collection). Larvae were allowed to feed for approximately 10–12 d after hatching. Pupae were placed in screen cages kept at room temperature where eclosed adults could mate and lay eggs on the aluminum foil sheets.

Metal + Metal Combination Experiments. Artificial diet was amended with metals to examine the effect of single, combination, and control treatments on DBM larvae. Each combination experiment compared DBM survival on diet containing each metal alone, diet containing both metals, and a control of unamended diet. Three combination experiments were conducted, using Zn

paired with Cd, Ni, or Pb. Metals were obtained as chloride salts from Sigma (St. Louis, MO, USA). Metal salts were dissolved in DI water to form stock solutions of 0.02 M Ni, 0.2 M Zn, 2 mM Pb, or 0.4 mM Cd. For each combination experiment, 100 ml of diet were amended with stock solutions to yield the concentrations of metal listed in Table 2. Experimental concentrations of metals were selected based on preliminary results that determined approximate lethal concentrations. Approximately 2–3 ml of diet were distributed into each 30-ml plastic rearing cup to give 12 replicates of each treatment within a combination experiment. A separate cup of 30 ml of diet from each treatment was saved for later metal concentration analysis.

DBM eggs were collected from a single cage containing adults that were 2–4 d posteclosion. Eggs were collected and sterilized in a 10% bleach solution and rinsed with DI water for 1 min. After egg sheets were dried, they were cut into strips containing approximately 80–100 eggs. Strips of eggs were arbitrarily distributed into diet cups by adding a strip to each cup in the first replicate (i.e.,

^aMolar concentrations are amounts added by dilution of stock solutions during diet preparation. Data for metals in $\mu\text{g g}^{-1}$ are from dry mass elemental analyses of diet samples.

^bAmounts of these elements were present in unamended (control) diets.

metal 1, metal 2, combination, control), then a strip to each cup in the second replicate, etc., until the cups in all 12 replicates had received an egg sheet.

Diet cups were placed into an incubator at 37°C and approximately 30–50% humidity. Egg sheets were removed from cups after larvae hatched and had begun to feed (approximately 60 hr after the sheets were collected). When egg sheets were removed, we counted the number of first instars in each cup. The number of live larvae was counted every 2–3 d thereafter. Once pupation began, numbers of live pupae also were counted, and each pupa was recorded as a surviving individual. Counting for all cups within a combination experiment ended when adults began to eclose from the control treatment (approximately 14–17 d after eggs were collected).

Nickel + Organic Chemical Experiments. Artificial diet was amended with combinations of Ni and an organic defense chemical. Each combination experiment compared DBM survival on diet containing each chemical alone, diet containing both chemicals, and a control of unamended diet. Nickel was paired with tannic acid, atropine, or nicotine. Organic chemicals were obtained from Sigma. To create a stock solution of tannic acid, we dissolved 400 mg of powdered tannic acid in 4 ml of ethanol and then diluted with DI water to form a 5-mg ml⁻¹ concentration stock solution. Atropine stock solutions were formed by dissolving 200 mg of atropine, in powdered form, in 4 ml of methanol and diluting with DI water to create a 1-mg ml⁻¹ solution. The stock solution of nicotine was made by dissolving 50 mg of powdered nicotine into 1 ml of ethanol and diluting with water to create a 0.25-mg ml⁻¹ solution. For each combination experiment, 100 ml of diet were amended with the Ni and organic chemical concentrations listed in Table 2. Experimental concentrations of metals and organic chemicals were selected based on preliminary results that determined approximate lethal concentrations to DBM. Diet was distributed into 30-ml plastic cups as with the metal–metal experiments, and a separate cup of 30 ml of diet from each treatment was saved for later metal concentration analysis. Addition of eggs, incubation, and counting of larvae and pupae followed the procedures of the metal–metal combination experiments described.

Elemental Analysis. Plant metal concentrations in the literature on accumulation and hyperaccumulation are expressed in µg g⁻¹ dry mass (e.g., Brooks, 1987; Reeves and Baker, 2000). We performed diet analyses to provide comparable data on metal concentration in each treatment expressed as µg g⁻¹ dry mass of diet. The 30-ml sample of diet retained from each metal concentration was dried at 60°C for 5 d and ground to a fine powder. Four 0.5-g dry mass subsamples from each metal concentration were wet digested using 10 ml of acid mix (700 ml concentrated HNO₃ + 300 ml concentrated HClO₄) within 250-ml glass digestion tubes for 24 hr. The next day, tubes were heated on a block digester within a perchloric acid fume hood at 190°C until digestion was complete. Once the tubes cooled, 2.5 ml of 1 M HCl were added

to each tube, and contents were transferred to 25-ml volumetric flasks. Contents of the volumetric flasks were brought to 25 ml by adding DI water and transferred to 100-ml plastic storage bottles (Nalgene, Rochester, NY, USA). Metal concentrations were determined using an inductively coupled argon plasma (ICP-AE) spectrophotometer (SPECTRO CIROS CCD, Cleves, Germany).

Statistical Analysis. Percent survival of DBM larvae for all treatments was calculated based on the final number of survivors (larvae plus pupae) on d 16 for all treatments (d 15 for the Ni + tannic acid experiment). Because our experiment was not a complete factorial design, we compared percent survival among metal + metal experiment treatments and Ni + organic chemical experiment treatments by using pairwise orthogonal contrasts after one-way analysis of variance (ANOVA) with JMP IN 5.1 (SAS Institute, 2005). Prior to analysis, percent survival data were arcsine square root-transformed to better fit the assumptions of ANOVA (Zar, 1996). The orthogonal contrasts allowed us to answer two questions for each combination experiment:

- 1) Did chemicals singly or in combination decrease survival relative to the control?
- 2) Did the combination of chemicals result in decreased survival compared to each chemical singly?

Differences in survival were considered significant at $\alpha \leq 0.05$.

We further examined the data to subdivide combination effects into additive or interactive (synergistic or antagonistic) effects. We converted DBM survival data into mortality data and, by using the technique of Salama et al. (1984), calculated an expected mortality for each combination treatment using the mean mortality from each chemical in a combination. These expected mortalities were compared to the actual combination mortality by using a chi-square test at $\alpha \leq 0.05$ (Salama et al., 1984). Significant deviation from expected values would indicate either synergy (if actual mortality were greater than expected) or antagonism (if actual mortality were lesser than expected).

To detect sublethal effects of treatments on DBM larvae, we compared pupation rates between treatments at the time pupae were first observed in the control treatment for each experiment. Thus, this measure included both mortality effects and decreased development time due to treatments. Pupae counts used for each experiment were taken from the data at 14 d for Zn + Ni, 10 d for Zn + Pb, 10 d for Zn + Cd, 9 d for Ni + tannic acid, 12 d for Ni + atropine, and 11 d for Ni + nicotine. We calculated % pupation by dividing the number of pupae in each cup by the maximum number of larvae that had been counted for that cup. Percent pupation values were arcsine square root-transformed to better fit the assumptions of ANOVA (Zar, 1996) and analyzed by one-way ANOVA to determine if treatments significantly affected pupation,

and pairwise orthogonal contrasts were used to compare means using JMP IN 5.1 (SAS Institute, 2005).

As with survival data, we further examined pupation data in cases where combinations had greater effects than single compounds to determine if this was caused by an additive or by an interactive (synergistic or antagonistic) effect. We calculated an expected percentage of larvae that did not pupate for each combination treatment by using the mean “failure to pupate” value from each chemical in a combination. As above, comparison of actual and expected values showed if synergy or antagonism had occurred.

RESULTS

Data analysis revealed statistically significant treatment effects for all experiments (ANOVA, $\alpha < 0.05$ in all cases). Here, we focus on the results from the pairwise orthogonal contrasts for each experiment. We use these to determine the concentrations of chemicals at which a combination effect was observed, defining a combination effect as when the survival or pupation rate for the combination treatment differed from that of both chemical treatments alone. We then ask if each combination effect is an additive or an interactive (synergy or antagonism) effect.

Metal + Metal Combination Experiments. For Zn + Ni, combination effects on survival were found at the two highest concentrations used: $1500 \mu\text{g Zn g}^{-1} + 170 \mu\text{g Ni g}^{-1}$ (Figure 1C) and $8900 \mu\text{g Zn g}^{-1} + 220 \mu\text{g Ni g}^{-1}$ (Figure 1D). Both these combination effects were additive. A combination effect for pupation (sublethal effect) occurred for the $1200 \mu\text{g Zn g}^{-1} + 110 \mu\text{g Ni g}^{-1}$ treatment, for which a combination effect was not detected from survival data. This combination effect was additive. Greater concentrations of Zn + Ni did not show combination effects for pupation because the Zn treatment produced almost no pupation in those cases.

For Zn + Pb, combination effects on survival were detected at $1200 \mu\text{g Zn g}^{-1} + 17 \mu\text{g Pb g}^{-1}$ and $10,000 \mu\text{g Zn g}^{-1} + 36 \mu\text{g Pb g}^{-1}$ (Figure 2B and D). These effects were additive. For pupation data, combination effects were observed for all but the lowest concentrations examined (Figure 2E–H). These effects also were additive.

Combination effects on larval survival for Zn + Cd treatments were detected for all concentrations except $1200 \mu\text{g Zn g}^{-1} + 6.5 \mu\text{g Cd g}^{-1}$ (Figure 3B). The effects were additive in all three cases (Figure 3A, C, and D). Pupation data revealed combination effects in all four trials (Figure 3E–H). These effects were striking, as pupation was zero for the combination treatments of all four trials, whereas at least some larvae pupated in all single metal treatments. The effects for the pupation data were additive in all cases.

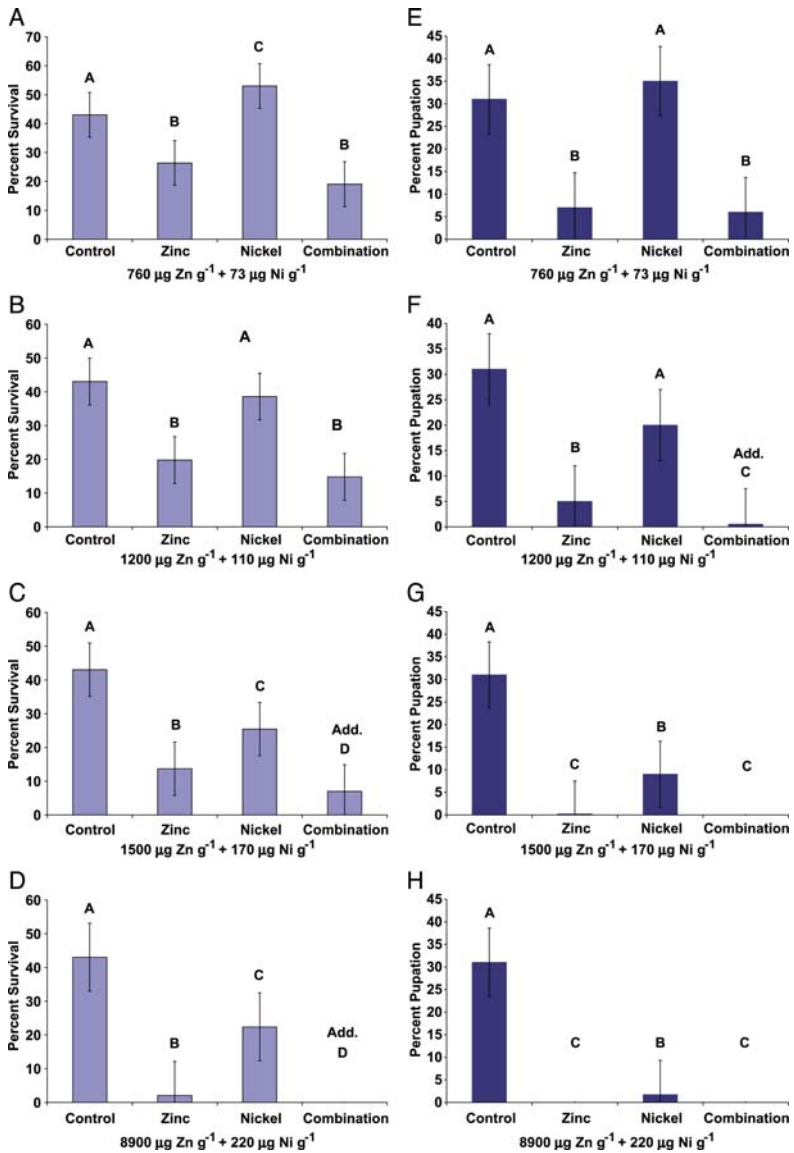

FIG. 1. Effects of Zn and Ni on diamondback moth (DBM) survival (A–D) and pupation (E–H). Bars on means denote SE. For each experiment, means with the same letters are not significantly different at $\alpha \leq 0.05$ (orthogonal contrasts of transformed data). Note that means and SE values in graphs are calculated for untransformed data. The notation “Add.” denotes those experiments for which a significant additive combination effect was detected.

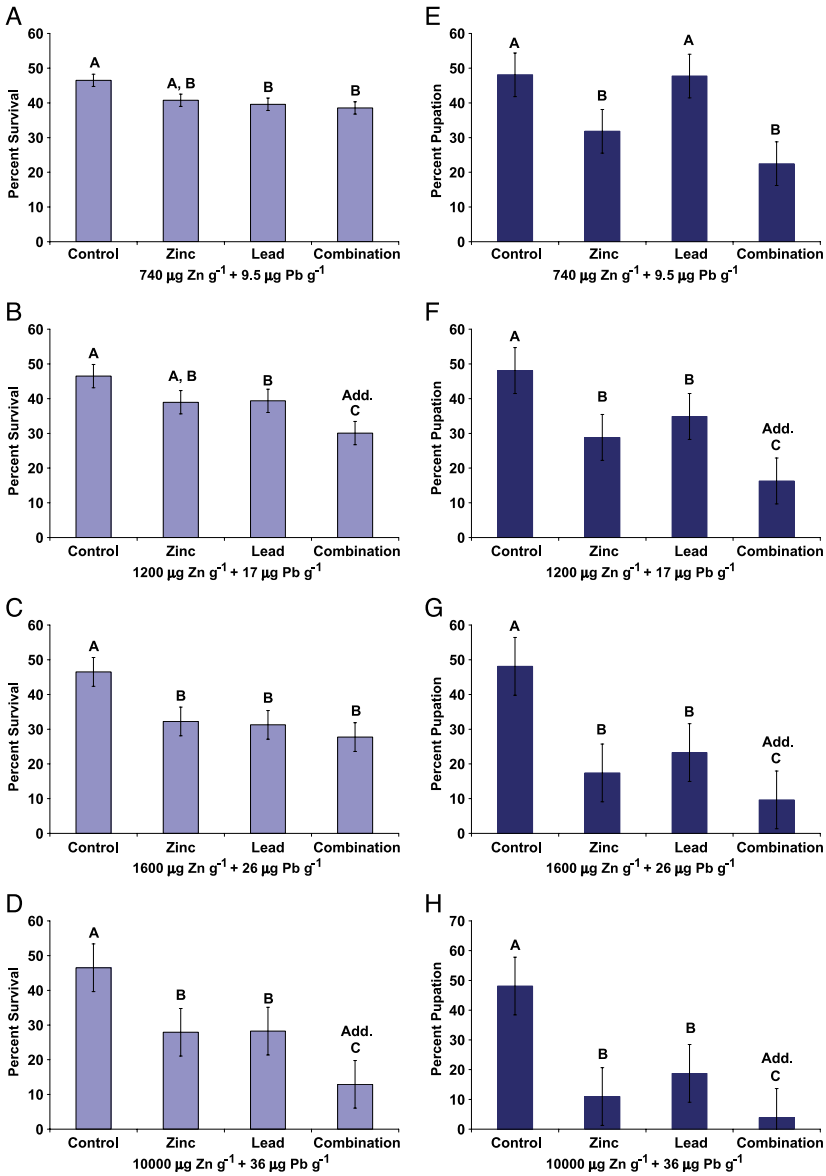

FIG. 2. Effects of Zn and Pb on DBM survival (A–D) and pupation (E–H). Bars on means denote SE. For each experiment, means with the same letters are not significantly different at $\alpha \leq 0.05$ (orthogonal contrasts of transformed data). Note that means and SE values in graphs are calculated for untransformed data. The notation “Add.” denotes those experiments for which a significant additive combination effect was detected.

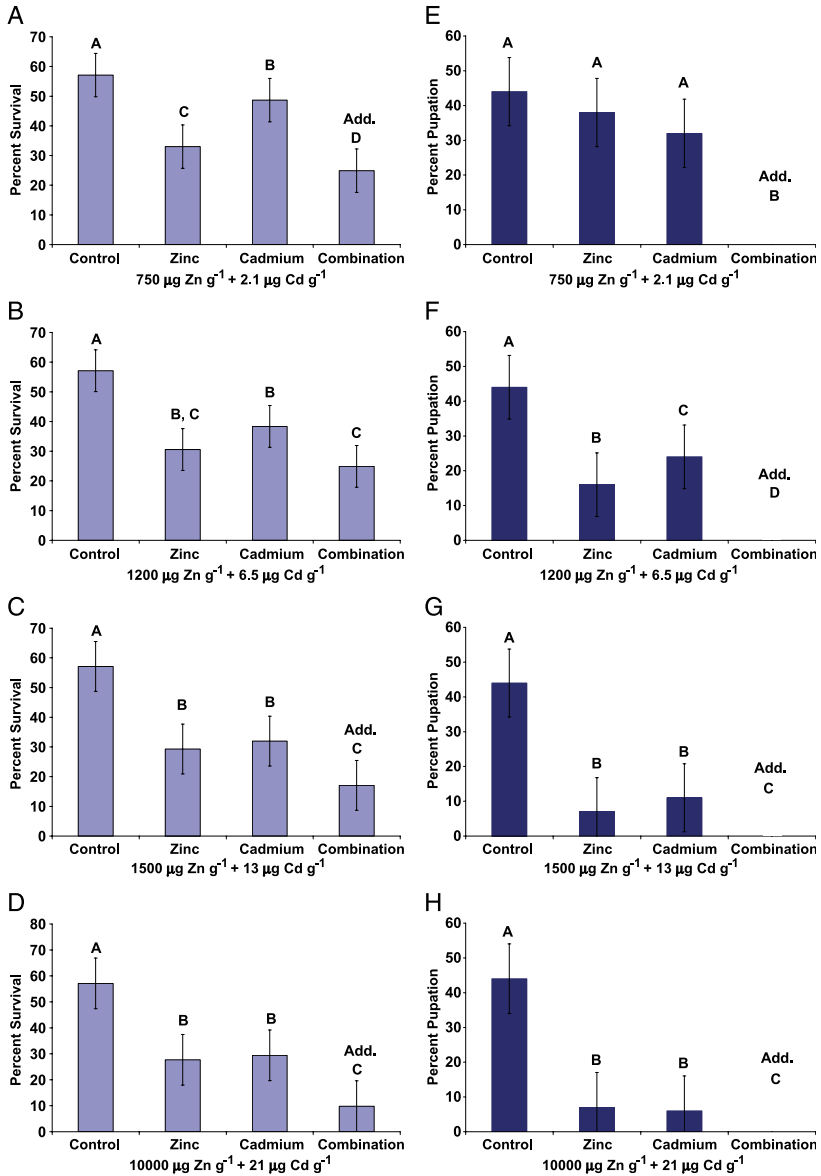

FIG. 3. Effects of Zn and Cd on DBM survival (A–D) and pupation (E–H). Bars on means denote SE. For each experiment, means with the same letters are not significantly different at $\alpha \leq 0.05$ (orthogonal contrasts of transformed data). Note that means and SE values in graphs are calculated for untransformed data. The notation “Add.” denotes those experiments for which a significant additive combination effect was detected.

Nickel + Organic Chemical Combination Experiments. Combination effects for Ni + tannic acid were detected for survival data for all but the lowest concentrations used ($77 \mu\text{g Ni g}^{-1} + 0.5 \text{ mg tannic acid ml}^{-1}$; Figure 4A). All were additive. Pupation data showed effects for all concentrations (Figure 4E–H), and all were additive.

For Ni + atropine, combination effects for survival data were detected for the two greatest concentrations used ($150 \mu\text{g Ni g}^{-1} + 0.08 \text{ mg atropine ml}^{-1}$ and $200 \mu\text{g Ni g}^{-1} + 0.1 \text{ mg atropine ml}^{-1}$; Figure 5C and D). Both the combination effects were additive. Pupation data showed effects for all trials (Figure 5E–H), and all were additive.

Combination effects on DBM survival in the Ni + nicotine experiment were detected for the two greatest concentrations ($160 \mu\text{g Ni g}^{-1} + 0.035 \text{ mg nicotine ml}^{-1}$ and $220 \mu\text{g Ni g}^{-1} + 0.04 \text{ mg nicotine ml}^{-1}$; Figure 6C and D). These were additive. For pupation data, effects were detected for all trials except that using the least concentrations ($77 \mu\text{g Ni g}^{-1} + 0.02 \text{ mg nicotine ml}^{-1}$; Figure 6E), and these effects were additive.

DISCUSSION

Our experiments provide a first test against an herbivore of the effects of metals in combination with other metals and with organic compounds. Defining a combination effect as a significantly greater impact in combination than for either chemical alone, we detected a combination effect for each pair of metals and for each Ni + organic chemical pairing (Figures 1–6). Furthermore, combination effects were found for both survival and pupation data. Results for the pupation data extended combination effects to still lower concentrations than were detected by the survival data for all experiments except Ni + tannic acid (in which all treatments showed significant combination effects; Figure 4) and Zn + Pb (Figure 2). Thus, we show that combination effects can magnify the protective effects of metals, and that metals may provide protection against herbivores at lower concentrations than previously believed. We note that combination effects were detected only at concentrations for which at least one of the chemicals alone had a significant negative effect on DBM relative to the control treatment (Figures 1–6). This indicated that the toxicity of one chemical made DBM more susceptible to the negative effects of the second chemical. Further tests will be needed to explore other metal + metal and metal + organic chemical combinations, but our results suggest that combination effects are common for the metals accumulated by plants.

All the combination effects we detected were additive. Boyd (1998) speculated that synergy between metals and organic defenses might magnify the effectiveness of each type of defense. We found no cases of synergy. We also

found no cases of antagonism, which would decrease the effectiveness of combinations of defensive chemicals. Our ability to detect interactive effects was limited because of the relatively high mortality rates of DBM larvae in our experimental trials (Hay, 1996; Pennings, 1996). This mortality rate was not unusual for a DBM colony (Shelton and Collins, 2000), but further explorations should be made for synergy/antagonism between metals, and between metals and organic chemicals, using another experimental system.

The demonstration of combination effects between metals and organic compounds (Figures 4–6) suggests that plants may be able to reduce production of organic defenses by sequestering metals. Martens and Boyd (1994) suggested that a trade-off between elemental and organic defenses allows hyperaccumulators to invest less carbon in the construction of organic defenses and yet remain defended. Tolrà et al. (2001), studying the Zn hyperaccumulator *Thlaspi caerulescens* J. & C. Presl. (Brassicaceae), demonstrated that hyperaccumulating plants possessed significantly lower concentrations of glucosinolates than low-Zn plants. Our study shows that additive effects between Ni and organic compounds enable Ni combined with a low concentration of organic compounds to provide the same defensive effect as higher levels of those organic compounds alone. Thus, plant uptake of metals to relatively low but defensively effective concentrations can allow reduced organic chemical production. Because organic chemical production must have a physiological cost (Agrawal, 2005), then the cost reduction may be significant.

Accumulation or hyperaccumulation of multiple metals may have selective value because plant enemies differ in susceptibility to different elemental defenses. For example, Boyd and Shaw (2004) showed that a plant pathogenic bacterium (*Xanthomonas campestris*) was particularly sensitive to Cu but not to Co. Therefore, an accumulator of both Cu and Co might be protected against this pathogen by its Cu concentration but not its Co concentration. However, Coleman et al. (2005) showed that low levels of Co ($40 \mu\text{g g}^{-1}$) are defensively effective against DBM, so that Co would protect a Co/Cu accumulator against DBM. Similar considerations regarding multiple natural enemies may explain contrasting results of tests of the defense hypothesis for single metals. For example, Zn hyperaccumulation in *T. caerulescens* is effective against some pathogenic fungi and some herbivores (lepidopteran larvae and grasshoppers; Pollard and Baker, 1997; Jhee et al., 1999) but ineffective against other herbivores (snails; Huitson and Macnair, 2003; Noret et al., 2005).

The evolution of hyperaccumulation is likely complex and may have occurred multiple times for each hyperaccumulated element (Borhidi, 2001) and under different selection pressures. However, Boyd (1998, 2004) suggested that defensive effects of elemental accumulation at levels below the hyperaccumulation threshold might have led to the evolution of hyperaccumulation. Coleman et al. (2005) showed that low concentrations (accumulator concentrations or less)

of most metals increase the mortality of DBM larvae. Our current work shows that relatively low concentrations of metals can be effective defenses because metal + metal and metal + organic chemical combinations increase the effectiveness of these metals. This suggests that low concentrations of metals in plants, even lower than those documented by Coleman et al. (2005), can contribute to plant defense. If these lower concentrations result in increased plant fitness, then plant traits responsible for relatively low levels of metal uptake and sequestration will be favored in plant populations faced with natural enemies. Metal accumulation ability may spread in a population and be enhanced in a stepwise process driven by increased defensive benefits of increased metal accumulation. These defensive effects, therefore, provide a likely pathway for the evolution of accumulation and hyperaccumulation of metals by plant populations.

Acknowledgments—The authors thank Rachel Foster for invaluable assistance with artificial diet experiments, Michael Buckman and Zandra Delamar for assistance with DBM colony maintenance, and Dr. John Odom for assistance with ICP analysis. The authors thank Dr. Debbie Folkerts and two anonymous reviewers for critically reviewing this manuscript.

Abstract—Cyanogenesis, the release of toxic HCN from damaged plant tissues, is generally considered as a constitutive plant defense. We found phenotypic plasticity of cyanogenesis in young leaves of lima bean *Phaseolus lunatus* based on increased activity of the β -glucosidase in response to herbivore attack. Two aspects of plant cyanogenesis have to be considered in ecological analyses: (1) the cyanogenic potential (HCNp), which indicates the total amount of cyanide-containing compounds present in a given tissue, and (2) the cyanogenic capacity (HCNc), representing the release of HCN per unit time. This release is catalyzed by specific β -glucosidases, whose activity is a crucial parameter determining overall toxicity. Enzymatic activity of β -glucosidase—and, in consequence, the rate of HCN release—was increased significantly after 72 hr of incubation with spider mites as compared to noninfested leaves. Feeding by L1 larvae of Mexican bean beetles also led to enhanced enzymatic activity, whereas mechanical damage of leaf tissue had no effect on β -glucosidase activity and the release of HCN. The results place plant cyanogenesis in the group of induced resistance traits, whose degree of activity depends on the feeding by a particular herbivore.

Key Words—Cyanogenesis, β -glucosidase, chemical defense, constitutive defense, phenotypic plasticity, *Phaseolus lunatus*, *Tetranychus urticae*, *Epilachna varivestis*, plant–herbivore interactions.

INTRODUCTION

Plant cyanogenesis, the release of hydrogen cyanide from cyanogenic precursors as response to cell or tissue disruption, is considered a constitutive plant defense against generalist herbivore attack (Nahrstedt, 1985; Belotti and Riss, 1994; Gleadow and Woodrow, 2002). Most studies focus on the variation of the content of cyanogenic plant compounds; however, cyanogenesis, if defined as the liberation of hydrogen cyanide per unit time, also has a kinetic character. Therefore, three different components have to be quantified to fully describe this phenomenon. These components are (1) the cyanogenic potential (HCNp), which gives the total amount of cyanide-containing compounds present in a given tissue (Loyd and Gray, 1970), (2) the activity of specific β -glucosidases, and (3) the resulting cyanogenic capacity (HCNc), defined as the release of hydrogen cyanide per unit time (Lieberei, 1988). In contrast to the widely studied HCNp, the capacity of plants or particular plant organs for HCN release following tissue damage is rarely studied, but data available on *Phaseolus lunatus* indicate a substantial role of such kinetics in herbivore deterrence (Ballhorn et al., 2005). In this context, two modes of defense have to be considered. The function of deterrence depends on the plants' ability for fast release of high amounts of HCN during the feeding process of the herbivore. In contrast, extensive consumption of plant material with lower cyanogenic features in the long term leads to an intoxication of the herbivore. This intoxication results from the endogenous release of hydrogen cyanide within the gastrointestinal tract, which appears to be more harmful to the herbivore than the development of gaseous HCN during the feeding process (Ballhorn et al., 2005; Miguel and Alberto, 2005).

The activity of specific β -glucosidases represents the most important parameter determining the kinetics of hydrogen cyanide release (Swain et al., 1992). However, studies on possible changes of specific β -glucosidase activity and resulting changes of the cyanogenic capacity in response to herbivore or fungal attack are lacking. Only a study on the cyanogenic rubber tree (*Hevea brasiliensis*) reported a distinct increase of β -glucosidase activity in response to local, mechanical damage of leaf tissue (Voß, 2001). For many cyanogenic plants such as rubber tree, cassava (*Manihot esculenta* Crantz), sorghum (*Sorghum bicolor* (L.) Moench), clover (*Trifolium repens* L. and *Lotus corniculatus* L.), bracken fern (*Pteridium aquilinum* (L.) Kuhn), and lima bean (*P. lunatus* L.) there is evidence for the protective effect of plant cyanogenesis (Jones, 1962; Cooper-Driver and Swain, 1976; Hruska, 1988; Bernays, 1991). Furthermore, experiments with genetically modified plants have underlined the effectiveness of cyanogenesis as an antiherbivore defense system. Transferring the complete pathway for synthesis of cyanogenic glycosides and a corre-

sponding, specific β -glucosidase into *Arabidopsis thaliana* provided resistance against *Phyllotreta nemorum*, a chrysomelid beetle that is specialized on cruciferous plants (Tattersal et al., 2001).

However, a broad range of factors on both sides of the plant–herbivore interaction affects the effectiveness of cyanogenesis as an herbivore deterrent. Focusing on the herbivores, the mode of feeding, the availability of alternative foods, as well as mechanisms of adaptation may affect the defensive potential (Walling, 2000; reviewed by Gleadow and Woodrow, 2002).

In the last decades, cyanogenesis has received considerable interest in analyses of ecological costs of plant defense (Kakes, 1989; Blaise et al., 1991; Lieberei et al., 1996; Hayden and Parker, 2002). A number of authors have described genetically based variation in cyanogenesis among populations (Lieberei, 1988; Shore and Obrist, 1992; Caradus and Forde, 1996). In addition to genotypic variability, the state of cyanogenesis may be correlated with the ontogenetic stage of the particular plant or specific plant organs (Lloyd and Gray, 1960; Till, 1987; Coley, 1980, 1988; Thayer and Conn, 1981; Schappert and Shore, 2000).

There seem to be some counteractive forces selecting against cyanogenesis because populations of some potentially cyanogenic plants are partly or even almost entirely composed of acyanogenic genotypes (Hughes, 1991; Schappert and Shore, 1995, 1999). Distribution of cyanogenesis within and among populations may depend on the presence or absence of herbivores, which lowers or increases the net fitness effects of this constitutive plant defense trait, respectively (Abbott, 1977; Ellis et al., 1977; Bokanga et al., 1994; Gleadow and Woodrow, 2000a,b). In addition, abiotic conditions, such as temperature and humidity, and their seasonal variation, as well as nutrient availability may have an impact directly on the status of cyanogenesis within a given plant and, therefore, can have the potential to affect the distribution of plant cyanogenesis at the level of populations (Jones, 1962, 1966, 1972; Cooper-Driver et al., 1977; Kakes, 1989; Calatayud et al., 1994; Calatayud and Le Rü, 1996). Thus, general problems of estimating the relevance of cyanogenesis in an ecological context arise from the highly dynamic nature of this trait that also comprises the putatively different responses of its separate parameters, i.e., HCNp, β -glucosidase activity, and HCNc.

In the present study, we use lima bean (*P. lunatus*) as a presumably obligate cyanogenic plant with high intraspecific and ontogenetic variability in its cyanogenic features (Baudoin et al., 1991; Debouck, 1991; Ballhorn et al., 2005). Spider mites (a generalist cell-content feeder) and larvae of the Mexican bean beetle (a specialist herbivore with chewing mouthparts) were used for analysis of phenotypic plasticity of β -glucosidase activity and the corresponding HCNc.

METHODS AND MATERIALS

Plants. The experiments were carried out with 12 accessions of *P. lunatus* including 11 domesticated lines and a wild type. For further characterization of the accessions see (Table 1). Trifoliolate leaves of these accessions were characterized by different concentrations of cyanide-containing compounds (Ballhorn et al., 2005). The cyanogenic potential (HCNp) of young leaves ranged from 7.4 ± 2.1 (accession 8071) to 65.3 ± 13.4 (accession 2357) $\mu\text{mol HCN per gram leaf fresh weight (fw; mean} \pm \text{SD; } N = 11 \text{ clonal plants per accession)}$. Seed material was provided by the Institute of Plant Genetics and Crop Plant Research (IPK) in Gatersleben, Germany.

Growing and Treatment of Plants. Single plants of the different accessions were vegetatively propagated (28 plants per accession) to reduce genetic variability of the experimental plants. These plants were used for the experiments when they were 8 wk old and had developed two fully expanded leaves. Clonal plant material was obtained by preparing one-node cuttings from the mother plant. Cuttings were rooted in water supplemented with Rhizopon AA 1%® (Rhizopon bv, Hazerwoude, Holland). The mother plants obtained from seeds as well as the cuttings were cultivated under green house conditions at a

^aAccession 2233 represents lima bean, *P. lunatus*, wild type (WT) with small seeds and small, relatively hard textured leaves.

^bYoung leaves of accessions were screened for their general cyanogenic potential ($N = 11$ individual plants per accession, values are means \pm SD) according to the method described in (Ballhorn et al., 2005).

light regime of 16:8 hr light–dark period by a photon flux density of $400 \mu\text{mol sec}^{-1} \text{m}^{-2}$ at the plant container and $900 \mu\text{mol sec}^{-1} \text{m}^{-2}$ on the top of the plants. Supplementary light was provided by 400-W high-pressure sodium lamps with plant grow broad-spectrum fluorescent bulbs (Son-Targo 400, Philips®). Temperature in the chamber was 30:20°C, and the ambient relative air humidity ranged between 60 and 70%. Plants were fertilized with a nitrogen–phosphate fertilizer (Blaukorn®–Nitrophoska®–Perfekt, Compo GmbH & Co. KG, Münster, Germany) twice a week and rooted in standard substrate (TKS®–1-Instant, Floragard®, Oldenburg, Germany) that was mixed with two thirds of washed sand with different grain size (0.3–0.7 and 1–2 mm). Plant containers with a diam of 18 cm were used for cultivation.

Selection of Leaf Material. Young leaves were selected for the experiments. Leaves of this developmental stage revealed the highest homogeneity of structural parameters among the accessions and the highest constancy of physiological traits (HCNp and general β -glucosidase activity) within the lines. This leaf developmental stage was classified by the position of leaf insertion at the stem as well as by leaf morphological parameters. By definition, “young leaves” are inserted near the top of the stem or a side stem. They were fully unfolded for at least 4 d, but no longer than 6 d, and the midrib of the central leaflet of these trifoliate leaves was about 4 cm long. Leaves of this ontogenetic stage were characterized by a bright green color and a soft texture.

Arthropods. Two-spotted spider mites (Acari: Tetranychidae: *Tetranychus urticae* Koch) and Mexican bean beetles (Coleoptera: Coccinellidae: *Epilachna varivestis* Mulsant) were used as activating agents. Both the maintenance culture of the spider mites as well as of the Mexican bean beetles were kept on *Phaseolus vulgaris* cv. “Saxa” under identical ambient conditions as experimental plants. The progenitors of the Mexican bean beetle culture were provided by C.P.W. Zebitz, Department of Applied Entomology, University of Hohenheim, Otto-Sander Str. 5, Germany.

Infestation of Leaves with Spider Mites. Fourteen clonal plants were used per accession. The terminal leaflet of one trifoliate leaf per plant was infested with 10 adult females that had been kept on *P. vulgaris* before. Experiments were carried out in the green house under identical ambient conditions as adjusted for plant cultivation. For analysis of plant responses to spider mite attack, the infested leaflets of selected trifoliate leaves were bagged with perforated, transparent polyethylene foil (approx. 9 holes/cm², each with a diam of 0.5 mm), whereas the other two leaflets of the leaf were bagged but remained uninfested. In addition, leaves of control plants were bagged in the same way. These plants were cultivated in a separate chamber under identical ambient conditions. In parallel experimental settings, mites were left on the leaflets for 24, 48, and 72 hr, respectively. The β -glucosidase activity of the infested leaflets was quantitatively compared to the two untreated leaflets of

the same leaf, which were pooled for analysis, as well as to leaves of the control plants characterized by the same ontogenetic stage. Leaflets of these control leaves were pooled for analysis of the β -glucosidase activity.

Leaf Damage by Mexican Bean Beetles. In experiments using the Mexican bean beetle as attacking herbivore, three freshly hatched L1 larvae were placed on the terminal leaflet of a trifoliolate leaf. Running time of the feeding trials and bagging of leaflets were consistent with the experiments using spider mites as herbivores. Noninfested control plants were used in the same way as mentioned above.

Effect of Artificial Damage. Artificial damage was applied to the leaflets using a plastic (PE) pin with a diam of 1.5 mm. Initially, 15 injuries were set per leaflet. In parallel experimental settings, additional 15 injuries were set every 24 hr to achieve an increasing damage of leaf tissue visually similar to the leaf area damaged by the Mexican bean beetles. The damaged leaflets were bagged in the same way, and untreated but bagged control plants were used as described for the plants wounded by herbivores.

Harvest of Leaves for Analysis. Leaves were cut off with a razor blade after the respective period of incubation. The three leaflets per leaf were separated by the criteria "treated" and "untreated" and were immediately prepared for analysis of β -glucosidase activity. Leaf material of control plants was prepared in the same way.

Extraction and Purification of β -Glucosidase. Whole leaflets were weighed and homogenized in a fourfold volume of 67 mmol l^{-1} phosphate buffer adjusted to pH 6.4. The extract was filtered through cotton fabric and centrifuged at $20,000 \times g$ and 4°C (RC5C, Sorvall). The protein-containing supernatant was concentrated by ammonium sulfate fractionation and filtered through membrane caps with a pore size $<10,000 \text{ kD}$ (Schleicher & Schuell BioScience GmbH, Dassel, Germany).

Constitutive β -Glucosidase Activity. The quantification of β -glucosidase activity in the extracts was based on the detection of *p*-nitrophenol released by hydrolysis of the chromogenic artificial substrate *p*-NP-glucoside (Merck; Hösel and Nahrstedt, 1975; Selmar, 1981, 1986). The standard incubation mixture for analysis of the enzymatic activity contained 1-ml substrate solution (2 mmol) in citrate buffer adjusted to pH 5.6. The incubation mixture was made up by citrate buffer (pH 5.6) to a volume of 4.9 ml, and finally 0.1 ml extract was added. After 10 min of incubation at 30°C , the reaction was stopped by adding 1 ml ice-cold sodium carbonate solution (1 mol/l), and the released *p*-nitrophenol was quantified spectrophotometrically at 400 nm (Pharmacia Biotech, Ultraspec 3000). The β -glucosidase activity was calculated per gram leaf dry weight as katal (kat). An enzyme activity of 1 kat is defined as a substrate conversion rate of 1 mol substrate per second under standard temperature and pressure. The calculation of the enzyme activity was carried out by use of a coefficient of extinction for *p*-nitrophenol ($\epsilon_{400 \text{ nm}} = 16,159 \text{ l/mol cm}$; Voß, 2001).

HCN Detection System. The kinetic analysis of HCN release from experimentally treated lima bean leaves was carried out using an airflow system (Ballhorn et al., 2005). This vessel system was passed by a constant airflow adjusted at 7.0 l/hr. Infested and noninfested leaflets of the experimental plants as well as terminal leaflets of the control plants were placed in the equipment, respectively. The leaflets were treated with chloroform (250 μ l/leaflet) to achieve complete tissue disintegration and, in consequence, the release of gaseous hydrogen cyanide from the accumulated cyanogenic precursors. At the discharge opening of the equipment, the air together with the transported HCN was led into a test tube containing 0.1 mol/l NaOH solution. Thus, cyanide was fixed as NaCN and then was spectrophotometrically quantified at 585 nm as a polymethine dye that was formed by use of Spectroquant® cyanide test (Merck). We used a coefficient of extinction of ($\epsilon_{585 \text{ nm}} = 131,600 \text{ l/mol cm}$) for calculation of the cyanide concentration in the samples following the product description.

Statistics. Statistical analyses were carried out with Statistica 6.0 (Statistica System Reference, 2001).

RESULTS

Variability of β -Glucosidase Activity. Substantial interaccession variability of β -glucosidase activity in young leaves was found among the 12 accessions of *P. lunatus* (Figure 1A). Among these lines, the enzymatic activity ranged from 0.016 to 3.765 μ kat per gram leaf dry weight ($N=9$ per accession) and varied significantly depending on the genotype (ANOVA: $F=21.861$, $df=11$, $P < 0.001$).

Attacking Period. In experimental settings that used spider mites as well as Mexican bean beetles as damaging agents, substantial increase of β -glucosidase activity was found after 72 hr of incubation, whereas no distinct increase of the enzymatic activity was observed after an incubation period of 24 and 48 hr. Thus, results presented hereafter refer to an incubation period of 72 hr (Figure 1B–D).

Effect of Spider Mite Infestation on β -Glucosidase Activity. A factor of β -glucosidase activity increase was calculated by dividing the enzyme activity (μ kat) of the infested leaflets by the values of activity of the noninfested leaflets belonging to the same leaves. Enzyme activity in untreated leaflets of treated leaves was not significantly different from activity in completely untreated leaves of control plants (ANOVA: $F = 0.012$, $df = 1$, $P = 0.917$). Relative increases in β -glucosidase activity are therefore expressed as a factor of β -glucosidase activity increase comparing the damaged and undamaged leaflets of single leaves. These factors generally gave values of 1 or more and indicated an increase of β -glucosidase activity following spider mite attack. Only the accession 1315 showed a slight decrease of enzymatic activity after infes-

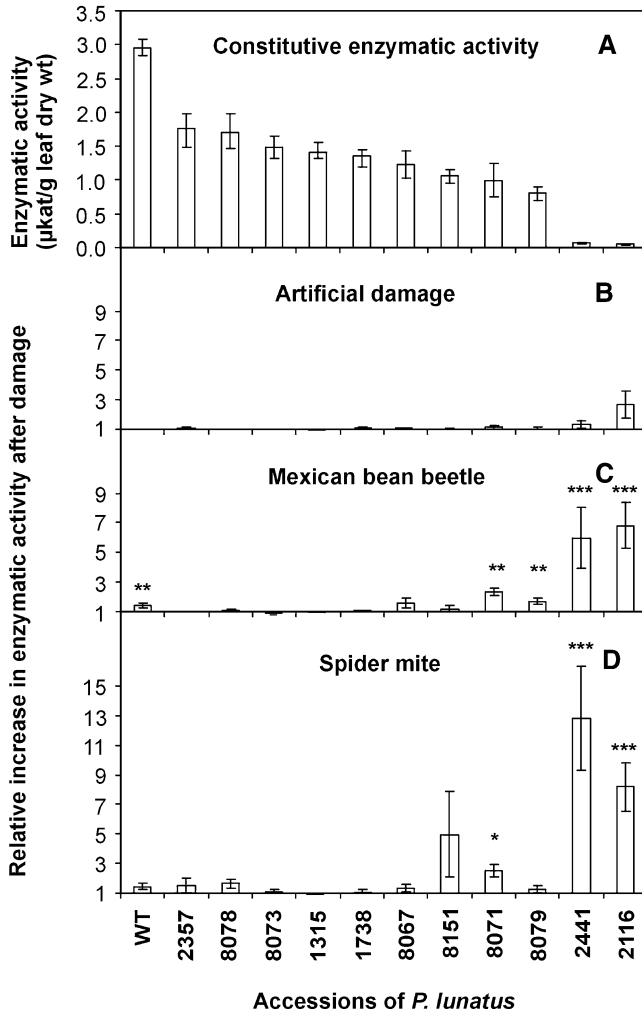

FIG. 1. Increase in β -glucosidase activity following leaf damage. Presented is the constitutive β -glucosidase activity in young *Phaseolus lunatus* leaves (A) and relative increases in enzyme activity in response to attack from artificial damage (B), larvae of Mexican bean beetles (C), and spider mites (D). Values are means \pm SE [($N = 9$ leaves per accession (A) and $N = 7$ leaflets of different plant individuals per accession (B–D))]. Asterisks represent significant increase in enzymatic activity (*** $P < 0.001$; ** $P < 0.01$; * $P < 0.05$).

FIG. 2. Increase in HCN liberation by enhanced β -glucosidase activity. The relative increase of gaseous hydrogen cyanide release per unit time was accelerated in response to increased β -glucosidase activity provoked by spider mite attack. Values are means \pm SE ($N = 7$ leaflets of different plant individuals per accession). Asterisks represent significant increases in HCN liberation (***) $P < 0.001$.

tation with spider mites (Figure 1B). The accessions 2441 and 2116 showed a substantial increase of enzymatic activity by the factor 12.8 ± 3.6 and 8.2 ± 1.6 (mean \pm SE), respectively. For these accessions, as well as for the accession 8071, the enzymatic activity in infested leaflets increased significantly in response to spider mite attack (ANOVA; 2441: $F = 130.614$, $df = 1$, $P < 0.001$; 2116: $F = 317.091$, $df = 1$, $P < 0.001$; and 8071: $F = 5477$, $df = 1$, $P < 0.05$). However, none of the other accessions showed significantly enhanced enzymatic activity following spider mite attack.

Effect of Damage by Mexican Bean Beetle Larvae on β -Glucosidase Activity. The β -glucosidase activity of selected *P. lunatus* accessions was increased by feeding of Mexican bean beetle larvae (Figure 1B). Exceptions are only the accessions 2357, 1315, and 8073, which showed a slight decrease of the enzymatic activity. Leaflets of the accessions 2116, 2441, 8071, and 8079 exhibited significantly increased β -glucosidase activity in response to leaf damage by these insects as compared to the nondamaged leaflets of the same leaf (2116: $F = 31.131$, $df = 1$, $P < 0.001$; 2441: $F = 23.968$, $df = 1$, $P < 0.001$; 8071: $F = 13.320$, $df = 1$, $P < 0.01$; 8079: $F = 14.052$, $df = 1$, $P < 0.01$; WT: $F = 10.397$, $df = 1$, $P < 0.01$). These nondamaged leaflets, in turn, never showed significant differences of β -glucosidase activity when compared to leaves of the control plants ($F = 0.006$, $df = 11$, $P = 0.994$).

Artificial Damage of Leaves. Among all accessions, injuries of leaflets set with a plastic pin had no effect on β -glucosidase activity in these leaflets as

compared to the remaining leaflets ($F = 0.055$, $df = 1$, $P = 0.815$). However, 8 among 12 accessions of *P. lunatus* showed factors of β -glucosidase activity increase higher than 1.

Effect of Increased β -Glucosidase Activity on HCNc. The increase in β -glucosidase activity in spider-mite-infested leaflets compared to untreated leaflets of the same leaves was correlated with increased HCN release from these leaflets as reaction to breakdown of cell integrity (Figure 2). Similar to the relative increase of enzymatic activity, we calculated a factor of relative increase of HCN release per unit time by dividing the amount of released HCN of the infested leaflets by the values of HCN release of noninfested leaflets belonging to the same leaves. The cyanogenic capacity of spider-mite-infested leaflets of the accessions 2116 and 2441 was accelerated compared to noninfested leaflets of these *P. lunatus* lines (2116: $F = 41.850$, $df = 1$, $P < 0.001$ and 2441: $F = 45.984$, $df = 1$, $P < 0.001$). The other accessions showed no increase of HCN release in response to spider mite attack. However, the increase in HCN release of the accession 2357 was close to statistical significance ($F = 4.52$, $df = 1$, $P = 0.051$).

DISCUSSION

Plant cyanogenesis represents a complex trait in herbivore defense because of high variability of the cyanogenic system. Besides the heterogeneous distribution of cyanogenesis among or within plant populations, the cyanogenic status of an individual plant is not static (Till, 1987). Therefore, analyses testing only for the presence or absence of cyanogenic glycosides and the general ability for HCN release do not address the variability of this constitutive herbivore defense.

In this study, enzymatic activity of β -glucosidase, a crucial factor limiting the rate of HCN release, increased in response to herbivore attack. Cyanogenesis thus comprises an inducible component, a finding placing it in the group of induced plant responses to herbivores. We found substantial interaccession variability because significant increases in β -glucosidase activity were observed only in some of the accessions tested. Furthermore, the responses of these accessions depended on the type of herbivores causing the damage. Spider mite attack generally led to a higher increase in β -glucosidase activity than leaf damage caused by larvae of the Mexican bean beetle (Figure 1C and D). This result most likely is a consequence of the different modes of feeding of these herbivores. Spider mites are cell-content feeders and damage single cells or limited areas of epidermal and mesophyll cells per feeding incident (Raven, 1983), whereas Mexican bean beetles remove larger areas. Furthermore, elicitors may be present in the herbivores' saliva, which can have varying

effects on resistance-related plant enzymes such as pectinases, cellulases, amylases, proteases, lipases, alkaline and acidic phosphatases, and peroxidases (Miles, 1999). Support for this interpretation comes from the observation that pure mechanical damage of similar leaf areas as damaged by the herbivores did not significantly induce β -glucosidase activity.

To test whether increased β -glucosidase activity, in fact, leads to increased HCN release, we used spider mite-infested leaves. The highly significant increases in β -glucosidase activity of the accessions 2116 and 2441 indeed were correlated with significant increases in HCN release (Figure 2). This finding underlined the impact of β -glucosidase activity on kinetic patterns of cyanogenesis. However, the increase in HCN release was quantitatively lower than the increase in β -glucosidase activity. Accessions 2116 and 2441 showed increases in β -glucosidase activity by factors greater than 8 and 12 (Figure 1D), whereas the magnitude in the relative increases in HCN release was less than twofold (Figure 2). This result can be explained when we assume that increased β -glucosidase activity occurred only in limited areas directly adjacent to the cells affected by spider mite feeding. In experiments with rubber tree, areas of enzymatic activation following leaf damage appeared to be local (Voß, 2001). Thus, increased enzymatic activity and enhanced HCN liberation because of herbivory might not affect the whole leaf. Another explanation for the non-proportional increase of β -glucosidase activity and HCN release could be the activity of hydroxynitrile lyases, which are catalyzing the dissociation of hydroxynitriles as the second step of cyanogenesis and, therefore, have the potential to limit the release of HCN (Selmar et al., 1989).

A further point to be regarded in this context is the multifunctional character of β -glucosidases as pointed out by Selmar et al. (1987), particularly the putative involvement of β -glucosidases in mechanisms belonging to systemic acquired resistance against pathogens (SAR). SAR represents a systemic and multigenic plant response to a local infection that leads to a broad-spectrum resistance to subsequent infections (Lamb and Dixon, 1997). SAR is primarily induced by pathogens, but tissue damage by piercing and sucking insects and mites induces similar responses (Russo et al., 1997; Bostock, 1999; Walling, 2000; Grinberg et al., 2005). Two important aspects of SAR are the accumulation of phytoalexins and enhanced local lignification of cell walls (Hammerschmidt, 1999a,b; Bruxelles and Roberts, 2001), and β -glucosidases are involved in both processes. Garcia et al. (1995) reported an essential function of β -glucosidases for the release of the phytoalexin scopoletin from its glycoside scopolin in leaves of the cyanogenic rubber tree (*H. brasiliensis*). The role of β -glucosidases for lignin biosynthesis in the course of defense reactions of *Triticum aestivum* against the fungal pathogen *Puccinia graminis* was demonstrated by Kogel et al. (1991). The induction of β -glucosidase reported is likely to have functions beyond the increase in HCN release.

Taken together, the results of our study underline the plastic character of plant cyanogenesis caused by phenotypic plasticity of β -glucosidase activity. This enzyme is an essential agent for the kinetics of HCN release, but further functions of the β -glucosidase present in *P. lunatus* cannot be excluded. Nevertheless, inducibility of β -glucosidase activity further adds to the ecological complexity in the interaction of cyanogenic plants with their biotic environment.

Mechanisms involved in the activation of specific β -glucosidases remain elusive. Voß (2001) reported immediate activation of specific β -glucosidase of the cyanogenic rubber tree (*H. brasiliensis*) as response to mechanical injury of leaves. This activation takes place within seconds. Hence, mechanisms of gene activation and mRNA synthesis could be excluded for this HCN-releasing plant, and posttranslational processes affecting the β -glucosidase activity have to be assumed. In *P. lunatus*, a significant increase of the enzymatic activity was measured at the earliest after 72 hr of incubation. This time lag of activation may be a result of mRNA synthesis in the course of gene activation.

The plastic character of enzymatic activity in *P. lunatus* (and therefore the plasticity of cyanogenesis) appeared to be local because feeding of spider mites and L1 larvae of the Mexican bean beetle on one single leaflet had no inductive effect on β -glucosidase activity in the other two leaflets of the same leaf. This was verified by comparing β -glucosidase activity of these untreated leaflets with leaves of entirely untreated clonal control plants, which were not significantly different. Thus, the increase in β -glucosidase activity of leaflets damaged by herbivores was only detected in the damaged leaflets. The lima bean represents an experimental plant that is well established for analyses of plant responses to herbivore damage. The focus of research lies on the mechanisms of VOC emission and the processes induced on the molecular level (Arimura et al., 2000) and, more recently, on the activation of extrafloral nectar in the field of indirect defenses (Heil, 2004). Cyanogenesis of the lima bean as a direct defense with high intraspecific and ontogenetic variability, as well as a certain state of phenotypic plasticity, represents an aspect that has to be considered in ecological analysis and evaluation of ecological costs of plant defense in this model system. Plant cyanogenesis of *P. lunatus* appears not to be a constitutive defense in the classical sense.

Acknowledgments—We thank A. Pietrowski, C. Reisdorff, and two anonymous reviewers for many valuable discussions and comments on earlier versions of this manuscript. We thank the “Institute of Plant Genetics and Crop Plant Research (IPK)” in Gatersleben, Germany, for providing seed material of *P. lunatus*.

Abstract—Both biotic and abiotic selection pressures can contribute to geographic variation in allelochemical production in plants. We examined furanocoumarin production in western North American populations of *Heraclium lanatum* and *Pastinaca sativa* that, at different latitudes and altitudes, experience different ultraviolet (UV) light regimes. Total furanocoumarins and linear furanocoumarins of fruits were negatively correlated with UV irradiance, whereas amounts of angular furanocoumarins, which are generally less phototoxic, were not. Another factor potentially influencing furanocoumarin production is the presence of the parsnip webworm *Depressaria pastinacella*, (Lepidoptera: Oecophoridae), an herbivore that feeds on reproductive structures of both plant species. These insects sequester lutein from their host plants; this carotenoid acts to ameliorate furanocoumarin toxicity. Although the concentration of lutein in fruits did not vary with UV irradiance, lutein sequestration by sixth instars was positively correlated with UV irradiance. Webworm populations are variably infested with the polyembryonic webworm parasitoid *Copidosoma sosares* Walker (Hymenoptera: Encyrtidae). *H. lanatum* fruits from populations with webworms parasitized by *C. sosares* had lower concentrations of furanocoumarins, with the exception of sphondin, than fruits from plants infested with webworms free from parasitism. Lower levels of these furanocoumarins may reduce negative effects on the fitness of this parasitoid. In contrast with the variation

in furanocoumarin content, the ability of webworms to metabolize furanocoumarins by cytochrome P450 did not differ significantly among populations from New Mexico to Alberta.

Key Words—Furanocoumarin, cytochrome P450, ultraviolet light, carotenoid, lutein, altitude, tritrophic interaction, geographic mosaic, *Depressaria pastinacella*, *Heracleum lanatum*, *Pastinaca sativa*, *Copidosoma sosares*.

INTRODUCTION

Chemical defenses in plants against biotic stress agents function in environments that influence their efficacy and, therefore, their adaptive value to the plant (Baldwin and Preston, 1999). Among plant allelochemicals that are particularly dependent on abiotic conditions are phototoxins, chemicals whose toxicity is enhanced by exposure to light (Arnason et al., 1992). Many phototoxic plants grow preferentially in sunlit habitats and maximize exposure of herbivores to photoactivating wavelengths (Berenbaum, 1981; Arnason et al., 1992). In that light itself can cause damage to plants, many phototoxic plants also produce antioxidant allelochemicals that ameliorate light-induced oxidative damage; the content of these antioxidant compounds in plants varies in response to oxidative stress created by high light exposure (Frankel and Berenbaum, 1999; Polle et al., 1999; Hansen et al., 2002). Because variation in light intensity can exist across the host range of a phototoxic plant and its herbivores, the relative benefit of a phototoxic allelochemical as a herbivore defense may vary on a landscape scale.

Specialist herbivores of phototoxic plants have behavioral and physiological adaptations that limit the effects of photoactivation (Aucoin et al., 1990, 1995; Arnason et al., 1992). Among these counteradaptations is sequestration of plant antioxidants that when ingested along with phototoxins can reduce toxicity (Ahmad and Pardini, 1990; Aucoin et al., 1995). Chief among these sequestered plant antioxidants are carotenoids and xanthophylls (Valadon and Mummery, 1978; Rothschild et al., 1986; Aucoin et al., 1990; Fields et al., 1990). These tetraterpenoids function as accessory pigments, photoprotectants, and antioxidants in photosynthetic tissues (Britton, 1993); as singlet oxygen quenchers and free radical scavengers (Burton and Ingold, 1984; Krinsky, 1989), carotenoids allow plants to cope with oxidative stress (Larson, 1988). Because light exposure presents oxidative challenges to herbivores as well as plants, carotenoids and xanthophylls also reduce phototoxicity in insects (Robertson and Beatson, 1985; Aucoin et al., 1990; Green and Berenbaum, 1994).

Lepidoptera do not synthesize carotenoids but rather acquire them directly from host tissues with little modification (Feltwell, 1978; Kayser, 1985). Among lepidoptera that consume phototoxic plants, most sequester lutein, the

predominant carotenoid in angiosperm photosynthetic tissues (Ahmad and Pardini, 1990; Britton, 1993). This selective sequestration allows lepidopteran specialists on phototoxic plants to reduce effects of phototoxins before and during photoactivation (Rothschild et al., 1986; Ahmad and Pardini, 1990).

One herbivore that encounters host plant phototoxins under a variety of light conditions is the parsnip webworm *Depressaria pastinacella*, an oligophagous caterpillar that feeds on the reproductive tissues of plants in the genera *Heraclium* and *Pastinaca* (Hodges, 1974; McKenna and Berenbaum, 2003). The interaction of the parsnip webworm with its host plants is mediated by furanocoumarins, phototoxic compounds activated by ultraviolet A (UVA) light (320–400 nm). Furanocoumarins cause damage in the presence of UVA by directly binding to DNA and proteins, and by forming reactive oxyradicals and free radicals that damage biologically sensitive molecules (Berenbaum, 1991). The parsnip webworm tolerates high concentrations of host plant furanocoumarins through rapid detoxification by cytochrome P450 monooxygenases (Nitao, 1989). In populations of the parsnip webworm and the wild parsnip *Pastinaca sativa*, its predominant host plant in the midwestern United States, furanocoumarin production by the plant and detoxification capabilities of the webworms are genetically variable traits subject to reciprocal selection pressures (Berenbaum et al., 1986; Berenbaum and Zangerl, 1992; Zangerl and Berenbaum, 1997). Parsnip webworms also cope with furanocoumarin phototoxicity by sequestering lutein and other xanthophylls from host plant tissues (Carroll et al., 1997). This selective sequestration of dietary lutein is associated with decreased behavioral avoidance of UVA light, presumably because of decreased oxidative stress from furanocoumarins (Carroll et al., 1997).

Although examined most intensively in the Midwest, the interaction between the parsnip webworm and its apiaceous host plants occurs throughout much of North America. The parsnip webworm was introduced to eastern North America about 150 yr ago and spread to disturbed habitats throughout eastern and northern North America (Riley, 1889; Berenbaum and Zangerl, 1991). It has since spread west and become established throughout the Pacific Northwest and the intermontane region of the western United States and southwestern Canada, although it occurs much more sporadically in the southern part of its range (Hodges, 1974; McKenna and Berenbaum, 2003).

Throughout much of its range, the parsnip webworm has acquired another host plant, a native cow parsnip, *Heraclium lanatum* (Berenbaum and Zangerl, 1991). In many western locales, the webworm utilizes the more abundant *H. lanatum* exclusively. Webworms feeding on *H. lanatum* fruits encounter concentrations of phototoxic furanocoumarins significantly different from webworms feeding on *P. sativa* fruits (Berenbaum and Zangerl, 1991; Zangerl and Berenbaum, 2003). Relative to eastern and midwestern congeners, western webworms encounter high intensities of photoactivating UVA light through the

southern half of their introduced range because of the occurrence of host plants at higher altitudes in lower latitudes (Young, 1985; Blumthaler et al., 1997). Through the combined effects of altitude and latitude on UVA light intensity, populations of *D. pastinacella* in western North America may vary more than twofold in experience of maximum UVA exposure along a UVA gradient from British Columbia to New Mexico.

The ability of webworms to act as selective agents on host plant chemistry may be affected not only by abiotic factors, such as UV intensity, but also by biotic factors, such as the presence of a third trophic level, e.g., a specialist parasitoid. Webworms in New Mexico, Utah, and southeastern Idaho are heavily attacked by the polyembryonic egg-larval parasitoid *Copidosoma sosares* Walker, an encyrtid wasp native to Europe that specializes on *Depressaria* spp. (Ode et al., 2004). *C. sosares* has not been previously observed in webworm populations in other regions of North America that lack webworm parasitoids of comparable impact (Ode et al., 2004). Significant rates of parasitism can lead to decreased selection pressure on host plant chemical defenses because of relaxation of herbivory (Price et al., 1980; but see Coleman et al., 1999). At the same time, host plant chemical defenses may negatively affect parasitoid fitness, especially if the parasitoid is more sensitive to the allelochemicals than its herbivore host (Reitz and Trumble, 1996; Ode et al., 2004; Ode, 2006). Dietary furanocoumarins can limit the size of polyembryonic parasitoid broods as well as the growth and development of individual parasitoid larvae in the host (Reitz and Trumble, 1996). Thus, host plants may experience selection for reduced chemical defense to increase parasitoid fitness (Turlings and Benrey, 1998; Ode et al., 2004).

Throughout its North American host range, the parsnip webworm has been introduced into a mosaic of different UVA light intensities, host plant furanocoumarin levels, and parasitoid infestation levels. In this study, we characterized the effects of geographically variable abiotic (UV) and biotic (parasitism) factors on the interaction between parsnip webworms and their apiaceous host plants. To quantify photochemical stresses encountered by webworms in these populations, we measured host plant furanocoumarin content. Because furanocoumarins are metabolically expensive to synthesize (Zangerl and Berenbaum, 1997) and because their toxicity is enhanced by photoactivating UVA, furanocoumarin content should be lower in populations that experience high UVA light intensities. We quantified individual linear and angular furanocoumarins separately in fruits because individual furanocoumarins differ in their contributions to resistance against the parsnip webworm (Berenbaum et al., 1986). Given the importance of metabolism in resistance to furanocoumarins (Nitao, 1989), we also compared the cytochrome-P450-mediated metabolism of furanocoumarins in webworms from different populations (Berenbaum et al., 1986; Berenbaum and Zangerl, 1998). Webworms experience higher mortality on host plant

Percent of plants attacked by *D. pastinacella* and webworms parasitized by the encyrtid *Copidosoma sosares* are given (for small populations) or estimated (for populations > 100). All the populations except for BBWA and SHID represent new locales for the parsnip webworm.

chemotypes that do not match their metabolic phenotype, presumably because of inefficient detoxification and subsequent accumulation of unmetabolized furanocoumarins (Berenbaum and Zangerl, 1998; Zangerl and Berenbaum, 2003). By examining populations with mismatched profiles, factors that vary predictably on a landscape scale can be identified that alter the efficacy of traits mediating the interaction (Thompson, 1999; Zangerl and Berenbaum, 2003).

Because UV irradiance also affects carotenoid production in plants (Jahnke, 1999), we measured lutein content of host plants across the

altitudinal/latitudinal gradient as well as lutein sequestration in sixth instar webworms from western populations experiencing different UV light regimes as a result of latitude and altitude. Arthropods can increase antioxidants and pigmentation in response to high UVA intensities (Vega and Pizarro, 2000; Borgeraas and Hessen, 2002). If parsnip webworms use dietary lutein to reduce oxidative stress associated with furanocoumarins, greater sequestration would be expected in western populations that experience high UVA radiation.

Finally, because parasitism by *C. sosares* constitutes a significant biotic factor that affects the chemical mediation of the interaction of western webworms and their host plants, we examined the effect of the presence of *C. sosares* on host plant furanocoumarin chemistry by comparing furanocoumarin content of fruits from populations with and without the parasitoid.

METHODS AND MATERIALS

Sampling of Insect and Plant Populations. We examined 13 populations of parsnip webworms and their host plants in western North America along a latitudinal and altitudinal gradient from 35.4°N to 53.2°N (Table 1; Figure 1). For one of these populations (LPID), *P. sativa* was the exclusive host, whereas *H. lanatum* was the exclusive host for the other 12 populations. In six populations in New Mexico, Utah, and southeastern Idaho, parsnip webworms were attacked by *C. sosares* (Table 1). These parasitoid populations represent a new record for *C. sosares* in North America (Ode, personal communication). Parasitism rates of webworms varied considerably among populations and years, ranging from 5% (Dalton Creek, NM) to over 90% (Payson Lakes, UT) of the sixth instars present, creating a mosaic of attacked and unattacked webworms across the North American range of this parasitoid (Table 1).

To minimize the degradation of lutein, samples for chemical analysis were collected directly onto powdered dry ice (Oliver and Palou, 2000). Half-filled fruits, which are regularly consumed by sixth instar webworms (Berenbaum et al., 1986), were sampled from host plants for analysis of furanocoumarins and lutein. Sixth instars collected for lutein quantification were separated from plant material and isolated for 2 hr to clear plant material from their guts before placement on powdered dry ice. Samples were kept in a -80°C freezer until extraction.

FIG. 1. Approximate locations of *Depressaria pastinacella* populations sampled in western North America. Populations are labeled by acronyms presented in Table 1 and the text. *Pastinaca sativa* is the only host plant present in the LPID population, whereas *Heracleum lanatum* is the only host plant found in all other populations.

TABLE 2. ESTIMATION OF DAILY UV IRRADIANCE (DUV) FROM THE COMPARISON OF COLLECTION SITE CHARACTERISTICS (LATITUDE, ALTITUDE, COLLECTION DATE) WITH DATA FROM THE NATIONAL ULTRAVIOLET MONITORING CENTER (NUVMC) MONITORING STATION

Population	Latitude (N)	Altitude (m)	Date	Station	Station latitude	Δ Elevation (m)	DUV (J/cm^2)
HXBC	53°15.760	702	08/09/01	Olympic	48°51	196	4596
CHAB	49°36.279	1243	08/08/01	Glacier	48°51	267	4272
BBWA	48°87.807	2	07/02/00	Olympic	48°51	-6	4797
AIWA	48°60.608	805	07/02/00	Olympic	48°51	799	5218
SHID	47°45.303	1439	07/03/00	Glacier	48°51	463	6198
MCID	42°19.851	1911	07/18/00	RMNP	40°03	-985	6427
LPID	42°09.853	1829	07/18/00	RMNP	40°03	-1067	6363
PLUT	39°56.185	2404	07/14/01	Canyonlands	38°47	1106	8516
DCNM	35°46.519	2250	07/13/01	Albuquerque	35°09	635	8340
LTNM	35°43.727	2560	07/13/01	Albuquerque	35°09	945	8603
BTNM	35°39.523	3006	07/13/01	Albuquerque	35°09	1391	8983

The latitude and collection date from the population site are used to determine on which day the monitoring station has the same solar angle as the population site. The raw DUV value acquired for this day is corrected for the difference in elevation between the population and monitoring station sites by methods described in the text. The acronyms for population sites are described in Table 1. NUVMC monitoring stations: Glacier—Glacier National Park; Olympic—Olympic National Park; RMNP—Rocky Mountain National Park; Canyonlands—Canyonlands National Park; Albuquerque—Albuquerque.

Estimates of Daily UV Irradiance. To estimate daily UV exposure at a population site, we used measurements of total daily UV irradiance collected by the National Ultraviolet Monitoring Center (NUMC; University of Georgia and Environmental Protection Agency, 2003) at seven sites throughout North America (Table 2). At each site, the total daily UV irradiance was measured by a Brewer spectrophotometer as the total combined flux of solar UVA (320–360

FIG. 2. Tissue concentrations of (A) total furanocoumarins, linear furanocoumarins, and angular furanocoumarins; (B) the linear furanocoumarins bergapten and imperatorin; (C) the linear furanocoumarins isopimpinellin and xanthotoxin; and (D) the angular furanocoumarins angelicin and sphondin in half-filled fruits of *H. lanatum* and *P. sativa* from populations in western North America. Populations are labeled by acronyms presented in Table 1 and the text. *P. sativa* is the only host plant present in the LPID population, whereas *H. lanatum* is the only host plant found in all other populations. Content means for each class of furanocoumarin significantly differ across populations by one-way analysis of variance (ANOVA; $P < 0.05$). Populations that do not share a superscript letter have significantly different mean contents by Tukey's honestly significantly different (HSD) test ($P < 0.05$). Error bars indicate one standard error ($N = 18$ –20 for each population, 176 total).

FIG. 2. (continued).

nm) and UVB irradiance (290–320 nm). To calculate daily UV irradiance by using the NUMC data, we had to compensate for differences in latitude and altitude between the sampling site and the monitoring station. The intensity of solar radiation varies with latitude on a given day, primarily because of differences in the angle of incidence between the sun and the horizon, as measured by the maximum solar angle at solar noon. However, sites at different latitudes may receive the same amount of UV irradiance on different days if they share the same maximum solar angle. To correct for differences in angle of incidence due to latitude, the maximum solar angle at solar noon was determined for the sampling site for the day of collection by using the site's latitude and longitude with a solar position calculator (NOAA, 2003). We then used the coordinates of the UV monitoring station and the solar position calculator to determine the precise day on which the UV monitoring station experienced the same maximum solar angle as the sampling site. Because UV irradiance is positively correlated with altitude due to a reduction in the amount of radiation intercepted or scattered by air molecules (Diffey, 1991; Schmucki and Philipona, 2002), the daily UV irradiance obtained from the NUMC data was corrected for differences in altitude as:

$$(\text{daily UV irradiance}) \times (1 + (\Delta \text{ altitude})(\text{altitude effect}))$$

where Δ altitude is [(altitude (sampling site) – altitude (UV monitoring site))] and the altitude effect, or change in the intensity of radiation with altitude, is 0.000107 per meter based on the studies conducted during the summer with recording stations over a wide range of elevation in midlatitude mountains (Blumthaler et al., 1997; Schmucki and Philipona, 2002).

Furanocoumarin Analysis of Plant Samples. *H. lanatum* and *P. sativa* furanocoumarins were quantified as in Berenbaum and Zangerl (1992). Freeze-dried fruits were weighed, crushed in an Eppendorf tube with a micropestle, and extracted with 1 ml ethyl acetate. Normal-phase liquid chromatography (HPLC) was performed on a Waters high-pressure liquid chromatograph with a Model 440 absorbance (254 nm) detector. Ten microliters of each diluted sample were auto-injected and separated on an Alltech Absorbosphere Silica 5U (150 × 4.6 mm) with a 55:32:3 cyclohexane/isopropyl ether/butanol eluent mixture. Furanocoumarins were quantified by comparison of the integrated peaks against a furanocoumarin standard containing known quantities of bergapten (Sigma Inc., St. Louis, MO, USA), xanthotoxin (Sigma Inc., St. Louis, MO, USA), imperatorin (Serva, Heidelberg, Germany), isopimpinellin (Indofine, Belle Mead, NJ, USA), angelicin (Sigma Inc., St. Louis, MO, USA), and sphondin (gift of Dr. W. Wulff, University of Chicago). Sample size (number of plants) varied from 18 to 20, depending on the number of intact half-filled fruits available from each population.

TABLE 3. DIFFERENCES IN FURANOCOUMARIN CONTENT OF *Heracleum lanatum* FRUITS FROM POPULATIONS WHERE THE WEBWORM PARASITOID *C. sosares* WAS PRESENT AND FRUITS FROM POPULATIONS WHERE THIS PARASITOID WAS ABSENT

Furanocoumarin	Concentration ($\mu\text{g}/\text{mg}$ dry mass)		<i>t</i> value	<i>df</i>	<i>P</i> value
	Population				
	<i>C. sosares</i> absent	<i>C. sosares</i> present			
Angelicin	1.546 (0.182)	1.043 (0.133)	2.235	114.906	0.027
Bergapten	4.243 (0.605)	0.670 (0.027)	5.898	57.223	<0.001
Imperatorin	5.549 (0.417)	3.531 (0.395)	3.512	139.221	0.001
Isopimpinellin	0.841 (0.089)	0.564 (0.629)	2.548	111.873	0.012
Sphondin	1.469 (0.213)	2.208 (0.117)	-3.032	91.751	0.003
Xanthotoxin	0.214 (0.020)	0.057 (0.011)	7.024	90.846	<0.001
Linear furanocoumarins	10.848 (0.382)	4.822 (0.411)	10.745	148.520	<0.001
Angular furanocoumarins	3.015 (0.335)	3.250 (0.192)	-0.608	94.684	0.544
Total furanocoumarins	13.863 (0.353)	8.072 (0.577)	8.563	148.024	<0.001

Furanocoumarin means are compared by an independent samples *t* test. Standard error is given in parentheses. Degrees of freedom (*df*) are corrected in each test because equal variances of samples are not assumed. Sample size is 58 from populations where *C. sosares* is present and 98 from populations where *C. sosares* is absent.

Furanocoumarin Metabolism in Parsnip Webworms from Different Populations. Because dietary exposure to plant components affects larval P450 enzyme activity, field-caught webworms were reared to adulthood and mated to obtain offspring reared under common environmental conditions. Parsnip webworms collected as late instar larvae or pupae were allowed to emerge as adults, then subjected to photoperiod and temperature parameters simulating winter conditions to break reproductive diapause (Nitao and Berenbaum, 1988). "Overwintered" adults were caged with wild parsnip leaves at 20°C and 16:8 light/dark photoperiod to allow for mating and oviposition. Neonates were reared to sixth instar on a semidefined artificial diet that lacks a significant carotenoid or furanocoumarin source (Carroll et al., 1997). Five of

FIG. 3. Two-dimensional plot of furanocoumarin concentrations of *H. lanatum* half-filled fruits against estimated daily ultraviolet (UV) irradiance for (A) linear, angular, and total furanocoumarins as well as (B) the individual furanocoumarins angelicin, bergapten, imperatorin, isopimpinellin, sphondin, and xanthotoxin. Univariate regression analysis was conducted for combined linear (bergapten, imperatorin, isopimpinellin, and xanthotoxin), combined angular (angelicin and sphondin), and total furanocoumarins (all six furanocoumarins) as well as the individual compounds. For each compound, a best-fit regression line has been added. The r^2 value and *P* value from the linear regression model are presented above each regression line ($N = 176$).

FIG. 4. Whole midgut metabolism rates for five furanocoumarins (xanthotoxin, bergapten, isopimpinellin, imperatorin, and sphondin) in sixth instar *D. pastinacella* from five populations in western North America. No significant differences were observed among population means for the metabolism of any furanocoumarin by a one-way ANOVA ($P < 0.05$). Error bars indicate one standard error. Sample size varied from 17 to 49, depending on the availability of sixth instars reared from parents collected in each population (LTNM—Little Tesuque, NM; DCNM—Dalton Creek Canyon, NM; BTNM—Big Tesuque, NM; LPID—Lower Paris, ID; CHAB—Cypress Hills, AB).

the 13 populations (Little Tesuque, NM; Big Tesuque, NM; Dalton Creek Canyon, NM; Lower Paris/Bear Lake, ID; Cypress Hills, Alberta) from which webworms were collected produced sufficient number of larvae to be used in metabolism bioassays. Sample size varied from 17 to 49, depending on the availability of sixth instars reared from parents collected in each population.

Midgut metabolism rates for five furanocoumarins (xanthotoxin, bergapten, isopimpinellin, imperatorin, and sphondin) in sixth instars were compared among populations according to Berenbaum and Zangerl (1992). Whole midguts were dissected, rinsed, and homogenized with a Model 985-370 Tissue Tearor (Biospec Products, Bartlesville, OK, USA). A portion of the homogenate (70 μ l) was added to 1 ml phosphate reaction buffer (pH 7.8) containing a mixture of xanthotoxin, bergapten, isopimpinellin, imperatorin, and sphondin. The reactions were run for 15 min in a 30°C water bath and terminated by exposure to an 85°C water bath for 5 min. Unmetabolized furanocoumarins were extracted

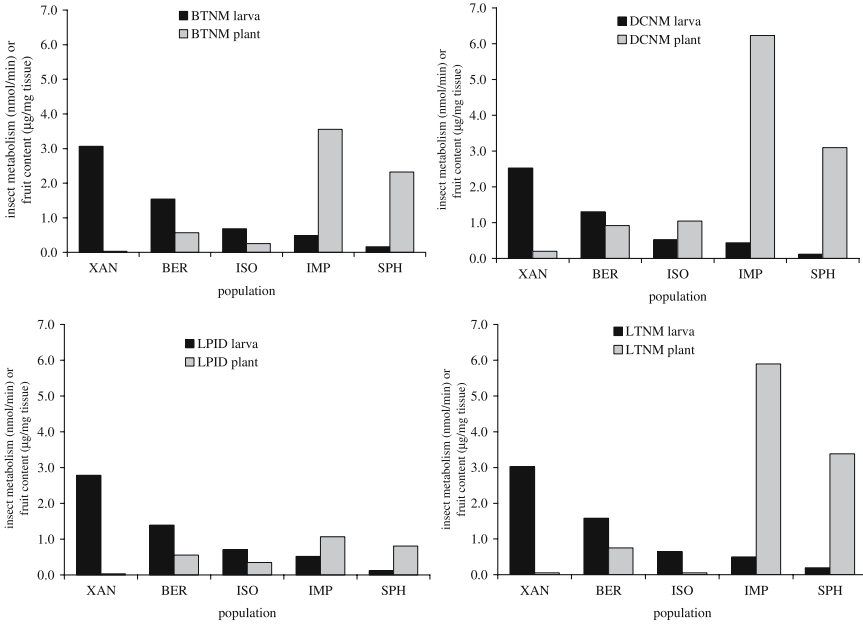

FIG. 5. Host plant furanocoumarin concentrations of half-filled fruits and whole midgut furanocoumarin metabolism rates of sixth instar *D. pastinacella* from the BTNM, DCNM, LTNM, and LPID populations in western North America. On the y-axis, the units for metabolism apply to the webworms, whereas the units for fruit content apply to the host plants. *P. sativa* is the only host plant present in the LPID population, whereas *H. lanatum* is the only host plant in all other populations. Furanocoumarin content for half-filled fruits and webworm midgut metabolic rates appear mismatched in all populations (LTNM—Little Tesuque, NM; DCNM—Dalton Creek Canyon, NM; BTNM—Big Tesuque, NM; LPID—Lower Paris, ID).

with ethyl acetate and analyzed by normal-phase HPLC (Berenbaum and Zangerl, 1992). The amount of each furanocoumarin metabolized in each reaction was determined by comparison against time-zero controls.

Lutein Analysis of Plant Samples. To quantify lutein in parsnips from different populations, plant material was extracted according to a protocol modified after Riso and Porrini (1997) and O’Neil and Schwartz (1992). All samples were kept frozen on dry ice and extracted under minimal light conditions to reduce degradation of lutein because of oxygen, light, and heat. Frozen plant material was weighed and crushed to a powder in liquid nitrogen with a mortar and pestle. Because of the sensitivity of plant material to lutein degradation, samples were not dried to obtain a direct measure of sample dry mass; instead, a subsample of the powdered plant sample was weighed,

removed, and freeze-dried for later calculation of a wet mass–dry mass conversion factor. Approximately 200 mg of powdered material were placed in a preweighed Eppendorf tube, weighed, and extracted with 1 ml methanol containing 0.1% of the antioxidant butylhydroxytoluene (BHT) (Oliver and Palou, 2000). The samples were vortexed and sonicated in a Model 250 Ultrasonic Cleaner (RAI Research) for 2 min and then placed on ice for 30 min under a nitrogen atmosphere to maximize the extraction of lutein while minimizing oxidation. The sample mixture was then microcentrifuged for 5 min at 14,000 rpm at 5°C. Samples were stored in the dark at –80°C until separation by reverse-phase HPLC. Sample size varied from 19 to 39 for each population.

Reverse-phase HPLC was performed with a Waters 996 photodiode array (PDA) detector with detection of xanthophylls at 445 nm. Separation of lutein from other xanthophylls was improved by the use of a Vydac 201TP54 C₁₈ column (Yeum et al., 1996). Twenty microliters of each sample were auto-injected and separated with a 90:10 methanol/acetonitrile eluent mixture containing 0.01% BHT and 0.05% of the solvent modifier triethylamine (Oliver and Palou, 2000). Three-dimensional UV–VIS spectral data were captured, analyzed, and quantified with Millenium³² System software. Lutein was identified and quantified by comparison of an integrated peak against a purified lutein standard generously supplied by Kemin, Inc. (Des Moines, IA, USA).

Lutein Analysis of Insect Samples. To extract lutein from webworms, preweighed whole frozen webworms were crushed to a powder in liquid nitrogen in a 2.0-ml Eppendorf tube with a micropestle. The powdered remains were extracted with 1 ml methanol containing 0.1% BHT, vortexed, sonicated for 2 min, and placed on ice for 30 min under a nitrogen atmosphere. The sample mixture was then microcentrifuged for 8 min at 14,000 rpm at 5°C to separate solid remains and refractory lipids from the lutein extract. Lutein was isolated by HPLC as described. Sample size varied from 11 to 14, depending on the availability of sixth instars from each population.

Statistical Analysis. For the half-filled fruits, amounts of total furanocoumarin, total linear furanocoumarin, and total angular furanocoumarin, as well as individual furanocoumarins and lutein concentrations, were compared among

FIG. 6. Lutein content of (A) half-filled fruits of *P. sativa* (LPID) and *H. lanatum* (all other populations) and (B) sixth instar *D. pastinacella* from populations in western North America. Populations are labeled by acronyms presented in Table 1 and are arranged left to right from north to south. *P. sativa* is the only host plant present in the LPID population, whereas *H. lanatum* is the only host plant in all other populations. Lutein content differs significantly across populations by a one-way ANOVA ($P < 0.05$). Populations that do not share a superscript letter have significantly different mean contents by Tukey's HSD test ($P < 0.05$). Sample size for each population varied from 19 to 39 for fruits and 11 to 14. Error bars indicate one standard error.

populations by one-way analysis of variance (ANOVA). Insect lutein and whole midgut metabolic rates (for each furanocoumarin) were also compared among populations by one-way ANOVA. Treatment means were compared among individual populations by Tukey's honestly significantly different test (SPSS, 1999). Univariate regression analysis was conducted to determine the effect of daily UV irradiance on plant and insect chemistry (SPSS, 1999).

To determine the effect of the presence of the parasitoid *C. sosares* on host plant chemistry, we compared the furanocoumarin concentration of cow parsnips from populations where the parasitoid was present with cow parsnips from populations where the parasitoid was absent by independent sample *t* tests (SPSS, 1999). Separate tests were conducted for total furanocoumarins, linear furanocoumarins, and angular furanocoumarins, as well as each individual furanocoumarin.

To evaluate the match between host plant furanocoumarin production and webworm metabolic capabilities within a population, we examined the interaction between furanocoumarins (host plant furanocoumarins and midgut metabolism capability) and organism (wild parsnip or parsnip webworm) as compared by repeated-measures multivariate analysis of variance (MANOVA), with furanocoumarins as the between-subject factor and organism as the within-subject factor (SPSS, 1999). Mean levels of furanocoumarin production by plants and midgut metabolism by webworms were compared separately for each population.

RESULTS

Furanocoumarin Analysis of Plant Samples. Significant differences were observed among populations for all measures of half-filled fruit furanocoumarin concentration (Figure 2, one-way ANOVA). Both total furanocoumarins and total linear furanocoumarins of fruits were negatively correlated with daily UV irradiance ($r^2 = 0.079$ and 0.166 , respectively, $P < 0.001$; regression analysis), whereas total angular furanocoumarin content of fruits was not correlated with UV light exposure ($r^2 = 0.015$, $P = 0.054$; regression analysis; Figure 3). Among the individual furanocoumarins in fruits, angelicin ($r^2 = 0.018$, $P = 0.042$), bergapten ($r^2 = 0.200$, $P < 0.001$), isopimpinellin ($r^2 = 0.035$, $P = 0.007$), and

FIG. 7. Two-dimensional plot of lutein concentrations of (A) *H. lanatum* half-filled fruits and (B) sixth instar *D. pastinacella* against estimated daily UV irradiance for the host plant's population. A regression line has been added, with the r^2 value and P value from the linear regression model presented above the line. Linear regression models indicate that daily UV irradiance is a good predictor of webworm, but not fruit, lutein content ($N = 155$ for fruits and 75 for webworms).

xanthotoxin ($r^2 = 0.168$, $P < 0.001$) were negatively correlated with daily UV irradiance, whereas sphondin ($r^2 = 0.130$, $P < 0.001$) was positively correlated with daily UV irradiance (Figure 3). Imperatorin ($r^2 = 0.003$, $P = 0.226$) was not significantly correlated with daily UV irradiance (Figure 3).

The furanocoumarin concentration of fruits from populations with and without *C. sosares* differed significantly for all individual furanocoumarins tested (Table 3). Fruits from populations with *C. sosares* present had lower concentrations of total furanocoumarins and linear furanocoumarins than fruits from populations where *C. sosares* was absent ($P < 0.05$, independent samples *t* test; Table 3). Total angular furanocoumarins did not differ in the presence or absence of *C. sosares* ($P > 0.05$, independent samples *t* test; Table 3). Among the individual furanocoumarins, angelicin, bergapten, imperatorin, isopimpinellin, and xanthotoxin were lower and sphondin was higher in *H. lanatum* populations where *C. sosares* was present ($P < 0.05$, independent samples *t* test; Table 3).

Furanocoumarin Metabolism in Parsnip Webworms from Different Populations. Despite the disparate geographical origins of the five webworm populations, the midgut metabolic rates for all five furanocoumarins did not differ among sixth instars ($P < 0.05$; one-way ANOVA; Figure 4). For four of these populations, fruit concentrations and insect metabolism rates were compared for five individual furanocoumarins. In all four, a significant interaction between furanocoumarin and organism type occurred in a comparison of fruit concentration and midgut metabolism [Pillai's Trace = 0.901 (BTNM), 0.915 (DCNM), 0.936 (LPID), and 0.958 (LTNM); $P < 0.001$; MANOVA], indicating that the relative amount of individual furanocoumarins metabolized by insects differed from the plant furanocoumarin profile (Figure 5). In particular, webworm capacity for metabolizing xanthotoxin proportionally exceeded the relatively low production of xanthotoxin in fruits, whereas webworm capacity for metabolizing imperatorin and sphondin was disproportionately less than the relative amounts of these two furanocoumarins in fruits.

Lutein Analysis of Plant and Insect Samples. Although mean lutein concentration of fruits varied among populations ($P < 0.05$, one-way ANOVA; Figure 6), daily UV irradiance was not a good predictor of fruit lutein ($r^2 = 0.001$, $P = 0.282$; regression analysis; Figure 7). By contrast, webworms from populations exposed to more intense daily UV irradiance had higher lutein ($r^2 = 0.236$, $P < 0.001$; regression analysis; Figure 7), with significant differences observed across the populations ($P < 0.05$, one-way ANOVA; Figure 6).

DISCUSSION

At high altitudes, *H. lanatum* produces less total furanocoumarin and linear furanocoumarins but not angular furanocoumarins in half-filled fruits than

plants under less intense UV light regimes at lower altitudes. *H. lanatum* from populations in the central and southwestern United States (New Mexico, Utah, and southern Idaho) produced more sphondin (range 0.9–3.5 $\mu\text{g}/\text{mg}$) and less xanthotoxin (range 0.0–0.2 $\mu\text{g}/\text{mg}$) than cow parsnips from the Midwest (0.4 $\mu\text{g}/\text{mg}$ sphondin and 1.1 $\mu\text{g}/\text{mg}$ xanthotoxin; Zangerl and Berenbaum, 2003). A similar pattern pertains to *P. sativa*: western wild parsnip populations from Lower Paris, ID, have higher fruit content of sphondin (0.9 $\mu\text{g}/\text{mg}$) and lower content of bergapten (0.6 $\mu\text{g}/\text{mg}$) and xanthotoxin (0.03 $\mu\text{g}/\text{mg}$) than parsnips from the Midwest (0.3 $\mu\text{g}/\text{mg}$ sphondin, 1.9 $\mu\text{g}/\text{mg}$ bergapten, and 4.0 $\mu\text{g}/\text{mg}$ xanthotoxin; Zangerl and Berenbaum, 2003) or the Netherlands (0.5 $\mu\text{g}/\text{mg}$ sphondin, 2.2 $\mu\text{g}/\text{mg}$ bergapten, and 2.7 $\mu\text{g}/\text{mg}$ xanthotoxin; Ode et al., 2004).

The differences between linear and angular furanocoumarins under high UV intensities may be partially explained by the relative importance of photoactivation to overall toxicity. Because linear furanocoumarins form diadducts with pyrimidine bases in the presence of photoactivating UVA light, their phototoxicity is greatly enhanced relative to their dark toxicity (Berenbaum, 1991). Most of the toxic effects of linear furanocoumarins against insect herbivores are attributed to photogenotoxicity rather than photooxidation (Berenbaum, 1991). In contrast, angular furanocoumarins form only monoadducts with pyrimidine bases because of steric inhibition, resulting in a more modest increase in phototoxicity over their dark toxicity and a greater reliance on photooxidation overall. In addition, the efficacy of furanocoumarin photogenotoxicity increases under lower oxygen partial pressures (Bianchi et al., 1996), such as those experienced at high altitudes. Because enhancement of linear furanocoumarin toxicity by UVA is proportionally greater and more dependent on photogenotoxicity, increases in UVA intensity at high altitudes should improve the efficacy of linear furanocoumarins more than angular furanocoumarins. Under consistently greater UVA light intensities experienced, proportionately fewer linear furanocoumarins yield equivalent toxicity toward herbivores. In *P. sativa*, furanocoumarin biosynthesis has a significant cost in terms of reproductive fitness (Zangerl and Berenbaum, 1997). If similar costs occur in *H. lanatum*, a reduction in linear furanocoumarin production could allow plants to shift resources to more costly production of angular furanocoumarins (Berenbaum et al., 1986; Zangerl and Berenbaum, 1997), resulting in the increase in sphondin observed here.

Decreased production of phototoxic allelochemicals in plants under high light intensities has also been observed with benzyloisoquinoline alkaloids, compounds activated in the near UV spectrum. Larson et al. (1991) compared the production of phototoxic isoquinoline alkaloids in the alpine columbine *Aquilegia caerulea* and the low-elevation columbine *A. canadensis* under ambient and elevated UVB radiation. Alkaloid concentrations in *A. caerulea* under elevated UVB were significantly lower than *A. canadensis* or *A. caerulea*

under ambient UVB, an effect the authors attributed to increased UVB-mediated destruction of the alkaloids; the possibility that reduced production may represent an adaptation to increased efficacy of chemical defenses under higher light intensities was not considered. Although isoquinoline alkaloids are photoactivated by near UV rather than UVB radiation (Larson et al., 1991), increases in near UV and UVB occur concomitantly under natural light conditions.

Previous studies of allelochemical variation along altitudinal and latitudinal transects have found a general trend toward lower concentrations of allelochemicals at high altitudes and latitudes, which has usually been attributed to reduced herbivory (Salmore and Hunter, 2001, but see Koptur, 1985 and Preszler and Boecklen, 1996). It is unlikely that differences in insect herbivory account for the results obtained in our study; in our limited survey over 2 yr, rates of attack by *D. pastinacella* in infested populations of *H. lanatum* did not vary consistently with UV intensity, altitude, or latitude. However, differences in furanocoumarin concentrations across populations may have arisen in response to selection pressures from other herbivores, including deer, tule elk, moose, black bear, and grizzly bear, as well as domesticated cattle (McMillan, 1953; Hamer et al., 1991; Holcroft and Herrero, 1991; Ralph and Pfister, 1992; Gogan and Barrett, 1995; Ramcharita, 2000).

An alternative and not mutually exclusive explanation for the differences in host plant furanocoumarins is the impact of the parasitoid *C. sosares*, which occurred in populations that experienced high ambient UV intensity at high altitudes. Compared to populations from western North America that lack a major parasitoid, plant populations associated with webworms parasitized by *C. sosares* display furanocoumarin profiles consistent with increased fitness of the parasitoid (Ode et al., 2004). In the Netherlands, the likelihood of parasitoid attack was negatively correlated with host plant isopimpinellin content, and the survivorship of all male and mixed-sex broods was negatively correlated with xanthotoxin content. Parsnips from the Netherlands had lower content of all linear furanocoumarins, including isopimpinellin and xanthotoxin, relative to parsnips from the midwestern United States, where *C. sosares* is absent; lower furanocoumarin content may be a response to selection for greater parasitoid fitness. In our survey of western *H. lanatum*, concentrations of all furanocoumarins except sphondin were lower in fruits from populations where *C. sosares* was present than in fruits from populations attacked by webworms in the absence of parasitoids. The furanocoumarin chemistry of host plants from these populations appears more conducive to the survival of the parasitoid and may have facilitated its ability to adapt to the parsnip webworm's host plant switch to the novel North American host plant *H. lanatum*.

The impact of *C. sosares* on host plant chemistry due to increased webworm mortality may be limited, because the host completes larval feeding before it is killed by the parasitoid (Ode et al., 2004); rather, *C. sosares* could

indirectly exert strong selection pressure on the host plant through changes in host physiology and behavior (Turlings and Benrey, 1998; Coleman et al., 1999). Koinobiont parasitoids can alter the foraging behavior (Karban and Englishloeb, 1997), developmental time (Harvey et al., 1999), consumption rates (Rahman, 1970; Slansky, 1978; Coleman et al., 1999), larval performance (Rahman, 1970; Coleman et al., 1999), and metabolism (Rahbé et al., 2002) of their hosts, all of which can be components of herbivore selection pressures on host plant chemistry.

That furanocoumarin metabolism rates did not vary among webworms from different populations in western North America contrasts with previous findings (Berenbaum and Zangerl, 1998; Zangerl and Berenbaum, 2003) that metabolic rates of midwestern webworms on wild parsnip differ across distances as small as 1 km. In these midwestern populations, phenotype mismatching increased with the presence of an alternative host plant (Zangerl and Berenbaum, 2003). We found significant overall differences between metabolic capabilities and host plant furanocoumarins in four western webworm populations despite the fact that only one host species was present. If anything, western webworm metabolic profiles resemble the furanocoumarin profiles of wild parsnip plants from the Midwest more closely than the host plants actually utilized by these caterpillars (Berenbaum and Zangerl, 1998; Zangerl and Berenbaum, 2003). These western webworms display metabolism rates near the maximum rates reported for webworms in the Midwest (Table 4; Berenbaum and Zangerl, 1998; Zangerl and Berenbaum, 2003); these rates may represent the maximum given the genetic variation present in North America.

If limits on P450 metabolism as a means of resistance against furanocoumarins exist, webworms from the southwestern populations may have other mechanisms that reduce the efficacy of host plant furanocoumarin defenses. The patterns of lutein sequestration among populations of *D. pastinacella* from western North America are consistent with the idea that webworms offset the stress of furanocoumarin toxicity by greater incorporation of dietary lutein under high UVA intensities, despite an absence of differences in host plant lutein concentrations. By sequestering carotenoid pigments from their host plants, parsnip webworms may extend the amount of time they remain exposed to UV light. Although exposure to photoactivating light can damage a specialist herbivore on phototoxic plants, complete light avoidance during foraging has costs in terms of reduced internal temperatures and increased developmental time (Rawlins and Lederhouse, 1981; Ali et al., 1990). In addition, increased pigmentation in itself can significantly improve absorption of solar radiation and raise internal body temperatures during foraging, resulting in faster development (Price et al., 1980; Goulson, 1994).

Increased pigmentation is a common characteristic in montane populations, where stress from high UV intensities, suboptimal foraging temperatures, and

The average furanocoumarin metabolism rates for each study are reported along with the geographic location (by state) and number of the populations covered by the study. If metabolism rates were quantified for more than one population in the study, a range of population means for furanocoumarin metabolism rates is presented. Because the presence of alternative host plants has a significant effect on the average metabolism rates in a population, metabolism rates are subdivided into categories by the webworm host plants (*H. lanatum* or *Pastinaca sativa*) present in or near the source populations.

the risk of oxidative damage from freezing are generally higher than at lower elevations (Bidigare et al., 1993; Jung et al., 1998). Conversely, pigmentation can increase convective cooling losses in microhabitats that experience wind and reduced irradiation, thereby reducing the chance of overheating in direct sunlight (Willemsen and Hailey, 1999). In summer, the montane habitat of the parsnip webworm in the Southwest is dominated by the North American monsoon, which results in frequent formation of cloud cover and thunderstorms in foothills and mountains (Adams and Comrie, 1997). Increased pigmentation by lutein sequestration may allow for thermal heating during sunny intervals while reducing stress related to furanocoumarin phototoxicity.

The higher rates of lutein sequestration observed in the montane populations may also be a result of the enhancement of carotenoid antioxidant and photoprotectant activities in the low oxygen partial pressures (pO_2) experienced at these altitudes. The ability of carotenoids to ameliorate both photogenotoxicity and photooxidation mechanisms is dependent on the ambient pO_2 , with loss of function occurring in heavily oxygenated tissues (Burton and Ingold, 1984; Palozza et al., 1997; Bianchi et al., 1996; Eichler et al., 2002). Because of the high efficiency of the insect tracheal respiratory system, where pO_2 declines

only slightly from the external atmosphere to the smaller tracheoles that penetrate tissues (Tenney, 1985; Timmins et al., 1999), the efficacy of lutein as an antioxidant in webworm tissues is largely dependent on the pO_2 of the surrounding atmosphere. At the altitudes of the New Mexico and Utah populations (above 2200 m), the partial pressure of oxygen is at least 25% lower than at sea level. The pO_2 of anoxic internal cavities that encounter high concentrations of furanocoumarins, such as the midgut lumen (Johnson and Barbehenn, 2000), would be even lower in these high altitude populations and, therefore, even more amenable to antioxidant and antigenotoxicity activities. Enhanced sequestration of lutein by the webworm at high altitudes under intense UV light is consistent with such physiological functions.

If dietary lutein serves as a means of reducing furanocoumarin toxicity, sequestration represents an exploitation of primary plant compounds that cannot be readily altered because of their critical roles in photosynthesis (Demmig-Adams and Adams, 1996). Costs associated with the loss of photosynthetic functions in lutein-deficient tissues may outweigh potential costs incurred by webworm herbivory, given the significant maternal contributions of photosynthetic reproductive tissues to the seeds of apiaceous plants (Zangerl et al., 2003). If so, the role of lutein as a photoprotectant could present an environmental constraint on changes in fruit lutein content of *H. lanatum* in montane populations in response to excess light stress that is more likely to occur under the intense UVA light regimes.

In summary, this study demonstrates that both abiotic (UV) and biotic (parasitism) factors can influence patterns of plant chemical defense production. Efforts to characterize mechanisms underlying geographic mosaics of coevolutionary interactions (Thompson, 1999), which focus primarily on biotic factors, must also take into account the abiotic environment in which species interactions are embedded; although abiotic forces themselves do not respond reciprocally, they can have tremendous influence on reciprocal selective responses among interacting species.

Acknowledgments—We thank Lynn Anderson for assistance with collections, Paul Ode for advice on *C. sosares*, John Noyes for wasp identification, John Erdman and Denise Deming for advice on carotenoids, and Kemin, Inc. for the lutein standard. Abstract—The native North American perennial grass *Achnatherum robustum* (Vasey) Barkworth [= *Stipa robusta* (Vasey) Scribn.] or sleepygrass is toxic and narcotic to livestock. The causative agents are alkaloidal mycotoxins produced from infections by a systemic and asexual *Neotyphodium* endophyte. Recent studies suggest that toxicity is limited across the range of sleepygrass in the Southwest USA. We sampled 17 populations of sleepygrass with varying distance from one focal population known for its high toxicity levels near Cloudcroft, NM, USA. For some, we sampled individual plants twice within the same growing season and over successive years (2001–2004). We also determined infection levels in each population. In general, all populations were highly infected, but infection levels were more variable near the focal population. Only infected plants within populations near the Cloudcroft area produced alkaloids. The ergot alkaloid, ergonovine, comprised the bulk of the alkaloids, with lesser amounts of lysergic and isolysergic acid amides and ergonovinine alkaloids. Levels of all alkaloids were positively correlated among individual plants within and between growing seasons. Infected plants that produced no alkaloids in 1 yr did not produce any alkaloids within the same growing season or in other years. Levels of alkaloids in sleepygrass populations declined with distance from the Cloudcroft population, although infection levels increased. Infected plants in populations in northern New Mexico and southern Colorado produced no alkaloids at all despite 100% infectivity. Our results suggest that only specific

Neotyphodium haplotypes or specific *Neotyphodium*–grass combinations produce ergot alkaloids in sleepygrass. The *Neotyphodium* haplotype or host–endophyte combination that produces toxic levels of alkaloids appears restricted to one locality across the range of sleepygrass. Because of the wide variation in alkaloid levels among populations, interactions between the endophyte and host, and consequences for herbivores, competitors, and pathogens and other components of the community, are likely to vary widely across the geographic range of this native grass.

Key Words—*Achnatherum robustum*, alkaloids, endophyte, ergonovine, geographical variation, lysergic acid amide, native grass, *Neotyphodium*, sleepygrass.

INTRODUCTION

Asexual, vertically transmitted endophytes in the genus *Neotyphodium* are renowned for causing livestock toxicosis and reduced invertebrate herbivory in two introduced and widespread agronomic grasses, tall fescue (*Lolium arundinaceum*) and perennial ryegrass (*Lolium perenne*) (Clay, 1988, 1990; Siegel and Bush, 1996; Schardl and Phillips, 1997; Clay and Schardl, 2002). The toxic and deterrent properties of these *Neotyphodium*-infected agronomic grasses to vertebrate and invertebrate herbivores result from alkaloids produced by the endophytes. Increased resistance to herbivores and seed predators via endophytic alkaloids is generally viewed as the primary route of mutualistic benefits provided by *Neotyphodium* to the host grass (Cheplick and Clay, 1988; Saikkonen et al., 1998; Clay and Schardl, 2002), although *Neotyphodium* infections may also increase resistance to drought (Bacon, 1993) or poor soil nutrient conditions (Malinowski and Belesky, 1999), and generally increase competitive abilities (Marks et al., 1991; Clay et al., 1993). However, because alkaloids are nitrogen-rich compounds, benefits gained via protection against herbivores may be offset by reduced nitrogen availability to other host grass growth and reproductive functions, similar to other defensive allelochemicals produced by the host plant (Faeth, 2002).

The types and levels of alkaloids in agronomic grasses vary with host and especially with endophyte genotype (Siegel et al., 1990; Bush et al., 1993; Christensen et al., 1993; Leuchtman et al., 2000; Bony et al., 2001). Recently, genes for alkaloid production in some *Neotyphodium* endophytes have been identified and manipulated (Spiering et al., 2005). Alkaloid levels in agronomic grasses are also influenced by environmental factors, such as soil moisture and nitrogen availability (Arechavaleta et al., 1992; Agee and Hill, 1994; Roylance et al., 1994; Malinowski et al., 1998; Hunt et al., 2005) and temperature (Huizing et al., 1991). Additionally, alkaloid production in tall fescue can be induced to higher levels by herbivory (Bultman et al., 2004).

Less is known about infection frequencies and alkaloid levels and types in native grasses, and particularly how alkaloids vary geographically or temporally. Some native grasses have long been known anecdotally as toxic to livestock (Hance, 1876; Bailey, 1903; Freeman, 1904; Marsh and Clausen 1929), but only recently has this toxicity been directly linked to infection by *Neotyphodium* endophytes (Kaiser et al., 1996; Miles et al., 1996; Jones et al., 2000; Moon et al., 2002). Early reports implied that infected grasses were toxic throughout their geographic range, and hence, common names such as “sleepygrass” (*A. robustum*) and “drunken horse grass” (*Achnatherum inebrians*) were ascribed to these species. However, recent studies suggest that many, if not all, of “toxic” grass species with *Neotyphodium* infections are toxic in only some parts of their range (Miles et al., 1996; Jones et al., 2000; Faeth, 2002). Limited toxicity in *Neotyphodium*-infected grasses also seems to hold for the widely planted agronomic grasses, perennial ryegrass (Bony et al., 2001), and tall fescue (Saikkonen, 2000; Saikkonen et al., 2004), when examined in their native ranges. This suggests that alkaloid types and levels vary widely within and among populations of *Neotyphodium*-infected native grasses known for high toxicity. Alkaloid concentrations may also vary within and among growing seasons with environmental (e.g., soil moisture and nutrients) and developmental (e.g., as endophytes grow with their hosts) factors (Belesky and Hill, 1997), adding additional variation to alkaloid levels in native grass populations.

To our knowledge, geographic and temporal alkaloid variation in native *Neotyphodium*-infected grasses have yet to be simultaneously documented for any of the known highly toxic grasses (about 9–10 species; Faeth, 2002). Yet, alkaloid variation is the key trait influencing herbivore, seed predator and pathogen resistance, community interactions, and ecosystem functions (Matthews and Clay, 2001; Omacini et al., 2001; Faeth, 2002; Rudgers et al., 2004; Müller and Kraus, 2005). In previous studies, samples from individual plants have been pooled from within or across populations (Jones et al., 2000), individual infected plants have not been sampled over time (Powell and Petroski, 1992), or sampled plants were grown from seeds collected from natural populations (Miles et al., 1996). To assess within and among population variation, as well growing season variation, it is necessary to: (1) sample individual plants from multiple populations and (2) sample the same individual plants repeatedly over time. This populational variation is essential to understanding the coevolution and ecology of species interactions in general (Thompson, 1994, 2005) and, specifically, the outcome of interactions between host grass and systemic endophytes (Faeth and Sullivan, 2003; Sullivan and Faeth, 2004).

To ascertain geographic and temporal variation in alkaloids, we sampled 17 populations of sleepygrass or robust needlegrass, *A. robustum* [Vasey]

Barkworth = *Stipa robusta* [Vasey] Scribn.], radiating outward from the known toxic population in the Sleepygrass Picnic area, Lincoln National Forest, NM, USA, near the town of Cloudcroft (Petroski et al., 1992), from 2001 to 2004. We assessed the frequency of *Neotyphodium* infections in all populations. In some populations, individual plants were marked and resampled both within (seasonal) and among growing seasons (yearly). We correlated within and between growing season alkaloid levels to estimate how much variation is caused by developmental or environmental factors. We also determined how alkaloid levels varied with distance from the Sleepygrass Picnic area site, known for toxicity to livestock.

METHODS AND MATERIALS

Study Grass and Endophyte. *A. robustum* (Vasey) (Pooideae: Tribe Stipeae) is a cool-season, native grass found at high elevations throughout Arizona, New Mexico, Colorado, Wyoming, and Montana on “sky islands” of the Rocky Mountains in the western USA (Jones et al., 2000). Sleepygrass is a perennial bunchgrass found in semiarid pine–grassland habitats and reproduces by seed (USDA, 1988). In some localities in New Mexico, it is referred to as “robust needlegrass” (Jones et al., 2000).

The *Neotyphodium* endophyte is commonly found in sleepygrass populations at high frequencies (Petroski et al., 1992; Jones et al., 2000). *Neotyphodium* in *A. robustum* has yet to be identified to species (Moon et al., 2004; Schardl, personal communication). Morphologically, it appears intermediate in characteristics between *Neotyphodium starii* and *N. chisosum* (Kaiser et al., 1996) and also different from *Neotyphodium* isolated from *A. inebrians*, an Asian grass species known to produce high levels of similar alkaloids (Miles et al., 1996). Moon et al. (2004) found that *Neotyphodium* in sleepygrass was genetically most related to the sexual forms *Epichloë festucae* and *E. elymi*. Here, we refer to the endophyte as simply *Neotyphodium*.

Populations and Sampling. From 2001 to 2004, we sampled 17 populations of sleepygrass in New Mexico and Colorado (Table 1). We centered our sampling on a population that has long been known for high toxicity (Marsh and Clawson, 1929; Smalley and Crookshank, 1976; Jones et al. 2000), Sleepygrass Picnic area in the Lincoln National Forest (SP, Table 1), and then we sampled populations outward from this locality. The SP site is at the southern edge of the Sacramento Mountains, and most populations of sleepygrass occur northward. Three populations (SC, GR, and WD, Table 1), however, were southward, but still occurred within the Sacramento Mountain range. We assumed that these sites were separate populations, given that the closest population (MV) was 2.5 km from SP. *Neotyphodium* in Arizona fescue exhibits low gene flow between

populations (much less than 2.5 km) because seeds in which it is transmitted are not dispersed far (<1 m) and fall near the maternal plant (Sullivan and Faeth, 2004). Seeds of *A. robustum* may be transported further because of relatively large awns that may attach to animal fur, but we expect little movement between these disparate populations.

Number of sampled plants varied among years at the different sites (Table 1) because of time constraints, accessibility, missing plants from year to year, and replacement plants added in successive seasons or years. We sampled 432 plants among the 17 populations. In each population at each sampling period, leaf sheath tissue was removed, and plants were marked with surveyor's whisks and numbered metal tags. Plant tissue was placed on ice and returned to the lab for determination of infection status and for alkaloid analyses. For 4 populations, the same plants were sampled twice within the same growing season, June and September 2003, at the beginning and the end of the growing season, respectively.

Infection and Alkaloid Analyses. Infection status of all plants was determined by a modified tissue immunoblot assay (Gwinn et al., 1991; Schulthess and Faeth, 1998) and was later confirmed by staining and microscopic examination of seeds for characteristic *Neotyphodium* hyphae (Saha et al., 1988). The remainder of all plant samples were frozen until they could be lyophilized. Freeze-dried samples were ground to a fine powder in a Wiley mill. Ergot alkaloids were analyzed by methods adapted from TePaske et al. (1993) and Jones et al. (2000). In brief, 5 ml methanol and 0.050 ml of concentrated ammonium hydroxide were added to 100 mg of ground plant tissue. Samples were rotated overnight and filtered. The filtrate was dried at 60°C under a flow of nitrogen, after which 2 ml of 1% acetic acid and 2 ml of chloroform were added, and the samples were mixed by rotation for 2–3 min. Samples were centrifuged to aid in layer separation, and a 1.0-ml aliquot of the upper acid solution was removed and placed into an high-performance liquid chromatography (HPLC) autosampler vial. Concentrated ammonium hydroxide was added (~0.030 ml) to adjust the pH to 9–10 along with 0.010 ml of a 100-ppm stock solution of monocrotaline (quantitative reference standard). Samples were analyzed by HPLC–mass spectrometry (MS). Separation and detection were achieved with a Betasil C18 reversed-phase HPLC column (100 × 2 mm, Keystone Scientific) and HP 1100 binary HPLC solvent pump coupled to an LCQ (Thermo Finnigan) mass spectrometer. Solvent elution was a gradient of methanol (A) and 20 mM ammonium acetate (B) starting at 25% (A) increasing to 55% (A) from 0 to 10 min. The mass spectrometer was operated under positive electrospray ionization and single ion monitoring of $m/z = 268.3$ and 326.3 . Alkaloids are reported as total alkaloids as a mixture of ergonovine, lysergic acid amide, isolysergic acid amide, and ergonovinine. Quantification of individual alkaloids was made by measurement of peak area vs. calibration

Samples were collected from some populations in June at the beginning of the growing season in 2003 (S 2003).
GPS = Global Positioning System.

curve generated using ergonovine standards. We assayed only for ergot alkaloids, the main alkaloid type found in *A. robustum* (Petroski et al., 1992; Jones et al., 2000); it is possible that other minor alkaloids were present but not detected by our methods.

Statistical Analyses. We summed all unique infected and uninfected plants ($N = 432$) within each population across seasons and years to determine infection frequencies (that is, no plant was included more than once for determining infection frequency). We determined yearly changes in alkaloids by correlating total levels and individual alkaloids in the same individual plants from 2001 to 2002 and from 2002 to 2003. If plants produced relatively the same levels from year to year, then we expect a strong positive correlation. Likewise, we correlated levels of alkaloids in the same individual plants in June 2003 (beginning of the growing season) to levels in September 2003 (end of the growing season) to ascertain if seasonal levels of alkaloids vary within a growing season.

To determine if alkaloids vary with distance among populations from the SP population, known for its high toxicity, we regressed mean total alkaloids and individual alkaloid fractions from each population with distance (in km) from this focal population.

FIG. 1. Infection frequencies and sample sizes (numbers above bars) for the 17 sleepy-grass populations. See Table 1 for site abbreviations and locations.

RESULTS

Infection Frequencies. Infection frequencies among populations were generally high, ranging from 50 to 100% (Figure 1). Notably, the northern New Mexico and southern Colorado populations (A–L, Figure 1) were 100% infected. Populations nearer the focal population SP were much more variable.

Alkaloid Levels. Total alkaloid levels were highly variable across populations (Figure 2). The highest levels were in infected plants in the focal SP population and the nearby MV and MS2 population (Figure 2). Some of the infected plants had >150 µg/g total ergot alkaloids, some of the highest known for *Neotyphodium*-infected plants. However, a few plants in these populations, although infected, never produced alkaloids, notably, the northern New Mexico and southern Colorado populations that were 100% infected (Figure 1, data not shown). Ergonovine was consistently the highest fraction with lesser amounts of lysergic and isolysergic amides (Figure 2). Ergonovine constituted the lowest fraction (data not shown).

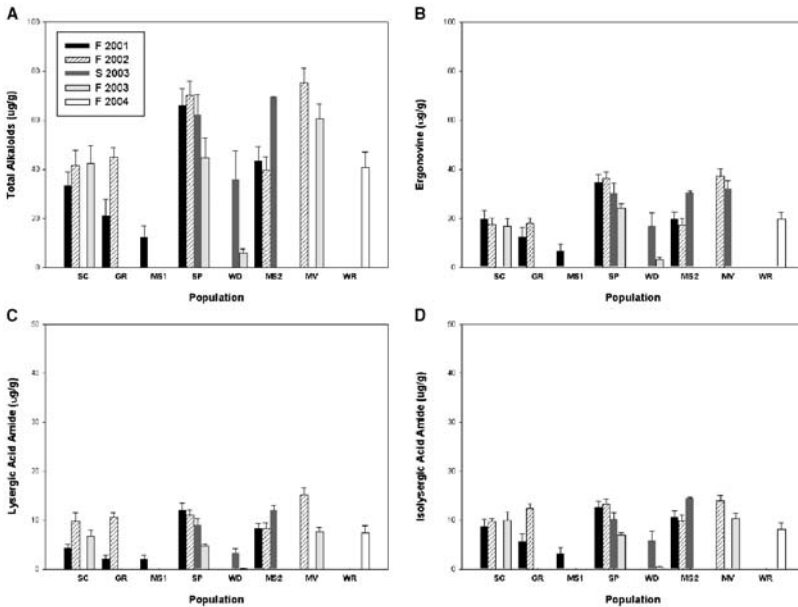

FIG. 2. Mean (±SE) concentrations (µg/g) of total (A), ergonovine (B), lysergic acid amide (C), and isolysergic amide (D) alkaloids from eight populations from 2001 to 2004. Infected plants from nine other populations in northern New Mexico and southern Colorado had zero alkaloids and are not shown. See Table 1 for site abbreviations. Note the difference in scale in boxes A, B and C, D.

Alkaloid levels in infected plants were positively correlated from 1 yr to the next. For the same individual plants sampled in fall of 2001 and 2002 ($N = 16$), concentrations of total (Pearson's correlation coefficient = 0.56, Bonferroni probability = 0.02), ergonovine (0.62, $P = 0.01$), isolysergic acid amide (0.53, $P = 0.04$), and ergonovine (0.54, $P = 0.03$) were positively correlated. Levels of lysergic acid amides were not significantly correlated ($P = 0.26$). For the same individual plants sampled in fall of 2002 and 2003 ($N = 50$), concentrations of total (0.33, $P = 0.02$), ergonovine (0.32, $P = 0.03$), lysergic acid amides (0.42, $P = 0.002$), and isolysergic acid amide (0.38, $P = 0.007$) were positively and significantly correlated. Levels of ergonovine alkaloids in fall of 2002 and 2003 were positively correlated (0.27), but only marginally significantly so ($P = 0.06$).

Within a growing season, alkaloid concentrations of the same individual plants ($N = 20$) were strongly and positively correlated. Levels of total alkaloids (0.71, $P < 0.001$), ergonovine (0.75, $P < 0.001$), lysergic acid amides (0.70, $P = 0.001$), isolysergic acid amides (0.64, $P = 0.002$), and ergonovine (0.69, $P = 0.001$) were positively and significantly correlated in the same plants sampled in the beginning (June 2003) and end (September 2003) of the growing season.

FIG. 3. Regression of mean (\pm SE) total alkaloids and log distance from site SP. Distances (km) were measured from the SP, the population used as the focal site (see text).

Mean Alkaloid Levels and Distance From The Focal Population. Mean levels of alkaloids in infected plants within each sampled population declined with linear distance from the focal population (SP; Figure 3). The best regression fit was alkaloid levels with log distance. Regressions of alkaloids levels with log distance were significant for mean total alkaloids ($N = 17$, adjusted $R^2 = 0.83$, $P < 0.001$, Figure 3), ergonovine (adjusted $R^2 = 0.80$, $P < 0.001$, data not shown), lysergic acid amides (adjusted $R^2 = 0.74$, $P < 0.001$, data not shown), isolysergic acid amides (adjusted $R^2 = 0.74$, $P < 0.001$, data not shown), and ergonovinine (adjusted $R^2 = 0.76$, $P < 0.001$, data not shown). Because all infected plants in the northern New Mexico and southern Colorado populations had no alkaloids, inclusion of all eight data points (Figure 3) could disproportionately skew the regression of alkaloid levels and distance towards a more negative relationship. Therefore, we also performed similar regressions of distance and alkaloid levels, but considered these eight distant populations as a single data point. The results were the same; mean total alkaloids and all mean alkaloid fractions rapidly and significantly declined with distance from the SP population.

DISCUSSION

Systemic fungal endophytes in cool-season, pooid grasses are well known for producing a wide variety of alkaloids that purportedly provide protection for the host against vertebrate and invertebrate herbivores (Cheplick and Clay, 1988; Breen, 1994; Siegel and Bush, 1996; Clay and Schardl, 2002; Faeth, 2002), root nematodes (West et al., 1988; Kimmons et al., 1990), some microbial pathogens (Burpee and Bouton, 1993), and possibly act as allelopathic agents (Peters and Zam, 1981). These effects are well known in two widespread agronomic grasses, tall fescue and perennial ryegrass, where *Neotyphodium* alkaloids are directly linked to livestock toxicoses and neurological disorders and increase resistance to generalized invertebrate pests (Bush et al., 1997; Schardl and Phillips, 1997). Much less is known about alkaloid levels in native grass populations harboring *Neotyphodium*. In general, relatively few *Neotyphodium*-infected native grasses are known for toxicity to livestock (Faeth, 2002). However, one of these, *A. robustum*, is toxic to horses, cattle, and sheep (Bailey, 1903; Marsh and Clawson, 1929; Petroski et al., 1992). Despite the central role of fungal alkaloids in agronomic and livestock production (Schardl and Phillips, 1997), and more generally to *Neotyphodium*-host grass interactions (Clay and Schardl, 2002; Faeth, 2002), there have been no studies of seasonal and yearly variation in alkaloid levels, or the relationship of alkaloid production to infection levels among populations, in infected native grasses.

Here, we show that ergot alkaloid levels in native sleepygrass populations are highly variable both within and among populations. The populations near Cloudcroft, NM, have high levels of ergot alkaloids on average, as previously reported (Petroski et al., 1992; Jones et al., 2000), but levels vary greatly, with some infected plants producing no alkaloids at all, whereas others produce more than 150 $\mu\text{g/g}$ total alkaloids (range = 0–156 $\mu\text{g/g}$). Most of the alkaloid fraction is ergonovine, with lesser amounts of lysergic acid, isolysergic amide, and ergonovine. This is in contrast to reports from Petroski et al. (1992) where ergonovine was lower relative to lysergic and isolysergic amides and other alkaloids. However, those plants were not sampled over time. In a study of the alkaloid content of a congeneric infected native grass from Asia, Miles et al. (1996) found that infected *A. inebrians* had high levels of ergonovine (up to 2500 $\mu\text{g/g}$) and lesser amounts of lysergic acid amide (up to 400 $\mu\text{g/g}$), similar to the relative amounts of alkaloids in sleepygrass but higher in absolute concentrations. Those plants, however, were grown in the greenhouse from seed, so it is not clear if the levels reflect alkaloid levels in natural populations. Nonetheless, in terms of alkaloid profiles, *Neotyphodium* in *A. robustum* and *A. inebrians* appear similar. Molecular studies would be fruitful to determine if *Neotyphodium* in these two geographically disjunct grass species are genetically related.

Lysergic and isolysergic acid amides are likely the alkaloids responsible for the dramatic narcotic effects of infected sleepygrass on livestock (Miles et al., 1996; Jones et al., 2000). Horses that feed on small amounts of infected sleepygrass tissue or seeds from the Cloudcroft region become narcotized and go into a deep sleep (Powell and Petroski, 1992). Consumption of larger amounts causes elevated body temperature, weakness, frequent urination, dizziness, hypersalivation, diarrhea, and possibly death (Smalley and Crookshank, 1976; Miles et al., 1996). Both lysergic acid and ergonovine are vasoconstrictors. Ergonovine is known as a stimulator of smooth muscles and used medically to induce uterine contractions (Powell and Petroski, 1992; Miles et al., 1996). Ergot alkaloids, in general, are deterrent and toxic to some invertebrate herbivores (Siegel et al., 1990), but it is not known if ergonovine generally deters herbivory by vertebrates or invertebrates as do lysergic acid amides, although vasoconstriction is associated with heat stress and tissue gangrene in livestock consuming other *Neotyphodium*-infected grasses. Ergonovine may also increase susceptibility of invertebrate herbivores to entomopathogenic nematodes (Kunkel et al., 2004).

That alkaloid levels are positively correlated both within and among growing seasons suggests that the endophyte species, endophyte haplotype, or the host–endophyte genotypic combination largely determines alkaloid levels. Although alkaloids varied slightly within population within and among growing seasons, in general, levels remained consistent (Figure 2), indicating that

environmental and developmental variation has lesser influences on alkaloid levels in infected sleepygrass. Alkaloid variation in infected agronomic grasses and some other native grasses appears largely dictated by endophyte species or haplotypes (Siegel et al., 1990; Leuchtmann, 1992, 1997; Bush et al., 1993; Christensen et al., 1993) and less so by host genotype and environmental factors (Siegel et al., 1990; Leuchtmann et al., 2000). However, host grass genotype in agronomic grasses (Siegel et al., 1990) and at least one infected native grass may drive alkaloid production (Faeth et al., 2002). Although we cannot distinguish here between endophyte and host genotype effects, or their interactions, on alkaloid production, consistent levels within and between growing seasons suggest that environmental factors play a lesser role. Furthermore, infected plants that produced no alkaloids in June never did so in the fall, and infected plants that produced no alkaloids in 1 yr did not in subsequent years, suggesting that a specific *Neotyphodium* species or haplotypes or specific host and endophyte genotypic combinations are necessary for alkaloid production.

That alkaloid levels in sleepygrass populations decline and disappear with distance from the SP population suggests that the specific strain or haplotype of *Neotyphodium* or endophyte–host genetic combination may be localized near Cloudcroft, NM. This strain or combination rapidly decreases with distance in frequency relative to less toxic and nontoxic strains or combination. The *Neotyphodium* endophyte in sleepygrass has yet to be identified to species or thoroughly examined for geographic genetic variation. Kaiser et al. (1996) found a diversity of spore morphologies in cultures of 10 New Mexico and Colorado populations. Moon et al. (2004) found a hybrid *Neotyphodium* in sleepygrass in one sample from southern Colorado. Based on gene sequences, they postulated that this hybrid was formed from *Epichloë elymi* and *E. festucae*. Hybridization is thought to occur when the sexual and spore-transmitted form *Epichloë* colonizes and hybridizes with *Neotyphodium* in the same host grass or when two *Epichloë* species hybridize. Hybridization is thought to rapidly infuse genetic variation into the population and create novel genetic combinations that may result in new alkaloid types (Schardl and Craven, 2003; Moon et al., 2004). The hybrid *Neotyphodium* in Moon et al. (2004) came from regions in southern Colorado where we found no alkaloids. Furthermore, the hybrid in Moon et al. (2004) does not harbor the gene for ergot alkaloids (Schardl, personal communication). In another native southwest US grass, Arizona fescue (*Festuca arizonica*), genetic variation in *Neotyphodium* is highly spatially structured, with the presence of hybrid and nonhybrid endophytes, and with little or no gene flow between grass populations that are less than 2 km apart (Sullivan and Faeth, 2004). Sullivan and Faeth (2004) also found that hybrids did not differ in levels or types of alkaloids relative to Arizona fescue with nonhybrid *Neotyphodium*. Thus, hybridization at least in native sleepygrass and Arizona fescue apparently is not a prerequisite for novel or high alkaloid

production. Future studies should focus on ascertaining the underlying genetic basis in the *Neotyphodium* endophyte for this steep gradient in alkaloid production in sleepygrass populations.

Interestingly, the sleepygrass populations near Cloudcroft are also more variable in infection frequency than northern New Mexico and southern Colorado populations (Figure 1). Infection frequency in the latter are 100%, but the *Neotyphodium*–grass symbiota produces no alkaloids. The variability in infection frequency and in alkaloid levels among infected plants near the SP population suggests that high alkaloid producing *Neotyphodium* endophytes may also incur substantial costs. Faeth (2002) argued that alkaloid production in infected grasses is costly in terms of nitrogen demand and metabolic costs. High levels may also be costly in terms of toxicity to the host, similar to alkaloidal allelochemicals produced directly by host plants (Karban and Baldwin, 1997). The benefits of high alkaloids may offset these costs when grazing or herbivory is intense and persistent and available soil nutrients are high (Faeth, 2002). The frequency of toxic infected *A. robustum* (Marsh and Clawson, 1929; Jones et al., 2000) and *A. inebrians* (Miles et al., 1996; Nan and Li, 2001) appears to have increased relative to nontoxic individuals because livestock grazing has intensified in the respective geographic range of these host grasses.

Our results indicate that *A. robustum*–endophyte interactions, in terms of alkaloids, are highly spatially structured across a wide geographic range of populations. Thompson's (1994, 2005) geographical mosaic theory predicts that interactions evolve or coevolve in metapopulations, with the interaction between local selection pressures, migration, and genetic drift creating a range of possible outcomes in species interactions geographically. Alkaloid levels in infected sleepygrass vary dramatically, and the notion of sleepygrass as a toxic grass because of endophyte infection only applies in a very restricted part of the geographic range of the host grass. Given that alkaloid production is considered the main trait that dictates the outcome of grasses infected with systemic, seed-borne endophytes with herbivores, pathogens, competing plants, higher trophic levels, community diversity, and even ecosystem functions (Saikkonen et al., 1998; Omacini et al., 2001; Clay and Holah, 1999; Clay and Schardl, 2002; Faeth, 2002; Faeth and Bultman, 2002; Rudgers et al., 2004), we predict that these interactions, and community and ecosystem repercussions, will also be highly variable across the geographic range of the sleepygrass. Understanding populational variation in alkaloids because of endophyte and host genetics, and not just infection status of grasses, will be necessary to unravel these complex host–endophyte interactions and their consequences at the community and ecosystem level.

Abstract—Herbivorous and carnivorous arthropods use chemical information from plants during foraging. Aqueous leaf extracts from the syringa tree *Melia azedarach* and commercial formulations from the neem tree *Azadirachta indica*, Neemix 4.5[®], were investigated for their impact on the flight response of two parasitoids, *Cotesia plutellae* and *Diadromus collaris*. *Cotesia plutellae* was attracted only to *Plutella xylostella*-infested cabbage plants in a wind tunnel after an oviposition experience. Female *C. plutellae* did not distinguish between *P. xylostella*-infested cabbage plants treated with neem and control *P. xylostella*-infested plants. However, females preferred infested cabbage plants that had been treated with syringa extract to control infested plants. Syringa extract on filter paper did not attract *C. plutellae*. This suggests that an interaction between the plant and the syringa extract enhances parasitoid attraction. *Diadromus collaris* was not attracted to cabbage plants in a wind tunnel and did not distinguish between caterpillar-damaged and undamaged cabbage plants. Headspace analysis revealed 49 compounds in both control cabbage plants and cabbage plants that had been treated with the syringa extract. Among these are alcohols, aldehydes, ketones, esters,

* To whom correspondence should be addressed. E-mail: charlestd@arc.agric.za

terpenoids, sulfides, and an isothiocyanate. Cabbage plants that had been treated with the syringa extract emitted larger quantities of volatiles, and these increased quantities were not derived from the syringa extract. Therefore, the syringa extract seemed to induce the emission of cabbage volatiles. To our knowledge, this is the first example of a plant extract inducing the emission of plant volatiles in another plant. This interesting phenomenon likely explains the preference of *C. plutellae* parasitoids for cabbage plants that have been treated with syringa extracts.

Key Words—Botanical pesticides, parasitoid behavior, *Plutella xylostella*, induced plant volatiles, elicitor.

INTRODUCTION

The diamondback moth *Plutella xylostella* (L.) (Lepidoptera: Plutellidae) is a major pest of crucifer crops and is found throughout the world (Talekar and Shelton, 1993). Natural enemies are recognized as important components in *P. xylostella* management strategies, particularly where control with chemicals has failed. However, they need to be integrated with other strategies for successful control. Botanical pesticides are thought to be compatible with biological control, as they tend to be relatively harmless to parasitoids and predators (Schmutterer, 1995, 1997; Charleston et al., 2005). In South Africa, 21 species of parasitoids are associated with *P. xylostella* (Kfir, 2003), providing a rich and abundant source for biological control. Botanical pesticides have not been registered for use in South Africa. However, the syringa tree *Melia azedarach* L. (Meliaceae) is an invasive plant found throughout South Africa. It has insecticidal properties (Ascher et al., 1995) and may provide the small-scale rural farmer with an alternative control tactic. It is important to investigate the impact that extracts have on the natural enemy fauna. Botanical pesticides act as repellents against a number of pest species, but little information is available concerning their effect on the behavioral responses of natural enemies of pests such as parasitoids and predators (Akol et al., 2003).

Plants influence carnivore behavior (Dicke et al., 1990; Turlings et al., 1990; Steinberg et al., 1993; Dicke and Vet, 1999; Vet, 1999; Dicke, 1999a; Hilker and Meiners, 2002). Plants that are attacked by herbivores emit volatile cues that can be used by natural enemies of the herbivore to find their hosts, and these plant volatiles may contain information on the identity of the herbivore (Turlings et al., 1990, 1993; Vet et al., 1991; Vet and Dicke, 1992; Dicke and Vet, 1999). The main components of the volatile blend released from cabbage plants are terpenoids and green leaf volatiles (Mattiacci et al., 1994; Shiojiri et al., 2001). Terpenoids are a major class among herbivore-induced synomones that attract carnivores (reviewed by Takabayashi et al., 1994; Dicke, 1994;

Turlings et al., 1995; Pichersky and Gershenzon, 2002). Terpenoids are released in analogous amounts in both herbivore-damaged and mechanically-damaged cabbage plants, as well as in undamaged plants (Mattiacci et al., 1994; Shiojiri et al., 2001). Plants emit green leaf volatiles during aging or when injury occurs (Visser and Ave, 1978; Hatanaka, 1993). However, there is a dramatic increase of green leaf volatiles in the headspace of damaged cabbage plants compared to undamaged plants, and this may play a role in parasitoid attraction (Mattiacci et al., 1994; Shiojiri et al., 2001; Smid et al., 2002). For example, *Cotesia rubecula* and *Cotesia glomerata* (Hymenoptera: Braconidae) can distinguish between damaged and undamaged Brussels sprout plants (Steinberg et al., 1992; Geervliet et al., 1996). Artificially damaged cabbage plants also produce volatiles, but these do not show any qualitative differences compared to the volatiles released when the plant is damaged by herbivores (Mattiacci et al., 1994; Geervliet et al., 1997; Shiojiri et al., 2001). However, there are quantitative differences (Mattiacci et al., 1994; Shiojiri et al., 2001). *Cotesia glomerata* did not distinguish between artificially damaged cabbage plants and plants damaged by its host *Pieris rapae* (L.) (Lepidoptera: Pieridae) (Shiojiri et al., 2001). However, *Cotesia plutellae* (Kurdjumov) (Hymenoptera: Braconidae) distinguished between artificially damaged cabbage plants and plants damaged by *Plutella xylostella* (Shiojiri et al., 2001), and the parasitoid spent longer searching infested cabbage plants than artificially damaged plants (Shiojiri et al., 2000a). Chemical analysis of the volatiles released by cabbage plants that had been damaged by two different host species, *P. xylostella* and *Pieris rapae*, indicated that there were slight qualitative differences (Agelopoulos and Keller, 1994) and many quantitative differences in the compounds produced in response to damage from these two herbivores (Agelopoulos and Keller, 1994; Geervliet, 1997; Shiojiri et al., 2001). *Cotesia plutellae* discriminated between cabbage plants infested with *P. xylostella* (host) and plants infested with *Pieris rapae* (nonhost) (Shiojiri et al., 2000b, 2001). The searching time of *C. plutellae* on cabbage leaves infested by host larvae was also longer than on leaves infested with the nonhost (Shiojiri et al., 2000a), which suggests that this parasitoid can discriminate between host- and nonhost-infested plants through antennal contact (Shiojiri et al., 2001, 2000a).

Cotesia plutellae and *Diadromus collaris* (Gravenhorst) (Hymenoptera: Ichneumonidae) are the two parasitoid species most commonly found in cabbage fields around Pretoria, South Africa. We have shown that aqueous leaf extracts from the syringa tree *Mella azedarach* and the neem product, Neemix 4.5[®], taken from the neem tree *Azadirachta indica* Juss. (Meliaceae) do not have a direct impact on the survival of these parasitoids (Charleston et al., 2005), and that they are still able to find their hosts when host-infested plants have been treated with the botanical extracts. In fact, in both greenhouse and field experiments, *C. plutellae* parasitize a greater proportion of *Plutella xylostella*

larvae on cabbage plants treated with syringa extracts than they do on control plants (Charleston et al., 2005). Small differences in plant volatiles can affect the attraction of parasitoids, and treating plants with botanical extracts may change the volatile profiles, which may have an impact on the responses by natural enemies. Here, we investigated the impact that these botanical extracts have on the volatile profile of cabbage plants and how this may influence the attraction of *C. plutellae* and *D. collaris*.

METHODS AND MATERIALS

Experimental Plants and Insects. Cabbage plants *Brassica oleracea* var. *capitata* L. (Cruciferae) were bought as seedlings, planted in black plastic bags, and left in a glasshouse ($30 \pm 5^\circ\text{C}$) to grow. The plants were fertilized with compost when planted and regularly watered. To reduce insect damage, the plants were placed inside a tent-like construction composed of fine nylon netting (mesh size <1 mm).

Plutella xylostella were from a culture originally collected near Pretoria ($28^\circ15'S$; $25^\circ44'E$) and Brits ($25^\circ38'S$; $27^\circ47'E$), South Africa. The laboratory culture was maintained on canola seedlings *Brassica napus* L. (Cruciferae). The two parasitoid species most common in cabbage fields near Pretoria, South Africa, were *Cotesia plutellae* and *Diadromus collaris*. Laboratory cultures of these were established in 1993. Each parasitoid species was kept communally in glass cages ($38 \times 27 \times 28$ cm) and exposed to *P. xylostella* larvae on canola seedlings three times per week. After exposure to *C. plutellae*, the second instar *P. xylostella* larvae were maintained on cabbage leaves in shallow plastic rearing containers until cocoon formation. To obtain fresh pupae for *D. collaris*, they were exposed to late fourth instar *P. xylostella*, which would pupate within 1 d. Cocoons of *C. plutellae* or *P. xylostella* pupae parasitized with *D. collaris* were placed into clean cages, and the emergence of wasps took place in clean cages without any plant or host material. The parasitoids were maintained on a diet of honey and water. Parasitoids used in the bioassays were 2–6 day old mated females.

All insect rearing was carried out in a controlled environment ($24 \pm 2^\circ\text{C}$; $65 \pm 5\%$ RH, 16:8 hr light/dark period).

Botanical Extracts. *Syringa*: *Melia azedarach* (hereafter referred to as syringa) leaves were collected from Rietondale in Pretoria, South Africa ($28^\circ15'S$, $25^\circ44'E$). Leaves were collected from trees at a height of about 1.5–3.5 m at the start of spring flush, in September 2002, placed in a glasshouse ($30 \pm 5^\circ\text{C}$) to dry, after which they were crushed into a fine powder and stored in an airtight container until use. The extract was made with 100 ml of distilled water. The water was heated to 48°C ; 5 g of leaf powder were added to the water, and the mixture was shaken for approximately 1 min. The extract was left in a refrig-

erator ($\pm 4^{\circ}\text{C}$) overnight. The following morning, it was filtered using Advantec[®] filter paper no. 2. Three drops of liquid detergent (Teepol[®]) were added to the final extract to act as a surfactant, without which the extract runs off the surface of the leaf.

Neem: A commercial preparation of *Azadirachta indica*, Neemix 4.5[®] (hereafter referred to as neem), was provided by Thermo Trilogly Corporation, Columbia, MD, USA. A dose of 32 μl per 100 ml of distilled water was used. Three drops of liquid detergent were added to the final solution.

Control: The control treatment used consisted of 100 ml of distilled water mixed with three drops of liquid detergent.

Wind Tunnel Design. A wind tunnel was set up within a tent-like construction (350 \times 300 \times 200 cm). It was placed in a room with a controlled temperature of $24 \pm 2^{\circ}\text{C}$. No daylight could enter the room. Illumination was provided by rows of lights in the roof of the tent, simulating daylight (2300 lx). Two table fans were placed at the end of a table; a sheet of gauze material (mesh size, 3 mm) was placed in front of the fans to reduce the wind speed and to provide a more laminar airflow. The wind speed at the release point was approximately 0.133 m/sec. The cabbage plants were placed on a table (180 \times 900 cm; Figure 1). The table was covered with white plastic sheeting to facilitate cleaning, and thick (4.7 cm) black strips of tape were placed at 30-cm intervals to provide a contrast for the flying insects. To contain the insects within the experimental arena and to create diffuse lighting, white cotton sheeting was placed across two poles 112 cm above the table and left to hang over the sides, enclosing the arena. An equilateral triangle (45 cm) was marked out on the table, and cabbage plants of the same age (± 5 wk after transplant) were placed in groups of four on either side of the base of the triangle. The plants were placed in a square around the mark, with 20 cm between the centers of each plant. One group of plants was treated with the botanical pesticide and the other with control solution. The plants were changed to opposite sides of the triangle after every five observations.

Behavioral Recordings. Parasitoids were released from a platform at a 20-cm height, at the apex of the equilateral triangle at the downwind end of the tunnel (Figure 1). A female parasitoid was faced with a choice between treated and control cabbage plants and was observed to assess which plant she landed on first. "Response" was recorded when the female left the release platform and landed on one of the plants. For each treatment, 60 responding females were observed. The number of females that did not respond was also recorded. "No response" occurred when the female failed to leave the platform after 5 min, or if the female landed on any surface other than a cabbage plant.

Choices between treated and control plants were analyzed by using binomial probability functions to assess a difference from a 50–50 distribution between the treatment and control.

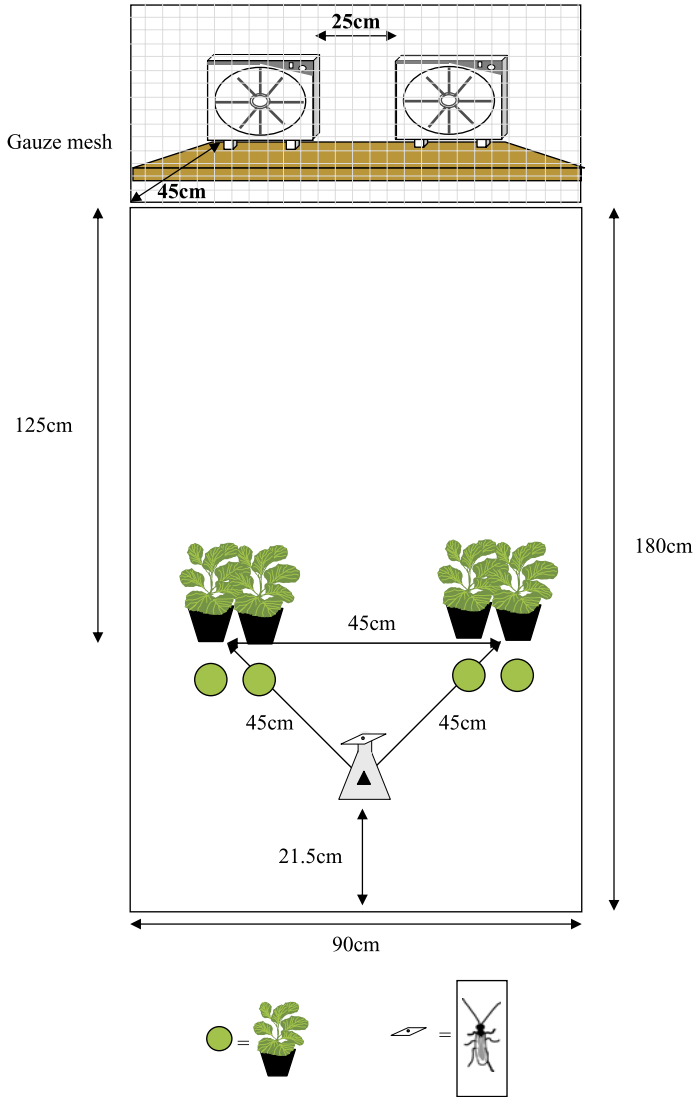

FIG. 1. Diagram showing the design of the wind tunnel.

Previous Experience. We observed that *Cotesia plutellae* did not respond in the wind tunnel without an oviposition experience. Potting et al. (1999) have shown that an oviposition experience significantly increased the response of *C. plutellae* to volatiles. Therefore, each *C. plutellae* female was exposed to a

cabbage leaf with feeding *Plutella xylostella* larvae. Each female was allowed to oviposit two to three times before being removed and placed into a glass vial with some honey for food. Approximately 1–2 hr later, she was released in the wind tunnel and observed.

Diadromus collaris females were also given an experience before they were released in the wind tunnel. In this case, the female was exposed to a cabbage leaf that had been damaged by *Plutella xylostella* larvae, which had subsequently pupated on the leaf just before exposure to *D. collaris*. The female was left to explore the leaf for 3 min, after which she was removed and placed in a glass vial with some honey for food, and released in the wind tunnel 24 hr later.

Experiments

Plant–Host Complex. Cabbage plants were first sprayed with either the botanical pesticide or the control (approximately 100 ml per plant) and then infested with 15 *Plutella xylostella* larvae (second instar for test with *Cotesia plutellae*, or late fourth instar for test with *Diadromus collaris*). Larvae were left to feed on the cabbage plants for 24 hr, after which infested plants were placed in the wind tunnel and the observations began. To compensate for any differences between the cabbage plants themselves, the experiment was carried out over three different days using different plants and different wasps each day.

Effect of Experience. This trial was also used to investigate whether previous experience on cabbage treated with the plant extracts had an influence on the subsequent flight behavior of the parasitoid in the wind tunnel. Each species was given experience with *Plutella xylostella* larvae (for *Cotesia plutellae*) or pupae (for *Diadromus collaris*) on either treated or untreated cabbage leaves, and the subsequent behavior was compared. Data were analyzed with a chi-square test.

Response of Pupal Parasitoid. Because *Diadromus collaris* showed a low responsiveness in the wind tunnel (<50% responded), we carried out an additional experiment to investigate whether this species responded to volatiles released from damaged plants. For this experiment, one group of cabbage plants was undamaged, and one group was damaged by 15 late fourth instar *Plutella xylostella* larvae, which were left to feed and pupate. Approximately 48 hr later, pupae were removed from the cabbage plants, and these plants were exposed to *D. collaris* in the wind tunnel, with undamaged plants for comparison. The groups of plants were replaced three times during the experiment. Again, less than 50% of the *D. collaris* females responded to the plants and, therefore, no further experiments were carried out with this species.

Different Syringa Doses. Further experiments were carried out with *Cotesia plutellae* using two lower doses of the syringa extract. The lower doses

were made with 1 and 3 g of leaf powder and 100 ml of distilled water, and prepared as described above ([Plant–Host Complex](#)).

Damaged Plants without Hosts. To investigate whether the presence of the host itself resulted in an attraction of *Cotesia plutellae*, the experiment was repeated as described above ([Plant–Host Complex](#)). However, *Plutella xylostella* larvae were allowed to feed for 24 hr and then removed from the plant before the plants were exposed to *C. plutellae* in the wind tunnel. Only the host larvae were removed; their by-products (frass, silk, etc.) remained on the plant.

Equally Damaged Plants without Hosts. Schuler et al. (1999, 2003) have shown that the amount of damage is an important factor influencing the response of *Cotesia plutellae*. Because botanical extracts reduce the feeding of *Plutella xylostella* larvae (Charleston, 2004), the experiment was repeated to compensate for any possible differences in the amount of damage. To create cabbage plants that had an approximately equal amount of damage, plants were first infested with 15 second instar *P. xylostella*. The larvae were left to feed on the plants for 24 hr, after which the larvae were removed. The plants were then sprayed with either the treatment or the control. The groups of plants were replaced twice during the experiment.

Undamaged Plants and Filter Paper. To investigate whether botanical pesticides influence parasitoid behavior, irrespective of the presence of damage, undamaged plants were also compared. Three doses of the syringa extract were tested: 1, 3, and 5 g (see description above for preparation of the extracts), and one dose of neem. Finally, a test was performed to investigate whether the syringa extract alone influenced parasitoid behavior. For this test, filter paper was dipped into either the 5-g syringa treatment or into the control, and parasitoid behavior was observed.

Analysis of Plant Volatiles. To investigate differences in volatile emission by cabbage plants (*Brassica oleracea* var. *gemmifera* cv. Cyrus) that had been treated with syringa extracts and control plants, headspace analysis was carried out. The 5-g syringa extract was made as described above, and 100 ml were applied to each clean, undamaged, cabbage plant. Plants that served as controls were sprayed with 100 ml of distilled water mixed with liquid detergent. The plants were left to dry for 60 min before being placed into 30-l collecting jars.

Pressurized air was filtered over silica gel, molecular sieves (8–12 mesh beads, 4-Å pore width, Sigma), activated charcoal, and a disposable Tenax-containing tube (90 mg Tenax TA) before entering the collecting jar. The air-inlet, air-outlet, filters, and sampling jars were connected with 0.8-cm diam Teflon tubing. Prior to the experiments and between each sample, the system was purged with purified air overnight at a flow rate of 500 ml/min.

Cabbage plants were carefully removed from the pots, taking care not to disturb the root system; then the entire soil and root system was covered in

aluminum foil. Plants were placed individually into the collecting jars, which were covered with a loose glass lid. A viton O-ring was placed between the jar and the lid, and the lid was tightly closed with a metal clamp. High-frequency fluorescent lights (30–35 $\mu\text{mol photons/m}^2/\text{sec}$) were placed 15 cm above the collection jars. The system with the plants was purged for 1 hr at 500 ml/min, after which the flow was reduced to 225 ml/min, and a Tenax (90 mg Tenax TA) trap was connected to the air outlet in the lid of the collecting jar. Volatiles were trapped at a rate of 175 ml/min by pulling the air through the trap by using an in-house vacuum. Volatiles were collected for 4.5 hr, after which the traps were refrigerated ($\pm 4^\circ\text{C}$) until they were analyzed. Four independent samples were collected for each treatment (5-g syringa and control). These independent samples were collected on consecutive days, and each was collected in the morning at the same time each day. After the second sample, and again after the final sample, two blank samples were taken from empty collecting jars to ensure that volatiles always present in filtered/clean air were not considered in the final analysis.

Samples of volatiles were also taken from the syringa extract mixed with liquid detergent. For this sample, 25 ml of extract were placed into a glass Petri dish and placed on top of an Erlenmeyer flask to provide sampling at approximately the same height as the cabbage plant. The Petri dishes were placed into the collecting jars, and the system was purged for 1 hr. After 1 hr, the airflow was reduced to 225 ml/min. A Tenax TA trap was used to collect the volatiles, and air was pulled through the trap at 175 ml/min. Volatiles were collected for 1 hr, after which the Tenax traps were refrigerated ($\pm 4^\circ\text{C}$) until they were analyzed. Four samples were collected from the syringa extract.

Volatiles were released from the Tenax traps with a thermodesorption cold trap setup (Markes, UK) by heating at 200°C for 10 min, with a He-flow of 30 ml/min. Desorbed volatiles were collected in the cold trap at -100°C . Volatiles were injected in splitless mode into the RTX-5Silms column (Restec, 30 m \times 0.32 mm ID, 0.33- μm film thickness) by heating the cold trap to 270°C . After an initial column temperature of 40°C for 2 min, the temperature was raised to 95°C at $3^\circ\text{C}/\text{min}$, then to 165°C at $2^\circ\text{C}/\text{min}$, and subsequently to 250°C at $15^\circ\text{C}/\text{min}$. The column was directly coupled to the ion source of a Finnigan quadrupole mass spectrometer, which was operating in the 70-eV EI ionization mode and scanning from mass 33 to 300 at 3 scans/sec. Compounds were identified by comparison of mass spectra with those in the NIST 98 and Wiley 7th edition spectral libraries and by checking the retention indices with those of authentic reference compounds.

For each compound, the mean peak area was calculated, and each compound was classified as being emitted in larger amounts by control or syringa-treated cabbage plants, based on mean peak area. A sign test was used to determine whether the number of compounds that were emitted in larger amounts by control or syringa-treated plants differed from a 50–50 distribution over the two treatments

(Sokal and Rohlf, 1995). To compare the total headspace composition of plants with and without syringa extract treatment, a principal component analysis (PCA) was carried out according to the description by Mumm et al. (2004).

RESULTS

Plant–Host Complex. Cabbage plants were sprayed with the botanical extracts or control solution and then infested with *Plutella xylostella*. Parasitoids were exposed to the entire plant–host complex in the wind tunnel. *Cotesia plutellae* did not show a preference for the treated or control plants when the plants were treated with the neem extract ($P = 0.093$; Figure 2). However, they did show a preference for plants that had been treated with the 5-g syringa extract ($P < 0.001$; Figure 2). When lower doses of the syringa extract were tested, *C. plutellae* still showed a clear preference for the 3-g syringa dose ($P = 0.029$). Differences were not significant at the lowest 1-g dose ($P = 0.052$; Figure 2). For further experiments with *C. plutellae*, the highest syringa dose (5 g) was used.

Diadromus collaris did not show a preference for the control or the treated cabbage plant for either of the botanical pesticides [neem, $P = 0.37$; syringa (5-g dose), $P = 0.36$].

FIG. 2. Effect of syringa extract and neem on the response of female *Cotesia plutellae* to cabbage plants infested with *Plutella xylostella*. Each plant was sprayed with the control or the botanical pesticide and then infested with *P. xylostella*. Parasitoids were exposed to the entire plant–host complex (PHC). Percentage indicates total number of landings on target per treatment group (no. of responding wasps = 60). Significant differences are indicated in the graph (binomial test, N.S., $P > 0.05$; * $P < 0.05$; *** $P < 0.001$). Number of females not responding is indicated on the right side of the figure.

FIG. 3. Effect of previous experience on the response of female *Cotesia plutellae* to cabbage plants infested with *Plutella xylostella*. (A) Response to plants treated with syringa extract (5-g dose); (B) response to plants treated with neem. Each plant was sprayed with the control or the botanical pesticide and then infested with *P. xylostella*. Parasitoids were exposed to the entire PHC. Percentage indicates total number of landings on target per treatment group (no. of responding wasps = 60). Significant differences are indicated in the graph (χ^2 , N.S., $P > 0.05$; binomial test: ns $P > 0.05$; *** $P < 0.001$). Number of females not responding is indicated on the right side of the figure.

Effect of Experience. The previous experience of female *Cotesia plutellae* with treated or control cabbage plants did not affect the response (neem, $\chi^2 = 0.93$, $df = 1$, $P = 0.64$; syringa, $\chi^2 = 1.679$, $df = 1$, $P = 0.44$; Figure 3A and B). Similar results were found for *Diadromus collaris*; the previous experience of the female with treated or control cabbage plants did not influence the subsequent behavior (neem, $\chi^2 = 0.031$, $df = 1$, $P = 0.97$; syringa, $\chi^2 = 0.304$, $df = 1$, $P = 0.86$; Figure 4A and B).

Response of Pupal Parasitoid. *Diadromus collaris* did not respond well in the wind tunnel, which is clear from the large number of “no responses” ($\pm 50\%$; Figure 4A and B). When damaged and undamaged cabbage plants were compared, females did not distinguish between them ($P = 1.0$), and less than 50% responded (Figure 4C). We, therefore, abandoned this parasitoid species for the remaining trials.

Damaged Plants without Hosts. Plants were sprayed with the botanical extract or control solution and damaged by *Plutella xylostella*, but before exposure to *Cotesia plutellae* in the wind tunnel, the *P. xylostella* larvae were removed. The removal of the hosts did not alter the response of the parasitoid.

FIG. 4. Effect of previous experience on the response of female *Diadromus collaris* to cabbage plants infested with *Plutella xylostella*. (A) Response to plants treated with syringa extract (5-g dose); (B) response to plants treated with neem. Each plant was sprayed with the control or the botanical pesticide and then infested with *P. xylostella*. Parasitoids were exposed to the entire PHC. (C) Caterpillar damaged vs. undamaged cabbage plants; these plants were not sprayed with any treatment. Percentage indicates total number of landings on target per treatment group (no. of responding wasps = 60). Significant differences are indicated in the graph (χ^2 , N.S., $P > 0.05$; binomial test: ns, $P > 0.05$). Number of females not responding is indicated on the right side of the figure.

Again, *C. plutellae* showed a preference for the plants that had been treated with the syringa extract ($P < 0.001$), whereas they did not for the treated or control plants if the plants had been sprayed with the neem extract ($P = 0.52$; Figure 5A).

Equally Damaged Plants without Hosts. To create equally damaged plants, the plants were infested with *Plutella xylostella* larvae for 24 hr, larvae were removed, and then plants were sprayed with botanical extract or control solution. *Cotesia plutellae* did not show a preference for the treated or the control plant when the plants had been treated with the neem extract ($P = 0.7$), but they again showed a highly significant preference for plants that had been treated with syringa extract ($P < 0.001$; Figure 5B).

Undamaged Plants and Filter Paper. *Cotesia plutellae* was exposed to undamaged cabbage plants that had been sprayed with the botanical extracts or the control, or to filter paper that had been dipped in the treatments. Despite the lack of damage, *C. plutellae* still showed a preference for plants that had been treated with the syringa extract, except at the lowest dose (1-g dose, $P = 0.092$; 3-g dose, $P = 0.027$; 5-g dose, $P < 0.001$). Again, there was no effect of treatment with the neem solution ($P = 0.52$; Figure 6). The number of females

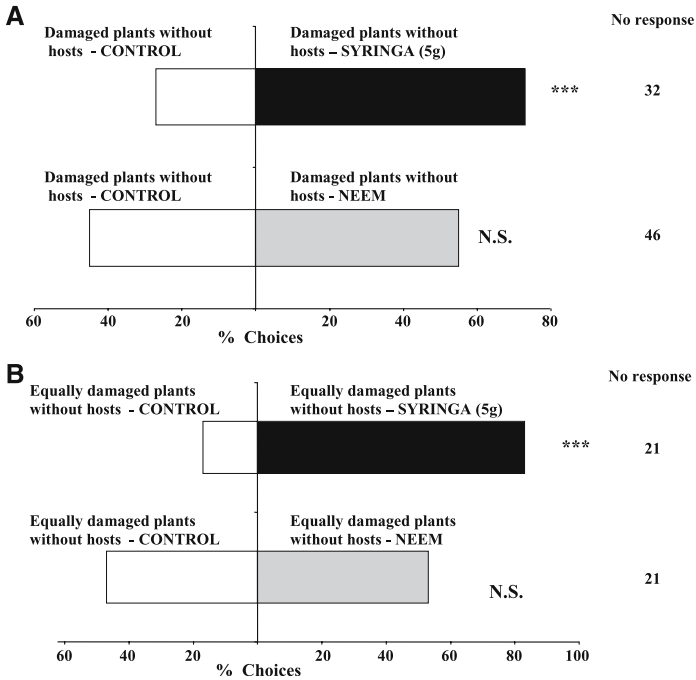

FIG. 5. Effect of syringa (5-g dose) and neem on the response of female *Cotesia plutellae* to treated cabbage plants. Percentage indicates total number of landings on target per treatment group (no. of responding wasps = 60). Significant differences are indicated in the graph (binomial test, N.S., $P > 0.05$; *** $P < 0.001$). Number of females not responding is indicated on the right side of the figure. (A) Cabbage plants had previously been infested with *Plutella xylostella* hosts. Each plant was sprayed with the control or the botanical pesticide and then infested with *P. xylostella*. The *P. xylostella* hosts were removed just before the cabbage plants were exposed to the parasitoids. (B) Cabbage plants were equally damaged. Each plant was infested with *P. xylostella* larvae for 24 hr, the larvae were removed, and then the plants were sprayed with the botanical pesticide or the control.

responding to undamaged plants was less than the number responding to caterpillar-damaged plants.

The attraction of the parasitoid to the syringa extract was lost when it was offered on filter paper instead of cabbage plants ($P = 0.70$; Figure 6).

Analysis of Plant Volatiles. Only compounds that were detected in two or more samples per treatment were included in the analysis. Headspace compositions of the control cabbage and syringa-treated cabbage were clearly different. The PCA resulted in a model with three significant principal factors,

FIG. 6. Effect of syringa and neem on the response of female *Cotesia plutellae* to undamaged cabbage plants or to filter paper dipped in the highest dose of the syringa treatment. Each plant was sprayed with the control or the botanical pesticide, but plants were not infested with *Plutella xylostella*. The filter paper was dipped into the control or the syringa extract (5-g dose). Percentage indicates total number of landings on target per treatment group (no. of responding wasps = 60). Significant differences are indicated in the graph (binomial test, N.S. $P > 0.05$; * $P < 0.05$; *** $P < 0.001$). Number of females not responding is indicated on the right side of the figure.

explaining 72.5% of the variance in the data (Figure 7). A total of 49 compounds, alcohols, aldehydes, ketones, esters, terpenoids, sulfides, and an isothiocyanate were found in both control and treated plants (Table 1). Fifteen of the volatiles in the headspace from cabbage plants that had been treated with the syringa extract were also present in the syringa extract itself: four alcohols, two aldehydes, two esters, two ketones, three terpenoids, and two unidentified compounds (Table 1). Six additional compounds were found in plants that had been treated with syringa extract but not in control cabbage plants (Table 1). The syringa extract itself produced 25 compounds that were not found in the control plants or in the cabbage plants that had been treated with the syringa extract (Table 2). The total quantities of volatiles produced by plants that had been treated with the syringa extract were significantly higher than the quantities produced by control plants: of the 49 compounds, 38 compounds were emitted in larger quantities (based on mean peak areas) by syringa treated plants, and 11 were emitted in larger quantities by control plants (sign test, $P < 0.001$).

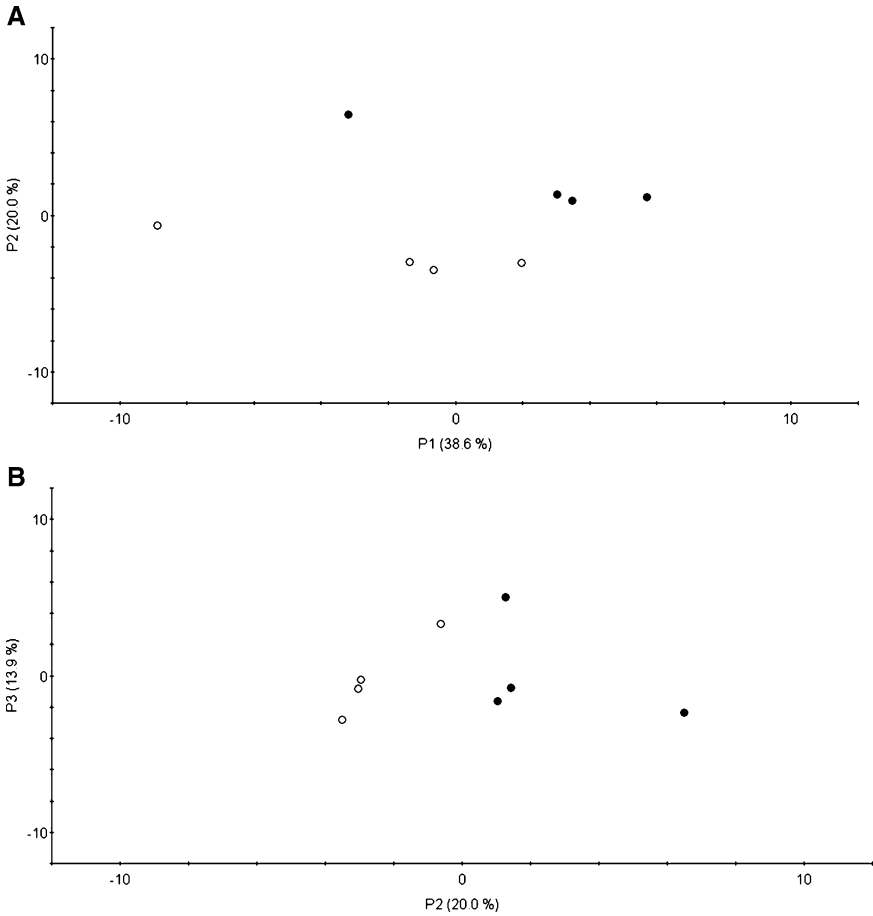

FIG. 7. Principal component analysis of the volatile patterns of differently treated cabbage plants. Score plots for the first (P1) vs. second (P2) significant principle factor (A) and for the second (P2) vs. the third (P3) significant principle factor (B) from partial-least-squares discriminant analysis based on absolute amounts of volatile constituents. Open circles represent samples of control cabbage plants, and filled circles represent samples for syringa-treated cabbage plants.

DISCUSSION

After an oviposition experience, *Cotesia plutellae* responded well in the wind tunnel. Females did not distinguish between cabbage plants that had been treated with the neem solution and plants that had been sprayed with the control.

N = no. of samples out of 4, in which the compound had been identified.

However, *C. plutellae* always preferred cabbage plants that had been sprayed with the syringa extract to the control plants, except at the lowest dose. *C. plutellae* appears to detect and respond differently to volatiles from plants treated with these two botanical extracts. Akol et al. (2003) have shown that *Diadegma molipla* is able to detect and distinguish between volatiles emitted by cabbage plants sprayed with two different neem formulations. In their experiment, they found that a neem seed oil formulation had a negative effect on the foraging of *D. molipla*, as females significantly preferred volatiles from control plants over those from plants sprayed with neem formulation. However, when *D. molipla* had a choice between plants sprayed with a solution from a neem kernel cake powder and control plants, they did not distinguish between

sprayed and control plants (Akol et al., 2003). *Uscana lariophaga*, an egg parasitoid of the bruchid *Callosobruchus maculatus*, was repelled by neem seed oils on cowpea beans, but the larval parasitoid *Dinarmus basalis* did not discriminate between control and neem-treated beans (Boeke, 2002; Boeke et al., 2003). In our study, the neem formulation Neemix 4.5[®] did not appear to have an adverse effect on foraging by *C. plutellae*.

Pre-flight experience can have a distinct effect on parasitoid behavior (reviewed by Turlings et al., 1993 and Vet et al., 1995). However, learning is thought to have a less important role for specialist parasitoids (Geervliet et al., 1998). Both *Cotesia plutellae* and *Diadromus collaris* are relatively specialized parasitoids attacking mainly *Plutella xylostella*, and results from this study show no indication that these parasitoids acquired a response to syringa through associative learning.

The response of *Cotesia plutellae* to volatiles from herbivore-damaged plants that had been treated with syringa extract was independent of the presence of host larvae. Previous studies have also shown that herbivore-damaged plants are attractive to *C. plutellae* (Shiojiri et al., 2001; Vuorinen et al., 2004) even after removal of the hosts (Potting et al., 1999).

Schuler et al. (1999, 2003) found that the amount of damage was an important factor influencing the flight responses of *Cotesia plutellae*. In previous studies, we have shown that *Plutella xylostella* damage is lower on cabbage plants treated with botanical extracts (Charleston, 2004). However, our data show that the response of *C. plutellae* was similar whether the cabbage plants had been sprayed with the botanical extracts first or whether plants were first damaged by *P. xylostella* larvae and then sprayed with the botanical extract. The difference in feeding damage between the treated and control cabbages may have been too small to affect the flight response of *C. plutellae*.

The pupal parasitoid *Diadromus collaris* was not attracted to volatiles emitted by cabbage plants in the wind tunnel and did not distinguish between caterpillar-damaged and undamaged plants. *D. collaris* is a pupal parasitoid, and while there is a wealth of knowledge available on the role of volatile cues used by parasitoids attacking larval stages of herbivores (Dicke and Vet, 1999), there is not much information about the chemical cues used by pupal parasitoids (Vet et al., 1995). Some pupal parasitoids have been shown to respond to plant volatiles. The stemborer pupal parasitoid *Dentichasmias busseolae*, for example, makes use of plant volatiles from maize and sorghum and is particularly attracted to herbivore-damaged plants (Gohole et al., 2003). For pupal parasitoids, as for all parasitoids, the possibilities of using direct host-derived cues are limited, and in addition, larvae often pupate away from the site of damage, restricting the use of predictable indirect cues by pupal parasitoids (Vet et al., 1995). The opportunity of using volatiles from larval feeding damage is limited to situations where the pupae stay in or on the plant, and larval and pupal stages co-occur. *Plutella xylostella* tend to pupate on the plant (although not directly

near feeding damage), and, because of fast development and overlapping generations, larval and pupal stages are often found together in the field. Hence, *D. collaris* could make use of plant volatiles to find its host. Electroantennogram (EAG) studies indicate that *D. collaris* does respond to cabbage volatiles (Lecomte and Pouzat, 1985), which further suggests that this parasitoid may make use of plant volatiles. However, in our studies, *D. collaris* did not appear to use herbivore-induced plant volatiles. Therefore, it is possible that *D. collaris* makes use of other strategies to find its host. *Cotesia plutellae* was attracted to cabbage plants treated with syringa extract. Even undamaged cabbage plants treated with syringa extract attracted the parasitoids. In contrast, *C. plutellae* did not show a preference for filter paper dipped in the syringa extract. Headspace analysis yielded a total of 49 compounds from both undamaged control cabbage plants and undamaged cabbage plants that had been treated with syringa extract. The volatile bouquet emitted after treatment with syringa extract is composed of the same components as emitted by untreated cabbage plants. This is comparable to what happens in response to herbivory: the composition of the bouquet is qualitatively similar to that emitted by intact or mechanically damaged plants, and consists of fatty acid derivatives, terpenoids, and a few sulfur-containing compounds such as methyl isothiocyanate and sulfides. However, the quantity of volatiles was significantly higher in the plants treated with the syringa extract. Some of the volatiles found in cabbage plants treated with the syringa extract were also present in the syringa extract itself. Yet, many of the volatiles emitted by the syringa extract were not emitted, or were only emitted at low rates, from cabbage plants treated with the syringa extract. This indicates that the enhanced emission of the plant volatiles from cabbage plants treated with the extract is caused by an induction of these volatiles in cabbage rather than an evaporation of the syringa extract from the treated plants. To our knowledge this is the first example of a plant extract causing an increased emission of plant volatiles, which is likely to explain the significant attraction of *C. plutellae* to plants that have been treated with the syringa extract. Which of the emitted volatiles attract the parasitoids remains to be elucidated. For crucifer–parasitoid interactions, a gas chromatography (GC)–EAG approach has limited the total number of compounds to be tested in behavioral tests to about 20 for the parasitoids *Cotesia glomerata* and *Cotesia rubecula* (Smid et al., 2002). A recent field study in an open field and a hop yard showed that 11 carnivorous arthropods were attracted to 13 herbivore-induced plant volatiles (James, 2005).

It is well-known that elicitors can induce parasitoid-attracting plant volatiles. Among these elicitors are, for example, compounds from herbivore regurgitant (Alborn et al., 1997; Mattiacci et al., 1995) or phytohormones (Dicke et al., 1999; Gols et al., 1999; Ozawa et al., 2000; Horiuchi et al., 2001). Furthermore, there is evidence that plants can affect the emission of volatiles in downwind neighboring plants (Dicke and Bruin, 2001; Pichersky and

Gershenzon, 2002; Choh et al., 2004; Engelberth et al., 2004). Some green leaf volatiles, i.e., (*Z*)-3-hexenol, (*E*)-2-hexenal, and (*Z*)-3-hexenyl acetate, induce gene expression in plants that are exposed to these compounds in an airtight container (Arimura et al., 2001). We have recorded (*E*)-2-hexenal in the headspace of the syringa extract. However, whether this compound is responsible for inducing the emission of parasitoid attractants in cabbage remains to be investigated.

Our data show that treatment of cabbage with syringa extract or Neemix 4.5[®] would not impair the process of host habitat location by *Cotesia plutellae* or *Diadromus collaris*. In fact, *C. plutellae* was always attracted to cabbage plants treated with the syringa extract, even when the plants were undamaged, which may indicate an interaction between a plant and a botanical extract that enhances natural enemy activity. This may have negative implications for biological control. If the parasitoids do not discriminate between infested and uninfested plants, then they may waste time searching uninfested plants, which may result in a reduction of the parasitization rate (Dicke et al., 1990). Treatment of plants with the plant hormone jasmonic acid results in an increased emission of plant volatiles, and this results in an attraction of parasitoids and predators (Dicke et al., 1999; Gols et al., 1999, 2003; Thaler, 1999; Ozawa et al., 2004). Yet, in field-grown tomatoes, a blanket treatment with jasmonic acid resulted in higher parasitization levels of *Spodoptera exigua* compared to control plots (Thaler, 1999). In our study, the parasitoids were only given a short preoviposition experience with cabbage leaves that were infested with host insects and were not given the opportunity to discriminate between damaged and undamaged plants. This is not representative for most foraging decisions in nature, where previous foraging experiences, both positive and negative, can be integrated (Vet et al., 1998; Dicke, 1999b). Under field conditions, infested and uninfested plants are likely to be in close proximity, and the parasitoid may soon learn to discriminate. It would be interesting to expand these observations to investigate the impact that these botanical pesticides have on parasitoid foraging behavior in field situations.

Acknowledgments—This research was carried out through a grant awarded under the IFS/ KNAW Carolina MacGillavry Ph.D. Fellowship Program. The ARC-PPRI provided the working space and facilities. Staff of the ARC-PPRI insectary provided the insects used in the experiments. Elisa Garzo converted the wind tunnel sketch into digital format and Roland Mumm helped with the principal component analysis.

Published Online March 23, 2006

Abstract—Nonirradiated males and females of *Anastrepha obliqua* (Macquart) were attracted to and landed more frequently on ripe fruits of *Spondias mombin* L. than on artificial fruit in wind tunnel bioassays. Porapak Q volatile extracts of *S. mombin* were also attractive and elicited landing on artificial fruit for both sexes. Combined gas chromatographic–electroantennographic detection (GC-EAD) analysis of volatile extracts showed that nine volatile compounds elicited repeatable antennal responses from females and males. The EAD-active compounds were identified by GC–mass spectrometry (MS) as follows: ethyl butyrate, isopropyl butyrate, hexan-1-ol, propyl butyrate, isobutyl butyrate, ethyl hexanoate, isopentyl butyrate, ethyl benzoate, and ethyl octanoate. In wind tunnel bioassays, males and females were attracted and landed more frequently on lures containing the nine-component blend of synthetic compounds than on unscented controls. Field cage bioassays showed that multilure traps baited with the nine-synthetic blend captured significantly more *A. obliqua* than traps baited with hydrolyzed protein or water.

Key Words—*Anastrepha obliqua*, mombin fruit, attractants, host volatiles, gas chromatographic–electroantennographic detection, wind tunnel.

INTRODUCTION

The West Indian fruit fly *Anastrepha obliqua* (Macquart) (Diptera: Tephritidae) has a wide distribution in the Americas. It has been recorded from the USA

* To whom correspondence should be addressed. E-mail: jrojas@tap-ecosur.edu.mx

(Florida and Texas) to South America, including the Caribbean Islands (Hernández-Ortiz and Aluja, 1993). *A. obliqua* is a highly polyphagous insect attacking fruits of 13 families (Norrbom et al., 2000), but females usually prefer to oviposit in fruit belonging to the Anacardiaceae family (Jirón et al., 1988; Hernández-Ortiz and Aluja 1993).

In Mexico, *A. obliqua* is considered a key pest of mango (*Mangifera indica* L.) and mombin (hogplum) fruits (*Spondias* spp.; Hernández-Ortiz and Aluja, 1993), making the production of some varieties unprofitable. Moreover, its presence in mango orchards is motive for strict quarantine from the USA, the main importer of the Mexican mango (APHIS, 1994). The most widely used system for monitoring *Anastrepha* fruit flies during the last 35 yr consists of glass and plastic versions of the McPhail trap containing a mixture of protein and water (Aluja, 1994). However, difficulties in handling, low capture efficiency, and capture of nontarget organisms (Epsky et al., 1993; Thomas et al., 2001) lead to investigations of potential attractants from different sources such as bacteria, bird feces, and fruits (e.g., Robacker et al., 1990, 1992; Nigg et al., 1994; Epsky et al., 1997). Most of the effort in the search for attractants of *Anastrepha* flies has concentrated on *Anastrepha ludens* (Loew) and *A. suspensa* (Loew), and few studies have been carried out with *A. obliqua* (Hedström, 1988; Ortega-Zaleta and Cabrera-Mireles, 1996; DeMilo et al., 1997). Ortega-Zaleta and Cabrera-Mireles (1996) evaluated the attractiveness of pineapple (*Ananas comosus* Merr.) juice, fermented pineapple juice, cow milk serum, and ether and ethanol extracts of *Spondias purpurea* L., *Spondias mombin* L., and *M. indica* as potential attractants for *A. obliqua*. They found that only the ethanolic extract of *S. purpurea* was more attractive than hydrolyzed protein when evaluated in a mango orchard.

We conducted this study to search for potential attractants in the fruit of *S. mombin*, which is a native and highly preferred host of *A. obliqua* (Hernández-Ortiz and Aluja, 1993). The objectives were to (1) evaluate the attraction of *A. obliqua* to ripe fruits of *S. mombin* and its volatile extracts in a wind tunnel, (2) locate the electrophysiological active compounds from fruit volatile extracts using gas chromatographic–electroantennographic detection (GC-EAD), (3) identify chemically the EAD-active compounds by GC-MS, and (4) evaluate the response of the flies to synthetic compounds in wind tunnel and field cage tests.

METHODS AND MATERIALS

Insects. Flies used for experiments came from a strain obtained from the Subtropical Agricultural Research Laboratory (ARS-USDA, Weslaco, TX). Insects were originally collected from infested *S. mombin* fruits in the State of

Veracruz, Mexico (Moreno et al., 1997). Prior to our experiments, this strain had been reared on an artificial diet for at least 110 generations at the Moscafrut mass-rearing facilities (SAGARPA-IICA) located in Metapa de Dominguez, Chiapas, without subsequent introductions of wild material (Dominguez et al., 2000). After emergence, fertile adults were placed in wooden cages with mesh sides ($65 \times 65 \times 45$ cm) and kept at $25 \pm 1^\circ\text{C}$, 60–70% relative humidity, and 12-hr light/12-hr dark photoperiod. Adults were fed *ad libitum* with a mixture of enzymatic yeast hydrolysate (ICN Biomedical, Costa Mesa, CA, USA), sucrose (1:3), and water provided in test tubes covered with cotton wicks. Males and females of 10–19 d old and 7–13 d old were used for laboratory assays (wind tunnel and GC-EAD analysis) and field cage tests, respectively.

Fruits. We obtained fruit specimens from mombin trees located near Tapachula, Chiapas, Mexico. Fruits were collected when they were orange in color (ripe), placed in plastic bags, and immediately carried to the laboratory for bioassays and volatile collection. To quantify the degree of ripeness more accurately, we measured the Brix value to determine sugar content. This value is used to measure liquid density, especially sugar concentration in fruit and vegetable juices (Hogness and Jones, 1984). The Brix values of the mombin fruits used ranged from 14.0 to 16.5 as measured by a manual refractometer (Iroscope, Mexico City).

Volatile Collection. We collected fruit volatiles using the dynamic head-space technique. Ripe healthy mombin fruits (400 g) were placed into a cylindrical glass aeration chamber (58 cm long \times 18.5 cm i.d.). A charcoal-filtered air stream (1 l/min) was maintained through the glass aeration chamber for 16 hr. Fruit volatiles were collected on 350 mg of Porapak Q (50–80 mesh, Water Associates, Inc., Milford, MA, USA) packed between plugs of silanized glass wool in a Pasteur pipette. The Porapak Q was previously cleaned using the procedure of Blight (1990). Volatiles were eluted from the Porapak Q with 2 ml of diethyl ether (HPLC grade, Aldrich, Toluca, Mexico). Final concentration to 600 μl was made by slow evaporation under a gentle stream of nitrogen. The extract was stored at a -20°C until bioassays, and chemical analysis could be performed. Samples were collected from five different lots of mombin fruits.

Wind Tunnel Bioassays. Behavioral observations were carried out in a flight wind tunnel, 120 cm long and 30 cm high and wide. The wind tunnel was constructed from 1 cm thick clear Plexiglas. A fan was used to pull air, filtered by activated charcoal, through the tunnel at a velocity of 0.4 m/sec. Illumination was provided by four fluorescent bulbs mounted 60 cm above the wind tunnel giving a light intensity of 2380 lx. We evaluated the insects in groups of 25 individuals (males or females) 18 hr after placing them in a plastic container (6 cm high \times 8-cm diam release cylinder) with screen top. Water, but no food, was provided in the containers. Flies were allowed to acclimatize in the wind tunnel under room condition ($25 \pm 1^\circ\text{C}$ and $60 \pm 5\%$ relative humidity) for at least 1 hr before

being assayed. In three different trials, the response of flies to host fruits, Porapak Q volatile extracts, and the synthetic blend was evaluated in no-choice tests. Polystyrene spheres (5-cm diam.), painted with vinyl acrylic water-based paints matching (as detected by the human eye) the orange color of the mombin fruit, were used for dispensing either the mombin extracts (second trial) or the synthetic blend (third trial), and as controls (in all trials). One hundred microliters of mombin extract (equivalent to 0.5 mg of fruit) or 1 mg of the synthetic blend prepared according to the relative proportions of each compound in the natural extracts (Table 1) were loaded on a rubber septum (Agrisense, England). The rubber septum was inserted into an orange-painted sphere. A rubber septum loaded with 100 μ l of diethyl ether and placed in an orange sphere was used as control. The target stimulus (e.g., fruit, unscented sphere, or scented sphere) was hung in the center of the wind tunnel, 16 cm from the upwind end.

Each observation was started by placing the release cylinder on a 12 cm high platform at the downwind end of the tunnel, and insects were released and observed for 10 min. The behavior of the insects was recorded during the test, specifically for upwind flight and for landing. Upwind movement was noted if insects passed a point two thirds of the distance from the release cylinder toward the odor source or control (Robacker and Fraser, 2002). Landing behavior was scored for either landing or walking onto the target stimuli. Generally, flies that responded remained in the upwind section of the tunnel or on the odor source for the rest of the bioassay. Ten replicates for each sex and treatment were carried out. The flies were only used once during the bioassays. All bioassays were conducted between 0800 and 1300 hr.

TABLE 1. EAD-ACTIVE COMPOUNDS FROM MOMBIN FRUIT DETERMINED BY INTEGRATION OF GC-MS TOTAL ION CURRENT USING ADSORBENT FIVE SAMPLES FROM RIPE FRUITS

Peak no. ^a	Compound	GC-MS mean (%)	WT and FC ^b
1	Ethyl butyrate	36.8	40
2	Isopropyl butyrate	0.8	1
3	Hexan-1-ol	0.8	1
4	Propyl butyrate	1.3	1
5	Isobutyl butyrate	3.6	5
6	Ethyl hexanoate	36.7	40
7	Isopentyl butyrate	3.8	5
8	Ethyl benzoate	12.6	15
9	Ethyl octanoate	3.6	5

^aNumbers correspond to labeled peaks in Figure 1.

^bWT and FC indicate the proportion of each compound in the synthetic blend used in wind tunnel and field cage experiments.

Chemicals. Synthetic chemicals were purchased from Sigma-Aldrich (Toluca, Mexico) and Bedoukian Research (Danbury, CT, USA), and the purities were >95% based on the results with the capillary gas chromatography.

Combined Gas Chromatographic-Electroantennographic Detection (GC-EAD). GC-EAD analysis (Arn et al., 1975) was carried out to locate the antennal active components from Porapak Q extracts. The system consisted of a gas chromatograph (Varian 3600, Palo Alto, CA, USA) coupled to an electroantennogram apparatus (Syntech, Hilversum, The Netherlands). The GC was equipped with a nonpolar DB-5 capillary column (30 m × 0.25 mm i.d., film thickness 0.5 µm; J&W Scientific, Folsom, CA, USA), a flame ionization detector (FID) and a split/splitless injector. The temperature oven was programmed at 50°C for 2 min, then 3°C/min to 280°C, and held for 10 min. Injector and detector temperatures were at 250 and 300°C, respectively. The injector was operated in splitless mode. Helium was used as carrier gas at 2 ml/min. At the end of the capillary column, a fixed outlet splitter (VSOS, Scientific Instruments Services, Ringoes, NJ, USA) distributed the effluent from the column to FID and to a transfer line towards the EAD preparation. Both connections were made of deactivated fused silica with the same length and diameter such that the column effluent was split in a ratio of 1 (EAG) to 1 (FID). Before injection of a sample, the antenna was stimulated with linalool to check sensitivity. If the antennae elicited a clear response different from background, then the mombin fruit extracts were injected. A minimum of 16 antennae per sex were used.

Chemical Analysis. Gas chromatography–mass spectrometry was conducted with a Varian Star 3400 CX gas chromatograph linked to a Varian Saturn 4D mass spectrometer (Palo Alto, CA, USA). The samples were analyzed using a nonpolar DB-5 capillary column (identical to the one used in the GC-EAD system described above) or a polar HP-FFAP capillary column (25 m × 0.25 mm i.d., film thickness 0.5 µm; J&W Scientific, Folsom, CA, USA). The temperature program was the same as that described for the GC-EAD analyses. The carrier gas was helium at constant flow rate (1.0 ml/min). The injector port temperature was held at 200°C. Compounds were identified by comparison of retention times and mass spectral matches of available standards. Quantification of the relative proportions of the EAD-active compounds was made from mombin extracts. Compounds quantification was made from the ion abundance from GC-MS analyses, or FID responses, according to the standard curves made from external standards of known concentrations.

Field Cage Tests. The attractiveness of the mombin blend was compared against hydrolyzed protein and water in no-choice and three-choice tests. Tests were performed in a seminatural condition using cylindrical clear nylon screen field cages (2.85-m diam. × 2 m high). In no-choice tests, one coffee (*Coffea arabica* L.) and mango-potted trees (1.20 m tall) were placed in the center of each cage. In three-choice tests, five coffee and six mango-potted trees were

placed inside of each cage, one tree of each species in each cardinal point, and two trees (one in the case of coffee) in the center of the cage. In no-choice tests, one Multilure trap (Better World Manufacturing Inc., Fresno, CA, USA) was placed 50 cm above the trees. In three-choice tests, three Multilure traps were placed 30 cm from the periphery of the cage with 185 cm between each trap. The traps were hung at 10 cm from the top of cage. The synthetic mombin blend was prepared according to the relative proportions in the Porapak extracts (Table 1), and 100 mg of this blend were loaded in rubber septa. The hydrolyzed protein Captor 300 (Promotora Agropecuaria Universal S.A. de C.V., Mexico City) was prepared using 5 g of borax mixed with 10 ml of hydrolyzed protein dissolved in 235 ml of water per trap. Water plus Tween 80 (ICI, Wilmington, DE, USA) was used to retain the flies in the traps baited with the synthetic mombin blend and water. About 25 (12 or 13 of each sex, in no-choice tests) and 150 flies (75 of each sex, in three-choice tests) with 15 hr of starvation were released in the center of the cage in the morning. The lures were placed in traps 15 min before the flies were released into the cage. Traps were hung from 0800 hr, and the number of insects caught by each trap was counted 24 hr later. Trap positions were rerandomized daily to reduce positional effects. During the period of the tests, the temperature ranged from 23 to 31°C and relative humidity from 60 to 95%. The experiments were replicated 12 times.

Data Analysis. All statistical analyses were carried out using the computer program Statistica (StatSoft, 2003). The wind tunnel data were analyzed using a *t* test to compare the proportions of fruit flies that were attracted and landed on odor source (fruit, extract, or synthetic blend) or sphere control. The proportions were transformed by arcsine of the square root before statistical analysis. Proportions of zero were replaced with $1/4n$ before transformation (Robacker and Fraser, 2002). Because an analysis by *t* test showed that the number of flies caught by traps did not significantly differ between sex in the field cage experiments, data for male and female were pooled and transformed with $\sqrt{x + 0.5}$

TABLE 2. MEAN RESPONSE (\pm SE) OF *Anastrepha obliqua* TO MOMBIN FRUITS AND SPHERE CONTROL, AND EXTRACT VOLATILES AND SPHERE CONTROL (WITH SOLVENT) WHEN OFFERING IN NO-CHOICE TESTS IN A WIND TUNNEL

Treatment	Moved upwind		Landed on source	
	Female	Male	Female	Male
Fruit	34.4 \pm 3.56b	24.0 \pm 3.44b	25.5 \pm 3.48b	9.2 \pm 2.3b
Control	11.2 \pm 1.64a	6.8 \pm 1.04a	2.0 \pm 1.04a	0.44 \pm 0.04a
Porapak Q extract	30.4 \pm 3.73b	20.8 \pm 2.94b	19.6 \pm 3.97b	9.4 \pm 1.67b
Control	12.0 \pm 1.68a	6.4 \pm 1.06a	6.8 \pm 1.68a	1.6 \pm 0.64a

Means followed by different letters within each comparison are significantly different at $P < 0.05$ level (*t* test). Total number of flies released was 250 per sex for each test.

before analyzing by one-way analysis of variance (ANOVA). When significant treatment effects were observed, means were separated by Tukey test ($P < 0.05$).

RESULTS

Response to Fruits and Porapak Q volatile Extracts. Flights consisted of either a general movement upwind towards the odor source or a direct upwind flight. In general movement upwind, females would often take flight from the platform, alight on the sides of the wind tunnel, and display cleaning of antennae and legs before resuming upwind flight. Oriented upwind flights were either straight line or a side-to-side zigzag movement. Sometimes, insects flew directly from the platform to the odor source. Flies that were not attracted normally flew to the floor, side, or top of the tunnel or remained in the release cylinder. Both

FIG. 1. Simultaneous responses of flame ionization detector (FID) and electroantennographic detection (EAD) using the antennae of female *Anastrepha obliqua* to headspace collected volatile from *Spondias mombin* fruits on a nonpolar capillary column. Numbered peaks indicate EAD-active compounds (see also Table 1).

FIG. 2. Mean percent response (\pm SE) of *A. obliqua* to sphere dispensing the mombin synthetic blend and sphere control (with solvent) when offering in no-choice tests in a wind tunnel. Differences between paired bars (*t* test) indicated by ***, $P < 0.001$. Total number of flies released was 250 per sex for each test.

females ($t = 6.0$, $df = 18$, $P < 0.001$) and males ($t = 4.8$, $df = 18$, $P = 0.001$) were more attracted to mombin fruits than to artificial fruits. Similarly, both sexes (females: $t = 4.6$, $df = 18$, $P < 0.001$; males: $t = 4.6$, $df = 18$, $P < 0.001$) were more attracted to the Porapak Q volatile extracts than to solvent control. Landing was also observed more frequently on fruits (females: $t = 7.2$, $df = 18$, $P < 0.001$; males: $t = 3.7$, $df = 18$, $P = 0.001$) and extracts (females: $t = 2.7$, $df = 18$, $P = 0.015$; males: $t = 3.8$, $df = 18$, $P = 0.001$) than on controls (Table 2).

GC-EAD analysis. The analyses by GC-EAD of the headspace sample of *S. mombin* fruits showed that *A. obliqua* male and female antennae responded strongly (>1 mV) to three compounds (peaks 1, 4, and 6; Figure 1). Weaker (<1 mV) but repeatable responses were also found to six other components (peaks 2, 3, 5, 7, 8, and 9). The corresponding EAD-active compounds were identified as ethyl butyrate (peak 1), isopropyl butyrate (peak 2), hexan-1-ol (peak 3), propyl butyrate (peak 4), isobutyl butyrate (peak 5), ethyl hexanoate (peak 6), isopentyl butyrate (peak 7), ethyl benzoate (peak 8), and ethyl octanoate (peak 9). The relative ratios of the EAD-active compounds in five adsorbent extracts of volatiles from *S. mombin* fruits are listed in Table 1. The EAD activity of compounds was verified by GC-EAD analysis with authentic standards.

Response to Mombin Blend in a Wind Tunnel. Attraction of *A. obliqua* to the nine-synthetic blend was different from control (females: $t = -8.5$, $df = 18$, $P < 0.001$; males: $t = 8.6$, $df = 18$, $P < 0.001$). Landing of both sexes on scented

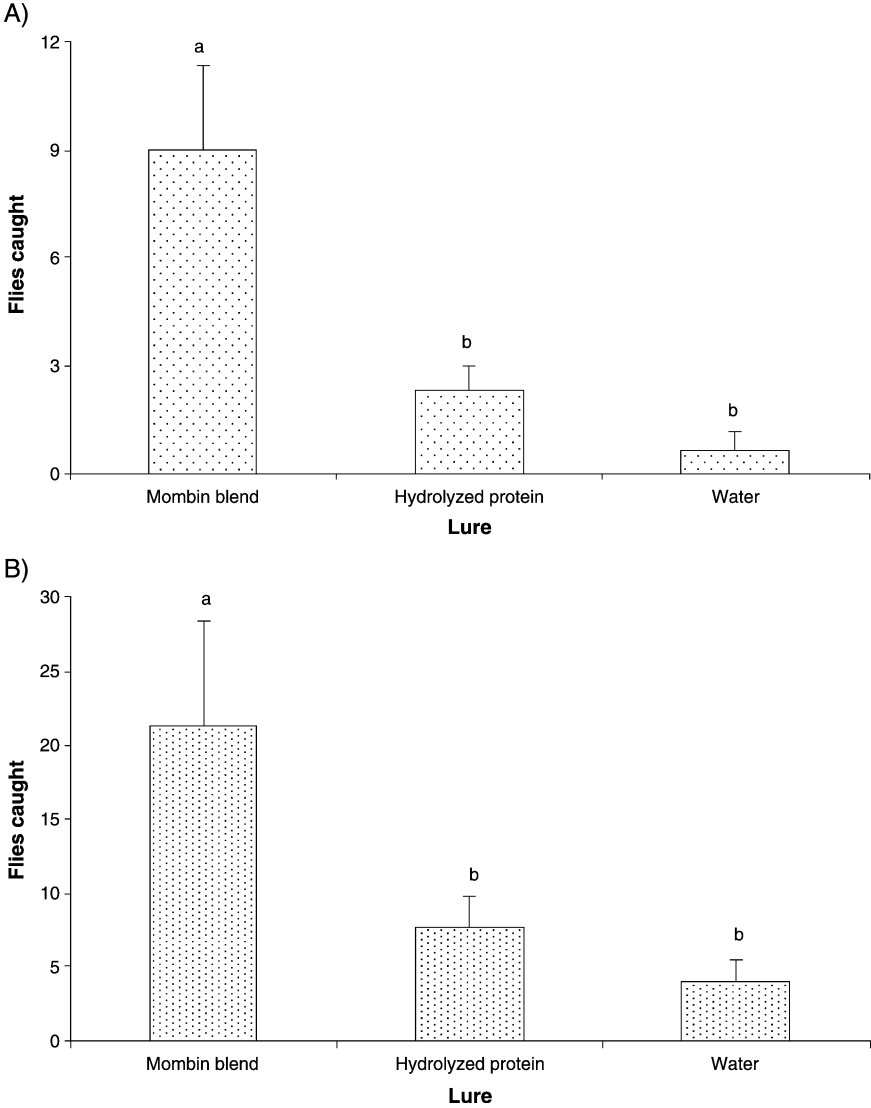

FIG. 3. Mean number (\pm SE) of males and females *A. obliqua* caught in Multilure traps baited with mombin volatiles blend, hydrolyzed protein and water in no-choice (A) and choice (B) tests. Columns with the same letters are not significantly different by Tukey test, $P > 0.05$. Total number of flies released was 300 and 1800 in no-choice and three-choice tests, respectively.

lures was different from the controls (females: $t = -6.13$, $df = 18$, $P < 0.001$; males: $t = 5.9$, $df = 18$, $P < 0.001$; Figure 2).

Field Cage Test. Field cage experiments showed that traps baited with the mombin blend caught more flies than traps baited with hydrolyzed protein and water in both no-choice ($F = 17.1$, $df = 2,35$, $P < 0.001$) and three-choice ($F = 7.5$, $df = 2,35$, $P = 0.001$) tests (Figure 3).

DISCUSSION

The results demonstrated that both sexes of *A. obliqua* were attracted to mombin fruits and Porapak Q volatile extracts in a wind tunnel. Furthermore, our approach of coupled GC-EAD analysis revealed that nine volatile constituents of the mombin extracts were EAD-active on the antennae of males and females. The compounds were identified as ethyl butyrate, isopropyl butyrate, hexan-1-ol, propyl butyrate, isobutyl butyrate, ethyl hexanoate, isopentyl butyrate, ethyl benzoate, and ethyl octanoate. Additionally, the nine-component blend of the synthetic compounds was attractive to both sexes of *A. obliqua* when evaluated in a wind tunnel, and field cage tests traps baited with the mombin blend caught significantly more flies than traps baited with hydrolyzed protein or water.

One potential criticism of our results is the fact that the behavioral and electrophysiological tests were made with flies reared for several generations in the laboratory. The biology of insects maintained in the laboratory may differ from the biology of wild insect of the same species. For instance, Briceño and Eberhard (2002) found that the mating behavior of mass-reared *Ceratitis capitata* (Wiedemann) males was different from that of wild males. We do not know if the host-finding behavior of *A. obliqua* is affected by the mass rearing. However, preliminary trials showed that wild males are caught by traps baited with nine-component blend of synthetic compounds in mango orchards (Toledo et al., unpublished data).

For most species of tephritid fruit flies, host plants and trees are important foraging sites (Jang and Light, 1996). We do not know whether the mombin volatiles identified here are used by *A. obliqua* as cues during the searching for food, mates, and/or oviposition sites. We observed that both sexes of *A. obliqua* fed on fruits and females attempted to oviposit on mombin fruits during the wind tunnel experiments. Therefore, it is possible that attraction of *A. obliqua* to fruit odors may represent food foraging for both sexes and oviposition foraging for females. Fruit volatiles also may affect the sexual behavior of *A. obliqua* as documented for other tephritid fruit flies (Robacker and Garcia, 1990; Landolt et al., 1992; Papadopoulos et al., 2001). For example, chapote odor almost

completely inhibited attraction of sexually mature *A. ludens* females to male pheromone (Robacker and Garcia, 1990). Future studies using fruits with different degree of ripeness (e.g., green, green-orange, and orange) and flies of different physiological state (age, mating status, and hunger level) are needed to investigate whether *A. obliqua* used the host volatiles as cues during the search for food, mates, and/or oviposition sites.

The predominant volatile compounds in the extracts of mombin fruits were esters and alcohols. In fact, of the compounds that elicited electrophysiological and behavioral responses from *A. obliqua*, eight were esters and only one was an alcohol. The volatiles of mango, another highly preferred host of *A. obliqua*, are characterized by monoterpenes and esters (MacLeod et al., 1988; Andrade et al., 2000; Jirovets, 2003). Three of the EAD-active compounds identified in the mombin volatiles have been found in mango volatiles: hexan-1-ol, ethyl hexanoate, and ethyl octanoate. Preliminary GC-EAD analysis of mango volatiles (CV Ataulfo) showed that six compounds elicited repeatable antennal responses from sexes of *A. obliqua* (Galindo-López, 2004). The EAD-active compounds were identified as ethyl hexanoate, *cis*-ocimeno, isoterpinolene, terpinolene, methyl octanoate, and ethyl octanoate. The six-component blend was more attractive for *A. obliqua* males and females than hexane control. The results with mango and mombin volatiles suggest that this generalist fruit fly species may use a wide range of fruit volatiles during its host location behavior. Díaz-Fleischer et al. (2000) proposed that fruit fly species with a narrow host range tend to be specialists in terms of host cues to which they respond during the host-finding process, whereas polyphagous species tend to be generalists. With regard of the chemical cues, the limited information available suggests that generalist fruit fly species respond to the odor of a broad range of unrelated volatiles released by ripening host fruits, whereas specialist species respond to narrow range of host fruit volatiles (Díaz-Fleischer et al., 2000).

Inexpensive attractants for fruit flies have been the objective of much research and would benefit fruit production and support fruit exports in many countries (e.g., McPhail, 1943; Steiner, 1952; Chambers, 1977). The mombin volatiles identified here may be used for developing a dry synthetic attractant that avoids the difficulties associated with the use of aqueous protein baits (Heath et al., 1995). For example, bait solutions may be spilled readily while managing the trap, and spilled bait offers an attractant source outside the trap. Also, it is expected that traps baited with fruit volatiles will capture mostly *A. obliqua*, whereas traps baited with hydrolyzed protein capture many other nontarget insects (Aluja, 1999). However, we recognize that the cost of synthesizing a bait from the mombin volatiles identified here may prove too expensive for practical use in the short term; particularly to poor fruit growers in Latin America.

Effective attractants for tephritid fruit flies have been developed from host fruits previously (Robacker et al., 1990, 1992; Nigg et al., 1994), and the most

remarkable, effective, and useful attractant developed from a host plant is that for the apple maggot *Rhagoletis pomonella* (Walsh) (Fein et al., 1982; Zhang et al., 1999). Initially, Fein et al. (1982) found that a seven-component blend of esters was highly attractive to both sexes of *R. pomonella* in laboratory bioassays and field trials (Reissig et al., 1982). The multicomponent lure was commercialized as an attractant for use in sticky red-sphere monitoring traps and for control programs (Jang and Light, 1996). Recently, a new five-component mix of volatiles from apples has been found by using solid-phase microextraction and GC-EAD techniques (Zhang et al., 1999). This five-component blend contains three compounds (propyl hexanoate, butyl hexanoate, and hexyl butanoate) in common with the previous seven-component blend, as well as two new components (butyl butanoate and pentyl butanoate). Wind tunnel experiments showed that the new blend was more attractive than the seven-component mix and butyl hexanoate, and field trials revealed that the five-component blend was superior to butyl hexanoate.

The results obtained here are encouraging in the search of a new attractant for males and females of *A. obliqua*. However, further research is needed before the mombin blend can be evaluated in mango and mombin orchards. Future trials will determine the minimal blend that effectively mimics the total blend in eliciting a behavioral response for *A. obliqua*. It is well known that, although a complex mixture of volatiles rather than one single compound is fundamental for the attraction of the phytophagous insects (Visser, 1986), not all the components contribute to the attractiveness of the blend in the same way (Phelan et al., 1991; Hartlieb and Rembold, 1996; Nojima et al., 2003). For example, Nojima et al. (2003) found that *R. pomonella* was attracted to a blend of six components identified from hawthorn fruit volatiles. Selected subtraction bioassays demonstrated further that the four-component blend of 3-methylbutan-1-ol, 4,8-dimethyl-1,3(*E*),7-nonatriene, butyl hexanoate, and dihydro- β -ionone elicited levels of attraction equivalent to the six-component mixture. Subtraction of the first component from the four-component mix resulted in complete loss of activity. Removal of the last three compounds from the four-component blend resulted in significant decreases in attraction compared to the four- or six-component mixtures. The optimal concentration and the ratios of the mombin components will be investigated in future experiments.

Acknowledgments—We are grateful for the technical assistance of Gustavo Rodas, Azucena Oropeza, and Milton A. Rasgado and the statistical advice of Javier Valle-Mora (ECOSUR). We thank Julio Domínguez, Moscafrut (National Fruit Fly Campaign, SAGARPA-IICA) mass-rearing facilities director, for providing the flies used in this study and Antonio Villaseñor, Director of Moscamed-Moscafrut program in Chiapas, for his encouragement. The English text was corrected by David Midgarden (USDA Medfly Program, Mexico). This project was supported by a grant from CONACYT (project 36490-B). A patent application has been filled for this discovery.

Abstract—Following oviposition, females of many Tephritid flies deposit host marking pheromones (HMPs) to indicate that the host fruit has been occupied. We describe the foraging behavior of these three economically important species (*Anastrepha ludens* and *A. obliqua* from the *fraterculus* species group and *A. serpentina* from the *serpentina* species group) when they encounter an artificial fruit (green agar spheres wrapped in Parafilm) marked with intra- and interspecific feces extracts that contain, among other substances, host marking pheromone. When flies encountered fruit treated with either 1 or 100 mg/ml feces extract, there were drastic and statistically significant reductions in tree residence time, mean time spent on fruit, and in the number of oviposition attempts or actual ovipositions when compared to the control treatment (clean fruit). These responses were almost identical irrespective of extract origin (i.e., fly species), indicating complete interspecific HMP cross-recognition by all three *Anastrepha* species tested. We discuss the ecological and practical implications of our findings.

Key Words—*Anastrepha*, Tephritidae, foraging behavior, host marking pheromones, infochemicals, evolution.

INTRODUCTION

When resources for foraging insects are fixed in space (e.g., leaf, fruit, larvae), the efficiency of females searching for an adequate oviposition substrate increases if they are able to quickly recognize and avoid already occupied hosts. A successful strategy to minimize overcrowding and to elicit movement away from areas with already occupied resources is the use of epideictic pheromones (among them host marking pheromones or HMPs) (Prokopy, 1981). According to Nufio and Papaj (2001), a marking pheromone is a “chemical signal associated with the host resource that signals occupation by conspecifics. Typically perceived by contact chemoreception, these pheromones are generally produced by females and placed onto or within larval resources following egg-laying.” Interestingly, these infochemicals can either deter or enhance oviposition depending, among other factors, on concentration (Papaj and Aluja, 1993). The existence of HMPs has been reported in the insect orders Coleoptera, Diptera (particularly in the family Tephritidae), Hymenoptera, Lepidoptera, and Neuroptera (Prokopy, 1981; Nufio and Papaj, 2001).

In the case of true fruit flies (Diptera: Tephritidae), host marking behavior has been described in the frugivorous genera *Anastrepha*, *Bactrocera*, *Ceratitis*, *Paraceratitella*, and *Rhagoletis* (work reviewed by Aluja et al., 2000a; Díaz-Fleischer and Aluja, 2000; Díaz-Fleischer et al., 2000; Nufio and Papaj, 2001). In nonfrugivorous tephritids, the phenomenon is less well studied but has been reported for *Tephritis bardanae* (Schrank) (Straw, 1989), *Chaetorellia australis* Hering (Pittara and Katsoyannos, 1990), and *Terellia ruficauda* (Fabricius) (Lalonde and Roitberg, 1992). Flies in the genera *Anastrepha*, *Ceratitis*, and *Rhagoletis* mark hosts by dragging of the aculeus tip on the fruit surface (Roitberg and Prokopy, 1987; Aluja et al., 2000a), while in the case of the olive fruit fly, *Bactrocera oleae* Gmelin, marking is achieved through labellar spreading of fruit juices oozing from an oviposition puncture (Cirio, 1971; Girolami et al., 1981).

The most striking behavioral responses exhibited by foraging female fruit flies upon encountering fruit covered with HMP are as follows: an increase in overall movement (e.g., number of leaf landings per minute, distance of between-tree displacements) and fruit visitation rates, reduction in tree residency time (Roitberg and Prokopy, 1984; Aluja and Boller, 1992a), reduction or increase in clutch size depending on HMP concentration and fruit size (Papaj et al., 1990, 1996; Papaj and Aluja, 1993), and a reduction in the propensity of a female to initiate oviposition (Nufio and Papaj, 2001). HMP recognition is contingent upon previous experience (Roitberg and Prokopy, 1981) but sensitivity to the pheromone is reduced if exposure is continual, apparently due to central habituation or peripheral adaptation of certain sensilla in the tarsi (Aluja and Boller, 1992a). In the case of males of species exhibiting

a resource–defense mating system (e.g., *R. pomonella*, *R. cerasi*), an encounter with an HMP-marked fruit causes arrestment (Prokopy and Bush, 1972; Katsoyannos, 1975).

Host marking behavior has been described for *A. suspensa* (Prokopy et al., 1977), *A. fraterculus* (Prokopy et al., 1982a), and *A. ludens* (Papaj and Aluja, 1993). In *Anastrepha*, as with *Ceratitis capitata* and some *Rhagoletis* species (Prokopy, 1972; Papaj et al., 1989), the presence of the HMP does not automatically deter other conspecifics from ovipositing and re-marking a fruit. *A. ludens* females laid eggs in grapefruit marked up to three previous times by conspecifics (Papaj and Aluja, 1993). Low concentrations of the HMP seem to stimulate continued host marking and an upper concentration threshold must be reached to deter further oviposition. These findings lead Papaj and Aluja (1993) to postulate that host marking in *A. ludens* is regulated by sensory adaptation or habituation to HMP, in conjunction with dosage-dependent restoration of inhibition of locomotory behavior.

The HMPs of *R. cerasi* (*N*[15(β -glucopyranosil)oxy-8-hydroxypalmitoyl]-taurine) and *A. ludens* (2-[2,14-dimethyl-pentadecanoylamino]-pentanedioic acid) were extracted from the feces of sexually mature females (Boller and Hurter, 1985; Hurter et al., 1987; Aluja et al., 2003; Díaz-Fleischer et al., 2004). They show some degree of similarity as both contain a long fatty acid and an amino acid. The *Anastrepha* HMPs are polar compounds (easily dissolved in water and methanol), which are remarkably stable under varying pH values and environmental light and temperature conditions (Díaz-Fleischer et al., 2004).

A topic of particular interest in the study of host marking behavior is the phenomenon of interspecific pheromone recognition. In some insects, this was attributed to phylogenetic relatedness among species (i.e., lineage effect). For example, in *Rhagoletis*, females within a species group (e.g., the *cingulata* group) recognize HMPs of heterospecifics, while females from unrelated groups (e.g., *cingulata* vs. *pomonella* groups) are usually not deterred by each other's HMP (Prokopy et al., 1976). In other insects, interspecific pheromone recognition may reflect an adaptive response to competition for common oviposition resources (see Nufio and Papaj, 2001 for details).

Here, we describe the foraging behavior of *A. ludens*, *A. obliqua*, and *A. serpentina* in response to their own and heterospecific fecal extracts, as these are known to contain the HMPs (Aluja et al., 2003; Díaz-Fleischer et al., 2004). Our hypothesis, based on the work on *Rhagoletis* and recent *Anastrepha* phylogenies (Norrbon et al., 2000; Norrbom, 2002; McPheron et al., 2000), was that interspecific recognition of the pheromone would exist for two species from the same intrageneric group (*A. ludens* and *A. obliqua*) but not for a species from a different group (*A. serpentina*) (Norrbon et al., 2000) given that in nature these three species rarely compete for resources.

METHODS AND MATERIALS

Study System. Fruit flies of the genus *Anastrepha* (Diptera: Tephritidae) are distributed from southern United States to northern Argentina (Hernández-Ortíz and Aluja, 1993). Of the ca. 200 species described so far (Norrbom et al., 2000), seven are considered important agricultural pests: *A. grandis* (Macquart), *A. fraterculus* (Wiedemann), *A. ludens* (Loew), *A. obliqua* (Macquart), *A. striata* Schiner, *A. suspensa* (Loew), and *A. serpentina* (Wiedemann) (Aluja, 1994). The three *Anastrepha* species we selected for this study are polyphagous species with different oviposition strategies. While *A. obliqua* deposits a single egg per oviposition bout, *A. ludens* and *A. serpentina* females can lay from 1 to over 20 eggs per oviposition (Aluja et al., 2000a). *A. ludens* attacks mainly fruit in the family Rutaceae (e.g., *Sargentia greggii* Coult., *Casimiroa edulis* Llave & Lex., *Citrus* spp.). It also attacks mangoes (*Mangifera indica* L.), but mainly at higher elevations (>800 m) (Aluja et al., 1987, 1996). *A. obliqua* preferentially attacks fruit in the family Anacardiaceae, especially in the genus *Spondias* (e.g., *S. mombin* L., *S. purpurea* L., *S. radlkoferi* J.D. Smith) (Díaz-Fleischer and Aluja, 2003b). It also attacks mangoes in lowland areas (therefore, simultaneous use of a mango fruit by *A. obliqua* and *A. ludens*, although possible, is not common) (Aluja et al., 1996). We note that mangoes were introduced by the Spaniards ca. 500 yr ago and therefore, from an evolutionary perspective, the interaction between the latter two *Anastrepha* species in such an exotic host is quite recent. Finally, *A. serpentina* attacks fruit in the family Sapotaceae (e.g., *Chrysophyllum caimito* L., *Manilkara zapota* (L.) P. Royen, *Mammea americana* L.) (Aluja et al., 1987, 2000b).

Study Site. All experiments were performed on the grounds of the Medfly Program at Metapa de Domínguez, Chiapas, México.

Research Arena. General bioassay protocols are described by Aluja and Boller (1992a). Eighteen potted mango trees (*M. indica* cultivar “criollo”) were placed in the center of a cylindrical 3 m (diam) \times 2 m (height) field cage (Chambers et al., 1983), on top of wooden stools at different heights so as to mimic the canopy of a mango tree (ca. 2 m \times 1.90 m). The cage was protected by a 25-m² metal frame with a corrugated fiberglass roof, and shading was provided by black greenhouse screen (2 mm fabric) placed on both the sides and the top. Approximately 35% of all leaves were removed to facilitate detection of a foraging fly within the canopy (details in Aluja et al., 1989 and Aluja and Prokopy, 1993), and trees were arranged so that a 50-cm walkway was left free to allow an observer to move around without encountering obstacles. Throughout this study (i.e., during fly maintenance phase and experiments), 3-cm-diam fruit mimics made of agar (Bacteriological Agar; Sigma, St. Louis, MO, USA) colored with green food dye (Colorante Alimenticio, Verde, McCormick, Herdez, Mexico) and wrapped in Parafilm (American National Can, Neenah,

WI, USA) (Boller 1968) were used instead of real fruit to control for intrinsic variations in both fruit quality and chemistry, as these influence fruit fly oviposition behavior (Papaj et al., 1992). There is ample evidence indicating that female flies accept such artificial oviposition substrates without perceptible behavioral differences with respect to natural hosts (Freeman and Carey, 1989; Jácome et al. 1999; Díaz-Fleischer and Aluja, 2003a).

Insects. All flies used were collected from infested fruit in the Soconusco Region, Chiapas and the vicinity of Xalapa, Veracruz, Mexico: *A. ludens* from *C. aurantium* L. and *M. indica*, *A. obliqua* from *Spondias* spp., and *M. indica*, whereas *A. serpentina* came from *M. americana* L. Details on handling of larvae and pupae are described elsewhere (Aluja et al., 1987).

Newly emerged females and males (25 of each sex per cage) were placed in 30 × 30 × 30 cm wooden screened cages with unlimited access to water and a sucrose/hydrolyzed protein mixture (3:1) (yeast hydrolysate enzymatic; ICN Biochemicals, Aurora, OH, USA) and held at 26°C, 70–85% RH, 12L:12D until 1 d prior to testing. Each cage had one *M. indica* branch with ca. 8 leaves to provide resting places for flies and maintain high RH levels. The latter was important because flies in bare cages break their wings by constantly hitting the walls, and relative air humidity influences the function of the tarsal chemoreceptors (Städler et al., 1987). In addition, 40 agar spheres were placed in each cage (ca. 10 hung from the roof and the rest on the floor) and replaced at least twice daily to avoid HMP accumulation on them, as flies maintained in an HMP-saturated environment become habituated/desensitized and lose their ability to discriminate between marked and clean fruit (Aluja and Boller, 1992a). The oviposition substrates were also important to familiarize females with bioassay conditions, and allow them to oviposit and mark fruit. Both aspects are critical in foraging behavior studies related to HMPs, because host acceptance in flies with a full complement of eggs increases after a period of host deprivation (Roitberg and Prokopy, 1983), which in turn “can make an individual prone to accept a host that would otherwise be rejected” (Jaenike and Papaj, 1992). Furthermore, females require prior experience with the HMP before they discriminate between marked and unmarked fruit (Roitberg and Prokopy, 1981).

Only sexually mature, mated females were used and their ages varied between 16 and 30, 18 and 32, and 22 and 30 d for *A. obliqua*, *A. ludens*, and *A. serpentina*, respectively. On the day prior to testing, two cages with flies and agar spheres were manually transferred from the lab to a field cage to allow flies to acclimate to test conditions. During this period, we constantly provided them with fresh oviposition substrates to avoid high oviposition drive and habituation/desensitization to high pheromone concentrations.

Test Compounds. Crude pheromonal extracts were obtained from *A. ludens*, *A. obliqua*, and *A. serpentina* feces, which, as documented by Aluja et al. (2003)

and Díaz-Fleischer et al. (2004), contain HMPs. For each species, ca. 3500 adult flies (extremely high density) were placed in a $30 \times 30 \times 30$ cm glass cage with two 13×25 cm sheets of glass to increase the exposed surface to flies. Food and water were offered continuously and after 30 d, the feces on the glass surfaces (without insect parts) were meticulously collected by scraping with a razor blade or a metal spatula. The samples were transferred to a ca. 500-ml glass bottle and frozen at -15°C until needed (further details in Aluja et al., 2003). The pheromone extracts (100 mg/ml) were prepared by mixing 1 g feces with 10 ml distilled water or methanol and were shaken manually for 15 min. The liquid was then centrifuged at 12,000 rpm for 20 min, and the resulting supernatant was used to treat test fruit for the bioassays. The same technique was used to prepare the 1 mg/ml concentration, but in this case only methanol was used as it proved to be a more efficient solvent than water (Díaz-Fleischer et al., 2004).

Bioassay Procedure. Following the protocol of Aluja and Boller (1992a), a single female was released into the cage and her behavior observed for a maximum of 1 hr or until it left the tree and flew to the cage walls. Every fly was released at exactly the same location (i.e., release leaf) and only used once (i.e., no repeated measures on same individual throughout study). In each assay, there were eight spheres, hung equidistant and at ca. the same height from branches in the external part of the canopy. The spheres were either pheromone treated (raw HMP extracts of the three fly species used during this study) or clean (treated with either water or methanol depending on which had been used as the solvent). On any given day, we tested all four treatments. An individual fly was either exposed to eight agar spheres treated with the HMP of one of the three *Anastrepha* species, or eight untreated control spheres (i.e., no choice conditions). Once observations with a particular fly were concluded (i.e., 1-hr time limit reached or fly flying to cage walls before time limit was over), another individual was released and exposed to spheres treated with the HMP of a different *Anastrepha* species or to untreated spheres. At the end of the daily ca. 4-hr observation period, the raw HMP extracts of all three *Anastrepha* species as well as the control treatment were tested (i.e., one replicate per treatment per day). Order of testing was randomized every day. Parameters recorded were total time on tree, time spent on fruit, time spent moving, cleaning and resting, and number of fruit visited. These variables are good descriptors of foraging activity (Roitberg et al., 1982) and, indirectly, of fly oviposition “drive” as flies will visit more fruits and generally spend more time on trees with unmarked fruits, than in those with HMP-marked ones (Prokopy et al., 1987; Aluja and Boller, 1992a). Once a fly landed on a sphere, time spent exploring [actively moving while head butting (repeatedly touching surface of fruit with frons)] or resting, attempting to oviposit or actually ovipositing and time spent dragging (walking on fruit surface with extruded aculeus through which HMP is released) were recorded. We also computed a “fruit irritation

Time at which tests were conducted indicated for every *Anastrepha* species. Values represent mean.

index'' (number of behavioral transitions while on fruit [walking–cleaning–resting–walking–cleaning] (Boller et al., 1987), which is a good indicator of host acceptance (Aluja and Boller, 1992a).

Assays were conducted approximately between 08:15 and 12:15 hr every day, but the actual time varied according to the different species-specific biorhythms (i.e., *A. obliqua* starts ovipositing earlier than *A. ludens* and *A. serpentina*; Aluja and Birke, 1993; Aluja et al., 2000a). Experiments were conducted between July and January, depending on host availability, with the 100 mg/ml HMP concentration assays being carried out in 1993 and the 1 mg/ml concentration during 1994–1995. In all cases, there was sufficient overlap in time of day and time of year to warrant formal comparisons between species (Table 1).

Data Analysis. As the two HMP concentrations were not simultaneously tested, we only compared one concentration at a time. Data were first analyzed by means of a two-way MANOVA (fly species \times HMP origin), followed by a two-way ANOVA given the significance detected (O'Brien and Kaiser, 1985). Multiple comparisons were carried out using a least square means *t*-test (SAS, 2003).

RESULTS

All HMP extracts tested, at concentrations of 1 and 100 mg/ml, elicited strong behavioral responses in the three *Anastrepha* species studied. MANOVA revealed differences among species (Pillai trace = 0.295, $F_{12,568} = 8.2$; $P < 0.001$; Pillai trace = 0.129; $F_{12,562} = 3.2$; $P < 0.001$; for 1 and 100 mg/ml, respectively) and HMP origin (Pillai trace = 0.921, $F_{18,855} = 21.0$; $P < 0.001$; Pillai trace = 0.975; $F_{18,846} = 22.6$; $P < 0.001$; for 1 and 100 mg/ml, respectively). There was also a significant interaction between fly species and HMP origin (Pillai trace = 0.546, $F_{36,1728} = 4.8$; $P < 0.001$; Pillai trace = 0.432; $F_{36,1710} = 3.7$; $P < 0.001$; for 1 and 100 mg/ml, respectively). Two-way ANOVA (summarized in Tables 2 and 3) revealed that clean fruit mimics (untreated agar spheres), treated with both HMP concentrations, elicited a drastic and statistically significant reduction in female tree residence time. Importantly, differences between species were not significant, independent of pheromone concentration. With respect to the interaction, it was nonsignificant at a concentration of 1 mg/ml and significant at 100 mg/ml (Figure 1, Tables 2 and 3). In the case of mean time spent on fruit, we found a statistically significant reduction in HMP-treated hosts at both pheromone concentrations. As was the case with total time spent on the tree, we found no differences among species when comparing total time spent on fruit. Nevertheless, the interaction was nonsignificant at a concentration of 1 mg/ml and significant at 100 mg/ml

(details on degrees of freedom, F and P values in Tables 2 and 3). *A. obliqua* females behaved differently after landing on unmarked control hosts when compared to the other two fly species (Figure 2).

Presence of HMP significantly altered the total number of fruit visited (Figure 3). Females visited more control fruit than treated ones at both HMP concentrations (details on statistical analyses in Tables 2 and 3). In the case of the number of oviposition attempts, we found differences between treatments and fly species at both HMP concentrations (also the case with respect to the interaction between factors). Consistent with the fact that flies tested here exhibit different oviposition strategies in nature (i.e., *A. obliqua* invariably lays

HMP extracts tested at a concentration of 100 mg/ml.

eggs singly, whereas *A. ludens* and *A. serpentina* tend to do so in clutches), responses to the control treatment (unmarked fruit) varied among species (Figure 4). With respect to actual ovipositions (aculeus insertion followed by dragging), we found significant differences when comparing all four treatments at both HMP concentrations. We also detected differences between species, as

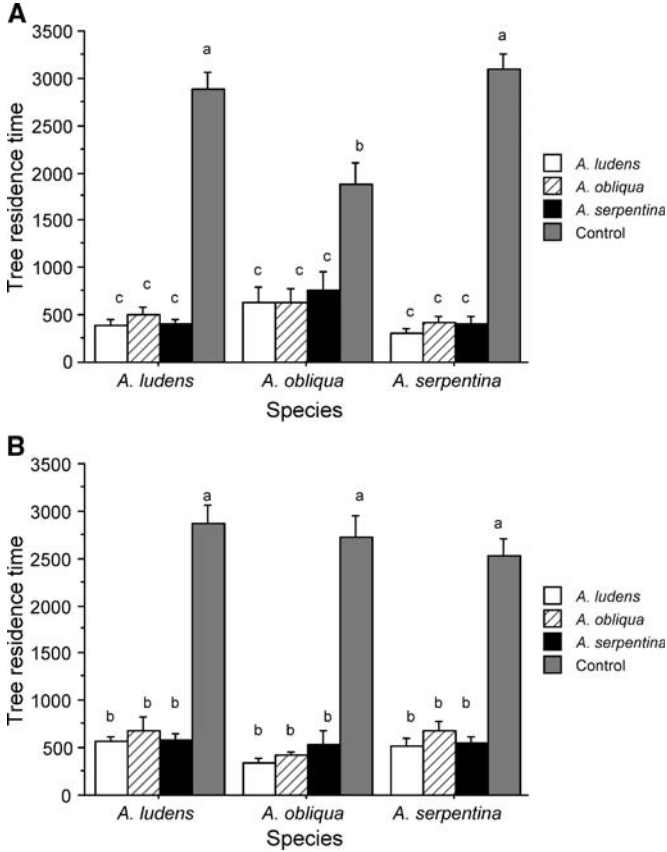

FIG. 1. Tree residence time (sec) (mean \pm SE) exhibited by three *Anastrepha* species exposed to untreated and HMP-treated oviposition substrates. (A) HMP crude extract dissolved in H₂O at 100 mg/ml; (B) HMP crude extract dissolved in MeOH at 1 mg/ml. $N = 25$ in every bar. Means followed by the same letter are not significantly different (least square means t -test).

A. obliqua females oviposited more often than *A. ludens* and *A. serpentina* females (Figure 5). The interaction was significant at both concentrations (Tables 2 and 3). Remarkably, these responses were almost identical irrespective of HMP origin (least square means t -test; SAS, 2003). That is, there was complete interspecific HMP cross-recognition by all three *Anastrepha* species tested.

Finally, the irritability index was significantly higher in HMP-treated than in control (clean) fruit at both concentrations (Figure 6). *A. serpentina* females were significantly less irritated than females of the other two species when

exposed to fruit covered with HMP at a concentration of 1 mg/ml, but not at a higher concentration. The interaction was not significant at either concentration (Tables 2 and 3).

DISCUSSION

We were able to document a clear pattern of HMP cross-species recognition between *A. ludens*, *A. obliqua*, and *A. serpentina*. Interestingly, although

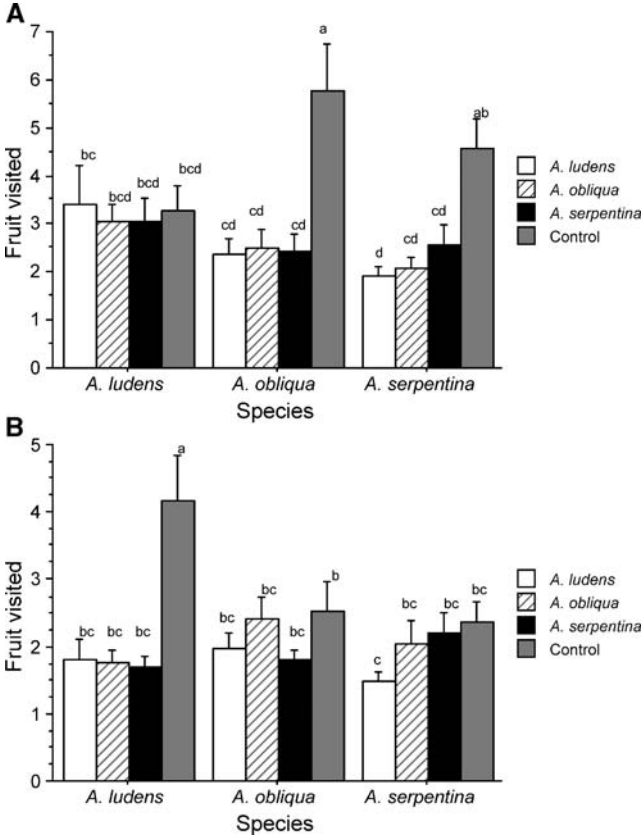

FIG. 3. Mean number (\pm SE) of host visited by three *Anastrepha* species exposed to untreated and HMP treated oviposition substrates. responses to fruit treated with the two HMP concentrations were practically identical among the three *Anastrepha* species (complete cross-recognition), when comparing the data on untreated, control fruit, clear behavioral differences were detected between the single egg/clutch layer *A. obliqua* and the multiple egg/clutch layers *A. ludens* and *A. serpentina* (discussion at the end of this section). Overall, the response pattern of females to HMP-marked and clean fruit closely resembled the one previously reported for *R. cerasi* (Aluja and Boller, 1992a and references therein). Results from the present study suggest that *Anastrepha* females increase patch persistence time when encountering unmarked hosts, but decrease search allocation following encounters with

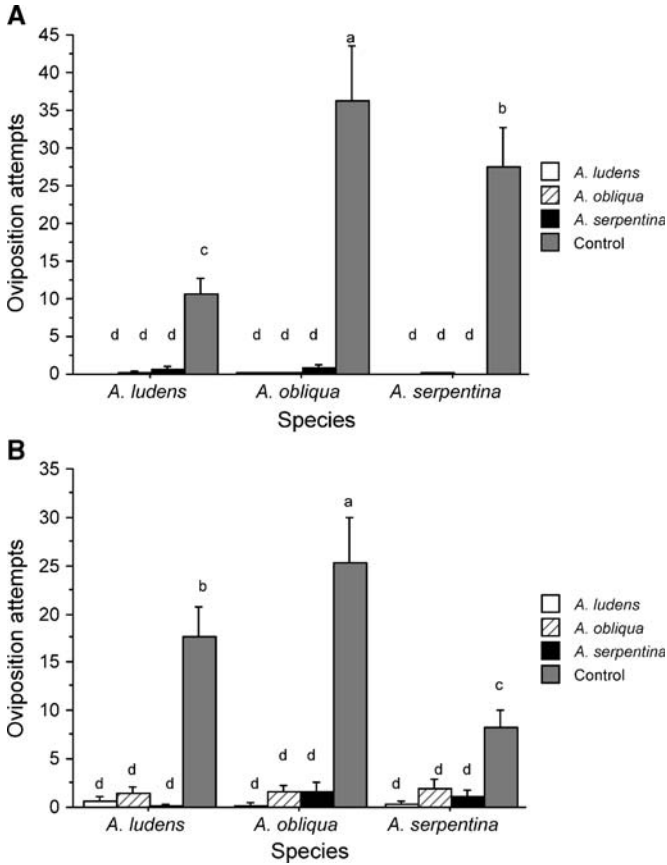

FIG. 4. Mean number (\pm SE) of oviposition attempts by three *Anastrepha* species exposed to untreated and HMP treated oviposition substrates. (A) HMP crude extract at 100 mg/ml; (B) HMP crude extract at 1 mg/ml. $N = 25$ in every bar. Means followed by the same letter are not significantly different (least square means t -test).

marked hosts. Furthermore, females not only increase host-searching time, but they also visited more hosts when they were unmarked. These responses are parallel to those reported by Prokopy et al. (1987) for *C. capitata* flies. Importantly, both HMP concentrations tested, although different by a hundred-fold factor, deterred oviposition in treated fruit. Flies respond strongly to the infochemical, even when present at low concentrations (1 mg/ml HMP in our case). Such a pattern of response to HMPs is similar to the one reported in other insects such as parasitoids (Bernstein and Driessen, 1996).

FIG. 5. Mean number (\pm SE) of ovipositions by females of three *Anastrepha* species exposed to untreated and HMP treated oviposition substrates. (A) HMP crude extract at 100 mg/ml; (B) HMP crude extract at 1 mg/ml. $N = 25$ in every bar. Means followed by the same letter are not significantly different (least square means t -test).

The fact that interspecific HMP cross-recognition exists in *Anastrepha* is particularly interesting given that individuals of the species studied rarely exploit the same resources in nature (Norrbon, 2003) and, at least in two cases, are not closely related according to the most recent phylogenies for the group (McPherson et al., 2000; Norrbom et al., 2000). Our prediction that due to a lineage effect there would be HMP cross-recognition between *A. ludens* and *A. obliqua* (*fraterculus* species group), but not *A. serpentina* (*serpentina* species group), was not supported. This finding, together with additional data (M. Aluja and F. D  az-Fleischer, unpublished data) suggests the possibility of shared

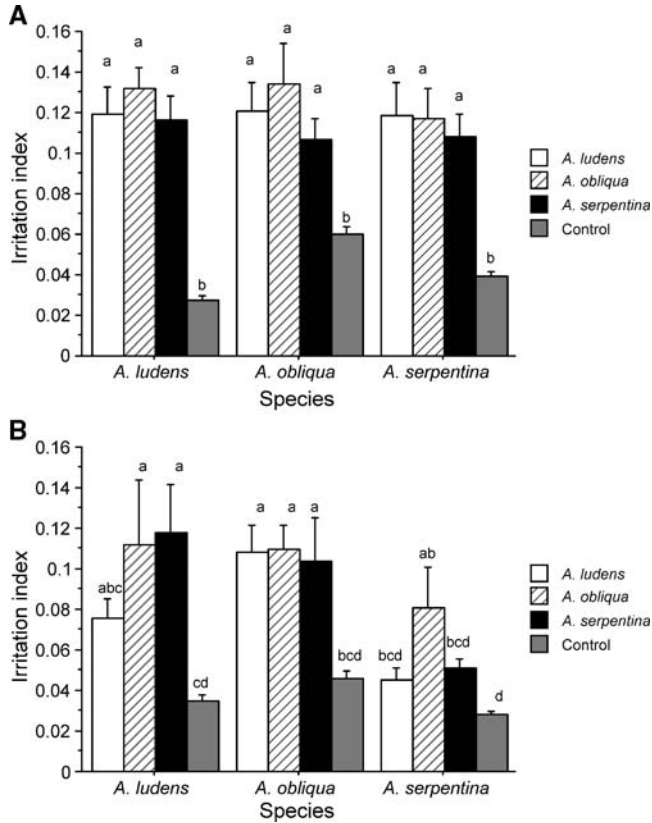

FIG. 6. Mean irritation index (\pm SE) exhibit by females of three *Anastrepha* species exposed to untreated and HMP treated oviposition substrates. active molecules in the HMP of all *Anastrepha* species). As only the HMP of *A. ludens* has been described (Aluja et al., 2003), it is too early to postulate meaningfully whether this pattern can be explained by convergent evolution or represents a plesiomorphy or synapomorphy. Our results differ from those for other tephritid flies (various species of the genus *Rhagoletis*), as Prokopy et al. (1976) found that “individuals from different species belonging to different species groups did not recognize each other’s marking pheromones” and that “different species within the same species group varied in reaction from complete to no cross-recognition.” However, it is important to note that these differences could be possibly related to bioassay conditions. Prokopy et al.

(1976) worked under artificial laboratory conditions using real fruit marked by live females (resulting in a variable HMP concentration and a possible effect of fruit volatiles on fly response), while we exposed live females to known concentrations of HMP extracts applied on artificial hosts in a field cage containing abundant foliage and foraging space. Thus, these different approaches could affect results, as deterrent activity of HMPs is dose-dependent (Bowdan, 1984; Schoonhoven, 1990; Papaj and Aluja, 1993), and varying numbers of natural marks are needed to obtain similar discrimination coefficients, at least when comparing different *Anastrepha* species (M. Aluja and F. Díaz-Fleischer, unpublished data).

The HMP cross-recognition pattern we report for *A. ludens*, *A. obliqua*, and *A. serpentina* is similar to several cases seen in Lepidoptera. In one case, two species within the same genus were involved (*Pieris rapae* L. and *P. brassicae* L.), with females of *P. rapae* recognizing the crude pheromone extracts of *P. brassicae* (Schoonhoven, 1990; Schoonhoven et al., 1990). In another case, a number of tortricid species from different genera, *Lobesia botrana* (Denis & Schiffermüller), *Eupoecilia ambiguella* (Hübner), *Cydia molesta* (Busck), and *C. pomonella* L., also showed cross-recognition (Thiery and Gabel, 1993; Gabel and Thiery, 1994). In the latter case, Thiery et al. (1992, 1995) and Gabel and Thiery (1996) suggested that a mixture of straight chain fatty acids and esters of fatty acids were most likely responsible for the observed deterrent effect, and the same mechanism may be working in *R. cerasi* and *A. ludens*, as the HMP of these two fruit fly species also contain long chain fatty acids (Hurter et al., 1987; Aluja et al., 2003).

Thiery and Gabel (1993) proposed the term “oviposition regulating synomone” for molecules or blends that influence the interspecific spacing of eggs when females of different species compete for the same oviposition resources in nature. However, in the genus *Anastrepha*, this condition only occurs occasionally. For example, *A. striata* and *A. fraterculus* may compete for various species of fruit in the genus *Psidium* (*P. guajava*, *P. sartorianum*, *P. guineense*) (Aluja et al., 2000b; Sivinski et al., 2004). Consequently, one must ask why is there such strong interspecific HMP recognition between *A. ludens*, *A. obliqua*, and *A. serpentina* when they rarely share the same oviposition resources in nature. As mentioned earlier, one explanation is the presence of shared active molecules in the HMP of all *Anastrepha* species. All HMP may contain substances intimately related to oogenesis (as they are only released by sexually mature females and not by males; Boller and Hurter, 1985; Städler et al., 1992), and could explain, in part, the presence of HMP in feces of species that do not exhibit marking behavior (Aluja et al., 2003; M. Aluja and F. Díaz-Fleischer, unpublished data). HMP is secreted into and accumulated in the gut lumen, to be released with other gut contents in both the marking trail and feces (Prokopy et al., 1982b). The fact that host marking is present in several unrelated groups of insects (Diptera, Lepidoptera, Coleoptera) and that

HMPs may have similar components (fatty acids in Diptera and Lepidoptera) suggest that this could reflect an ancestral physiological process that has remained unchanged over evolutionary time (a plesiomorphy). Such speculation is supported by the fact that, at least in the case of *R. cerasi*, HMP is related to cerebrosides and gangliosides, compounds found in nerve cell membranes (Hurter et al., 1987). Differences in the life histories of species in the genera *Rhagoletis* and *Anastrepha* may also help explain why the chemical structures of their HMPs differ, as most *Rhagoletis* species are monophagous and univoltine (Zwölfer, 1983; Prokopy and Papaj, 2000), whereas the *Anastrepha* species under study here are polyphagous and multivoltine (Aluja et al., 2000a). Thus, digestive processes used to deal with fruit defenses may be quite different as specialist insects develop specific adaptations to confront plant defenses (Lambdon, 2001). If this is the case then, the specialization in *Rhagoletis* flies could have resulted in the HMP molecule, purportedly a by-product of the digestive process, becoming more complex than that observed in *Anastrepha*.

Anastrepha obliqua, an egg-limited species (Aluja et al., 2001; Díaz-Fleischer and Aluja, 2003b), exhibited more oviposition attempts and had more oviposition bouts than either *A. ludens* or *A. serpentina*, two time-limited species (Figures 4 and 5). These behaviors are probably adaptations to cope with highly ephemeral resources [fruit that appear and disappear (fall to the ground) within 4 wks] and could partly explain why *A. obliqua* exhibited a high and uniform irritation index when exposed to low concentrations of all three pheromone sources (it is highly sensitive to fruit quality) (Figure 6).

HMPs have potential as a means of control of insect pests, as shown for *R. cerasi* (Aluja and Boller, 1992b; Aluja et al., 2003). Our present results show that, there is a possibility that one synthetic HMP could offer a viable alternative to the widespread use of insecticides for the management of all three *Anastrepha* species examined in this study. However, when designing deployment strategies, one must remember that HMPs evolved as messages not deterrents (Roitberg and Prokopy, 1987; Schoonhoven, 1990). Consequently, females deprived of suitable oviposition sites may end up exploiting available fruit even in the presence of HMPs (i.e., there is no absolute oviposition deterrence). Furthermore, and as documented by Quiring and McNeil (1984) and Averill and Prokopy (1987), heavy rains can potentially reduce efficacy due to wash off given the water-soluble nature of the substance (but see Katsoyannos and Boller, 1976, 1980), and plants along crop edges should remain unsprayed to maintain high response thresholds to the HMP. Additional research is required to exploit the full potential of this management tool.

Acknowledgments—We are indebted to Jesús Reyes-Flores, former director of the Mexican Campaña Nacional Contra Moscas de la Fruta for encouraging us to conduct this research and for facilitating our research. We thank S. Aceituno, J. Arredondo, J.L. Márquez, and F. Avendaño (all

Programa MoscaMed, Tapachula, Chiapas, Mexico) for expert assistance during field collections, fly feces collections and maintenance of study insects. We thank Walther Enkerlin, Dina Orozco, Juan Rull, Carlos Fredersdorff, and Pablo Montoya (all Programa MoscaMed, Tapachula, Chiapas, Mexico) for providing materials, laboratory equipment, and providing critical administrative support. Javier Valle Mora (El Colegio de la Frontera Sur, Tapachula, Chiapas, Mexico) offered statistical advice and Nicoletta Righini (Instituto de Ecología, A.C.) helped during the writing and formatting stages. Finally, we acknowledge the insightful reviews by the two referees and an associate editor. This work was principally financed by the Mexican Campaña Nacional Contra Moscas de la Fruta (Secretaría de Agricultura, Ganadería, Desarrollo Rural y Pesca–Instituto Interamericano de Cooperación para la Agricultura [SAGARPA–IICA]). We also received a series of anonymous donations.

Published Online April 5, 2006

Abstract—The monoterpene 1,8-cineole is a major constituent of the essential oils that adversely influence intake of sagebrush by herbivores, but little is known about the mechanisms of its action. We investigated the influence of 1,8-cineole on the feeding behavior of two groups of sheep, one group dosed intravenously and the other intraruminally. In the first study, we infused 40 mg/kg BW of 1,8-cineole intravenously into four lambs on wk 1, 2, and 4. In the second, we administered 125 mg/kg BW of 1,8-cineole into the rumen of four lambs as a single-bolus dose in wk 1 and 2. Lambs dosed intravenously spent less time feeding than controls (28 vs. 60 min; $P < 0.05$), as did lambs dosed intraruminally (35 vs. 60 min; $P < 0.05$). Dosed lambs ate less than controls during rumen dosing studies ($P < 0.05$). For the intravenous infusion studies, rates of elimination did not differ among weeks ($P < 0.05$). For the rumen infusion studies, however, the absorption rate constant increased from 0.035/min to 0.076/min from wk 1 to 2, while the absorption half-life declined from 24 to 10 min ($P < 0.05$). Maximum plasma concentrations and time to reach maximum plasma concentrations were no faster in wk 2 than wk 1, but the primary elimination rate constant was 2.3 times higher in wk 2 (0.058/min) than in wk 1 (0.025/min) ($P < 0.05$). Dosed lambs exhibited clinical effects—licking of lips, drowsiness, staggering, and 1,8-cineole-

smelling breath—that were much more pronounced with intravenous than rumen infusions. Dosing did not affect the acid–base balance. Collectively, these data suggest 1) rapid absorption and distribution of 1,8-cineole was responsible for initiating satiety, while more prolonged excretion was responsible for the duration of the satiety effect, and 2) lambs more readily adapted to 1,8-cineole in the rumen-dose study than in the intravenous-dose study.

Key Words — 1,8-Cineole, monoterpenes, feeding, kinetics, elimination, rumen microbes, sheep.

INTRODUCTION

The monoterpene cyclic ether 1,8-cineole is a major component of essential oils from sagebrush (*Artemisia tridentata* Nutt) (Welch and Pederson, 1981; Kelsey et al., 1982; Welch et al., 1983; Personius et al., 1987). Along with several other monoterpenes, it adversely affects the preferences of herbivores for sagebrush (Welch and Pederson, 1981; Personius et al., 1987), but its mechanisms of action are not well known. In general, terpenes are toxic when consumed or dosed at too high concentrations (Johnson et al., 1976). However, animals never consume sagebrush in quantities large enough to result in lethal effects. Rather, they limit intake, at least in part, due to aversive postingestive feedback from compounds such as terpenes (Provenza, 1995). Possible postingestive mechanisms of action of terpenes include toxicity (Johnson et al., 1976), suppressed rumen microbial activity (Ngugi et al., 1995), and disturbed acid–base balance (Foley et al., 1987, 1995; Illius and Jessop, 1997). These mechanisms are not mutually exclusive and may act in concert to cause postingestive effects that lead to cessation of feeding.

Our objectives were to investigate the effects on feeding behavior, systemic kinetics, clinical effects, and systemic pH balance of repeated exposure of lambs to 1,8-cineole administered intravenously or into the rumen. These studies are essential for understanding how monoterpenes limit intake of sagebrush and for developing ways to increase intake of sagebrush as a means to enhance and maintain biodiversity in landscapes dominated by the sagebrush steppe (Provenza et al., 2003; Dziba et al., 2006).

We hypothesized that 1,8-cineole: (1) causes toxin satiation (Freeland and Janzen, 1974; Provenza, 1995, 1996), (2) inhibits rumen microbial activity (Nagy et al., 1964; Oh et al., 1968; Ngugi et al., 1995), (3) inhibits elimination pathways (Pass et al., 1999), and (4) challenges acid–base balance (Foley et al., 1995, 1999). Based on these hypotheses, we predicted that: (1) we would find evidence of centrally mediated satiation due to an increase in systemic concentrations of 1,8-cineole, (2) exposure to 1,8-cineole would suppress rumen

microbes due to the bacteriocidal effect of essential oils, (3) kinetic elimination rates would decline with repeated exposure to 1,8-cineole due to inhibition of elimination pathways, and (4) blood pH would decline as lambs metabolize 1,8-cineole, producing hydrogen ions that disturb the acid–base balance. We predicted these mechanisms would lead to a decline in food intake following dosing with 1,8-cineole.

METHODS AND MATERIALS

Animals and Diet. Twelve lambs weighing 45.6 kg (SE = 0.97) were used for intravenous infusion and eight lambs weighing 34.0 kg (SE = 0.83) were used for rumen dosing. Lambs were exposed as a group to experimental conditions until they were familiar with alfalfa pellets and with the experimental diet, which was similar in nutrient content to sagebrush in the fall (Welch and Pederson, 1981; Kelsey et al., 1982; NRC, 1985). The diet was formulated from a mixture of beet pulp, grape pomace, and soybean meal at a ratio of 49:43:8 to provide 2.44 Mcal/kg digestible energy (DE), 8.77% crude protein (CP), and 52% total digestible nutrients (TDN) (NRC, 1985). During the first week of conditioning, lambs were also fed alfalfa pellets to meet their daily maintenance requirements, until intake of the experimental diet was adequate. During the second week of conditioning and throughout the trials, lambs were fed only the experimental diet from 0900 until 1200 hr. They were habituated to individual metabolism cages (1.5 × 1.0 m) and housed in a lighting-controlled room (12-hr light–dark cycle) for 1 wk prior to dosing. Feeding behavior was monitored for 1 hr during the intravenous infusions and for 1 hr immediately following rumen dosing. After 1 hr, lambs were allowed access to the experimental diet for another 2 hr. They were deprived of food overnight to ensure that food refusals during testing were due to treatment effects. We observed the nature and extent of any clinical signs exhibited by animals in response to 1,8-cineole during and following dosing. Throughout conditioning and during infusions and dosing, lambs had free access to water and trace mineralized salt blocks (American Stockman[®], Overland Park, KS, USA). This study was approved by the Institutional Animal Care and Use Committee at Utah State University (IACUC # 1078).

Dose and Dosing Materials. Intralipid (20% emulsion; CAS# 68890-65-3) was purchased from Sigma-Aldrich (St. Louis, MO, USA) and 1,8-cineole (99% purity; CAS# 470-82-6) from Sigma-Aldrich (Milwaukee, WI, USA). High-performance liquid chromatographic (HPLC)-grade ethyl acetate and HPLC-grade water were purchased from Fisher Scientific (Fair Lawn, NJ, USA).

For the intravenous infusion experiment, 2 g of 1,8-cineole were placed in 50 ml intralipid (1,8-cineole to intralipid concentration of ~2 g/52 ml), and the

solution was thoroughly mixed using a vortex mixer. For rumen administration, 5 g 1,8-cineole were mixed thoroughly in 20 ml vegetable oil (1,8-cineole to oil concentration of ~5 g/25 ml). Intravenous and rumen doses were established via preliminary dosing trials. The starting point was based on known dietary intake from previous feeding experiments with sagebrush monoterpenes (Dziba and Provenza, 2006), and the knowledge that marsupials exhibit a significant first-pass effect of approximately 80% for 1,8-cineole (Stuart McLean, personal communication). The rate and dose used were based on trials with lambs fed diets containing different concentrations of terpenes that resulted in cessation of feeding in less than 1 hr in previous trials (Dziba and Provenza, 2006).

Intravenous Infusion. The objective of the intravenous infusion experiment was to determine the clinical effects, kinetic rates, effects on systemic pH, and influence on feeding behavior of 1,8-cineole in lambs with repeated administration. Intravenous infusion avoids effects due to taste, rumen degradation, absorption, and first-pass metabolism. Twelve lambs were randomly assigned to three treatments: (1) 1,8-cineole in intralipid, (2) intralipid only, and (3) control, no infusion. Intravenous infusions were administered $\times 3$ on the same day of each week on wk 1, 2, and 4 to test for potential systemic inhibition of elimination pathways. This was assessed by comparing alpha and beta elimination rates, as well as feeding behavior, over the three periods. The control treatment was repeated $\times 3$ to compare feeding behavior of dosed lambs to that of controls over the three trials. The intralipid-only treatment was not repeated because lambs in this treatment behaved the same way as non-treated control lambs.

Infusion was used instead of bolus i.v. administration to slowly increase plasma concentrations without the potential of acutely toxic effects. The solution of 1,8-cineole and intralipid was delivered at a constant rate infusion of 1 ml/min for 1 min/kg BW using a VWR[®] variable flow peristaltic pump (VWR Scientific Products, Buffalo Grove, IL, USA). This provided a total dose of 40 mg/kg over a period of 40–50 min. To ensure that the intravenous formulation was sterile, the dosing materials were mixed in the lab each morning of the experiment. A sterile needle was used to transfer 1,8-cineole directly into the bottle of intralipid used for the infusion. All surgical materials were sterile.

The infusion line was attached to an Abbocath[®]-T, 18 G \times 2 in. indwelling intravenous jugular catheter (Abbott Ireland, Sligo, Ireland) and secured to the back and the ear of the lamb to ensure the line stayed in place. The catheter was fitted with a lock-surflo injection plug (Terumo[®] Medical Group, Elkton, MD, USA) for repeated blood collection. A control blood sample was collected before the infusion. Postinfusion sampling was initiated at the time infusion was stopped and denoted as time = 0. Blood samples (10 ml) were collected into EDTA-coated blood collection tubes (Vacutainer[®]; Tyco Healthcare Group LP, Mansfield, MA,

USA) at 0, 1, 3, 6, 12, 18, 30, 45, 60, 90, 120, 180, 240, 360, and 480 min after the infusion. Heparized 0.9% NaCl injectable solution (3 ml) was used to flush the catheter after the infusion and after each blood sample collection to prevent clotting. A total of 16 blood samples were collected from each lamb for systemic pH and pharmacokinetic analyses.

During the infusion, lambs were offered the experimental diet for 1 hr. Feeding behavior was monitored throughout dosing and for 1 hr thereafter. The variable we monitored was feeding time, which we defined as the time it took lambs to stop feeding. The criterion for stopping was 60 sec of continuous nonfeeding activity. We also recorded the time it took lambs to return to feeding after the end of the infusion.

Rumen Dosing. The objective of the rumen dosing experiment was to determine the absorption and elimination rates of 1,8-cineole administered directly into the rumen, as well as effects on feeding behavior. To do so, eight lambs were randomly assigned to two treatments: (1) four lambs dosed with 1,8-cineole in vegetable oil and (2) four control lambs that were not infused. Based on previous studies, we expected no effect of vegetable oil on feeding behavior, and so a vegetable oil control was deemed unnecessary (Dziba and Provenza, 2006). Rumen dosing was repeated 7 d after the first exposure in wk 1 to determine whether repeated exposure to 1,8-cineole altered the kinetics or feeding behavior. By comparing rumen dosing and intravenous infusions, we were able to indirectly assess the effects of degradation of 1,8-cineole in the rumen.

The solution of 1,8-cineole was delivered as a single bolus dose of 0.625 ml/kg BW directly into the rumen with the needle of an Abbocath[®]-T 16 G × 2 in. catheter (Abbot Ireland). This dose provided 1,8-cineole at 125 mg/kg BW. An Abbocath[®]-T, 18 G × 2 in. indwelling intravenous jugular catheter (Abbott Ireland) was inserted for sample collection. Blood samples (10 ml) were collected into EDTA-coated Vacutainer[®] blood collection tubes at 2, 4, 6, 12, 18, 30, 45, 60, 90, 120, 180, 300, and 420 min following the single bolus dose. Heparized 0.9% NaCl injectable solution (3 ml) was used to flush the catheter after each blood sample collection to prevent clotting.

Lambs were offered food at the beginning of the trial, and the remaining feed was weighed every 30 min until all food was consumed. Intake (g) of the experimental diet was measured by difference. Feeding behavior, as previously defined, was monitored for 1 hr following dosing. Lambs had *ad libitum* access to food for the duration of the trials.

Sample Processing and Analyses. Blood samples were analyzed for pH immediately after collection during intravenous infusions. A Beckman Instruments (Irvine, CA, USA) Φ 44 pH Meter with a Thermo Orion Combination pH Probe (Beverly, MA, USA) was used for pH analyses. The probe was rinsed and dried prior to each analysis. The instrument was calibrated daily by using three

buffer solutions of pH 4, 7, and 10. Blood samples were centrifuged for 10 min at 3000 rpm with an IEC HN-SII series centrifuge (Damon/IEC Division, Needham, MA, USA).

Plasma was separated, frozen immediately, and stored at -18°C until gas chromatographic (GC) analysis. The analytical method for 1,8-cineole in plasma is described in detail by Kimball et al. (2004). Briefly, Isolute Solid Phase Extraction columns (C18, 500 mg sorbent, 10-ml reservoir) were used for the extractions (Argonaut Technologies, Foster City, CA, USA). The SPE columns were conditioned with 5 ml HPLC-grade methanol followed by 10 ml HPLC-grade water. Three ml of plasma were passed through the column followed by 10 ml HPLC-grade water (column wash). The columns were allowed to dry under vacuum for 10 min and then immediately eluted with 1.00 ml HPLC-grade ethyl acetate or stored frozen at -18°C for later elution. The column eluate was placed in a GC autosampler vial.

The chromatographic system consisted of a Shimadzu GC 17A Series (Shimadzu Corporation, Columbia, MD, USA) equipped with an FID and an autosampler. The analytical column was a 30 m \times 0.25 mm DB-5.625, 0.25 μm (J&W Scientific, Folsom, CA, USA). One- μl splitless injections (split time of 1.0 min) were made under the following conditions: injection temperature of 200°C and detector temperature of 325°C . The initial oven temperature of 40°C was maintained for 0.5 min. The first oven ramp was at $5^{\circ}\text{C}/\text{min}$ to 110°C . The final ramp was at $20^{\circ}\text{C}/\text{min}$ to a final temperature of 300°C . The total run time was 24 min. The carrier gas was helium delivered at a constant 39 cm/sec by using electronic pressure control. The detector gases were hydrogen (30.0 ml/min), nitrogen (makeup; 30.0 ml/min), and air (400 ml/min).

To provide an analytical matrix match for the eluted samples, five 1,8-cineole standards in ethyl acetate in the range of interest (1.0, 5.0, 10.0, 30.0, and 60.0 $\mu\text{g}/\text{ml}$) were injected at the beginning of each run and after half of the samples had been run. Ethyl acetate blanks preceded and followed each of the standard runs to ensure the column was free of contamination. Linear regression analyses for the standards were used to verify linearity and consistency, and were then used to calculate concentrations from the sample area obtained during the GC-FID analyses.

The plasma concentration–time data for 1,8-cineole were fitted to the following equation using PK Solutions 2.0 for Noncompartmental Pharmacokinetics Data Analysis (Summit Research Services, Montrose, CO, USA):

$$C_t = D \cdot e^{-\alpha t} + E \cdot e^{-\beta t}$$

where C_t is 1,8-cineole plasma concentration at time = t ; α and β are the exponential equation constants representing alpha elimination–distribution and beta elimination, respectively. D and E represent the y -intercept for the alpha

elimination–distribution and beta elimination, respectively. The intravenous study was based on an infusion method of dosing, so we determined only αk_e (alpha elimination–distribution rate constant) and βk_e (terminal or beta elimination rate constant). We used an equation for intravenous bolus dosing, based on the instantaneous cessation of infusion, because no data were collected during the infusion. Data were only collected immediately after the intravenous infusion. Time = 0 is the time of the cessation of infusion.

For the rumen dosing studies, the following kinetic parameters were determined: k_a (absorption rate constant), αk_e (primary or alpha elimination rate constant), and βk_e (terminal or beta elimination rate constant). The plasma concentration–time data for 1,8-cineole were fitted to the following equation:

$$C_t = A \cdot e^{-at} + D \cdot e^{-\alpha t} + E \cdot e^{-\beta t}$$

where C_t is 1,8-cineole plasma concentration at time = t ; a , α , and β are the triexponential equation constants of absorption, alpha elimination–distribution, and beta elimination, respectively. **A**, **D**, and **E** represent the y -intercepts for absorption, alpha elimination–distribution, and beta elimination, respectively. The absorption intercept, **A**, is mathematically derived as a negative value by the PK Solutions software. Thus, the mathematical term, $A \cdot e^{-at}$ represents the amount remaining to be absorbed at time = t . Area under the curve ($AUC_{0-\infty}$) was determined by the trapezoidal rule.

Statistical Analyses. Kinetic data were analyzed with one-way ANOVA. The response variables for both the intravenous infusion and rumen dosing experiments were α and β elimination rates and half-lives. Absorption rates and half-lives were additional response variables for the rumen dosing experiments. Feeding behavior data for the intravenous infusion experiment were analyzed using repeated measures mixed ANOVA with two treatments (dosed lambs and controls). Feeding time was the response variable. Feeding behavior of controls and carrier controls did not differ, so carrier controls were excluded from the analyses. The experiment was repeated on wk 1, 2, and 4, and week was the repeated measure. The error term for treatments was lambs nested within treatments, whereas the error term for week and the Week \times Treatment interactions was lambs nested within Treatments \times Weeks. The fixed effects were treatment and week and lambs (4/treatment) were the random effect. For the rumen dosing experiment, the data were analyzed similarly, except that there were only 2 wk (1 and 2); response variables were feeding time and food intake. Blood pH was analyzed by a paired Student's t -test to determine if the pH of postinfusion blood samples differed from that of the predosing control sample. Mean comparisons were conducted using the Tukey procedure, where significant differences existed among treatments.

FIG. 1. Mean feeding time of four lambs dosed intravenously with 40 mg/kg BW 1,8-cineole compared to controls over the three periods. Bars are standard errors.

FIG. 2. Mean intravenous plasma concentration time curves of four lambs dosed with 40 mg/kg BW 1,8-cineole during wk 1, 2, and 4.

RESULTS

Intravenous Infusion

Feeding Behavior. On average, lambs dosed intravenously stopped feeding at 28 min (SE = 1.8), whereas controls spent 60 min (SE = 0.7) feeding ($P < 0.05$). Time spent feeding tended to decline over the three periods, although the differences were not significant ($P = 0.29$; Figure 1). The time lambs took to resume feeding following dosing decreased over the three periods from 18 min (SE = 3.5) in wk 1 to 8 min (SE = 1.5) and 7 min (SE = 2.0) in wk 2 and 4, respectively ($P < 0.05$).

Clinical Signs and Blood pH. All treatment lambs licked their lips during and shortly after the infusion. They were all rather sleepy and slightly ataxic, and two of them were also tachypnic. All treatment lambs had the distinct smell of 1,8-cineole on their breath following the infusion. Staggering and licking of lips were also apparent, and to the same extent, in wk 2 and 4. Blood pH remained relatively stable and was not different from the baseline following infusion ($P > 0.05$). Blood pH remained within expected physiological extracellular fluid pH of 7.42 (SE = 0.059).

Pharmacokinetics. The elimination rate curves were similar for each week the lambs were dosed. The plasma time curve for 1,8-cineole was best fit by a biexponential model with a rapid primary (α) elimination phase, and a relatively slow terminal (β) elimination phase (Figure 2). Primary elimination rates did not differ among weeks ($P > 0.05$); the rate constants were 0.074/min in wk 1, 0.099/min in wk 2, and 0.087/min in wk 4 (Table 1). The average primary elimination half-life of 9 min did not change among periods ($P > 0.05$; Table 1). Concentrations of 1,8-cineole declined more slowly during the terminal elimination phase, and the terminal elimination rate constants were 0.003/min in wk 1, 0.005/min in wk 2, and 0.003/min in wk 4 (Table 1). Terminal elimination half-lives differed among weeks, with a lower half-life in wk 2 (153 min) than in wk 1 (216 min) and 4 (236 min) ($P < 0.05$; Table 1).

Rumen Dosing

Feeding Behavior. Cineole influenced the feeding behavior of lambs when administered as a single bolus dose into the rumen ($P < 0.05$). Treatment lambs stopped feeding sooner than controls (Figure 3). Feeding time increased from wk 1 (17 min; SE = 2.7) to wk 2 (53 min; SE = 7.5) for treatment lambs ($P < 0.05$; Figure 3). During wk 1, controls consumed more food than treatments at both 30 and 60 min ($P < 0.05$), while during wk 2 lambs did not differ in the amount of food they consumed, although the trend was still decreased intake by lambs dosed with 1,8-cineole (Figure 4).

Clinical Effects. All lambs licked their lips in the first week of the rumen dosing, but during the second week, none did. We saw none of the other clinical signs apparent during the intravenous infusion experiment.

TABLE 2. MEAN KINETIC PARAMETERS FOR FOUR LAMBS ADMINISTERED A SINGLE RUMEN DOSE OF 125 MG/KG BW 1,8-CINEOLE

Week	k_a (1/min)	$A_{t1/2}$ (min)	A_{ke} (1/min)	$\alpha_{t1/2}$ (min)	β_{ke} (1/min)	$\beta_{t1/2}$ (min)	C_{max} (µg/ml)	T_{max} (min)
1	0.035 (0.0087)	24 (5.5)	0.025 (0.0075)	39 (11.5)	0.009 (0.0011)	85 (10.1)	7.7 (0.56)	68 (22.8)

Mean	0.056 (0.0084)	17 (5.3)	0.041 (0.0097)	29 (10.4)	0.008 (0.0006)	98 (12.5)	10.2 (1.80)	55 (13.9)

Standard errors in parentheses.

Pharmacokinetics. The plasma level–time curve fitted a triexponential mathematic model, with an exponential absorption component and biexponential distribution–elimination components. Absorption was rapid followed by a rapid primary (α) distribution–elimination phase and a relatively slow terminal (β) elimination phase (Figure 5). The absorption rate constant increased from 0.035 to 0.076/min from wk 1 to wk 2, while the absorption half-life declined from 24 to 10 min ($P < 0.05$; Table 2). C_{\max} , calculated maximum plasma concentration for 1,8-cineole, did not differ between weeks (Table 2). Time to reach maximum plasma concentration (T_{\max}) for 1,8-cineole was no faster in wk 2 (42 min) than wk 1 (68 min). The primary elimination rate constant was 0.025/min in wk 1 and 0.058/min in wk 2 ($P > 0.05$; Table 2). The primary elimination half-life declined from 39 min in wk 1 to 19 min in wk 2 (Table 2). The terminal elimination rate constant was 0.0098/min in both weeks (Table 2). The average terminal elimination half-life of 98 min did not change between weeks (Table 2). $AUC_{0-\infty}$ did not differ between wk 1 (1305 $\mu\text{g min/ml}$) and wk 2 (1286 $\mu\text{g min/ml}$).

DISCUSSION

Intravenous Infusion. Lambs dosed intravenously with 1,8-cineole stopped feeding sooner than controls in all three periods. This finding supports the satiety hypothesis, which predicts high plasma concentrations of secondary metabolites such as 1,8-cineole induce cessation of feeding (Provenza, 1995, 1996). The possibility that postabsorptive feedback from terpenes exerts serious effects on feeding behavior has been ignored, except in marsupials (Foley et al., 1987; Boyle et al., 2001; Boyle and Mclean, 2004). Nevertheless, feedback from cells and organs in response to nutrients and toxins influences which foods and how much of those foods are eaten by an animal (Provenza, 1995; Provenza and Villalba, 2006). While some authors suggest sagebrush monoterpenes are expelled quickly or degraded in the rumen (Cluff et al., 1982; White et al., 1982; Welch et al., 1983), there have been no definitive analyses of their potential postabsorptive effects (Meyer and Karasov, 1991). Rather, most work has focused on the effects of terpenes on rumen microbes (Nagy et al., 1964; Oh et al., 1968; Ngugi et al., 1995). Our results show that 1,8-cineole exerts significant physiological influences that cause cessation of feeding.

The time lambs fed declined over the three periods (Figure 1), suggesting increased sensitivity to infusions due to progressively stronger physiological effects (Jaffe, 1990; Rozman and Klaassen, 2001), which were conditioning an aversion to the food (Provenza and Villalba, 2006). The sharp decline in plasma concentration of 1,8-cineole during alpha elimination apparently caused these responses. Rapid alpha elimination occurs as a compound is distributed into other

tissues and is thus out of the central circulation; it is then redistributed to maintain equilibrium between blood and tissue concentrations. Rapid alpha elimination is likely critical in limiting intake and conditioning aversions. To protect the body from overingesting a toxin, feedback from cells and organs must be rapid, and in our studies rapid absorption and alpha elimination were better correlated with cessation of feeding than were plasma concentrations during excretion (beta elimination) (see also discussion on rumen infusions). With the toxin LiCl, cessation of feeding and food aversions occur as the toxin is being absorbed into the body, not during the much longer elimination phase (Provenza et al., 1993). Thus, terpenes cause lambs to satiate quickly, and when alternative foods are available, food-specific satiety mediated by toxins causes animals to eat other foods (Provenza, 1995, 1996; Provenza et al., 2003; Villalba et al., 2004).

The time to return to feeding postdosing declined from trial 1 (18 min) to trials 2 (8 min) and 3 (7 min). Apparently, cessation of dosing and lower plasma concentrations allowed lambs to resume feeding sooner. Secondary elimination was slow, and plasma concentrations did not change much from 3 to 8 hr after dosing. Under natural foraging conditions, slow secondary elimination may prolong the effects of 1,8-cineole on eating by influencing the duration and frequency of feeding bouts (Dziba and Provenza, 2006), and if suitable alternatives are available, animals eat them in preference to plants high in terpenes during beta elimination (Villalba et al., 2004). Thus, absorption and alpha elimination are likely responsible for initiating satiety, whereas beta elimination is likely responsible for the duration of the satiety effect.

The efficiency of elimination of toxins can increase through induction of liver enzymes including various CYP450 enzymes (Cheeke, 1998; Pass et al., 1999). Conversely, these enzymes can also be inhibited by the activity of toxins, decreasing rates of elimination (Pass et al., 1999; Pass and Mclean, 2002). Thus, feeding behavior may be positively or negatively influenced as metabolism and elimination of toxins is enhanced or depressed, respectively, during repeated exposure to toxins. In the case of intravenous infusions of 1,8-cineole, there was no evidence of induction or inhibition following initial exposure. Primary elimination rates did not differ among trials, yet *in vitro* studies have shown the induction of certain cytochrome P450 enzymes by 1,8-cineole in marsupials (Pass et al., 1999). In retrospect, our study of induction or inhibition was compromised by several days to weeks of no exposure to 1,8-cineole between periods. Daily exposure of animals would yield a more accurate account of whether 1,8-cineole induces or inhibits elimination rates.

Production of hydrogen ions can reduce pH in the central circulation and alter the acid–base balance (Foley et al., 1995; Illius and Jessop, 1997; Loudon et al., 1999). However, in our study, 1,8-cineole did not induce measurable changes in acid–base balance—blood pH was maintained within its narrow

range of 7.35–7.45—indicating a capacity in the acid–base balance to cope with the increase in acidic metabolites (Foley et al., 1995). Urinal excretion of hydrogen ions is one way animals can effectively maintain acid–base balance (Foley et al., 1995; Guyton and Hall, 2000). In addition, liberation of CO₂, as a means of regulating acid–base balance, could explain the observed tachypnea in lambs (Mudge and Weiner, 1990). Measuring urine pH or using other sensitive methods for monitoring urine output and chemistry might have given better information about possible challenges to acid–base balance for lambs fed terpene-containing foods (Dearing et al., 2001, 2002).

The effect of 1,8-cineole on various target organs is unknown, but observed clinical effects suggest neural affects on feeding behavior. In humans, 1,8-cineole affects the central nervous system, and common symptoms include respiratory depression and hypoventilation, depression of reflexes, convulsions, and loss of consciousness (Tibballs, 1995). Drowsiness occurs following ingestion of 1,8-cineole (Craig, 1953), which is consistent with our observations that lambs were sleepy and mildly ataxic. In humans, 1,8-cineole also causes abdominal pain, nausea and vomiting, and diarrhea.

Most of these clinical signs do not occur in herbivores, as they regulate intake of terpenes below levels that induce these symptoms (Foley et al., 1999; Dziba and Provenza, 2006). Animals experience mild versions of these and other clinical effects that lead to loss of appetite and nausea, which decrease intake by causing mild (transient) to strong (persistent) food aversions, which in turn are conditioned by aversive postingestive feedback from toxins, not by drowsiness, heavy breathing, and ataxia (Garcia et al., 1985; Garcia, 1989; Provenza et al., 1993; Provenza, 1995, 1996).

Rumen Dosing. Feeding behavior was influenced by rumen administration of 1,8-cineole. Lambs dosed with 1,8-cineole stopped feeding sooner than controls, which provides additional evidence of satiation (Provenza, 1995, 1996). Lambs also adapted to repeated dosing with 1,8-cineole. They fed longer and ate more during wk 2 than wk 1. The absorption rate constant increased from 0.035 to 0.076/min from wk 1 to 2, while the absorption half-life declined from 24 to 10 min from wk 1 to 2. The maximum plasma concentrations and the time to reach maximum plasma concentrations were no greater in wk 2 than in wk 1, but the primary elimination rate constant was 2.3 times higher in wk 2 (0.058/min) than wk 1 (0.025/min). Previous studies have also shown that animals steadily and dramatically increase their intake of sagebrush over time (Banner et al., 2000; Villalba et al., 2002; Dziba et al., 2006). These data suggest lambs adapted to 1,8-cineole in the rumen-dose study but not in the intravenous-dose study.

Several mechanisms may increase feeding time and intake. Primary elimination was much faster after the initial exposure to 1,8-cineole, although Foley et al. (1999) suggest elimination rates may have to increase as much as threefold to change feeding behavior. First-pass rates of metabolism may also

increase (Benet et al., 1990; Cheeke, 1998). Finally, rumen microbes adapt to monoterpenes (Nagy et al., 1964; Oh et al., 1968; Johnson et al., 1976), and given time, larger amounts of 1,8-cineole may be degraded in the rumen, resulting in lower levels of plasma concentrations, reduced toxic effects of 1,8-cineole, and increased food intake. Results of the rumen dosing trials, compared with the intravenous infusions trials, suggest that rumen degradation, absorption, and first-pass metabolism of 1,8-cineole all may have played important roles in detoxification and adaptation of lambs to 1,8-cineole.

In humans, 1,8-cineole quickly elicits toxic effects, suggesting rapid absorption and distribution (Patel and Wiggins, 1980). Our study also confirmed rapid absorption and immediate postabsorption effects that influenced feeding behavior. As mentioned, rates of absorption are likely critical for setting limits on intake, and in the rumen dosing studies the absorption phase was better correlated with cessation of feeding than were plasma concentrations. This makes sense; to protect the body against a toxin threat, feedback from cells and organs must be rapid. Rumen dosed lambs had a more rapid alpha elimination–distribution during the second period, yet lambs spent more time feeding and ate more during this second period. Rapid alpha elimination–distribution occurs as a compound is distributed into other tissues and later redistributed to maintain equilibrium between blood and tissue. This distribution effect likely enabled lambs to eat more after a single rumen dose of terpenes, since the infusion dosing resulted in higher plasma concentrations that likely resulted in much higher tissue concentrations. Thus, the lambs appear to more easily acclimate to the lower tissue concentrations and the resultant negative feedback on ingestion.

In addition, the increased plasma concentrations during the second period may not have been enough to change feeding behavior, particularly because the total dose was the same. Tolerance—reduced response to a toxic compound following prior exposure—of 1,8-cineole might also explain the increased feeding time and food intake (Jaffe, 1990; Rall, 1990). While all lambs licked their lips during the first rumen dosing, no lambs did during the second week. The absence of other clinical signs during rumen dosing suggests a more subdued effect of 1,8-cineole with rumen dosing than with the intravenous infusions.

Finally, our results have implications for managing rangelands dominated by sagebrush. Because 1,8-cineole limits intake by causing satiation, any mechanism that increases elimination rates or enhances ruminal adaptation might enhance use of sagebrush by sheep. Thus, prior exposure to a terpene-containing diet, training animals to mix sagebrush with other nutritious forages, and strategic supplementation to enhance detoxification processes are all likely to enhance use of sagebrush and biodiversity of landscapes dominated by sagebrush (Provenza et al., 2003).

Abstract—Insect cuticular hydrocarbons (CHCs) were probed by matrix-assisted laser desorption/ionization (MALDI) time-of-flight (TOF) mass spectrometry with a lithium 2,5-dihydroxybenzoate matrix. CHC profiles were obtained for 12 species of diverse insect taxa (termites, ants, a cockroach, and a flesh fly). MALDI spectra revealed the presence of high molecular weight CHCs on the insect cuticle. Hydrocarbons with more than 70 carbon atoms, both saturated and unsaturated, were detected. When compared with gas chromatography/mass spectrometry (GC/MS), MALDI-TOF covered a wider range of CHCs and enabled CHCs of considerably higher molecular weight to be detected. Good congruity between GC/MS and MALDI-TOF was observed in the overlapping region of molecular weights. Moreover, a number of previously undiscovered hydrocarbons were detected in the high mass range beyond the analytical capabilities of current GC/MS instruments. MALDI was shown to hold potential to become an alternative analytical method for insect CHC analyses. The ability of MALDI to discriminate among species varying in the degree of their relatedness was found to be similar to GC/MS. However, neither MALDI-MS nor GC/MS data were able to describe the phylogenetic relationships.

INTRODUCTION

Hydrocarbons represent universal constituents of the insect cuticle (Wigglesworth, 1965; Blomquist and Dillwith, 1985; Hadley, 1985; Chapman, 1998). Cuticular hydrocarbons (CHCs) are considered to be stable end products of genetically controlled metabolic pathways (Ross et al., 1987; Grunshawn et al., 1990); insects are known to synthesize most hydrocarbons *de novo* by elongation–decarboxylation pathway (review, Blomquist and Dillwith, 1985; Lockey, 1985, 1988; Howard and Blomquist, 2005). The common function of CHCs is to protect against desiccation. In social insects, CHCs are regarded as the main signals responsible for nestmate recognition (review, Blomquist et al., 1998; Howard and Blomquist, 2005; ants, see Lenoir et al., 2001; termites, see Clément and Bagnères, 1998), although this premise has been confirmed only in a few cases (e.g., Takahashi and Gassa, 1995; Lahav et al., 1999). As evidenced by gas chromatography (GC), the hydrocarbon mixture usually contains up to 100 different hydrocarbons (Nelson et al., 1981). The length of hydrocarbon chains usually varies from 23 to 47 carbon atoms (Blomquist and Dillwith, 1985). Species living in dry conditions generally contain longer hydrocarbon chains in comparison to their relatives living in wet conditions (review, Blomquist and Dillwith, 1985; Lockey, 1988). Insect species usually possess complex mixtures of hydrocarbons including *n*-alkanes, branched mono-, di-, or trimethylalkanes, and others (Jackson and Blomquist, 1976). Unsaturated CHCs are also present and the position of the double bond varies within the chain (Howard and Blomquist, 1982; Blomquist and Dillwith, 1985; Lockey, 1985, 1988). Hydrocarbon profiles may serve as fingerprints defining particular species. The composition of CHCs has been extensively studied in social insects, and in termites it is often used in taxonomic discrimination (Watson et al., 1989; Kaib et al., 1991; Bagine et al., 1994; Haverty et al., 1996; Takematsu and Yamaoka, 1997; Haverty and Nelson, 1997) and sibling species recognition (Haverty and Nelson, 1997).

To date, coupled gas chromatography-mass spectrometry (GC/MS) has been the primary tool for CHC analysis. However, both GC and electron ionization MS (EI-MS) have limitations for high molecular weight compounds. For these compounds, special high-temperature GC columns have to be used to withstand the temperatures needed. However, high temperatures can cause samples to decompose. Moreover, EI-MS identification of high-mass hydrocarbons is problematic because the molecular ion is virtually absent. Thus, GC/MS enables detection of only some of the hydrocarbons present on the insect

cuticle. To obtain a more complete picture of the composition of the cuticular waxy layer, other techniques have to be employed. Laser desorption/ionization (LDI) and matrix-assisted laser desorption/ionization (MALDI) mass spectrometry have been shown to be suitable methods for analyzing hydrocarbons and hydrocarbon polymers. Published methods (Kuhn et al., 1996; Yalcin et al., 1997; Dutta and Harayama, 2001; Pruns et al., 2002) used silver or copper ionization to produce ions that were subsequently detected. Recently, a new method utilizing lithium ions was described (Cvačka and Svatoš, 2003). A simple isotopic pattern of lithium adduct ions greatly simplifies spectrum interpretation. Accurate masses measured by time-of-flight (TOF) mass spectrometry have been used for the assignment of molecular structure.

In this work, the utility of MALDI-MS for characterizing CHCs was demonstrated especially for those of high molecular weight. Our objectives were to learn (1) the range of CHCs' molecular weights, (2) the types of hydrocarbons that form the high molecular weight portion of CHCs, and (3) whether MALDI mass spectra can be used for discriminating among species and for chemotaxonomical purposes. Results obtained by MALDI-MS were compared with data from GC/MS, a well-established method for CHC studies. Most work on CHCs has been done on social insects; therefore, termites were selected as our model group. Species representing different ecological strategies were chosen. In addition to termites, two ant species, the American cockroach, and a flesh fly were selected to represent related and nonrelated, social and nonsocial insects.

METHODS AND MATERIALS

Chemicals and Materials. Reagent grade standards of saturated hydrocarbons (triacontane, hexatriacontane, and tetracontane; $\geq 97\%$ pure) were obtained from Aldrich; tetratetracontane, pentacontane, and hexacontane from Fluka. Apolane-87 (24,24-diethyl-19,29-dioctadecylheptatetracontane) was from Alltech Associates (Deerfield, MA, USA). Squalane (2,6,10,15,19,23-hexamethyltetracosane) C grade was purchased from the California Corporation for Biochemical Research (Los Angeles, CA, USA), and squalene (2,6,10,15,19,23-hexamethyl-2,6,10,14,18,22-tetracosahexaene, min. 98%) from Sigma. Polyethylene glycol (PEG) oligomers (PEG 300, PEG 600, and PEG 1000) were purchased from Aldrich. Other hydrocarbon standards, 9-methylheptacosane, nonadecylcyclohexane, and icosylcyclopentane were synthesized and provided by Dr. Karel Stránský (IOCB, Prague, Czech Republic). Solvents used for sample and matrix preparation (chloroform, diethyl ether, hexane, and methanol) were distilled in glass from analytical-grade solvents.

Preparation of Lithium 2,5-Dihydroxybenzoate. Lithium-6 hydroxide monohydrate (0.55 g, 95 at.% ^6Li ; Aldrich) or lithium-7 hydroxide

monohydrate (0.55 g, 97 at.% ^7Li ; Aldrich) was dissolved in 6 ml ultrapure water and treated with freshly recrystallized 2,5-dihydroxybenzoic acid (1.50 g, Aldrich) at room temperature. The solution was cooled in a refrigerator, and the resulting white needles were washed with CHCl_3 (10 ml) and dried under vacuum. Elemental analyses revealed that both salts ($^6\text{LiDHB}$ and $^7\text{LiDHB}$) crystallize from water as tetrahydrates. For $\text{C}_7\text{H}_5\text{O}_4^6\text{Li}\cdot 4\text{H}_2\text{O}$ calc. 36.36% C, 5.68% H; Found 36.41% C, 5.59% H; for $\text{C}_7\text{H}_5\text{O}_4^7\text{Li}\cdot 4\text{H}_2\text{O}$, calc. 36.20% C, 5.65% H; Found 36.29% C, 5.65% H, respectively. A MALDI matrix solution was prepared fresh daily in CHCl_3 /acetone mixture (1:2, v/v) in a concentration of 7.5 mg/ml.

Insects. Subterranean and dry wood termite species (Isoptera: Rhinotermitidae and Kalotermitidae) used in this study originated from laboratory colonies where they were kept at $24 \pm 2^\circ\text{C}$ after being collected. Samples included 20 workers of *Reticulitermes lucifugus* (Rossi, 1792), abbreviated RL, collected in Crocemoschito, 70 km SE of Rome, Italy, 1998; 20 workers of *Reticulitermes (lucifugus) grassei* (Clément, 1981), abbreviated RG, collected in Forêt de la Coubre, near Bordeaux, France, 1998; 20 workers of *Reticulitermes santonensis* (de Feytaud, 1928), abbreviated RS, collected in Forêt des Saumonards, Ill D'Oleron, France, 1998; 20 workers of *Reticulitermes virginicus* (Banks, 1907), abbreviated RV, collected in Fort Lauderdale, FL, USA, 2003; 20 workers of *Coptotermes formosanus* (Shiraki, 1909), abbreviated CF, from a colony established in 1992 from alates from a colony collected in Hsin-hui, Guandong, China, 1963; 20 pseudergates of *Neotermes castaneus* (Burmeister, 1839), abbreviated NC, collected in Caimito, La Habana, Cuba, 1978; 20 pseudergates of *Neotermes cubanus* (Snyder, 1922), abbreviated NCub, collected in Topes de Collantes, Cuba; and 20 pseudergates of *Cryptotermes declivis* (Tsai and Chen, 1963), abbreviated CD, a colony obtained from the Guandong Institute of Entomology, Guangzhon, China, 1992. Flesh fly, cockroach, and ant species also originated from laboratory cultures where they were reared after being collected: 10 or 100 imagos of gray flesh fly *Neobellieria bullata* (Parker, 1916) (Diptera: Sarcophagidae), abbreviated NB; 1 or 10 males of the American cockroach, *Periplaneta americana* (Linnaeus, 1758) (Blattaria: Blattidae), abbreviated PA, from laboratory breedings of the Research Institute of Crop Production, Prague, Czech Republic; 7 individuals of the leaf-cutting ant *Acromyrmex echinator* (Forel, 1899), abbreviated AE, collected in a Paracou field station in French Guiana, 2001; and 6 individuals of *Atta colombica* (Guerin-Meneville, 1844) (Hymenoptera: Formicidae), abbreviated AC, collected in Barro Colorado Island, Panama, 1998. The relatively high number of insect individuals in this study was used to optimize experiments; routine measurements require at most a few individuals for successful MALDI experiments.

Sample Preparation. Insects were immobilized in the cold and stored frozen at -18°C . Prior to extraction, they were placed in a desiccator for 1 hr to get rid of surface moisture. CHCs were extracted with CHCl_3 (3–6 ml, elution time ca. 5 min) in a small glass column sealed on the bottom with precleaned cotton wool. Solvent from the extract was evaporated almost to dryness under a stream of argon. The crude extract was fractionated on precleaned glass thin layer chromatography plates (TLC, 36×76 mm) coated with Adsorbosil-Plus [Applied Science Labs; layer thickness 0.2 mm with gypsum (12%)] using hexane as a mobile phase. Spots were visualized by spraying Rhodamine 6G solution (0.05% in ethanol). To isolate both saturated and unsaturated hydrocarbons, the silica corresponding to a “relative to front” (R_F) value of 0.22 and 1.0 was scraped off the plate and extracted with 10 ml freshly distilled diethyl ether. The solvent was evaporated to dryness under a stream of argon, and the residues were weighed. The residues were reconstituted in CHCl_3 to a concentration of 1% and stored in sealed glass ampoules at -18°C . Silver ion chromatography was carried out using the same size TLC plates with a silica gel stationary phase impregnated with AgNO_3 (20%), and hexane as a mobile phase. To isolate the saturated hydrocarbons, silica around the solvent front was scraped off the plate; unsaturated hydrocarbons were isolated from all the rest. Simultaneously with preparative TLC, an analytical TLC (both normal-phase and silver ion) was run for each sample. Spots were visualized by heating the plates after spraying with conc. sulfuric acid containing ethyl vanillin. A stainless steel MALDI sample target (100 positions, Micromass) was cleaned stepwise with water, acetone, and dichloromethane (sonication for 15 min) to remove possible contamination. Chloroform extract (0.5 μL) was spotted onto a MALDI target, and, after drying, the sample was covered with 0.75 μL LiDHB matrix solution and allowed to dry in air; isotopically pure $^7\text{LiDHB}$ was used for routine measurement. For internal calibrations, 0.2 μL of a mixture of PEG oligomers (PEG 300, PEG 600, and PEG 1000, 0.1 mM each in acetone) was added to a sample. Plastic equipment was avoided during all manipulations with the samples and solvents to prevent possible contamination.

Infrared Spectroscopy and Nuclear Magnetic Resonance. IR spectra were taken as KBr pellets using a Bruker Equinox 55/S FT NIR spectrometer. ^1H NMR and ^{13}C NMR spectra were recorded using a Bruker AVANCE-500 (500.1 MHz for ^1H and 125.8 MHz for ^{13}C) FT NMR spectrometer in CDCl_3 , using Me_4Si as an internal standard at 300 K.

Gas Chromatography. GC/MS experiments were performed using a Fisons 8000 series GC equipped with MD800 quadrupole mass detector. A nonpolar DB-5 MS column (30 m \times 0.25 mm i.d., phase thickness 0.25 μm ; J&W Scientific, Folsom, CA, USA) was used to separate CHCs. The injector was operated in splitless mode at 220°C . The detector temperature was set to 200°C ;

standard 70 eV spectra were recorded at 1 scan/sec. The temperature of the GC oven was programmed as follows: 50°C/min, 10°C/min to 320°C, hold at 320°C for 10 min. Helium was used as a carrier gas at 1 ml/min. The data were analyzed using the MassLab (ver. 1.4) program. CHCs were quantified from chromatograms reconstructed from the m/z 57 ion; all hydrocarbons eluting after 15 min were integrated.

Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry. Matrix-assisted laser desorption/ionization experiments were performed on a ToFSpec 2E instrument (Micromass, Manchester, UK) operated in a reflectron mode using delayed extraction (Cvačka and Svatoš, 2003). Desorption and ionization were accomplished using a nitrogen UV laser. Matrix ions were suppressed with a low mass (300 Da or less) cutoff. Scans were accumulated using 20 laser shots and the spectra were averaged from at least 20 consecutive scans. Baseline subtracted data were smoothed, centered, and calibrated with lithium adducts of PEG. Data were collected and analyzed with MassLynx 3.2 software running on a PC workstation.

Statistical Analyses of CHCs. Statistical analysis of data from 12 insect species was carried out to compare the ability of MALDI-MS and GC/MS to discriminate among species. The Nei distances (or the Nei indices of identity) between all possible pairs of species were computed by using their CHC profiles as proposed by Nei (1972) and applied by Gush et al. (1985), Nowbahari et al. (1990), and Kaib et al. (1991). The relative ratios of the 63 most prominent peaks of GC/MS chromatograms and 492 peaks of MALDI-MS spectra were selected for the analysis. The matrices of Nei distances were submitted to cluster analyses using single linkage and UPGMA clustering methods. Hierarchical trees based on this clustering were drawn. The clustering was performed using the Statistica 6.0 program (StatSoft, Inc., Tulsa, OK, USA).

RESULTS AND DISCUSSION

Hexane is the most commonly used solvent for extraction of insect CHCs. It dissolves hydrocarbons of low and medium molecular weight, i.e., hydrocarbons that can be analyzed by gas chromatography. However, its ability to extract long-chain hydrocarbons from complex matrices is somewhat limited. Based on our laboratory experiences, we selected CHCl_3 for hydrocarbon extractions. It can efficiently dissolve the entire wax layer, including long-chain hydrocarbons and more polar compounds present on the insect cuticle. The hydrocarbon fraction was isolated from the whole extract by TLC on silica, eluting with hexane. Although retention behavior of hydrocarbons and related compounds bearing functional group(s) in TLC is commonly known, we conducted experiments to ensure that very long hydrocarbon chain(s) do not affect

retention of polar compounds considerably. We observed that even very long-chain triacylglycerols, fatty acids, and alcohols stayed at the origin. Wax esters and long-chain ethers were also retained [R_F of behenyl behenate ($C_{44}H_{88}O_2$) was 0.05 and R_F of dioctadecyl ether ($C_{36}H_{74}O$) was 0.08]. Thus, when CHC extracts were separated on silica TLC plates, polar compounds remained at or close to the origin, whereas one to three spots were observed close to the solvent front, with R_F values of 0.85–1.00. These were due to hydrocarbons with various structural features, such as branching, double bonds, or rings. For selected samples, the hydrocarbon fraction was further separated on silver ion TLC. Saturated CHCs migrated with or close to the solvent front, whereas unsaturated CHCs formed zone(s) close to the origin ($R_F = 0.10$ –0.26).

Cuticular Hydrocarbons Analyzed by FT-IR, 1H NMR, and ^{13}C NMR. To obtain basic information on CHC mixtures extracted using $CHCl_3$, a TLC-separated hydrocarbon fraction was examined by IR and NMR spectroscopy. Because these methods require relatively large amounts of samples, the experiments were performed only with the extract of *N. bullata*, which was available in sufficient quantity. The goal of these experiments was to learn more about the structural features of hydrocarbons present in the sample and to confirm that no compounds containing polar functionalities remained in the hydrocarbon fraction. The IR spectrum showed intense methyl and methylene C–H stretching and bend absorptions, methylene ($-(CH_2)_n-$) rocking absorptions, and bend absorption of methyl group. Alkene C–H stretching absorption gave weak signals in the spectrum. No frequency that can be attributed to polar functional groups was found in the spectrum. In the 1H NMR spectrum, signals of hydrogens in methylene groups and in terminal methyls were recorded. Allylic protons were also observed. ^{13}C NMR revealed the presence of methylene groups of long-hydrocarbon chains and terminal and nonterminal methyls. Carbons of methylene groups next to methyl branching or next to quaternary carbon atoms were also detected. As in 1H NMR, signals indicating the presence of isolated double bonds on a long hydrocarbon chain were observed. No signals that would suggest the presence of six-membered rings or saturated polycyclic structures were found. Based on the IR and NMR spectra, it was concluded that *N. bullata* CHC fractions contained only saturated and unsaturated long-chain hydrocarbons, some of which were branched.

Cuticular Hydrocarbons Analyzed by Gas Chromatography. CHC fractions of $CHCl_3$ extracts were analyzed by GC/MS using a conventional nonpolar capillary column, and individual hydrocarbons were identified based on their mass spectra (Doolittle et al., 1995) and retention behavior (Katritzky et al., 2000). In the samples, *n*-alkanes, methylalkanes, or alkadienes (*P. americana*) were the main components; di- and trimethylalkanes and alkenes were also present (Table 1). The hydrocarbon profile was noticeably different in the *A. colombica* sample, in which long-chain CHCs (>30 carbon atoms) formed

^aRelative composition in percent based on the peak areas integrated in reconstructed chromatograms based on the *m/z* 57 ion. CN = carbon number.

about 60% of the total peak area. We compared our GC/MS results with literature data; reports for *R. grassei*, *R. santonensis*, *C. formosanus*, *A. colombica*, *P. americana*, and *N. bullata* were available (Martin and MacConnell, 1970; Jackson, 1972; Jackson et al., 1974; Arnold and Regnier, 1975; Haverty et al., 1990, 2000; Vauchot et al., 1998). We found a good correlation between published data and our results with all the main compounds being detected. Minor differences were observed for unsaturated CHCs, where some alkenes were not found, probably due to coelution with other hydrocarbons. The integration of reconstructed chromatograms based on the m/z 57 ion also underestimated unsaturated hydrocarbons. Although direct comparison of the extraction using CHCl_3 and the common method with hexane was not performed, the agreement with literature data suggests that both extraction methods are comparable. As expected, silver ion TLC efficiently separated saturated CHCs from unsaturated CHCs. In *N. bullata*, almost all CHCs detected by GC/MS were saturated, with only a few tiny peaks due to unsaturated compounds being detected. Using GC/MS, we observed CHCs with up to 35 carbons. Higher injector and analysis temperatures would probably shift the CHC profile toward the hydrocarbons of slightly higher molecular weights, but it is clear that GC/MS discriminates against higher molecular weight components, if they are detected at all.

Cuticular Hydrocarbons Analyzed by MALDI-TOF. When irradiated with a laser pulse, the LiDHB matrix produced a mixture of matrix ions. Spectra of $^7\text{LiDHB}$ measured without ion suppression showed intense lithium cation signals at m/z 7.0 and an intense ion series at m/z 161.0, 167.1, and 173.1, corresponding to protonated $^7\text{LiDHB}$ and to protonated $^7\text{LiDHB}$, with one and two hydrogen atoms replaced with ^7Li , respectively. An ion at m/z 143.0 was formed from loss of water from protonated $^7\text{LiDHB}$. For a short time at the beginning of irradiation, we observed two more ion series representing clusters of two and three molecules of LiDHB with a various number of hydrogens replaced by lithium. These ions had the general structures $\text{C}_{14}\text{H}_{10-n}\text{Li}_{2+n}\text{O}_8$ and $\text{C}_{21}\text{H}_{15-n}\text{Li}_{2+n}\text{O}_{12}$, where $N = 0-4$; they disappeared quickly after several laser shots. Another lithiated ion series separated by 28 mass units at m/z 409.3, 437.3, and 465.3 was observed in the spectra. These ions were probably not related to the matrix and came from contamination; however, we were not able to trace the source of the contamination. The relatively small number of matrix ions enabled spectra to be recorded starting from m/z 200. However, because compounds with low molecular weights are somewhat volatile, compounds with molecular weights of <400 Daltons were not analyzed. Thus, with the exception of the matrix and contamination peaks mentioned above, clean, featureless blank matrix spectra were routinely obtained.

Using the $^7\text{LiDHB}$ matrix, lithium adduct ion formation was studied for several hydrocarbon standards. Representatives of diverse hydrocarbon classes were analyzed, including long-chain saturated hydrocarbons (triacontane, hexa-

triacontane, tetracontane, tetratetracontane, pentacontane, and hexacontane), branched saturated hydrocarbons (9-methylheptacosane, squalane, Apolane-87), and unsaturated and cyclic hydrocarbons (squalene, nonadecylcyclohexane, icosylcyclopentane). The sample (0.5 μg) was spotted onto a MALDI target. For all these compounds, single signals at m/z $[M + {}^7\text{Li}]^+$ with the expected isotope pattern were observed in the spectra. No cluster ions (e.g., $[2M + \text{Li}]^+$) were observed for any of the compounds or for mixtures. At this concentration range, no dehydrogenation was observed; however, at 10 times the concentration, a minor peak two mass units lower than that of $[M + {}^7\text{Li}]^+$ was detected. In no case did the relative intensity of this peak exceed 10% of the adduct ion. The mechanism of formation of these dehydrogenated ions is unclear. However, a tentative explanation could be laser-induced hydrocarbon dehydrogenation, which may be more pronounced at low matrix/hydrocarbon ratios. The alkenes formed likely have more affinity for complexing with the Li ion and therefore appear more abundant. Different ionization efficiencies of diverse hydrocarbon classes (saturated vs. unsaturated) were observed but not quantified because of the lack of sufficiently nonvolatile standards.

When CHC samples were subjected to MALDI-TOF analysis, distinctive profiles were observed for individual insect species (Figures 1–3). The most intense ions were observed roughly between m/z 500 and 700. In some samples, a second series of hydrocarbons also appeared around m/z 800–850. The largest hydrocarbons observed in the spectra had more than 70 carbon atoms. In the low-mass region of MALDI-TOF spectra, ions that correspond to hydrocarbons measured by GC/MS were observed. An example of the low-mass region of *R. lucifugus* spectrum is shown in Figure 4. When compared with GC/MS results (see Table 1), the peaks of high intensity in the MALDI-TOF spectrum can be assigned as follows: m/z 387.4 corresponds to the sum of heptacosane and 2-methylhexacosane; m/z 401.4 can be explained by a sum of methylheptacosanes and octacosane; m/z 415.4 represents nonacosane; and m/z 429.4 is the sum of methylnonacosanes. In the MALDI-TOF spectrum, there were also peaks that were not seen in the GC/MS traces. These ions might be unsaturated or cyclic derivatives of heptacosane (m/z 383.4) and nonacosane (m/z 409.4; m/z 411.4; and m/z 413.4). There are two possible explanations for why these compounds were observed in MALDI but not in GC/MS traces. First, these compounds form cationic adducts efficiently in MALDI experiments. Second, these compounds may decompose in GC injectors. In order to characterize ions observed in the MALDI spectra more precisely, the samples were mixed with an internal calibrant (PEG) and mass spectra were recorded. Because the nominal mass of methylene group is the same as the nominal mass of 14 hydrogens, one can easily confuse a hydrocarbon having seven double bonds or rings with a hydrocarbon that is one methylene group shorter. The difference (CH_2 -14H) is 0.094 u, which can be reliably measured with instruments having a resolution in

FIG. 1. MALDI-TOF mass spectrum of cuticular hydrocarbons of (a) *Reticulitermes virginicus*, (b) *Coptotermes formosanus*, and (c) *Neotermes cubanus*. $^7\text{LiDHB}$ matrix ions were eliminated by using a low mass (300 Da) cutoff, scans were accumulated from 20 laser shots, and spectra shown are averages of at least 20 consecutive scans. Baseline subtracted data were smoothed, centered, and m/z scale calibrated using lithium ions of polyethylene glycol standards.

the range of 5000–10,000. Such resolution is possible among current TOF analyzers. The mass precision achieved with our instrument was affected by a relatively low sampling rate (500 MHz) giving roughly 8 data points per spectrum peak, but internal calibration provided mass precision of measurements to about 75 ppm. The ions observed in the spectra were identified with the help of a software (available upon request) that calculates the possible hydrocarbon adduct ions of the general structure C_xH_yLi and scores the hits based on the mass error. Hits with the best matches were considered positively identified.

The mass spectra of *Reticulitermes* termite samples indicated the presence of saturated acyclic hydrocarbons up to roughly C45 (e.g. *R. virginicus*, Figure 1a). These compounds were the main constituents and were found in all samples of this genus studied in this work. Differences between species were in the intensity of particular hydrocarbons and in the presence of other hydrocarbons. *Reticulitermes* species also showed a second series of lithium adduct ions corresponding to highly unsaturated or cyclic C55–C65 hydrocarbons with 18–19 sites of unsaturation. The CHCs of *C. formosanus* (Figure 1b) were quite complex. The first series reached its maximum around C36–C38, and the second around C60. A surprisingly high number of sites of unsaturation (27) was

calculated for an ion at m/z 669.43 (C51). However, the presence of such large numbers of double bonds or rings in both the *Reticulitermes* species and *C. formosanus* remains to be confirmed by other methods. Mass spectra of CHCs from two *Neotermes* species differed greatly from one another. The *N. cubanus* sample (Figure 1c) contained mainly saturated acyclic hydrocarbons up to C46. A few peaks of highly unsaturated or cyclic C55–C65 CHCs were also present. The mass spectrum of *N. castaneus* CHCs (Figure 2a) showed groups of ions with 0–4 sites of unsaturation. As with *C. formosanus*, a distinct peak at m/z 669.45 as well as a second series around C60–C70 was observed. A MALDI mass spectrum of *C. declivis* is shown in Figure 2b. Internal calibration for this sample was not performed because of insufficient sample amounts. Thus, the interpretation was done based on external calibration data only. Both saturated and unsaturated or cyclic hydrocarbons were identified. The spectrum showed distinct intense peaks interpreted as C43 and C45 with 3–4 sites of unsaturation. The MALDI spectrum of *P. americana* (Figure 2c) showed two groups of hydrocarbons (C41 and C43) with 1 and 3 sites of unsaturation. A mass spectrum of flesh fly *N. bullata* CHCs (Figure 3a) showed a distribution of C36–C50 hydrocarbons. Lithium adduct ions formed groups corresponding to acyclic saturated hydrocarbons and unsaturated or cyclic CHCs with 1–4 sites of unsaturation. Hydrocarbons with an odd number of carbon atoms were more intense compared to those with an even number of carbons. In the mass spectrum of a leaf-cutting ant *A. colombica* (Figure 3b), a distribution of C34–C42 CHCs was found. Adduct ions formed groups corresponding to saturated hydrocarbons and those having 1–2 sites of unsaturation. The sample from another leaf-cutting ant, *A. echinator* (Figure 3c), contained almost exclusively odd-numbered CHCs (C41–C49). Lithium adduct ions in the spectra corresponded to compounds with 1–4 sites of unsaturation.

To obtain more in-depth insight into CHCs, fractions of saturated and unsaturated hydrocarbons were analyzed separately. Figure 5 shows the MALDI spectrum of saturated (Figure 5a) and unsaturated (Figure 5b) hydrocarbons of *P. americana*. The most intense signals in the spectrum of saturated CHCs give alkanes with 25 and 26 carbons; they were identified by GC as pentacosane and 3-methylpentacosane (Table 1, Jackson, 1972). Less abundant higher hydrocarbons, C27 and C42, were previously characterized as heptacosane and 3-methylhentetracontane (Jackson, 1972). Few other saturated CHCs (C29, C40, and C44) were observed in the MALDI spectrum. The spectrum of unsaturated hydrocarbons from *P. americana* (Figure 5b) showed alkenes with 1–3 sites of unsaturation. An ion at m/z 383.43 is a lithium adduct of (*Z,Z*)-6,9-heptacosadiene, previously identified from this cockroach (Jackson, 1972; Suiter et al., 1996). Two clusters of CHCs with 41 and 43 carbons probably contain trienes, dienes, and monoenes. Trienes had not previously been described, whereas monoenes were identified as *cis*-15-hentetracontene and

FIG. 5. MALDI-TOF mass spectrum of (a) saturated and (b) unsaturated CHCs of *Periplaneta americana*. For details, see Fig. 1.

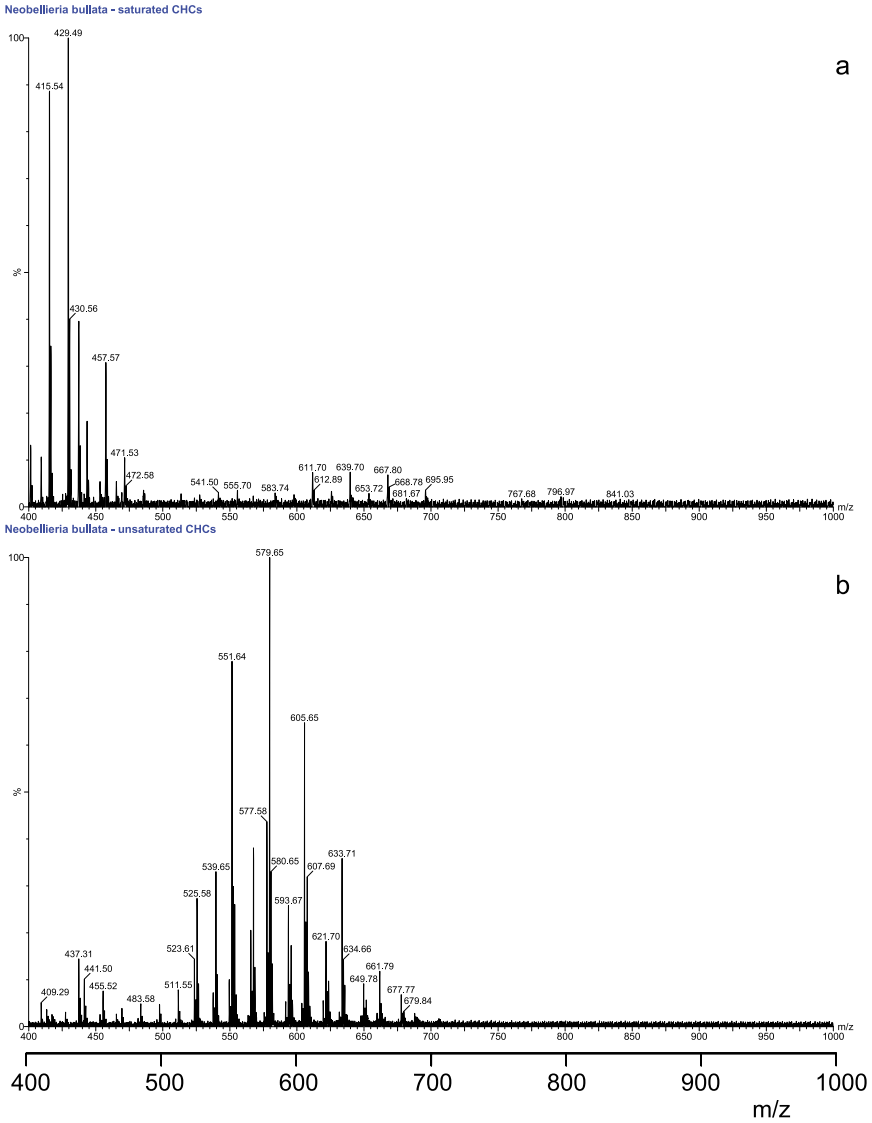

FIG. 6. MALDI-TOF mass spectrum of (a) saturated and (b) unsaturated CHCs of *Neobellieria bullata*. For details, see Fig. 1.

cis-15-tritetracontene (Jackson, 1972). In the MALDI spectra, low-intensity signals of CHCs with 42 and 45 carbons and 3 sites of unsaturation were also detected. Thus, our MALDI spectra was in agreement with published data. In addition, hydrocarbons with 3 sites of unsaturation, which are present in significant amounts, were newly revealed. Another example of separately analyzed saturated and unsaturated CHCs (*N. bullata*) is given in Figure 6a and b. The spectrum of saturated CHCs shows alkanes with up to 47 carbons. The literature (Jackson et al., 1974; Arnold and Regnier, 1975) and our results from GC/MS identified these peaks as nonacosane (C29), methyl nonacosanes (C30), hentriacontane (C31), methyl hentriacontane and dotriacontane (C32), and tritriacontane (C33), whereas the others had not been described previously. When Figure 6b is compared with Figure 3a, it is apparent that almost all MALDI peaks in *N. bullata* are due to the unsaturated CHCs. As described above, CHCs with up to 4 sites of unsaturation were detected, with those having an odd number of carbons being most abundant. We regard the presence of rings as unlikely (no evidence exists for rings from NMR experiments) and consider these structures to be mono-, di-, tri-, and tetraenes.

The spectra of all CHCs were a simple sum of the spectra of saturated and unsaturated CHCs because unsaturated compounds more effectively compete for lithium ions, resulting in saturated CHCs being less pronounced in the composite spectra. Therefore, crude extracts should be fractionated into saturated and unsaturated hydrocarbons by silver ion chromatography before analysis of complex hydrocarbon mixtures. Importantly, silver ions do not appear to contaminate CHC fractions during separation, because no silver ion adducts were observed in the MALDI spectra. To summarize, distinctive CHC profiles were recorded for all tested species using MALDI-TOF analysis. Saturated hydrocarbons, as well as hydrocarbons with varying degrees of unsaturation, were found. It is likely that polyunsaturated CHCs readily ionize, increasing their intensities in the spectra. Also, the exact structures of the unsaturated hydrocarbons could not be determined from the MALDI-TOF spectra.

The MALDI technique was also tested for reproducibility and capacity for quantitatively measuring CHCs, for its possible use in chemotaxonomy. Although LDI and MALDI are not techniques generally considered suitable for quantitation, their usefulness in this field has been demonstrated (Dutta and Harayama, 2001). Pruns et al. (2003) applied principal component analysis to LDI-TOF mass spectra to characterize paraffin oils and petrolatum samples. In our experiment, spectra of a model sample (paraffinum liquidum, 5.0 µg) spotted in triplicates onto two MALDI targets were recorded. Averaged spectra from 20 to 120 scans were compared, and similar-looking spectra differing slightly in peak intensities were obtained. To quantify the reproducibility of the measurement, relative standard deviations (RSDs) were calculated for ratios of selected peaks. Low RSDs (<10%) were calculated for ratios of peaks differing

in 14 mass units (adjacent alkanes). However, the reproducibility of ratios of peaks differing by more than 100 mass units was worse, with RSDs between 20 and 50% being obtained. Several factors affect the reproducibility of the signals in MALDI experiments. First, the homogeneity of sample deposition and uniform incorporation of analyte molecules into the matrix is critical. The LiDHB matrix is polar and finding a suitable solvent system that allows the dissolution of both the sample and the matrix is not straightforward. Nonuniform samples with variable concentrations of sample components across the sample well on the MALDI target can result. Uniform samples can be achieved using solvent-free preparation methods, but a substantially larger amount of sample is needed. Another method to obtain homogenous MALDI samples is electrospray sample deposition (Hanton et al., 2004). Second, lower molecular weight hydrocarbons under the low pressure in the ion source may tend to volatilize off the target. Therefore, the time between the introduction of the target plate into the vacuum and sample measurement should be controlled. Third, a substance-dependent time delay between the beginning of the irradiation of the sample and the appearance of the signal in the spectrum was observed, with long-chain saturated hydrocarbons taking a longer time (or laser shots) to appear in the spectrum. Therefore, the relative intensities of peaks in the spectra depend on the acquisition time. Thus, precise control of experimental parameters will increase reproducibility. The reproducibility that exists in GC/MS measurements cannot be achieved but the quality of the MALDI data is sufficient for statistical processing and discriminating among species. The work described below summarizes results from two sets of experiments (including extraction steps) that were performed consecutively over 6 months. Comparable CHC profiles were obtained for all model species.

Statistical Analysis. Nei distances proved to be an appropriate tool for evaluating phenotype distances within CHCs among studied species. The clustering of Nei distances among CHC profiles (Figure 7) showed a high potential for discriminating with both GC/MS and MALDI-MS data. The consistency between hierarchical classifications calculated by two different methods (UPGMA and single linkage) was similar for both MALDI-MS and GC/MS. The position of a single species (*C. formosanus* in MALDI-MS and *N. cubanus* in GC/MS) was the only difference between the two statistical methods used (the interchange of *P. americana* and *C. declivis* in Figure 7d and e is due to the different insertion of *C. formosanus*). When compared with GC/MS, MALDI-MS data showed similar efficiency in discriminating among particular species (compare Figure 7a–d). With both techniques, some related species were repeatedly grouped together (e.g., *R. santonensis* and *R. virginicus* in GC/MS, the whole genus *Reticulitermes* in MALDI), whereas others were consistently separated (both ant species, both *Neotermes* species). The CHC profile of an unrelated species, the cockroach *P. americana*, measured by GC/

MS, differed quite notably from all others. It consisted primarily of three CHCs (Table 1). Moreover, the major compound (6,9-heptacosadiene, 71%) was unique to this species, which set it apart from all others (Figure 7a,b). In the MALDI spectrum of *P. americana* CHCs, all 25 peaks (the average number is 199 for the other species studied) had the same mass as peaks in other species, and therefore the cockroach was placed deeply inside the tree (Figure 7c,d).

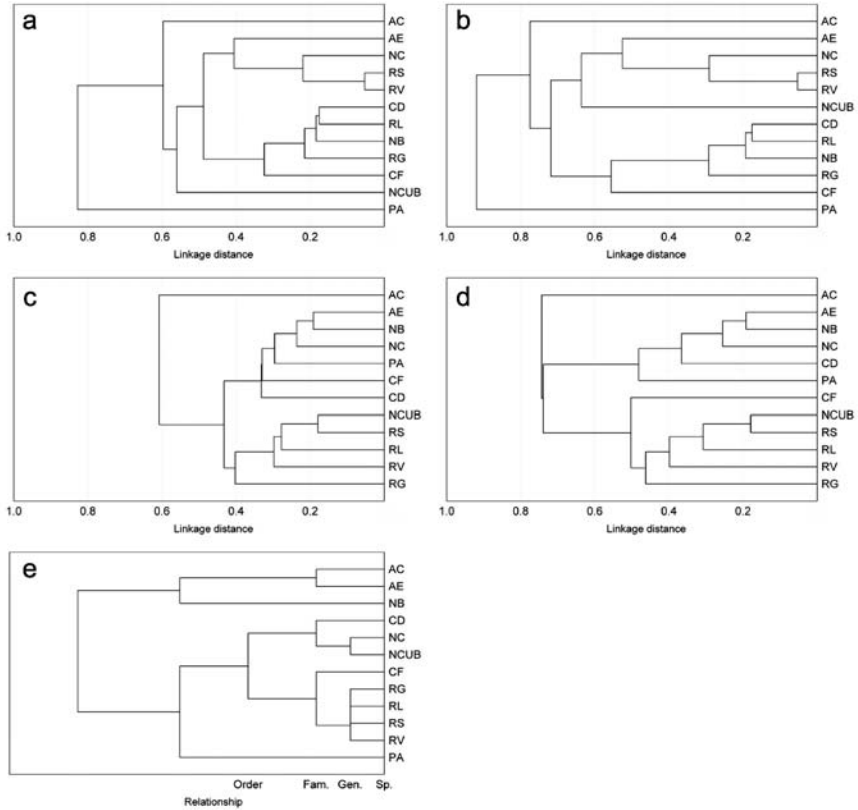

FIG. 7. Hierarchical tree made by single linkage clustering of Nei distances among cuticular hydrocarbon profiles analyzed by GC/MS (a), made by UPGMA clustering of Nei distances among cuticular hydrocarbon profiles analyzed by GC/MS (b), made by single linkage clustering of Nei distances among cuticular hydrocarbon profiles analyzed by MALDI MS (c), made by UPGMA clustering of Nei distances among cuticular hydrocarbon profiles analyzed by MALDI MS (d), hierarchical tree representing the general phylogenetic relationships among the 12 analyzed species (e). Abbreviations of insect species are listed in [Insects](#); Sp.: species, Gen.: genus, Fam.: family.

Conversely, because few peaks in both the GC/MS and MALDI spectra of *A. colombica* CHCs are shared with other species, this ant species was always placed apart from the others (Figures 7a–d).

The primary function of CHC, water regulation, may be largely independent of their composition. Therefore, CHCs may be good candidates for phylogenetic characters. However, this selection neutrality may also enable rapid changes in CHC profiles during evolution, which could conceal the real relatedness even in closely related species. Support for this hypothesis is provided by the considerable differences found in CHC profiles of many closely related species (Watson et al., 1989; Kaib et al., 1991; Golden et al., 1992; Bagine et al., 1994; Haverty et al., 1996; Haverty and Nelson, 1997; Takematsu and Yamaoka, 1997). On the other hand, CHCs were shown to reliably indicate the relatedness on the lowest levels, i.e., at the (sub)species, population, or colony level (Kutnik et al., 2004). Not surprisingly, neither GC/MS nor MALDI-MS was able to figure out the phylogeny of the studied species. Contrary to our expectations, none of the groups of closely related species were separated from nonrelative species in any of the tests. On the other hand, MALDI-MS data grouped together all four species from the genus *Reticulitermes*, but, unfortunately, also with *N. cubanus*. Nevertheless, MALDI-MS of CHCs may have some utility in phylogenetic and chemotaxonomic studies.

In conclusion, MALDI-TOF mass spectrometry with a lithium 2,5-dihydroxybenzoate matrix revealed the presence of high molecular weight hydrocarbons on insect cuticles, including saturated hydrocarbons, and highly unsaturated and/or cyclic compounds. A detailed investigation of *N. bullata* CHC extracts using IR and NMR confirmed the presence of structural features commonly observed in GC/MS analyses, such as long hydrocarbon chains with some methyl branching and double bonds, but no evidence of rings. MALDI-MS spectra for the same samples corroborated the presence of hydrocarbons with 0–4 double bonds. The samples of other species, however, gave composite spectra possibly consistent with a considerably higher number of double bonds and/or rings. However, no independent proof of such hydrocarbons has been obtained yet. Both MALDI mass spectra and GC/MS chromatograms were able to discriminate among the species studied. Therefore, MALDI-MS has the potential to become an alternative or complementary analytical technique for chemotaxonomic studies, enabling us to extend the range of molecular weights of compounds studied. Further instrumentation developments may provide even more information about analyzed samples, for example, by interfacing of MALDI with high-performance liquid chromatography (Esser et al., 2000) or supercritical fluid chromatography (Planeta et al., 2002). Furthermore, excellent quality data (mass accuracy, resolution, and sensitivity) can be obtained with MALDI Fourier-transform ion cyclotron resonance mass spectrometry, and MS experiments might help to elucidate structures of unknown CHCs. Further research is needed

to elucidate complete structures of the high molecular weight hydrocarbons found in this study, and subsequently, to determine their possible biological activity.

Acknowledgments—We gratefully acknowledge financial support provided by the Max Planck Institute, Jena, and the Institute of Organic Chemistry and Biochemistry, Prague (project Z4 0550506). (Z)-9-NONACOSENE—MAJOR COMPONENT OF THE
CONTACT SEX PHEROMONE OF THE BEETLE
Megacyllene caryae

Abstract—Male *Megacyllene caryae* (Gahan) (Coleoptera: Cerambycidae) respond to females only after touching them with their antennae, indicating that mate recognition is mediated by a contact sex pheromone. Gas chromatography-mass spectrometry analyses of whole-body solvent extracts of male and female *M. caryae* revealed substantial differences in hydrocarbon profiles, with nearly half of the compounds in the extracts from females being absent from those of males. Biological activities of fractions of crude extracts of females, and reconstructed blends of the most abundant straight-chain (nC_{27} , nC_{28} , nC_{29}), methyl-branched (2Me- C_{26} , 9Me- C_{29} , 11, 13, 15Me- C_{29}), and unsaturated (Z9: C_{29} , Z13: C_{29} , Z14: C_{29} , Z13: C_{31} , Z14: C_{31} , Z15: C_{31}) compounds in extracts of females were tested in arena bioassays, assessing four steps in the mating behavior sequence of males (orientation, arrestment, body alignment, mounting and attempting to couple the genitalia). Males showed limited response to dead females treated with fractions of the crude extract or blends of synthetic straight-chain and methyl-branched alkanes, but responded strongly to the blend of synthetic monoenes. Further trials determined that the complete sequence of mating behaviors, up to and including coupling the genitalia, was elicited by Z9: C_{29} alone. Z9: C_{29} is a homolog of the contact pheromone (Z9: C_{25}) of the congener *M. robiniae* (Förster). Previous work with *M. robiniae* suggested that wipe sampling of cuticular

hydrocarbons of females by solid phase microextraction yielded a more representative profile of components actually encountered by a male's antennae, and so provided a more readily interpretable profile of potential semiochemicals present in the wax layer than does solvent extraction. We tested this hypothesis by comparing hydrocarbon profiles of female *M. caryae* by the two sampling methods. Z9:C₂₉ was the only compound among the dominant hydrocarbons that was present in higher abundance in SPME than in solvent extracts (~12% vs. ~8%, respectively), supporting this hypothesis.

Key Words—Cerambycidae, mating behavior, cuticular hydrocarbon, solid-phase microextraction, contact sex pheromone.

INTRODUCTION

The wax layer on the insect cuticle is a complex mixture of long-chain hydrocarbons, fatty acids, alcohols, esters, aldehydes, and ketones that protects insects from desiccation (Gibbs, 1998). Some of these compounds also have secondary roles as contact pheromones (Blomquist et al., 1993). Contact pheromones mediate mate recognition in several species of cerambycid beetles (Kim et al., 1993; Fukaya et al., 1996, 1997, 2000; Wang, 1998; Ginzl and Hanks, 2003; Ginzl et al., 2003a,b). We report here the results of studies on a cuticular sex pheromone of female *Megacyllene caryae* (Gahan) (Coleoptera: Cerambycidae).

M. caryae is endemic to north-central North America (Linsley, 1964). Adults are diurnal, aposematically colored wasp mimics, ~2 cm long, and are active in spring. Adults of both sexes are mutually attracted to volatiles emanating from their larval hosts, stressed or weakened hickory trees (Ginzl and Hanks, 2005). Males orient to females only after contacting them with their antennae, and mate recognition is cued by contact chemoreception (Ginzl and Hanks, 2003). After touching a live or freeze-killed female with his antennae, a male *M. caryae* aligns his body with that of the female and attempts to copulate, bending his abdomen to couple with the female's genitalia (Ginzl and Hanks, 2003). Males did not display any of these behaviors when presented with solvent-extracted, freeze-killed females, but reapplying crude solvent extract to solvent-washed female carcasses restored activity, demonstrating that mate recognition and subsequent mating behaviors are cued by extractable chemicals in the cuticular wax layer (Ginzl and Hanks, 2003).

We report here the identification of an important component of the female-produced contact sex pheromone for *M. caryae*. Two methods of sampling were used: the traditional whole-body solvent extraction and solid phase microextraction (SPME) wipe sampling. SPME has been suggested as an alternative to solvent extraction of insect cuticular hydrocarbons (e.g., Turillazzi et al.,

1998; Peeters et al., 1999; Liebig et al., 2000; Sledge et al., 2000; Roux et al., 2002) and reportedly yields samples that are qualitatively and quantitatively similar to those obtained by solvent extraction (Moneti et al., 1997; Monnin et al., 1998; Bland et al., 2001; Tentschert et al., 2002). However, study on the contact pheromones of a congener of *M. caryae*, *M. robiniae* (Förster) revealed that whole-body solvent extraction and SPME wipe sampling of female elytra, the most likely surfaces contacted by antennae of males, yielded markedly different hydrocarbon profiles (Ginzel et al., 2003b). The contact pheromone of female *M. robiniae*, Z9:C₂₅, comprised ~16% of the total hydrocarbons in hexane extracts of females and was codominant with two other hydrocarbons that were not active. In contrast, in SPME wipe samples of several areas of the cuticle, Z9:C₂₅ appeared as the single dominant peak, comprising ~35% of the sampled hydrocarbons (Ginzel et al., 2003b). This finding suggested that hydrocarbons that cue mate recognition are more abundant on the surface of the cuticular wax layer in females where they are readily accessible to the antennae of males. We concluded that wipe sampling by SPME may yield a more representative profile of cuticular components actually encountered by the antennae of male insects, and so may provide a more representative profile of potential semiochemicals present on the body surface than does solvent extraction. We tested this hypothesis in the present study by sampling cuticular hydrocarbons of female *M. caryae* by both methods, predicting that compounds which cue mate recognition would be present in higher relative proportions in SPME wipe samples of the female cuticle than in whole-body extracts.

METHODS AND MATERIALS

Source of Beetles. The trunk of a shagbark hickory that was wind-thrown during spring 2002 at Brownfield Woods (Champaign County, IL) and infested with immature *M. caryae* was sectioned in March 2003 and the bolts stored in a 4°C walk-in cooler to prolong prepupal diapause. As adult beetles were needed for bioassays in May through August 2003, we moved logs to an indoor cage at ambient temperature to induce emergence. As adult beetles emerged, we housed individual males and females separately in 0.3 m³ cages of aluminum window screen held under ambient laboratory lighting and temperature conditions. Caged beetles were provided feeder vials of 10% sucrose solution (glass vial with a cotton dental roll; Patterson Dental Supply, South Edina, MN, USA), and feeders were replaced every 2–3 d. Beetles used in preparation of extracts and in bioassays were vigorous and active in cages. Thirty adult male and female *M. caryae* that had emerged in 2003 were caged with shagbark hickory bolts (~30 cm diam, ~45 cm long) from a tree collected

at Allerton Park (Piatt County, IL, USA). Following oviposition, the bolts were stored at ambient temperature, and adults that emerged the following May were used in bioassays during 2004.

Preparation of Whole-body Extracts and Identification of Cuticular Hydrocarbons. Cuticular chemicals were extracted from 10 freeze-killed virgin female and male *M. caryae* by individually immersing each beetle in two 1-ml aliquots of hexane for 2 min each. The two aliquots were combined and concentrated to 1 ml under nitrogen. Extracts were initially analyzed at the University of Illinois at Urbana–Champaign (UIUC) by coupled gas chromatography-mass spectrometry (GC-MS) with electron impact ionization (EI, 70 eV) using a Hewlett-Packard (HP) 6890 GC (Hewlett-Packard, Sunnyvale, CA, USA) equipped with a DB-5MS capillary column (30 m \times 0.25 mm \times 0.25 μ m film; J&W Scientific, Folsom, CA, USA) in splitless mode, interfaced to an HP 5973 mass selective detector (MSD), with helium carrier gas. The column was programmed from 50°C/1 min, 10°C/min to 240°C, then 240 to 300°C at 2°C/min with a 5 min hold at 300°C. Injector and transfer line temperatures were 280°C. Quantitative data presented in Table 1 and Figure 1 were produced by these analyses.

Compounds in whole-body extracts were identified in the laboratory of J.G.M. with an HP 6890 GC equipped with a DB-5MS column (30 m \times 0.25 mm \times 0.25 μ m film) and interfaced to an HP 5973 MSD. The temperature program was 100°C/1 min, 10°C/min to 280°C, with a hold at 280°C for 20 min. Injector and transfer line temperatures were 280°C. To determine the positions of double bonds in alkenes in the extracts, the crude extracts were epoxidized by treating an aliquot of an extract with a few drops of *m*-chloroperbenzoic acid in CH₂Cl₂ (25 μ l of a 2 mg/ml solution). After 2 hr at room temperature, the mixture was extracted with 1 M aqueous NaOH, and the hexane layer was dried over anhydrous Na₂SO₄, and then analyzed as described above.

Solid Phase Microextraction. We sampled cuticular components of five adult female *M. caryae* by gently rubbing the dorsal surface of the elytra with a 100 μ m (film thickness) polydimethylsiloxane SPME fiber (Supelco Inc., Bellefonte, PA, USA) for 30 sec. The same beetles also were sampled by whole-body hexane extraction, allowing us to compare profiles produced by the two sampling methods. Samples were analyzed at UIUC by GC-MS by desorbing the SPME fiber for 1 min in the injection port (250°C) with the same temperature settings that were used in analyzing extracts (see above).

Fractionation of Whole-Body Extracts. A column prepared from a Pasteur pipette plugged with a small plug of glass wool was loaded with 400 mg silica gel impregnated with AgNO₃ (10% w/w) and oven-dried overnight at 120°C. After cooling, the column was rinsed with hexane, then loaded with a concentrated composite extract of the whole-body extracts from six females in hexane (~0.5 ml total volume). The column was eluted sequentially with 4 ml hexane

(saturated hydrocarbons fraction), 2 ml 20% cyclohexene in hexane (alkenes fraction), and 3 ml ether (polar compounds). One half of the saturated alkanes fraction was concentrated to dryness under a stream of N₂, then 0.5 ml isooctane was added, and the extract was concentrated to dryness again to remove traces of hexane. The residue was taken up in 2 ml isooctane and stirred overnight with 50 mg oven-dried powdered 4 Å molecular sieve. The resulting slurry was filtered through a glass wool plug, yielding a branched alkanes fraction. The various fractions were tested for contact pheromone activity in bioassays.

Chemical Standards. C₂₇–C₂₉ straight-chain hydrocarbons were purchased from Sigma-Aldrich (St. Louis, MO, USA) and Lancaster Synthesis (Pelham, NH, USA). The syntheses and spectral data of other standards, including Z9:C₂₉, Z13:C₂₉, Z14:C₂₉, Z13:C₃₁, Z14:C₃₁, Z15:C₃₁, 7Me-C₂₅, 11Me-C₂₅, 2Me-C₂₆, 9Me-C₂₉, 11Me-C₂₉, 13Me-C₂₉, 15Me-C₂₉, 13Me-C₃₁, and 15Me-C₃₁, are described in the online Supplementary Information available for this article, at <http://dx.doi.org/10.1007/s10886-005-9010-y> and is accessible for authorized users.

Bioassays with Fractions and Hydrocarbon Standards. Hexane solutions of hydrocarbon standards were prepared in concentrations that approximated the original extracts of female *M. caryae* (quantified by comparing peak areas from integrated total ion chromatograms with that of an internal standard). We tested the activity of the crude hexane extract of females, then the saturated hydrocarbon, branched alkane, and alkene fractions of the crude hexane extract, and then reconstructed the blends of the most abundant compounds based on chemical class. We then tested for synergistic responses of males to the monoenes, the most bioactive functional group (see Results), and the straight-chain alkanes. Next, we tested the bioactivity of the monoenes blend without Z9:C₂₉, the most abundant alkene in the hexane extract and SPME samples of the female cuticle (see Results). We then tested Z9:C₂₉ alone and in combination with the straight-chain alkanes and methyl-branched alkanes (see Results). The bioactivities of these blends and individual compounds were tested with the following bioassay (see Ginzel et al., 2003a,b) in May–June 2003 and 2004:

- (1) A female was freeze-killed (−4°C for 20 min), then the carcass was warmed to room temperature (~15 min), and presented to a male in a clean glass Petri dish lined with filter paper. An attempt to mate was taken as evidence that recognition cues were intact and that a behavioral response by the female was not necessary for mate recognition.
- (2) We removed cuticular components from the dead female by immersing her in two sequential 1-ml aliquots of analytical-grade hexane for 2 min each.
- (3) The solvent-washed female carcass was air-dried for 30 min to allow the solvent to evaporate and then presented to the same male. Lack of a

response by the male was evidence that chemical recognition cues had been eliminated.

- (4) We tested the bioactivity of extracts, fractions of extracts, and individual or blends of hydrocarbon standards by pipetting solutions onto the body of the solvent-washed female, allowing the solvent to evaporate, and presenting the treated carcass again to the same male. We used 0.8 female equivalents (FE) in 20 μ l hexane, because males responded best to this dosage of crude extract (Ginzl and Hanks, 2003). Test solution was applied to the solvent-washed female carcass and 20 μ l hexane were applied to another solvent-washed female carcass as a control. The two carcasses were then presented to individual males simultaneously, on opposite sides of a Petri dish arena, with their positions randomized to control for location effects.

For all bioassays, we presented each of at least five dead females to two or three different males ($N = 10$ –20 males). We videotaped responses of males in the Petri dish arenas. Males used in bioassays had not mated for 24 hr prior to bioassays and were used in bioassays only once per day. After a male *M. caryae* contacted a living female with his antennae, a clear progression of behaviors led to copulation: (1) the male oriented to (turned toward) the female, (2) the male stopped walking (= arrestment), (3) the male aligned his body with the female, and (4) the male mounted the female and attempted to couple the genitalia. Thus, our assessment of behavioral response was cumulative: males must perform steps 1 through 3 to reach step 4.

A trial was scored as a “response” if the test male displayed at least the first behavior (turning toward female), within 5 min after first contacting a treated or control female carcass with his antennae. A trial was scored as “no response” if the male showed none of these behaviors within 5 min of initial antennal contact, but rather continued to walk after contacting either a treatment or a control with his antennae. Statistical significance of the response of males to treatments was tested with Fisher’s exact test (Sokal and Rohlf, 1995), (a) comparing numbers responding to crude extract (i.e., reaching behavioral step 1 at least) vs. solvent controls, (b) comparing numbers responding to treatments vs. crude extract, and (c) comparing numbers showing a complete mating response (i.e., reaching behavioral step 4) to treatments vs. crude extract.

RESULTS

Preliminary Bioassays. As a prelude to further investigation, we determined that male *M. caryae* could discriminate between female and male conspecifics by contact chemoreception, by pairing males with females and males with males in Petri dish arenas ($N = 10$ for each combination of sexes). Every

male attempted to mate with the female immediately after first antennal contact, but males only briefly antennated other males, then subsequently avoided them. The responses of male *M. caryae* to females and other males were consistent with earlier laboratory studies (Ginzel and Hanks, 2003; M.D. Ginzel, personal observation). These findings suggested that the chemical cues that males use to recognize females are absent in males, or that males have other compounds that inhibit the mating response.

Identification of Cuticular Hydrocarbons. Hexane extracts of female and male *M. caryae* contained saturated, branched, and unsaturated hydrocarbons (Table 1, Figure 1). Cuticular hydrocarbon components were identified by comparison of mass spectra and retention times with those of standards, or from the parent M^+ ions and the corresponding molecular formulae, retention times relative to straight-chain compounds, and diagnostic mass spectral fragments that unequivocally demonstrated the position of methyl branches, as thoroughly documented by previous researchers (e.g., Nelson, 1993; Nelson and Blomquist, 1995). Double bond locations and geometries of monoenes were determined by epoxidation of extracts followed by GC-MS analysis of the resulting derivatives. The epoxides gave large diagnostic fragments from cleavage on either side of the epoxide, unequivocally demonstrating the position of the double bond in the parent molecule. GC-MS analysis of the epoxides of *E* and *Z* isomers determined that the *E* isomers eluted before the *Z* isomers on the DB-5MS column.

There were consistent, sex-specific differences in the hydrocarbon profiles of males and females, with the dominant compounds in solvent extracts of females including 2Me-C₂₆ (peak 1), 2Me-C₂₈ (peak 8), and coeluting 11-, 13-, and 15Me-C₂₉ (peak 12). Extracts of males contained some of the compounds present in females as minor components, but also several longer chain hydrocarbons that were specific to males, primarily alkenes and mono- and dimethyl-branched alkanes.

Solid Phase Microextraction. Samples of cuticular hydrocarbons from female *M. caryae* taken by SPME wipe sampling yielded a profile of hydrocarbons that was similar to that of the whole-body solvent extracts (Table 1; Figure 1 middle and bottom). All components present in SPME samples were also present in solvent extracts. The most conspicuous difference between profiles from solvent extraction and SPME sampling was a 50% increase in the relative amount of Z9:C₂₉ in SPME samples (peak 10, Table 1; Figure 1, middle and bottom; means for two sampling methods significantly different, ANOVA: $F_{1,9} = 8.85$, $P < 0.018$). Z9:C₂₉ was the only one of the dominant hydrocarbons that showed this increase in relative abundance, suggesting that it might be an important component of the contact pheromone of females.

Synthesis of Cuticular Hydrocarbons. Two strategies were used for the synthesis of monomethyl-branched hydrocarbons. The first strategy used Wittig

Route A:**Route B: Building blocks synthesis**

SCHEME 1. Synthetic routes for the preparation of monomethyl branched hydrocarbons.

reaction between a 2-alkanone and the appropriate phosphonium salt to generate methylalkenes, followed by catalytic hydrogenation (Scheme 1, route A). The commercial availability of many 2-alkanones (varying from acetone to 2-octadecanone) and *n*-alkylphosphonium salts rendered this two-step methodology simple and straightforward. Eight methyl-branched hydrocarbons were obtained using route A (Scheme 1), with overall yields varying from 38% to 65% (for details, see online Supplementary Information available for this article, at <http://dx.doi.org/10.1007/s10886-005-9010-y> and is accessible for authorized users). In the first step, the Wittig reaction was nonselective, producing the methylalkenes as mixtures of the *Z* and *E* isomers (ratios, 54:46 to 64:36). The EI mass spectra of these alkenes were characterized by distinct molecular ions (ca. 5–12% of the base peak) and two pairs of enhanced fragment ions, with ions in each pair separated by 15 mass units (Scheme 2). These ions indicated the position of the methyl group in the parent compound, but did not indicate which side the double bond was on. Catalytic hydrogenation of the methylalkenes then produced the desired methyl-branched alkanes, the structures of which can be unambiguously determined by EI mass spectrometry from the small molecular ions, and the enhanced even-mass ions from cleavage

SCHEME 2. EI-mass spectral fragmentation trends for monomethyl branched alkenes. Fragments from 11-methyl-11-pentacosene are illustrated.

on either side of the methyl group with a hydrogen transfer. A small M-15 fragment also was usually observed in the spectra, helping to confirm the M^+ ion.

The second synthetic route was designed to provide a flexible synthesis of compounds for which intermediates were not commercially available (Scheme 1, route B). This strategy is illustrated by the synthesis of 2Me-C₂₆. Thus, a double-ended building block was used, with introduction of the methyl branch at the desired position at one end by coupling a branched alkylmagnesium bromide and an O-protected tosylate with dilithium tetrachlorocuprate catalysis (Burns et al., 1997; Krause and Gerold, 1997). This was followed by deprotection of the other end of the building block and elongation of the chain to the desired length. Our first attempt at chain elongation by oxidation of 15-methylhexadecan-1-ol to the corresponding aldehyde, to be followed by Wittig reaction, failed due to polymerization of the aldehyde. Instead, the alcohol was converted to the iodide, followed by coupling with an alkyne (Corey et al., 1983) and reduction (Scheme 1, route B). Overall, this general strategy is amenable to production of a branched alkane with the branch in any desired position, and any desired chain length. It would also be amenable to the production of chiral hydrocarbons by attachment of a chiral rather than a racemic fragment in the first coupling step.

Bioassays with Fractions and Hydrocarbon Standards. All male *M. caryae* (100% of 200 trials) attempted to mate with freshly freeze-killed females, confirming that mate recognition cues were intact on female carcasses. Males did not respond to dead females after solvent extraction, consistent with earlier studies (Ginzal and Hanks, 2003; Ginzal et al., 2003a,b) and demonstrating that the contact sex pheromone(s) had been removed. None of the males (0 of 200 trials) showed any response to solvent-extracted dead female carcasses treated with pure solvent (controls) that were paired with hydrocarbon-treated females (Fisher's exact test of comparison with response to crude extract, $P < 0.001$).

TABLE 2. RESPONSE OF MALE *Megacyllene caryae* TO SOLVENT-WASHED DEAD FEMALES TO WHICH HYDROCARBON EXTRACTS OR STANDARDS HAD BEEN APPLIED IN DOSAGES OF 0.8 FE

Compound(s)	No. of males tested	Percent of males responding per step in behavioral sequence ^a

Behavior of responding males was categorized according to the natural sequence of mating behavior (see [Methods and Materials](#)). Males did not respond to any of the solvent-washed controls.

^aResponses of males to treatments vs. crude extracts were tested with Fisher's exact tests (* $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$).

^bNumber of males responding to treatments as measured by reaching behavioral step 1 was compared to responses to crude extract (H_0 = treatment and crude extract do not differ in activity).

^cNumber of males reaching behavioral step 4 in response to a treatment was compared to the response to crude extract (H_0 = treatment and crude extract do not differ in activity).

All of the males ($N = 20$) responded to females treated with 0.8 FE of their own crude extract, although only 40% reached behavioral step 4 (mounting the female and attempting to couple the genitalia; Table 2). Males showed a weaker response in behavioral step 1 to fractions (saturated hydrocarbons, branched alkanes, alkenes) of crude solvent extract of female cuticle when compared to their response to crude extract (Table 2), but the proportion of males that reached behavioral step 4 was similar for the saturated fraction and crude extract (Table 2).

We further evaluated the activity of structural classes by testing blends of synthetic components (Table 2). In these bioassays, the number of males re-

sponding (behavioral step 1) to a reconstructed blend of straight-chain alkanes was lower than the response to crude extract, as was the number of males reaching behavioral step 4 (Table 2). A reconstructed blend of branched alkanes did not differ from crude extract in bioactivity for the first step of the behavioral sequence, but no males reached behavioral step 4 (Table 2). Males responded most strongly to the reconstructed blend of the dominant monoenes, and addition of the straight-chain alkanes did not significantly affect activity (Table 2). Similar numbers of males reached behavioral step 4 in response to the blend of monoenes compared to crude extract (Table 2). However, activity of the alkene blend was reduced (no males reaching step 4) when Z9:C₂₉ was eliminated. When tested separately, Z9:C₂₉ elicited a response from males that was equivalent to that elicited by the complete blend of monoenes. Combining Z9:C₂₉ with the blend of alkanes again did not affect the level of response compared to that elicited by Z9:C₂₉ alone (Table 2). Finally, combining Z9:C₂₉ with the dominant methyl-branched alkanes reduced its activity with respect to behavioral step 4 (Table 2).

DISCUSSION

Identification and Bioassay of Cuticular Hydrocarbons. Recent research on several longhorned beetle species in the subfamily Cerambycinae has suggested that mate location and recognition involves three distinct behavioral stages (Ginzel and Hanks, 2005): (1) the sexes are mutually attracted to volatiles emanating from host plants, (2) males on host plants produce volatile pheromones that draw females into their proximity over short or moderate distances (reviewed by Lacey et al., 2004), and (3) males recognize females by contact chemoreception with the antennae (see Ginzel and Hanks, 2003; Ginzel et al., 2003a,b). In the study reported here, the lack of response by male *M. caryae* to solvent-extracted female carcasses, or dead females treated with solvent alone, indicated that contact pheromones were the primary signals used for mate recognition, with tactile or visual cues possibly playing a subordinate role. The activity of Z9:C₂₉ in bioassays indicated that it is an important component of the contact sex pheromone of female *M. caryae*, if not the sole component. Combinations of this compound with other cuticular chemicals failed to identify any synergists. Furthermore, Z9:C₂₉, is a homolog of Z9:C₂₅, the contact sex pheromone of the congener *M. robiniae*. The structural similarity in their contact pheromones is not unexpected given their close phylogenetic relationship. In fact, females of the two species share 13 cuticular hydrocarbons, including Z9:C₂₉ (representing ~1% of the total hydrocarbons of female *M. robiniae*), and another seven of the 30 cuticular hydrocarbons of female *M. caryae* have chain-length analogs in *M. robiniae* (Ginzel et al.,

2003b). Other insect congeners, such as species in the *Drosophila melanogaster* group (Coyne, 1996), are known to share cuticular hydrocarbon components.

The role of Z9:C₂₉ in mate recognition was further supported by its complete absence in males. In fact, extracts from male and female *M. caryae* were qualitatively very different, with sex-specific compounds representing almost half of the hydrocarbons of females and a third of the hydrocarbons of males (Table 1, Figure 1). Extracts from males contained a greater percentage of higher molecular weight, longer chain compounds, as appears to be true for some longhorned beetle species (Ginzel et al., 2003a,b). However, in other cerambycids, including *M. robiniae*, hydrocarbon profiles of males and females are qualitatively more similar, with most components being present in extracts from both sexes (Ginzel et al., 2003a,b).

The male-specific compounds of *M. caryae* may serve as abstinons (chemical deterrents to mating), although this function has yet to be investigated in cerambycids. Other types of insects, such as tsetse fly (Nelson and Carlson, 1986) and the bark beetle *Ips lecontei* Swaine (Page et al., 1997), have sex-based differences in alkyl chain lengths of cuticular hydrocarbons, but with higher molecular weight compounds predominating in females rather than males.

The fact that male *M. caryae* frequently did not exhibit mating behaviors toward solvent-extracted female carcasses that had been treated with their own crude extracts was unexpected, because males of other cerambycid species typically show strong responses to female carcasses treated with extracts of females in identical bioassays (e.g., Ginzel et al., 2003a,b). Males of a congener, *M. robiniae*, may respond more strongly to reconstituted wax layers of females than male *M. caryae* because the contact pheromone was a dominant hydrocarbon in crude extracts (Ginzel et al., 2003b), while that of *M. caryae* was considerably less abundant.

Z9:C₂₉ was not as dominant in hydrocarbon profiles determined by SPME of female *M. caryae* as was the contact pheromone of female *M. robiniae* (Ginzel et al., 2003b). Nevertheless, examination of Figure 1 revealed that Z9:C₂₉ was the only compound among the dominant hydrocarbons that was present in higher abundance in SPME wipe samples than in solvent extracts. These findings support the hypothesis that identification of contact pheromones may be facilitated by comparing hydrocarbon profiles of solvent extracts and SPME, to determine which compounds are present in higher abundance on the surface of the wax layer (SPME) as opposed to throughout the wax layer (solvent extracts).

Acknowledgments—We thank the University of Illinois at Urbana-Champaign (UIUC) Committee on Natural Areas for use of Brownfield Woods for our research, and E. S. Lacey, J. Mohler, K. Rinkenberger, and J. Westberg for assistance in rearing and collecting beetles and

maintaining colonies. This research was in partial fulfillment of a PhD degree for M.D.G. from UIUC. We appreciate funding support from the Alphawood Foundation of Chicago, the U.S. Forest Service (agreement #01-JV-11231300-088), and grants to MDG from the Herbert Holdsworth Ross Memorial Fund of the Illinois Natural History Survey and the UIUC Graduate College.

Abstract—We investigated the origin and chemical composition of the queen sex pheromone of the primitively eusocial bumblebee, *Bombus terrestris* (Apidae). Physiologically and behaviorally active compounds were identified by coupled gas chromatography electroantennography (GC-EAD), gas chromatography-mass spectrometry (GC-MS), and laboratory behavioral tests. In the behavioral assays, virgin queens frozen previously at -20°C were highly attractive to males. Dummies impregnated with surface and cephalic extracts obtained from virgin queens that had been frozen at -50°C were more attractive to males than odorless dummies. Male mating behavior was stimulated by components of cephalic secretions that are smeared onto the cuticle surface by the queen. Overall, 21 compounds present in surface and cephalic extracts evoked electroantennographic responses in male antennae. These included saturated and unsaturated fatty acids, ethyl- and methyl esters of the fatty acids, heptacosene, 2-nonanone, and geranyl geraniol. A blend of synthetic versions of these compounds elicited typical male mating behavior. Since solvent-impregnated dummies were approached by the males, but did not release copulatory behavior, visual cues may be important in the initial

* To whom correspondence should be addressed. E-mail: Manfred.Ayasse@uni-ulm.de

step of stimulating male mating behavior. Close-range olfactory signals are more important for releasing male mating behavior as well as for species recognition. In further behavioral assays, the attractiveness of a frozen virgin queen decreased as the storage time at -20°C increased from 2 hr to 1 d. Therefore, the chemical composition of the sex pheromone may change during freezing as behaviorally active compounds may decompose.

Key Words—Hymenoptera, Apoidea, Apidae, *Bombus terrestris* L., queen sex pheromone, chemical communication, mating behavior, chemical analysis, electroantennography

INTRODUCTION

Chemical communication has reached an advanced and sophisticated form in social insects (Vander Meer et al., 1998). Insect pheromones are often produced by exocrine glands that are modifications of epidermal cells of the integument (Ayasse et al., 2001). Exocrine glands generate an array of biologically active compounds, mediating almost every facet of social behavior in bees (Hymenoptera: Apidae) (Vander Meer et al., 1998). Sex pheromones of bees stimulate one or more behavioral reactions in the opposite sex, bringing the sexes together for the purpose of mating (Shorey, 1973).

In general, little is known about the chemical composition of sex pheromones in bees (Ayasse et al., 2001). Compounds that elicit the copulatory behavior in males have rarely been identified. The first sex pheromone identified in bees was 9-keto-(2*E*)-decanoic acid (9-ODA), a compound produced in the mandibular glands of the queen honey bee, *Apis mellifera* L. (Apidae), and which stimulates mating behavior in drones (Butler, 1971; Gary, 1962). In many bee species, the female sex pheromone is located on the cuticle surface (Ayasse et al., 2001). Isopentenyl esters of unsaturated fatty acids identified in the surface extracts of *Lasioglossum malachurum* (Halictidae) females play a key role in eliciting mating behavior of males (Ayasse et al., 1999). However, the site of production remains unknown. Since bees frequently produce an array of volatiles (Duffield et al., 1984), electrophysiological investigations provide important tools for the identification of potential pheromones in multi-component mixtures. For example, in the solitary bee *Andrena nigroaenea* (Andrenidae), saturated and unsaturated hydrocarbons triggered electroantennographic responses in male antennae (Schiestl et al., 1999, 2000). In field experiments, synthetic forms of these compounds induced copulatory attempts by males.

Bees have evolved a remarkable variety of mating strategies (Eickwort and Ginsberg, 1980). In the genus *Bombus*, mating behavior varies even between species (Haas, 1949). Volatile signals acting at long and/or short distances seem

to play a key role in mating behavior and are produced by either males or females depending on the species' mating strategy (Ayasse et al., 2001). Newman (1851) and, later, Darwin (1886), first described the flight routes of *Bombus* males. In addition, Sladen (1912) noticed that males patrol along more or less fixed flight routes and deposit scent on landmarks. Unmated conspecific queens are attracted by the long-range signals and remain at the marked place of the rendezvous site, until the patrolling male reappears (Bergman, 1997), as is typical for many non-resource-based mating strategies (Alcock et al., 1978). However, many investigations have shown that the male mating signal does not elicit copulation behavior (Free, 1971; Kullenberg, 1973; Tengö, 1979; Borg-Karlson and Tengö, 1986). Female-produced pheromones acting proximally may be responsible for species and sex recognition as well as for eliciting copulatory behavior (Djegham et al., 1994).

Krüger (1951) and Free (1971) were the first to perform behavioral experiments with the objective of localizing the source of sex pheromone production in virgin bumblebee queens. Free (1971) found that isolated heads and thoraces offered to males elicited more copulation attempts than the amputated abdomen alone. Further experiments with a number of bumblebee species (*B. terrestris* L., *B. pratorum*, and *B. hypnorum*) indicated that the mandibular glands are the source of a species-specific queen sex pheromone (Van Honk et al., 1978). Living queens with extirpated mandibular glands stimulated relatively fewer mounting events and copulation attempts by males than did untreated living queens. A study on the chemical composition of glands from mated *B. terrestris* queens revealed that the mandibular glands contain more than 180 compounds (Hefetz et al., 1996). Cahlíková et al. (2004) provided a more detailed description of the composition of secretions of various glands from virgin *B. terrestris* queens. However, to date, no investigations have been undertaken with the objective of identifying the behaviorally active compounds.

B. terrestris, a frequently cultivated species for pollination in greenhouse crops, is one of the best studied bumblebee species with respect to its sociobiology (Röseler et al., 1990). This primitively eusocial species produces a single generation during the summer season in temperate regions (Westrich, 1989). In early spring (March), the fertilized solitary queens leave their hibernaculum and establish monogyne colonies. During the initial period of colony development, the queen first produces workers, whereas in a subsequent phase males and virgin queens are reared (Plowright and Lavery, 1984). Six days after emergence, the sexuals leave the nest for mating (Röseler et al., 1990). The queens normally mate only once (Estoup et al., 1995; Schmid-Hempel and Schmid-Hempel, 2000; Paxton et al., 2001) and hibernate in special chambers in the soil. The mated queens are the only survivors of the original colonies, whereas the workers and males do not overwinter (Wilson, 1971).

We performed behavioral experiments with synthetic compounds and solvent extracts of virgin *B. terrestris* queens; with living and dead frozen queens; and conducted electrophysiological and chemical analyses with these stimuli in order to identify chemical compounds that elicit mating behavior in the males. The objectives of this study were to answer the following questions: (1) Where does the queen sex pheromone originate? and (2) Which volatile compounds are active in stimulating mating behavior in the males? In a further series of behavioral tests, we also investigated whether the attractiveness of dead virgin queens is influenced by storage conditions.

METHODS AND MATERIALS

Sample Collection. Young virgin *B. terrestris* queens, provided by Koppert Biological Systems (The Netherlands), were freeze-killed at -50°C . Surface extracts were obtained by rinsing the whole bodies for 1 min in 0.5 ml diethyl ether (Uvasol, Merck). Subsequently, the heads were dissected from the thorax, the mandibles were gently opened to allow solvent penetration into cephalic glands, and the heads were extracted in 0.2 ml diethyl ether. Extraction lasted for at least 24 hr at room temperature (21°C). Thoraces and abdomens were extracted under the same conditions. Resulting extracts (natural samples) were concentrated to 100 μl /queen equivalent in a water bath (40°C). From each sample (5 queen equivalents), 90% of the total volume was used for behavioral tests and 10% was used for chemical and electrophysiological analyses by gas chromatography with simultaneous flame ionization detection (GC-FID) and electroantennographic detection (GC-EAD).

Attractiveness of Various Groups of Females. In a series of behavioral assays, the attractiveness of frozen virgin queens, frozen workers, and living virgin queens ($N = 8$) to males was investigated. Virgin queens were put in Eppendorf tubes and frozen at -20°C for either 2 hr ($N = 11$) or 1 d ($N = 10$) to investigate whether the attractiveness of dead virgin females is influenced by different storage conditions. An additional group of virgin queens was killed in liquid nitrogen by shock freezing for 3 sec ($N = 17$). Workers were frozen at -20°C for 2 hr ($N = 9$). Before they were offered to males, frozen individuals were kept for 8 min at room temperature and fixed on insect pins (through the thorax). Five types of male behavioral responses were recorded (modified after Van Honk et al., 1978; Djegham et al., 1994): (1) *no attention*—male shows no typical mating behavior and does not react to the female; (2) *approach*—male flies toward a female; (3) *touch*—male hovers in flight with antennal inspection of the female; (4) *mounting*—male mounts the female; and (5) *copulation*—male attempts to copulate with the female by placing his middle legs around her

abdomen and trying to insert his genitalia. To avoid habituation effects, the female position in the flight cage was changed after each test, and males were renewed at least once per day. Each female was only used once per day. To ensure comparable test conditions for the various experimental groups, frozen queens and natural samples were tested alternatively. Behavioral tests with shock-frozen queens were conducted in a glasshouse at the University of Vienna; the other tests were carried out in Utrecht.

Location of the Queen Sex Pheromone. Dead virgin *B. terrestris* queens were exhaustively Soxhlet-extracted with dichloromethane for 48 hr, dried at 45°C in an oven for 12 hr, and fixed on insect pins. During bioassays these dummies served as controls and as solid supports for testing natural or synthetic samples. In a first series of tests in Utrecht (Laboratory of Comparative Physiology, Social Ethology, Univ. of Utrecht), the behavioral activity elicited by dummies impregnated with queen extracts was assayed to locate the source of the sex pheromone in virgin *B. terrestris* queens. Males used for the tests were collected from rearing colonies. Behavioral tests were carried out from 9:00 A.M. to 12:00 noon in a flight cage (50 × 50 × 70 cm). A mercury lamp (HPL-N 250 W; Philips, Vienna) was fixed above the cage to improve light conditions, which in turn increased the flight activity of males (Ayasse, unpublished observation). In each test, a single dummy was treated with 100 µl of a test sample or dichloromethane (solvent control) and offered to seven males simultaneously for 10 min. The test mixture was applied to the body surface by using a microsyringe (Hamilton, 1710N, Bonaduz, Switzerland). Before the treated or control dummy was fixed in the flight cage, the solvent was allowed to evaporate for 1 min. The behavioral responses of males toward the dummies were recorded as described above. Each dummy was only used once per day. After each test, the dummy was Soxhlet-extracted with dichloromethane (200 ml) for 24 hr and dried at 45°C in an oven for 12 hr.

Attractiveness of Synthetic Compounds. Synthetic versions of GC-EAD-active compounds identified from samples that were attractive to males (e.g., surface extracts, cephalic extracts) were mixed in the relative proportions and total amounts as they occurred in natural samples (Table 1). Behavioral assays of these synthetic blends were carried out in a flight cage (60 × 60 × 60 cm) at the University of Vienna. Due to sufficient light conditions in the glasshouse, no mercury lamp was used. Since part of the solution might be trapped in the dummy (Schiestl and Ayasse, 2000), we applied five-female equivalents to each dummy. The attractiveness of each dummy was tested in the flight cage with 30 males simultaneously present for 10 min. Males were obtained from Koppert Biological Systems.

Electrophysiology (GC-EAD). For GC-EAD investigations, 1 µl of a behaviorally active extract was used. Separations were carried out by using an HP 6890 gas chromatograph, equipped with a DB5-MS column (30 m × 0.25 mm ×

^aNumbers are the same as in Figure 3.

^bSignificantly different in both extracts: Mann–Whitney *U* tests, $P < 0.05$.

^cSeparation was impossible.

0.25 μm film thickness; J&W Scientific, Folsom, CA, USA). The following conditions were applied: splitless injection at 50°C for 1 min, temperature program 50–310°C at a rate of 10°C/min, 1.5 ml/min helium as carrier gas, injector and detector temperature 310°C. At the end of the column, a GC effluent splitter (press-fit connection; split ratio 1:1) was used to supply an FID and an EAD, whose signals were simultaneously recorded. To operate the EAD, effluent from the GC column was added to a purified and humidified air stream passed over the excised antenna from a *B. terrestris* male. The tip of the

antenna was cut off, and the antenna was mounted between two electrodes. Each end of the antenna was embedded in electrode gel (spectra 360, electrode gel; Parker Laboratories, Orange, NJ, USA) applied on electrode holders. The EAD signal was transferred via an interface board (IDAC; Syntech, Hilversum, The Netherlands) to a PC. The gel method allows the simultaneous use of several antennae to increase the EAD signal. To discriminate electroantennographic responses from noise, 10–15 GC-EAD runs were performed with each behaviorally active sample. The reproducibility of all responses was checked at the respective retention times. GC-EAD-active compounds were identified by performing GC-EAD runs using reference substances and GC-MS analysis.

Chemical Analyses. Surface extracts and cephalic extracts were analyzed with an HP 5970 GC (Hewlett-Packard, Palo Alto, CA, USA) equipped with a DB5 capillary column (30 m × 0.32 mm, 0.25 µm film thickness; J&W Scientific). The gas chromatograph was operated under the following conditions: splitless at 50°C for 30 sec, followed by a programmed increase to 280°C at 4°C/min, 1.5 ml/min helium as carrier gas, injector and detector temperature of 310°C. For quantitative analysis, 1 µg *n*-octadecane was added to each sample to serve as an internal standard. Structure elucidation of individual compounds was based on coupled gas chromatography-mass spectrometry (GC-MS) analysis (VG70/250 SE instrument; Vacuum Generators, Manchester, England). The MS was linked to an HP 5890 GC (gas chromatographic condition as mentioned above). Mass spectra were compared with those reported in the literature (McLafferty and Stauffer, 1989), and gas chromatographic retention times of unknowns were compared with those of authentic reference samples (by coinjection). Double-bond positions in unsaturated compounds were assigned according to Buser et al. (1983) and Dunkelblum et al. (1985). Structural confirmation was carried out with authentic reference compounds.

Synthetic Compounds. The following compounds were purchased from Aldrich (Taufkirchen, Germany): 2-nonanone, methyl decanoate, methyl tetradecanoate, ethyl tetradecanoate, methyl hexadecanoate, ethyl hexadecanoate, hexadecanoic acid, octadecanoic acid, methyl oleate, oleic acid, methyl linoleate, linoleic acid, linolenic acid. Alkenes and alkenoic acids were prepared by Lindlar hydrogenation (Lindlar catalyst from Lancaster, UK) of the corresponding alkynoic precursors. The latter were synthesized according to laboratory standards (Brandsma, 1988) and purified by column chromatography on silica (Merck 60, 120–400 mesh/hexane); final purity was higher than 95%. Esters were obtained from the corresponding acid chlorides and the appropriate alcohols according to standard laboratory methods. Mass spectra of synthetic compounds were in accord with expected patterns (Francke et al., 2000). The synthesis of optically pure 3-hydroxydecanoic acid has been described earlier (Hefetz et al., 1996).

Statistical Analyses. Since the flight activity of males during the test periods differed and test periods of different lengths were used, male reactions were standardized into a behavioral score (mean proportion of male reaction). The number of male reactions for each of the five behavioral categories was divided by the total number of male reactions and multiplied by 100. The data were analyzed with the SPSS 10.0 statistical system (SPSS Inc., 2000). Since the mean proportion of male reactions elicited by solvent application did not differ significantly (Mann–Whitney U test, $P > 0.05$; Sokal and Rohlf, 1995) between the test series performed either in Utrecht or in Vienna, solvent groups were pooled and used as one control group for all groups. The mean proportions of male reactions (no attention, approach, touch, mounting, and copulation) in the different test groups were compared with the mean proportion of reactions toward the control group with the Mann–Whitney U test (Sokal and Rohlf, 1995). An analysis of variance (ANOVA) followed by a multiple comparison test (LSD test) was used for comparisons among all treatment groups.

RESULTS

*Attractiveness of Various Groups of *B. terrestris* females.* In the test series with whole insects, living queens elicited more copulation attempts from the males compared to dead frozen queens (ANOVA, LSD test, $P < 0.001$; Figure 1). Furthermore, the attractiveness of a queen as a copulatory target was dependent on the freezing duration. Shock-frozen queens elicited the highest amount of copulatory events, whereas males rarely tried to copulate with queens that were frozen 1 d before.

During our behavioral assays, the “no attention” event only occurred with frozen workers and the control. In all test groups, males approached the scented dummies intensively, and there was no difference in this category of response between any of the experimental treatments and the control (Figure 1). The mean proportion of male touch events was lower for 1-d-frozen queens, higher for 2-hr-frozen queens, and highest for shock-frozen queens. The mean proportion of male mounting reactions for each of the queen groups and for the worker group were always significantly higher than that of the control. The result that living queens were seemingly less frequently mounted than frozen or shock-frozen queens can be explained by the higher number of copulation events with living queens. Similar to the touch event with frozen queens, the copulation attempts progressively increased from 1-d-frozen queens via 2-hr-frozen queens to shock-frozen queens (Figure 1). Consequently, under storage conditions of -20°C , the attractiveness of a queen is negatively correlated with the duration of freezing. Frozen workers were attractive to males, but they never stimulated copulatory events.

FIG. 1. Mean proportions of male reaction to virgin frozen and virgin living *Bombus terrestris* queens and workers. Various freezing durations were tested: 2 hr = 2 hr in freezer at -20°C (queens: $N = 11$, workers: $N = 9$); 1 d = 24 hr in freezer at -20°C ($N = 10$); shock = 3 sec in liquid nitrogen ($N = 17$). In the control test, 100 μl of solvent was used ($N = 31$) (* $P < 0.05$; ** $P < 0.001$, relative to control, Mann–Whitney U test).

Location of the Queen Sex Pheromone. Our behavioral tests showed that surface extracts, cephalic extracts, and abdominal extracts (i.e., natural extracts) of virgin queens were each more attractive than the control for several of the behavioral criteria (Figure 2). The cephalic extract stimulated significantly more touching reactions in the males compared to the control. Surface, cephalic, and abdominal extracts elicited a higher proportion of the more intensive male mounting reaction than the control group. Most males showed approaches toward all dummies tested, and there was no difference in approach reactions between various queen extracts tested (ANOVA, LSD test, $P > 0.05$). Males never tried to copulate with impregnated dummies from any treatment group.

Electrophysiologically Active Compounds in Surface and Cephalic Extracts. In GC-EAD experiments with surface and cephalic extracts, we found 21 peaks that elicited electroantennographic responses in male antennae (Table 1, Figure 3). Most of the electrophysiologically active compounds belong to two main chemical classes: fatty acids and various types of corresponding esters.

FIG. 2. Mean proportions of male reaction to natural extracts and mixtures of synthetic compounds from virgin *B. terrestris* queens. In the control test, 100 μ l of solvent was used ($*P < 0.05$; $**P < 0.001$, relative to control, Mann–Whitney *U* test; Syn: mixture of synthetic compounds).

Furthermore, heptacosene, 2-nonanone, and the diterpene geranyl geraniol were identified. The following pairs of compounds could not be separated under the GC conditions used: (*Z*)-13- and (*Z*)-12-heptacosene, as well as linoleic acid and geranyl geraniol. Most of the GC-EAD-active compounds occurred in both surface and cephalic extracts; however, the absolute amounts of single compounds differed. Methyl hexadec-7-enoate, methyl linoleate, and (*Z*)-13-heptacosene/(*Z*)-12-heptacosene were found in similar amounts in surface cephalic extracts (Table 1); all the other compounds differed significantly in quantity. While methyl oleate and oleic acid were found in higher amounts in surface extracts, most of the other compounds were higher in cephalic extracts. 3-Hydroxydecanoic acid was identified in a 250-fold higher amount on the cuticle surface. In some cases, it was difficult to quantify neighboring peaks, because of incomplete separation (Figure 3, peaks 16–20).

Attractiveness of Synthetic Compounds. Mixtures of 21 synthetic compounds (for compositions, see Table 1) identified in surface and cephalic extracts and applied to dummies elicited a higher mounting response than solvent-treated dummies did (Figure 2). The cephalic extract applied to dummies elicited a higher approach index than the solvent-treated dummies. This response exceeded that of all other treatments in this category. Synthetic

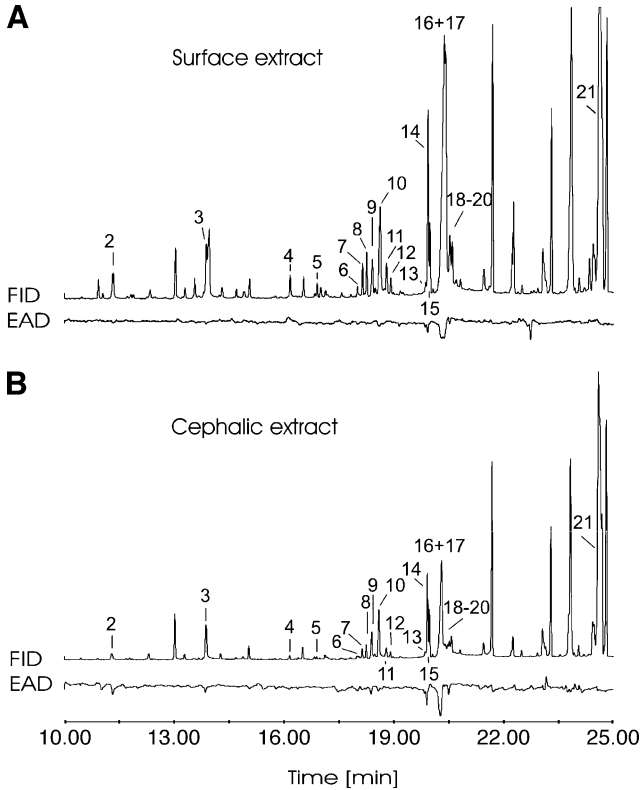

FIG. 3. Gas chromatographic analyses with flame ionization (FID) and electroantennographic (EAD) detection by male *Bombus terrestris* antennae to (A) surface extract of *B. terrestris* queens and (B) cephalic extract of *B. terrestris* queens. Numbered peaks correspond to compounds (Table 1) that elicit electroantennographic responses. To detect all “physiologically active” compounds and to discriminate electrophysiological responses from noise, 10–15 GC-EAD runs were performed for each type of sample to check the reproducibility of responses at the same retention times. Compound no. 1 has a retention time less than 10 min and is therefore missing in the figure.

blends of surface or cephalic extracts elicited smaller amounts of the “no attention” event as compared to the control.

DISCUSSION

How Important are Olfactory Cues in Mate Recognition by B. terrestris Males? In most species of bees, olfactory cues are essential in mate attraction and in eliciting mating behavior in the opposite sex (Ayasse et al., 2001).

However, in certain species, visual stimuli may also play a role for males locating females (Butler, 1965; Meyer-Holzapfel, 1984). Visual cues alone may be responsible for attracting a male toward a female (approaches), whereas volatiles elicit more intense male behavior (touching and mounting). Virgin *B. terrestris* queens seem most willing to mate 6 d after emergence (Gretenkord, 1997), at the time when chemical cues that stimulate premating behavior might be optimally established. Our data support a greater role for olfactory cues than visual stimuli in eliciting intense male mating behavior. Scentless *B. terrestris* dummies elicited significantly lower indices of the more intense categories of male mating behavior (touch, mounting, copulation) than living or dead gynes, or dummies impregnated with extracts of females. It is the shape, color, and size of female bumblebees, i.e., visual cues, which are most important in stimulating male approaches (Free, 1971). In bumblebees, body size might help the males distinguish queens from males and/or workers or other insects from a certain distance.

The importance of olfactory cues is indicated by experiments comparing the attractiveness of living queens with the attractiveness of queens whose mandibular glands had been extirpated (Van Honk et al., 1978). While a similar number of males approached and inspected both groups of queens, more males tried to copulate with untreated queens.

Where is the Sex Pheromone Located? Sex pheromones of female bees are produced in various glands and show a complex chemistry (Ayasse et al., 2001). In many bees, the sex pheromone is associated with the cephalic glands or more specifically with the mandibular glands as in *Bombus* (Free, 1971), *Eucera grisea* (Apidae) (Kullenberg, 1973), *Xylocopa sulcatipes* (Apidae) (Velthuis and Gerling, 1980), *Colletes cunicularius* (Colletidae) (Cane and Tengö, 1981), *Panurgus banksianus* and *P. calcaratus* (Andrenidae) (Tengö et al., 1988), *Nomia* (Apidae) (Wcislo, 1992), and in eusocial stingless bees (Engels et al., 1997). Van Honk et al. (1978) concluded that the compounds stimulating copulatory behavior are produced in the mandibular glands and are smeared onto the cuticle surface. Our results support this idea, since intense male responses were observed when the dummy bees were impregnated with surface and cephalic extracts.

Dispersion of the sex pheromone through grooming onto the cuticle of the queen may explain the attractiveness of the surface extracts (Figure 2). Attractiveness of abdominal extracts can be explained by the continued presence of behaviorally active compounds on the cuticle that were not entirely removed by solvent extraction of the surface. Cuticular lipids of insects have been thought to function primarily to prohibit loss of water (Hadley, 1984). Recent studies have shown, however, that in many insects they do more than prevent desiccation and regulate cuticular permeability. In bees, for example, specific cuticular lipids may function secondarily as sex pheromone components

(Ayasse and Dutzler, 1998; Ayasse et al., 1999, 2001; Schiestl et al., 1999). In most bee species, the site of sex pheromone production remains unclear, and a combination of the secretion from several glands might generate the behaviorally active bouquet on the cuticle surface.

Chemistry and Biology of the Sex Pheromone. In bees, chemical structures of female sex pheromones have been identified in only a few species (reviewed in Ayasse et al., 2001). In the stingless bee, *Scaptotrigona postica* (Apidae), 2-alcohols attracted males, and when combined with 2-ketones, they elicited male copulatory behavior (Engels et al., 1997). Macrocyclic lactones, which are produced in the Dufour's gland, stimulated mating behavior in the social sweat bee, *L. zephyrum* (Smith et al., 1985), and female-produced isopentenyl esters of unsaturated fatty acids play a key role in male mating behavior of *L. malachurum* (Ayasse et al., 1999).

This is the first report on the identification and composition of a female sex pheromone in bumblebees. It consists of fatty acids, various types of corresponding esters, heptacosene, 2-nonanone, and the diterpene geranyl geraniol. In electrophysiological analyses of surface and cephalic extracts, we demonstrated that all compounds triggered receptor potentials in male antennae (Figure 3). In behavioral experiments, synthetic mixtures of these GC-EAD compounds released typical mating behavior of the males. So far, mostly male marking pheromones have been identified (Kullenberg et al., 1970; Vinson et al., 1982; Bergman, 1997; Hovorka et al., 1998; Kindl et al., 1999). In a recent investigation, Cahlíková et al. (2004) gave a detailed description of the composition of secretions of virgin *B. terrestris* queens. They did not, however, perform behavioral experiments to identify the compounds that compose the sex pheromone. In the mandibular glands of virgin and breeding *B. terrestris* queens, about 180 chemical compounds have been identified (Hefetz et al., 1996; Cahlíková et al., 2004). Fatty acids as well as their methyl and ethyl esters are widespread and particularly abundant in bees (Wheeler and Duffield, 1988). They have already been identified as constituents of a sex pheromone in the solitary bee, *Osmia rufa* (Megachilidae) (Ayasse and Dutzler, 1998; Ayasse et al., unpublished data), and they also belong to the EAG-active compounds of *B. terrestris* queens. Many of the chemical compounds that trigger electrophysiological responses in the antennae of male *B. terrestris* antennae also have a pheromonal function in other Hymenoptera. For example, hexadecanoic acid is produced in the Dufour's gland of various *Colletes* bees and is used for nest cell lining (Albans et al., 1980). Ethyl tetradecanoate and ethyl hexadecanoate, which are produced in the female mandibular glands of several species of *Exoneura* (Allodapini), seem to have a defense function against intruders (Cane and Michener, 1983). Ethyl and methyl esters are found on the cuticle surface of honey bee, *A. mellifera*, larvae, and are reported to attract the bee mite, *Varroa jacobsoni* (LeConte et al., 1989).

Aliphatic hydrocarbons are ubiquitous in the Hymenoptera. Alkenes were found to have a function as a sex pheromone in the alfalfa leaf-cutter bee *Megachile rotundata* (Megachilidae) (Paulmier et al., 1999) and in *A. nigroaenea* (Schiestl et al., 2000). In *B. terrestris*, hydrocarbons produced in the tarsal glands, are deposited on rewarding food sources (Schmitt et al., 1991).

The identification of sex pheromones in bees has proven difficult, and in most cases the male reactions elicited by dummies impregnated with mixtures of synthetic compounds were found to be weak (Tengö, 1979; Cane and Tengö, 1981; Bergmark et al., 1984; Smith et al., 1985; Paulmier et al., 1999). There are several conceivable reasons for the diminished behavioral activity that we also registered in our experiments with *B. terrestris*: (1) Pheromone components may be thermally unstable. (2) The physicochemical properties of the dummy surface that accounts for adequate volatilization of the active compounds are not the same as those under natural conditions. Hydrocarbons represent the most abundant group of chemical compounds on the cuticular surface of *B. terrestris* females (Hefetz et al., 1996). Since most of them do not seem to have a communicative function, they may serve to solubilize and slowly release the active pheromone components (Ayasse et al., 2003). The surface of Soxhlet-extracted dummies that we used in our experiments is not covered with those hydrocarbons and does not possess the same physicochemical properties as it does on living or frozen queens. Thus, active compounds may not evaporate in the same proportions. (3) The dummies that were used do not provide important tactile cues. In the *Ophrys* pollination system, flowers not only imitate the females of their pollinators in scent and color, but also in the direction of the hairs on the flower surface in order to attract (and arrest) males for pollination (Ågren et al., 1984; Borg-Karlson, 1990). In behavioral experiments, the physicomachanical properties of the surface of the flower labellum or the female's cuticle are important cues that guide the landed male to a special position in order to initiate copulatory behavior. We cannot exclude the fact that the copulatory behavior of bumblebee males is stimulated by hairs on the cuticle surface of females. The hairs on the surface of the dummies often stick together during Soxhlet extraction and do not have the same arrangement as the hairs on a living female. Therefore, the tactile cues are probably missing. (4) The solvent extracts of the cuticle surface used in our bioassay may contain compounds that diminish the attractiveness of impregnated dummies. It has been shown that during copulation *B. terrestris* males transfer a sticky gelatinous product of their accessory glands, the so-called "mating plug," into the genital chamber of the queens (Duvoisin et al., 1999). Components of this mating plug are four fatty acids (palmitic acid, linoleic acid, oleic acid, stearic acid), which we also found in *B. terrestris* queen extracts (and which generated EAD responses in male antennae), as well as the 2,5-diketopiperazine made up of two proline molecules (Baer et al., 2000). Baer et al. (2001) performed behavioral assays showing that

linoleic acid in a queen's genital chamber reduced her willingness to mate and might repel mating attempts by *B. terrestris* males. Linoleic acid is a common natural product that can be found in the fat body of insects as well as on the cuticular surface (Lockey, 1988). Wasps use linoleic acid and oleic acid to repel ants (Dani et al., 1996). Since the queens that we used in our experiments were unmated and since linoleic acid is a compound that occurs in the hemolymph and fat body, a possible explanation for the lack of copulatory attempts in our experiments with cuticle extracts could be that linoleic acid was extracted from one of the cuticular layers of the queens. In future investigations, samples from the cuticle surface should be collected by solid phase microextraction (SPME) (Liebig et al., 2000), which permits sampling from the outer surface of the cuticle only. Chemical analyses of these samples may show the abundance of linoleic acid in various layers of the cuticle lipids.

Since *B. terrestris* males tried to copulate with frozen queens, the sex pheromone is still present and can be stabilized by freezing (Figure 1). Unlike the behavioral tests with frozen queens, no copulation attempts of males were recorded in tests with dummies impregnated with natural extracts. The temperatures and the duration of freezing may influence the chemical composition of the sex pheromone. While shock-frozen queens were highly attractive, queens stored at -20°C lost attractiveness with increasing freezing duration. In conclusion, elevated temperature combined with long freezing duration has a negative effect on the biological activity of the sex pheromone.

Questions concerning the loss of activity in natural extracts with time remain to be clarified. None of the compounds listed in Table 1 is supposed to rapidly decompose, nor should proportions of relevant components change under the storage conditions that we used. Assuming that the "active principle" is produced in the mandibular glands (see above), it is interesting to consider the relative ratios of electrophysiologically active components found in surface and cephalic extracts. Some compounds occurred preferentially in cephalic extracts in highly biased proportions (Table 1). Among these, methyl decanoate, 3-hydroxydecanoic acid, and 2-nonanone may be biogenically closely related: β -oxidation of a decanoyl precursor would yield the corresponding β -keto acyl compound, which could be easily transformed to 3-hydroxydecanoic acid or decarboxylated to 2-nonanone. The intermediate, 3-oxodecanoic acid or even its methyl ester would easily decompose on the injection port of a GC yielding 2-nonanone (W. Francke, unpublished data) and remain invisible upon analysis. Continuous production and release of β -ketoacids by a live organism may, however, generate a powerful chemical signal. We regard 3-oxodecanoic acid or a homolog as well as (*S*)-hydroxydecanoic acid (Hefetz et al., 1996) as reasonable candidates and are testing these compounds with respect to their behavior mediating capacity in sexual interactions of bumblebees.

Role of Sex Pheromones in the Mating Biology of B. terrestris. The function of sex pheromones in insects is to bring the sexes together for mating and to stimulate courtship behavior and copulation (Shorey, 1973). In *B. terrestris*, female- and male-produced compounds act as sex pheromones. Males establish flight routes that they patrol and along which they deposit a species-specific scent mark that acts as a premating, attractive signal to virgin queens (Bergman, 1997). After a virgin queen has landed in the patrolling area of a male, the pheromone produced by the female stimulates the mating behavior of males patrolling in close vicinity (Bergman, 1997). Our experiments with frozen females and dummies showed that visual cues attract males from a distance. At close range, olfactory cues are responsible for eliciting copulation behavior from a conspecific male. *B. terrestris* workers do not mate, and in our behavioral assays male reactions toward workers were intense, but males never attempted copulation. Free (1971) made similar observations with *B. pratorum*. Males reacted to workers but did not try to copulate. Djegham et al. (1994) suggested that the female sex pheromone does not elicit immediate copulation attempts. Alternatively, the sex pheromone, in addition to its role as a species-specific sex attractant, seems to have a contextual effect where it acts like an aphrodisiac.

Our understanding of how the sex pheromone operates should benefit from future investigations that focus on the role of temperature and its effect on the chemical composition of the sex pheromone. Future mating tests should examine the effect of single compounds on the whole sequence of precopulatory mating behaviors.

Abstract—In spite of the importance of chemoreception in social organization and sexual selection of lizards, there is a lack of general knowledge on how the characteristics of chemical signals mediate these behaviors. Moreover, it is unknown which are the mechanisms that might confer honesty to the information provided by chemical signals. We analyzed here whether characteristics of the lipophilic fraction of femoral gland secretions of *Lacerta monticola* male lizards can be related to the morphology, physical condition, and health state of the sender. Our results indicated that some male traits, such as body size, number of blue spots, and number of femoral pores and their level of fluctuating asymmetry, were related to variability in the relative proportions of some lipophilic chemical compounds found in secretions. Thus, conspecifics could obtain reliable information on the producer of a scent mark based on chemicals alone, and this might be the basis of female choice observed in this lizard. Moreover, only males with a greater T-cell immune response had higher proportions of two steroids (ergosterol and dehydrocholesterol) in their femoral secretions, which might suggest that the signal is honest and costly to produce. We suggest that only high-quality males could divert these compounds from metabolism to secretions in order to produce an exaggerated and honest “chemical ornament.”

Key Words—Lizards, femoral glands, fatty acids, steroids, condition-dependent signaling, sexual selection.

INTRODUCTION

While insect chemical ecology has received a great deal of interest in the last five decades, considerably less is known about many comparable aspects of vertebrate chemical ecology (Eisner and Meinwald, 1995; Wyatt, 2003). For example, despite the importance of chemoreception in social organization of many vertebrates, such as mammals or reptiles (Stoddart, 1980; Mason, 1992; Wyatt, 2003), there is a lack of general knowledge on how the characteristics of chemical signals mediate these behaviors. Chemical cues play an important role in the intraspecific communication of lizards (Mason, 1992). Several studies have shown pheromonal detection in different species, which is often based on precloacal and femoral gland secretions (e.g., Alberts, 1993; Labra and Niemeyer, 1999; Aragón et al., 2001a). The femoral pores are epidermal structures on the ventral surface of the thigh of many squamates connected to glands that produce copious amounts of holocrine secretion. The secretory activity of the femoral glands is greatest in the mating season, males produce more secretion than females, and androgens can influence their development and maintain their activity (reviewed in Mason, 1992; Alberts, 1993).

Studies have described the chemical composition of skin or gland secretions in a few species of lizards (Chauhan, 1986; Weldon and Bangall, 1987; Alberts, 1990; Mason and Gutzke, 1990; Weldon et al., 1990; Alberts et al., 1992; Escobar et al., 2001, 2003; López and Martín 2005a). Secretions are composed of both proteins and lipids, but the latter are thought to be the main compounds involved in communication (Mason, 1992). The presence and relative concentration of chemical components in femoral glands secretions seem to vary not only between sexes, but also consistently among individuals, which may convey information on the individual identity and serve a variety of functions (Alberts, 1993). For example, the ventral location of the femoral pores suggests that secretions are passively deposited on the substrate as lizards move through their home ranges. Moreover, behavioral experiments showed that scents of male lizards could advertise residence in a home range, and/or could convey information about the social status and competitive ability of the sender (Aragón et al., 2001a,b, 2003; López and Martín, 2002). Experiments have also suggested that secretion from the femoral pores might transmit chemical information about a male's traits or genetic compatibility, which may be used by female lizards in mate choice (Martín and López, 2000; López et al., 2002, 2003; Olsson et al., 2003). Therefore, chemoreception may be especially important in social organization, and play an important role in sexual selection processes in lizards (López and Martín, 2004). However, the role of specific chemical compounds as chemical signals in sexual selection of lizards remains largely unknown.

Sexual selection suggests that male sexual ornaments or signals may allow females or male rivals to evaluate a male's quality. However, if signaling were based on features that are not directly related to an individual quality, individuals might benefit from "cheating," that is, signaling at too high a level (Krebs and Dawkins, 1983). Thus, theoretical models have predicted that signals can only be evolutionarily stable if they are honest and condition-dependent, or costly to the signaler, and if the cost is correlated with the signaler's quality (Zahavi, 1975; Pomiankowski, 1988; Grafen, 1990; Zahavi and Zahavi, 1997). Although evidence for indicator models of sexual selection has been found in many empirical studies (see reviews in Jennions et al., 2001; Kotiaho, 2001), research has focused almost exclusively on visual or acoustic signals, often ignoring chemical signals (but see Penn and Potts, 1998; Rantala et al., 2003; Zala et al., 2004). Because parasitic infections and health state seem to affect the information conveyed by chemical signals (Penn and Potts, 1998; Zala et al., 2004), it is possible that pheromones also function as condition-dependent signals of mate quality. However, in vertebrates, it is unknown which are the mechanisms that might confer honesty to information provided by chemical signals.

The Iberian rock lizard (*Lacerta monticola*) is a small, diurnal lacertid lizard found mainly in rocky habitats of some high mountains in the Iberian Peninsula (Pérez-Mellado, 1998). Differential tongue flick rates to chemicals presented on cotton swabs and on substrate deposits have demonstrated that males can detect and discriminate between self-produced scents from the femoral pores and those of conspecific males, and between odors of familiar and unfamiliar males (Aragón et al., 2001a). Thus, scent-marked substrates may function in home range advertisement to other males (Aragón et al., 2001b), but also be used by females to choose mates (Martín and López, 2000; López et al., 2002, 2003).

In this paper, we examined whether characteristics of the lipophilic fraction (i.e., composition and relative proportions of each compound) of femoral secretions of males can be related to the morphology, physical condition, and health state of the sender. By examining the type of chemicals found in secretions, and how their proportions vary with the characteristics of males' traits and with their health state, we explored whether allocating specific compounds to femoral secretions can be condition-dependent. Thus, we aimed to understand how honesty of information contained in chemical signals could be achieved.

Specifically, we first examined whether chemical signals may give information on male traits known to play an important role in intrasexual selection and social organization between males. Thus, we measured morphological traits that reflect the social dominance of male lizards. Body and head size are known to determine the outcome of intrasexual agonistic contests, with males having larger body size and relatively larger heads being

more dominant (López et al., 2002). Also, many male lizards show a conspicuous row of small but distinctive blue spots that runs along the body side on the outer margin of the belly. The number of blue spots may function as a long-distance visual signal enhancing body size of older/dominant males (López et al., 2004).

Second, we examined whether chemical signals may give reliable information on male traits potentially used by females in intersexual selection processes (i.e., mate choice). Previous studies have suggested that female *L. monticola* preferred scents of males with more femoral pores and with a symmetric number of femoral pores in each leg (Martín and López, 2000; López et al., 2002). Symmetry presumably indicates the developmental stability of an individual and, thus, its ability to cope with genetic and environmental perturbations during development (Møller and Swaddle, 1997). Females may also select males based on their body condition and health state, which might affect the content of chemical signals (Penn and Potts, 1998; López et al., 2002; Rantala et al., 2003). During the mating season, the intensity of hemoparasite infection was greater in male than in female *L. monticola*, and parasite load had a negative effect on body condition (Amo et al., 2004). Thus, parasite load might be an indication of a lizard health state. Immune function can also be used as an indicator of health state of an animal (Sheldon and Verhulst, 1996; Westneat and Birkhead, 1998; Svensson et al., 2001), and females of other lizard species might base their mate choice on the quality of the males' immune system (López and Martín, 2005b).

METHODS AND MATERIALS

Lizards' Morphological Measurements. We captured (by noosing) 68 adult male *L. monticola* from May 17 to June 22, 2003, which coincided with the mating season of lizards, in different places over a 5-km² area ("Puerto de Navacerrada," Guadarrama Mountains, Central Spain). Only adult lizards with intact or fully regenerated tails were considered. We measured lizard body size with a ruler [snout-to-vent length (SVL), $\bar{x} \pm \text{SE} = 72 \pm 1$ mm; range = 63–78 mm) and their weight with a pesola spring scale ($\bar{x} \pm \text{SE} = 7.0 \pm 0.1$ g; range = 4.7–9.0 g). Head height ($\bar{x} \pm \text{SE} = 8.2 \pm 0.1$ mm; range = 7.0–9.5 mm) was measured with a digital caliper (to the nearest 0.01 mm) as the greatest vertical distance through the snout from the highest portion of the head to the bottom of the lower jaw. We removed the influence of body size on head height measurements by regressing each against SVL (all variables log-transformed) and used the residuals in further analyses. We also noted the number of blue spots on each side of the lizards and calculated an average number for both sides ($\bar{x} \pm \text{SE} = 6.0 \pm 0.3$ spots/side; range = 0–13.5 spots/side).

We counted under a magnifying glass the number of femoral pores on the right and left hindlimbs of males. Individuals with symmetric femoral pores are also more symmetric in several other meristic characters (P. López and J. Martín, unpublished data). We have previously shown that counts of femoral pores are highly repeatable, and that the absolute value of asymmetry of the femoral pores (asymmetry values ranged between -2 and $+2$), calculated as the unsigned right-minus-left number of pores, exhibits the properties of fluctuating asymmetry (FA) (Møller and Swaddle, 1997; see Martín and López, 2000, for statistical analysis of FA of femoral pores in this lizard species).

Lizard Condition and Health State. To assess differences in the physical condition of otherwise similar individuals, we calculated the body condition of each individual as the residuals from the regression equation of body mass (in g) on SVL (in mm), both variables log-transformed, which may represent an index of the relative amount of fat stored, and, hence, an estimation of individual physical condition or nutritional status (Bonnet and Naulleau, 1994).

To examine hemoparasite load, a smear was made on a microscope slide from blood taken from the lizards' postorbital sinus by using one 9- μ l heparinized hematocrit tube. Blood smears were air-dried. The smears were fixed in absolute methanol for 10 min and then stained in Giemsa diluted 1:9 with phosphate buffer (pH 7.2) for 40 min before their examination for parasites. The only hemoparasites found in this population were intraerythrocytic hemogregarines (Amo et al., 2004). Parasite intensity was estimated for each lizard by counting at $400 \times$ the number of infected red blood cells found in approximately 2000 cells ($\bar{x} \pm SE = 0.75 \pm 0.16$ infected cells in 2000 erythrocytes; range = 0–9.11).

To assess the T-cell-mediated immune (CMI) response, we used a delayed-type hypersensitivity test, the phytohemagglutinin (PHA) injection test. This is a reliable measure of T-cell-dependent immunocompetence *in vivo* (Lochmiller et al., 1993), which has been used in numerous studies on many animals including lizards (Svensson et al., 2001; Belliure et al., 2004). A subset ($N = 34$) of all captured lizards were individually housed at "El Ventorrillo" Field Station (Navacerrada, Madrid Province), 5 km from the capture site in outdoor opaque plastic cages (80 \times 50 cm) containing rocks for cover. We marked a point with permanent ink on the foot pad of both hindlimbs. We then measured the thickness at this point with a pressure-sensitive spessimeter (to the nearest 0.01 mm) to standardize pressure during measurements. Immediately after, we injected 0.02 mg PHA dissolved in 0.01 ml phosphate-buffered saline (PBS) water in the right foot pad, and the same volume of PBS in the left foot pad. Lizards were released in their terraria, and after 24 hr we measured again the foot pad thickness at the marked points. The CMI response was calculated as the difference between pre- and postinjection measures on the right foot pad (PHA injected) minus the same difference on the left foot pad (control, PBS injected)

(CMI, $\bar{x} \pm \text{SE} = 0.52 \pm 0.06$ mm; range = 0.10–0.93 mm) (Belliure et al., 2004). The only appreciable effect of the PHA injection was a slight swelling of the skin due to the immune response, which disappeared after 48 hr. No lizard showed any sign of stress or pain for these tests, and all looked healthy. The same day, lizards were released to their initial sighting location prior to the capture.

Extraction of Femoral Gland Secretions and Analyses of Chemicals. Immediately after capture, we gently pressed with forceps around the femoral pores of male lizards, and directly collected secretion in glass vials with Teflon-lined stoppers. Vials were stored at -20°C until analyses. We also used the same procedure on each sampling occasion, but without collecting secretion, to obtain blank control vials that were treated in the same manner to compare with the lizard samples, to exclude contaminants from the handling procedure or from the environment where lizards were found, and for further examining impurities in the solvent.

Samples were analyzed with a Finnigan-ThermoQuest Trace 2000 gas chromatograph (GC) fitted with a poly(5% diphenyl/ 95% dimethylsiloxane) column (Supelco, Equity-5, 30 m length \times 0.25 mm ID, 0.25- μm film thickness) and a Finnigan-ThermoQuest Trace mass spectrometer (MS) as detector. We injected in the splitless mode 2 μl of each sample (dissolved immediately before the analyses in 250 μl *n*-hexane; Sigma, capillary GC grade). Column temperature was kept at 50°C for 10 min, then raised to 280°C at a rate of $5^{\circ}\text{C}/\text{min}$, and maintained at this temperature for 30 min. Initial identification of secretion components was done by comparison of mass spectra in the NIST/EPA/NIH 1998 computerized mass spectral library. Impurities identified in the solvent and/or the control vial samples were not considered. Identifications were confirmed by comparison of spectra and retention times with those of authentic standards (from Sigma-Aldrich Chemical Co.).

Statistical Analyses. In total, 41 chemical compounds were identified in femoral gland secretions (see López and Martín, 2005a). The relative amount of each component was determined as the percent of the total ion current (TIC). Then, we selected the peaks that represented $>0.1\%$ relative peak area and that were present in all individuals (which altogether represent 98% of the total TIC area) to reduce the number of variables to be used in multivariate statistical analysis (Aitchison, 1986; Dietemann et al., 2003). The relative areas of the 28 selected peaks were restandardized to 100% and transformed following Aitchison's formula: $[Z_{ij} = \ln(Y_{ij} / g(Y_j))]$, where Z_{ij} is the standardized peak area i for individual j , Y_{ij} is the peak area i for individual j , and $g(Y_j)$ is the geometric mean of all peaks for individual j (Aitchison, 1986). The homogeneity of variance of these variables was tested with Levene's test, and Bonferroni's correction was applied. Only 26 variables had homogeneous variances and were considered. The transformed areas were used as variables in a principal component analysis (PCA). To examine whether we could use

proportions of chemicals to predict the characteristics of each of the variables describing the morphology, condition, and health state of lizards, we used forward stepwise general regression models (GRM) with the six principal components (PC) extracted as potential predictors. Because some morphological and health measures might be related to body size, we included SVL in some of the initial models as a potential predictor. The relationship between FA in femoral pores and PC scores describing chemical compounds was estimated by using generalized linear models (GLZM), with the absolute value of femoral pores symmetry following a binomial distribution ($\chi^2 = 0.11$, $P = 0.74$).

RESULTS

Chemicals in Femoral Secretions. The lipophilic fraction of femoral secretion of *L. monticola* is a mixture of steroids (mainly cholesterol) and carboxylic acids that range between $n\text{-C}_6$ and $n\text{-C}_{22}$, and their esters, but we also found alcohols, ranging from 16 to 22 carbons, and squalene (Table 1). On average, the five most abundant chemicals were cholesterol (71.4% of TIC), campesterol (5.9%), dimethyl cholesta-5,7-dien-3-ol (5.0%), hexadecanoic acid (3.9%), and octadecenoic acid (2.4%). The PCA for relative proportions of chemical compounds in femoral gland secretions produced six components [principal components (PCs)] with eigenvalues greater than 1 that together accounted for 77.3% of the variance (Table 1).

Lizard Morphology and Chemicals. Stepwise general regression modeling (GRM) showed that (snout-to-vent-length SVL) of lizards was positively correlated with PC-1 and PC-3 ($R^2 = 0.14$, $F = 5.28$, $df = 2,65$, $P = 0.007$) (Table 2). A similar relationship was found for body mass ($R^2 = 0.16$, $F = 6.22$, $df = 2,65$, $P = 0.003$). Therefore, secretions of lizards of different size/age were different. For example, larger lizards had secretions with relatively higher proportions of steroids such as cholesterol, campesterol, or sitosterol, and of nonanoic, dodecanoic, and octadecanoic acids, among others, and lower proportions of cholesta-5,7-dien-3-ol, and of octadecadienoic, hexadecenoic, and octanoic acids (see Table 1).

With respect to the traits that may be indicators of social status between males, relative head height was not significantly correlated with any PC, but the number of blue spots was positively correlated with PC-4 and negatively correlated with PC-5 ($R^2 = 0.12$, $F = 4.59$, $df = 2,65$, $P = 0.01$) (Table 2). Thus, lizards with a higher number of blue spots have lower proportions of chemicals such as docosanol, dimethyl-cholest-en-ol, or ergosta-dien-ol, and higher proportions of tetradecanoic and eicosanoic acids.

Femoral Pores and Chemicals. Lizards had an average (\pm SE) of 18.7 ± 0.2 (range = 16–23) femoral pores on each leg. The number of femoral pores was

^aMarked correlations are significant at $P < 0.001$.

not related to body length ($R^2 = 0.01$, $F = 0.69$, $df = 1,66$, $P = 0.41$). The number of femoral pores was negatively correlated with PC-1 ($R^2 = 0.11$, $F = 8.42$, $df = 1,66$, $P = 0.005$) (Table 2). Thus, lizards with more femoral pores had secretions with relatively higher proportions of cholesta-5,7-dien-3-ol, and octadecadienoic and hexadecenoic acids, but lower proportions of steroids such as cholesterol or campesterol, and nonanoic and dodecanoic acids (Table 1).

The value of fluctuating asymmetry (FA) in femoral pores was negatively correlated with PC-2 (GLZ model, intercept: Wald's $\chi^2 = 44.18$, $P < 0.001$; PC-2: Wald's $\chi^2 = 5.26$, $P = 0.02$) (Figure 1). Thus, more symmetric lizards have relatively higher proportions of hexadecanoic and octadecenoic acids,

and lower proportions of cholesta-3,5-diene, and cholesta-4,6-dien-3-ol (Table 1).

Lizard Health and Chemicals. Body condition was not significantly correlated with any PC, but the CMI immune response was negatively

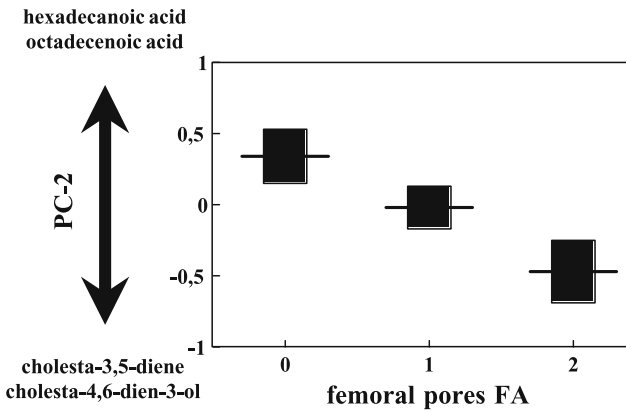

FIG. 1. Principal component analysis (PCA). PC scores (mean \pm SE) of male lizards with different fluctuating asymmetry (FA) values in their femoral pores, in the PC-2 axis extracted in a PCA for relative proportion of chemicals in their femoral gland secretions.

FIG. 2. Principal component analysis (PCA). Relationship between the PC-6 axis, extracted in a PCA for relative proportion of chemicals in femoral gland secretions of male lizards, and their T-cell-mediated immune (CMI) response.

correlated with PC-6 ($R^2 = 0.35$, $F = 17.48$, $df = 1,32$, $P < 0.001$) (Table 2). Thus, lizards with relatively higher proportions of ergosterol and cholesta-5,7-dien-3-ol in their femoral secretions have a better health state, as indicated by their greater CMI immune response (Figure 2). Hemoparasite load was not significantly correlated with any PC, although it was negatively related to CMI immune response ($R^2 = 0.19$, $F = 7.73$, $df = 1,32$, $P = 0.009$). Thus, males with a higher CMI response had a lower parasite load.

DISCUSSION

Our results indicate that some of the morphological traits of male *L. monticola* lizards, and also their health state, can be inferred from variability in the relative proportions of lipophilic chemical compounds found in their femoral secretions. Thus, conspecific lizards could obtain reliable information on the producer of a scent mark by assessing the information provided by chemicals contained in the signal. Lizards have a well-developed vomeronasal system and are able to make discriminations of many different scents, from prey, conspecifics, or predators, based on chemicals alone (Mason, 1992; Cooper, 1994). However, only a few studies have examined whether lizards can discriminate between different types of chemical compounds (Cooper and Pérez-Mellado, 2001; Cooper et al., 2001, 2002). These studies showed that the lacertid lizard, *Podarcis lilfordi*, can discriminate between lipids, proteins, and carbohydrates (Cooper et al., 2001), and also among different lipids such as

glycerol, cholesterol, and oleic and hexadecanoic acids (Cooper et al., 2002). It is likely that lizards may discriminate between many other similar chemicals found in femoral secretions and used in social contexts.

Behavioral experiments made with *L. monticola* lizards had previously indicated that lizards may discriminate among different individuals according to their morphological traits based on their scent alone. For example, the responses of males to scent marks of other unfamiliar males depended on the body size difference between both males (Aragón et al., 2001b), which suggested that males can assess body size and associated competitive ability of unknown males. The results of the current study indicate that body size could be inferred from the variability in chemicals found in femoral secretions. The number of lateral blue spots also correlated with the proportions of some specific chemicals. The number of spots seems to be a character showing ontogenetic change, as older males (territorial and dominant) showed more blue spots than younger ones (sneakers and subordinate) (López et al., 2003, 2004). These chemicals may be actually related to age and, thus, indirectly to the potential social status of a male. In contrast, we did not find any direct relationship between chemicals and relative head size or body condition, two morphological traits directly related to the social status of males of similar age (López et al., 2002). Females preferred to associate with substrates scent marked by older males (López et al., 2003). Females may increase their opportunities to mate with better males, because viability selection leads to older males of higher genotypic quality than younger males. Alternatively, females may select territorial old males to avoid harassment by sneaking young males. If the variation in compounds present in femoral secretions were directly related to age-related differences in, for example, hormonal levels, then chemical signals would be a reliable indicator of male age/size.

Previous experiments showed the following results. When we offered the scents of two male *L. monticola* of similar age and body size, females associated preferentially with scents of males with low FA in their femoral pores, and also with scents of males with a higher number of femoral pores (Martín and López, 2000; López et al., 2002). This suggested that chemical signals enabled the females to assess the males' ability to produce femoral secretions. The results of the current study indicated that the proportion of some chemical compounds are related to the number of femoral pores, and, moreover, to FA in this character. Particularly, lizards with more pores and more symmetry had relatively higher proportions of cholesta-5,7-dien-3-ol and unsaturated fatty acids, such as octadecadienoic, hexadecenoic, and octadecenoic acids, but lower proportions of steroids, such as cholesterol or campesterol, and short-chain saturated fatty acids. However, at this stage, we cannot prove (but see below) that there is a direct relationship between the proportions of these compounds in secretions and the "quality" of a male.

Also, there was a clear relationship between the CMI immune response of a male and femoral secretions with higher proportions of ergosterol and cholesta-5,7-dien-3-ol (=dehydrocholesterol). Ergosterol was also occasionally found in some individuals of the iguanid lizard *Liolaemus fabiani* (Escobar et al., 2003), but all male *L. monticola* examined presented these two steroids. Interestingly, proportions of these varied greatly among individuals (Ergosterol, range = 0.11–2.51% of TIC, coefficient of variation = 61.2%; Dehydrocholesterol, range = 0.05–0.99% of TIC, coefficient of variation = 90.5%). This suggests that their variability may be a good indicator of variability in the male immune system characteristics, which might be used by females to select mates. In fact, female *Podarcis hispanica* lizards prefer male scents that signal a better CMI response (López and Martín, 2005b). Our data also suggest that the signal might be honest and costly to produce, as only males with a greater CMI response had higher proportions of these two steroids in their femoral secretions.

Signals used to indicate the quality of a male should be costly to produce or to maintain, and should be condition-dependent, in order to be honest and evolutionarily stable (Zahavi, 1975; Pomiankowski, 1988; Grafen, 1990; Zahavi and Zahavi, 1997; Kotiaho, 2001). Knowledge of the biosynthesis and metabolic function of the specific chemical compounds of lizards will enable us to understand the mechanisms that relate “quality” of a male with these compounds. For example, cholesta-5,7-dien-3-ol present in the skin is transformed into vitamin D₃ after exposition to sun UV-B irradiation (Fraser, 1995; Carman et al., 2000). Vitamin D₃ is essential in calcium metabolism of lizards and other vertebrates (Allen et al., 1994; Laing and Fraser, 1999). Therefore, by allocating this precursor of vitamin D₃ to femoral secretions, males are diverting it from other metabolism. Such a divergence might be especially costly for low-quality individuals if they do not have enough body reserves of this steroid. Moreover, as hypervitaminosis D produces soft tissue calcification, the excess of its precursor might be partly eliminated in femoral secretions. In any case, its presence in high proportions in femoral secretions would indicate honestly the quality of metabolism in a male. In addition, vitamin D₂ has to be acquired from the diet, as only fungus can convert it from ergosterol under UV irradiation (Hay and Watson, 1977). It remains possible that ergosterol and vitamin D₂ were associated in invertebrate prey eaten by these lizards, and that the amount of ergosterol in femoral secretions was an indicator of the amount of vitamin D₂ that the male was able to acquire from the diet.

Similarly, the octadecadienoic (=linoleic) acid, found in higher proportions in secretions of males with more femoral pores, is an essential fatty acid that lizards must obtain through their dietary intake, as desaturation of oleic acid to linoleic acid occurs only in plants. Linoleic acid is involved in the maintenance of the epidermal water barrier (Hansen and Jensen, 1985). Animals require this acid for the production of n-6 and n-3 polyene acids, which are precursors of

prostaglandins, prostacyclin, and thromboxanes that mediate a wide range of physiological responses (Ziboh et al., 2000). Its presence in high proportions in femoral secretions might be costly and indicates the ability of a male to obtain it from the diet in sufficient quantity for maintaining both metabolism and the scent signal.

In other systems of sexual signals, the costs of producing and maintaining components of the immune system may have a major effect on condition, thus creating a link between immune system and condition-dependent sexual advertisement (Wedekind, 1992; Wedekind and Folstad, 1994). A trade-off is expected if sexual advertisement and immune responses use the same resources (Kotiaho, 2001). Only individuals in good condition apparently can mount a strong immune defense and produce an extravagant sexual ornament (Sheldon and Verhulst, 1996; Westneat and Birkhead, 1998). Our results show a relationship between immune response and the presence of cholesta-5,7-dien-3-ol and ergosterol in secretions. Thus, it seems that only males with a high CMI immune response might afford to allocate high proportions of these potentially costly chemicals to femoral secretions to produce an exaggerated and honest “ornament.”

We conclude that chemical compounds in femoral secretions of lizards may provide reliable information on the morphological traits and health state of a male. Further experimental studies are needed to test whether chemical signaling is costly and honest, which would clarify the basis of the mechanisms of sexual selection processes based on chemoreception observed in this and other lizard species.

Abstract—The event chain leading to germination blockage in durum wheat (*Triticum turgidum* ssp. *durum* Desf.) seeds exposed to the allelochemical coumarin (2*H*-chromen-2-one) was studied. The physiological and biochemical aspects thought to be critical for a successful seed germination were measured. At concentrations above 200 μM , coumarin inhibited seed germination in a concentration-dependent manner. Inhibition occurred early during seed imbibition (phase I), was rapid, and irreversible. During phase I, coumarin inhibited water uptake, electrolyte retention capacity, and O₂ consumption. Later on, coumarin delayed the reactivation of peroxidases, enhanced the activity of superoxide dismutase, decreased the activities of selected marker enzymes for metabolic resumption, and repressed the transcription of molecular chaperons involved in secretory pathways. Insufficient and/or late seed rehydration caused by coumarin could have delayed membrane stabilization or decreased respiratory O₂ consumption, both of which are conducive to an overproduction of reactive O₂ species. Being unbalanced by an adequate upsurge of antioxidant defense systems, the resulting oxidative stress might have ultimately interfered with the germination program.

Key Words—Allelochemicals, coumarin, seed germination, antioxidants, molecular chaperons, durum wheat, *Triticum turgidum* ssp. *durum* Desf.

INTRODUCTION

Coumarins form a large class of allelochemicals widely distributed in both natural plant communities and crops (Zobel and Brown, 1995). Being localized on the leaf, seed surface, and pollen wall, and released into the environment by living plants or by decomposing plant material, coumarins are involved in ecological interactions in both managed and natural plant communities (Rice, 1984; Zobel et al., 1991; Bertin et al., 2003; Bais et al., 2004).

Coumarin (2*H*-chromen-2-one), the simplest compound of this class, affects root form and function (Abenavoli et al., 2001, 2004), decreases respiration and photosynthesis (Moreland and Novitzky, 1987), and influences nitrogen uptake and metabolism (Abenavoli et al., 2001, 2003). Coumarin is a strong inhibitor of seed germination. This may confer an advantage to the producing plant species by reducing competition in its immediate environment, and/or by delaying germination of its own seeds under unfavorable conditions (Zobel and Brown, 1995).

To explain this inhibitory action, coumarin has been hypothesized to be either a blocker of the cell cycle (Zobel and Brown, 1995), uncoupler of oxidative phosphorylation (Ulitzer and Poljakoff-Mayber, 1963; Khan and Zeng, 1985), or to interfere with amino acid transport and protein synthesis (Van Sumere et al., 1972). Aliotta et al. (1992, 1993) reported that coumarin is an inducer of coat-imposed dormancy through the inhibition of water uptake during seed imbibition. Such a multiplicity of proposed roles suggests that the key mechanism(s) by which coumarin affects seed germination remains to be identified.

In the present work, we looked at the early events leading to the blockage of germination in durum wheat (*Triticum turgidum* ssp. *durum* Desf. cv. Simeto) seeds exposed to coumarin. To fulfill such an aim, and keeping as a reference scheme the triphasic germination time course (Bewley, 1997), the effects of different coumarin concentrations were evaluated on relevant physiological and biochemical processes associated with seed imbibition and germination.

METHODS AND MATERIALS

Germination Experiments. Seeds of *T. turgidum* ssp. *durum* Desf., cv. Simeto were surface-sterilized for 20 min into 20% (v/v) NaClO solution, and rinsed several times with sterile distilled water. Fifteen seeds were evenly placed into Petri dishes (9 cm diam) on moist filter paper soaked with 5 ml sterilized aqueous coumarin solution adjusted to pH 5.8, whose final concentrations ranged from 0 to 1000 μM . Seeds were incubated in darkness in a growth chamber at 24°C and 70% RH. Seeds showing at least a 2-mm-long extrusion of the radicle after 36 hr of imbibition were considered to have successfully completed their germination. Germination counts were expressed as percentages of the total number of seeds.

In a series of recovery experiments, Simeto seeds were exposed to 0, 100, or 1000 μM coumarin for 1, 3, 6, 12, or 24 hr and then transferred under sterile conditions onto filter paper containing 5 ml sterile distilled water until the end of germination (36 hr). This is referred to as the *ab initio* experiments. In a complementary set of experiments aimed at evaluating the time window that coumarin inhibition is effective, the Simeto seeds were initially placed into distilled water for 1, 3, 6, 12, or 24 hr and then exposed to 0, 100, or 1000 μM coumarin for the time remaining to complete germination (36 hr). This is referred to as the *in itinere* experiments.

Water Content. The amount of water taken up by the seeds was determined as the percent increase in weight of imbibed seed with respect to the initial dry weight of the seed (Aliotta et al., 1994; Baskin et al., 1998). Prior to weighing, seeds were paper-blotted for 10 sec.

Respiration. Oxygen consumption in germinating seeds was measured with a Clark-type electrode (Hansatech Ltd., King's Lynn, UK). For each measurement, two seeds (approx. 150 mg fw each) were placed for approximately 20 min into a cuvette containing 1 ml air-saturated distilled water at $25 \pm 0.5^\circ\text{C}$.

Electrolyte Leakage. For each measurement, 2.0 g seeds (ca. 15 seeds) were bathed in 0, 100, or 1000 μM aerated coumarin solutions (20 ml) and incubated at 25°C for 10 min. The conductivity of the solution was then measured by a MPC227 conductimeter (Mettler-Toledo, Greifensee, Switzerland).

Assays of Metabolites and Enzymes. After 1, 3, 6, 12, 24, or 36 hr during imbibition, seeds were collected, immediately frozen with liquid N_2 , and kept at -80°C until used. Frozen seeds were ground in liquid N_2 , with mortar and pestle. The fine powder (ca. 1 g) was then homogenized with 4 vol. of ice-cold 0.1 M HEPES buffer (pH 7.50), made with 5 mM 2-mercaptoethanol, 10 mM MgCl_2 , 2 mM dithiothreitol, 2 mM Na_2 ethylene diamine tetraacetic acid, 0.1 mM phenylmethylsulfonyl fluoride, 1% (w/v) bovine serum albumin, and 1% (w/v) insoluble polyvinylpyrrolidone. To measure the ascorbate peroxidase (APX) activity, 1 mM ascorbic acid (AsA) was added to the grinding buffer

(Amako et al., 1994). When assaying the glutathione (GSH) pool, 0.1 N hydrochloric acid was used as the extraction medium (Schwanz et al., 1996). The supernatants, obtained after filtering the seed extracts through four layers of cheesecloth and centrifuging at $39,000 \times g$ for 30 min, were used as sources of analytes.

All tested metabolites and enzymes were assayed spectrophotometrically (Lambda 5 double-beam spectrophotometer; Perkin-Elmer, Norwalk, CT, USA), essentially as reported by Sanità di Toppi et al. (2005). Ascorbate peroxidase activity (EC 1.11.1.11) was monitored by following the oxidation of AsA at 290 nm in the presence of H_2O_2 as the cosubstrate. Superoxide dismutase activity (SOD, EC 1.15.1.1) was followed by the superoxide-dependent oxidation of hydroxylamine to nitrite, followed by the colorimetric detection of nitrite at 540 nm; by intercepting O_2^- , SOD is able to inhibit the final colorimetric reaction in a concentration-dependent manner. Catalase activity (CAT, EC 1.11.1.6) was determined by following the consumption of H_2O_2 at 240 nm. Dehydroascorbate reductase activity (DHAR, EC 1.8.5.1) was monitored at 265 nm as it was formed from dehydroascorbic acid (DHAsA). Monodehydroascorbate reductase activity (MDHAR, syn. ascorbate free radical reductase, EC 1.6.5.4) was determined by following the NADH consumed to reduce the monodehydroascorbate radical generated from AsA by the action of ascorbate oxidase. Ascorbate and DHAsA were assayed according to the method Wang et al. (1991), in which the AsA-mediated reduction of Fe^{3+} to Fe^{2+} is followed by the formation of a red chelate among Fe^{2+} and 4,7-diphenyl-1,10-phenanthroline (bathophenanthroline), which absorbs at 534 nm. A standard curve covering the range 0–10 nmol AsA was used. Total and oxidized glutathione (glutathione disulfide, GSSG) were measured by following the 5,5'-dithiobis(2-nitrobenzoic acid)-GS-SG reductase recycling procedure proposed by Griffith (1985); GSSG was determined after removal of GSH from the plant extracts by derivatization with 2-vinylpyridine. Changes in absorbance of the reaction mixtures were measured at 412 nm and 25°C. GSH was determined by subtracting GSSG (as GSH equivalents) from the total glutathione content.

Glucokinase activity (GluK, EC 2.7.1.1) was determined by monitoring the rate of glucose-6-phosphate dehydrogenase-coupled reduction of $NADP^+$ (Espen et al., 1995). Malate dehydrogenase activity (MDH, EC 1.1.1.37) was determined by following the NADH oxidation by α -oxalacetate at 340 nm (Queiroz, 1969). Glucose-6-phosphate dehydrogenase activity (G6PDH, EC 1.1.1.49) was assayed by measuring the reduction of NADP to NADPH in the presence of glucose-6-phosphate (Deutsch, 1983). Pyruvate kinase activity (PyrK, EC 2.7.1.40) was determined by monitoring the rate of NADH oxidation at 340 nm (Pirovano et al., 1996). Both α -amylase (α -AMY, EC 3.2.1.1) and β -amylase (β -AMY, EC 3.2.1.2) activities were determined by monitoring the release of maltose units (assayed against a maltose standard at 546 nm) at 25°C, by using soluble starch as the substrate. α -AMY activity was measured at pH

7.0, and β -AMY at pH 4.8, a value that renders α -AMY inactive (Bergmeyer et al., 1983).

Total soluble protein was estimated according to the method of Bradford (1976) using bovine serum albumin as the standard. All of the above analyses were performed at 4°C.

Nucleic Acid Extraction and Analysis. The procedures used for total RNA extraction, its electrophoretic (25 μ g per sample) transfer to nylon membrane, prehybridization, hybridization and washing of the nylon filters, and Northern blotting were the same as employed by Ciaffi et al. (2000).

cDNA probes were labeled by incorporating digoxigenin-11-dUTP via polymerase chain reaction (PCR), following the method of Ciaffi et al. (1999). As DNA templates, the following sequences were used: *PDICDW-FI-RI* (AJ277379), a 1.695-kbp reverse transcription (RT)-PCR product containing the entire coding sequence of protein disulfide isomerase (*PDI*) gene obtained from ripening caryopses of *T. turgidum* ssp. *durum* cv. Langdon and cloned into pGEM[®]-T (Promega Italia, Linate, Italy; Ciaffi et al., 2000); a partial 1.0-kbp cDNA clone [in pBluescript[®] (SK-)] coding for the luminal binding protein (BiP), isolated from *Triticum aestivum* L. (Grimwade et al. 1996); an RT-PCR product isolated from *T. aestivum* by using a pair of primers designed based on the thioredoxin *h* (*TRX*) gene sequence reported by Gautier et al. (1998).

Experimental Replication and Statistics. Each reported value represents the mean of measurements carried out at least in triplicate and obtained from three independent experiments \pm SD. Two-way ANOVA was performed for germination (*ab initio* and *in itinere* experiments), water content, conductivity, O₂ uptake, and the antioxidant metabolites and enzyme activity parameters, to test the effects of coumarin concentration and time of imbibition. The data were checked for deviations from normality and homogeneity of variances prior to analysis. *A posteriori* comparisons were carried out using the Tukey test to check the significant differences of each parameter among coumarin concentrations within each time of imbibition.

One-way ANOVA and, then, *a posteriori* comparisons by Tukey's test were carried out to check the significant differences of germination parameters (dose-response curve) among the coumarin concentrations. Statistical analysis was conducted using the Systat v.8.0 software package (SPSS Inc., Evanston, IL, USA).

Nucleic acid extraction and analysis were carried out on seeds obtained from three independent experiments.

RESULTS

Seed Germination. Two hundred μ M coumarin was the concentration threshold beyond which coumarin inhibited seed germination (Figure 1a). A

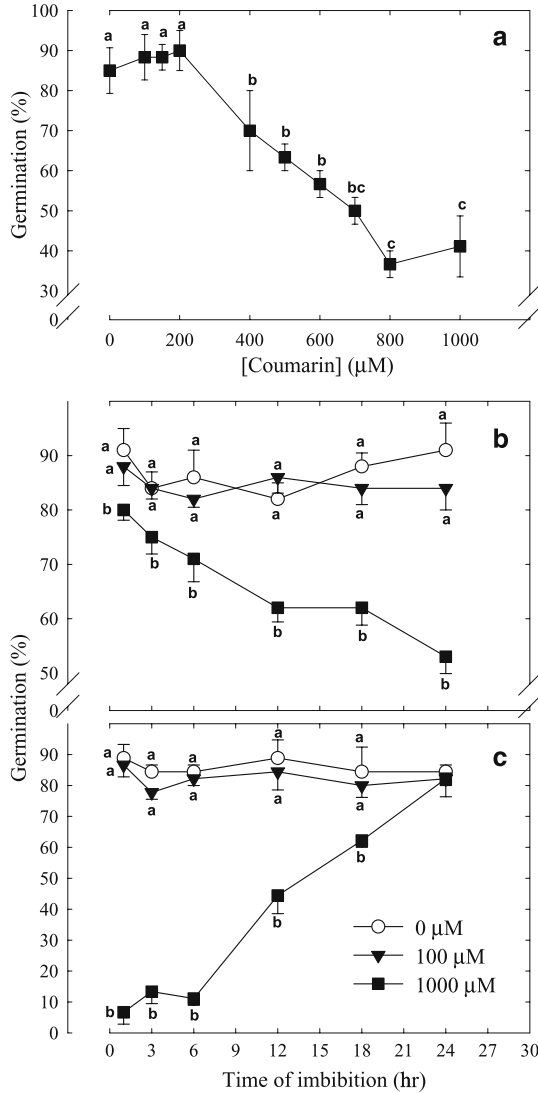

FIG. 1. Effects of coumarin on the germination of durum wheat cv. Simeto seeds. (a) Dose-response curve; (b) the *ab initio* experiment: seeds were exposed to coumarin for the indicated times and transferred into water until completion of germination (36 hr); (c) the *in itinere* experiment: imbibition started in water followed by exposure of the seeds to coumarin for the indicated times. Each value is the mean \pm SD ($N=9$). (a) Different letters indicate significant difference at $P < 0.05$ (Tukey's test). (b, c) Different letters within time of imbibition groups indicate significant difference among treatments ($P < 0.05$, Tukey's test). No letters within time of imbibition groups indicate no significant difference among the treatments ($P > 0.05$, Tukey's test).

maximum of more than 60% inhibition was reached with the highest coumarin concentration, i.e., 1000 μM . No macroscopic change in morphology was observed in coumarin-inhibited seeds (not shown).

Based on Figure 1a, 100 and 1000 μM were adopted in the subsequent experiments as representatives of the no-effect and of the inhibitory coumarin concentration ranges, respectively.

Exposing seeds to different coumarin levels was interrupted at variable periods, allowing them to recover in distilled water (36 hr; referred to as the *ab initio* experiment in [Methods and Materials](#)). A 1-hr exposure to 1000 μM coumarin was sufficient to cause a 20% inhibition of germination. Inhibition increased almost linearly with increasing exposure to the allelochemical, reaching 50% inhibition after 24 hr (Figure 1b).

In a complementary experiment, seeds were first placed into distilled water for variable periods, and then exposed to coumarin until the end of germination (36 hr; the *in itinere* experiment). Exposure to 1000 μM coumarin 1, 3, or 6 hr after the beginning of imbibition, but not to 100 μM at these same times, inhibited germination up to 90% with respect to control seeds (Figure 1c). However, inhibition was significantly decreased when seeds were exposed to 1000 μM coumarin either 12 or 18 hr after the beginning of imbibition, and completely disappeared when the treatment was administered after 24 hr (Figure 1c).

Early Events in Germination. After 1 hr exposure, either 100 or 1000 μM decreased the amount of water taken up by seeds by about 40 or 80%, respectively (Figure 2a). However, seeds recovered to the control level after 3–5 hr. Thereafter, coumarin had no remarkable effect on water (Figure 2a).

A thirty min exposure to 1000 μM coumarin, but not 100 μM , caused a 20% higher solute leakage with respect to the control, and this remained constant until the end of the experiment (Figure 2b).

Respiratory O_2 consumption showed a complex, apparently multiphasic, pattern both in control and in treated seeds (Figure 2c). Coumarin tended to abolish the burst of O_2 consumption during phase I, in a concentration-dependent manner. Both 100 and 1000 μM significantly potentiated the respiratory burst occurring during phase II.

Antioxidant Systems. During germination, AsA was often almost undetectable, although drastic but transient increases were observed after 3 or 12 hr of exposure to either 100 or 1000 μM , respectively (Figure 3). In contrast, the concentration of its oxidized form, DHAsA, was higher and appeared to drastically increase from 24 hr of imbibition onwards, but not in the presence of 1000 μM coumarin.

In the case of GSH, balance among the reduced and oxidized form (GSSG) was almost constantly in favor of the former during germination (Figure 3). However, at the beginning of imbibition, seeds contained almost exclusively GSSG, which increased after 1 hr of water uptake (phase I), regardless of the

presence of coumarin. Control and 1000- μM -treated seeds showed almost identical GSH and GSSG profiles, whereas 100 μM coumarin decreased the GSH level and increased the GSSG level (Figure 3).

In both treated and control seeds, APX activity was detectable only after 24 hr of imbibition (phase III; Figure 3). Enzyme activity dramatically increased thereafter, except in 1000- μM -treated seeds, where only 25% of control activity was present after 36 hr. In contrast, both DHAR and MDHAR activities were detectable, in both treated and control seeds, during the early stages of imbibition (Figure 3). Coumarin (1000 μM) inhibited MDHAR activity after 1 hr of imbibition and then again after 24 hr (about -70% compared to control), a 30% reduction compared with control seeds and being apparent at the end of germination.

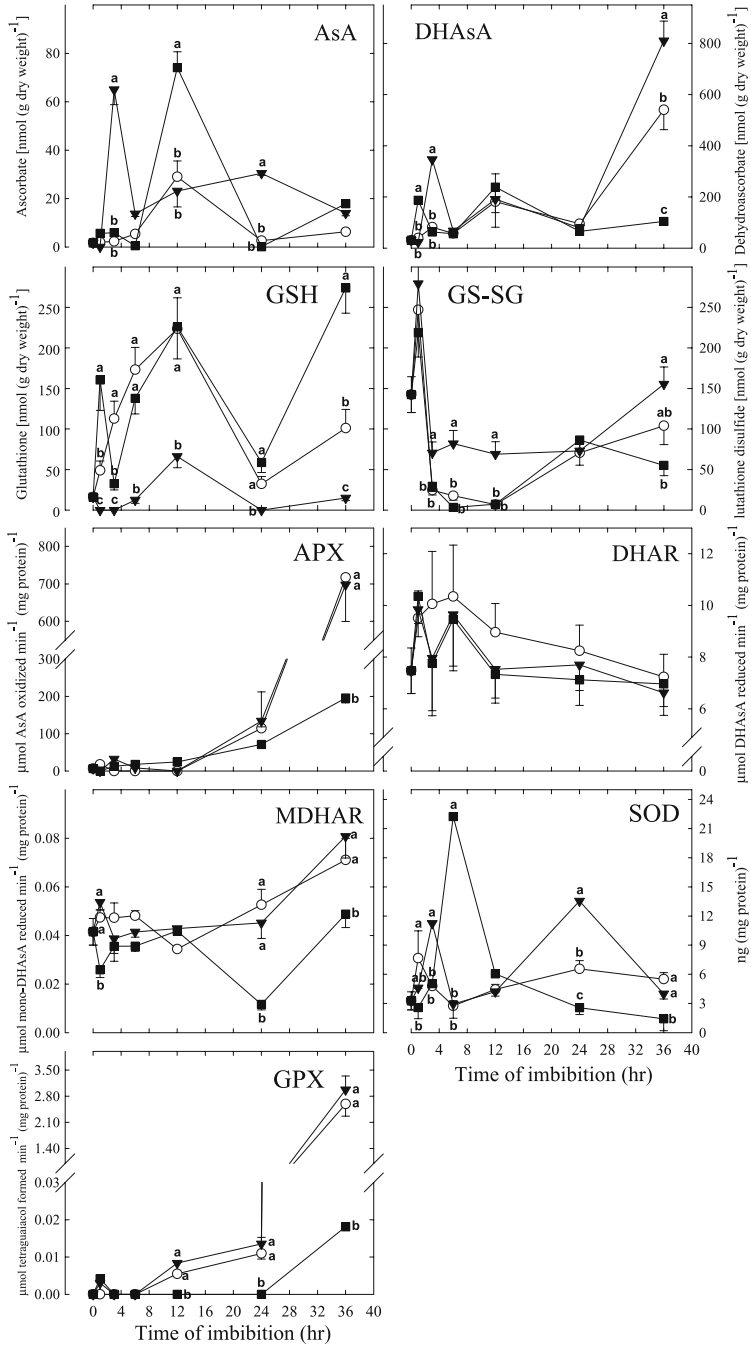

Like APX, GPX activity was also undetectable during the first 12–24 hr of imbibition, with its latency prolonged by the presence of 1000 μM coumarin. Again, like APX, GPX activity increased dramatically during the 12- to 36-hr period up to 400-fold. However, the late burst of activity was almost completely abolished in seeds exposed to 1000 μM coumarin (Figure 3).

Contrary to the peroxidases, SOD activity peaked during the early periods of imbibition (phase I; Figure 3). Coumarin delayed the early upsurge and increased its amplitude, in a concentration-dependent manner. A second peak in SOD activity occurred after 24 hr of imbibition (phase III), but not in the 1000- μM -treated seeds. No CAT activity was detected in germinating seeds.

Marker Enzymes for Metabolic Reactivation. Enzymatic markers for metabolic reactivation, such as α - and β -AMY (starch mobilization), GluK and PyrK (reactivation of glycolysis), G6PDH (oxidative pentose phosphate pathway, OPPP), and MDH (Krebs cycle) were all detectable from the start of germination (Figure 4).

From 12 hr onwards, 1000 μM coumarin caused a 20% decrease in α -AMY activity. This same coumarin level also prevented the gradual increase in GluK activity that occurred in control seeds during the first 12 hr of imbibition, and caused a 20–40% inhibition of enzyme activity through the end of the experimental period. Coumarin at 100 μM also had an inhibitory effect during the early stages of germination, but GluK tended to recover to the control level during phase III. No clear difference among the treatments was observed for

FIG. 2. Water uptake during germination of Simeto seeds in the presence of varying levels of coumarin (a). Solute leakage in germinating Simeto seeds exposed to different levels of coumarin (b). Oxygen consumption in germinating Simeto seeds exposed to different levels of coumarin (c). Symbols for coumarin levels as in Figure 1c. Roman numerals and dotted lines are intended to indicate different phases during seed germination. Each value is the mean \pm SD; $N = 3$. Statistics as in Figure 1b, c.

PyrK and MDH activities. G6PDH was initially depressed by the presence of 1000 μM coumarin, but from 3 hr of imbibition onwards there was no significant difference with respect to the control. Conversely, this same activity was stimulated by the presence of 100 μM coumarin during phase III.

Molecular Chaperones and Protein-Modifying Enzymes. The time courses for *BiP* and *PDI* transcript accumulation were similar (Figure 5). In both cases, a weak Northern hybridization signal appeared after 1 hr of imbibition (phase I) and tended to increase in intensity thereafter. A strong *BiP* and *PDI* hybridization signal appeared after 24 hr of imbibition in the presence of 0 and 100 μM coumarin, but not in 1000- μM -treated seeds. Compared to *BiP* and *PDI*, *TRX* transcripts were abundant from the early stages of imbibition, and did not increase thereafter (Figure 5). In contrast to *BiP* and *PDI*, 1000 μM coumarin enhanced the accumulation of the *TRX* transcripts from 6 hr of imbibition onwards.

DISCUSSION

Our results confirm that coumarin inhibits seed germination (Aliotta et al., 1992, 1994) and that a threshold concentration of about 200 μM is required for inhibition to occur in durum wheat seeds. Notwithstanding, 100 μM coumarin was employed here because it is more representative of the levels of cinnamic acid derivatives commonly found in soils (Macias, 1995).

Coumarin inhibited durum wheat germination in a concentration-dependent manner. Inhibition by coumarin was rapid, apparently irreversible, and cumulative, as it increased along with increasing time of exposure. Our results suggest that coumarin irreversibly blocks or prevents one or more key germination event(s) during phase I or early phase II. Weak or no inhibitory effects were observed when seeds were exposed to the allelochemical during phase III.

Aliotta et al. (1994) reported that inhibition of radish seed germination caused by 5-methoxypsoralen, which belongs to the coumarin family, was associated with an inhibition of water uptake. Such inhibition only became

FIG. 3. Antioxidant metabolites [ascorbate (AsA) and glutathione (GSH)], and their respective oxidized forms [dehydroascorbate (DHAsA) and glutathione disulfide (GS-SG)], and antioxidant enzymes [ascorbate peroxidase (APX), superoxide dismutase (SOD), and guaiacol peroxidase (GPX)] and antioxidant-regenerating enzymes [dehydro- (DHAR) and monodehydroascorbate reductase (MDHAR)], in germinating Simeto seeds exposed to different levels of coumarin. Symbols for coumarin levels as in Figure 1c. Each value is the mean \pm SD ($N = 3$). Statistics as in Figure 1b, c.

evident during phase II and was protracted during phase III. In the present work, coumarin reduced water uptake during phase I, but the decrease was recovered during phase II. This suggests that germination arrest occurred during phase I. Interestingly, both 100 and 1000 μM coumarin inhibited water uptake, but only

FIG. 5. Typical Northern blot hybridization profile of the luminal binding protein (BiP), protein disulfide isomerase (PDI), and thioredoxin *h* (TRX) mRNA transcripts accumulation during the germination of Simeto seeds exposed to different levels of coumarin. the latter inhibited seed germination. Only the lesser coumarin concentration allowed reaching that minimal rehydration threshold during phase I that must be achieved for the germination program to be successfully executed.

Water influx into the cells of dry seeds provokes a transient perturbation to membrane structure, which causes an immediate and rapid leakage of solutes into the surrounding medium. After a short time of rehydration, stable configuration is restored and solute leakage stops (Bewley, 1997). Here, as a consequence of early inhibition of water uptake, 1000 μM coumarin could delay, or even prevent, the recovery of a stable membrane configuration. Indeed, phenolic compounds can induce rapid depolarization of plant membranes (Glass and Dunlop, 1974) as well as peroxidation of membrane lipids (Baziramakenga et al., 1995), both of which lead to an increased efflux of solutes.

Interference with membrane functions, and/or delay in taking up an adequate amount of water (Bove et al., 2001), might also explain the early inhibition of O_2 consumption induced by 1000 μM coumarin during phase I. Indeed, Moreland and Novitzky (1987) suggested that coumarins, being able to perturb the membrane systems that sustain electron transport, can inhibit both respiration and photosynthesis.

Water uptake, membrane perturbation, and resumption of respiration may all promote the generation of reactive oxygen species (ROS), including superoxide radical anion, hydroxyl radical, and H_2O_2 , during seed germination (De Gara et al., 1997). However, ROS scavenging may be problematic during germination because, in dry seeds, SOD, which converts superoxide into H_2O_2 , is present with modest activity. Likewise, APX, which removes toxic levels of H_2O_2 , is almost absent during the early stages of germination (De Gara et al., 1997; Figure 3). Therefore, a primary antioxidant strategy during the early stages might be reduction of DHAsA to AsA by using GSH as the electron donor, which is catalyzed by DHAR. Indeed, our results indicate that during the early stages of germination, seeds are substantially devoid of AsA, APX, and CAT activities, but contain DHAsA and show DHAR activity. Coumarin at 1000 μM inhibited DHAR and MDHAR activities, and decreased DHAsA levels, but this occurred only during phase III, i.e., after the arrest of germination had already occurred. Late effects of coumarin were also apparent as far as the glutathione pool and redox ratio is concerned.

Delayed resumption of APX activity could leave the 1000- μM -treated seeds without an adequate ROS scavenging capacity during germination, things being made worse by the absence of a measurable CAT activity. De Gara et al. (1991) reported that a decrease in APX activity may be related to a loss of seed germination capacity in *Dasypyrum villosum* (L.) Borb. Again, however, the coumarin-dependent inhibition of APX reactivation, albeit drastic, became apparent in a late stage of the germination process, so that it probably cannot be regarded as the primary target of coumarin action.

In contrast, the drastic and transient increase in SOD activity induced by 1000 μM coumarin was much closer in time to phase I, during which coumarin-induced arrest of germination was supposed to occur. This transitory stimulation of SOD activity might indirectly indicate a need to face an early burst of superoxide production. However, neither superoxide nor H_2O_2 , the product of SOD catalysis, were measured in this study.

Instead, 1000 μM coumarin prevented the activation of the other peroxidase, GPX, well in advance of phase III. This suggests a rather direct link, on a time basis, with the unknown early event targeted by coumarin. IAA at supraoptimal concentrations may inhibit germination of apple seeds and thus participate in the maintenance of dormancy (Nikolaeva et al., 1987). We might speculate that the 1000- μM -treated seeds, being deficient in GPX, were also lacking in IAA oxidase activity (Foyer et al., 1997). The resulting excess of IAA could then contribute to the blocking of germination. If, instead, a major role of GPX during seed germination is protection from oxidative damage (Stacy et al., 1996), then lack of GPX activation might worsen the consequences of APX inhibition (see above), thus further weakening the overall ROS scavenging capacity of the 1000- μM -treated seeds. According to Bewley

(1997), within a few hours from the beginning of imbibition, glycolysis, OPPP, and the Krebs cycle are activated and seeds achieve their full metabolic status. Since a limited number of marker enzymes was considered here, and coumarin's effects on their *in vivo* activity could not be evaluated, considering the results obtained with 1000 μM coumarin, no obvious failure in the reactivation of the main ATP- and NAD(P)H-producing pathways is apparent.

In germinating cereal seeds, α -AMY activity is rapidly induced through *de novo* synthesis and secretion of the enzyme by the aleurone layer. In contrast, β -AMY is constitutive, deposited during seed development in a zymogenic form, which is converted into the active enzyme during germination (Kruger, 1979). Khan (1969) reported that 340 μM coumarin completely inhibited α -AMY synthesis in barley seeds. Accordingly, here, 1000 μM coumarin inhibited α -AMY activity, but such effect only became evident in an advanced stage of germination.

One function of the endoplasmic reticulum (ER) is to synthesize a large group of vacuolar or secreted proteins, such as proteases, hydrolases, and amylases. Among the intrinsic components of the ER, central roles in the correct folding, and oligomerization, and formation of disulfide bridges of nascent secretory proteins are assigned, respectively, to chaperonine-like enzymes, such as BiP, and to protein-modifying enzymes, such as PDI. The former is likely to bind transiently to all nascent protein chains and to associate permanently to malfolded proteins; the latter is a member of the thioredoxin superfamily, responsible for the introduction and isomerization of disulfide bonds that are often present in secreted- and cell surface proteins (Ciaffi et al., 2000). Coumarin (1000 μM) had opposite effects on the transcript abundances of ER-resident- (BiP and PDI) and of cytosolic molecular chaperons (TRX h in the present study). Livesley et al. (1992) reported that the germination rate of bread wheat (*T. aestivum* L.) seed populations was correlated with the PDI activity of microsome-enriched fractions extracted from the aleurone layer. Our results indirectly support these findings and suggest that one coumarin target could be the transcriptional activation of genes involved in the assemblage and stabilization of secretory proteins, which could decrease α -AMY synthesis and secretion (Figure 4), eventually affecting storage mobilization and metabolic reactivation during seed germination. On the other hand, early increase in the TRX transcript abundance suggests that exposure to 1000 μM coumarin causes oxidative perturbation in the cytosol, requiring the activation of compartment-specific mechanisms of redox homeostasis.

In summary, beyond a concentration threshold of about 200 μM , coumarin was able to rapidly and significantly inhibit the germination of durum wheat seed during the early stages of imbibition. This inhibitory effect produced a series of changes that were either transitory (e.g., the inhibition of seed water uptake), too late to be directly traceable to the early arrest during the ger-

mination process, or whose extent was much lower than proportional to the severity of the inhibition observed. As a result, we cannot precisely identify the primary structure or function targeted by coumarin. Neither can we assess whether one or more critical events were affected.

We are prompted to speculate that, in Simeto seeds exposed to 1000 μM coumarin, a less-than-sufficient rehydration in the very early stage of imbibition may prevent or delay the attainment of a stable configuration of membrane systems. This could lead to a prolonged loss of osmotically active substances and substrates, and delay resumption of respiration. A reduced utilization of O_2 as the terminal electron acceptor may lead to an increase in mitochondrial $p\text{O}_2$, and result in an electron overflow. Both of these conditions are conceivably conducive to increased ROS generation. This may explain the observed drastic increase in SOD activity during phases I–II, with compensatory purposes, which could in turn result in a burst of H_2O_2 . H_2O_2 overproduction could escape the control operated by the endogenous scavenging systems, since both GPX, during phase II, and APX, later on, failed to reactivate in the 1000- μM -treated seeds. This may eventually cause oxidative stress, which explain the enhanced transcription, already occurring during phase II, of genes involved in redox homeostasis, such as *TRX*. Since redox regulation is of critical importance for most, if not all, processes in the aerobic cell, including signal perception and transduction, cell-to-cell communication, and the cell cycle itself (Foyer et al., 1997), an altered redox balance caused by exposure to coumarin may ultimately hamper, or even block, the execution of the germination program.

Abstract—The structural and biosynthetic diversity of allelochemicals in plants is thought to arise from selection for additive toxicity as a consequence of toxin mixture or for enhanced toxicity as a result of synergism. In order to understand how insects cope with this type of plant defense, we tested the effects of some allelochemicals in host plants of the black swallowtail *Papilio polyxenes* on the xanthotoxin-metabolic activity of CYP6B1, the principal enzyme responsible for the detoxification of furanocoumarins in this caterpillar. Additionally, the effects of some synthetic compounds not normally encountered by *P. polyxenes* on CYP6B1 were tested. These studies demonstrate that the integrity of furanocoumarin structure is important for competitive binding to the active site of CYP6B1, even though the carbonyl group on the pyranone ring apparently does not affect its inhibitory capacity, as in the case of furanochromones. Angular furanocoumarins are generally less phototoxic to many organisms than linear furanocoumarins due to their reduced capacity for cross-linking DNA strands, yet they are more toxic than linear furanocoumarins to black swallowtail larvae. This enhanced toxicity *in vivo* may be due to the ability of angular furanocoumarins to bind to the active site of CYP6B1 without being rapidly metabolized. This binding reduces the availability of CYP6B1 to metabolize other linear furanocoumarins. The structure-activity relationships for methylenedioxyphenyl compounds, flavonoids, imidazole, and imidazole derivatives are also discussed in light of their capacity to inhibit the xanthotoxin-metabolic activity of CYP6B1.

Key Words—Cytochrome P450 monooxygenases (P450s), enzyme inhibition, furanocoumarins, furanochromones, methylenedioxyphenyl compounds, flavonoids, plant-insect interactions.

INTRODUCTION

Virtually all plant species produce a diversity of secondary plant compounds or allelochemicals for defense against herbivores. Among the compounds that are toxic to a broad range of organisms are furanocoumarins, which are found in plants from several families including Apiaceae and Rutaceae (Berenbaum, 1981, 1991). These compounds are toxic owing to their ability to interfere with the processes of DNA replication and transcription by forming covalent cross-links with DNA helices in the presence of long-wavelength UV light and/or to inactivate proteins by irreversible binding (Berenbaum, 1991). Despite this toxicity, some specialist insects, e.g., the black swallowtail (*Papilio polyxenes*) and the parsnip webworm (*Depressaria pastinacella*), are able to feed exclusively on host plants containing furanocoumarins. They rapidly and efficiently detoxify furanocoumarins encountered in their diet via cytochrome-P450-mediated detoxification systems (Ivie et al., 1987; Nitao, 1989; Schuler, 1996; Berenbaum, 2002; Nitao et al., 2003). Metabolic transformation of the furan ring is mediated by P450s in both mammals (Koenigs and Trager, 1998a) and specialist insects (Ivie et al., 1986, 1987; Baudry et al., 2003; Nitao et al., 2003). In mammals, the epoxidation and subsequent opening of the furan ring lead to irreversible inactivation of some P450s due to the formation of stable P450 metabolite complexes through covalent bonding, a process called suicide inactivation or mechanism-based inhibition (Koenigs and Trager, 1998a). The epoxidation and subsequent opening of the furan ring lead to the detoxification and excretion of furanocoumarin metabolites in both the black swallowtail (Bull et al., 1986) and the parsnip webworm (Nitao et al., 2003). Cloning and expression of P450s from the black swallowtail have identified CYP6B1 as the principal enzyme responsible for the detoxification of furanocoumarins (Cohen et al., 1992; Ma et al., 1994; Chen et al., 2002; Baudry et al., 2003; Wen et al., 2003). CYP6B3 was identified in this butterfly species as a related enzyme with an overall lower capacity for furanocoumarin metabolism (Hung et al., 1995a; Wen et al., unpublished).

In addition to furanocoumarins, many other allelochemicals occur in the host plants of *P. polyxenes*. Among these are methylenedioxyphenyl (MDP) compounds including myristicin and safrole, simple coumarins, furanochromones including visnagin and khellin, and flavonoid compounds including flavone (Berenbaum, 1985, 1990; Berenbaum and Neal, 1987; <http://www.arsgrin.gov/duke/index.html>). Some of these chemicals are known to modulate

P450 activities by acting either as P450 inducers or inhibitors (Cohen et al., 1989; Prapaipong et al., 1994; Hung et al., 1995a,b; Ono et al., 1996; Scott, 1996; Koenigs et al., 1997; Koenigs and Trager 1998a,b; Guo et al., 2000; Scott et al., 2000; Ho et al., 2001; Petersen et al., 2001; Tantcheva-Poor et al., 2001; Zhang et al., 2001; Baudry et al., 2003). In the same way that plant allelochemicals consumed in the human diet alter the bioavailability and the efficacy of certain drugs by modulating drug-metabolizing P450 activities (McKinnon and Evans, 2000; Zhou et al., 2004), modulation of toxin-metabolizing P450s in herbivorous insects by chemicals coexisting with host plant toxin(s) have potential for affecting their ability to detoxify plant allelochemicals and, consequently, to utilize certain plants. Some allelochemicals in complex mixtures may not be toxic themselves, but they may enhance the toxicity of co-occurring toxicants by inhibiting key enzymes (e.g., P450s) that detoxify them. While certain toxic chemicals can significantly alter host plant utilization patterns by particular groups of insects, suites of allelochemicals via additive toxicity or synergism can provide more effective defense against a range of herbivorous insects (Berenbaum, 1985; Berenbaum and Neal, 1987).

In *P. polyxenes*, Neal and Berenbaum (1989) demonstrated that both myristicin and safrole inhibit ρ -nitrophenol and ρ -nitroanisole O-demethylation activities in *P. polyxenes* to an extent that is much lower than their ability to inhibit these same activities in the caterpillar *Helicoverpa zea*, a polyphagous species that rarely utilizes furanocoumarin-containing host plants. Zumwalt and Neal (1993) further demonstrated that xanthotoxin inhibits ρ NA O-demethylation activity in *P. polyxenes* to a lower extent than in *Manduca sexta*, a sphingid specialist on Solanaceae that never encounters furanocoumarins. The reverse is true, however, for xanthotoxin inhibition of aldrin epoxidation activity in these two species. Additionally, xanthotoxin inhibition of aldrin epoxidation activity in both species and ρ NA O-demethylation activity in *M. sexta* is irreversible, whereas its inhibition of ρ NA O-demethylation activity in *P. polyxenes* is reversible. Given the complexities of P450 systems due to isoform multiplicity and often broad yet overlapping substrate specificity, any given midgut P450 activity of *P. polyxenes* against synthetic substrates may represent the combined activities of multiple individual P450s. The inhibitory profiles for such activities using synthetic substrates may not be the same as the inhibitory profiles for P450 activities that have evolved in a particular ecological and phytochemical context. Examination of inhibitory profiles for individual toxin-metabolizing P450s by allelochemicals that coexist with the major furanocoumarin toxins is more relevant for understanding the complexity of plant-insect interactions.

The identification of CYP6B1 as the principal furanocoumarin-metabolizing enzyme in *P. polyxenes*, and the successful establishment of a heterologous

CYP6B1-house fly P450 reductase coexpression system have allowed us to directly evaluate not only the binding of host plant-specific allelochemicals and synthetic compounds with CYP6B1 but also the effects of these chemicals on CYP6B1 metabolism of xanthotoxin, the major toxin in the host plants of *P. polyxenes* (Baudry et al., 2003; Wen et al., 2003). These studies provide insight into the mechanisms underlying the evolution of phytochemical diversity in plants by demonstrating that compounds with structures different from that of the furanocoumarin nucleus can significantly block CYP6B1 metabolism of xanthotoxin.

METHODS AND MATERIALS

Chemicals. Xanthotoxin (8-methoxypsoralen), bergapten (5-methoxypsoralen), psoralen, and angelicin were purchased from Indofine Chemical Co. (Belle Mead, NJ, USA). Coumarin, myristicin, cimetidine, imidazole, ketoconazole, β -NADPH, heat-inactivated fetal bovine serum (FBS), and hemin were obtained from Sigma (St. Louis, MO, USA). Visnagin, khellin, flavone, flavanone, α -naphthoflavone, piperonyl butoxide (PBO), safrole, isosafrole, and 2,3-benzofuran were purchased from Aldrich Chemical Co. (Milwaukee, WI, USA). Molecular biology reagents, Sf9 insect cells, SF-900 serum-free medium, pFastBac1 expression vector, and DH₁₀BAC competent cells were purchased from GibcoBRL/Life Technology (Grand Island, NY, USA). Solvents for HPLC were obtained from Fisher Scientific (Fair Lawn, NJ, USA).

Expression of CYP6B1 Protein. CYP6B1 was coexpressed with house fly cytochrome P450 reductase at a multiplicity of infection (MOI, pfu/cell) ratio of 2:0.05 or 2:2 in a baculovirus-Sf9 cell system as described in Wen et al. (2003) and Pan et al. (2004). Briefly, Sf9 cells infected with CYP6B1 and house fly P450 reductase virus were harvested 72 hr post infection by centrifugation at $3000 \times g$ for 10 min, washed once with one-half cell culture volume of 100 mM cold sodium phosphate buffer (pH 7.8) and once with one-tenth cell culture volume of cold cell lysate buffer [100 mM sodium phosphate (pH 7.8), 1.1 mM EDTA, 0.1 mM dithiothreitol, 0.5 mM phenylmethylsulfonyl fluoride, 5 μ g/ml (w/v) leupeptin, 20% glycerol]. The cells were resuspended in one-tenth cell culture volume of cold cell lysate buffer, sonicated twice for 30 sec with an interval of 1 min in 5-ml batches on ice, vortexed for 15 sec, and centrifuged at $3000 \times g$ for 10 min. These low-speed cell lysates cleared of cell debris were analyzed directly or frozen in liquid nitrogen and stored at -80°C . P450 content was determined as described previously (Wen et al., 2003).

Assays for CYP6B1 Inactivation by Xanthotoxin. The effects of xanthotoxin on the metabolic activity of CYP6B1 against xanthotoxin were assayed in two-phase reactions using CYP6B1 coexpressed with house fly P450 reductase

at an MOI ratio of 2:2. In the first phase, three sets (A, B, C) of 500- μ l reactions containing 0.1 μ M CYP6B1 in cell lysate buffer were set up in duplicate: Set A reactions, which served as control, contained 3 μ l methanol; set B reactions, which examined the effects of NADP⁺ on CYP6B1 activity, contained 0.3 mM NADP⁺ and 3 μ l methanol; and set C reactions contained 0.3 mM β -NADPH and varying concentrations of xanthotoxin (0.1, 1, 10, and 25 μ M) delivered in 3 μ l methanol. The first-phase reactions were incubated for 30 min at 30°C in a shaking water bath starting with the addition of NADPH to set C reactions. Under these conditions, xanthotoxin in all of the set C reactions disappeared at the end of the first-phase reaction as analyzed by HPLC. At the end of this reaction, 100 μ l of a solution containing xanthotoxin (3 μ l 20 mM stock in methanol) and NADPH (60 μ l 3 mM stock) in cell lysate buffer were added to all reactions (sets A, B, and C), bringing the total volume of all second-phase reactions to 600 μ l, with a final xanthotoxin concentration of 100 μ M and NADPH concentration of 0.3 mM or higher (if NADPH was not completely consumed in set C reactions in the first phase). The second-phase reactions were incubated at 30°C for 20 min and terminated by adding 150 μ l 2 N HCl. Psoralen, which served as an internal standard for extraction efficiency, was added to all reactions at the same xanthotoxin concentration. Unmetabolized xanthotoxin was extracted with 2 ml ethyl acetate, and 10 μ l of the extract were directly analyzed on a normal-phase HPLC system using an isocratic solvent containing 80% cyclohexane/18% ethyl ether/2% 1-butanol. Experiments run in duplicate were independently replicated at least three times. CYP6B1 activity in the second-phase reactions was expressed as xanthotoxin turnover. Xanthotoxin turnover by CYP6B1 in set A reactions that were devoid of both xanthotoxin and NADP⁺ in the first-phase reactions was set as 100% CYP6B1 activity. Comparison of CYP6B1 activity in sets B (containing NADP⁺ in the first phase) and C (containing both NADPH and xanthotoxin in the first phase) reactions with that of set A (control) allowed the evaluation of the effects of NADP⁺ and xanthotoxin on CYP6B1 metabolism of xanthotoxin.

Assays for CYP6B1 Inhibition by Other Allelochemical and Xenobiotics. Chemicals were tested for their effect on xanthotoxin metabolism by CYP6B1 using a series of concentrations ranging from 0 to 3 mM, which varied depending on the compounds tested, in 500 μ l reactions. For each, chemicals (imidazole delivered in 15 μ l cell lysate buffer and all other chemicals in 15 μ l methanol) were preincubated with cell lysates containing 0.05 nmol CYP6B1 coexpressed with housefly P450 reductase (MOI ratio of 2:0.05) in a volume of 350 μ l for 5 min at 30°C in a shaking water bath. At the end of this time period, 100 μ l of a xanthotoxin solution containing 2.5 μ l of 5 mM xanthotoxin stock (final concentration 25 μ M) in methanol and 97.5 μ l cell lysate buffer were added to each incubation, and the reaction was incubated for an additional 20 min at 30°C in a shaking water bath after addition of 50 μ l 3 mM NADPH (final

concentration of 0.3 mM) to initiate the reactions. Following this incubation, the reaction was stopped by adding 125 μ l 2 N HCl, and psoralen at the same concentration as xanthotoxin was added as an internal standard. Unmetabolized xanthotoxin was extracted with 500 μ l ethyl acetate, and 10 μ l of this extract were directly analyzed on a normal-phase HPLC system as described above. Control reactions were either stopped at time zero or contained no NADPH. Xanthotoxin metabolic activity of CYP6B1 incubated with varied concentrations of each test chemical was expressed as percentage of that obtained for CYP6B1 incubated without inhibitors. IC₅₀ values (the concentration of a test chemical that inhibits 50% of CYP6B1 metabolic activity) were obtained using the nonlinear regression program of GraphPad software (San Diego, CA, USA).

Spectral Binding Analysis. Spectral binding analyses were performed using split cuvette and double beam mode on a CARY 100 spectrophotometer as described by Wen et al. (2003). Briefly, 1 ml cell lysate buffer was added to half of each reference and sample cuvette, and 1 ml of cell lysate containing 50 nM CYP6B1 coexpressed with house fly P450 reductase (MOI ratio of 2:0.05) was added to the other half of each reference and sample cuvette. Following a baseline correction scan from 350 to 500 nm, test compounds with stock concentrations ranging from 5 to 200 mM were added sequentially in small volumes (0.2–2 μ l) to the cell lysate buffer in the reference cuvette and to the P450-containing cell lysate in the sample cuvette. Spectra were recorded 30 sec after each addition. Given the fact that some CYP6B1 substrates elicit strong, while others elicit much weaker binding spectra as exemplified in the type I binding of angelicin to CYP6B1 (Wen et al., 2003), we used the minimum concentration that elicits a type I or type II binding spectrum as a parameter to measure each compound's relative ability to bind to the heme in the CYP6B1 catalytic site.

RESULTS

Xanthotoxin is a well-known mechanism-based inhibitor for many P450s. To determine if xanthotoxin similarly inhibits the CYP6B1 protein, we set up a two-phase reaction system assaying CYP6B1 activity after preincubating it in the first phase with different concentrations of xanthotoxin in the presence of NADPH. If xanthotoxin is a mechanism-based inhibitor of CYP6B1, xanthotoxin metabolism in the second phase should be dependent on the concentration of xanthotoxin in the first-phase preincubated reaction containing NADPH. Results of these assays (Figure 1) indicate that the remaining CYP6B1 activities toward xanthotoxin in the second phase were nearly the same for reactions with

FIG. 1. Effects of xanthotoxin preincubation in the presence of NADPH on CYP6B1 activity toward xanthotoxin. The metabolic activity of CYP6B1 against xanthotoxin was analyzed in a two-phase reaction. Following the first-phase preincubation of 50 pmol CYP6B1 with various concentrations of xanthotoxin in the presence of NADPH (bars designated 0.1, 1, 10, 25), metabolism of xanthotoxin by CYP6B1 was compared with that of CYP6B1 preincubated devoid of xanthotoxin and NADPH in the first phase (bar designated CK) and that of CYP6B1 preincubated in the presence of only NADP⁺ in the first phase (bar designated NADP⁺). Bars show mean % activity \pm SE ($N = 3$).

varying concentrations of xanthotoxin (0.1–25 μM) preincubated in the presence of NADPH in the first phase and for reactions preincubated in the presence of NADP⁺ but devoid of xanthotoxin in the first phase. The decrease in the activities of CYP6B1 preincubated with different concentrations of xanthotoxin in the presence of NADPH in the first-phase reactions is apparently due to the feedback inhibition by NADP⁺, the product of NADPH, but not to the suicide inactivation of CYP6B1 by xanthotoxin.

To define the extent to which CYP6B1 metabolism of furanocoumarins is affected by allelochemicals co-occurring with furanocoumarins in the host plants of *P. polyxenes* and by synthetic chemicals, each chemical was tested at a series of concentrations (0 to 3 mM depending on the compound under analysis) for its effect on CYP6B1 metabolism of xanthotoxin. In these assays (Figure 2), CYP6B1 activity toward xanthotoxin in the presence of a test chemical, expressed as percentage of CYP6B1 activity toward xanthotoxin in the absence of inhibitors, is plotted as a function of the log concentration of that compound. IC₅₀ values, the concentration of a test chemical at which 50% of CYP6B1 activity is inhibited, were obtained using nonlinear regression (curve fitting) of GraphPad Prism software.

It is evident from this analysis that furanocoumarins inhibit xanthotoxin metabolism by CYP6B1, with linear furanocoumarins being slightly more

FIG. 2. Xanthotoxin metabolic activity of CYP6B1 in the presence of plant allelochemicals and synthetic compounds compared to that of CYP6B1 in the absence of test chemicals (defined as 100% activity). IC₅₀ (µM), the concentration of a test chemical that inhibits 50% of the CYP6B1 metabolic activity, was obtained using the nonlinear regression program of GraphPad software. Mean % activity ± SE are given. N = 3 for each component tested.

inhibitory than angular furanocoumarins. The order of IC₅₀ values in this study was 66.8, 105, and 154 µM for bergapten, psoralen (linear), and angelicin (angular), respectively (Figure 3). All of these furanocoumarins elicited typical type I binding spectra with an absorbance trough at 420 nm and a peak at 390 nm. Type I binding reflects the ability of substrates/inhibitors to displace water as the sixth ligand to the P450 heme iron (Jefcoate, 1978). The minimum concen-

FIG. 4. Effects of methylenedioxyphenyl (MDP) compounds on xanthotoxin-metabolic activity of CYP6B1. IC₅₀ was expressed in micromoles per liter with the 95% confidence interval in parentheses. Min con, minimum concentration to elicit type I binding spectrum; ND, no type I binding detected. $N = 3$.

trations needed for detection of a type I spectrum are 1.0–2.5 μ M for bergapten and 5–10 μ M for psoralen and angelicin. In contrast, coumarin, which lacks a furan ring, had an IC₅₀ value of 925 μ M and a minimum concentration of 100 μ M to elicit a type I binding spectrum. Benzofuran, which lacks a pyran ring, had an IC₅₀ value of >3000 μ M and did not elicit a type I binding spectrum. Khellin and visnagin, furanochromones that differ from linear furanocoumarins

flavonoids

flavone

flavanone

 α -naphthoflavone

chemicals	IC ₅₀ (95% CI) (μ M)	spectral binding	
		type	min con (μ M)
flavone	698 (402-1213)	I	20-40
flavanone	>3000	ND	
α -naphthoflavone	>3000	ND	

FIG. 5. Effects of flavonoids on xanthotoxin-metabolic activity of CYP6B1. IC₅₀ was expressed in micromoles per liter with the 95% confidence interval in parentheses. Min con, minimum concentration to elicit type I binding spectrum; ND, no type I binding detected. $N = 3$.

mainly in the position of the carbonyl group on the pyran ring, had IC_{50} values of 100 and 172 μM , respectively, and did not elicit any type I binding spectra.

Among the MDP compounds tested, the potency of compounds inhibiting CYP6B1 metabolism of xanthotoxin varied greatly, with IC_{50} values ranging from 265 μM for myristicin to >3000 μM for PBO (Figure 4). Isosafrole, with an IC_{50} value of 428 μM , was twofold more potent than its structural isomer safrole, which had an IC_{50} value of 1030 μM . Among these compounds, only myristicin, the most potent CYP6B1 inhibitor, elicited a typical type I binding spectrum at concentrations higher than 40–100 μM .

Among the flavonoid compounds, flavone did not strongly inhibit CYP6B1 metabolism of xanthotoxin (IC_{50} value of 698 μM) although it elicited a type I binding spectrum at concentrations higher than 20–40 μM (Figure 5). Both flavanone and α -naphthoflavone had IC_{50} values >3000 μM , and neither compound elicited any discernible change in spin state of the heme.

Among the imidazole derivatives, ketoconazole and imidazole had IC_{50} values of 95 and 251 μM , respectively (Figure 6). At very low concentrations

chemicals	IC_{50} (95% CI) (μM)	spectral binding	
		type	min con (μM)
imidazole	251 (115-548)	II	1
cimetidine	>3000	II	200 – 400
ketoconazole	95 (62-145)	II	2

FIG. 6. Effects of imidazole and its derivatives on xanthotoxin-metabolic activity of CYP6B1. IC_{50} was expressed in micromoles per liter with the 95% confidence interval in parentheses. Min con, minimum concentration to elicit type II binding spectrum. $N = 3$.

(1–2 μM), both compounds elicited typical type II binding spectra with an absorbance trough at 414 nm and a peak at 434 nm, respectively, typical of N-containing compounds coordinating with the heme. Although cimetidine was capable of eliciting a typical type II binding spectrum at high concentrations (200–400 μM), its IC_{50} value was >3000 μM (Figure 6).

DISCUSSION

Evolution of efficient detoxification of plant toxins by P450-mediated reactions is one of the most important mechanisms responsible for the adaptation of specialist insects to host plants containing toxic allelochemicals (Berenbaum, 1999). Exclusive feeding by *P. polyxenes* larvae on host plants containing furanocoumarins is attributable largely to the rapid detoxification of these toxins by P450s, specifically CYP6B1, a protein that has been extensively characterized (Ma et al., 1994; Berenbaum, 1999; Chen et al., 2002; Baudry et al., 2003; Wen et al., 2003, 2005; Pan et al., 2004). Here, we provide evidence that xanthotoxin does not suicide-inactivate CYP6B1. In combination with the facts that furanocoumarins are capable of inducing CYP6B1 expression (Prapaipong et al., 1994; Hung et al., 1995a,b; Petersen et al., 2001) and are efficiently detoxified by CYP6B1 (Ma et al., 1994; Chen et al., 2002; Baudry et al., 2003; Wen et al., 2003, 2005; Pan et al., 2004), our results support the identification of CYP6B1 as the principal enzyme responsible for the detoxification of furanocoumarins in *P. polyxenes*.

Our data indicate that both linear (bergapten, psoralen) and angular (angelicin) furanocoumarins inhibit xanthotoxin-metabolic activity of CYP6B1. The rank order of the IC_{50} values for the tested furanocoumarins (66.8, 105, and 154 μM for bergapten, psoralen, and angelicin, respectively) is the same as the rank order of the minimum concentrations needed to elicit type I binding spectra (1.0–2.5, 5–10, and 5–10 μM for bergapten, psoralen, and angelicin) that define the ability of these chemicals to displace water coordinated to the heme iron in the CYP6B1 catalytic site (Jefcoate, 1978). These results, together with the fact that these furanocoumarins are metabolized by CYP6B1 in an order inversely related to their ability to inhibit xanthotoxin metabolism (19.9, 16.9, and 4.5 $\text{nmol min}^{-1} \text{nmol}^{-1}$ P450 for bergapten, psoralen, and angelicin, respectively; Wen et al., 2005), suggest that the inhibition of xanthotoxin metabolism is most likely due to the competition of these chemicals with xanthotoxin for the CYP6B1 active site.

Angular furanocoumarins are generally less phototoxic to many organisms than linear furanocoumarins due to their ineffectiveness at cross-linking DNA strands in the presence of UV light (Berenbaum, 1991). That they are more toxic *in vivo* than linear furanocoumarins to black swallowtail larvae (Berenbaum and

Feeny, 1981) may be a reflection more of their capacity for analogue synergism than of their ability to intercalate into DNA. Black swallowtail larvae metabolize angelicin (an angular furanocoumarin) at rates threefold lower than rates at which the linear furanocoumarin psoralen is metabolized. This ratio is similar to the overall ratio at which these compounds are metabolized *in vitro* by CYP6B1 in the presence or absence of CYP6B3 (3.3-fold by CYP6B1 and CYP6B3 combined, 3.7-fold by CYP6B1 alone; Wen et al., unpublished). The fact that the IC_{50} ratios for these compounds indicate that psoralen is 1.5-fold more competitive for the CYP6B1 active site than angelicin suggests that, in the absence of rapid metabolism, binding of the angular furanocoumarin angelicin in the CYP6B1 active site limits the amount of enzyme available for metabolism of co-occurring linear furanocoumarins psoralen and xanthotoxin.

The competitive inhibition of CYP6B1 by furanocoumarins contrasts with furanocoumarins acting as mechanism-based inhibitors for several well-known mammalian P450 activities [e.g., coumarin 7-hydroxylase of human CYP2A6 (Koenigs and Trager, 1998a)] and insect P450 activities [e.g., ρ NA O-demethylase of *M. sexta*, aldrin epoxidase of *M. sexta* and *P. polyxenes* (Zumwalt and Neal, 1993; Neal and Wu, 1994)]. While it is not clear whether CYP6B1 contributes to the ρ NA O-demethylation activity that can be reversibly inhibited by xanthotoxin (Zumwalt and Neal, 1993), the mechanistic inhibition of *P. polyxenes* aldrin epoxidation activity by xanthotoxin suggests that at least one P450 isoform other than CYP6B1 is responsible for the aldrin epoxidation activity in this species.

The integrity of the coumarin nucleus and furan ring present in furanocoumarins is apparently important for their biochemical properties. Compared with furanocoumarins, the inhibition potency is dramatically lower for coumarin ($IC_{50} = 925 \mu\text{M}$), which lacks the furan ring, and absent for benzofuran ($IC_{50} > 3000 \mu\text{M}$), which lacks the coumarin core structure (this work; Baudry et al., 2003). Metabolic analysis has demonstrated that coumarin is only marginally metabolized by CYP6B1 ($0.08 \text{ pmol min}^{-1} \text{ pmol}^{-1}$ P450; Wen et al., 2005). Moreover, molecular modeling of CYP6B1-coumarin interactions suggests that this compound inhibits effectively by binding in a distal region of the catalytic site and preventing xanthotoxin from being metabolized (Baudry et al., 2003).

Furanochromones, whose structures are comparable to furanocoumarins except for the position of the carbonyl group on their pyran ring, inhibit xanthotoxin metabolism by CYP6B1 with potencies similar to psoralen and angelicin ($IC_{50} = 100 \mu\text{M}$ for khellin and $172 \mu\text{M}$ for visnagin), but they fail to elicit type I binding spectra. Given that furanochromones are poorly metabolized by CYP6B1 ($0.14 \text{ pmol min}^{-1} \text{ pmol}^{-1}$ P450 for khellin; $0.36 \text{ pmol min}^{-1} \text{ pmol}^{-1}$ P450 for visnagin; Wen et al., 2005), it is likely that furanochromones also inhibit CYP6B1 by active site competition.

The co-occurrence of MDP compounds, which are well-known P450 inhibitors, with toxic plant allelochemicals has been hypothesized to enhance plant defense against insect herbivores (Berenbaum, 1985; Berenbaum and Neal, 1985, 1987; Neal, 1989). However, inhibitory capacity of MDP compounds varies substantially depending on their functional groups, the length of side chains, and even the position of the double bond in the side chain attached to the benzene ring. Among the compounds tested, myristicin, which contains a methoxy group and a short side chain at the R3 position, was the most potent CYP6B1 inhibitor ($IC_{50} = 265 \mu\text{M}$) and the only MDP compound capable of eliciting a typical type I binding spectrum. Compounds such as safrole, which lacks this methoxy group and has the same short side chain at an alternate R2 position, are significantly less potent CYP6B1 inhibitors ($IC_{50} = 1030 \mu\text{M}$). Simply switching the double bond within this side chain alters the IC_{50} value more than twofold, from $1030 \mu\text{M}$ for safrole to $428 \mu\text{M}$ for isosafrole. Piperonyl butoxide (PBO), widely used as insecticide synergist and tool to demonstrate the involvement of P450s in insecticide metabolism, failed to inhibit CYP6B1, even though the original demonstration of P450s in furanocoumarin detoxification in black swallowtails utilized PBO for the general inactivation of P450s (Bull et al., 1986). Based on our results, it is likely that CYP6B1 isoforms other than CYP6B1 and CYP6B3 that are sensitive to PBO inhibition also contribute to the efficient detoxification of furanocoumarins in this species.

Flavonoids are generally poor inhibitors for CYP6B1, with flavone being most potent, having an IC_{50} of $698 \mu\text{M}$. Flavanone, lacking a double bond in the pyran ring, and α -naphthoflavone failed to inhibit CYP6B1 activity. In view of the fact that they are poorly metabolized by CYP6B1 ($0.56 \text{ pmol min}^{-1} \text{ pmol}^{-1}$ P450 for flavone and α -NF; Wen et al., 2005), and that only high concentrations of flavone ($20\text{--}40 \mu\text{M}$) elicit type I binding spectra, our results suggest that flavonoids, due to their size, may not fit well into the catalytic site of CYP6B1. Imidazole and its derivatives inhibit P450 by binding to the heme iron. Although all three compounds elicit a typical type II binding spectrum for CYP6B1, ketoconazole was the most potent inhibitor for CYP6B1 among imidazole and its derivatives.

One major strategy allowing specialist insects to feed exclusively on toxin-containing host plants is the evolution of P450-mediated detoxification of plant toxins. As a coevolutionary response to this process, plants accumulate a range of secondary compounds that act collectively against these herbivores (Berenbaum, 1985; Berenbaum and Neal, 1987). This study contributes toward a mechanistic explanation for how naturally occurring synergists can interfere with insect metabolism of (and hence resistance to) plant defense compounds, and in doing so sheds light on the functional significance of the phytochemical diversity that characterizes angiosperm plants in general. In view of the ubiquity

of P450-mediated insect resistance to host plant allelochemicals in plant-insect interactions, it is likely that the type of inhibition we have documented here is a widespread and evolutionarily important phenomenon.

Abstract—Within the genus *Papilio*, the *P. glaucus* group contains the most polyphagous *Papilio* species within the Papilionidae. The majority of *Papilio* species are associated with hostplants in the families Rutaceae and Apiaceae, and characterizing most are secondary metabolites called furanocoumarins. Recent phylogenetic studies suggest that furanocoumarin metabolism is an ancestral trait, with the *glaucus* group derived from ancestors associated with furanocoumarin-containing Rutaceae. In this study, we examined this relationship by conducting a gravimetric analysis of growth that used various concentrations of the furanocoumarin xanthotoxin. *Papilio multicaudatus*, the putative ancestor of the *glaucus* group, includes at least one furanocoumarin-containing rutaceous species among its hostplants; this species can consume leaf tissue containing up to 0.3% xanthotoxin with no detectable effect on relative growth rate, relative consumption rate, or efficiency of conversion of ingested food. As is the case for other *Papilio* species, xanthotoxin metabolism is mediated by cytochrome P450 monooxygenases (P450s). Ingestion of xanthotoxin by ultimate instar *P. multicaudatus* increases activity up to 30-fold in a dose-dependent fashion. Midguts of induced larvae can also effectively metabolize six other furanocoumarins, including both linear (bergapten, isopimpinellin, imperatorin) and angular (angelicin, sphondin) forms. A metabolite of xanthotoxin in the frass from xanthotoxin-treated larvae, identified as 6-(7-hydroxy-8-methoxycoumaryl)-acetic acid by MS–MS and NMR analyses, is identical to one from the frass of *P. polyxenes*. The occurrence of this metabolite in two swallowtails and the presence of a second metabolite of xanthotoxin, 6-(7-hydroxy-8-methoxycoumaryl)-hydroxyethanol in the frass of both *P. polyxenes* and *Depressaria pastinacella* are consistent with the suggestion that lepidopterans share as the first step of xanthotoxin metabolism the P450-mediated epoxidation of the furan ring 2'–3' double bond.

INTRODUCTION

More than 40 years ago, Ehrlich and Raven (1964) demonstrated that phylogenetic patterns of hostplant use within the Lepidoptera can provide insights into the evolution of specialization and adaptation to plant chemical defense. In coevolutionary interactions, key innovations in behavior or physiology are thought to underlie host use patterns and facilitate hostplant switches; molecular methods now allow the identification and characterization of genes encoding enzymes that play key roles in this reciprocal adaptive process (Berenbaum et al., 1996). The swallowtail butterflies of the family Papilionidae, a cosmopolitan group of 500+ species, has been the focus of coevolutionary studies for many years (Feeny, 1992). Early estimates of phylogenetic relationships within the family were based on morphological characteristics, larval food plant associations, and geographic distributions. Munroe (1961) split *Papilio* into five sections, which corresponded to differences in utilization of the principal food plants in the families Annonaceae, Lauraceae, Rutaceae, and Apiaceae (Berenbaum, 1995). Plants in the Apiaceae and Rutaceae contain furanocoumarins as defense chemicals (Berenbaum, 1983). *Papilio* sections II and IV generally utilize species in the family Apiaceae and Rutaceae as hostplants (Scriber et al., 1991; Scriber, 1995), whereas section III species, which tend to have more polyphagous diets, only occasionally use these furanocoumarin-containing hostplants (Cohen et al., 1992). There are no known associations between species in sections I and V and furanocoumarin-containing plants.

Prior to molecular analysis, sections III and V were believed to be basal within the genus *Papilio* based largely on male genitalia, morphology, and larval hostplant preferences. Analyses have utilized allozyme variations (Hagen and Scriber, 1991), mitochondrial RNA (Sperling, 1993; Sperling and Harrison, 1994; Caterino and Sperling, 1999; Reed and Sperling, 1999), and DNA sequencing (Aubert et al., 1999; Vane-Wright et al., 1999; Yagi et al., 1999) to elucidate relationships within the genus. Zakharov et al. (2004), conducting a meta-analysis to generate an accurate phylogeny, split the genus into two distinct lineages, one including the subgenera *Princeps* and *Papilio* (*sensu stricto*) (section II) and the other including the subgenera *Heraclides*, *Pterourus*, and *Chilasa* (sections IV, III, and V, and I, respectively). Although *Pterourus* is paraphyletic, the *glaucus* group is considered the most advanced of these clades. According to this analysis, *P. multicaudatus* is the basal species within section III, the *glaucus* group in the subgenus *Pterourus*.

In both polyphagous section III species and oligophagous section II species, the ability to utilize furanocoumarin-containing hostplants in Apiaceae and

Rutaceae is associated with metabolism by cytochrome P450 monooxygenases (P450s), which are detoxificative enzymes that catalyze the NADPH-associated reductive cleavage of oxygen to produce a functionalized product and water. The genes encoding these enzymes (<http://drnelson.utmem.edu/CytochromeP450.html>) constitute one of the largest superfamilies known. The furanocoumarin-metabolic activity of CYP6B proteins in *Papilio* species is associated with the probability of encountering hostplant furanocoumarins. Catalytic activity was compared in two closely related CYP6B4 and CYP6B17 groups in the polyphagous congeners *Papilio glaucus* and *Papilio canadensis* (Li et al., 2003). Generally, P450s from *P. glaucus*, which feeds occasionally on furanocoumarin-containing hostplants, display higher activities against furanocoumarins than those from *P. canadensis*, which normally does not encounter furanocoumarins. These P450s in turn catalyze a larger range of furanocoumarins with lower activity than CYP6B1, a P450 from *Papilio polyxenes*, which feeds exclusively on furanocoumarin-containing apiaceous hostplants. Reconstruction of the ancestral CYP6B sequences using maximum likelihood predictions and comparisons of the sequence and geometry of their active sites to those of contemporary CYP6B proteins indicate that hostplant diversity is inversely related to substrate specificity. These predictions suggest that, in the lineage leading to *Papilio* P450s, the ancestral highly versatile CYP6B protein presumed to exist in a polyphagous ancestor evolved through time into a more efficient and specialized CYP6B1-like protein in *Papilio* species with continual exposure to furanocoumarins.

P. multicaudatus specializes on only three genera of plants within three families: Rutaceae, Rosaceae, and Oleaceae. One host genus, *Ptelea*, is known to contain furanocoumarins (Murray et al., 1982). The purpose of our study was to examine furanocoumarin disposition in this species, putatively basal to the polyphagous species in section III, in order to determine whether (1) tolerance is intermediate between that of section II furanocoumarin specialists and section III generalists, (2) inducibility of furanocoumarin metabolism is conserved between sections, and (3) metabolites generated by P450-mediated metabolism, reflective of the detoxificative transformation, are similar across sections. Interpreting detoxificative metabolism of hostplant phytochemicals in a phylogenetic context can allow for reconstruction of host shifts and diversification.

METHODS AND MATERIALS

Insects. Adult *P. multicaudatus* were captured at Kitt Peak in Pima County, Arizona, at 5000 ft elevation on 11 August 2004 and subsequently transported to Champaign County, Illinois. The captive butterflies were allowed to mate within a 1 × 1 × 1-m screen mesh cage. Juvenile *Ptelea trifoliata* and *Prunus serotina* trees were placed within the cage for oviposition. The eggs were allowed to

hatch within the cage. Second instar larvae were removed from the cage and placed in 15l rearing tubs. Each rearing tub was constructed of durable, opaque plastic lined with moist paper towels. Air vents were cut into the lids. Fresh *P. serotina* leaves were exchanged on a daily basis. No rearing tub contained more than 30 larvae at any time. The caterpillars were maintained at 25°C and 16:8 light/dark photoperiod for the duration of the experiment.

Reagents for Detoxification Studies. Xanthotoxin used in gravimetric analyses of performance was obtained from Sigma (St. Louis, MO, USA). Other furanocoumarins, used as substrates in metabolism assays, including angelicin and isopimpinellin from Indofine Chemical Co. (Belle Mead, NJ, USA), bergapten and psoralen from Sigma (St. Louis, MO, USA), and imperatorin from Feinbiochemical (Heidelberg, Germany); sphondin was a gift from Ralph Mumma. NADPH was obtained from Sigma, and HPLC solvents from Fisher Scientific L.L.C. (Pittsburgh, PA, USA).

Gravimetric Estimates of Xanthotoxin Tolerance. Using ultimate instar *P. multicaudatus* larvae, we conducted a gravimetric estimate of performance with varying concentrations of xanthotoxin, a linear furanocoumarin, topically applied to the hostplant. Fifth instar larvae were collected from the rearing tubs within 2 hr of the final larval molt. Each caterpillar was weighed and placed in a 9-cm Petri dish with moistened filter paper. Approximately 1 g of *P. serotina* leaf material, which lacks furanocoumarins, was weighed and topically treated with either acetone or an acetone solution of xanthotoxin. Xanthotoxin solutions of different concentrations were prepared, so that equal volumes could be applied to obtain diets containing xanthotoxin at 0.1, 0.2, 0.3, and 0.4% fresh weight. These concentrations were based on previous studies of *P. polyxenes* and its host plant, flat-leaf parsley, *Petroselinum sativum* (Cohen et al., 1989). One hundred larvae were distributed among the five treatments.

Larvae were allowed to feed for 24 hr and then placed in a -20°C freezer for 30 min. Subsequently, larvae, remaining leaf material, and frass were placed in a 60°C drying oven for 24 hr to obtain dry weight. All fresh and dry weights were recorded, and fresh weight was converted to dry weight by using a conversion factor based upon five caterpillars that were frozen and dried within 2 hr of the final molt and five dried *P. serotina* leaves.

Standard gravimetric parameters of performance were calculated, including relative growth rate (RGR), the efficiency of conversion of ingested food to body substance (ECI), and relative consumption rate (RCR) or weight gain (Waldbauer, 1968). Data were analyzed by using analysis of variance (ANOVA), Dunnett's test, and analysis of covariance (ANCOVA) (Raubenheimer and Simpson, 1992). Regression analysis was conducted to determine the effect of xanthotoxin on relative growth rate.

Inducibility of Xanthotoxin Metabolism. Newly molted fifth instars were individually placed on 1 g fresh weight foliage of *P. serotina*, topically treated

with varying amounts of xanthotoxin dissolved in 250 μ l acetone (0, 1, 2, and 4 mg). Four replicate larvae were used for each concentration. After 48 hr, midguts were dissected on ice, and each midgut was homogenized in 600 μ l of 0.1 M ice-cold sodium phosphate buffer (pH 7.8) containing 20% glycerol, 1.1 mM EDTA, 0.5 mM PMSF, and 5 μ g/ml (w/v) leupeptin. The homogenates were centrifuged at 5000 rpm for 5 min at 4 °C. Metabolism reactions were set up with 30 μ l of the supernatant. Each reaction mixture contained 0 (control) or 50 μ l of NADPH (10 mg/ml in 0.1 M phosphate buffer, pH 7.8), 2 μ l of xanthotoxin (10 mM in methanol), and 468 μ l (in control) or 418 μ l of 0.1 M phosphate buffer, pH 7.8. The reactions were incubated for 30 min in a 30°C shaking water bath followed by incubation for 5 min at 70°C to inactivate the P450s. The reaction mixture was extracted with 500 μ l of ethyl acetate after addition of 5 μ l of 1 mM psoralen as an internal standard and centrifuged at 14,000 rpm for 5 min using a benchtop centrifuge at room temperature. Ten microliters of the ethyl acetate phase were removed and analyzed by normal-phase HPLC (Econosphere 5- μ m silica column, 150 \times 4.6 mm) with a solvent system containing 55% cyclohexane, 42% isopropyl ether, and 3% amyl alcohol to determine the amount of unmetabolized xanthotoxin remaining.

Metabolism of Furanocoumarins by Homogenates of Xanthotoxin-Induced Larval Midguts. To determine the substrate-specificity of P450-mediated furanocoumarin metabolism in *P. multicaudatus*, metabolism reactions were carried out as described except that homogenate supernatants were prepared from midguts of larvae induced with 4 mg xanthotoxin per gram wild cherry leaves and six furanocoumarin substrates, including the angular furanocoumarins angelicin and sphondin, and the linear furanocoumarins bergapten, imperatorin, isopimpinellin, and psoralen. They were analyzed, with 5 μ l of 100 nM xanthotoxin added to the reaction as an internal standard before ethyl acetate extraction.

Isolation and Structural Elucidation of Xanthotoxin Metabolite from Frass. *P. multicaudatus* larvae starved for 3 hr were presented with foliage of wild cherry treated with 0 mg (control) or 4 mg xanthotoxin/g fresh weight (fw) foliage (treatment). After 24 hr of feeding, frass was collected. To detect the xanthotoxin metabolite in frass and determine a suitable metabolite extraction method, frass from caterpillars on each diet was extracted with water and methanol, and the extracts were analyzed by reverse-phase HPLC (4- μ m C-18 column, Waters Novapak, 4.7 \times 150 mm). To purify the metabolite, gradient elution (solvent A, 5% glacial acetic acid in water; solvent B, 100% acetonitrile) was performed at a flow rate of 1 ml/min with gradient conditions ranging from 100% A/0% B to 90% A/10% B over 5 min, to 60% A/40% B over 30 min; after 5 min at 60% A/40% B, a gradient was run to 100% A/0% B. The spectra for water and methanol extracts of treatment frass were compared with those of the corresponding control frass at wavelengths

between 210 and 400 nm (996 Diode array detector, Waters, Milford, MA, USA); peaks unique to xanthotoxin-fed larvae were considered to represent metabolites.

To obtain sufficient amounts of metabolites to characterize, frass was again collected as described from fifth instars on control or treated (4 mg xanthotoxin/gfw) foliage. The frass collected was extracted with methanol. After drying the extract with N₂, the residue was redissolved in the same original volume of HCl-acidified distilled water (pH 2). The water phase was then extracted with the same volume of ethyl acetate after extraction with the same volume of chloroform. The water phase was collected, frozen in liquid nitrogen, and lyophilized. Finally, the residue was resuspended in 0.5 ml methanol for separation by reverse-phase HPLC (as described earlier, except that UV absorbance was set at 325 nm).

Mass spectrometric analysis of purified metabolite was performed at the Mass Spectrometry Service Facility at the University of Illinois at Urbana-Champaign; the instrument used was a Finnigan LCQ Deca XP MAX ion trap mass spectrometer (Thermo Electron Corporation). For MS-MS analysis, a collision energy of 25 was used for the metabolite of MW 250. The ¹H NMR spectrum was obtained with a Bruker (Billerica, MA, USA) Avance 400 NMR spectrometer equipped with a 5-mm inverse broadband Z-gradient probe (¹H, 400 MHz). The NMR spectrum was recorded in methanol-*d*₄, which served as the internal reference (¹H NMR, 3.30 ppm). Data were analyzed using the Advanced Chemistry Development, Inc., SpecManager 1D Processor and the HNMR Predictor software suite (Toronto, Ontario, Canada).

RESULTS

Gravimetric Estimates of Xanthotoxin Tolerance. There were no statistically significant differences among treatments in consumption rate or efficiency of conversion (Table 1). The only significant effect of treatment evidenced in calculated gravimetric ratios evaluated by ANOVA was for RGR ($F = 3.004$, df 4, 97, $P = 0.022$) (Table 1). Growth rates in diet containing 0.2% xanthotoxin were lower than growth rates of caterpillars placed on control diet ($P = 0.031$), and RGR for caterpillars exposed to 0.4% xanthotoxin were marginally lower than those on control ($P = 0.053$).

ANCOVAs were performed to compare consumption and weight gain on the five diets. In both analyses, the assumption of homogeneity of slopes was not violated ($P > 0.12$), but there were no significant differences in consumption or growth among treatments. A marginally significant negative regression of

Calculated gravimetric estimated ratios per treatment of xanthotoxin. The only significant treatment effect was for RGR ANOVA ($F = 3.004$, $df 4, 97$, $P = 0.022$). RGR = relative growth rate ($\text{g g}^{-1} \text{d}^{-1}$ dry weight); ECI = the efficiency of conversion of ingested food to body substance (%); RCR = relative consumption rate ($\text{g g}^{-1} \text{d}^{-1}$ dry weight).

^aTreatments that were significantly different from control (Dunnett’s test, $P < 0.05$).

relative growth rate on xanthotoxin concentration (Figure 1) suggests a mild negative effect of ingesting increasing amounts of xanthotoxin ($P = 0.061$, $r^2 = 0.04$).

Inducibility of Xanthotoxin Metabolism. Cytochrome P450-mediated xanthotoxin metabolism in the midgut of *P. multicaudatus* was induced in a dose-dependent fashion, increasing 13-, 16-, and 23-fold when ultimate instars were fed foliage treated with xanthotoxin at 1, 2, and 4 mg/g fw, respectively; constitutive levels of metabolism, in the absence of furanocoumarins, were very low (Figure 2). Larvae with midgut metabolism induced by ingestion of hostplant treated with xanthotoxin (4 mg/g fw) were capable of metabolizing six

FIG. 1. Regression plot of relative growth rate as a function of xanthotoxin concentration.

FIG. 2. Dose-dependent inducibility of xanthotoxin metabolism in *P. multicaudatus* midgut microsomes.

furanocoumarins other than xanthotoxin, including not only linear furanocoumarins (bergapten, imperatorin, isopimpinellin, psoralen) but also angular furanocoumarins (angelicin, sphondin). Metabolism rates were 4.38, 12.95, 6.28, 12.62, 4.97, and 10.89 nmol/min per midgut for angelicin, bergapten, imperatorin, isopimpinellin, psoralen, and sphondin, respectively (Figure 3).

Isolation and Structural Elucidation of Metabolite. Comparison of UV spectra of aqueous and methanolic extracts of frass from caterpillars on control and xanthotoxin diets revealed only a single metabolite, which absorbed strongly at 325 nm. This was isolated and purified by reverse-phase HPLC after chloroform and ethyl acetate extraction (Figure 4) and found to have a molecular weight of 250 (Figure 5). Collection of the metabolite fraction from

FIG. 3. Metabolism of six furanocoumarins by the midgut of *P. multicaudatus* larvae fed with 4 mg xanthotoxin per gram leaf of *P. serotina* (wild cherry).

reverse-phase HPLC and subsequent drying by speed vacuum method yielded sufficient crystalline material to perform structure-elucidation analyses.

Identification of the isolated metabolite was accomplished by both MS–MS and NMR spectroscopy. The MS–MS spectrum of the metabolite shows that the coumarin ring is intact, but the furan ring is no longer closed (Figure 5). Proton NMR shows a singlet of three protons at $\delta = 3.98$ ppm corresponding to the 8-methoxy group. The protons at C-3 and C-4 give rise to two doublets at $\delta = 6.22$ and 7.85 ppm, respectively, whereas the isolated proton at C-5 shows a singlet at $\delta = 7.20$ ppm. A singlet of two aliphatic protons at $\delta = 3.67$ indicates the adjacent presence of a carboxylic acid resulting from metabolic cleavage of the furan ring (Figure 6). Thus, both MS–MS and NMR spectra suggest that the metabolite in frass is HCA, 6-(7-hydroxy-8-methoxycoumaryl)-acetic acid (Figures 5 and 6).

DISCUSSION

Physiological and biochemical analyses confirm that *P. multicaudatus*, the putative ancestor to the *glaucus* group swallowtails, maintains the ancestral capacity to tolerate furanocoumarins, in contrast with the more derived species, *P. canadensis* and *P. glaucus*, which have a reduced ability to tolerate these compounds (Li et al., 2002) (Table 1). This conclusion is supported by larval hostplant associations; most section III *Papilio* species utilize Lauraceae as primary larval hostplants and Magnoliaceae as secondary larval hostplants.

FIG. 6. 400 MHz NMR spectrum of metabolite dissolved in methanol- d_4 . Peaks 4.87 and 3.33 represent H_2O and methanol- d_4 peaks, respectively.

P. multicaudatus and *P. glaucus* are the only two section III species known to use Rutaceae as larval hostplants (Aubert et al., 1999).

As is the case for both Section II (Cohen et al., 1989) and Section III swallowtails (Li et al., 2003), xanthotoxin is a strong inducer of its own P450-mediated metabolism. When larvae were induced with 0.4% fresh weight xanthotoxin, the rate of xanthotoxin metabolism increased to over 5.23 nmol/min per midgut, more than 20 times the rate of its constitutive metabolism (0.23 nmol/min per midgut). Compared with the Section II black swallowtail, *P. polyxenes*, in which induction increased xanthotoxin metabolism 3- to 8-fold over constitutive levels at dietary concentrations of 0.1 to 0.5%, and the section III tiger swallowtail, *P. glaucus*, in which induction increased 30-fold over constitutive levels at dietary concentrations of 0.2% (Figure 2, Li et al. 2001), induced metabolism and maximum tolerance increased induction approximately 20-fold in *P. multicaudatus* at dietary concentrations of 0.2% fresh weight xanthotoxin, levels that are intermediate, as predicted. This intermediate inducibility and tolerance are consistent with the frequency with which furanocoumarins are encountered by these species. *P. polyxenes*, all of whose hosts contain furanocoumarins, maintains high constitutive levels of furanocoumarin metabolism that are only slightly inducible before maximum capacity is reached; *P. multicaudatus*, one-third of whose known hosts contain furanocoumarins, maintains intermediate constitutive levels of furanocoumarin metabolism that are substantially inducible; and *P. glaucus* and *P. canadensis*, which rarely and never encounter furanocoumarins in their respective diets, maintain vanishingly low levels of constitutive xanthotoxin metabolism that are highly inducible if furanocoumarins are encountered (Li et al., 2003).

Like the other more generalized section III swallowtails, *P. multicaudatus* larvae can effectively metabolize not only xanthotoxin, but six other furanocoumarins, including linear and angular forms. In the section III swallowtails, this ability to metabolize a diverse array of furanocoumarins is attributable in part to a greater number of furanocoumarin-inducible P450 genes, each of which has broad substrate specificity (Li et al., 2003). *CYP6B4*, *CYP6B17*, and *CYB6B2*, which are all furanocoumarin-inducible in *P. glaucus*, and *CYP6B26*, which is furanocoumarin-inducible in *P. canadensis* (Li et al., 2001), have overlapping substrate specificities, and all can metabolize both linear and angular furanocoumarins (Li et al., 2003). In contrast, in the furanocoumarin specialist *P. polyxenes*, the enzyme CYP6B1 (Cohen et al., 1992) is furanocoumarin-inducible, but it is highly specialized and can metabolize angular furanocoumarins only to a limited extent and cannot metabolize imperatorin, a linear furanocoumarin. Whether *P. multicaudatus* owes its tolerance to furanocoumarins to multiple furanocoumarin-inducible P450s with broad substrate specificities, like the other *glaucus* group swallowtails, remains to be determined.

Some insight into the nature of the metabolic transformations that contribute to *P. multicaudatus* furanocoumarin tolerance can be gained by an examination of the structure of the metabolites produced. Only a single metabolite was isolated and identified from frass. The metabolite, HCA (Figures 5, 6, and 7), likely arises as a result of cleavage of the furan ring at the 2'-3' position, because the electron density at that position is higher than at the 3-4 position, and oxidative pathways usually prefer electron-rich π bonds (Schmid et al., 1980). This metabolite has also been found in frass of *P. polyxenes* as well as in the noctuid generalist *Spodoptera frugiperda* after xanthotoxin consumption. Both of these species produce a second metabolite, 6-(7-hydroxy-8-methoxycoumeryl)-hydroxyacetic acid (HCHA) (Ivie et al., 1983); HCHA constitutes the sole xanthotoxin metabolite in frass of the oecophorid caterpillar *Depressaria pastinacella*, which feeds exclusively on furanocoumarin-containing species in the apiaceous genera *Pastinaca* and *Heracleum* (Nitao et al., 2003). Collectively, these findings suggest that the furan ring is an important site of metabolic alteration of xanthotoxin in Lepidoptera. In this context, we suggest that P450-mediated epoxidation at the 2'-3' position on the furan ring is the first step of xanthotoxin metabolism in *P. multicaudatus* (Figure 7), as is postulated to occur in *P. polyxenes*, *S. frugiperda* (Ivie et al., 1983), and *D. pastinacella* (Ivie et al., 1983; Nitao et al., 2003).

Formation of an epoxide as part of a metabolic transformation presents a toxicological challenge to organisms. In general, epoxides are highly reactive, so the epoxide metabolites of furanocoumarins, if they accumulate in any quantity, may seriously interfere with normal physiological function. In mammals, this problem is resolved by use of rapid conjugation of xanthotoxin with glucuronic acid, glutathione, and sulfate to increase their stability and hydrophilicity (Hayes and Pulford, 1995), for ultimate transport and excretion via ATP-binding cassette (ABC) transporter genes (Dean and Annilo, 2005). To date, no conjugates of xanthotoxin or any other furanocoumarins have been found in insects. The widespread occurrence of metabolite products consistent with epoxidation in Lepidoptera that encounter furanocoumarins suggests that

FIG. 7. Proposed pathway of xanthotoxin metabolism in *P. multicaudatus* larvae. The presumptive epoxide is in brackets.

conjugation may play a more important role in detoxification and hostplant specialization than has hitherto been realized.

Abstract—*Betula pubescens* bud flavonoid aglycones reportedly have negative effects on the performance of first instar *Epirrita autumnata* and, thus, may defend birch leaves from larval defoliation. We hypothesized that the detrimental effects of these lipophilic flavonoids on larvae are due to their high levels in birch buds and/or the inability of naïve neonates to glycosylate them, which we have shown to occur in fifth instars. To test the latter hypothesis, we investigated the biochemical transformation of bud flavonoids in first instar *E. autumnata*. We found that newly hatched larvae have the ability to glycosylate birch bud/leaf flavonoid aglycones into corresponding glycosides. Moreover, we suggest that glycosylation may depend upon the chemical character of the aglycone and is an important factor in the performance of first instars.

Key Words—*Betula pubescens*, *Epirrita autumnata*, flavonoid aglycones, first instar.

INTRODUCTION

The highest mortality of lepidopteran larvae usually occurs during their first instar. The causes are not always clear, and may be the sum of various factors that

* To whom correspondence should be addressed. E-mail: makahe@utu.fi

affect larval survivorship. The first days are critical in larval life; during these neonates need to establish a feeding site and cope with different plant characters, microclimatic conditions, predators, parasitoids, and pathogens (Zalucki et al., 2002). The first stages of larval development are critical from the point of view of the plant as well. If conditions on the host plant are not favorable for larval development, this could dramatically reduce future biomass losses of the plant (Karban and Baldwin, 1997). It has been proposed that the most effective strategy for plant defense against herbivores is the synthesis of defensive compounds in young leaves rather than mature ones (Laitinen et al., 2002). Interaction between the timing of herbivory and the seasonally changing leaf chemistry was first suggested by Paul Feeny in his seminal paper (Feeny, 1970).

Even though the first instar may well be the most important—or at least the most vulnerable—stage in the life of herbivore larvae, there have been few studies conducted with neonates. This is presumably due to methodological problems, e.g., the small size of first instars (Zalucki et al., 2002). In earlier studies concerning the mechanisms of birch resistance and interactions between herbivores and birch foliar chemistry (e.g., Kause et al., 1999; Ossipov et al., 2001; Haukioja et al., 2002; Henriksson et al., 2003), the larvae have been in their later (third, fourth, or fifth) instars. A study with first instar *E. autumnata* was reported in Lahtinen et al. (2004), in which the biological activities of white birch (*Betula pubescens*) leaf surface exudates were investigated. We showed that tree-specific mortality of first instars correlated strongly with tree-specific contents of surface flavonoid aglycones in emerging leaves. Correlations between the contents of individual aglycones and larval performance [relative growth rate (RGR) and instar duration] also were found. In the same study, it was observed that flavonoid aglycones did not have harmful effects on fifth instar *E. autumnata* that feed on fully expanded leaves. This may be due to the lower contents of flavonoid aglycones in mature leaves (Valkama et al., 2004). In addition, we have previously shown that fifth instar *E. autumnata* can at least partially detoxify birch leaf flavonoid aglycones *via* glycosylation (Salminen et al., 2004), which may explain how last instars cope with lipophilic aglycones.

On the basis of these earlier findings, we suggested that the explanation for the strong negative correlations between the contents of certain birch leaf surface flavonoid aglycones and performance of first instar *E. autumnata* could be the high contents of these aglycones on buds. We also hypothesized that first instars may not have the ability to glycosylate flavonoid aglycones. To investigate the latter hypothesis, the biochemical transformation of birch bud flavonoids in first instar *E. autumnata* was studied by comparing the composition of flavonoid compounds (aglycones and glycosides) in larval frass to that in their leaf diet. This is the first time that individual compounds have been analyzed in the frass of first instar *E. autumnata*.

METHODS AND MATERIALS

Study Organisms. *Epirrita autumnata* (Borkhausen) is a univoltine geometrid moth commonly found on birch species in northern Europe. It is a destructive pest especially in northern and high-altitude populations of mountain birch [*B. pubescens* ssp. *czerepanovii* (Orlova) Hämet–Ahti], where its population densities fluctuate at intervals of approximately 9 to 10 yr, causing severe local outbreaks (Tenow, 1972; Haukioja et al., 1988; Ruohomäki et al., 2000). *E. autumnata* is best classified as a polyphagous species; it is able to attain comparable performance on leaves of host trees from several genera (Neuvonen et al., 1987) and can be found feeding on other hosts besides *Betula* in the field. Larvae of the autumnal moth hatch in the spring simultaneously with bud break and feed on young growing birch foliage.

Bioassay Design. About 200 first instar *E. autumnata* were reared in two large (12 l) pails on April 23–28, 2004. One branch of *B. pubescens*, with buds at the appropriate early phenological stage, was placed into each pail in a jar filled with water (100 ml) with added sucrose (1 g/vase) and sealed with parafilm. In practice, the appropriate phenological stage means opening buds with the tips of the emerging leaves visible. Larval frass was collected every 24 hr on filter-paper discs, which were placed at the bottom of each pail. Filter papers were the size of the bottom of the pail. Since despite the relatively high number of larvae, the amount of frass produced was low so the frass from 2 d at a time (1st + 2nd, 3rd + 4th, and 5th + 6th) was pooled for HPLC samples. Bud samples (three buds per branch) were collected from the same branches at the beginning of the bioassay before larvae were placed onto branches.

Sample Preparation. To analyze water-soluble flavonoids, six buds were extracted for 1 hr with 70% aqueous acetone (3×1 ml) in Eppendorf tubes. Aqueous acetone (70%) was earlier found to be a suitable and efficient solvent for (birch) leaf water-soluble phenolics (Hagermann, 1988; Salminen, 2003). We had three replicates of samples because each pair of two buds (one from both branches) was extracted in one tube. Three frass samples were extracted similarly, but the volume of the extraction solvent was 3×250 µl. After extraction, acetone was evaporated from samples, and the water phases were filtered for HPLC analysis. To analyze lipophilic flavonoid compounds, the non-water-soluble residues of the frass and bud samples were dissolved in 95% ethanol (1 ml). All extracts were filtered through 0.45-µm PTFE filters (Titan PTFE, 13 mm i.d., Scientific Resources Inc., USA) before analysis.

HPLC–DAD, HPLC–ESI–MS, and NMR Analyses. Extracts were analyzed by using HPLC–DAD (at 280 and 349 nm) and HPLC–ESI–MS systems. The analytical HPLC system (Merck–Hitachi, Tokyo, Japan) with diode array detector is described by Salminen et al. (2004). Column and chromatographic

conditions were as described by Salminen et al. (1999), except that 0.1 M H_3PO_4 was replaced with 0.05 M H_3PO_4 . HPLC–ESI–MS analyses were conducted as in Salminen et al. (1999), except that the data system used was Analyst Software 1.1. NMR spectra were acquired using a Bruker Avance 500 spectrometer (equipped with a BBI–5–mm–Zgrad–ATM probe) operating at 500.13 MHz for ^1H . Spectra were recorded at 25°C, using acetone– d_6 (and a few drops of D_2O) as a solvent. Proton spectra were referenced internally to the TMS signal using a value of 0.00 ppm.

Isolation of Flavonoid Aglycones. For structural elucidation of flavonoid aglycones, 5 g of dried lipophilic white birch bud extract (extracted $\times 1$ for 1 hr, with 100 ml of 95% aqueous ethanol) was dissolved in methanol and fractionated on Sephadex LH–20 column (40 \times 3.8 cm i.d., Pharmacia, Umeå, Sweden), with methanol as eluent. Fractions that contained flavonoid aglycones (checked with HPLC–DAD) were evaporated to dryness under reduced pressure, dissolved in petroleum ether, and fractionated on a silica column (10 \times 2.0 cm i.d., 70–230 mesh, 60 Å) with 50–ml fractions of petroleum ether containing increasing amounts of ethyl acetate. After fractionation, the fractions were again evaporated to dryness and dissolved in methanol. Flavonoid aglycones were further purified with a semipreparative Diasorb–130–C16T column (250 \times 15 mm i.d., 6 μm , BioChimMac, Russia–Austria–Germany), using a step gradient of CH_3CN (from 30 to 70%) in 0.1% HCOOH (in water). Samples were injected onto the column through a 500– μl loop valve.

Compound Identification and Quantification. Flavonoids were identified mainly on the basis of their spectra (UV and mass spectra) and retention times, as reported in the literature (Ossipov et al., 1995, 1996; Valkama et al., 2003; Lahtinen et al., 2004; Salminen et al., 2004). In addition to previously identified compounds, apigenin, kaempferol 4',7–dimethyl ethers, and kaempferol 3,4'–dimethyl ether were isolated and identified based on spectral properties (retention time, UV and mass spectra). The ^1H NMR spectra of apigenin and kaempferol 4',7–dimethyl ethers were also analyzed and compared to the literature (Erdtman et al., 1966; Herrera et al., 1996). All these flavonoids have been identified previously from *B. pubescens* by Wollenweber (1975). The identification of new fecal flavonoid glycosides was performed with HPLC–DAD and HPLC–ESI–MS. The structure of a glycoside was confirmed if mass spectral fragmentation revealed the ion peak of the aglycone part in addition to the molecular ion peak. Flavonoid glycosides were quantified as the corresponding aglycones: naringenin derivatives as naringenins, apigenin derivatives as apigenins, kaempferol derivatives as kaempferols, and quercetin derivatives as quercetins. Since there was no variation in the compound composition of the frass samples analyzed, the results were calculated as the mean values of these three samples. The contents of bud compounds were similarly calculated as the means of three replicates.

RESULTS

Analysis and Identification of Flavonoids. In order to study all the various flavonoids in buds and frass, first we extracted water-soluble compounds (mainly flavonoid glycosides) followed by the ethanol-soluble ones (mainly flavonoid aglycones). Bud flavonoid aglycones, which have not been identified previously (Valkama et al., 2003; Lahtinen et al., 2004; Salminen et al., 2004), were isolated and identified. All main aglycones of *B. pubescens* are shown in Figure 1. The aglycones were various methyl ethers of naringenin, apigenin, and kaempferol, which Wollenweber (1975) reported from *B. pubescens* buds. We also detected traces of a quercetin monomethyl ether and a pentahydroxy flavone trimethyl ether (identified in Valkama et al., 2003). These compounds may be quercetin 3'-methyl ether (according to UV and mass spectra), which Wollenweber (1975) reported in his work, and kaempferol 4',6,7-trimethyl ether (according to UV, mass and ¹H NMR spectra). Their precise structures were not characterized because of the relatively small amounts in the buds. The

^aCorrelation values are calculated between the contents of flavonoid aglycones and changes in the duration of instar and in the mean relative growth rate (RGR). (Values base on the data from the experiment reported in Lahtinen et al., 2004).

distribution of flavonoids in the ethanol-soluble and water-soluble fractions of bud and frass samples is shown in Table 1.

Flavonoids in Ethanol-Soluble Fractions. The ethanol fraction of bud samples contained 12 flavonoid aglycones in variable amounts. The main compound was naringenin 7-methyl ether (285 µg/ml, Table 1) as in the ethanol extract of fully expanded white birch leaves (Valkama et al., 2003). Other predominant compounds in buds were naringenin 4',7-dimethyl ether, kaempferol 3,4'-dimethyl ether, and kaempferol 4'-methyl ether (contents >100 µg/ml). In contrast, as observed in the earlier study with fifth instars (Salminen et al., 2004), the ethanol fraction of frass samples was almost totally free of flavonoid aglycones. Only traces of naringenin mono- and dimethyl ethers were detected. This suggests that nearly all bud flavonoid aglycones were either absorbed into the larval tissues or transformed/degraded into other compounds in the larvae.

Flavonoids in Water-Soluble Fractions. In the water-soluble fractions of both bud and frass samples, the flavonoids were different flavonoid glycosides (Table 1). Bud extracts also showed traces of aglycones. The main glycosides in buds, as in fully expanded birch leaves (Ossipov et al., 1996), were quercetin glycosides. However, according to HPLC-DAD and HPLC-ESI-MS, the main flavonoid glycosides in the frass samples were glycosides of the main bud aglycones (naringenin 7-methyl ether, kaempferol dimethyl ethers, and apigenin 4'-methyl ether). These compounds were not present in the larval leaf diet (Table 1); thus, they are evidently formed in the larvae, as we have previously observed in fifth instar *E. autumnata* (Salminen et al., 2004).

DISCUSSION

Glycosylation in First Instars. Fifth instar *E. autumnata* have the ability to glycosylate foliar flavonoid aglycones into the corresponding glycosides (Salminen et al., 2004). The absence of lipophilic aglycones in the ethanol-soluble frass fraction and the presence of their glycosides in the water-soluble frass fraction (Table 1) confirms that first instars have a similar ability to handle bud flavonoids by glycosylating them. Glycosylation transforms lipophilic compounds into water-soluble ones, which are easier for the larva to excrete. Fifth instar *E. autumnata* excreted foliar flavonoid glycosides almost unaltered (Salminen et al. (2004) and led to the suggestion that all new nonfoliar glycosides in frass were formed from foliar aglycones. However, in the present study myricetin glycosides were not detected in frass samples (Table 1). Thus, it is possible that some of the content of new fecal glycosides also may be the degradation products of foliar flavonoid glycosides. If so, some dehydroxylation

reactions in the B-ring of myricetin glycoside molecules also would have occurred in first instars in addition to glycosylation.

Glycosylation and Larval Performance. In the hypothesis of this study, we suggested that the negative effects of aglycones on larval performance are due to their high levels in birch buds and/or the inability of first instars to glycosylate them. Even though we observed that neonate larvae have the ability to glycosylate, it was impossible to calculate the efficiency of glycosylation without trustworthy data on larval consumption, which in larvae this small are practically impossible to obtain. Because there are a variety of possible factors affecting glycosylation, there may be differences in the glycosylation rates of different aglycones. For example a decrease in number of free hydroxyl groups may diminish glycosylation because *O*-glycosides seem to be more common in *E. autumnata*'s frass than *C*-glycosides (Salminen et al., 2004). In addition, increased *O*-methylation may make molecules less prone to glycosylation (Wollenweber, 1994). Glycosylation may also be affected by the lipophilic character of aglycones; a more lipophilic molecule is more easily absorbed into larval tissues and may not be available for glycosylation in the larval digestive tract.

Lahtinen et al. (2004) found a strong negative correlation between the levels of individual birch bud flavonoid aglycones and the performance (RGR and instar duration) of first instar *E. autumnata*. The correlation coefficients in question are shown in Table 1. The seemingly most harmful compounds [both (absolute) *r* values >0.65] were naringenin 4',7-dimethyl ether, apigenin 4',7-dimethyl ether, and kaempferol 4'-methyl ether. Of these, the first two are highly lipophilic, highly methylated, and have only one free hydroxyl group in their structures. These compounds may be difficult for larvae to glycosylate and can cause negative effects on larval performance because they are not excreted as such.

The amounts of the glycosides naringenin 4',7-dimethyl and apigenin 4',7-dimethyl ether in frass indeed indicates some problems in their glycosylation, e.g., glycosides of apigenin 4',7-dimethyl ether were totally absent from the frass (Table 1). Although no direct correlation was obtained between the amounts of compounds in buds and in frass, the glycosides of the main bud aglycones [i.e., naringenin 7-methyl ether and kaempferol dimethyl ethers (3,4'- and 4',7-dimethyl ethers calculated together)] were the main compounds in frass and it is reasonable to suspect that the levels of aglycones in buds would predict the amounts of the corresponding glycosides in frass if the rate of glycosylation is constant for different aglycones. The level of the glycoside of naringenin 4',7-dimethyl ether in frass is relatively low (12.7 µg/ml) despite its high concentration in buds (140.8 µg/ml) (Table 1) and may indicate a low rate of glycosylation. On the basis of these results, we suggest that the glycosylation ability of first instar *E. autumnata* larvae can depend on the chemical character

of the aglycone and may be an important factor in the successful performance of first instar larvae.

Acknowledgments—This work was supported in part by grants from the Emil Aaltonen Foundation (to M.L.). We are grateful to Jari Sinkkonen and Jaana Liimatainen for help with NMR analysis, and to Saira Sillanpää for supplying larvae for the experiment. We would also like to thank Profs. Erkki Haukioja and Kalevi Pihlaja for their valuable comments on this manuscript.

Abstract—The biogeography of pungency in three species of wild chili in the chaco and surrounding highland habitats of southeastern Bolivia is described. We report that *Capsicum chacoense*, *C. baccatum*, and *C. eximium* are polymorphic for production of capsaicin and its analogs, such that completely pungent and completely nonpungent individuals co-occur in some populations. In *C. chacoense*, the density of plants and the proportion of pungent plants increased with elevation. Above 900 m, all individuals in all populations except two were pungent; nonpungent individuals in at least one of the two polymorphic populations were likely a result of spreading by humans. The occurrence of pungent and nonpungent individuals in three species of ancestral *Capsicum* and the geographic variation of pungency within species suggest that production of capsaicin and its analogs entails both costs and benefits, which shift from one locality to another. Determining the selection pressures behind such shifts is necessary to understand the evolution of pungency in chilies.

INTRODUCTION

Geographically structured phenotypic variation in plant morphology, physiology, and chemistry has provided a window into the evolution and coevolution of plant–animal interactions (Berenbaum and Feeny, 1981; Berenbaum and Zangerl, 1998; Schemske and Bradshaw, 1999; Thompson and Cunningham, 2002; Fornoni et al., 2004; Siepielski and Benkman, 2004). Such variation is often used to infer constraints on the course of evolution and to discern the relative importance of various traits in the diversification of clades (Futuyma and Mitter, 1996; Berenbaum and Zangerl, 1998). The explicit examination of intraspecific variation in plant chemistry has led to major advances in our understanding of plant–pollinator and plant–herbivore interactions (Lerdau et al., 1994; Adler et al., 1995; Cronin and Hay, 1996; Zangerl et al., 1997; Berenbaum and Zangerl, 1998; Baldwin, 1998; Schemske and Bradshaw, 1999; McDonald et al., 1999; Redman et al., 2001; Cipollini et al., 2002; Rowell and Blinn, 2003; Fornoni et al., 2004). In contrast, studies of intraspecific variation in the chemistry of ripe fruit are almost nonexistent (Izhaki et al., 2002; Tsahar et al., 2002; Tewksbury, 2002), despite the importance of secondary metabolites in fruit–frugivore interactions (Cipollini and Levey, 1997; Cipollini, 2000).

In some taxa, the defining feature of fruit is chemical, and it is in these taxa where variation may have the largest impacts on fruit–frugivore interactions. This is exemplified in *Capsicum*, the wild chilies. *Capsicum* contains 23–27 wild species and more than 2000 cultivars, derived from 3 to 5 of the wild species (Andrews, 1995; DeWitt and Bosland, 1996). Capsaicin (8-methyl-*N*-vanillyl-6-nonenamide) and a series of homologous alkyl vanillylamides, called capsaicinoids, are responsible for the heat, or pungency, in chili pepper fruit (Iwai et al., 1979; Kawada et al., 1985; Govindarajan, 1986; Cordell and Araujo, 1993). Given that roughly a quarter of the world's population consume chilies each day (Cordell and Araujo, 1993), capsaicinoids are among the most widely used secondary metabolites in the world. To date, capsaicinoids have only been identified in the genus *Capsicum* (Govindarajan et al., 1987; Govindarajan and Sathyanarayana, 1991; Bosland, 1994). They are produced only in the fruit (Suzuki et al., 1980; Fujiwake et al., 1982) and are concentrated around the seeds and in the pericarp (Fujiwake et al., 1982; Suzuki and Iwai, 1984). Early taxonomies used the presence of capsaicinoids as a defining trait to characterize the genus *Capsicum* (Morton, 1938; Heiser and Smith, 1958), but not all *Capsicum* species produce capsaicinoids (D'Arcy and Eshbaugh, 1974).

Recent investigations support the hypothesis that capsaicinoid production is a monophyletic derived trait, as *Capsicum ciliatum*, a nonpungent species, appears basal to all pungent taxa (Walsh and Hoot, 2001), and pungency has been found in all taxa more derived than *C. ciliatum*. Furthermore, a single quantitative trait loci, *cap*, has been identified and accounts for 34–38% of the

phenotypic variation in capsaicinoid content (Blum et al., 2003). The only comprehensive theory advanced to explain the origin of pungency in *Capsicum* centers on an initial radiation from arid, high-elevation interior valleys of Bolivia (McLeod et al., 1982). The proposed ancestral species in this radiation was a form of *Capsicum chacoense*. More recent work using nuclear and chloroplast DNA supports a radiation of pungent taxa from drier mountainous regions, either in Bolivia or Peru (Walsh and Hoot, 2001), based on the earliest-branching pungent species (*Capsicum eximium* and *C. cardinasii*) and inconclusive bootstrap values separating the baccatum clade (*C. chacoense* and *C. baccatum*). Finally, the late discovery of a natural polymorphism for fruit pungency in an accession of *C. chacoense* from southeastern Bolivia (1959 collection by Paul Smith, USDA #PI260433, polymorphism discovered by P. Bosland, N.M. State) demonstrated that this species may not always have pungent fruit. Although early collectors have noted rare encounters with nonpungent plants (D'Arcy and Eshbaugh, 1974), details of this polymorphism have never been examined. The discovery and description of zones of polymorphism for capsaicinoid production may be a first step in understanding the origination and adaptive significance of capsaicinoids in wild fruit and their role in the radiation of the genus.

Our goal was to rediscover and map the occurrence of nonpungent *C. chacoense*, examine patterns of occurrence in light of natural and human-caused dispersal, and use this as a springboard to examine the biogeography of pungency in a broader taxonomic context. *C. chacoense*, *C. baccatum*, and *C. eximium* comprise three of the five most ancestral pungent *Capsicums* (Walsh and Hoot, 2001). All occur in southeastern Bolivia and northern Argentina, near to where the nonpungent form of *C. chacoense* was inadvertently collected in 1959. Our sampling and analysis focus on *C. chacoense*, and variation in capsaicinoid production across all three species in southeastern Bolivia, is examined.

METHODS AND MATERIALS

Field Sampling. We looked for *Capsicum* in the semiarid chaco and neighboring highland habitats in southwestern Bolivia (19°–22°S, 63°–65°W), sampling 29 natural populations of *C. chacoense*, 15 of *C. baccatum*, and 1 of *C. eximium* from February through April 2002–2005. These three species are easily distinguished by leaf and flower morphology, as well as plant stature. We examined all sampled populations for signs of obvious spatial patterning in the location and size structure of pungent and nonpungent plants that might be used to infer recent colonization of one form or another. Such patterns are described where present. In each population, ripe fruits were tasted from as many fruiting

^aYears sampled.

^bAverage number of plants sampled for pungency each year (range, if more than 1 yr).

^cAverage percent of plants pungent (range if multiple years). Percent pungent and plant density were calculated only for populations where >10 individuals were sampled.

^dDensity was estimated as follows: low is <10 plants per hectare; mid is 10-100 plants per hectare; high is >100 plants per hectare.

plants as possible to determine the ratio of pungent to nonpungent plants. This is an accurate method of capsaicinoid detection because humans can detect these compounds at <1.5 ppb (Scoville, 1912), a concentration far lower than is found in any pungent wild chili (see Results), and capsaicinoids are produced before fruit ripening. In field-testing plants for pungency, false positives are virtually impossible (if a plant lacks capsaicin, it will never taste pungent), but false negatives are possible if a particularly mild pungent plant is tasted after a more pungent plant. To guard against false negatives, multiple fruits from any plant that was determined to lack pungency were sampled, and we had multiple people check the pungency of the fruits. If anyone tasted capsaicin, the plant was considered pungent. In addition, some populations were sampled in multiple years to determine the stability of the ratios of pungent to nonpungent plants (Table 1). Voucher specimens were taken from each population and deposited at the Museo Historia Natural “Noell Kempff Mercado” and the Bolivian National Herbarium.

In one population (Figure 1, c3), permanent tags were affixed to all plants, and these were sampled in multiple years to verify that individual plants consistently produced either pungent or nonpungent fruit. In addition, seeds from pungent and nonpungent plants in five populations were collected and grown under identical conditions to quantify biogeographic variation in the concentrations of various capsaicinoids.

The density of individuals in all populations were estimated based on the area searched and the number of plants encountered. Because of differences in terrain and plant detectability among sites, all populations were classified into broad density classes. Low-density populations had <10 plants per hectare, medium-density populations had between 10 and 100 plants per hectare, and high-density populations had >100 plants per hectare. GPS locations of all populations were determined at the time of collection. In two populations (Table 1, c3 and c19), the location of all plants also was mapped, allowing us to examine fruit chemistry in a spatially explicit format.

Capsaicinoid Profiles of C. chacoense. To verify that nonpungent plants completely lacked capsaicinoids and to test for genotypic differences in capsaicinoid concentrations between populations of *C. chacoense*, seeds from five *C. chacoense* populations were collected and grown in a greenhouse to avoid environmental effects on capsaicinoid production (Harvell and Bosland, 1997). All plants were grown in 4-in. pots filled with uniform clay particles (Turface®, Profile Products LLC, Buffalo Grove, IL, USA) and kept moist through daily watering. The nutrient solution used was a standard 20–10–20 (NPK), rotated weekly with a 17–5–17 blend. Greenhouse temperatures averaged 23.4°C during the day and 17.4°C at night, under a 13:11 light/dark cycle. Fruit production started 90 days after germination. Fruits from pungent and nonpungent plants were analyzed from each population separately. Within

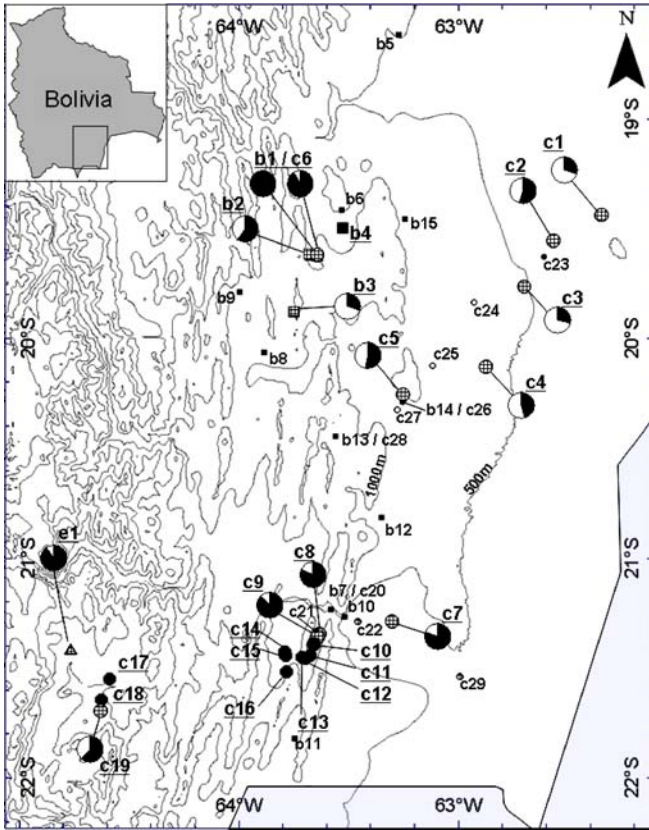

FIG. 1. Pungency distribution in sampled populations of *C. chacoense* (circles), *C. baccatum* (squares), and *C. eximium* (triangle) in southwestern Bolivia. Large symbols indicate populations where ≥ 10 plants were sampled for pungency; small symbols indicate the location of populations in which < 10 plants were sampled. Black symbols are completely pungent populations, hatched symbols are polymorphic populations, and white symbols indicate populations where no pungent plants were sampled. Pie charts indicate percent of plants pungent (black slice) in all polymorphic populations with ≥ 10 plants sampled. Contour lines represent 500-m elevation changes. Letter-number combinations refer to population data in Table 1.

each pungency by location combination, fruits from multiple plants with different maternal genotypes were bulk-sampled, creating a single, homogenous sample for analysis (10–30 genotypes used for each location by pungency combination). All fruit samples were harvested when fully mature, dried 48 hr at 65°C directly after harvest, and ground to a uniform particle size (skin, pulp, and seeds). This powder was then digested in 100% acetonitrile solution for 4 hr

at 85°C, following Collins et al. (1995). Total capsaicinoid concentrations (mg/g dry weight of the chili) and concentrations of capsaicin, dihydrocapsaicin, and nordihydrocapsaicin were measured for each population using an Agilent 1100 high-performance liquid chromatography (HPLC), equipped with an autosampler and an Agilent XDS Zorbax C-18 Column. HPLC conditions and mobile phases followed established protocols for the analysis of individual capsaicinoids (Collins et al., 1995). Concentrations were derived by comparing peak area of samples to external standards of 1 mg/ml for capsaicin and dihydrocapsaicin (Sigma-Aldrich Co.).

Analysis. The relationship between the percent of pungent individuals in a population and elevation (log transformed) was examined using linear regression. Linear regression was also used to examine the effect of elevation on the concentration of total capsaicinoids, as well as the three individual capsaicinoids that were resolved. In this analysis, we corrected for multiple tests on the same data by using sequential Bonferroni adjustment, with a total of four tests (Rice, 1989). The relationship between population density and elevation was examined by using analysis of variance. In the one population where spatial structure was found in the location of nonpungent plants, we mapped the structure and tested for significance using a chi-squared test. Mapping of populations was performed using ArcGIS 9.0.

RESULTS

A total of 1481 *C. chacoense* plants in 28 populations, 93 *C. baccatum* plants in 15 populations, and 10 *C. eximium* plants in a single population (Table 1) were sampled. In all three species, populations composed of plants that produced only pungent fruit and other plants that produced only nonpungent fruits were found (Figure 1). These were termed polymorphic populations.

Biogeography and Habitat Associations of C. chacoense, C. baccatum, and C. eximium. The proportions of pungent plants in all populations in which 10 or more plants were sampled are reported, totaling 21 *C. chacoense* populations, 4 *C. baccatum* populations, and 1 *C. eximium* population. The smaller number of polymorphic *C. baccatum* and *C. eximium* populations prevent detailed analysis of patterns of polymorphism, but the biogeographies of all three species are described, detailing overlapping distributions, where appropriate.

C. chacoense populations were found primarily in xeromorphic chaco forest at lower elevations (Figure 1, c1–c5, c7), grading into montane dry forest in the inter-Andean valleys at higher elevations to the west (Figure 1, c14–c16), and extending to the transitional zones around Tarija (Figure 1, c17–c19). In the lower chaco forests, *C. chacoense* were found in stands dominated by *Schinopsis*, *Aspidosperma*, *Ziziphus*, and *Prosopis*. Other species producing

fleshy fruit concurrent with *C. chacoense* included *Celtis*, *Vallesia*, *Capparis*, and *Ravenna*. In localities where *C. chacoense* was found at intermediate elevations (Figure 1, c8–c16), the vegetation was similar to lowland chaco, with increasing moisture toward the west (Figure 1, c16–c18). Here, chilies were found in woodlands with extensive *Prosopis*, *Schinopsis*, and *Bromelia*. Between these two dry ecoregions, and along the eastern flank of the Andes, *C. baccatum* was found, located in moister habitat (Ribera et al., 1994). In the transition between the wet yungas and the dry chaco, *C. chacoense* and *C. baccatum* co-occurred (Figure 1, b1/c6, b14/c26, b13/c28, b7/c20). At higher elevations around Tarija, *C. chacoense* (Figure 1, c17–c19) and the lone population of *C. eximium* (e1) were found in a more open habitat characterized by *Prosopis nigra* and other leguminous trees. In these habitats, *Commiphora*, *Celtis*, *Cassia*, and *Capparis* were all seen fruiting at the same time as *Capsicum*.

Pungency, Plant Density, and Elevation. The proportion of pungent plants, the capsaicinoid content of pungent fruits, and the density of chili plants all increased with elevation for *C. chacoense* (Figure 2A and B). In all but two populations higher than 800 m, greater than 90% of the plants were pungent, creating a bounded association between proportion of plants pungent and elevation (Figure 2A). This relationship can be decomposed into populations below 800 m, where a significant increase in pungency with increased elevation was found (Figure 2; adj $r^2=0.53$, $P=0.01$; 10 populations < 800 m), and a zone of consistent high incidence of pungency above 800 m (Figure 2A).

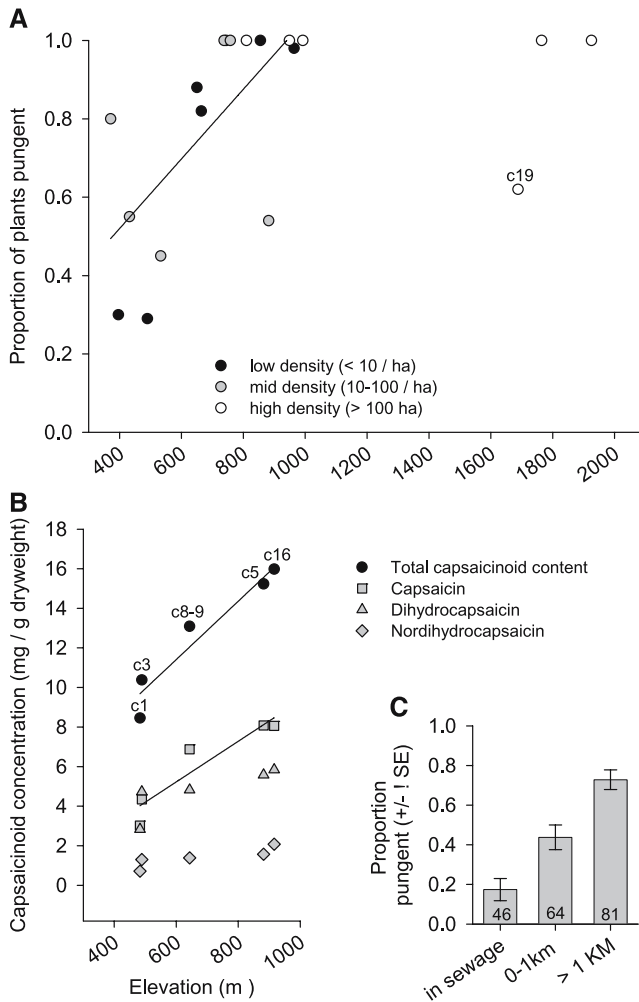

Population density also increased with elevation (Figure 2A; $F_{2,16}=6.8$, $P=0.007$); the mean elevation of low-density populations (<10 plants per hectare) was 530 m ($N=5$, $SE=73$ m), the mean elevation of mid-density populations (10–100 plants per hectare) was 778 m ($N=8$, $SE=75$ m), and high-density populations (>100 plants per hectare) averaged 1288 m in elevation ($N=6$, $SE=228$ m). Thus, compared to lower elevation populations, higher-elevation populations generally had more plants, and more of these were pungent.

In the five populations in which capsaicinoid production was analyzed, nonpungent plants were completely free of capsaicinoids, and total capsaicinoid content increased significantly with increasing elevation (adj $r^2=0.90$, $P=0.009$). All three capsaicinoids generally increased in higher-elevation populations (Figure 2B), with capsaicin showing the largest change with increasing elevation (adj $r^2=0.83$, $P=0.021$). This change was marginally significant after correction for multiple tests (Rice, 1989). Increases in dihydrocapsaicin and nordihydrocapsaicin with elevation (adj r^2 's=0.56 and 0.63, respectively) were not significant (P 's > 0.05).

In pungent plants, capsaicin was the most common of the capsaicinoids in four out of five populations (Figure 2B), averaging 6.07 ± 0.46 mg/g dry mass in

a ripe chili or $46.7 \pm 1.5\%$ of the total capsaicinoid content. Dihydrocapsaicin was the next most common, averaging 4.76 ± 0.24 mg/g dry mass or $37.8 \pm 0.9\%$ of the total capsaicinoid content, and nordihydrocapsaicin made up most of the remainder, averaging 1.4 ± 0.09 mg/g dry mass or $11.0 \pm 0.4\%$ of the total capsaicinoid content. In populations c3 where we sampled the same plants repeatedly over 4 yr, all plants consistently produced either pungent or nonpungent fruit ($N=25$ plants sampled across 3 yr, $N=15$ across 4 yr).

Dispersal by Humans. In one of the high-elevation polymorphic populations of *C. chacoense* (c19), the distribution of nonpungent plants appeared

highly clumped around two large (>1.4 m) nonpungent plants growing in a sewage outflow drainage for the town of Calamuchita. We sampled this population extensively to examine this pattern (232 plants sampled for pungency). Nonpungent plants in this population ($N = 88$) were concentrated around the two large plants (Figure 2c; $\chi^2_{2,189} = 35.1$, $P < 0.005$), and pungent plants became more and more dominant at increasing distance from these two large nonpungent plants (Figure 2c). Except for these two large individuals, all other nonpungent plants were small (<60 cm in height). This clumped pattern was not evident in other populations, and in the one low-elevation population in which we marked and mapped plants explicitly (c3, 123 plants), we found no clumping of nonpungent or pungent plants.

DISCUSSION

Genetic regulation of pungency occurs at a single locus, *C*, in *Capsicum annum* where accessions recessive for *c* fail to produce capsaicinoids (Blum et al., 2002). The gene required for production of capsaicinoids in cultivated chilies is *pun1* (Stewart et al., 2005). This understanding of the genetic control of pungency in *C. annum*, a highly derived species, may not apply to wild populations of *C. chacoense*, *C. baccatum*, and *C. eximium*, where our discovery of polymorphism for pungency demonstrates that pungency is not consistently present in more ancestral taxa of *Capsicum*. Of the five most ancestral wild species (Walsh and Hoot, 2001), *C. chacoense*, *C. baccatum*, and *C. eximium* are the only species with relatively wide ranges. *C. chacoense* is found throughout the chaco in Paraguay and Argentina (McLeod et al., 1982)

FIG. 2. (a) Proportion of plants in *C. chacoense* populations that are pungent, as a function of the elevation, for all populations with ≥ 10 plants sampled. Two high-elevation polymorphic populations are labeled. Linear fit is included for all populations <1200 m ($r^2 = 0.47$, $P = 0.0034$). (b) Concentration (mg/g dry mass) of total capsaicinoids (black circles), and the three individual capsaicinoids found in all three populations: capsaicin (gray squares), dihydrocapsaicin (gray triangles), and nordihydrocapsaicin (gray diamonds), as a function of the population elevation, for five populations grown from seed in identical greenhouse conditions (population labels indicated above black circles). Linear fit lines indicate significant relationships between elevation and the concentration of total capsaicinoids, and the primary capsaicinoid, capsaicin. (c) The distribution of nonpungent plants in relation to two large plants found in a sewage discharge drainage basin is shown for population c19. Bars are arcsine square-root-transformed percentage of plants pungent, error bars indicate one standard error of the mean, and number of plants sampled is indicated within the bars.

and as far west as Tarija and Sucre. According to McLeod et al. (1982, 1983), *C. chacoense* may be ancestral to *C. baccatum* and *C. eximium*. *C. baccatum* is also found in Paraguay and Argentina, but extends further north and west than *C. chacoense*—being found in Brazil and Peru as well (Eshbaugh, 1970), where it may have given rise to *C. tovarii*, a species endemic to southern Peru (Eshbaugh et al., 1983). Based on hybridization studies, *C. tovarii* is tightly linked to the *C. baccatum* complex (Tong and Bosland, 1999). *C. eximium* is a higher-elevation species, extending from the mountains in Argentina through the highlands in Bolivia, Peru, and Ecuador (Eshbaugh, 1976). *C. eximium* may be the progenitor of *C. cardinasii*, an endemic found only in the La Paz region in Bolivia with which it crosses readily (Eshbaugh, 1976; Walsh and Hoot, 2001).

If this interpretation is correct, the three most ancestral species of pungent chilies all have both pungent and nonpungent forms. Furthermore, while both *Capsicum cardenasii* and *C. tovarii* are reported as pungent, systematic sampling of these species has not occurred; they may be polymorphic, too. This interpretation fits well with McLeod et al. (1982) suggestion of a “nuclear area” of inter-Andean valleys northeast of Sucre, where divergent selection on ancestral *C. chacoense* led to both the purple-flowered group (*C. eximium*) and the white-flowered group (*C. baccatum*). According to this hypothesis, *C. chacoense* gave rise to *C. eximium*, which expanded into the dry highlands, and the white-flowered group (*C. baccatum*), which occupies semimoist lowlands. McLeod et al. further suggest that *C. baccatum*, through eventual migration down river to the Rio Grande, then into the moist tropics of the Amazon basin, radiated to form the moisture-loving *C. annum* group found in Brazil. This hypothesis relies on the importance of ecotones and heterogeneity in the physical environment in the creation of geographically explicit selection pressures (Stebbins and Major, 1965; Stebbins, 1972). Molecular data are currently insufficient to test this hypothesis (Walsh and Hoot, 2001), but the existence of polymorphic populations in *C. chacoense*, *C. baccatum*, and *C. eximium* refocuses attention to this area as a zone where early evolution of pungency may have occurred.

A more complete understanding of the early evolution of capsaicinoid production will require additional information on the link between nonpungent species, such as *C. ciliatum* (D’Arcy and Eshbaugh, 1974) and this clade of polymorphic species that appears to be ancestral to pungent *Capsicum* (Walsh and Hoot, 2001). Still, the finding that the first pungent *Capsicum* may all exhibit polymorphisms for capsaicinoid production has several implications for the ecology and evolution of these secondary metabolites.

The clinal variation in capsaicinoid production seen in *C. chacoense* and the existence of polymorphic populations of *C. baccatum* and *C. eximium* both suggest that capsaicin production is not uniformly beneficial. Furthermore, *C.*

chacoense populations are diffuse and widely scattered in the lowland chaco, and yet consistently exhibit polymorphisms for pungency, with at least 25% of the plants pungent in all populations in which at least 10 plants were sampled (Table 1). This pattern suggests either some form of frequency-dependent selection on pungency that prevents the pungent or nonpungent form from becoming fixed in the population, or some form of oscillating selection pressure, in which conditions favor pungent plants at some times and nonpungent plants at others, regardless of the frequency of the two phenotypes (Futuyma, 1998).

Teasing apart these possibilities will require a greater knowledge of the selective pressures acting on the entire fruit phenotype and the costs and benefits of secondary metabolite production (Berenbaum, 1995). Although the array of potential selective pressures on fruit secondary metabolites has been outlined (Cipollini and Levey, 1997; Cipollini, 2000), the full array of adaptive hypotheses has not been addressed in any system. The work that comes closest is that on emodin in *Rhamnus* fruit (Izhaki, 2002; Izhaki et al., 2002; Tsahar et al., 2002). This is the only system in which the effects of intraspecific variation in fruit secondary metabolites have been studied systematically. Variation in emodin concentrations among plants is correlated with nutrient concentrations (Izhaki et al., 2002). It affects both invertebrate and vertebrate fruit consumers (Tsahar et al., 2002, 2003) and shows intra- and interannual variations in its effect on consumers (Tsahar et al., 2002). These complex selective environments suggest that multiple adaptive functions may be the norm for secondary metabolite production (Schmitt et al., 1995; Cipollini and Levey, 1997), but a general theory of the pressures governing this variation has yet to appear and is unlikely until we place the adaptive benefits into a mechanistic framework that includes not only the benefits, but also the costs and potential trade-offs of secondary metabolite production (Berenbaum, 1995).

The discovery of three basil lineages all with polymorphisms for the production of a major secondary metabolite creates an unprecedented opportunity to examine both the costs and benefits of secondary metabolite production and to test these theories in three closely related taxa. Furthermore, in *C. chacoense*, nonpungent plants dominate populations in low-elevation chaco, and, among pungent plants, capsaicinoids (particularly capsaicin) occur at relatively low concentrations. As elevation increases, plant density increases, pungent plants dominate, and capsaicinoid concentrations become higher. These correlated patterns further suggest shifts in the relative costs and benefits of capsaicinoid production across elevation, and they may point to developmental or allocation trade-offs during fruit maturation. Because the pungent forms of all three of these species are harvested and consumed by locals, and *C. baccatum* (var. *baccatum*) has been domesticated (*C. baccatum* var. *pendulum*), human movement of genotypes might obscure evolutionary relationships. This applies equally to nonpungent forms of these species, as nonpungent plants are

indistinguishable from the pungent forms, except by tasting the fruit. We see possible evidence of the influence of humans in Calamuchita (c19) where nonpungent plants were concentrated around two large nonpungent individuals in the sewage outflow, suggesting that the large nonpungent plants may have arrived through human consumption of nonpungent chilies from elsewhere, followed by a gradual radiation from these two founders. This interpretation is speculative, but *Capsicum* are typically long-lived plants in the wild (Tewksbury et al., 1999), providing sufficient opportunity for establishment and subsequent local radiation to occur. More rigorous explanations will have to wait for information on relatedness and gene flow between populations. The existence of nonpungent forms at high elevations in two locations (c5 and c19) does suggest that whatever selective forces are responsible for the general shift from polymorphic to completely pungent populations with increasing elevation are not uniform: nonpungent plants can grow and reproduce in some high-elevation locations.

The clinal variation in pungency and percent of pungent individuals suggest either a lack of gene flow that prevents mixing of the pungent and nonpungent forms across this gradient, or a shift in selective pressures such that both pungent and nonpungent forms are maintained in the lowland chaco, but selection favors pungent plants at most high-elevation locations. We view the former explanation as unlikely for the entire gradient, given the clinal pattern across elevation and the fact that the distances between polymorphic and completely pungent populations are often small. For example, population c9, in which 18% of plants sampled lacked pungency, is less than 30 km from populations c14 and c15, in which 200 plants were sampled and all were pungent. Between these two populations, we found small populations of chilies that were totally pungent (Figure 1; populations c10–c13). The major dispersers of chili seeds in Bolivia are *Elaenia parvirostris* and *Turdus amaurochalinus*, both austral migrants (Jahn et al., 2002). Thirty kilometers is not an unreasonable distance for a migrant bird to carry seeds, and given the existence of suitable chili habitat between these populations, there appears to be ample opportunity for gene flow between populations, even for a predominantly self-pollinated species such as *C. chacoense* (McLeod et al., 1982).

If changes in capsaicinoid production are instead due to changes in selective pressures acting on fruit phenotypes, it presents a rare opportunity to identify and characterize the selective pressures that favor the production of a major secondary metabolite. We know that birds readily eat both pungent and nonpungent chilies (Tewksbury and Nabhan, 2001; Tewksbury unpublished data). Many aspects of the biotic and abiotic environment likely vary across this 1000-m altitudinal gradient, any one of which might shift in favor of pungent plants at higher elevations. For example, nonpungent fruits in polymorphic populations are much more likely than pungent fruits to be damaged by fungi

(Tewksbury and Levey, unpublished data), and the risk of damage may vary across elevation. In addition, in one polymorphic population (c3), capsaicinoids appear to protect seeds from seed predators when fruits fall directly to the ground (Tewksbury and Levey, unpublished data). All of these results suggest complex interactions among different aspects of fruit phenotype. Fruit removal rates, invertebrate seed predation, and fungal pathogen load may all change with elevation and interact with plant density, which varies by more than an order of magnitude from diffuse low-elevation populations to dense high-elevation populations. Thus, there are potentially many biotic and abiotic selective pressures that could influence the chemical phenotype of chili fruits across this gradient.

Acknowledgments—This research was made possible through grants from the National Science Foundation (DEB-0129168) and the National Geographic Society Committee for Research and Exploration (7190-02). We thank Paul Martin, Robert Dobbs, Ian Horn, Meribeth Huzinga, Alex Jahn, Uco Sapag, and Don Odon for assistance in the field. We thank Damian Rumiz, Andy Noss, and Natalia Araujo, as well as WCS Bolivia, Fundación Amigos de la Naturaleza, and Museo de Historia Natural “Noel Kempf Mercado” for logistic support. We thank two anonymous reviewers for helpful critiques of early versions of this manuscript.

Abstract—The volatile chemicals produced by four poaceous plant species, blue thatching grass, *Hyparrhenia tamba*, Napier grass, *Pennisetum purpureum*, sorghum, *Sorghum bicolor*, and maize, *Zea mays*, which are host plants for the lepidopterous stemborers, *Chilo partellus* and *Busseola fusca*, were collected by air entrainment and analyzed by gas chromatography. The total quantities of volatiles collected hourly, over a 9-hr period, from *P. purpureum* and *H. tamba* showed an approximately hundredfold increase in the first hour of the scotophase. Thereafter, the amount decreased rapidly to levels present during photophase. Although onset of scotophase also triggered an increase in quantities of volatiles collected from two cultivars of *S. bicolor* and two out of three cultivars of *Z. mays*, these increases were less dramatic than in the two wild grasses, being only up to 10 times as much as in the last hour of photophase. Analysis showed that up to 95% of the increase in volatiles at the onset of the scotophase was due to just four compounds, the green leaf volatiles hexanal, (*E*)-2-hexenal, (*Z*)-3-hexen-1-ol, and (*Z*)-3-hexen-1-yl acetate, with the latter dominating the volatile profile. Volatiles from *P. purpureum* were also collected at 10-min intervals for 70 min spanning the transition from light to dark. The vast increase in production of the green leaf volatiles in this species occurs in the first 10 min of the scotophase followed by a rapid decline within the next 20 min. The relevance of these results to the control of stemborers in a “push–pull” strategy is discussed.

Key Words—Stemborer, maize, sorghum, diel periodicity, green leaf volatile, oviposition, host location.

INTRODUCTION

Maize, *Zea mays* L., and sorghum, *Sorghum bicolor* Moench, are essential food and cash crops for millions of people in the largely mixed crop–livestock farming systems of sub-Saharan Africa. Lepidopterous stemborers, predominantly the indigenous *Busseola fusca* Fuller (Noctuidae) and the introduced *Chilo partellus* (Swinhoe) (Crambidae), are major constraints to efficient production causing reported losses of 20–40% in maize in the region (Seshu-Reddy and Sum, 1992), the latter being more injurious (van den Berg et al., 1991). Stemborers are difficult to control, largely because of the cryptic and nocturnal habits of the adult moths and the protection provided to the immature stages by the stem of the host plant (Ampofo, 1986; Seshu-Reddy and Sum, 1992). A “push–pull” system for controlling stemborers in African smallholder maize and sorghum production has been established (Khan et al., 2000, 2001). This involves the use of a trap crop (pull) surrounding the plot and repellent (push) plants as intercrops between the rows of sorghum or maize. A number of wild hosts can be used as the trap crop, including Napier grass, *Pennisetum purpureum* Schumach, which are considerably more attractive to gravid female stemborer moths than the crop itself (Ndemah et al., 2002; Rebe et al., 2004). Although the semiochemicals mediating the repellent effects of intercrops such as *Melinis minutiflora* Beauv. and *Desmodium uncinatum* (Jacq.) have been identified (Khan et al., 2000; Khan and Pickett, 2004), the basis for the differential attraction/oviposition between wild and cultivated hosts is not understood.

Many insects show different sensitivities to host-derived semiochemicals throughout the day, and this sensitivity can be under the control of circadian clocks (reviewed by Lazzari et al., 2004). Most oviposition by gravid females of *C. partellus* takes place during the first 2 hr of scotophase (Päts, 1991), and this behavior may be an example of such effects. However, it may also be that this insect and other stemborer species showing similar behavior have adapted to take advantage of the release of volatile cues by host plants. Physiologically active volatile chemicals of host plants have been identified (Birkett et al., unpublished data), and the current investigation into the temporal pattern of their emission was undertaken to determine whether a transient release of volatile chemicals could be attracting moths at the time of day appropriate for host location.

METHODS AND MATERIALS

Plants. Plant species used in this study were maize, *Z. mays* (Western Seed Company Hybrids 502 and 909, and a UK cultivar, Earliking), sorghum, *S. bicolor* (var. Serredo and Gadam), Napier grass, *P. purpureum*, and blue thatching grass, *Hyparrhenia tamba*. Seeds were planted individually for maize and sorghum and in a group for *H. tamba* in plastic pots filled with compost. *P. purpureum* was grown from cut stems planted in compost, 2–3 in a pot. All plants were grown in an insect- and pathogen-free glasshouse under controlled conditions with a 16-hr photoperiod, 60% relative humidity, and 27–30°C during photophase and 22–25°C during scotophase. Supplementary lighting, comprising sodium lamps (SON-T, 600 W) that gave photosynthetically active radiation (PAR) of approximately 300 $\mu\text{mol m}^{-2} \text{sec}^{-1}$ at bench height, was used, and the lights were switched off at 20:30 hr, approximately 30 min after sunset but approximately 30 min before civil twilight, so that the light–dark transition was relatively sharp. Plants used in experiments were 19–27 d old, although the ages of plants from the same species were within 1–2 d of each other.

Collection of Headspace Volatiles from Intact Plants. Volatile compounds were collected via entrainment of intact plants by using portable equipment developed at Rothamsted (Agelopoulos et al., 1999; Birkett et al., 2003). To avoid causing plant stress by transfer, all entrainments were performed at the site where the plants were being grown. Part of the plant was enclosed in an open-bottomed glass cylinder (100 mm OD \times 600 mm), and the bottom was closed with two semicircular aluminum plates that fitted closely together, except for a hole in the middle that fitted around the plant. To accommodate stems of different shapes and sizes, the holes comprised circular openings of 2 cm (for *H. tamba*) and 1 cm diam (for *P. purpureum* and *S. bicolor*), and an elliptical opening of 2 \times 1.3 cm (for *Z. mays*). Any large gaps between the plates and the stem(s) were packed with silanized and baked glass wool. Air was pumped into the vessel through an activated charcoal filter, via a port in one of the aluminum plates, at 1.2 l min^{-1} , and volatiles were collected on Tenax TA (60/80 mesh, 0.05 g) packed into a glass tube (80 mm \times 5 mm OD) inserted into a collection port at the top of the vessel. Air was drawn out through the collection tube by another pump at 1 l min^{-1} . The differential flow rates eliminated the risk that unfiltered air could be drawn into the vessel from outside, while obviating the need for an injurious tight seal around the stem(s). All connections were made with polytetrafluoroethylene (PTFE) tubing and ferrules, and as much as possible of the equipment, especially the glassware, was heated at 180°C for at least 5 hr before use. Glassware was washed in soapy water and rinsed with

Results are in ng g⁻¹ h⁻¹, actual amounts (mean ± SE, N = 5). Within each species and compound, means bearing the same superscript are not significantly different, P < 0.001. Scotophase began at 20:30.
 nd: below the detection limits of 0.02 ng g⁻¹ h⁻¹.

distilled water and then acetone before conditioning. Tenax tubes were washed with redistilled diethyl ether and conditioned at 220°C with filtered nitrogen pumped through for 2 hr before use. After each collection, water vapor was removed from the Tenax tubes by passing filtered air through them for 30 min at approximately 500 ml min⁻¹.

In the first series of experiments, plant volatiles were collected for 1-hr periods for 9 hr, the last 6 hr of photophase, and the first 3 hr of scotophase. In these experiments, plants were inserted into the entrainment vessels 3 hr before collection of volatiles commenced, in order to minimize any effects due to the initial stress on the plants caused by manipulating them into the entrainment vessel. Each experiment was replicated five times with different plants, except for *Z. mays*, hybrid 502, for which there were only three replicates. When the entrainment was finished, the part of the plant entrained was excised and its fresh weight recorded.

A second series of short entrainment experiments was performed only with *P. purpureum* (five plants), since this is the main trap crop used in the “push-pull” strategy. In these, volatile collections were made for 10-min periods for 70 min starting 20 min before the transition from light to dark and 1 hr or more after inserting the plant into the vessel.

Analysis of Volatiles. Gas chromatography (GC) of the collected volatiles was carried out on a nonpolar (HP-1, 50 m × 0.32 mm ID × 0.52 μm film thickness) capillary column using an HP6890 GC (Agilent Technologies, UK) fitted with a flame ionization detector (FID). Volatiles collected on the Tenax absorbent tubes were transferred directly onto the GC column by thermal desorption using an Optic 2 programmed temperature vaporization (PTV) inlet (Anatune, UK), programmed for rapid heating from 30 to 220°C in 12 sec. Each Tenax tube was spiked with 100 ng *n*-tetradecane (in 0.5 μl redistilled hexane), as an internal standard, before inserting the tube into the PTV. Compounds of interest had already been identified by GC-mass spectrometry, and coinjection with solutions of volatiles collected in the same way but on Porapak Q and over a longer time period (Birkett et al., unpublished data).

Statistics. For analysis, a one-way analysis of variance (ANOVA) was applied. Least significant difference (LSD), at the 1% level, between means on the transformed scale, was used to assess comparisons of interest.

RESULTS

Nine-Hour Time-Course Entrainments. The results for the total amounts of volatiles collected in each hour on a per-gram fresh weight basis are shown in Table 1. Since it was not possible to determine response factors for all

components, the amounts shown are estimates based on the total area under the peaks compared with the peak area of the internal standard (100 ng). This assumes the same detector response to every compound. There was considerable plant to plant variation in the quantity of volatiles emitted (from the SE associated with the means), despite the plants being the same age and chosen for their similarity in size. Even so, the differences between the amounts emitted in the first hour of scotophase and the amounts emitted in the last hour of photophase are highly significant except in all three cultivars of maize.

Further analysis showed that the large increases in total volatile production are due to just four compounds (e.g., Figure 1): hexanal, (*E*)-2-hexenal, (*Z*)-3-hexen-1-ol, and (*Z*)-3-hexen-1-yl acetate. Table 2 shows the time course for the emission of each of these compounds by the four species, although only one cultivar for sorghum and maize. Here, results are absolute amounts (as opposed to the estimates in Table 1) of the four compounds since the response factor for each compound was determined relative to the internal standard, and the results corrected accordingly. In all four plant species, (*Z*)-3-hexen-1-yl acetate showed the largest increase relative to the other compounds, although in *P. purpureum* and *H. tamba*, the, albeit smaller, increases in (*Z*)-3-hexen-1-ol are slower to decline, still showing a slight elevation in the third hour of scotophase (Table 2).

Results are in ng g⁻¹, estimated for total volatiles and actual for compounds (mean ± SE, N = 5). Within each column, means bearing the same superscript are not significantly different, P < 0.001. Scotophase began at 20:30. nd: below the detection limits of 0.02 ng g⁻¹.

Interplant variation in actual amounts, within a species, was high, as reflected by the large values for SE.

Short Time Course. The detailed results for the estimated total volatile amounts and for the actual amounts of the four individual compounds emitted by *P. purpureum* are shown in Table 3. These results show that approximately 74% of the total volatiles collected in the first 50 min of scotophase are actually emitted in the first 10 min, and a further 23% in the next 10 min.

DISCUSSION

It has long been known that the time of release of floral volatiles varies greatly among plant species, and that this can be associated with behavior of the associated pollinator. The foliage of some tree species is also known to release large transient bursts of acetaldehyde during light to dark transitions (Holzinger et al., 2000; Karl et al., 2002). Furthermore, a number of volatile C₂–C₆ compounds, including (*Z*)-3-hexen-1-yl acetate, have been identified, together with a number of monoterpenes and their oxidation products, above a boreal coniferous forest, by using a ground-based chemical ionization mass spectrometer, and found to exhibit a clear diurnal variation (Sellegrri et al., 2004). Recently, Graus et al. (2004), using proton transfer reaction-mass spectrometry, have shown that, in addition to acetaldehyde, several C₆ compounds are released by gray poplar, *Populus × canescens* (Aiton) Smith, in considerable quantities after light–dark transitions. The first compound to show an increase in emission was hexenal (isomer not specified) after 30 sec, with the other aldehydes, alcohols, and esters appearing after a further 20 sec. However, whereas hexenal and acetaldehyde emissions only lasted for about 3 min, the high levels of the others lasted for up to 15 min. These C₆ compounds comprise some of the green leaf volatiles, which also include the compounds that have shown such large increases in the present study, hexanal, (*E*)-2-hexenal, (*Z*)-3-hexen-1-ol, and (*Z*)-3-hexen-1-yl acetate, and are normally associated with leaf damage, whether caused by herbivory or abiotically (Turlings et al., 1998; Ngi-Song et al., 2000).

Green leaf volatiles are produced from linolenic and linoleic acids through the lipoxygenase pathway (Paré and Tumlinson, 1996). They are liberated from membranes as a result of damage, by the action of a lipoxygenase enzyme that produces hydroperoxides initially. A hydroperoxide lyase enzyme then converts the hydroperoxides to hexanal (from linoleic acid) and (*E*)-2-hexenal (from linolenic acid), which undergo further reactions to give other C₆ aldehydes, alcohols, and esters (Hatanaka, 1993; Bate and Rothstein, 1998). The same pathway seems to be involved in the production of green leaf volatiles at the

change from light to dark conditions as indicated in the work of Graus et al. (2004), who showed that anoxic conditions at the light–dark transition eliminated production of the green leaf volatiles, the lipoxygenase enzyme requiring molecular oxygen (Hatanaka et al., 1987). If the reason for the production of green leaf volatiles on plant damage is attributable to release from storage pools, loss of the normal compartmentalization of the enzyme and the substrates in the intact cell, or simply the release of fatty acid substrates from the membrane, it is difficult to understand why the light–dark transition would do the same. It has been proposed that the sudden big change from a condition of saturating photosynthetic photon flux density to one of darkness causes significant disturbances in membranes, thereby inducing the typical wounding responses, in the absence of any visible leaf damage (Graus et al., 2004). The light–dark transition used in these studies was relatively sharp, which may cause a more dramatic effect on membranes than a gradual change. However, the conditions used here are similar to those at nightfall in Africa, near the equator, where related field studies have been conducted (Khan et al., 2000, 2001; Khan and Pickett, 2004).

A study on the induction of volatile emission from *Nicotiana tabacum* by caterpillars of *Heliothis virescens*, *Helicoverpa zea*, and *Manduca sexta* (De Moraes et al., 2001) showed that a number of herbivore-induced chemicals were produced only at night, and the production of other daytime volatiles was also increased during the scotophase. The compounds involved were mainly C₆ aldehydes, alcohols, and their esters, some of which are the same compounds as those showing large increases in production during the light-to-dark transition in the current study. Although, in the light of our results, it is possible that the increased production of these green leaf volatiles observed by De Moraes et al. (2001) was due to the onset of darkness rather than caterpillar induction, other plants of *N. tabacum* showed increases, albeit smaller, in the amounts of nocturnal volatiles produced when the caterpillars of *H. virescens* were removed from the plant several hours before dark. Clearly, the temporal emission of volatile chemicals by plants both as a normal response to the light–dark transition and as a response to biotic and abiotic damage needs further careful investigation.

Studies on the electrophysiological responses of *C. partellus* and *B. fusca* to components of the headspace volatiles of the same four species of host plant (as used in this study) identified the four green leaf volatiles that showed increases at light–dark transition as eliciting EAG responses in both insects' antennae (Birkett et al., unpublished data), although behavioral activity associated with these responses has not yet been determined. Gravid female stemborer moths are known to seek oviposition sites during the first 6 hr of scotophase, with most of the activity in the first 2 hr (Päts, 1991). Further behavioral studies are required, not only to determine the behavioral activity of

these green leaf volatiles but also to investigate the possible correlation between the production of large amounts of these compounds with time of oviposition flights by moths. The existence of such a correlation could explain why wild grasses are more attractive than the cultivated crop plants for egg laying since these plants produce much larger amounts of the green leaf volatiles at nightfall than the maize and sorghum. It is interesting to note that within the cultivated hosts, more oviposition by *C. partellus* takes place on sorghum than on maize (Kfir, 1992), which is also consistent with these results.

Abstract—In insect parasitoids, fitness is dependent on the host finding and recognition abilities of the female. Host recognition cues have been described for various host–parasitoid systems, but are still under investigation in aphid parasitoids. Our study aimed to clarify the respective role of physical and chemical cues in recognition of the aphid cuticle. Shed aphid exuviae were used as an elicitor in order to avoid any influence of color, movement, or volatiles present in a living aphid. We assessed the effect of chemical and heat treatments on the texture of the cuticle by using scanning electron microscopy and tested the recognition of treated cuticles by the parasitoid. We showed that recognition cues of the cuticle can be removed chemically (using combined treatments with n-hexane and methanol). Moreover, heat treatment destroyed the physical texture of the cuticle without significantly reducing parasitoid recognition. In a second step, we showed that epicuticular extracts deposited on pieces of paper triggered female attack behavior. First results concerning the chemical composition of the active extract are presented. This study shows that chemical compounds extractable by organic solvents mediate cuticle recognition by aphid parasitoids.

Key Words—Cuticular kairomones, chemical cues, oviposition behavior, Aphidiinae, *Sitobion avenae*, cuticular hydrocarbons, wax esters.

INTRODUCTION

In insect parasitoids, fitness depends to a considerable extent on the host recognition capabilities of the adult female. The host recognition process involves both physical and chemical factors (Godfray, 1994). Host body size (Shirota et al., 1983; Kouamé and Mackauer, 1991), host cuticle texture (Arthur, 1981), shape (Vinson, 1985), and color (Ankersmit et al., 1981, 1986; Michaud and Mackauer, 1994, 1995; Battaglia et al., 2000), as well as host movements (Arthur, 1981; Mackauer et al., 1996; Dippel and Hilker, 1998) act as cues triggering the attack behavior of female parasitoids. It has also been frequently reported that host recognition is mediated by semiochemicals (Strand and Vinson, 1982; Grasswitz and Paine, 1992; Battaglia et al., 1993).

Several authors have pointed out the role of epicuticular factors in host recognition by aphidiine wasps (Pennacchio et al., 1994). For example, in three aphid parasitoid species, females are not able to distinguish between host and nonhost species at a short distance, and an antennal contact is needed for recognition at the species level (Le Ralec et al., 2005). Oviposition attempts of aphid parasitoids toward host exuviae have been occasionally observed (Michaud, personal communication; Outreman, personal communication). Exuviae are useful biological material in behavioral analyses because visual factors like movement, color, and global shape are excluded as well as semiochemicals secreted by living aphids. Moreover, from the perspective of chemical analysis, only cuticular compounds are extracted from exuviae without any contaminants from the internal body (Grasswitz, 1998). Exuviae from *Acyrtosiphon pisum* elicit attacks by *Aphidius ervi* even when coarsely crushed (Battaglia et al., 2000). This response is still observed under red light, indicating that visual cues are not involved. Nevertheless, the attack behavior is not observed if the parasitoid is prevented from touching the exuviae with its antennae. Battaglia et al. (2000) evoked the “possibility that a cuticular compound, which functions as recognition kairomone,” occurs in the cornicle secretion and on the cuticle of exuviae. When antennal contact is required for host recognition, nonvolatile chemical compounds are likely to be involved, and a role for the cuticle texture must be considered (Godfray, 1994). Moreover, *Aphidius* wasps present both chemo- and mechanoreceptors on the antennae (Battaglia et al., 2002). Scanning electron micrographs of aphid epicuticle show the occurrence of wax secretion in a bloom covering (Retnakaran et al., 1979; Pope, 1983). Besides its waterproofing function (Pope, 1983), the epicuticular wax layer can also play a key role in communication. Hydrocarbons of the wax layer of the insect cuticle may be involved in, e.g., species, gender, and nestmate recognition, as well as in chemical mimicry (Howard and Blomquist, 2005). Therefore, the integration of both chemical and physical factors is a tentative explanation for the mechanism of host recognition by aphidiine parasitoids.

In order to assess the respective roles of cuticular wax semiochemicals and/or texture in parasitoid host recognition, exuviae were treated in various ways. In the first step, potential semiochemicals were washed off with solvents. During the second step, cuticle texture was altered by using a heat treatment. The effect of the solvent extraction on cuticular surface texture was studied by scanning electron microscopy (SEM), and the consequences of heat treatment and solvent extraction on parasitoid behavior were analyzed. To further assess the role of chemical cues, we observed the behavior of the parasitoid towards a cuticular extract. Finally, the chemical composition of the extract was investigated by coupled gas chromatography–mass spectrometry (GC–MS).

Our biological model was the aphid–parasitoid system, *Sitobion avenae* Fabricius–*Aphidius rhopalosiphi* De Stefany Perez. *A. rhopalosiphi* is one of the most abundant Aphidiinae species in cereal fields in North Europe (Jones, 1972; Stilmant, 1997) and has shown potential for biological control of aphids (Levie et al., 2005).

METHODS AND MATERIALS

Insect Rearing. *A. rhopalosiphi* individuals were collected in winter wheat fields near Louvain-la-Neuve, Belgium, in summer 2000, and reared on *S. avenae* maintained on winter wheat (*Triticum aestivum* cv. Windsor). Colonies of both *A. rhopalosiphi* and *S. avenae* were kept in the laboratory under the following conditions: $19.5 \pm 0.6^\circ\text{C}$, 40–50% relative humidity, and 16:8 hr L:D photoperiod. Parasitoids were reared on synchronized L2 aphid colonies. In a framed wooden cage (50 × 50 × 30 cm) with fine mesh on the sides, pairs of parasitoids (one pair per 50 aphids) were released for 24 hr. Ten days later, mummies were removed from wheat with a scalpel and kept in Petri dishes in groups of 50 individuals each. To avoid possible influences of hunger or mate-searching behavior (Michaud, 1994), emergent females were given access to food (honey–water) and males. All females were naive (no access to host) when tested.

Collection of Exuviae. Sheets of paper were placed for 1–3 d under aphid colonies of mixed age. Exuviae falling from the colony were collected and carefully separated from dead aphids and waste material. They were weighed with a 0.1-mg-precision balance (Ohaus explorer).

Experiment 1: Effect of Solvent Washing of the Exuviae. Exuviae were washed in methanol (SoxM) or hexane (SoxH) for 4 hr by using a soxhlet. Exuviae were recovered and allowed to dry for 24 hr before use in behavioral assays. Unwashed exuviae were used as controls. In a second part of the experiment, cuticular compounds present on the surface of exuviae were extracted (1) for 4 hr at room temperature with only one solvent, methanol (M), or n-hexane (H), or (2) sequentially for 1.5 hr by two successive solvents—

n-hexane followed by methanol (H + M), or methanol followed by n-hexane (M + H), and finally (3) for 4 hr with a mixture of n-hexane/methanol (ratio 1:2 v/v). During the extraction process, exuviae were held in a glass bottle and shaken at 100 rpm. In all cases, 1 mg exuviae was added to 10 ml solvent.

Experiment 2: Effect of Heat Treatment of the Exuviae. Exuviae were heated for 16 hr in an oven at 80°C. At the same time, a control batch was kept at room temperature. Needles and grips were washed in n-hexane and methanol prior to use in each treatment to avoid chemical transfer between specimens. Exuviae of the same experiment came from the same collection.

Scanning Electron Microscopy Method. In order to investigate the surface of aphid epicuticle, exuviae were studied by two different SEM methods. First, exuviae were sputter-coated with fine gold and directly observed in a Philips XL20 SEM (INRA, Rennes). Second, using a SEM (Oxford CT1500 cryosystem) at the microbiology laboratory (MBLA unit, UCL), specimens were flash frozen (-212°C) in liquid nitrogen under vacuum for cryo-SEM, transferred to the preparation chamber, and then to the SEM chamber where the frozen samples were sublimated (-80°C) to remove ice particles. Specimens were viewed under 2–5 kV at -190°C to -170°C (SEM Phillips XL20). To normalize the observations, all illustrations reported here represent the surface of wing buds of a “fourth instar exuvia” (between L4 and adult instar of the aphid). To ensure that observed differences were not due to individual variation, at least 20 exuviae were observed for each treatment.

Behavioral Assays. Glass Petri dishes (diam. 5 cm, height 1.5 cm, Schott®) were prepared by washing them with ethanol and deionized water and placed on a light table (2500 lx). Sixteen exuviae per dish were regularly disposed 1 cm apart in four rows of four exuviae each. Exuviae were maintained within a droplet of deionized water that dried at room temperature for 30 min before use. One parasitoid female was released at the center of the Petri dish and observed for 15 min. The behavioral items noted were “encounter with exuviae” (ENC), “antennal contact on exuviae” (ANT), and “abdominal bending towards exuviae” (ABD). In order to minimize variability, each set of experiments was completed during the same working day. Between 20 and 30 females were tested per treatment, each female being tested against one substrate only. The temperature during experiments was $23 \pm 1^\circ\text{C}$.

Experiment 3: Assay of the Cuticular Extract Activity. Exuviae were extracted as described above with a mixture of n-hexane/methanol (1:2, v/v) for 15 min. The extract was filtered and concentrated using a rotavapor (R110, Büchi, Switzerland) to 2 ml. The extract was deposited at the bottom edge of a filter paper (Whatman No. 1, 3 × 3 cm) held vertically, the solvent moving up the paper by absorption. The paper was allowed to dry at room temperature for 2 hr before the behavioral test. Small pieces (1 × 1 mm) were cut from the filter paper by using a scalpel parallel to the front of migration. Sixteen pieces of

paper were deposited in a glass Petri dish, and a behavioral test was conducted as described above except that the tests stopped after 5 min. New scalpel blades and clean grips were used for each treatment.

Chemical Analysis of the Cuticular Extract of Exuviae. Exuviae (20 mg) were extracted with an n-hexane/methanol (1:2, v/v) mixture for 15 min (as described above). After evaporation of the solvent in a rotavapor, the crude extract was dissolved in 2 ml of n-hexane/methanol, and 1 μ l was analyzed by GC-MS. The GC-MS investigations were performed on a Hewlett Packard HP 5989 Mass Spectrometer coupled with an HP 6890N gas chromatograph equipped with an HP-5 (cross-linked 5% phenylmethylpolysiloxane) column (30 m \times 0.25 mm I.D.; film thickness 0.25 μ m). The operating conditions were fixed as follows: split-splitless injector at 280°C; carrier gas, helium at 1 ml min⁻¹; temperature program, from 50°C to 300°C at 15°C min⁻¹, then at 300°C for 25 min. The mass spectra were recorded in the electron impact mode at 70 eV (source temperature, 230°C; scanned mass range, 35 to 700 amu). The detected peaks were identified by their retention time data and their characteristic fragmentation patterns. The mass spectra of the compounds were also compared with those of the NBS75K.L and Wiley275K.L computer MS Libraries. Four batches of 20 mg exuviae were analyzed by the described method.

Statistical Analysis. Data were analyzed using SAS System (SAS Institute, Cary, NC, 1999). PROC UNIVARIATE was first used to test the distribution of all behavioral observations. Data were log transformed in case of significant deviation from normality. To compare the number of behavioral events, variance analyses were performed using PROC GLM with Scheffé's multiple comparison method. To represent the proportion of exuviae rejected for oviposition after antennal analysis, a rejection ratio (Rej) was computed as follows: $1 - (\text{ABD}/\text{ANT})$ (where ABD = number of abdominal bendings, ANT = number of antennal contacts). As each female rejected a proportion of exuviae after antennal contact, this ratio was calculated for each female. Since these data cannot be normalized by any transformation, the ratios were analyzed by using the Kruskal-Wallis test with multiple comparisons following Siegel and Castellan (1988). The effect of cuticular extract was compared to the control using chi-square tests.

RESULTS

Experiment 1: Chemical Treatments. SEM observations revealed that the cuticular surface of the control exuviae is coated by a bloom of epicuticular waxes (Figure 1). The surface became smooth after soxhlet extraction (Figure 1), whereas the ornamentation remained intact when methanol was used on its own at room temperature (Figure 2). The SEM studies revealed no differences between individual exuviae that received the same treatment.

FIG. 1. Cuticular surface of the wing bud of fourth instar exuviae after chemical treatments in Soxhlet apparatus. Sox H = exuviae treated with n-hexane in soxhlet, Sox M = exuviae treated with methanol in soxhlet.

Analysis of variance showed a significant effect of washing exuviae with hot solvents on the behavioral response of the parasitoid (Table 1). The number of encounters ($F_{2,66} = 21.98$; $P < 0.001$), antennal contacts ($F_{2,66} = 35.50$; $P < 0.001$), and abdominal bendings ($F_{2,66} = 14.99$; $P < 0.001$) were clearly reduced by chemical treatment. The rejection ratio followed the same trend with a higher level of rejection after chemical treatment. The rejection ratio could not be tested statistically due to the high number of females that made no antennal contact. In this experiment, extraction with methanol inhibited recognition stronger than the n-hexane extraction.

At room temperature, solvent extraction had no significant effect on exuviae recognition (Table 2). However, successive chemical treatments with two solvents had a significant effect on host acceptance compared to control. The number of abdominal bendings towards exuviae was strongly reduced when both solvents were used sequentially or in a 1:2 mixture ($F_{5,108} = 19.57$; $P < 0.001$). Again, the rejection ratio followed the same trend with a strong increase in rejection for treatments employing both solvents.

Heat

FIG. 2. Cuticular surface of the wing bud of fourth instar exuviae after chemical treatment at room temperature or after heat treatment. M(rt) = exuviae treated with methanol at room temperature, Heat = exuviae heated in drying oven at 80°C.

TABLE 1. MEAN NUMBER OF BEHAVIORAL ITEMS OBSERVED ON SOXHLET-EXTRACTED EXUVIAE

	<i>N</i>	Enc	Ant	Abd	Rejection ratio
Sox M	24	9.3 ^b (1.5)	1.8 ^c (0.6)	0.17 ^c (0.09)	0.91
Sox H	22	14.6 ^b (2.3)	4.8 ^b (1.0)	1.18 ^b (0.3)	0.76
Control	23	34.8 ^a (4.2)	21.4 ^a (2.9)	6.87 ^a (1.6)	0.61

Standard errors are given in brackets. Means of the same column sharing the same letter are not significantly different ($\alpha = 0.05$). Enc = encounter, Ant = antennal contact, Abd = abdominal bending, Sox H = exuviae treated with n-hexane in soxhlet, Sox M = exuviae treated with methanol in soxhlet.

Experiment 2: Heat Treatment. Heating exuviae up to 80°C caused a “melting” of the epicuticular waxes that led to a “smoothing” of their typical microstructures. Indeed, when heated, the lipid surface constituents became amorphous with some spots that we considered as accumulated material (Figure 2). Heat treatment did not significantly affect the behavioral responses of the parasitoids ($F_{1,36} = 0.04$; $P = 0.847$ for encounter, $F_{1,36} = 0.41$; $P = 0.526$ for antennal contact, $F_{1,36} = 2.00$; $P = 0.166$ for abdominal bending) (Table 3).

Experiment 3: Activity of the Cuticular Extract. The parasitoids were stimulated to attack pieces of filter paper containing the cuticular extract (Figure 3). More than 75% of the females ($N = 20$) showed repeated abdominal bendings towards the extract. Only one female ($N = 17$) showed a single abdominal bending event on the control paper. Both the top ($\chi^2_2 = 28.3$, $P < 0.001$) and the bottom ($\chi^2_2 = 204.0$, $P < 0.001$) portion of the filter paper had a significant effect on parasitoid behavior compared to the control filter paper.

TABLE 2. MEAN NUMBER OF BEHAVIORAL ITEMS OBSERVED ON EXUVIAE TREATED WITH SOLVENTS AT ROOM TEMPERATURE

	<i>N</i>	Enc	Ant	Abd	Rejection ratio
H + M	29	24.4 ^b (2.4)	11.4 ^d (1.6)	1.0 ^b (0.4)	0.91 ^A
M + H	10	16.0 ^b (2.0)	6.4 ^{cd} (1.1)	0.6 ^b (0.2)	0.91 ^A
[HM]	15	34.0 ^{ab} (4.3)	13.2 ^{bcd} (2.6)	0.3 ^b (0.2)	0.97 ^A
Hrt	18	34.2 ^{ab} (4.1)	23.6 ^b (2.8)	9.5 ^a (1.7)	0.60 ^B
Mrt	17	33.9 ^{ab} (3.9)	26.2 ^b (3.3)	11.4 ^a (2.2)	0.57 ^B
Control	20	51.1 ^a (4.3)	41.1 ^a (3.8)	15.4 ^a (2.1)	0.63 ^B

Standard errors are given in brackets. Means of the same column sharing the same letter are not significantly different ($\alpha = 0.05$). Enc = encounter, Ant = antennal contact, Abd = abdominal bending, H + M = exuviae sequentially treated with n-hexane and then methanol, M + H = exuviae sequentially treated with methanol and then n-hexane, [HM] = exuviae treated with a n-hexane/methanol (1:2) mixture, Hrt = exuviae treated with n-hexane, Mrt = exuviae treated with methanol.

TABLE 3. MEAN NUMBER OF BEHAVIORAL ITEMS OBSERVED ON HEATED AND CONTROL EXUVIAE

	N	Enc	Ant	Abd	Rejection ratio
Heat	18	31.8 ^a (5.8)	20.9 ^a (3.9)	6.4 ^a (1.3)	0.69 ^A
Control	20	32.2 ^a (4.7)	23.4 ^a (3.6)	9.3 ^a (1.5)	0.60 ^A

Standard errors are given in brackets. Means of the same column sharing the same letter are not significantly different ($\alpha = 0.05$). Enc = encounter, Ant = antennal contact, Abd = abdominal bending. Heat = exuviae heated in drying oven.

Chemical Composition of the Cuticular Extract. The cuticular extract composition consists of compounds belonging to four major classes of compounds: approximately 20 hydrocarbons, 3 wax esters, 2 alcohols, and 2 aldehydes. The list of the detected compounds is presented in Table 4. The hydrocarbon fraction consists of a homologous series of n-alkanes (C25 to C31), branched monomethyl alkanes (X-MeC25 to X-MeC31), and one dimethyl alkane (11,13-DiMeC29). The wax esters detected at the end of the run (Table 4) were medium-chain fatty acids (C16) esterified to long-chain alcohols (C18 to C22). The extract is also characterized by the occurrence of two long-chain aldehydes (C28 and C30). The identification of the octacosanal (C28) has

FIG. 3. Behavioral response of the females to pieces of paper covered with the cuticular extract. Encounter = proportion of females that did not react when encounter the extract, Antennal contacts = proportion of females that showed antennal drumming, Abdominal bendings = proportion of females that showed abdominal bendings. “Top” and “bottom” refer to the part of the filter paper that received the cuticular extract, the front of migration of the extract being from bottom to top. “Control” refers to filter paper that received pure solvent.

DISCUSSION

This study used aphid exuviae in order to better understand the role played by semiochemicals and/or texture associated with wax secretions in host

recognition by the parasitoid *A. rhopalosiphi*. The results confirm that epicuticular factors are involved in host recognition. When these factors are chemically removed, the exuviae lose their activity in terms of eliciting responses from the parasitoid. Secondly, the results show that the tactile recognition of the epicuticular wax layer by the parasitoid is not involved in host recognition. The microstructure of the epicuticular wax layer is destroyed by the heat treatment, but these exuviae retain their activity for the parasitoid. We observed that the wax layer was still present on the heated cuticle, although its microstructure was destroyed. However, soxhlet extraction took away epicuticular waxes. The behavioral study revealed significant activity when the wax layer was still present regardless of its physical state. Rather, the kairomones embedded within epicuticular waxes seem to play a role in recognition of the host cuticle. The parasitoid's response was lost when the host cuticle received specific chemical treatments. First, hot chemical treatment was efficient, using n-hexane or methanol. Second, at room temperature, the solvents had to be combined to destroy the recognition response. Long extraction time (4 hr) in the soxhlet apparatus led to complete extraction of epicuticular constituents, some of which were not fully extracted at room temperature. With simple macerations at room temperature, two solvents of different polarities (hexane and methanol) were necessary for complete extraction of the active factor. At the 1:2 ratio, n-hexane and methanol are fully miscible and form a mixture that can be considered as a novel solvent with novel properties, such as e.g., polarity and boiling point. The use of the two solvents, sequentially or in mixture, enabled us to extract the active compounds from the cuticle. This suggests that the activity is due to several compounds with different polarities, rather than to a single compound. Moreover, heat treatment of the exuviae reduced the parasitoid's response but did not completely inactivate the cuticle. This suggests that the kairomonal activity of the exuviae is due more to a (mixture of) contact chemical(s) rather than to a mixture of short-range volatiles, as these would certainly almost be destroyed or removed by heating. Finally, the presence of cuticular kairomones was unequivocally proven by the parasitoid's responses towards pieces of paper impregnated by the extract. This represents the first direct evidence of the occurrence of cuticular kairomone(s) that elicit aphid parasitoid attacks. The results also show that a rough fractionation of the extract can be made by using the absorption capacity of the filter paper, since the bottom of the filter elicits a stronger reaction of the parasitoid than the top.

Hydrocarbons are known to be commonly involved in insect communication (Chapman, 1998). For example, chemical mimicry can often be attributed to cuticular hydrocarbons of similar composition (Dettner and Liepert, 1994; Liepert and Dettner, 1996; Allan et al., 2002). Methylene chloride extract of the cuticle of *S. avenae* revealed n-alkanes ranging from 23 to 35 carbon atoms and

several methyl-branched homologues (Hebanowska et al., 1989). However, these results were obtained by extracting whole aphids for 2 weeks, and contamination from internal body contents cannot be excluded (Grasswitz, 1998). In our study, the compounds extracted by the hexane/methanol mixture were not exclusively hydrocarbons. Wax esters as well as long-chain alcohols were also present in the extract. The cuticular extract also contained two aldehydes that are not often reported in studies on insect cuticles (Howard and Lord, 2003) and, to our knowledge, never on aphid cuticles. Moreover, we cannot exclude that other molecules such as sugars were extracted from the cuticle but not detected by the GC-MS technique. In further studies, the extract will be fractionated, and the different fractions will be assayed for recognition activity in order to identify the active compounds by a biologically guided chemical analysis.

In the experiments presented here, all oviposition attempts on exuviae were preceded by antennal contacts. This is not the case when a parasitoid faces a living aphid (Battaglia et al., 1993). *A. rhopalosiphi* usually starts its oviposition sequence on aphids without antennal contact, approaching the host with the antennae bending backwards (van Baaren et al., 2004). The differences in the behavioral sequence may be due to the nature of the stimulus involved. Both short-range (color, movement) and contact (kairomones) cues are present on the aphid, whereas on the cuticle, the chemical contact kairomones are the only remaining cues. These kairomones can be recognized antennal contact and also during ovipositor contact. The ovipositor of the Aphidiinae consists of three pairs of valvulae (Le Ralec and Rabasse, 1988; Le Ralec et al., 2001). At rest, the valvulae 1 and 2 are protected inside the third ones. During the stinging, the third valvulae weigh upon the host cuticle and separate from each other allowing the penetration of the valvulae 1 and 2. The third valvulae have been shown to wear both mechano- and chemoreceptors that could receive information from the cuticle of the host (Le Ralec and Rabasse, 1988). This means that the parasitoid may use two sequential tools to acquire information about the cuticular chemical cues of its host.

It has been shown that host feces or host secretions may play a role in the host-searching process and act as cues for location of host colonies (Weseloh, 1981). With regard to Aphidiine wasps, several authors have demonstrated a role for aphid honeydew in the host-location process (Budenberg, 1990). A similar mechanism seems to be involved in the recognition of exuviae: chemical traces inform the parasitoid of the host presence. If exuviae recognition by the parasitoid is advantageous to host location, the ecological significance of the attacks of exuviae is unclear. Indeed, the attack of an exuvia should be costly in time and energy for the parasitoid, and this behavior should vanish by natural selection. A possible explanation could come from the "Neo-Hopkins principle" (Jaenike, 1983; Corbet, 1985): the response to cuticular compounds could come

from the chemical environment experienced by the parasitoid at the emergence from the mummy. This conditioned chemosensory responsiveness can influence the host-searching and host-recognition behaviors of the adult. This effect on host location has already been shown for *A. rhopalosiph* (van Emden et al., 2002) but remains to be tested at the host-recognition level. From an applied point of view, the identified chemical stimulus could provide opportunities to manipulate parasitoid behavior in order to enhance oviposition in artificial rearing systems (Battaglia et al., 1995).

Acknowledgments—We thank Catherine Boegen, Ana Maria Dos Santos, Olivier Lebbe, and Vincent Cambier for help in laboratory work and stimulating discussion. The authors are grateful to Profs. J.P. Michaud and M. Mackauer for their useful review of the manuscript. Thanks to Prof. B. Morris for providing 1-octacosanal. This study was supported by funds from the Ministry of Research and Technological Development of the Walloon Region, by the Fund for Fundamental and collective research (FRFC), and from the FRIA (Fonds pour la Recherche dans l'Industrie et l'Agriculture). Our paper is publication BRC029 of the Biodiversity Research Centre (Université catholique de Louvain).

LEAF EPICUTICULAR WAX CHEMICALS
OF THE JAPANESE KNOTWEED *Fallopia japonica*
AS OVIPOSITION STIMULANTS FOR *Ostrinia latipennis*

Published Online April 4, 2006

Abstract—Extraction, fractionation, and gas chromatography–mass spectrometry analyses guided by bioassays have shown that *n*-alkanes and free fatty acids in leaf epicuticular wax of the Japanese knotweed *Fallopia (Reynoutria) japonica* stimulate oviposition in the Far-Eastern knotweed borer, *Ostrinia latipennis* (Lepidoptera: Crambidae). *n*-Alkanes made up 48.1% of the total amount of epicuticular wax, and their carbon chain length was in the C₁₆–C₃₃ range, with *n*-nonacosane (*n*-C₂₉) most abundant, followed by *n*-C₂₇, *n*-C₂₅, and *n*-C₃₁. Free fatty acids with C₉–C₂₂ accounted for 22.3%, and hexadecanoic acid was predominant. A mixture of authentic *n*-alkanes and fatty acids of the composition found in the epicuticular wax, a mixture of *n*-alkanes, and a mixture of fatty acids significantly enhanced oviposition. Thus, it was demonstrated that both *n*-alkanes and free fatty acids in leaf epicuticular wax of *F. japonica* are naturally occurring oviposition stimulants for *O. latipennis*.

Key Words—*Fallopia japonica*, *Ostrinia latipennis*, alkane, fatty acid, oviposition stimulant.

INTRODUCTION

The chemical composition of the epicuticular wax on the aerial surface of a plant varies among species, varieties within a species, parts within a plant, and different stages of development (e.g., Städler, 1986; Eigenbrode and Espelie, 1995; Shepherd et al., 1999, and references therein). Such variations provide substantial information by which many insect herbivores in the Lepidoptera, Diptera, and Coleoptera evaluate potential host plants. Knowledge of the kairomones in epicuticular wax may be useful in conjunction with pest management programs for improved monitoring of female populations in the field, possible disruption of egg-laying behavior, and genetic manipulation of host plants to create stimulant-free varieties (Metcalf, 1985).

The genus *Ostrinia* (Lepidoptera: Crambidae) includes important agricultural pests, such as the European corn borer *O. nubilalis*, the Asian corn borer *O. furnacalis*, and the adzuki bean borer *O. scapularis*. Although other members of *Ostrinia* have attracted little attention, the genus actually contains 21 closely related species with diverse host plant ranges (Mutuura and Munroe, 1970; Ishikawa et al., 1999; Ohno, 2003). Studies on the kairomones of respective host plants could provide clues to pest management, in addition to information on how host plant recognition systems have changed in association with the diversification of host plants during species divergence. Among the many *Ostrinia* species, however, only oviposition stimulants for *O. nubilalis* on maize have been studied to date (Udayagiri and Mason, 1997).

As a first step toward the comprehensive clarification of oviposition attractants/stimulants for the genus *Ostrinia*, we started by analyzing stimulants on the host plant of an oligophagous species, since it is likely that oligophagous species use more host-specific compounds as cues for host selection than polyphagous species, and hence should show a clearer behavioral response in bioassays. The Far-Eastern knotweed borer *O. latipennis*, a species of current interest, is oligophagous and usually uses either the giant knotweed *Fallopia (Reynoutria) sachalinensis* or the Japanese knotweed *F. japonica* as a host plant. The present study was conducted to elucidate oviposition stimulants in the leaf epicuticular wax of *F. japonica*.

METHODS AND MATERIALS

Insects. Egg masses of *O. latipennis* were collected from leaves of the giant knotweed *F. sachalinensis*, at Towa (39.9°N, 141.2°E) in July 2002. Larvae were reared as broods in clear plastic jars filled with 200 g of a commercial diet for insects (Insecta LF™, Nosan Corp., Yokohama, Japan). The environmental conditions were 24 ± 1°C, a 15-hr light–9-hr dark photoregime,

and 60% R.H. After pupation, females and males were segregated, based on the morphology of the abdominal terminal segments.

Extraction of the Leaf Epicuticular Wax. Twenty *F. japonica* plants naturally growing at five different sites on the Yayoi campus of Tokyo University were selected, and three leaves at upper, middle, and lower positions of each plant were collected. The area and weight of each leaf were measured, and these 60 leaves were dipped individually into 400 ml of dichloromethane for a period of 5 sec. The epicuticular wax solution was concentrated under a stream of nitrogen to a volume of 5 ml and stored at -20°C prior to use.

Fractionation. The leaf dichloromethane extract was analyzed for lipid classes by spotting an aliquot on a 5×20 cm TLC plate (Silica gel 60 F₂₅₄, Merck Japan Limited). The sample was developed using hexane/diethyl ether/formic acid (80:20:1 v/v/v). After drying, the developed plate was stained with iodine vapor or with 5% H₂SO₄ in 95% ethanol according to Nelson et al. (2002). Six distinct bands with R_f values of 0.03 (B1), 0.10 (B2), 0.19 (B3), 0.38 (B4), 0.68 (B5), and 0.74 (B6) were visualized. Band positions were compared with standards of nonacosane and octadecanoic acid.

Chemicals. All *n*-alkanes (>99% purity) from C₁₉ through C₃₁ (*n*-C₁₉–*n*-C₃₁), except *n*-C₂₇, were purchased from Tokyo Kasei Kogyo Co. Ltd. (Tokyo, Japan). Tridecyl acetate, *n*-C₂₇, tridecanoic acid (13:0), hexadecanoic acid (16:0), heptadecanoic acid (17:0), octadecanoic acid (18:0), and (*Z*)-9-octadecenoic acid (18:1) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Dodecanoic acid (12:0) was from Nacalai Tesque Inc. (Kyoto, Japan). Other fatty acids used in the present study were obtained from Aldrich Chemical Co. (Milwaukee, WI, USA).

Bioassay. Bioassays were carried out in the same environmental conditions as outlined above. Before the test, about 20 pairs of newly emerged females and males were placed into a fabric screen cage (20 × 20 × 20 cm) for arbitrary mating for a period of two nights to obtain mated females. Leaves of the Japanese knotweed, their epicuticular extract, TLC fractions (B1–B6), and the blends of chemicals identified were assayed by no-choice and two-choice tests. One-milliliter test solution containing materials equivalent to 15-cm² fresh leaf and the same amount of solvent were applied to cut halves of a filter paper circle (9-cm diam) as the treatment and control, respectively. No-choice test: Clear plastic cups (9-cm diam and 4.5 cm high) were used for the no-choice test. The treated or control filter paper was introduced into each plastic cup. Two-choice test: Fabric screen cages were used for the two-choice test. The halves of the control and treatment filter paper were taped together and stapled onto the ceiling of the fabric screen cage 2 hr before the start of scotophase. In both tests, one female was introduced into the container to avoid any possible influence on oviposition by other females. The following morning, numbers of egg masses and/or eggs were counted. Each test was replicated more than 20

times. A female usually laid 1–6 egg masses the night after copulation, and each egg mass included 60–140 eggs. After each test, the *bursa copulatrix* was removed from the females and dissected to check for the presence of a spermatophore, which is an index of successful mating. Only those data obtained using mated females were used for statistical analyses.

Chemical Analysis. Epicuticular wax, B3, and B6 were dried under a stream of nitrogen and redissolved in hexane containing 1 ng/ μ l of tridecyl acetate as an internal standard. An aliquot (2 μ l) of the solution was injected into a gas chromatograph (GC-17A, Shimadzu, Kyoto, Japan) fitted with an FID, a split/splitless injector, and a fused silica capillary column (DB-Wax or DB-35ms, 30 m \times 0.25 mm i.d., film thickness 0.25 μ m, J&W Scientific, Folsom, CA, USA). The oven temperature was controlled as follows: DB-Wax—maintained at 100°C for 2 min, programmed to increase at 15°C/min to 220°C, then 5°C/min to 230°C, and held at 230°C for 40 min; DB-35ms—100°C for 2 min, increased at 20°C/min to 310°C, then at 2°C/min to 330°C, and held at 330°C until all components eluted. The injector and detector temperatures were 220°C (DB-Wax) or 310°C (DB-35ms). The carrier gas was nitrogen. The quantity of each compound was calculated based on the peak area and calibrated by comparing it with that of tridecyl acetate.

Epicuticular wax, B3, and B6 were analyzed by gas chromatography–mass spectrometry (GC-MS) directly or after derivatization with *N,O*-bis(trimethylsilyl)-trifluoroacetamide according to the method of Shepherd et al. (1995). A QP-5050A GC-MS (Shimadzu) system equipped with a DB-wax or DB-35ms column was run under the same temperature conditions as described for the GC analysis. Helium was used as the carrier gas. The mass spectrometer was used in the electron impact mode (70 eV) and scanned over the mass range 40–600 *m/z*. The interface and ion source temperatures were 250 and 270°C, respectively.

Chemicals were tentatively identified by matching their mass spectra with those in the NIST library using the software CLASS-5000 (Shimadzu). Fatty acids and alkanes were further verified by comparison of the diagnostic ions and the GC retention time with those of the respective authentic standard.

RESULTS

Influence of Leaf and Its Epicuticular Wax on Oviposition. The no-choice test showed that fresh leaves of *F. japonica* significantly increased both the number of egg masses and the number of eggs laid by *O. latipennis* females. The epicuticular wax derived from the leaves had similar effects (Table 1). In the two-choice tests, the epicuticular wax-treated filter papers received significantly more egg masses than the solvent-treated ones (Table 2).

^a Percentage of each compound in the B6 fraction.

most abundant components (48.1%), and free fatty acids followed (22.3%). B3 and B6 had R_f values similar to those of octadecanoic acid and nonacosane, respectively. These two bands were characterized by GC-MS directly or after the formation of trimethylsilyl derivatives. As expected, B3 were fatty acids. Their chain lengths were from C_9 to C_{22} , and even carbon numbers were predominant. Among them, 16:0 was most abundant followed by 18:0 and 14:0 (Table 3). Alkanes were the only chemicals in B6. They had chain length in the range of C_{16} – C_{33} , with odd carbon numbers abundant. Among these alkanes, n - C_{29} dominated, followed by n - C_{27} , n - C_{25} , n - C_{31} , and n - C_{23} (Table 4).

Effects of Alkanes and Fatty Acids. A synthetic mixture of n -alkanes and fatty acids was prepared according to the composition found in epicuticular wax of the leaves of *F. japonica* and was tested by both no-choice and two-choice experiments. Treatment with the mixture caused a significant increase in oviposition in both bioassays (Tables 1 and 2). When a mixture of n -alkanes and a mixture of fatty acids were tested independently, each exhibited similar oviposition-stimulating activity (Tables 1 and 2).

DISCUSSION

A gravid lepidopteran female usually exhibits an obvious sequence of behavior to obtain epicuticular information from a potential host plant as soon as she alights on it (Renwick and Chew, 1994), demonstrating that sensory cues on the plant's surface are crucial for host acceptance. The no-choice test in the present study showed that the leaf epicuticular wax of *F. japonica* significantly increased the numbers of egg masses and eggs laid by *O. latipennis* females, thus indicating significant stimulatory effects on oviposition. The two-choice bioassay showed that females of *O. latipennis* prefer to lay their eggs on filter paper substrates treated with leaf epicuticular wax or fractions thereof. Observations of oviposition behavior and wind tunnel experiments are necessary to determine whether the apparent preference is attributable to attractiveness or oviposition-stimulatory effects.

n -Alkanes with chain lengths from C_{16} to C_{33} were the most abundant components in leaf epicuticular wax of *F. japonica*. An analysis of the steam volatile oil from *F. japonica* leaf showed similar results: n -alkanes in the range C_{10} – C_{30} were predominant (Miyazawa and Kameoka, 1976). A mixture of authentic n -alkanes of the natural composition exhibited significant oviposition-stimulating effects on *O. latipennis*. Similarly, in *O. nubilalis*, n - C_{26} , n - C_{27} , n - C_{28} , n - C_{29} , and n - C_{33} alkanes had significant oviposition-stimulating effects when applied individually to filter paper substrate (Udayagiri and Mason, 1997). In the corn earworm *Helicoverpa zea*, several n -alkanes (n - C_{25} and n - C_{32}), 2-methyl (C_{28} , C_{29} , C_{30} , and C_{32}), and 3-methyl-isomers (C_{29} and C_{31}) were

shown to be oviposition stimulants (Breedon et al., 1996). In the diamondback moth *Plutella xylostella*, both paraffin and a mixture of C₁₆ through C₂₉ *n*-alkanes caused marked increases in the relative acceptability of an aqueous homogenate of cabbage leaf (*Brassica oleracea*) and sinigrin, demonstrating obvious synergistic effects (Spencer, 1996).

The present study shows that a mixture of synthetic fatty acids of natural composition also enhanced oviposition in *O. latipennis*. Several aliphatic acids, 8:0, 9:0, 10:0, 11:0, 12:0, 13:0, linolenic acid (18:3), and hexadecatrienoic acid (16:3), together with β -bergamotenoic, curcumenoic, and farnesoic acids, are oviposition stimulants for *H. zea* (Breedon et al., 1996). Five saturated acids (8:0, 9:0, 10:0, 11:0, and 12:0) and two unsaturated acids [18:1 and linoleic acid (18:2)] significantly enhanced oviposition in the spruce budworm *Choristoneura fumiferana* (Grant et al., 2000). Moreover, 18:1, 20:0, 22:0, and 24:0 fatty acids caused a large increase in oviposition in the cowpea weevil *Callosobruchus maculatus* (Parr et al., 1998). In mango pulp weevil *Sternonchetus frigidus*, fractions containing several fatty acids (12:0, 14:0, 12-methyl-pentadecanoic acid, 14-methyl-heptadecanoic acid, 16-methyl-8-octadecenoic acid, and 9,12-octadecadienoic acid) stimulated oviposition (De Jesus et al., 2003). Furthermore, 18:1 and 18:2 fatty acids provide the orientation of the flight of gravid females of the navel orangeworm *Amyelois transitella* toward the source of an odor in a wind tunnel (Phelan et al., 1991).

In our previous study (Li and Ishikawa, 2004), five fatty acids (16:0, 18:0, 18:1, 18:2, and 18:3) were found in larval frass of *O. latipennis* and three other congeners, *O. furnacalis*, *O. scapularis*, and *O. zealis*, and a mixture of these fatty acids deterred the oviposition of females of all four species. Among these acids, 18:1 was recently shown to be the active deterrent (Li and Ishikawa, 2005). The apparent inconsistency between the previous and present studies can be explained if we assume that 18:1 has different functions depending on its concentration. At low concentrations, as found on the surface of Japanese knotweed, 18:1 exerts a stimulatory effect, whereas the same compound exhibits an opposite effect at high concentrations as found in larval frass. A similar case has been reported in the cowpea weevil *C. maculatus* (Parr et al., 1998). The substance 18:1 is the main component in epicuticular wax of mung seeds, a preferred host of the weevil. The fatty acid mixture as found in the epicuticular wax of mung seeds stimulated oviposition; however, an increase of 18:1 in the mixture resulted in deterrence.

n-Alkanes and free fatty acids are major constituents in epicuticular wax of numerous plant species and are biosynthesized through a highly conserved pathway within the plant kingdom (Kolattukudy, 1996; Ohlrogge and Jaworski, 1997). These chemicals have been shown to attract and/or stimulate oviposition of many insect species in Lepidoptera and Coleoptera (Eigenbrode and Espelie, 1995). In contrast, species-specific secondary metabolites are key factors

attracting and stimulating oviposition of oligophagous moths (Renwick and Chew, 1994; Honda, 1995). Consistent with this, we also found that *F. japonica* leaves still significantly stimulated oviposition even after the extraction of epicuticular wax (Li, unpublished data). Further analyses and the identification of these chemicals need to be carried out. For these analyses, however, a more discriminative bioassay has to be devised because the present one is not ideal in that a substantial number of eggs are laid on the control.

HARD CLAMS (*Mercenaria mercenaria*) EVALUATE PREDATION RISK USING CHEMICAL SIGNALS FROM PREDATORS AND INJURED CONSPECIFICS

Abstract—Hard clams, *Mercenaria mercenaria*, are sessile, filter-feeding organisms that are heavily preyed upon by blue crabs, which find their clam prey using chemical cues. Clams may evade blue crabs by reducing their pumping (feeding) behavior when a threat is perceived. The purpose of this study was to determine the type of signals that clams use to detect consumers. Clams decreased their pumping time in response to blue crabs and blue crab effluent, but not to crab shells, indicating that chemical signals and not mechanical cues mediated the response of clams to distant predators. Because predator diet can influence prey evaluation of predatory threats, we compared clam responses to blue crabs fed a steady diet of fish, clams, or that were starved prior to the experiment. In addition, we used injured clams as a stimulus because many organisms detect predators by sensing the odor of injured con- or heterospecifics. Clams reduced feeding in response to injured conspecifics and to blue crabs that had recently fed. Clams reacted similarly to fed crabs, regardless of their diet, but did not respond to starved blue crabs. Because blue crabs are generalist predators and the threat posed by these consumers is unrelated to the crab's diet, we should expect clam reactions to blue crabs to be independent of the crab's diet. The failure of clams to react to starved blue crabs likely increases their vulnerability to these consumers, but clam responses to injured conspecifics may constitute a strategy that allows animals to detect an imminent threat when signals emanating from blue crabs are not detectable.

Key Words—Blue crab, chemical cue, clam, diet, flume, foraging, predator avoidance, predator–prey interaction, risk evaluation.

INTRODUCTION

Predators often have profound impacts on prey populations and on the organization and function of communities in general (Paine, 1966; Carpenter et al., 1985; Schmitz et al., 1997; Schmitz, 1998; Menge, 2000). The overall effect of predators on communities is determined by interactions between individual predators and prey (Lima, 1998, 2002). Therefore, the ability of predators to forage and the ability of prey to avoid consumers influence the magnitude of top-down forces in a given system (Menge, 2000; Werner and Peacor, 2003). Because decisions made by prey under the risk of predation have important consequences for both prey populations as well as entire communities, it is important to understand how prey evaluate and respond to predation risk (Lima and Dill, 1990; Werner and Peacor, 2003).

Although avoiding consumers is of great importance to prey, predator avoidance is often costly and results in decreased growth or fecundity (e.g., Lima and Dill, 1990; Peckarsky, 1996; Katz and Dill, 1998; Leonard et al., 1999; Nakaoka, 2000). Prey may minimize predator avoidance costs by using flexible avoidance strategies that balance the frequency or magnitude of predator avoidance responses with a perceived level of risk (Sih et al., 1985; Schmitz et al., 1997; Schmitz, 1998; Chivers and Smith, 1998; Katz and Dill, 1998; McIntosh and Peckarsky, 1999). Thus, prey require stimuli that accurately reveal the level of risk to determine when and how predator avoidance strategies should be employed.

Prey commonly use chemical signals to evaluate risk (Chivers and Smith, 1998; Katz and Dill, 1998) because chemical cues typically provide prey with accurate information concerning the location and intentions of predators (Chivers and Smith, 1998; Katz and Dill, 1998; Brown et al. 2000). This is particularly true in aquatic environments where visual or mechanical cues are often unavailable (Zimmer and Butman, 2000; Weissburg et al., 2002). Additionally, predators can more easily manipulate their posture or behavior to appear less threatening to prey than change their chemical signature (Katz and Dill, 1998; Brown et al., 2000).

Chemical cues indicative of danger may emanate from predators, from injured conspecifics, and sometimes from sympatric species (Petranka et al., 1987; Mathis and Smith, 1993; Chivers and Smith, 1998; Katz and Dill, 1998). Prey may use one or combinations of these signals to evaluate risk (Chivers and Smith, 1998; Katz and Dill, 1998; Bryer et al., 2001; Smith and Belk, 2001) and respond differently to chemical signals depending on other factors such as time of day (e.g., Peckarsky, 1996). Signals released from predators provide the most accurate indication of a predatory threat, and prey may minimize their predator avoidance costs by exclusively responding to these signals (reviewed by Katz and Dill, 1998). Although cost effective, an avoidance strategy in which prey

respond only to predator odors may increase their vulnerability when these chemicals are difficult to detect or when predators reach prey prior to the arrival of their chemical signals (e.g., when olfactory predators find prey by searching upstream). In contrast, chemical cues released by injured conspecifics may provide a stronger but less reliable indication of danger (reviewed by Katz and Dill, 1998). Yet, prey may overutilize predator avoidance tactics and incur high costs if they depend on less reliable signals (Lima and Dill, 1990; Katz and Dill, 1998).

Some prey limit their responses to predators that have eaten conspecifics or closely related species (e.g., Chivers and Smith, 1998; Katz and Dill, 1998; Chivers and Mirza, 2001; Mirza and Chivers, 2001; Smith and Belk, 2001; Brown and Dreier, 2002; Madison et al., 2002), and this predator detection strategy has been hypothesized to minimize predator avoidance costs. However, prey that depend on predator diet cues before initiating antipredator measures may be vulnerable to generalist predators that switch diets frequently (Bryer et al., 2001; Chivers and Mirza, 2001). Bryer et al. (2001) and Chivers and Mirza (2001) hypothesized that prey responses that are dependent on predator diets should only occur in systems where the threat posed by a predator is directly related to that predator's most recent foraging activity.

In this study, we examined the effects of a generalist predator's diet on the response of a common prey organism using blue crabs *Callinectes sapidus* and hard clams *Mercenaria mercenaria* as model organisms. Blue crabs *C. sapidus* are important predators and scavengers in southeastern estuaries (Eggleston et al., 1992; Micheli, 1997) and are the primary consumer of juvenile hard clams *M. mercenaria* in these areas (Micheli, 1995, 1997). Blue crabs are also a threat to adult clams, as they can nip their siphons and decrease their feeding efficiency, growth, and fecundity (Peterson, 1986; Coen and Heck, 1991; Irlandi, 1994). Clams release attractive chemicals into the water as they feed, and blue crabs follow these waterborne chemical odor plumes to locate their clam prey (Weissburg and Zimmer-Faust, 1993; Weissburg et al., 2002). Irlandi and Peterson (1991) found that clams responded to the presence of predators by reducing their feeding time and hypothesized that feeding reductions would make clams less apparent to consumers. Indeed, caging predators near clam beds decreases clam mortality (Smee and Weissburg, in press), but clam growth and reproductive output are diminished by long-term exposure to predators (Nakaoka, 2000). Thus, clam responses to predators are adaptive and costly.

We hypothesized that clams detect approaching blue crab predators by using chemical signals or hydrodynamic signals or both. We exposed clams to both chemical and hydrodynamic signals from blue crabs to verify the type of cue that clams used to detect blue crabs. The results indicate that clams were responding to chemical cues emanating from blue crabs, and we conducted a second experiment to determine the nature of these signals. In the second

experiment, we compared changes in clam behavior when exposed to blue crabs that had been fed different diets and to injured conspecifics. Our results suggest that prey respond to a generalist predator regardless of diet, presumably because the dietary history of such a predator does not predict the risk to its potential prey. Furthermore, there are limits to prey perceptual abilities that may result in increased predation risk. For example, prey may be unable to detect starved predators, although a highly motivated consumer increases the chance that potential prey may be attacked.

METHODS AND MATERIALS

Animal Capture and Maintenance. Animals were collected from Wassaw Sound, GA, USA, and associated tributaries. Hard clams *M. mercenaria* were hand dug with clam rakes and fingers in the intertidal zone, and blue crabs *C. sapidus* were captured with commercially purchased crab pots. After capture, animals were returned to the Skidaway Institute of Oceanography (SkIO) near Savannah, GA, and housed in flow-through sea tables supplied by water pumped from the Skidaway River. Sea table water was filtered through both gravel and sand filters, and the water temperature and salinity in the sea tables ranged from 25 to 30°C and from 25 to 30 ppt, respectively. Clams acclimated in the sea tables for at least 6 hr prior to behavioral assays (see below) and were used in behavioral assays within 48 hr after removal from the field. Blue crabs were kept in the sea tables for at least 1 wk prior to use in the behavioral assays. Crabs were fed with a daily diet of either fish (*Menhaden* sp.) or clams (*M. mercenaria*) or were starved during the 1-wk acclimation period. We returned each clam or crab to the field after a single use (except for a few clams that were injured as part of the experiment or used for food; see below).

Experimental Arena. Experiments were conducted in a paddle-driven racetrack flume at SkIO (4.8-m-long working section \times 1 m wide \times 0.33-m water depth). The upstream bend of the flume is divided into five 23-cm channels to reduce secondary circulation. Flow is further conditioned by honeycomb baffling (5 cm thick with 7-mm openings) at the downstream end of this bend and by a polyvinyl chloride (PVC) flow straightener (10 \times 4.5-cm openings) placed at the end of the working section to prevent back-flow. The working section contains a false bottom (0.30-m diam. \times 0.15 m deep) located 2.3 m downstream from the entrance point of the working section and is in the center of the flume to minimize wall effects. Both the working section and false bottom of the flume were filled to a uniform depth of 1 cm with commercially purchased sand (grain size 0.04 ± 0.04 cm). The flume was supplied by the same water source as the sea tables and had similar temperature and salinity. Flume water passed through both gravel and sand filters as

well as a 10- μm filter bag. Flow speed was maintained at 3 cm sec^{-1} in all experiments. This flume produces stable and reproducible boundary layers at current speeds ranging from 1 to 15 cm sec^{-1} . See Ferner and Weissburg (2005) for a detailed flume description and characterization of the flow environment boundary.

Behavioral Assays. Experiments utilized changes in clam pumping (feeding) behavior as assays for the ability of clams to detect predation risk. Although previous investigators have assumed that clams are actively pumping only when their siphons are extended (e.g., Irlandi and Peterson, 1991), we performed preliminary experiments to verify this supposition. We visualized the excurrent from clams by carefully pipetting a 0.1% solution of fluorescein dye above the excurrent siphon of a clam. Thirty-six clams that had their siphons extended were tested in this manner, and all were releasing an excurrent. We tested 15 clams with open shells but withdrawn siphons, and only three were pumping. Thus, we concluded that siphon extension was indicative of pumping.

Behavioral trials consisted of challenging clams to detect and respond to blue crab predators, injured clams, predator-conditioned water, and predator shells. We judged clam responses to predation risk by determining if clam feeding (no. of siphon extension observations) was significantly less in response to these treatments when compared to a control that lacked predators or injured conspecifics. In each assay, we placed five clams in the false bottom of the flume and allowed them to acclimate for 30 min. Clam density in these experiments was five clams per 0.07 m^2 and mimics densities observed in natural habitats (Walker, 1987; Smee and Weissburg, unpublished data). We introduced predators, crushed conspecifics, or predator-conditioned water at the conclusion of the 30-min acclimation period by placing a tethered crab, injured clam, or the nozzle (see below) from our delivery system 0.5 m upstream from the clam bed. We recorded the siphon position of each clam (extended or not) prior to introduction of the predator treatments and at 5-min intervals after introduction for 30 min. Thus, each clam could have been observed feeding (pumping) a maximum of seven times, and we used the total number of observations in which clams were pumping as our measure of clam pumping time. That is, the response of each clam in a trial was measured by a single number between 0 and 7, which indicated how many times we observed an individual clam pumping.

The order of treatments and controls in these experiments was randomly assigned each day, and each treatment and the control were replicated at least five times (5 trials \times 5 clams per trial = 25 clams for each treatment and control). Each clam and predator was used only once. Clams that neither pumped nor burrowed were excluded from the analysis, and we excluded approximately 25% of the clams from the experiment by using this criterion.

Including inactive clams in our analysis would have enhanced our results, but we excluded them because we could not clearly determine the causes of clam inactivity.

Characterization of Predator Cues. Preliminary observations suggested that clams pumped significantly less when tethered blue crabs were placed upstream. We hypothesized that potential predators created hydrodynamic signals, chemical signals, or both that mediated the response of clam prey. Therefore, we conducted two experiments to determine the cue that clams use to detect predators. We tested responses of clams to hydrodynamic cues by placing an empty predator shell 0.1 m upstream from the clams and comparing clam pumping between this treatment and the control. Qualitative flow visualization with dye indicated that the turbulence created by the predator shells dissipated within the first 0.25 m downstream, although we could not exclude the possibility that a more exacting analysis of flow would reveal that perturbations induced by the shell extended farther downstream. Thus, we placed the predator shell 0.1 m upstream from the clam bed to ensure that the clams were in its turbulent wake.

To determine if clams were detecting chemical signals from predators, we designed a chemical delivery system to transport blue crab effluent to the experimental clams. The delivery system pumped water out of the flume and into a container ($0.31 \times 0.24 \times 0.36$ m) that was left empty (control) or that housed a blue crab that had recently eaten clams. The water from the container was released into the flume 0.5 m upstream from the clam bed via a 0.076-m diam PVC pipe oriented parallel to the flow. Water moved through the delivery system at a velocity of 3 cm sec^{-1} , which matched the free stream flow velocity in the flume. The large diameter pipe was selected because it was of similar size to a blue crab, which allowed us to simulate water passing over the crab at a rate similar to that occurring in experiments with clams exposed to a live predator.

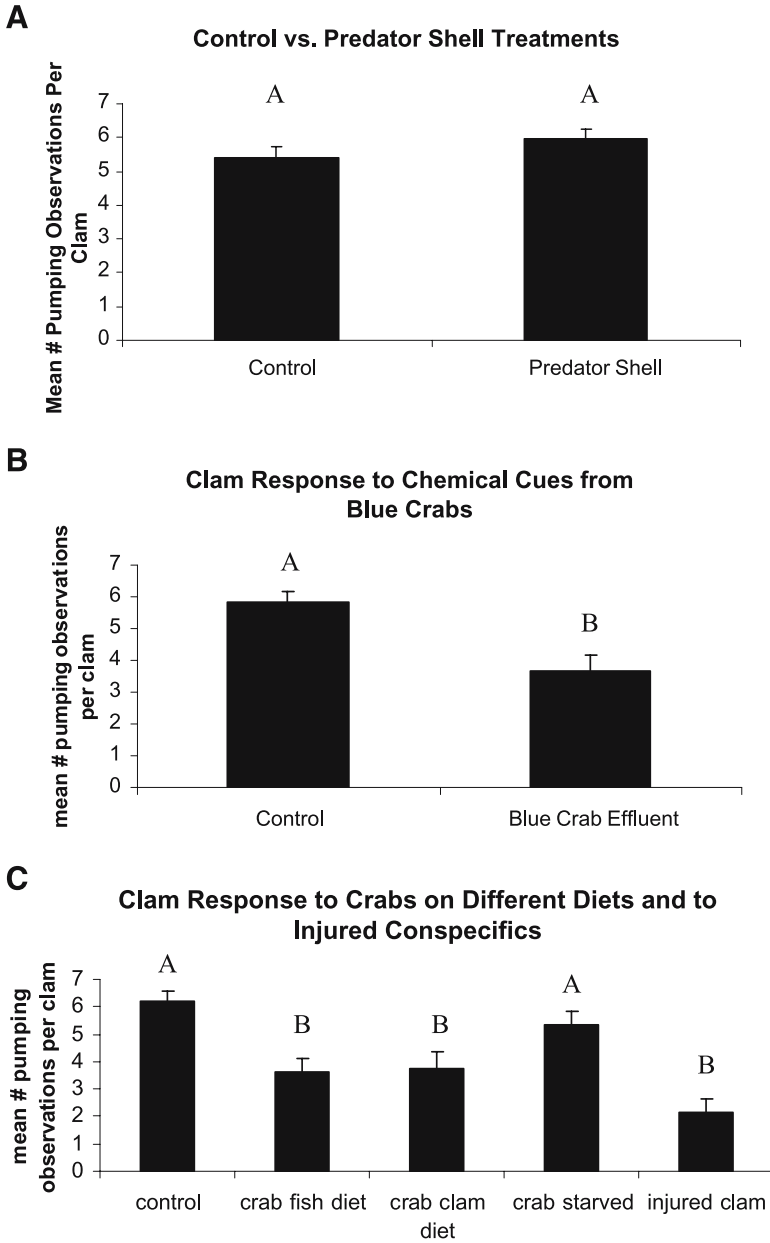

We realize that the flow diversion method may only crudely approximate the flux of chemicals experienced by a prey organism directly upstream of a crab predator. Although our approach replicates the rate of water movement over the animal, mixing in the delivery system and introduction through a pipe will probably change the chemical signal dynamics relative to that produced by water flowing over an individual crab. However, the flow diversion method we employed is a more realistic alternative than prey soaks or body washes because the volumetric rate at which water passes over the crabs in the diversion system is roughly equal to that passing over a crab in the flume. In contrast, soaks or body washes concentrate predator metabolites using arbitrarily determined volumes and time periods, and so produce unknown metabolite concentrations that will not be experienced by naturally foraging animals.

Effects of Predator Diet and Response of Clams to Injured Conspecifics. In this experiment, we measured the responses of clams when presented with odors from injured conspecifics as well as crabs that were fed with different diets prior to behavioral assays. The injured clam treatment was prepared by striking a clam with the blunt edge of a kitchen knife, removing the top valve, and making multiple lacerations on the visceral mass. This treatment mimicked crab feeding and insured that clam metabolites were released into the water. To measure the impact of crab diet on clam responses, collected blue crabs were fed with a daily diet of fish or clams for 1 wk or were starved for 1 wk prior to the experiment. We allowed clams to acclimate in the flume using the same methodology previously described, then placed a tethered blue crab or injured clam 0.5 m upstream from the clam bed, and monitored clam feeding.

Data Analysis. We initially examined the percentage of times that adjacent clams were feeding simultaneously to determine if interactions occurred between clams. Clams in control trials pumped during 87% of our observations. Thus, the proportion of time that two adjacent clams should be pumping simultaneously is 0.87^2 (0.76), assuming that adjacent animals do not influence each other. Adjacent clams ($N = 25$ pairs) in control trials pumped simultaneously in 70% of our assays, a value not significantly different from the random expectation (Sokal and Rohlf, 1995).

Since clams were not influencing each other, observations of pumping behavior of individual clams (number of siphon extensions observed for each clam) were arcsine transformed to meet analysis of variance (ANOVA) assumptions and were then compared using a nested ANOVA that examined the effects of predator treatment and trial nested within treatment (Sokal and Rohlf, 1995). The use of a nested ANOVA allowed us to determine if variations in clam responses were affected by variability in cue quality or quantity across replicate treatments, which is a source of uncontrolled variation in the experiments. The P value for the nest effect was greater than 0.20 in all experiments, indicating that clams in different groups were reacting similarly to the same treatments. The lack of a significant nest effect permitted us to lump trials within treatments and test the significance of the main effect by using the pooled error variance (Sokal and Rohlf, 1995). The absence of a nest effect suggests that cues from predators and injured conspecifics were roughly similar between replicate trials.

Experiments using tethered predators, predator effluents, and predator shells were conducted at different times over a period of several months. Therefore, each experiment was analyzed separately because it would be inappropriate to compare treatments to one another under these conditions. Separate control experiments were performed for each experiment to account for any variation in animal or general experimental conditions. Trials that used different predator diets or injured conspecifics were intermingled and, on a daily

basis, were presented in random order to test clams. After completing the nested ANOVA, a Tukey–Kramer *post hoc* analysis was employed to test for pairwise differences between treatments (Sokal and Rohlf, 1995).

RESULTS

Characterization of Predator Cues. Data from experiments using the predator shells indicated that there were no significant differences in clam pumping between the predator shell treatments and the controls ($F_{1,83} = 2.56$, $P > 0.11$, Figure 1A). Although not significant, we observed a higher clam-pumping rate in trials with predator shells. Thus, turbulence generated by the predator shell did not alter clam pumping, which suggested that clams were not using a hydrodynamic cue to detect predators.

In contrast to the results obtained with empty predator shells, clam pumping was significantly reduced ($\approx 40\%$) when clams were exposed to water released from the delivery system that had passed over a blue crab as compared to water passing through the empty system without blue crabs present ($F_{1,35} = 8.69$, $P < 0.01$, Figure 1B). Additionally, clam feeding was affected similarly by predator-conditioned water and (nonstarved) predators placed directly in the flume (see below). The failure of clams to cease pumping in response to hydrodynamic signals, combined with the positive response to predator-conditioned water delivered under environmentally realistic conditions, suggested that clam responses to predators were chemically mediated.

Effects of Predator Diet and Response of Clams to Injured Conspecifics. The data revealed that clam feeding decreased by 40% when exposed to blue crabs that had recently been fed and by 65% in the presence of injured conspecifics as compared to controls that lacked predators or injured clams ($F_{4,84} = 10.28$, $P < 0.001$, Figure 1C). Starved blue crabs caused a slight (15%) but insignificant reduction in clam feeding. Additionally, *post hoc* analysis revealed that clams pumped significantly more in the presence of starved blue crabs than those that were recently fed, and clam responses to crab predators

FIG. 1. Mean number of pumping observations per clam (\pm SE). Letters denote means that are significantly different based on a Tukey–Kramer *post hoc* test. Each clam could have been observed pumping a maximum of seven times during the 30-min observation period. (A) Control vs. predator shell placed 0.1 m upstream, $N = 42$ and 43 clams, respectively. (B) Control vs. blue crab effluent released from our delivery system, $N = 16$ and 21 clams, respectively. (C) Clam pumping in the presence of crabs fed with different diets and injured conspecifics. Sample sizes for each treatment are 24, 16, 15, 19, and 15 for the control, crab fed with fish, crab fed with clams, starved crab, and injured clam treatments, respectively. Differences in sample size result from exclusion of inactive clams from analyses.

were similar regardless of their diet. Although not significantly different from responses to fed crabs, clams reduced their feeding time almost 40% more after detecting an injured conspecific than a crab that had recently eaten (Figure 1C). Thus, clam feeding was affected more by the presence of injured clams than by the odors of fed predators, although both caused significant reductions in clam feeding as compared to controls and starved crab treatments.

DISCUSSION

Our results indicate that clams use chemical signals to detect upstream blue crabs and respond to these predators by reducing their feeding (pumping) behavior. Other bivalves (e.g., mussels) also use chemical cues to detect predators and respond by changing their morphology (e.g., Leonard et al., 1999) or behavior (e.g., Cote' and Jelnikar, 1999). Previous studies have shown that blue crabs depend on chemical cues to locate clam prey (Weissburg and Zimmer-Faust, 1993; Finelli et al., 2000; Weissburg et al., 2002). The modulation of the blue crab–clam predatory interaction by chemicals is perhaps unsurprising given that the water in our study area is extremely turbid, and chemical cues are likely the only signals that can be detected from a distance in this habitat. Both blue crabs and their prey use the same sensory modality to detect each other, so the conditions that affect the transmission of chemical signals will affect the sensory abilities of both organisms. Thus, the outcome of interactions between these organisms may differ considerably between areas that enhance chemical signaling as compared to those that impede it.

In nature, clam feeding rates may be influenced by other factors (e.g., food availability, temperature) that were not considered in the present study. Reactions to predators may change in the field depending on a variety of factors besides the perceived level of risk. Still, long-term exposure to predators has been shown to significantly decrease clam growth in the field (Nakaoka, 2000). In a related field study, Smee and Weissburg (in press) found that clam survival was significantly higher in clam plots with predators caged nearby as compared to control plots with empty cages. These studies indicate that clam reactions to predators, while costly, reduce mortality and suggest that clams react to predators across a range of natural conditions. Therefore, the clam reactions to predators and injured conspecifics observed in the present study should be indicative of the cues used by clams to avoid predation in the field.

Clams only responded to cues released by blue crabs if the crabs had recently been fed and not if they had been starved for 1 wk. Clams responded similarly to fed crabs regardless of whether the crab's diet consisted of fish or clams prior to behavioral assays. In addition, clams altered their feeding behavior in the pres-

ence of injured conspecifics, suggesting that they also use these signals to detect predatory threats.

The ability of clams to react to injured conspecifics may compensate for their inability to detect hungry blue crabs. Prey organisms may benefit from living in close proximity to conspecifics or related species, as neighbors can provide for shared vigilance against consumers or early warnings of danger (Hamilton, 1971; Powell, 1974; Sullivan, 1984; Fitzgibbon, 1990; Aukema and Raffa, 2004). The benefit provided by neighbors is particularly strong in organisms that respond to the odors of injured conspecifics or heterospecifics, as consumption of neighbors reveals a predatory threat (e.g., Mathis and Smith, 1993). Hard clams are commonly found in dense beds and can reach densities in excess of 50 clams m^{-2} in our study area (Walker, 1987; Smee and Weissburg, unpublished data). Clams living in dense beds may be better able to avoid unapparent predators, as neighbors that are eaten may warn of imminent peril.

Responses of prey that are dependent on predator diets have been found in many predator-prey systems (Crowl and Covich, 1990; Chivers et al., 1996; Stabell and Lwin, 1997; Chivers and Mirza, 2001; Smith and Belk, 2001) but are notably absent from others (Petranka and Hays, 1998; Bryer et al., 2001). The existence of diet-dependent responses may be contingent on whether the recent dietary history of the predator is correlated with risk to prey. For instance, seasonally hunting predators may pose a risk for prey only at certain times, so that predator diet may predict the potential threat level to that prey species (Chivers and Mirza, 2001). Alternatively, Bryer et al. (2001) suggest that diet-dependent responses to predators may not be beneficial when prey are hunted by generalist predators, such that the risk level posed by the predator is unrelated to its foraging habits. Bryer et al. (2001) observed that slimy sculpin responses to brook trout predators were unaffected by the trout's diet. They reasoned that the threat posed by brook trout to sculpins is unrelated to the trout's foraging habits, and thus, it would not be advantageous for the sculpin to base risk evaluation on predator diet cues.

The response of clams to blue crabs in our experiment was not dependent on the crab's diet. Because blue crabs are generalist consumers and eat almost anything alive or dead (Virnstein, 1977; Eggleston et al., 1992; Micheli, 1995, 1997), the threat of predation by crabs is unrelated to the crab's recent foraging activity. As in the previous example with slimy sculpins, knowledge of a blue crab's diet provides no valuable information for their prey, suggesting that it is not advantageous for clams to rely on diet cues as their sole means of evaluating risk.

Cost-benefit analyses are often used to explain the variability in responses to predators across predator-prey systems. However, cost-benefit explanations currently are focused on response specificity as opposed to response sensitivity and may be inadequate when prey fail to detect actual predatory threats because predators have not recently fed (Howe and Harris, 1978). If predators stop

releasing chemical signals or release chemicals that are difficult to detect, then organisms may not adequately perceive the true risk level. Starved predators often show enhanced search responses relative to those that are well fed, as revealed by increases in the duration and frequency of search bouts in response to a given stimulus level or decreases in the threshold stimulus levels that are required to initiate or maintain search (Mackie and Shelton, 1972; Zimmer-Faust and Case, 1982). Therefore, the threat posed by a starved crab is equal to, or possibly greater than, that posed by a crab that has recently foraged. Thus, it would be prudent for clams to respond to starved crabs, and their failure to do so suggests that starvation renders blue crabs less detectable to clam prey. Prey may be more likely to depend on the odors of injured con- or heterospecifics to detect consumers when predators are commonly undetectable, although this hypothesis has not been empirically tested.

We have yet to develop risk-based models for the sensitivity of potential prey to cues derived from their consumers, and research that attempts to quantify the stimulus levels necessary to elicit prey reactions is lacking. Prey with low sensitivity thresholds may experience large costs (e.g., reductions in the opportunity to feed), particularly if prey use general metabolites to detect their predators, as these substances may come from a variety of sources. In contrast, prey with higher sensitivity thresholds may decrease predator avoidance costs but may also be more vulnerable to their enemies. Recent technological advances in our ability to characterize and identify chemical signals (e.g., Millar and Haynes, 1998), as well as our ability to examine chemical signal transport in aquatic systems (e.g., Webster and Weissburg, 2001; Weissburg et al., 2002), may allow us to investigate threshold sensitivity and its relationship to predation risk in a more thorough manner than has been previously attempted.

Acknowledgments—The authors thank S. Smee, L. Smee, and J. Jackson for help in collecting animals in the field and M. Ferner for maintaining the SKIO flume. Funding for this project came from the NSF IGERT grant to the Georgia Institute of Technology and NSF grant OCE #0424673 to MJW.

HERITABLE VARIATION IN THE SEX PHEROMONE OF THE ALMOND MOTH, *Cadra cautella*

JEREMY D. ALLISON* and RING T. CARDÉ

Department of Entomology, University of California, Riverside, CA 92521, USA

(Received September 22, 2004; revised October 26, 2005; accepted October 31, 2005)

Published Online April 4, 2006

Abstract—The sex pheromone of the female almond moth, *Cadra cautella*, constitutes a highly variable signal. Age and period of the L/D cycle had significant effects on the variation in titers of (*Z,E*)-9,12-tetradecadienyl acetate (*Z9,E12-14:Ac*) and (*Z*)-9-tetradecenyl acetate (*Z9-14:Ac*) and the ratio of *Z9,E12-14:Ac* to *Z9-14:Ac*. Across age classes, minimum and maximum mean titers (ng ± SE) of *Z9,E12-14:Ac* and *Z9-14:Ac* ranged from 8.7 ± 0.46 to 21 ± 1.0 and from 2.0 ± 0.14 to 2.9 ± 0.15 , respectively; the mean ratio of *Z9,E12-14:Ac* to *Z9-14:Ac* ranged from 5.2 ± 0.21 to 11 ± 0.40 . The titers of *Z9,E12-14:Ac* and *Z9-14:Ac* and the ratio of *Z9,E12-14:Ac* to *Z9-14:Ac* were highest at the onset of the scotophase and lowest at the onset of the photophase. Similarly, the titer of *Z9,E12-14:Ac* and the ratio of *Z9,E12-14:Ac* to *Z9-14:Ac* were highest in females sampled 1 d postemergence and declined over all age classes. The titer of *Z9-14:Ac* increased from day 1 to day 2, and then declined to levels equivalent to day 1. Analysis of pupal and adult mass demonstrated a positive correlation ($r = 0.874$, $P < 0.001$); however, the titer of neither *Z9,E12-14:Ac* or *Z9-14:Ac* nor the ratio of *Z9,E12-14:Ac* to *Z9-14:Ac* were significantly correlated with pupal mass. Age-related variations in pheromone titer and ratios were heritable. The narrow-sense heritability of the observed variation in 1-d-old females, 1 hr into the scotophase is 1.2 ± 0.32 , 0.75 ± 0.24 , and 0.46 ± 0.17 for the titer of *Z9,E12-14:Ac* and *Z9-14:Ac* and the ratio of *Z9,E12-14:Ac* to *Z9-14:Ac*, respectively. A significant additive genetic correlation was observed between that of *Z9,E12-14:Ac* and *Z9-14:Ac*, but not between that of either *Z9,E12-14:Ac* or *Z9-14:Ac* and the ratio of *Z9,E12-14:Ac* to *Z9-14:Ac*. The results of the genetic analyses suggest that the traits of titer of *Z9,E12-14:Ac* and *Z9-14:Ac* have a greater potential to respond to selection than the trait of ratio of *Z9,E12-14:Ac* to *Z9-14:Ac*.

INTRODUCTION

Among moths (Lepidoptera), the behavioral mechanisms used in pair formation are typically the same ones that prevent hybridization (Cardé, 1986). In most species reproduction is preceded by long-distance attraction of mates and short-range courtship, both of which are mediated by pheromones (see Cardé and Haynes, 2004). Specificity in the chemical communication channel is predominately the result of species-specific male and female pheromone blend compositions and male response profiles and courtship behavior (Tumlinson et al., 1974; Cardé et al., 1977; Phelan and Baker, 1987, 1990; Löfstedt et al., 1991; McElfresh and Millar, 2001). Phenological and diel differences in reproductive behavior may also contribute to reproductive isolation by temporal isolation of heterospecific reproductively mature males and females (Teal et al., 1978; Greenfield and Karandinos, 1979; Haynes and Birch, 1986).

Species-specific pheromone communication channels have been interpreted as indirect evidence of the selective effects of competition for the communication channel and/or reinforcement of isolating mechanisms over evolutionary time (see Cardé and Baker, 1984). These paradigms have been challenged by the recognition concept (reviewed by Löfstedt, 1993; Linn and Roelofs, 1995) and theories involving intraspecific competition for mating opportunities (see West-Eberhard, 1984). As Löfstedt (1993) pointed out, “Regardless of which type of selection one advocates as a major evolutionary force the mechanism for change in a communication system constitutes a problem.” In other words, because natural selection should favor signaling systems that maximize the ratio of the received signal relative to background noise (Endler, 1992), stabilizing selection should minimize signal variation, yet directional selection is required for change. In apparent contradiction to these arguments, the sex pheromones of some dytrisian Lepidoptera are characterized by high coefficients of variation (e.g., the coefficient of variation for the proportion of the triene pheromone component in *Phthorimaea operculella* pheromone glands was 23% and 31% for a California and Nagoya, Japan, population; Ono et al., 1990).

Geographic variation in moth sex pheromones has been observed in many species [e.g., *Agrotis segetum* (see Löfstedt, 1993); *Hemileuca eglanterina* (McElfresh and Millar, 2001)]. Age, diel (Tang et al., 1992), and temperature effects (Ono, 1993, 1994) also influence quantitative and qualitative variation in sex pheromones. To further understand the basis of variation in moth

pheromone signals, we studied the pheromone biology of a stored-products pest, the almond moth, *Cadra cautella* (Walker) (Lepidoptera: Pyralidae). Specifically, we tested the null hypotheses that mean titer of (*Z,E*)-9,12-tetradecadienyl acetate (*Z9,E12-14:Ac*) and (*Z*)-9-tetradecenyl acetate (*Z9-14:Ac*) (the major and minor pheromone components of *C. cautella*; Brady et al., 1971; Read and Haines, 1979) and the ratio of *Z9,E12-14:Ac* to *Z9-14:Ac* were independent of: (1) female age, (2) the period of the L/D cycle during which females were assayed, (3) whether or not females had access to water as adults, and (4) the temperature that females were reared at as larvae. We also measured the intensity of association between pupal and adult mass, and between pupal mass and the titers and ratio of *Z9,E12-14:Ac* to *Z9-14:Ac*. Finally, because selection is only expected to act on heritable variation, we also examined the heritability of the variation observed in the titers of *Z9,E12-14:Ac* and *Z9-14:Ac*, and the ratio of *Z9,E12-14:Ac* to *Z9-14:Ac* under controlled ages and rearing conditions.

METHODS AND MATERIALS

Insect Rearing. The colony of *C. cautella* was initiated in 1989 with ca. 500 larvae and pupae obtained from Kansas State University, Manhattan, KS, USA. Since then, the colony has been maintained in continuous culture at or above 400 mating pairs. The insects were reared in a controlled environment rearing room kept at a mean temperature of 26°C (range 25–27°C), with a photoperiod of L/D 16:8 hr and 50–60% RH. These rearing conditions were periodically verified with a Hobo® sensor (Onset Computer Corporation, Bourne, MA, USA). Egg and larval stages were reared in 1-l jars on diet made from 3 kg poultry laying mash, 2 kg rolled oats, 100 g brewer's yeast, and 200 ml glycerin. Last instars of both sexes were harvested and held in groups in inflated Ziploc® plastic bags with Kimwipe® tissues inserted as pupation substrate. Adults were collected as they emerged and placed in 25 × 25 × 25 cm plastic gauze rearing cages where mating and oviposition occurred. Eggs were collected from these cages and used to seed 1-l jars for the next generation.

Pheromone Extraction. Male testes are easily seen through the dorsal larval cuticle, allowing for rapid sex determination of wandering last instar larvae. For pheromone analyses, female larvae were collected and individually reared in 30-ml plastic cups in a light box kept in the rearing room described above. Conditions in the light box were identical to the rearing room (verified with a Hobo), except that the photoperiod was offset (ca. 4 hr) from the photoperiod of the rearing room. The rearing protocol described above provided a continuous culture of adult moths with emergence occurring daily. As a consequence, the progeny of a cohort of adults emerged over a span of ca. 7 d.

Female moths were held between the thumb and index finger, and even, gentle pressure was applied to the abdomen to extrude the ovipositor and pheromone gland. The pheromone gland, and as few terminal abdominal segments as possible, were excised using a pair of fine forceps and a razor blade. Before each group of dissections, new razor blades were rinsed in ethyl acetate and allowed to dry in the fume hood for 30 min. After each gland dissection, the forceps were rinsed in hexane and wiped with a Kimwipe. Excised glands were individually extracted in 25 μl hexane containing 1 ng/ μl of the internal standard, 13:Ac (not present in female glands, $N = 10$). Pheromone glands were excised in the second hour of the scotophase (unless otherwise noted) and extracted for 1 hr (optimized extraction time maximizing the ratio of the amount of pheromone extracted to extraneous material), after which the solvent extract was transferred to a clean glass insert inside a Teflon-lined, screw-capped 4-ml glass vial and stored at -20°C until analysis.

Gas Chromatography. Extracts were concentrated under a stream of nitrogen to ca. 3–4 μl , from which ca. 1 μl was injected into a gas chromatograph (GC) in splitless mode (injector 250°C). A Hewlett-Packard 6890 Series GC equipped with split/splitless injectors, flame ionization detectors, and interfaced to a computer with HP Chem Station Rev. A.04.02 was used for all analyses. The GC was fitted with DB-1 and DB-5 capillary columns (J&W Scientific, Folsom, CA, USA, 30 m length, 0.25 mm ID, 0.25 μm film thickness). The carrier gas was helium (linear flow rate of 28 cm/sec), detector temperature was 250°C , and an oven temperature program of 50°C for 1 min, $10^{\circ}\text{C}/\text{min}$ to 250°C for 10 min was used.

Experiment #1: Effect of Age on Titer and Component Ratio. On the day they were to be extracted and 1 hr prior to the onset of their scotoperiod, individual female moths were moved to an identical light box kept in the rearing room. This enabled us to access moths for experiments without exposing the overall population of moths to light during their scotoperiod. This protocol was followed for all other experiments except for the 21°C treatment of Experiment #4 (see below). Emergence was checked daily, and all female moths emerging each day were randomly assigned to one of the following treatments: 1, 2, 3, 4, or 5 d postemergence, and the pheromone gland dissected and extracted on the appropriate day as described above.

Experiment #2: Effect of the L/D Cycle on Titer and Component Ratio. All female moths emerging on a day were randomly assigned to one of the following treatments: gland excision and extraction at the onset of the scotoperiod (9:00 A.M.), mid-scotoperiod (1:00 P.M.), end of the scotoperiod (5:00 P.M.), or mid-photoperiod (1:00 A.M.). All females were assayed 1 d postemergence.

Experiment #3: Effect of Access to Water on Titer and Component Ratio. All female moths emerging on a day were randomly assigned to the treatments 1, 3, and 5 d postemergence, corresponding to the number of days

postemergence that female pheromone glands were extracted. Half of the females assigned to a treatment were reared with access to a wick partially immersed in a 4 ml-glass vial filled with water, and the other half were reared with access to a wick partially immersed in an empty 4-ml glass vial.

Experiment #4: Effect of Larval Rearing Temperature on Titters and Component Ratio. Ten 1-l glass jars containing the diet described above were seeded with ca. equal volumes of eggs. Simultaneously, five jars were maintained at 26°C in the rearing room described above and the other five were held at 21°C in an environmental chamber with a photoperiod of L/D 16:8 hr and 50–60% RH (verified with a Hobo). The pheromone glands of 10 females per jar were extracted for analysis. There were slight differences in the developmental rates of the larvae (larvae reared at 26°C developed faster). All females were assayed 1 d postemergence.

Experiment #5: Correlation Between Female Pupal and Adult Mass, and Pupal Mass and Titters and Component Ratio. To determine the correlation between pupal mass and adult mass, an empty 30-ml plastic cup was weighed to the nearest 0.1 mg and then reweighed with the addition of one pupa ($N = 30$). On the day of emergence, a second plastic 30-ml cup was similarly weighed with and without the adult moth. To determine the correlation between the pupal mass and pheromone titters, pupae and emergent adult females were weighed, and the pheromone glands of the adults were extracted as described above, respectively.

Statistical Analyses. The Shapiro–Wilk and Kolmogorov–Smirnov goodness-of-fit tests and Bartlett’s test were used to test for homogeneity of variances and normality for the data from Experiments #1–3. In Experiments #1–3, the data were not normally distributed and had heterogeneous variances. Although we were able to use the Box–Cox transformation to identify transformations that normalized the data (done only in Experiment #1), the transformed data still had heterogeneous variance. Despite the variance heterogeneity, none of the comparisons involved a ratio greater than 10 (this is the level of acceptable variance heterogeneity using the F_{\max} test; Tabachnick and Fidell, 2001). Given the outcome of these statistical tests of normality and variance heterogeneity, we elected to use a multiresponse permutation procedure (MRPP), which is free from the assumptions of the normality and homogeneity of variance (Mielke and Berry, 2001), to analyze the data from Experiments #1–4. We tested the null hypotheses that mean titters of Z9,E12-14:Ac and Z9-14:Ac, and the ratio of Z9,E12-14:Ac to Z9-14:Ac were independent of (1) the number of days postemergence that females were assayed, (2) the period of the L/D cycle in which females were assayed, (3) whether or not females had access to water as adults, and (4) the temperature that females were reared at as larvae. Under the experimental design used to test all four hypotheses, the treatment effect may also have included day effects; however, because

the cohorts of females analyzed were progeny of the same group of adults, were reared under controlled conditions, and all extractions were performed by the same individual, we expect that any day effect would be small relative to the treatment effect. Pairwise comparison of treatment groups within an experiment were performed using MRPP, which has a multiple-range test function. The intensity of the associations between pupal and adult mass and between pupal mass and mean titers of Z9,E12-14:Ac, Z9-14:Ac, or the ratio of Z9,E12-14:Ac to Z9-14:Ac were measured using simple linear correlation. In each case, we tested the null hypothesis $H_0: \rho = 0$ against $H_A: \rho \neq 0$ for $r_{0.05(2),28} = 0.361$. MRPP tests were performed using Blossom Statistical Software, version 2001-8d, (USGS, Fort Collins Science Center; www.fort.usgs.gov/products/software/blossom/blossom.asp).

Genetic Analysis. A half-sibling breeding design was used to characterize the genetic basis of the observed variation in the titers and ratio of the pheromone components. Wandering last instar male and female *C. cautella* larvae were randomly chosen from the laboratory colony and kept in 180-ml plastic cups in groups of 10 for pupation (males and females were kept separately). Virgin adults were paired 1–2 d after emergence in 180-ml cups with ca. 50 g of artificial diet for 1 d. The next day, the male moth was removed and similarly paired with a new 1- to 2-d-old virgin female. The original, mated female was placed individually in a new cup with artificial diet (1 d after mating). The following day (2 d after mating), the original mated female was placed in a third cup of artificial diet (3 d after mating) where she remained until death. Each dam was similarly placed on new media the 2 d following mating. On the third day, each male was paired with its third and final virgin female. The progeny of each female were reared, and extracts were prepared and assayed from pheromone glands from 1-d postemergence females during the second hour of the scotophase as described above. In total, 32 sires were mated to three dams each yielding 96 families. From these 96 families, the pheromone gland contents of 926 progeny were analyzed (an average of 9.7 progeny/family) (Figure 1). The genetic variances and covariances were estimated by restricted maximum likelihood using PROC MIXED (Fry, 2004) of SAS (1988). Heritabilities were estimated as described by Roff (1997) for a half-sibling design. Standard errors for the narrow-sense heritabilities and genetic correlation were determined following Roff (1997) and Robertson (1959), respectively. The null hypothesis that the additive genetic correlation did not differ from zero ($r_A = 0$) was tested as described by Fry (2004). The additive genetic coefficient of variation (CV_A) describes the “evolubility” (Houle, 1992) of a trait and was estimated for each trait using the equation $CV_A = 100 \times [(V_A)^{1/2}/\bar{X}]$, where V_A is the additive genetic variance of the trait (see above).

FIG. 1. The nested half-sibling design for genetic analysis of *C. cautella*. Thirty-two sires (square) were each mated to three dams (diamonds). From each dam, the pheromone glands of ten 1-d-old female offspring (octagons) were removed 1 hr into the scotophase and analyzed for the titers of Z9,E12-14:Ac and Z9-14:Ac and for the ratio of Z9,E12-14:Ac to Z9-14:Ac.

RESULTS

Analysis of Variation

Experiment #1: Effect of Age on Titer and Component Ratio. Mean titers of Z9,E12-14:Ac and Z9-14:Ac, and the ratio of Z9,E12-14:Ac to Z9-14:Ac varied significantly with female age (Figure 2). Female *C. cautella* had more Z9,E12-14:Ac 1 d postemergence than females from all other age classes. Similarly, females had more Z9,E12-14:Ac at 2 and 3 d postemergence than females from all older age classes. Unlike Z9,E12-14:Ac, the amount of Z9-14:Ac in female pheromone glands peaked at 2 d postemergence. Two- and 3-d-old females had more Z9-14:Ac than 1- and 5-d-old females, and 2-d-old females had more Z9-14:Ac than 4-d-old females. The ratio of Z9,E12-14:Ac to Z9-14:Ac was higher 1 d postemergence than for all other age classes, and at 2 and 3 d postemergence it was higher than at 4 and 5 d postemergence. In summary, the titer of Z9,E12-14:Ac and the ratio of Z9,E12-14:Ac to Z9-14:Ac decrease with increasing female age, whereas the titer of Z9-14:Ac initially increases with age and subsequently decreases.

FIG. 2. The effect of age of newly emerged female *C. cautella* on mean titer (+SE) of Z9,E12-14:Ac (hatched bars) and Z9-14:Ac (open bars), and the ratio of Z9,E12-14:Ac to Z9-14:Ac (dashed line). Females were extracted 1 hr into the scotoperiod 1 d ($N = 97$), 2 d ($N = 101$), 3 d ($N = 105$), 4 d ($N = 101$), and 5 d ($N = 101$) postemergence. Hatched bars with different letters are significantly different ($P < 0.001$; except 1 vs 2 d postemergence, $P < 0.05$). Open bars with different letters are significantly different ($P < 0.001$; except for 1 vs. 3 d and 3 vs. 5 d postemergence, $P < 0.01$; and 2 vs. 4 d postemergence, $P < 0.05$). Filled diamonds from the dashed line with different letters are significantly different ($P < 0.001$; except for 3 vs. 4 and 5 d postemergence $P < 0.05$).

Experiment #2: Effect of the L/D Cycle on Titer and Component Ratio. Female *C. cautella* had Z9,E12-14:Ac and Z9-14:Ac present in their pheromone glands at all sampling times of the L/D cycle, but the mean titers of Z9,E12-14:Ac and Z9-14:Ac, and the ratio of Z9,E12-14:Ac to Z9-14:Ac varied significantly with L/D cycle (Figure 3). Females had more Z9,E12-14:Ac and Z9-14:Ac at the onset of the scotoperiod than at all other times. The amount of Z9,E12-14:Ac in female pheromone glands decreased throughout the scotoperiod and rose from the end of the scotoperiod to mid-photoperiod. Female Z9-14:Ac titers were higher mid-scotoperiod and at the end of the scotoperiod than mid-photoperiod. The mean ratio of Z9,E12-14:Ac to Z9-14:Ac was highest at the onset of the scotoperiod, decreased throughout the scotoperiod, and rose again to its maximum by mid-photoperiod. The only significant difference observed was between the ratio at mid-scotoperiod and mid-photoperiod.

Experiment #3: Effect of Access to Water on Titer and Component Ratio. The amount of Z9,E12-14:Ac decreased from 1, 3, to 5 d postemergence, whereas the amount of Z9-14:Ac was highest 3 d postemergence in females with and without access to water (Figure 4). The ratio of Z9,E12-14:Ac to Z9-

FIG. 3. The effect of L/D cycle on mean titers (+SE) of Z9,E12-14:Ac (hatched bars) and Z9-14:Ac (open bars) produced by female *C. cautella*, and on the ratio of Z9,E12-14:Ac to Z9-14:Ac (dashed line). Females were kept singly in cups within a light box on a 16:8 L/D cycle with the onset of the scotoperiod at 9:00 A.M. Female moths were extracted at the onset of the scotoperiod (9:00 A.M.) ($N = 58$), mid-scotoperiod (1:00 P.M.) ($N = 59$), end of the scotoperiod (5:00 P.M.) ($N = 60$), and mid-photoperiod (1:00 A.M.) ($N = 60$). Hatched bars with different letters are significantly different ($P < 0.001$). Open bars with different letters are significantly different ($P < 0.001$; except for 1:00 P.M. vs 1:00 A.M., $P < 0.05$). Filled triangles from the dashed line with different letters are significantly different ($P < 0.001$).

14:Ac decreased from 1 to 3 d postemergence. At 1, 3, and 5 d postemergence, there was no effect of access to water on the amount of Z9,E12-14:Ac ($P = 0.30$, $P = 0.57$, $P = 0.078$), Z9-14:Ac ($P = 0.30$, $P = 0.57$, $P = 0.17$), or the ratio of Z9,E12-14:Ac to Z9-14:Ac ($P = 0.18$, $P = 0.69$, $P = 0.82$) (Figure 4).

Experiment #4: Effect of Larval Rearing Temperature on Titer and Component Ratio. The mean titers of Z9,E12-14:Ac ($P = 0.28$) and Z9-14:Ac ($P = 0.87$) and the ratio of Z9,E12-14:Ac to Z9-14:Ac ($P = 0.61$) in the pheromone glands of females 1 d postemergence did not differ when larvae were reared at 21 or 26°C (Figure 5).

Experiment #5: Correlation Between Female Adult and Pupal Mass, and Pupal Mass and Titer and Component Ratio. Adult and pupal mass were positively correlated ($r = 0.87$, $P < 0.001$). The correlations between pupal mass and the amount of Z9,E12-14:Ac ($r = 0.082$) was not significant. The correlation between pupal mass and the amount of Z9-14:Ac ($r = -0.11$) and pupal mass and the ratio of Z9,E12-14:Ac to Z9-14:Ac ($r = 0.29$) also were not significant (Figure 6).

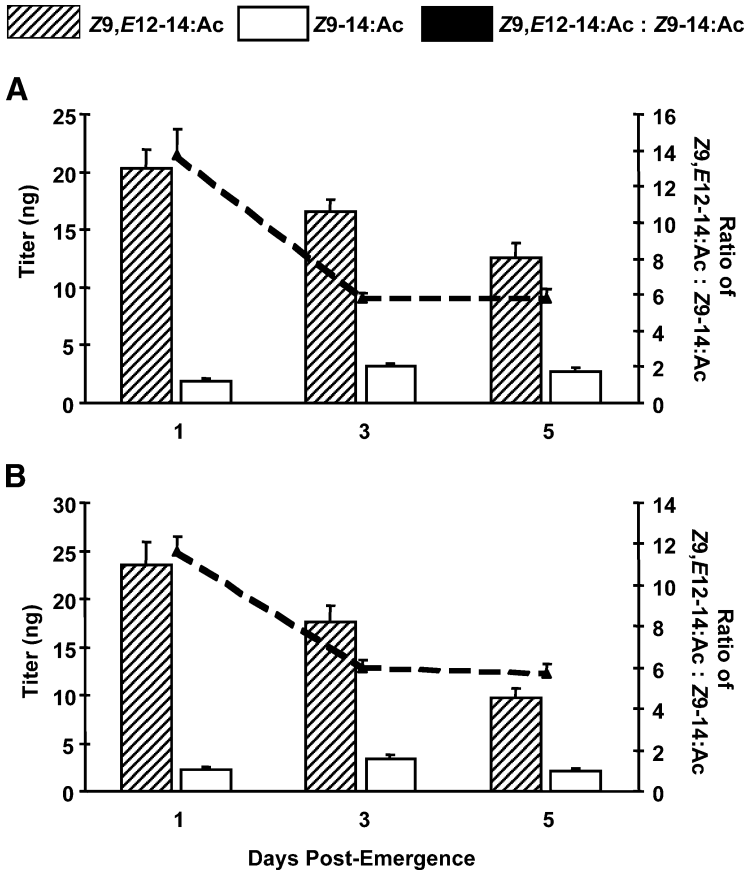

FIG. 4. The effect of access to water on mean titers (+SE) of Z9,E12-14:Ac (hatched bars) and Z9-14:Ac (open bars) produced by female *C. cautella*, and on the ratio of Z9,E12-14:Ac to Z9-14:Ac (dashed line). Titers and ratio 1, 3, and 5 d postemergence with access to water (A) and same without access to water (B). There was no effect of access to water on the amount of Z9,E12-14:Ac ($P = 0.30$, $P = 0.57$, $P = 0.078$), Z9-14:Ac ($P = 0.30$, $P = 0.57$, $P = 0.17$), or the ratio of Z9,E12-14:Ac to Z9-14:Ac ($P = 0.184$, $P = 0.692$, $P = 0.821$) 1, 3, and 5 d postemergence, respectively ($N = 30$).

Genetic Analyses

The considerable variation in both the titers and ratio of pheromone components among and within age classes and periods of the L/D cycle (Figures 2 and 3) and the absence of environmental effects in Experiments #3–4 (Figures 4 and 5) suggested a genetic basis to the observed variation in these traits.

FIG. 5. Effect of larval rearing temperature on mean titers (+SE) of Z9,E12-14:Ac (hatched bars) and Z9-14:Ac (open bars) produced by female *C. cautella*, and on the ratio of Z9,E12-14:Ac to Z9-14:Ac (dashed line). There was no effect of rearing temperature on the titers of Z9,E12-14:Ac ($P = 0.28$) and Z9-14:Ac ($P = 0.87$), or on the ratio of Z9,E12-14:Ac to Z9-14:Ac ($P = 0.61$) ($N = 50$).

Heritability of Titer of Z9,E12-14:Ac and Z9-14:Ac. The mean titers of Z9,E12-14:Ac and Z9-14:Ac (\pm SE) among the F1 females were 25.73 ± 0.44 and 2.09 ± 0.047 ng ($N = 926$), respectively. Family means for Z9,E12-14:Ac and Z9-14:Ac (\pm SE) ranged from 12.66 ± 1.72 to 62.37 ± 3.62 and from 0.81 ± 0.11 to 7.24 ± 1.19 ng, and significant differences were found among families (Z9,E12-14:Ac and Z9-14:Ac, $P < 0.001$; ANOVA). The sire- and dam-based estimates of narrow-sense heritability (\pm SE) for Z9,E12-14:Ac are 1.20 ± 0.32 and 0.26 ± 0.10 , and for Z9-14:Ac are 0.75 ± 0.24 and 0.44 ± 0.09 , respectively (statistically significant, $h^2 > 2SE$). These moderate to high heritabilities (Arnold, 1994) suggest that a significant portion (26–100%) of the observed variation has an additive genetic basis.

Heritability of Ratio of Z9,E12-14:Ac to Z9-14:Ac. The mean ratio of Z9,E12-14:Ac to Z9-14:Ac (\pm SE) was 14.36 ± 0.19 ($N = 926$) among the F1 females. Family means ranged from $7.65 \pm 0.79:1$ to $23.04 \pm 3.55:1$, and differences were found among families ($P < 0.001$; ANOVA). The sire- and dam-based estimates of narrow-sense heritability (\pm SE) for this trait are 0.46 ± 0.17 and 0.56 ± 0.20 , respectively (statistically significant, $h^2 > 2SE$). These moderate heritabilities (Arnold, 1994) suggest that a significant portion (46–56%) of the observed variation has an additive genetic basis.

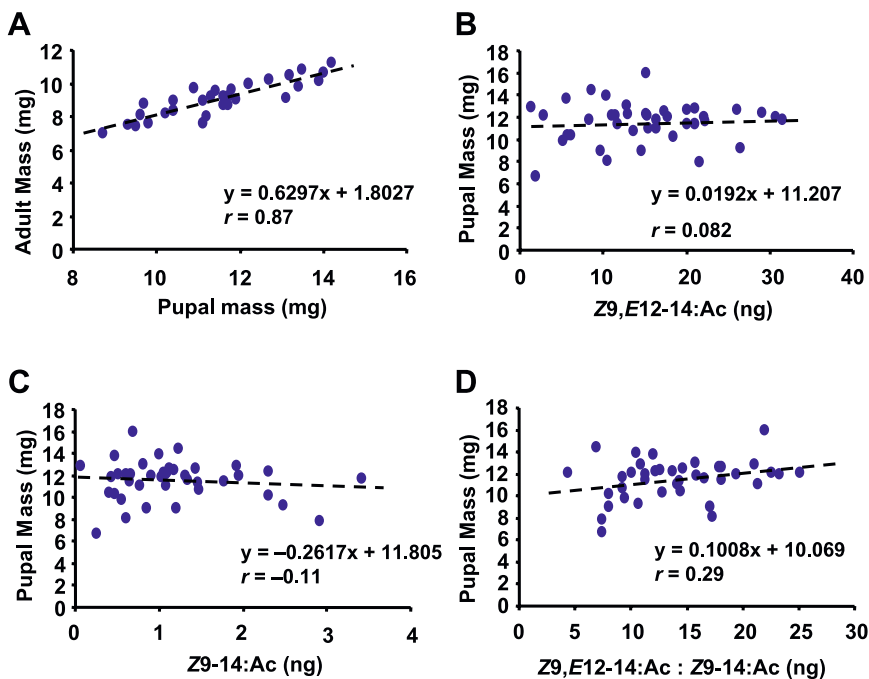

FIG. 6. Correlation analyses between adult mass and pupal mass (A); pupal mass and the major pheromone component Z9,E12-14:Ac (B), pupal mass and the minor pheromone component Z9-14:Ac (C), and pupal mass and the ratio of Z9,E12-14:Ac to Z9-14:Ac (D). Each dot represents one female moth ($N = 30$). The only correlation coefficient (ρ) significantly different than zero was observed between adult mass and pupal mass ($P < 0.001$).

Coefficients of Additive Genetic Variance and Genetic Correlations. The coefficients of additive genetic variance were high for both the sire- and dam-based estimates of all three traits (Table 1). The sire-based estimates of the genetic correlation (\pm SE) between the titers of Z9,E12-14:Ac and Z9-14:Ac, between the titer of Z9,E12-14:Ac and the ratio of Z9,E12-14:Ac to Z9-14:Ac, and between the titer of Z9-14:Ac and the ratio of Z9,E12-14:Ac to Z9-14:Ac are 0.85 ± 0.06 , 0.32 ± 0.2 , and -0.23 ± 0.34 , respectively (Table 1).

DISCUSSION

Analysis of Pheromonal Variation. The titers of Z9,E12-14:Ac and Z9-14:Ac, and the ratio of Z9,E12-14:Ac to Z9-14:Ac varied with age. In moths

that mate soon after eclosion, the sex pheromone titer is generally low on the day of eclosion, increases for ca. 1 day, and then declines progressively until death (Schal et al., 1987; Tang et al., 1992; Kamimura and Tatsuki, 1993; Gemeno and Haynes, 2000). The data from our study are consistent with the general pattern of decreasing pheromone titer with age.

The diel periodicity of the titers of both the major and minor sex pheromone components of *C. cautella*, and the ratio of the two components peaked at the onset of the scotophase, decreased throughout the calling period (scotophase), and reached a minimum at the end of the scotophase. In this species, pheromone gland titers appear to decrease during calling and increase between calling periods. Similar diel periodicities of gland titer have been observed in other moth species (Konno, 1986; Ono et al., 1990; Hunt and Haynes, 1990; Delisle and Royer, 1994). However, in other moth species, pheromone titers have been observed to be synchronous with calling peaks (Pope et al., 1982; Delisle and McNeil, 1987; Tang et al., 1992; Kamimura and Tatsuki, 1993). The reduction in titers of both pheromone components during the scotoperiod suggests that the rate of release of pheromone from the gland exceeds the rate of biosynthesis, or that little biosynthesis occurs during the scotophase, or both.

The biosynthetic pathway used by female *C. cautella* to synthesize Z9,E12-14:Ac and Z9-14:Ac involves a Δ11 and Δ12 desaturase, and both pheromone components share a common precursor (Z9-14:CoA), upstream of the Δ12 desaturase (Jurenka, 1997). This suggests that the decrease in the ratio of

Z9,E12-14:Ac to Z9-14:Ac with age and photoperiod is due to reduced activity or titers of the $\Delta 12$ desaturase later in the photoperiod and in older moths.

Adult *C. cautella* have functional mouthparts and are capable of feeding. Ryne et al. (2002) speculated that water sources are limited in the habitat of *C. cautella*, and male and female *C. cautella* are attracted to traps baited with water (Chow et al., 1977; Ryne et al., 2002).¹ However, access to water had no effect on the titer of either Z9,E12-14:Ac or Z9-14:Ac, or the ratio of Z9,E12-14:Ac to Z9-14:Ac.

Variation in the temperature experienced during pupal and adult development can affect the age of first calling, the calling periodicity, and the calling duration in females, and the age of maximum responsiveness to pheromone, the selectivity of/preference for pheromone blends, and the periodicity of orientation behavior in males (reviewed in McNeil, 1991). Temperature was also observed to affect pheromone gland content (Raina, 2003), as well as the emission rate and blend ratios of pheromone from forcibly extruded pheromone glands (Liu and Haynes, 1994). Ono (1993, 1994) found that the ratio of the sex pheromone components of the potato tuberworm moth, *P. operculella* (Zeller) [(E,Z)-4,7-tridecadienyl acetate and (E,Z,Z)-4,7,10-tridecatrienyl acetate] varied with temperature [mean percent of (E,Z,Z)-4,7,10-tridecatrienyl acetate ranged from ca. 80% at 15°C to 38% at 35°C]. Contrary to these observations, the sex pheromone blend in our study species was not affected by temperature. One possible explanation may be the range of temperatures experienced. In our study, moths were reared at 21 and 26°C, whereas Ono (1993, 1994) reared moths at 15, 25, and 35°C. It is possible that a significant effect of temperature may be realized in moths reared at more extreme temperatures.²

As expected, adult mass was positively and significantly correlated with pupal mass. However, the pheromone titers of Z9,E12-14:Ac and Z9-14:Ac, and the ratio of Z9,E12-14:Ac to Z9-14:Ac were not significantly correlated with pupal mass. These results are consistent with those observed with other species (e.g., *Argyrotaenia velutinana*, Miller and Roelofs, 1980; *Holomelina lamae*, Schal et al., 1987).

Genetic Analysis of Pheromone Variation. According to Fisher's fundamental theorem, additive genetic variance for total fitness should rapidly be eliminated by selection (Fisher, 1930). An extension of this concept is that characters closely related to fitness should have low heritabilities (Falconer and Mackay, 1996). However, the heritability of a character is not completely

¹ The study of Chow et al. (1977) did not differentiate between *C. cautella* and *Plodia interpunctella*. The study of Ryne et al. (2002) identified specimens to species and sex, thus definitively demonstrating attraction of adult *C. cautella* to water.

² Our experimental design included a 31°C treatment. The survivorship of moths reared at this temperature was so low that we were unable to obtain enough females for analysis.

defined by the amount of additive genetic variance, but rather by the amount relative to total phenotypic variance. Consequently, characters with little additive genetic variance will have low heritabilities only when the amount of additive genetic variance is far lower than the total phenotypic variance. Theoretical arguments also suggest that additive genetic variance can exist for fitness components when negative genetic correlations with other fitness components exist. Despite this, the literature generally supports the prediction that the heritability of a character is negatively correlated with fitness consequences (Gustafsson, 1986; Roff and Mousseau, 1987; Mousseau and Roff, 1987). For example, Roff (1997) summarized published laboratory and field-based heritability estimates of life history, behavioral, and morphological traits. As predicted, heritability estimates increased with decreasing trait importance [mean heritabilities of life history, behavioral, and morphological traits were 0.28 ($N = 87$), 0.34 ($N = 27$), and 0.54 ($N = 240$), respectively].

Unlike dam-based heritability estimates, sire-based estimates are not influenced by maternal and common environmental effects or dominance variance and are consequently more accurate. The sire-based heritability estimates observed for the titers of Z9,E12-14:Ac and Z9-14:Ac were both greater than the mean for morphological traits (see above) and were all consistent with published estimates (Table 2). The heritability of the ratio of Z9,E12-14:Ac to Z9-14:Ac was intermediate to the observed mean of behavioral and morphological traits. One way to interpret these data is that variation in pheromone component titers and ratios may have minimal fitness consequences.

One of the primary goals of studies of genetic variation is to predict the potential for the evolution of the mean phenotype of a population (hereafter referred to as “evolvability” *sensu* Houle, 1992). In the short term this will be determined by the amount of additive genetic variance. To generate evolvability estimates, it is necessary to partition trait variance into additive genetic variance, V_A , and residual variance, V_R (Falconer and Mackay, 1996). Traditionally, narrow-sense heritability has been used to describe variance partitioning. Houle (1992) argued that measures of variation standardized by trait means are more accurate comparative measures of evolvability than measures standardized by total phenotypic variance (V_P) (narrow-sense heritability). The additive genetic coefficient of variation (CV_A) describes the amount of additive genetic variance standardized by the trait mean. Although the narrow-sense heritability of a trait describes the potential for a response to selection in absolute terms, the CV_A describes the potential in relative terms (Houle, 1992). The sire-based coefficients of variation observed for the titers of Z9,E12-14:Ac and Z9-14:Ac and for the ratio of Z9,E12-14:Ac to Z9-14:Ac were notably high (55.99, 59.76, and 25.91) [mean CV_A for developmental time, longevity and fecundity in *Drosophila melanogaster* are 2.47 ($N = 2$), 9.89 ($N = 7$), and 11.90 ($N = 12$); see Houle, 1992]. Comparison of the CV_A for all

TABLE 2. SIGNIFICANT NARROW-SENSE HERITABILITY ESTIMATES OF PHEROMONE TITERS AND RATIOS

Species	Design	Trait	$h^2 \pm SE$	Reference
<i>Pectinophora gossypiella</i>	Full-sibling	Titer of Z7, E11-16:Ac plus Z7, Z11-16:Ac	0.41 ± 0.09	Collins and Cardé, 1985

three pheromonal traits suggests that the titers of both pheromone components have an equivalent potential response to selection that is approximately twofold greater than that of the ratio of Z9,E12-14:Ac to Z9-14:Ac.

Individual traits are commonly not inherited independently, but rather two or more traits are often associated with each other (Lande, 1979; Lande and Arnold, 1983). We observed a strong, positive genetic correlation between the titer of Z9,E12-14:Ac and the titer of Z9-14:Ac (0.85 ± 0.06), suggesting that the genetic factors controlling the synthesis of the two pheromone components are either identical or closely linked. Neither of the genetic correlations between the titers of Z9,E12-14:Ac and Z9-14:Ac and the ratio of Z9,E12-14:Ac to Z9-14:Ac were significant (0.32 ± 0.20 and -0.23 ± 0.34 , respectively). The significant correlation between the pheromone titers, but not between the titer of either component and the component ratio, suggests that the pheromone titers and their ratio are determined by independent genetic factors and should consequently follow separate evolutionary trajectories. The existence of opposing pleiotropic effects in the genes for these traits would result in an overestimation of the degree of independence between these characters (Falconer and Mackay, 1996).

In *C. cautella*, the sex pheromone signal is extremely variable not only within and across-age classes but also throughout the L/D cycle. Although we observed more variability and higher gland titers and ratios of Z9,E12-14:Ac to Z9-14:Ac, the results generally agree with those of previous less comprehensive studies (Brady, 1973; Kuwahara and Casida, 1973; Coffelt et al., 1978; Coffelt and Vick, 1987; Barrer et al., 1987; Shani, 1990). The existence of a significant, positive genetic correlation between the pheromone component titers and the higher sire-based heritability and CV_A estimates for the pheromone component titers than for the ratio are all consistent with the hypothesis that pheromone component ratio has a lower potential response to selection than component titers.

Models of sex pheromonal signal evolution (see Cardé and Haynes, 2004) predict an asymmetry in the strength of selection experienced by males and females. In lepidopteran mating systems with female-biased investment in the zygote, selection is predicted to favor male response profiles broad enough to include most or all of the females in a population (see Phelan, 1997). Consequently, species with high signal variance should have male response profiles that are similarly broad, whereas male response profiles can be broad or narrow in species with low signal variance. These ideas can be extrapolated to make predictions about the evolvability of female signals and male response profiles. In general, signal and response profile variance should be positively correlated with their evolvability.

We observed high levels of heritable variation for both pheromone component titers and ratios. The high levels of heritable variation found in this

study may be a consequence of the release of this population from the “natural” selection regime, which includes the need for males to locate females over relatively long distances. Alternatively, such variation suggests that the paradigm that variation in pheromone titers and ratio has negative fitness consequences and is minimized by stabilizing selection may need reevaluation. Specifically, it suggests that male *C. cautella* response profiles should be similarly broad.

Acknowledgments—We are grateful to K. Buhrmeister, T. Berhane, and A. Kuszynski for technical assistance; D. A. Roff for aid with the genetic analyses; and J. G. Millar, J. D. Hare, R. A. Redak, D. Abstract—The mandibular gland secretions of worker castes from wild colonies of the leaf-cutting ants *Atta sexdens sexdens* and *Atta opaciceps* were analyzed quantitatively by gas chromatography–mass spectrometry. The secretions comprised a complex mixture of volatile, mainly oxygenated compounds, and their profiles exhibited considerable qualitative and quantitative variations among species and castes. The known alarm pheromone 4-methyl-3-heptanone was common to both species. The elevated relative proportions of this ketone found in the secretions of gardeners and generalists suggest that such castes are primarily responsible for the production and release of the alarm pheromone. Quantitative variations (but no qualitative differences) in the profiles of secretions of soldiers from different colonies of *A. sexdens sexdens* were detected, supporting the view that intraspecific colony recognition is mediated through mandibular gland secretions. Subsequent laboratory assays showed that, among the compounds identified by GC–MS, 4-methyl-3-heptanone elicited a strong alarm response in workers of *A. sexdens sexdens* and *A. opaciceps*.

Key Words—Alarm pheromone, *Atta sexdens sexdens*, *Atta opaciceps*, hymenoptera, formicidae, myrmicinae, attini.

INTRODUCTION

Leaf-cutting ants possess a sophisticated mechanism of communication, the principal function of which is associated with the maintenance of the complex social structure of their highly territorial colonies (Jaffe, 1979; Whitehouse and Jaffé, 1995). The mandibular glands of the Formicidae constitute important sources of volatile organic compounds that mediate ant behaviors (Hölldobler and Wilson, 1990) such as alarm behavior, typically characterized by highly accelerated movements and accompanied by attack (Brown et al., 1970). However, for ants that live in small, less well-organized colonies, alarm pheromones may act rather as signals for evacuation because such insects are not well equipped for defense (Regnier and Wilson, 1969). In the majority of ant species belonging to the subfamily Myrmicinae, for example, *Atta* and *Acromyrmex*, the mandibular glands produce secretions containing mixtures of components that frequently include alcohols or ketones of low molecular weight and high volatility that could be involved in the communication of such a state of alarm (Blum, 1969).

The first alarm pheromone from leaf-cutting ants to be analyzed was a mixture of 4-methyl-3-heptanone, neral, and geranial isolated from workers of *Atta sexdens sexdens* (Butenandt et al., 1959). Moreover, 4-methyl-3-heptanone was found to be the component that elicited alarm pheromone activity in workers of *A. texana*, *A. robusta*, *A. bisphaerica*, *A. capiguara*, and *A. sexdens* (Moser et al., 1968; Blum, 1969; Riley et al., 1974; Hughes et al., 2001b). Recent studies (Hernández et al., 1999; Hughes et al., 2001b) have further revealed that 4-methyl-3-heptanone is commonly found in *A. laevigata*, *A. capiguara*, and *A. bisphaerica*, together with other ketones such as 2-heptanone, 4-methyl-2-heptanone, 2-octanone, and 3-octanone, and the related alcohols 2-hexanol, 2-heptanol, and 4-methyl-3-heptanol.

Colonies of *Atta* sp. are highly polymorphic and exhibit polyethism: Workers may be separated into four castes (Wilson, 1980), namely, minors (gardeners or nurses), generalists, foragers, and majors (defenders or soldiers). In the case of leaf-cutting ants, the composition of the alarm pheromone can vary significantly among the castes. Thus, for *Atta sexdens rubropilosa*, the mandibular gland secretions of the major castes consisted of a complex mixture with the citral isomers (geranial and neral) as the major components, whereas those of the gardeners and generalists were dominated by 4-methyl-3-heptanone, and practically no citral isomers were found (Do Nascimento et al., 1993). A similar situation was reported for *A. laevigata*, in which the secretions of the minor workers contained much higher levels of 4-methyl-3-heptanone than those of the major castes (Hughes et al., 2001b). Furthermore, for *A. capiguara* and *A. bisphaerica* the mandibular gland secretions can vary in composition among castes within the same colony (Hughes et al., 2001b).

Although such reports confirm the existence of a relationship between the nature of the alarm pheromone and the different castes of leaf-cutting ants, further investigations involving other species need to be made in order to establish a verifiable explanation for the variation of pheromone composition.

Whereas most studies have been conducted using single defined colonies of leaf-cutting ants (Moser et al., 1968; Schildknecht, 1976; Do Nascimento et al., 1993; Hernández et al., 1999, 2002), variations among colonies have been described by some authors. Thus, Whitehouse and Jaffé (1995) reported that specimens of *A. laevigata* responded in a much more aggressive manner to the presence of macerated heads of ants derived from a different colony compared to macerated heads of ants from their own colony. Moreover, Hughes et al. (2001b) detected small but consistent intraspecific differences in various colonies of *A. capiguara* and *A. bisphaerica*. Taken together, these findings suggest that the intercolony differences in the alarm pheromones of leaf-cutting ants can be detected by the ants. However, details of the variation in chemical composition of alarm pheromones among colonies and among castes of leaf-cutting ants is limited to a few species.

The mandibular gland secretion of *A. sexdens sexdens* is yellow in color, possibly due to the presence of degradation products of the citral isomers that are characteristic of this species. These aldehydes are released from the cephalic capsule of *A. sexdens sexdens* when the head of the ant is crushed and are readily recognized by their strong lemon smell, giving rise to the Brazilian name of “saúva-limão” for this ant (Blum et al., 1968). In contrast, the mandibular gland secretion of *A. opaciceps* is a transparent liquid, the chemical composition of which has not yet been studied. The aim of the present work was to identify the components present in the mandibular gland secretions of these two species of leaf-cutting ants and to determine any qualitative and/or quantitative variations among colonies and castes of the species. In addition, laboratory-based experiments were conducted to test the effects of mandibular gland compounds on workers of *A. sexdens sexdens* and *A. opaciceps*.

METHODS AND MATERIALS

Identification of Ants. Nests of leaf-cutting ants (two of *A. sexdens sexdens* and one of *A. opaciceps*), situated at different locations on the campus of the Federal University of Alagoas, were initially selected on the basis of the constant and discrete foraging activities of workers. Ten specimens from each nest were collected, representing the different worker castes, namely, two gardeners, two generalists, two foragers, and four soldiers. Specimens were stored separately in 70% alcohol in appropriately labeled glass containers and

deposited at the Centro de Pesquisa, Laboratório de Mirmecologia-CEPEC/CEPLAC, Itabuna-BA, Brasil. Specimens were identified and authenticated by Dr. Jacques H. C. Delabie (myrmecologist at CEPEC/CEPLAC).

Collection of Ants. Specimens of all castes of both species were collected at their nest entrances and along foraging trails. Collections were made as carefully as possible, using clean entomological forceps, in a manner that minimized the release of any volatile components. Specimens were transferred immediately to ice-cold glass tubes (4×2 cm i.d.) that were closed with rubber caps, packed in ice, and transported to the laboratory, where they were stored at 4°C until required for the preparation of extracts.

Preparation of Extracts. Based on the classification proposed by Della Lucia et al. (1993), castes were distinguished according to the width of the cephalic capsule. Mandibular glands and/or cephalic capsules from different castes of *A. sexdens sexdens* and *A. opaciceps* were separated with the aid of forceps under a Wild Leica M3B stereoscopic microscope equipped with a Wild Leica MPS05 camera. The glands or capsules were ground in 2 ml of hexane, and the extracts obtained were stored in sealed ampoules in the freezer until required for analysis. In order to provide satisfactory GC-MS analyses, extracts were prepared separately using 16 cephalic capsules of gardeners, eight cephalic capsules of generalists, two pairs of mandibular glands of foragers, or one pair of mandibular glands of soldiers.

Identification of Volatile Constituents. Extracts of mandibular glands and cephalic capsules were analyzed by GC-MS using a Shimadzu model 17A chromatograph coupled to a Shimadzu QP5050A mass-selective detector controlled by a Pentium 2 (200 MHz) computer running 5000 Class software. The volatile components of the extracts were separated on a fused-silica polydimethylsiloxane-coated column (30 m \times 0.25 mm i.d.) (0.5 μ m film thickness) and operated under the following conditions: carrier gas, helium at 1 ml/min; oven temperature, 30°C increasing at 8°C/min to 250°C; injector temperature, 200°C; injection mode, splitless; detector temperature, 270°C; ionization energy, 70 eV. Compounds were identified from their mass spectra and confirmed by comparison of retention time and mass spectrum with purchased or synthesized standards. 4-Methyl-3-heptanone and β -citronellol were used as external standards for quantification of components. Standards of *trans-p*-mentha-1[7]-8-dien-2-ol, *trans*-2-carene-4-ol, dihydrolinalool, (*E*)-myrtenol, limonene isomer, *cis*-4-decenal, δ -decalactone, and 2,3-dihydro-6-*trans*-farnesol were not available. These compounds were tentatively identified from matches with database or published mass spectra (Wiley 275 data base; McLafferty and Stauffer, 1989).

Quantitative Analysis of Volatile Constituents. The average amount of each component in a gland was calculated from its GC peak area expressed as a percentage of the total peak area of all components detected.

Ethological Assays. Bioassays were carried out in an olfactometer as described by Löfgren et al. (1983). The unfiltered output from an air pump was passed, via plastic tubing, through a Pasteur pipette containing a segment of filter paper impregnated with an appropriate test solution. The outlet of the pipette was loosely plugged with cotton wool to provide a uniform flow of stimulus-laden air. This air stream was passed over a moistened disc of filter paper, lining a glass Petri dish arena (19-cm diam). This arena was covered with red cellophane to prevent disturbance of the ants by visual stimulation from the surroundings.

Chemicals. Except for 4-methyl-3-heptanone, the synthetic standards listed in the tables were purchased (Sigma-Aldrich Co. Ltd., USA). 4-Methyl-3-heptanone was prepared from the corresponding alcohol by sodium hypochlorite oxidation, which gave a racemic mixture of 4-methyl-3-heptanone 99% pure by gas chromatography.

Bioassays of Alarm Pheromone. The responses of workers of *A. sexdens sexdens* and *A. opaciceps* to hexane solutions of synthetic compounds found in the secretion of the mandibular gland of generalists, the caste that produces compounds that elicit alarm behavior in nestmates (Wilson, 1980; Hernández et al., 1999; Hughes et al., 2001b; unpublished results), was observed. Ten ants (*A. sexdens sexdens* or *A. opaciceps*) were introduced into the arena and left for a 5-min acclimation period. Then the air stream from a pipette containing a filter paper impregnated with 10 μ l of the test solution passed over the arena. The concentration of each compound used in these bioassays was similar to that found in the mandibular gland secretions of generalists from each species. A piece of filter paper treated only with hexane was used as a control.

The criteria used to measure the responses of forager workers were similar to those reported by Hernández et al. (2002), as follows: (1) antennation: inspection of arena, followed by vigorous movement of antennae; (2) opening the mandibles: the ants attacked the outlet of the odor source (cotton swab) with their mandibles (biting). These behaviors were quantified and recorded continuously for 10 min.

Extracts were applied in randomized sequence, and each extract was tested separately 10 times. After each replication, the olfactometer was cleaned, the filter paper and cotton wool plug were changed, and 10 new insects were introduced into the arena. All of the bioassays were conducted at night (after 1800 hr) to coincide with the time that the ants would normally commence foraging. The temperature and relative humidity in the arena were $26 \pm 0.2^\circ\text{C}$ and $60 \pm 10\%$, respectively.

Statistical Analysis. Because the secretions of soldiers contained the largest number of individual components their compositions were used to assess proportional differences in the main constituents of the alarm pheromones between members of the two nests of *A. sexdens sexdens*. Each such constituent

was considered independently and, therefore, the percentage content of each component in the two colonies analyzed could be compared using one-way ANOVA (or F test) as well as by *t* test, both at the 5% level of significance. Tukey's test (at a significance level of 5%) was applied to compare means.

RESULTS

Identification of Volatile Components in Secretions from Different Castes of A. sexdens sexdens from Different Colonies. GC-MS analysis of extracts of the mandibular glands and cephalic capsules of different castes of workers from

different colonies of *A. sexdens sexdens* revealed that the components present were mainly low molecular weight ketones, aldehydes, alcohols, and mono-terpenoids (Tables 1 and 2). Geranial and neral were the major components in the extracts of glands of forager and soldier castes from both of the colonies analyzed, followed by small amounts of 4-methyl-3-heptanone. In contrast, extracts of cephalic capsules of generalists contained lower proportions of

aldehydes, and the major compound was 4-methyl-3-heptanone. Indeed, this ketone was the only component detected in extracts from cephalic capsules of gardeners. Because extracts from the mandibular glands of soldiers presented the greatest variety, these results were used to assess differences in the composition of secretions among individuals from different colonies of *A. sexdens sexdens*. Accordingly, Table 3 shows that the proportions of 4-methyl-3-heptanone and geranial were different in the mandibular gland secretions of soldiers from different nests.

Identification of Volatile Components in Secretions from Different Castes of A. opaciceps from the Same Colony. Extracts of mandibular glands and cephalic capsules of different worker castes of *A. opaciceps* from the same nest contained mainly low molecular weight ketones and alcohols (Table 4). Again, extracts from soldiers exhibited the greatest variety, the most important compounds were 2-heptanone followed by 2-heptanol. Only trace amounts of the former were found in extracts of glands from foragers, and none at all in extracts from generalists and gardeners. Thus, 2-heptanol was unique to the extract from soldiers. 4-Methyl-3-heptanone was present in the extracts from all castes and was the major component present in the extract from foragers. Whereas only small amounts of this component could be detected in extracts of generalists and gardeners, no other volatile components appeared to be present.

Evaluation of Alarm Response of A. sexdens sexdens and A. opaciceps to Compounds in Mandibular Gland Secretions. Forager workers of *A. sexdens sexdens* and *A. opaciceps* exhibited different levels of response to various mandibular gland components. Workers from both nests of *A. sexdens sexdens* responded most strongly to 4-methyl-3-heptanone. The response of workers from Nest 1 to citral was as strong as the response to 4-methyl-3-heptanone, whereas workers from Nest 2 responded less strongly to citral. Similarly, workers from Nest 1 exhibited a weak but significant response to geraniol,

whereas the response of Nest 2 workers to geraniol was no different from the response to the hexane control. Workers from both nests showed no response to nerylacetone. Foragers of *A. opaciceps* responded strongly to 4-methyl-3-heptanone, but showed no response to 2-heptanone (Figures 1 and 2).

DISCUSSION

Chemical compositions of secretions of mandibular glands of a number of species of leaf-cutting ants of the genus *Atta* have been previously reported (Blum et al., 1968; Moser et al., 1968; Riley et al., 1974; Do Nascimento et al., 1993; Hernández et al., 1999; Hughes et al., 2001b). Thus, Blum et al. (1968) demonstrated that geranial and neral accounted for ca. 90% of the mandibular gland secretion in *A. sexdens*, and these aldehydes were also shown to be the most abundant components in the mandibular glands of soldiers and foragers of *A. sexdens rubropilosa* (Do Nascimento et al., 1993). However, geranial and neral did not provoke alarm reactions when tested against a number of species of leaf-cutting ants including *A. sexdens* (Blum, 1969). Della Lucia et al. (2001) suggested that these aldehydes might be used in defense because they are present in the mandibular glands of the soldier castes. On the other hand, 4-methyl-3-heptanone, a major component of the mandibular gland secretions of a number of *Atta* species, has been demonstrated to be an alarm pheromone for *A. texana* (Moser et al., 1968), *A. laevigata* (Hernández et al., 1999), *A. bisphaerica*, and *A. capiguara* (Hughes et al., 2001a).

It had been previously reported that the nature of the alarm pheromone can vary among castes of leaf-cutting ants (Hughes et al., 2001b), and this was confirmed in the present study by the demonstration that the proportion of 4-methyl-3-heptanone in the mandibular gland secretions increased as the size of the cephalic capsule decreased. Such results are also consistent with the

hypothesis that gardeners and generalists of leaf-cutting ants are principally responsible for the production and release of alarm pheromone, a proposition arising from the finding of Do Nascimento et al. (1993) that the mandibular gland secretions of gardeners and generalists of *A. sexdens rubropilosa* consisted almost entirely (89.5%) of 4-methyl-3-heptanone. Such views have received further support from Hernández et al. (1999) who demonstrated that this ketone is the major component of the secretions of lower workers of *A. laevigata*.

The present results reveal that in *A. sexdens sexdens* variations occur in the chemical profiles of the mandibular gland secretions derived from the same castes belonging to different colonies: The differences in the amounts of the two major components (4-methyl-3-heptanone and geranial) were particularly significant. Similar results were obtained by Hughes et al. (2001b) who found quantitative differences in the secretions of different colonies of *A. capiguara* and *A. bisphaerica*, although such variations were smaller than the differences observed between the species.

In some species of ants, for example, *Oecophyla longinoda* (Bradshaw et al., 1979) and *Formica lugubris* (Cherix, 1983), qualitative and quantitative variations in the chemical compositions of the alarm pheromones of the mandibular glands have been observed among members of different colonies in the same location. For leaf-cutting ants, some authors (Bonavita-Cougourdan et al., 1987) have suggested that cuticular compounds are responsible for defense and alarm behavior, whereas other researchers (Jaffe, 1979; Salzman and Jaffe, 1991) have shown that such behaviors are associated with the presence in the environment of the odors of recognition released from the cephalic capsules of ants from different colonies. Furthermore, Hernández et al. (2002) compared cuticular extracts with those from mandibular glands and were able to demonstrate that intraspecific recognition was based on odors from the cephalic capsule and that such odors derived primarily from mandibular gland secretions. These findings confirmed a previous report of Hughes et al. (2001b) in which the mandibular glands were described as the producers of the alarm pheromone to which was attributed the function of intracolony recognition. Therefore, the intercolonial differences in the chemical profiles presented herein support the view that such secretions really are involved in intraspecific colony recognition.

The secretion of the mandibular glands of *Atta opaciceps* is a colorless liquid, whereas that from *Atta sexdens sexdens* is yellow in color. Whereas the mandibular secretions of most *Atta* species, including *A. opaciceps*, are relatively similar in composition, those of *A. sexdens sexdens* are different in that the secretions of the majority of worker castes contain large amounts of citral. In contrast, the secretions of *A. opaciceps* consist of alcohols and ketones, typical of those found in other species of leaf-cutting ants (Table 4), although the amounts present appeared to be much reduced. This is probably because these ants are very aggressive when perturbed, and it is likely that a considerable

proportion of the alarm pheromone was liberated during specimen collection. Nevertheless, 4-methyl-3-heptanone was identified in all worker castes, further supporting the view that the ketone is characteristic of the mandibular gland secretion of all species of the genus *Atta* (Blum et al., 1968; Do Nascimento et al., 1993; Hernández et al., 1999; Hughes et al., 2001a,b). The major component of the mandibular gland secretion of *A. opaciceps* soldier castes was 2-heptanone, a compound that has been detected in other species of the subfamily Myrmicinae, including the genus *Atta*, and is considered a common component of alarm pheromones (Hölldobler and Wilson, 1990).

It has been previously reported (Hughes et al., 2001b) that 2-heptanone and 4-methyl-3-heptanone are the main components of the mandibular gland secretions of *A. capiguara* and *A. bisphaerica*, although the proportions of these ketones vary among castes. In the present study, 2-heptanone was not detected at all in gardeners and generalists of *A. opaciceps*; 4-methyl-3-heptanone was the sole compound found in the secretions of these castes. Behavioral bioassays performed in an earlier study involving *A. opaciceps* (unpublished results) indicated a greater stimulation of alarm behavior by minor castes in comparison with major castes. Because chemical analysis of the mandibular gland secretions of the minor castes suggested that 4-methyl-3-heptanone was the major (or perhaps only) component, we suggest that, as is the case for *A. sexdens sexdens*, it is the gardeners and generalists that are responsible for the production and release of the alarm pheromone in *A. opaciceps*.

4-Methyl-3-heptanone elicited strong alarm response in foragers of *A. sexdens sexdens* and *A. opaciceps*. The number of times a single forager exhibited an alarm response to this compound was higher than to any other tested compound. This result agrees with earlier studies carried out with workers of *A. texana*, *A. sexdens*, *A. cephalotes*, *A. capiguara*, and *A. bisphaerica*, which showed 4-methyl-3-heptanone as the alarm pheromone (Blum et al., 1968; Moser et al., 1968; Riley et al., 1974; Knapp, 1995; Pow, 1996; Hughes et al., 2001a). In addition, this alkanone was also found as the major component in mandibular secretions of *A. colombica* and *A. robusta* (Blum et al., 1968). Thus, 4-methyl-3-heptanone seems to be the alarm pheromone of *Atta* and *Pogonomyrmex* species as suggested in the literature (Wilson, 1965; Blum, 1969; Vick et al., 1969; McGurk et al., 1996; Vander Meer and Alonso, 1998).

The role that volatile compounds from the mandibular gland secretions of *A. sexdens sexdens* and *A. opaciceps* play in intraspecific recognition is not known. Further studies need to be conducted to determine what role these compounds may play in nestmate recognition.

Acknowledgments—The authors thank Dr. Jacques H.C. Delabie (CEPLEC/CEPLAC, Itabuna-BA, Brazil) for identification of the leaf-cutting ants, and FAPEAL and CNPq for the provision of grants.

Abstract—The major component of the mandibular gland secretion of queen honeybees (*Apis mellifera* L.), 9-ODA ((2*E*)-9-oxodecenoic acid), has been known for more than 40 yr to function as a long-range sex pheromone, attracting drones at congregation areas and drone flyways. Tests of other mandibular gland components failed to demonstrate attraction. It remained unclear whether these components served any function in mating behavior. We performed dual-choice experiments, using a rotating drone carousel, to test the attractiveness of 9-ODA compared to mixtures of 9-ODA with three other most abundant components in virgin queen mandibular gland secretions: (2*E*)-9-hydroxydecenoic acid (9-HDA), (2*E*)-10-hydroxydecenoic acid (10-HDA), and *p*-hydroxybenzoate (HOB). We found no differences in the number of drones attracted to 9-ODA or the respective mixtures over a distance. However, adding 9-HDA and 10-HDA, or 9-HDA, 10-HDA, and HOB to 9-ODA increased the number of drones making contact with the baited dummy. On the basis of these results, we suggest that at least 9-HDA and 10-HDA are additional components of the sex pheromone blend of *A. mellifera*.

Key Words—Sex pheromone, mating behavior, mandibular gland, honeybee, *Apis mellifera*, (2*E*)-9-oxodecenoic acid, (2*E*)-9-hydroxydecenoic acid, (2*E*)-10-hydroxydecenoic acid.

INTRODUCTION

In insects, the most elaborate chemical communication systems have evolved in the context of mating and social behaviors (Wilson, 1971; Phelan, 1992; Ayasse et al., 2001). In honeybees, these communication systems are closely linked because the virgin queen uses the mandibular gland secretions to attract drones on her mating flights (Gary, 1962; Butler et al., 1967), whereas the mated queen uses mandibular gland secretions to signal her presence to workers in the hive (Velthuis, 1985; Free, 1987; Slessor et al., 1988; Brockmann et al., 1998). The complex and phase-dependent (i.e., virgin vs. mated) chemical compositions of queen mandibular gland secretions (Plettner et al., 1997; Free, 1987) suggest that single components or mixtures of components are addressed differentially to these two receiver groups and may serve different functions in specific behavioral contexts.

In the 1970s, (2*E*)-9-oxodecenoic acid (9-ODA), the major component of the mandibular gland secretions, was shown to attract drones to queen dummies (Butler, 1971; Gary and Marston, 1971; Boch et al., 1975; Free, 1987). Further investigations suggested that other components of the secretion might play a role in the communication between sexes (for a detailed discussion of these experiments, see Free, 1987; Koeniger and Koeniger, 2000). More recent experiments, which tested the attractiveness of the six most abundant mandibular gland components: 9-ODA, (2*E*)-9-hydroxydecenoic acid (9-HDA; 85% (*R*)-(-), 15% (*S*-(+)), (2*E*)-10-hydroxydecenoic acid (10-HDA), *p*-hydroxybenzoate (HOB), and 4-hydroxy-3-methoxyphenylethanol (HVA), demonstrated that 9-ODA—but none of the other components—attracted drones from a distance (Loper et al., 1996). However, the inability of a single component to attract drones does not necessarily exclude a pheromonal function of a particular component as part of a blend (Linn et al., 1986; Christensen, 1997). Thus, it was not clear whether honeybee sex pheromone communication was based on a single substance or a multicomponent blend, and if the latter, which of the other mandibular gland compounds are also sex pheromone components. In contrast, in the communication between queens and workers, it has been shown that a blend of five mandibular gland substances is necessary to elicit worker retinue behavior [9-ODA, 9-HDA (85% (*R*)-(-), 15% (*S*-(+)), HOB, and HVA] (Slessor et al., 1988; Plettner et al., 1996, 1997).

In the experiments reported here, the potential sex pheromonal function of mandibular gland components were assessed in dual choice experiments using a motor-driven drone carousel, by testing attractiveness of 9-ODA vs. different combinations of 9-ODA and minor mandibular gland components.

METHODS AND MATERIALS

Experimental Site. Experiments were conducted in the vicinity of a drone congregation area close to the bee station and apiary of the Beegroup Würzburg

from May to July 2002. The experimental site was identified by presenting queen dummies containing $70.4 \mu\text{g}$ 9-ODA (equals the amount of 9-ODA in virgin queens' glands; Plettner et al., 1997) on the tip of a 3 m long rod at different spots within an area of about 0.3 km^2 between the bee station and the Biocenter of the University of Würzburg, Germany. The drone carousel was placed in an open meadow near a tree line at the edge of an orchard (marked by an "x" in Figure 1). No drones were detectable at the experimental site when no pheromones were presented, but when we offered a pheromone bait, drones

FIG. 1. General map of experimental site. (+) indicates sites at which drones could be attracted; (-) indicates sites at which drones could not be attracted by an artificial pheromone lure attached to a rod (3 m high), containing 1 Qeq of 9-ODA. (x) Position of the drone carousel; (H) position of closest bee hives.

appeared immediately. In some cases, we observed drones coming directly out of the trees lining the field. Thus, we assume that they were either cruising close to or were waiting on the trees. Prior to the experiments, we conducted a dose-response test to determine a pheromone dose that attracted an appropriate number of drones that still could be resolved on videotapes. Despite the use of standardized pheromone doses, drone numbers varied from day to day and between experiments on a single day.

Two-armed Drone Carousel. The drone carousel was a modification of that developed by Renner and Vierling (1977) and further improved by Gries and Koeniger (1996). It was composed of an upright column (adjustable for height from 4 to 6 m) carrying two opposing horizontal aluminum rods (each 2 m in length). The arms could be rotated with an electric motor around the vertical axis with a velocity of 3.1 m/sec at the tips of the arms. The queen dummies were fixed at the distal tips of the arms using a thin nylon thread (10 cm; height of dummies, 4.95 m above ground). A dummy was made of a black aluminum bar (3.5×1.1 cm) with inserted pheromone impregnated glass rods. A video camera was fixed next to the central axis on each arm, facing toward the dummies. Cameras monitored an area of about 1 m² in the plane of a dummy with the dummy in its center.

Pheromone Components and Artificial Blends. 9-ODA, 9-HDA, and 10-HDA were obtained from Phero Tech Inc. (Delta, BC, Canada) and HOB was obtained from Sigma-Aldrich (Taufkirchen, Germany). All compounds were dissolved in absolute ethanol. Test blends were mixed according to published data on the composition of the mandibular secretion in *Apis mellifera* virgin queens (Plettner et al., 1997). The complete artificial virgin queen blend (virgin queen equivalent = $Qe_{q_{\text{virgin}}}$) contained the following: 70.4 μg 9-ODA, 12.6 μg 9-HDA, 76.7 μg 10-HDA, and 0.3 μg HOB. Test blends differed in the number of components. Dose-response tests showed that a dose of 0.1 $Qe_{q_{\text{virgin}}}$ was adequate to attract a sufficient number of drones at our experimental site (see Results). Glass bars (10–12 mm in length) with a small groove in which 10 μl pheromone blends dissolved in ethanol were deposited were used as pheromone dispensers. The solvent was allowed to evaporate for 5 min. Then the glass rods were wrapped in aluminum foil and kept on ice until use. Immediately before the field tests started, the glass rods were fixed to the aluminum dummies.

Two-choice Experiments. On each experimental day, five to nine test runs were conducted with different pairs of pheromone blends in random order, depending on drone abundance. Each test lasted for 15 min, of which the first 5 min were used to attract drones to the carousel and were excluded from the data analysis. Prior to each test run, the video cameras were synchronized to analyze identical periods for both dummies. Altogether, we conducted 86 tests (out of which 63 were included in the analysis, see below) with five different pairs of

pheromone blends: 9-ODA vs. 9-ODA ($N = 11$; control experiment); 9-ODA vs. 9-ODA + 9-HDA ($N = 11$); 9-ODA vs. 9-ODA + 10-HDA ($N = 13$); 9-ODA vs. 9-ODA + 9-HDA + 10-HDA ($N = 13$); and 9-ODA vs. 9-ODA + 9-HDA + 10-HDA + HOB ($N = 15$). The number of drones attracted to each dummy during the 10-min test interval was determined by counting the number of drones every 20 sec, i.e., on 31 video freeze images per test. Because the numbers of drones attracted to the carousel differed strongly among experimental runs (see Figure 3A), we calculated the relative number of drones attracted to each of the two dummies for each test by taking the sum of all drones that were counted on the 62 images from both sides per test as 100%. Only test runs that attracted at least 10 drones to the carousel were included in the analysis. The numbers of drone contacts with the dummies were determined by counting all contacts during each 10-min test interval. Only intense and unambiguous contacts with the dummy, i.e., clinging to the dummy in a clear mounting attempt, were counted. Again, to allow comparisons between tests despite the variation in absolute numbers of drones present in the vicinity of the carousel, we calculated the relative number of contacts to each of the two dummies for each test run. Only test runs in which at least five contacts were scored were included in the final analysis. To test for significant differences of drone numbers or numbers of contacts between the two arms, we applied the Wilcoxon signed-rank test for each of the five pairs of pheromone combina-

FIG. 2. Effect of different concentrations of synthetic queen pheromone on the attraction of drones to the carousel. One virgin queen equivalent contained 70.4 μg 9-ODA, 12.6 μg 9-HDA, 76.7 μg 10-HDA, and 0.3 μg HOB. Treatments were presented on a dummy at one arm of the carousel. Box and whisker plot indicates median (black dot), first and third quartile (box) and maximum number (whisker) of drones attracted to the dummy per 10-min experimental run.

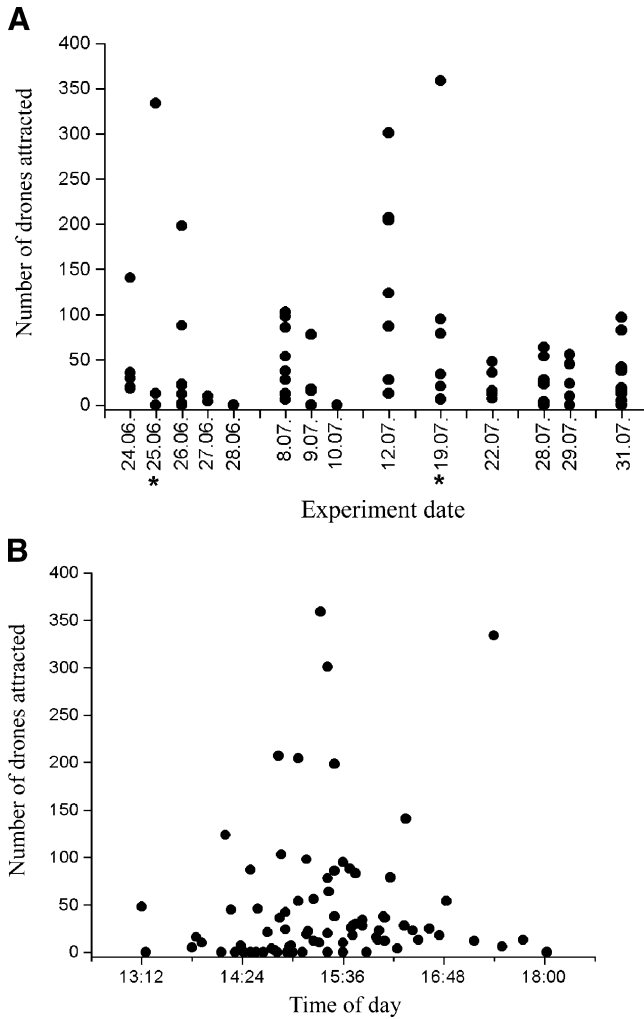

FIG. 3. (A) Number of drones attracted on different days. Each dot indicates number of drones per 10-min experimental run (median = 23, first quartile = 7.3, third quartile = 56, minimum = 0, maximum = 1248). During two experimental runs, a large number of drones were attracted: 528 drones (*) on June 25, and 1248 drones (*) on July 19. These two data points were omitted from both figures. (B) Effect of time of day on the attraction of drones. Dots indicate the number of drones attracted per run for all experimental replicates.

FIG. 4. (A) Proportion of drones attracted (\pm SD) to the vicinity of the treatment and control lures. (B) Proportion of drone contacts with the treated and control dummies. White bars, 9-ODA only; black bars, test blends. *Significant differences between 9-ODA and the blend ($P < 0.05$).

tions. All data were arcsine-transformed prior to analysis. P values exceeding 0.05 were considered as not statistically significant.

RESULTS

Attraction of drones to a synthetic pheromone lure was locally restricted to an area of ~ 100 m in diameter (Figure 1). The distance to the closest honeybee colonies was about 150 to 300 m. The number of drones attracted to the drone carousel was pheromone dose dependent (Figure 2), demonstrating that drones were attracted to treated dummies by olfactory, rather than visual, cues. Numbers of drones attracted to the carousel were stable during each test run but varied among test runs and among test days (Figure 3A,B).

To ensure that there was no bias between the two dummies, we first treated both lures with identical doses of 9-ODA, which resulted in equal numbers of drones being attracted to both dummies (Figure 4A). In subsequent trials, 9-ODA as a single substance was as attractive as any other combination of 9-ODA and minor components (Figure 4A).

We also found no evidence for any asymmetry in drone contacts when equal amounts of 9-ODA were presented on both arms (Figure 4B). Adding 10-HDA or 9-HDA to 9-ODA did not increase the number of contacts compared to 9-ODA alone. However, blends that were more similar to the natural pheromone composition (9-ODA + 9-HDA + 10-HDA or 9-ODA + 9-HDA + 10-HDA + HOB) resulted in significantly higher numbers of contacts with the queen dummy containing the blend compared to the dummy with 9-ODA alone ($Z = -2.81$, $P = 0.005$, and $Z = -2.85$, $P = 0.004$, respectively; Figure 4B).

DISCUSSION

Mating behavior in honeybees is highly competitive between drones, much more than in most other insects. In all honeybee species, drones and virgin queens leave their colonies for mating flights at species-specific times of the day. In our experiments, drones were present at the drone congregation area between 1:00 and 6:00 P.M., with a peak time around 3:30 P.M. Drones gather at the drone congregation areas (estimated sizes range from 50 to 200 m in diameter), waiting for virgin queens to appear (Ruttner, 1985). Upon detection of the queen's sex pheromone, drones initiate their visually driven chasing behavior, all competing for the queen and only a few being successful. To catch a queen, the drones must be fast and precise in detecting and chasing. Although detailed analysis of honeybee mating behavior is still lacking, one may assume that the

chasing behavior of drones is based on a succession of different behavioral steps including detection of the pheromone, searching the sky for small dark flying objects, a rapid pursuit of the queen (Gries and Koeniger, 1996), and finally successful grasping and mounting of the queen.

Our experiment to determine the location of a drone congregation area showed that the effective range of the pheromone was limited to a circular area with a diameter of ~100 m. We assume that the location of this drone congregation area is stable over the years, because of previous reports that one could attract drones with pheromone lures in that area (J. Tautz, pers. comm.). The closest beehives (marked by an “H” in Figure 1) were located about 150–300 m north, with entrances facing south in the direction of the drone congregation area. The most obvious visual feature of the site is the boundary of the orchard and the open meadow, and this may be one of the constitutive visual cues. If drones from the specified colonies join this drone congregation area, the boundary between the orchard and the meadow might function as a visual “stop and stay” stimulus; however, this remains to be investigated.

Our drone carousel experiments demonstrated that in addition to 9-ODA (the so-called queen substance), other components of the queen mandibular gland secretion, particularly 9-HDA and 10-HDA, play a role in pheromone communication between queens and drones. The latter two compounds are not attractive to drones from a distance (Loper et al., 1996), but added to 9-ODA they increased the drone’s contacts with a queen dummy. Whether HOB also mediate drone behavior cannot be inferred from our experiments. The effect of 9-HDA and 10-HDA on the frequency of mounting suggests that 9-HDA and 10-HDA only act over a short range. However, we can not exclude the possibility that these compounds are active at long range (tens to hundreds of meters), because our experimental set-up did not specifically test for those distances. A similar increase in the frequency of mounting behavior in drone carousel experiments was also found when tergite gland extracts were added to 9-ODA (Renner and Vierling, 1977). The conclusion from both experiments is that adding either 9-HDA and 10-HDA or tergite gland secretions to 9-ODA increases the effectiveness of the artificial stimulus, leading to a stronger response and a more complete performance of the mating behavior sequence. Whether the components of the mandibular gland and the tergite gland have distinct functions in the sequence of the mating behavior remains unknown.

It is intriguing to compare our findings on sex pheromone communication with those on queen–worker communication. Slessor et al. (1988) and Keeling et al. (2003) showed that a blend of 9-ODA, 9-HDA, HOB, and HVA similar to that found in mated queens elicited worker retinue behavior. 10-HDA, which is reduced in quantity in mated compared to virgin queen glands, does not play any role in queen–worker communication (Slessor et al., 1988). In contrast to

those experiments, we found clear evidence that 10-HDA, which is produced in large amounts by virgin queens, does have a pheromone function in mating behavior. Taken together, the data suggest that *A. mellifera* queens produce different signals during their adult life stages in relation to different communication contexts. As virgin queens they produce a signal to attract drones on mating flights, and as mated queens they produce a signal for the workers. The signals are produced by the same gland and comprise almost identical substances, but the relative composition changes between virgin and mated queens. This change in mandibular gland composition may be induced by successful mating.

9-ODA is viewed as the major long-distance sex attractant for all honeybee species (Butler et al., 1967; Ruttner and Kaissling, 1968; Shearer et al., 1970; Sanasi et al., 1971; Koeniger and Koeniger, 2000), and it is the main component in the queen mandibular glands of all species except *A. florea* (Plettner et al., 1997), in which 10-HDA is the most abundant mandibular gland component. Our finding that the two other most abundant decenoic acids also have a pheromonal function in *A. mellifera* suggests that they might have sex pheromone functions in other honeybee species as well (Brockmann and Brückner, 2005). Thus, it is likely that 10-HDA is a sex pheromone component for *A. florea*, and it might even be the major functional pheromone component, replacing 9-ODA in this species. In addition, differences in the relative composition of mandibular gland components might be effective in reproductive isolation between sympatric species. GC analyses show that the relative composition of mandibular gland components varies among different *Apis* species (Plettner et al., 1997). Whether drones use these relative differences to discriminate between queens of their own and sympatric species remains to be determined.

Acknowledgments—We thank G. Eisenmann and N. Schneider, who built the drone carousel, and K. Galmbacher and P. Bernbauer, who helped with data collection. J.S. and A.B. were supported by the German Research Foundation DFG (SFB554 and Graduiertenkolleg 200).

Published Online April 26, 2006

Abstract—This study describes the identification of a sex pheromone component of a cossid moth, *Cossus insularis*. Coupled gas chromatographic–electroantennographic detection (GC–EAD) analysis of solid-phase micro-extraction (SPME) collections of volatiles released by live female moths showed that two compounds elicited EAG responses from the antennae of male moths. These compounds were identified as (*E*)-3-tetradecenyl acetate (*E*3-14:Ac) and (*Z*)-3-tetradecenyl acetate (*Z*3-14:Ac) by mass spectral analysis and retention index comparisons with synthetic standards. The ratio of *E*3-14:Ac and *Z*3-14:Ac was 95:5 in the effluvia of a female. In field bioassays, sticky traps baited with blends of *E*3-14:Ac and *Z*3-14:Ac showed that *E*3-14:Ac is an essential component of the pheromone. However, the role of *Z*3-14:Ac is unclear, because *E*3-14:Ac as a single component was as attractive to male moths as blends of *E*3-14:Ac and *Z*3-14:Ac, including the 95:5 blend released by live female moths.

Key Words—Carpenterworm moth, *Cossus insularis*, (*E*)-3-tetradecenyl acetate, (*Z*)-3-tetradecenyl acetate, GC–EAD, SPME, sex pheromone.

INTRODUCTION

The carpenterworm moth, *Cossus insularis* (Staudinger) (Lepidoptera: Cossidae) is found in Honshu, Kyushu, and Tsushima Islands of Japan (Tadauchi and Inoue, 2000). Although host plants of this species are not well known, Kitajima et al. (1998) reported an aggregation of 236 larvae from a 3.2-cm-diameter branch of a willow tree. Recently, Nakanishi (2005) reported the first incidence of *C. insularis* larvae in Japanese pear, *Pyrus pyrifolia* var. *culta*. On both host trees, aggregations of larvae were observed to bore into woody stems, causing significant damage and frequent mortality. Because burrows are not exposed, insecticides are not a practical measure for control. Isolation and identification of the sex pheromone of *C. insularis* would be useful to help monitor and possibly control populations of this species.

In the Family Cossidae, sex pheromones for *Cossus cossus* L. (Capizzi et al., 1983), *Holcocerus hippophaecolus* Hua (Fang et al., 2005), *Holcocerus insularis* (Zhang et al., 2001), *Prionoxystus robinae* Peck (Solomon et al., 1978), and *Zeuzera pyrina* L. (Tonini et al., 1986) have been identified, and sex attractants for three other species, *Acossus centerensis* Lintner (Doolittle et al., 1976), *Cossus mongolicus* Erschoff (Qi et al., 1985), and *Prionoxystus piger* Grote (Landolt et al., 1985) have been reported. Most of the attractive components for these cossid moths are mono- or diunsaturated 10-, 12-, 14-, or 18-carbon alkenyl acetates. The aim of the present study was to isolate and identify the sex pheromone of *C. insularis*.

METHODS AND MATERIALS

Insects. Late instar larvae and pupae of *C. insularis* were collected from heavily infested logs of willow trees at the Forestry and Forest Products Research Institute, Tsukuba, Japan, in March 2004. Field-collected larvae were reared individually on artificial diet (Insecta LF[®], Nihon Nosan, Yokohama, Japan) under 14L:10D at 25 ± 1°C. Newly emerged female and male moths were used for solid-phase microextraction (SPME) collection of volatiles and coupled gas chromatographic–electroantennographic detection (GC–EAD) analyses, respectively.

Collection of Volatiles from Female Moths. We used SPME for collecting airborne volatiles emitted by the female moths. SPME fibers (100 µm polydimethylsiloxane, Supelco, Bellefonte, PA, USA) were preconditioned for 30 min at 250°C. Newly emerged females were isolated in a 100-ml glass bottle (Sibata, Tokyo, Japan) with a screw cap lined with an acrylic nitril butadiene rubber/Teflon septum (45 mm diameter) with a hole (26 mm ID). Two SPME fibers were inserted into each bottle through a small hole in the septum. The

fibers were exposed to the moths for approximately 16 hr, from 1700 hr until 0900 hr next morning, at $25 \pm 1^\circ\text{C}$. The loaded SPME fiber was then desorbed into the injection port of either a GC–EAD or a GC–MS system. The bottles for volatile collection were ultrasonicated in a detergent solution for 10 min, rinsed, and dried at 100°C before use.

To evaluate the SPME sampling method, we placed 1 mg each of (*E*)-3-tetradecenyl acetate (*E*3-14:Ac) and (*Z*)-3-tetradecenyl acetate (*Z*3-14:Ac) in 100 μl *n*-hexane solution on the bottom surface of a 100-ml glass bottle. An SPME fiber was inserted into the bottle after the *n*-hexane evaporated and kept for one night at $25 \pm 1^\circ\text{C}$. Ten different SPME fibers were used to collect volatiles from the headspace of the bottle and were then desorbed in the injection port of a GC.

Coupled Gas Chromatographic-Electroantennographic Detection (GC–EAD) Analysis. Volatiles collected on the SPME fiber were analyzed by GC–EAD in splitless mode with a Hewlett-Packard 5890 series II GC equipped with a DB-23 column (30 m \times 0.32 mm ID, 0.25 μm film thickness, J & W Scientific, Folsom, CA, USA). Oven temperature was $45^\circ\text{C}/1$ min, $15^\circ\text{C}/\text{min}$ to 150°C , $2^\circ\text{C}/\text{min}$ to 180°C , and then $10^\circ\text{C}/\text{min}$ to 230°C , where it was held for 20 min.

Although the GC effluent splitter followed the general design of Struble and Arn (1984), some parts were replaced with those made from inactivated material. To achieve proper elution of the sample to the flame ionization detector (FID) and the EAD, nitrogen makeup gas (30 ml/min) was introduced into the stainless T-union, in which the end of the analytical capillary column (0.32 mm ID) was inserted into a deactivated fused-silica capillary column (0.53 mm ID, Agilent Technologies, Wilmington, DE, USA). The effluent was split between the FID and the EAD with a press-fit Y splitter (Agilent Technologies). Deactivated fused-silica capillary columns (0.53 mm ID, Agilent Technologies) were also used as transfer lines from the Y splitter to each detector. The GC effluent for EAD emptied into a glass transfer tube (15 mm ID) mounted on the GC and was mixed with humidified air (300 ml/min, 20°C) passing through the tube.

An excised antenna was placed on the antenna holder of an EAG probe (Syntech, Hilversum, the Netherlands). The antenna was connected with the recording and indifferent electrode with electrode gel (Spectra[®] 360, Parker Lab. Inc., Orange, NJ, USA). EAG and FID signals were fed into a computer through an analog-to-digital conversion board (IDAC-232, Syntech). Signal reception and analysis was performed with GC–EAD software (Syntech).

Preparative Gas Chromatography. An HP 5890 Series II gas chromatograph modified for GC–EAD as described above was converted to a preparative GC by exchanging a press-fit Y splitter with a press-fit column connector (Agilent Technologies). The GC–EAD active compounds were trapped in a

glass capillary (5.5 mm ID, 107 mm long) placed on the column outlet after removing the collector nut, an igniter castle, a collector, and collector insulators from the FID port of the GC. The glass capillary was eluted with *n*-hexane, and the eluate was stored at -5°C until analysis. The same column and temperature program as the GC-EAD system was used to trap the compounds of interest except that nitrogen makeup gas flow was adjusted to 15 ml/min.

Chemical Analysis. Samples collected by SPME were analyzed with an Agilent 6890N GC interfaced to an Agilent 5973 mass-selective detector run in electron impact ionization mode at 70 eV. The GC-MS was equipped with a DB-23 column (30 m \times 0.25 mm ID, 0.25 μm film thickness, J & W Scientific), using a temperature program of $120^{\circ}\text{C}/1$ min, $5^{\circ}\text{C}/\text{min}$ to 200°C , and held for 10 min. Helium was used as carrier gas (1 ml/min).

Double bond positions and geometries in unsaturated compounds were determined from dimethyldisulfide (DMDS) adducts of the insect-produced compounds (Buser et al., 1983). Fifty microliters of DMDS and 5 μl of iodine solution (60 mg I_2 in 1 ml diethyl ether) were added to 50 μl of *n*-hexane solution containing EAD-active compounds from female volatiles collected by preparative GC. The mixture was stored at 60°C for 24 hr, and then quenched with 200 μl of 5% $\text{Na}_2\text{S}_2\text{O}_3$ solution in distilled water, and the mixture was extracted with 100 μl *n*-hexane. EI-MS spectra of the derivatives were obtained with the same GC-MS system described above equipped with an HP-5MS capillary column (30 m \times 0.25 mm ID, 0.25 μm film thickness, J & W Scientific), using a temperature program of $100^{\circ}\text{C}/5$ min, $5^{\circ}\text{C}/\text{min}$ to 280°C .

Geometry of the double bond in each monounsaturated compound was determined by comparing the GC retention time (Rt) of DMDS adducts of a compound eliciting an antennal response with those of synthetic standards using the same HP-5MS column described above.

Chemicals. Samples of *E*3-14:Ac (purity > 95%) and *Z*3-14:Ac (purity > 95%) were kindly provided by Prof. Chul-Sa Kim of Kochi University, Japan, and Dr. Huang Yongping of Shanghai Institute of Plant Physiology and Ecology, China, respectively.

For field trapping we synthesized Δ 3-14:Ac from Δ 3-tetradecen-1-ol (Δ 3-14:OH). Thus, the Grignard reagent from 1-dodecyne (Tokyo Kasei Kogyo Co., Ltd., Tokyo) was reacted with ethylene oxide in dry tetrahydrofuran. The product (3-tetradecyn-1-ol) was reduced to Δ 3-14:OH by hydrogenation over Lindlar's catalyst. The *E/Z* ratio of synthesized Δ 3-14:OH was 2:98. To enrich the *E* isomer, isolated Δ 3-14:OH was isomerized by stirring for 3 hr at 80 – 90°C after mixing with 2% (w/w) of nitric acid as a catalyst (Terauchi et al., 2002), which was then acetylated with acetic anhydride by standard techniques. Crude *E*3-14:Ac of 76% isomeric purity was purified by a urea adduct method (Fukumoto et al., 1999). Thus, the crude *E*3-14:Ac was poured into a saturated methyl alcohol solution of urea at 50 – 60°C and stirred for 5 min. To precipitate

the urea adduct, the solution was cooled to room temperature over 2 hr and further to 10°C by immersion in an ice-water bath. The free acetate was removed by extraction of the cooled methyl alcohol solution with *n*-hexane. After removal of the *n*-hexane layer, precipitated *E* isomer-rich urea adduct was dissolved by warming the methyl alcohol to 50–60°C. Two cycles of *Z* isomer-rich free acetate removal from the urea adduct solution gave *E*3-14:Ac of > 99.9% isomeric purity.

To obtain *Z*3-14:Ac, Δ 3-14:OH synthesized as above was acetylated and purified by the urea adduct method (Fukumoto et al., 1999), resulting in *Z*3-14:Ac of > 99.9% isomeric purity.

Field Trapping. Delta traps with removable sticky bottoms (SE trap[®], Sankei Chemical Co. Ltd., Tokyo, Japan) were baited with synthetic *E*3-14:Ac and *Z*3-14:Ac (1 mg in total) mixed in a series of different ratios (Table 1). The pheromone components were impregnated in gray halobutyl isoprene blend elastomer septa (West Co., Singapore). Three replicates of the trap treatments were placed in a randomized block design in a pear orchard in Tokushima, Japan, from June 7 to August 10, 2004. Traps were hung from tree branches at a height of about 2 m. Traps were inspected at 3- to 6-d intervals and shifted at each inspection to reduce positional effects. Sticky panels within the traps were replaced when they became saturated with captured moths.

Statistics. Data from field tests were analyzed using JMP (SAS Institute, Cary, NC, USA). The analyzed variable was the trap catch after $\sqrt{(X + 0.5)}$ transformation followed by ANOVA. Significantly different means were separated by Tukey–Kramer’s HSD test.

TABLE 1. MEAN AND TOTAL CATCHES OF *C. insularis* IN TRAPS BAITED WITH MIXTURES OF (*E*)-3-TETRADECENYL ACETATE AND (*Z*)-3-TETRADECENYL ACETATE

Blend tested % (<i>E</i> 3: <i>Z</i> 3)	Average catch/trap (mean \pm SE)	Total number of moths captured
100:0	173.0 \pm 21.4a	519
95:5	113.7 \pm 28.3a	335
80:20	124.3 \pm 20.7a	370
60:40	145.7 \pm 23.1a	429
20:80	74.3 \pm 6.8b	223
0:100	10.3 \pm 4.5c	31
Control	0	0

Means followed by the same letter are not significantly different ($P = 0.05$, Tukey–Kramer’s HSD test). Control was omitted from ANOVA to avoid heterogeneity among variances (Levene test).

RESULTS

Injections of SPME-collected volatiles released by an unmated female of *C. insularis* into the DB-23 column gave two consistent EAD responses with retention times of 13.72 (peak I) and 13.89 (peak II) min, respectively (Figure 1a). Although some EAD responses different from those to peak I and II were observed (Figure 1a), they were not consistent, suggesting that they were artifacts and, therefore, not subjected to further analysis.

Although it did not show a molecular ion, the EI-MS spectrum for GC peak I (Figure 2) showed m/z 61 ($\text{CH}_3\text{COOH}_2^+$), a diagnostic fragment ion for an acetate ester, and a characteristic fragment ion at m/z 194 ($\text{M}^+ - 60$). This suggested that the compound was a 14-carbon monounsaturated acetate.

FIG. 1. Coupled GC-EAD responses from an antenna of a male *C. insularis* to female volatiles collected by SPME from an unmated female moth (a) and to synthetic *E3-14:Ac* and *Z3-14:Ac* (b).

FIG. 2. Mass spectrum of peak I in Figure 1a.

The mass spectrum of the DMDS adduct of GC peak I showed diagnostic fragments at m/z 87 ($\text{CH}_3\text{COOC}_2\text{H}_4^+$, 31%), 147 ($\text{CH}_3\text{COOC}_2\text{H}_4\text{CH}=\text{SCH}_3^+$, 3%), 201 ($\text{H}_3\text{CS}^+=\text{CH}-\text{C}_{10}\text{H}_{21}$, 100%), and 348 (M^+ , 11%), demonstrating that the peak I was a $\Delta 3$ -14:Ac isomer.

Retention times of the DMDS adducts of GC peak I and peak II on the HP-5MS column were 34.39 and 34.29 min, respectively, which were the same as those of the DMDS adducts of the synthetic *E*3-14:Ac (34.38 min) and *Z*3-14:Ac (34.29 min). The GC retention times of the synthetic *E*3-14:Ac and *Z*3-14:Ac on a DB-23 column matched those of peak I and II compounds from female moths. Each of the synthetic compounds elicited as strong an EAG response as elicited by the natural compounds (Figure 1b).

The mixture ratio of the *E* and *Z* isomers of $\Delta 3$ -14:Ac was estimated from the area of each peak obtained from the GC analysis of SPME-collected samples. The *E*:*Z* ratio was $95 \pm 0.9\%$ to $5 \pm 0.9\%$ ($N = 12$), indicating that individual variation in pheromone ratio among females was low. GC analysis of the samples collected by SPME from a 1:1 mixture of synthetic *E*3-14:Ac and *Z*3-14:Ac gave an *E*/*Z* ratio of $48.5 \pm 2.0\%$ *E* and $51.5 \pm 2.4\%$ *Z* isomer, which was not different from 1:1 ($P > 0.05$, Binomial test, $N = 10$). This demonstrated that the ratio of $\Delta 3$ -14:Ac isomers collected by SPME reflected the actual ratio released by the female moths.

Traps baited with lures of *E3-14:Ac* and *Z3-14:Ac* mixed in different ratios captured 1907 male moths from June 7 to August 10. All the lures tested attracted *C. insularis* (Table 1). Numbers of males attracted to the 100:0 to 60:40 blends of *E3-14:Ac* and *Z3-14:Ac* were equivalent (Table 1), whereas the 20:80 and 0:100 blends of *E3-14:Ac* and *Z3-14:Ac* attracted fewer males. No moths were captured in control traps.

DISCUSSION

Our data indicate that *E3-14:Ac* is the main and possibly only component of the sex pheromone of *C. insularis*. Although the *Z* isomer itself was weakly attractive (Table 1), it does not appear to be a critical component of the pheromone because 100% *E3-14:Ac* was as attractive as the 95:5 naturally produced ratio. Alcohols, aldehydes, or acetates of 14-carbon compounds are known sex pheromones and attractants for many lepidopteran species (Mayer and McLaughlin, 1991). However, 14-carbon compounds with the double bond in position 3 are rare. *E3-14:Ac* has been identified only from *Symmetrischema tangolias* (Gelechiidae) (Griepink et al., 1995) and *H. hippophaecolus* (Cossidae) (Fang et al., 2005) as a sex pheromone component, and also has been reported as a sex attractant for two gelechiid moths (Priesner, 1987; Tóth and Doolittle, 1992) and a cossid moth (Doolittle and Solomon, 1986). *Z3-14:Ac* has been identified only from two cossid moths, *H. insularis* (Zhang et al., 2001) and *H. hippophaecolus* (Fang et al., 2005), and has been reported as a sex attractant for several gelechiid species (Priesner, 1987; Willemse et al., 1987).

A cossid moth, *H. insularis* Staudinger, occurs in China where the larvae inflict serious damage to broad-leaved trees (Wang and Zhang, 1993). The genus *Holcocerus* was established as a subgenus of *Cossus* Fabricius, 1793 (Fletcher and Nye, 1982). However, Inoue (1987) considered it doubtful whether to separate *Holcocerus* Staudinger, 1884 from *Cossus* Fabricius, 1793 as a different genus. He did not conclude that *H. insularis* was a synonym of *C. insularis* because he had not checked the type species, *Cossus nobilis* Staudinger, 1884. Because the male genital structures of *C. insularis* from Japan and *H. insularis* from China are nearly identical (Yoshimatsu, personal communication), these moths are probably the same species, but this remains to be conclusively demonstrated. At the present time, therefore, we take the position that *C. insularis* and *H. insularis* are different species, meaning that the sex pheromone of *C. insularis* has been identified for the first time in the present study.

Furthermore, the sex pheromone identified from *H. insularis* was a 51:39:10 blend of *Z3-14:Ac*, (*E*)-3-tetradecen-1-ol, and (*Z*)-3-tetradecen-1-ol, but *E3-*

14:Ac, the main pheromone component of *C. insularis*, was not positively identified (Zhang et al., 2001). *E*3-14:Ac has been identified as a sex pheromone component from another cossid moth, *H. hippophaecolus*, but it attracted male moths only when it was combined with (*Z*)-7-tetradecenyl acetate in a 1:1 ratio (Fang et al., 2005). Thus, our study is the first to demonstrate *E*3-14:Ac as an attractive pheromone component by itself. The Δ 3-14:Ac motif has appeared in several closely related species in *Cossus* and *Holcocerus*, but the role of the isomers differed between species, as described above. It will be intriguing to study sex pheromones in other *Cossus* or *Holcocerus* species to understand the phylogenetic relationships among these genera.

Because the larvae of many forest insect species, especially wood borers, have long life cycles and low emergence rates even when reared on artificial diet (e.g., Ohya and Ogura, 1993), it is not easy to obtain sufficient numbers of adults for pheromone research. *C. insularis* takes about 6 months to complete its life cycle when reared on artificial diet, and the survival rate is not high (Chen, unpublished), resulting in a limited number of adult moths emerging. Thus, conventional extraction methods used with other lepidopteran species were not practical. In the present study, female sex pheromone components could be collected repeatedly from the same individual by SPME, demonstrating the value of SPME for collecting volatiles repeatedly from organisms that are available only in limited quantities.

Agelopoulos and Pickett (1998) mentioned that the ratio of compounds such as pentan-3-ol, 4-penten-1-ol, hexan-1-ol, 6-methyl-5-hepten-2-one, hexyl acetate, and limonene in samples collected by SPME can deviate markedly from samples collected by syringe or porous polymers, and that for estimation of proportions, SPME should be used in conjunction with another sampling method. However, the results presented here from the live females and the standard synthetic compounds show that SPME sampling can be used in the determination of the relative mixture ratios of geometric isomers because the vapor pressures of the isomers and their absorption to polydimethylsiloxane do not differ.

Three species of *Cossus* (*C. cossus orientalis*, *C. ezoensis*, and *C. insularis*) occur in Japan (Tadauchi and Inoue). The larvae of these species feed on broad-leaved trees including poplar and willows. However, the previous reports on the genus *Cossus* in Japan may have confused these three species because of a poor understanding of their life histories, distributions, and host plants (Enda, 1994). It is now possible to document the distribution, phenology, and abundance of *C. insularis* using the sex pheromone identified in the present study.

Acknowledgments—We thank Dr. Shin-ichi Yoshimatsu of the National Institute of Agro-Environmental Sciences, Tsukuba, Japan, for identification of *C. insularis* and Dr. Zhang Zhen of the Chinese Academy of Forestry, Beijing, China, for specimens of *H. insularis*. We also thank

Dr. Joseph Patt of USDA-ARS for his review of the manuscript and two anonymous reviewers for invaluable comments. One of the authors (X. C.) is grateful to the former Science and Technology Agency (current Ministry of Education, Culture, Sports, Science, and Technology) of Japan for financial support.

Abstract—The aggregation pheromone of *Riptortus clavatus* (Heteroptera: Alydidae) consists of (*E*)-2-hexenyl (*Z*)-3-hexenoate (E2HZ3H), (*E*)-2-hexenyl (*E*)-2-hexenoate (E2HE2H), and myristyl isobutyrate (MI). Experiments were conducted to examine the attraction of *Piezodorus hybneri* (Heteroptera: Pentatomidae) to the pheromone components of *R. clavatus*, individually and in combination, and to determine if *P. hybneri* produces these compounds. Electroantennogram (EAG) responses of *P. hybneri* to E2HE2H were significant in a dose dependent manner, while those to E2HZ3H were not significantly different from those to hexane and air. Field trapping tests using E2HZ3H, E2HE2H, and MI, individually or in combination, showed that only E2HE2H was attractive to *P. hybneri*. E2HE2H was not detected in whole-body extracts or volatile collections from either sex of *P. hybneri* adults. We propose that the response of *P. hybneri* adults to the *R. clavatus* aggregation pheromone may be related to finding suitable host plants.

Key Words—Pentatomidae, Alydidae, bean bug, (*E*)-2-hexenyl (*Z*)-3-hexenoate, (*E*)-2-hexenyl (*E*)-2-hexenoate, myristyl isobutyrate, aggregation pheromone, soybean.

INTRODUCTION

A number of stink bug species are important pests of soybean, sweet persimmon, citrus, grapevine, and rice production in Korea. *Riptortus clavatus* (Thunberg) (Heteroptera: Alydidae) and *Piezodorus hybneri* (Gmelin) (Heteroptera: Pentatomidae) are the most important pests of soybean in Korea (Son et al., 2000), while *P. hybneri* is a key pest in Japan (Higuchi, 1999; Osakabe and Honda, 2002; Endo et al., 2003) and Australia (Brier, 1993).

Adult *R. clavatus* males release a pheromone consisting of (*E*)-2-hexenyl (*Z*)-3-hexenoate (E2HZ3H), (*E*)-2-hexenyl (*E*)-2-hexenoate (E2HE2H), and myristyl isobutyrate (MI) in a ratio of 1:5:1 (Leal et al., 1995). This blend attracts conspecific nymphs and adults of both sexes, as well as the egg parasitoid, *Ooencyrtus nezarae* Ishii (Numata et al., 1990; Leal et al., 1995; Mizutani et al., 1997, 1999; Masuta et al., 2001; Huh and Park, 2005).

We caught a large number of *P. hybneri* in traps when evaluating the response of *R. clavatus* to different blends of its synthetic aggregation pheromone components in the field. Endo et al. (2003) reported similar findings in Japan and suggested that E2HE2H was responsible for the attraction. Higuchi (1999) observed that live *P. hybneri* males attracted both males and females, suggesting the presence of an aggregation pheromone based on the attraction. However, the male produced pheromone in *P. hybneri* is a sex pheromone consisting of β -sesquiphellandrene, (*R*)-15-hexadecanolide, and methyl 8-(*Z*)-hexadecenoate (ratio: 10:4:1) (Leal et al., 1998). Therefore, we conducted detailed experiments to gain insights into this intriguing phenomenon of cross attraction by examining the response of *P. hybneri* to the three components of the *R. clavatus* pheromone, individually and in combination, as well as determining if *P. hybneri* actually produces them.

METHODS AND MATERIALS

Insects Used for GC Analyses and EAG Recordings. A colony of *P. hybneri* was started from individuals captured in traps baited with aggregation pheromone of *R. clavatus* in soybean fields in Sacheon, Korea in the autumn of 2002. The colony was maintained at $25 \pm 2^\circ\text{C}$, $50 \sim 70 \pm 10\%$ R.H., under a 16:8 L-D photoperiod. Insects were regularly provided with fresh water, soybeans, and peanuts.

Syntheses of Pheromone Components. E2HZ3H and E2HE2H were easily prepared from commercially available (*Z*)-3-hexenoic acid and (*E*)-2-hexenoic acid, respectively. They were chlorinated with oxalyl chloride, then esterified with (*E*)-2-hexenol to give 75% and 96% overall yield, respectively. The MI

was obtained through esterification of isobutyryl chloride with myristol with 80% yield. The reactions were carried out in oven-dried glassware under nitrogen and anhydrous solvents. ^1H and ^{13}C -NMR experiments were conducted on Bruker AW-500 spectrometer. HREIMS was obtained on a JEOLJMS-700 mass spectrometer. IR spectral data were obtained on Bruker IFS66 spectrometer. Gas chromatography (GC) analysis was performed on a GC-14A (Shimadzu, Japan) using a Supelco wax 10 column (60 m \times 0.32 mm; 0.25 μm). The oven temperature was programmed at 80°C for 5 min, increased to 120°C at a rate of 20°C/min, held at this temperature for 30 min, increased to 260°C at a rate of 4°C/min, held for 50 min. Details of NMR, IR, and HREIMS spectroscopic assignments for the three compounds are described in a previous paper (Huh et al., 2005).

Preparation of Pheromone Lures. The synthetic pheromone components were diluted in hexane (97%, Merck, Germany) at the required ratios for each experiment. Rubber septa (13 mm O.D., Sigma-Aldrich, Germany) were filled with 2 mg of the test solutions, placed in a fume hood for around 3 hr for absorption of the chemical(s) and evaporation of hexane, then packed in polyethylene lined foil pouchs (6.5 \times 10 cm, Green Agro-Tech, Korea), and stored at 4°C until used. Rubber septa impregnated with hexane only served as controls.

Field Bioassays. Two field experiments were carried out in 3 ha of soybean field in Sacheon city, Korea. Traps (17 cm O.D., 33 cm long), similar to gee minnow trap (BioQuip, USA) with netted funnel inlets at both sides, were mounted on poles 1 m above ground, and set 12 m apart. Three traps were employed in each treatment.

*Effect of MI on Attractiveness of *P. hybneri*.* This trial was done from September 7 to October 4, 2002, testing MI alone at 1, 10, 50, and 100 mg per septum or together with E2HZ3H and E2HE2H (at 7 and 36 mg, respectively) at 0.1, 1, 7, and 50 mg. The ratio of E2HZ3H and E2HE2H (1:5) was based on the results of Leal et al. (1995). This experiment was repeated 7 times and the number of *P. hybneri* captured were counted and sexed every three days. At the same time, the placement of traps was interchanged randomly.

*Attractiveness of E2HZ3H and E2HE2H to *P. hybneri* Adults.* The attractiveness of E2HZ3H + E2HE2H (mg) at ratios of 10 + 0, 0 + 50, and 10 + 50 were tested from August 2 to August 29, while 10 + 0, 0 + 50, and 50 + 50 mixtures were tested from August 30 to September 19, 2004. Hexane and ten live males of *R. clavatus* were used as blank and positive control, respectively. Trials were repeated 4 and 3 times, respectively, with counts and trap rotation being carried out once a week.

*EAG Responses of *P. hybneri* to E2HZ3H and E2HE2H.* The antennae of 3–4 wk old males and females reared in a group were used. The recording and gold reference electrodes were connected with electrode gel (Spectra 360,

PARKER, USA) to the distal antennal segment and the base of the antenna, respectively. Based on the results of preliminary experiments we tested 0 + 2, 0 + 5, 2 + 0, 2 + 2, 2 + 5, 5 + 0, 5 + 2, and 5 + 5 mg of E2HZ3H and E2HE2H applied to a piece (2 mm×50 mm) of filter paper (Toyo No. 2), with a filter paper strip alone and another strip treated with 20 µl hexane as blank controls. One strip of the test filter paper was inserted into a glass Pasteur pipette (15 cm long) that was inserted into a glass tube (10 mm O.D., 18 cm long) positioned 10 mm from the antennal preparation. An air stimulus controller (CS-05, Syntech, the Netherlands) was used for air and odor delivery at a constant flow of 2 l/min. Stimulations, from the lowest to the highest dose, each lasted for 1 sec at 20 sec intervals. EAGs to air and hexane were recorded before the test compounds and then after every 8 recordings. Pasteur pipettes, filter paper strips, and antenna were changed after 3 sets of 10 stimuli.

GC Analyses. *P. hybneri* whole body extracts were obtained from either 4 males or females (12–16-d old virgins) by immersing them in 1 ml hexane for 3 min. One µl of the extract, was submitted to GC analysis and compared with those of 1 µl of laboratory-synthesized E2HZ3H, E2HE2H, and MI (each at 0.05 µl per ml hexane). In all cases, the test materials contained 0.0001 µl *trans*-2-hexenyl acetate as an internal standard (IS). This analysis was triplicated.

Volatile collections were taken from either 4 virgin males or females (all 12–16-d old), using solid phase microextraction (SPME). The bugs were anesthetized by CO₂, placed in a 100 ml glass vial with five soybeans. After they had recovered, the vial was sealed with parafilm. All volatile collections were done from 10–13 hr after the photophase by inserting the SPME fiber [Supelco, Bellefonte, PA, USA: blue type polydimethylsiloxane/divinylbenzene (PDMS/DVB) 65-µm film thickness] into the vial for 10 min. The sample was immediately analyzed by introducing the fiber into the heated injector for 2 min. The volatiles from 20 µl of synthetic E2HZ3H, E2HE2H, and MI (0.5 µl each per ml hexane) on filter paper were collected using the same protocol. Twenty µl of IS solution were dropped on a separate strip of filter paper in the vial which contained *P. hybneri* adults or pheromone compounds.

Samples were analyzed by gas chromatography (GC: Shimadzu 17-A, Japan) equipped with DB-wax capillary column (30 m×0.25 mm; 0.25 µm) and RTx-225 capillary column (60 m×0.25 mm; 0.25 µm) for whole body extract analyses, and DB-wax capillary column for volatile collection analyses. The GC was operated in splitless mode. The oven temperature was programmed at 50(1)-210(10)/10 for DB-wax column, and at 80(2)-150(1)/15-200(3)/10-210(10)/5 for RTx-225 column.

Statistical Analyses. Data for EAG response and the transformed [$\log(x + 1)$] trap catches were analyzed by ANOVA followed by Duncan's multiple range test (DMRT) (SAS Institute, 1998).

Bars with the same upper or lower cases are not significantly different (Duncan’s multiple range test at $\alpha = 0.05$).

RESULTS

Effect of MI on Attractiveness of P. hybneri in the Field. A total of 147 females and 254 males were captured during the entire experimental period. Interestingly, all the females were non-reproductive (i.e., they did not have any developed eggs in their ovaries). Generally, the tertiary blends of E2HZ3H,

^b No treatments.

E2HE2H, and MI attracted higher number of females ($df = 16,8$; $F = 6.11$; $P = 0.001$) and males ($df = 16,8$; $F = 6.74$; $P < 0.001$) than those baited with MI alone or the control (Figure 1). Increasing the concentration of MI did not affect the attractiveness of the blends (Figure 1).

Attractiveness of E2HZ3H and E2HE2H to P. hybneri Adults in the Field. There was a significant effect of treatment on the two sexes in both trials (females, $df = 12,4$; $F = 8.92$; $P = 0.001$ and $df = 8,4$; $F = 57.17$; $P < 0.001$; males, $df = 12,4$; $F = 7.39$; $P = 0.003$ and $df = 8,4$; $F = 15.74$; $P < 0.001$) (Table 1). E2HE2H alone always attracted the highest number of females while

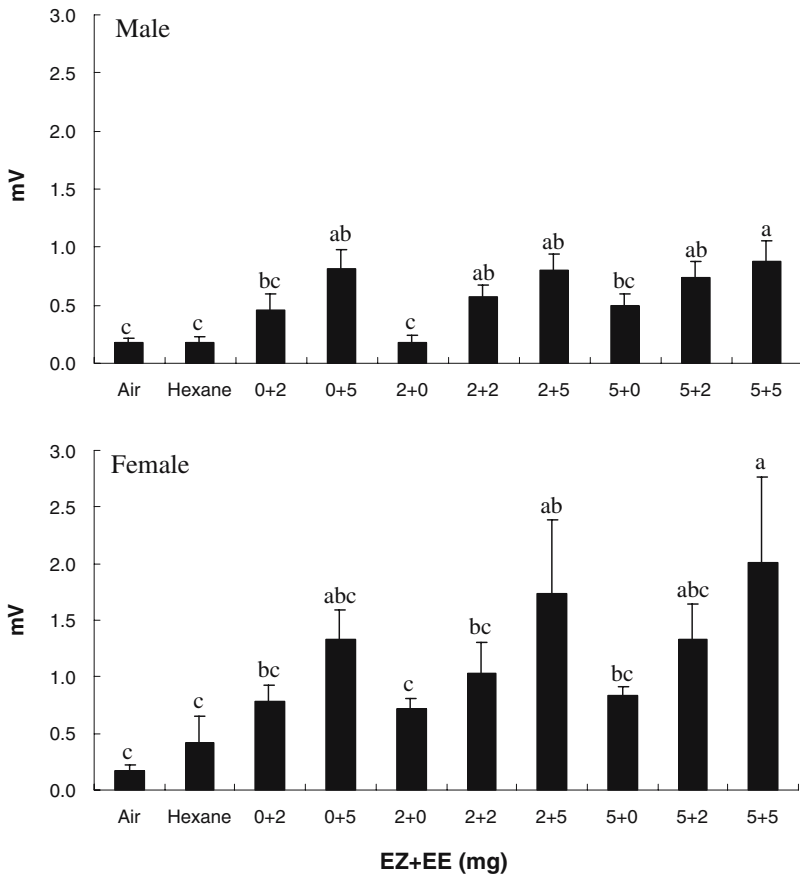

FIG. 2. EAG responses (mean \pm SE) of antennae from male and female *Piezodorus hybneri* adults to blends of E2HZ3H and E2HE2H. Bars with the same letters are not significantly different (Duncan's multiple range test at $\alpha = 0.05$).

E2HZ3H alone was no more attractive than the controls. The addition of 10 or 50 mg of E2HZ3H to E2HE2H did not increase trap catches, and resulted in a decrease in the number of bugs caught in trail 1 (Table 1).

EAG Responses of P. hybneri to E2HZ3H and E2HE2H. There were effects of increasing amount of E2HE2H on both males ($df = 30,9; F = 5.41; P < 0.001$) and females ($df = 30,9; F = 2.48; P < 0.03$), with the latter showing somewhat stronger responses ($N = 40, t = -4.545, P < 0.001$). In the case of males 5 mg of E2HE2H alone and all binary combinations gave responses significantly higher than the controls, while in females only the 2 + 5 and 5 + 5 blends of E2HZ3H and E2HE2H did so (Figure 2).

FIG. 3. Chromatograms of synthetic E2HZ3H, E2HE2H, MI, and whole body extracts of *Piezodorus hybneri* adult females and males. The retention times of internal standard (no. 1), *trans*-2-hexenyl acetate, were 6.645, 6.647, and 6.664 min in upper, middle, and lower graphs, respectively. The retention times of E2HZ3H, E2HE2H, and MI (no. 2, 3, and 4) were 11.922, 12.769 and 16.505 min, respectively.

FIG. 4. Chromatograms of volatiles from synthetic E2HZ3H and E2HE2H, and adult *Piezodorus hybneri* females and males, using SPME. The retention times of internal standard (no. 1), *trans*-2-hexenyl acetate, were 6.630, 6.629, and 6.635 min in upper, middle, and lower graphs, respectively. The retention times of E2HZ3H and E2HE2H (no. 2 and 3) were 11.916 and 12.763 min, respectively.

GC Analyses of P. hybneri Adults. None of the three compounds of the *R. clavatus* aggregation pheromone were detected in either the whole body extracts (Figure 3) or the volatiles (Figure 4) collected from *P. hybneri* females and males.

DISCUSSION

The results of the field trials show that *P. hybneri* adults are attracted to E2HE2H, but not to either MI or E2HZ3H. Furthermore, adding MI or E2HZ3H to E2HE2H did not increase the number of insect captured. Endo et al. (2003)

also reported that neither MI nor E2HZ3H were attractive to *P. hybneri*, even though MI increased the attractiveness of E2HZ3H and E2HE2H to *R. clavatus* (Mizutani et al., 1997; Endo et al., 2005; Huh et al., 2005).

The attraction of *P. hybneri* to E2HE2H, a component of the *R. clavatus* aggregation pheromone, is intriguing. There are a number of examples of different hemipteran species having some of the same components in their pheromone blends (Kitamura et al., 1984; Aldrich et al., 1993; Borges et al., 1999), so lures containing a single common component could attract adults of several species. However, this is not the case for *P. hybneri* and *R. clavatus*, as neither sex of *P. hybneri* produce E2HE2H. One alternate explanation is that E2HE2H could be a component of the volatiles produced by host plants. However, this seems somewhat unlikely as soybean and horse bean seeds, common food sources for these two bug species, do not produce this compound (Leal et al., 1995).

As both *P. hybneri* and *R. clavatus* share a number of host plants, we postulate that the response of *P. hybneri* to one component of the *R. clavatus* aggregation pheromone is an adaptation that increases the probability of finding suitable host plants. If this is true, then one can expect that traps baited with *R. clavatus* males will capture *P. hybneri* adults, but this was not the case (Table 1). However, in another experiment run August 2 to November 22, 2004, traps baited with *R. clavatus* caught 19 female and 14 male *P. hybneri* adults, while the control traps captured none. Why there is such variability in the attractiveness of *R. clavatus* for *P. hybneri* is unknown, and further research is required, examining factors such as the physiological state of males in traps and the actual densities of *P. hybneri* at the sites. It does not seem likely that the differences are related to the physiological status of *P. hybneri*. The majority of females we captured in traps baited with E2HE2H from September 7 to October 4 in Jinju (latitude, about 35° 2') were sexually immature, suggesting they were in reproductive diapause. In their study from July 29 to August 12 in Kumamoto (latitude, about 32° 8'), Endo et al. (2003) captured both of *P. hybneri* adults and nymphs, and it is likely that the adults captured were sexually mature, because diapausing individuals usually appear around mid September at this location (Higuchi, 1994).

There are a number of studies showing that hemipteran parasitoids (Leal et al., 1995; Masuta et al., 2001; Huh and Park, 2005) or predators (Zegelman et al., 1993; Mendel et al., 1995) use host pheromones as kairomones to locate suitable prey/hosts. However, we believe this is the first suggestion that the aggregation pheromone of one herbivorous bug may serve as a kairomone for a second herbivorous species. It has been shown that *Halyomorpha mista* (=halys) was attracted to traps baited with aggregation pheromone [methyl (E,E,Z)-2,4,6-decatrienoate] of *Plautia stali* in Japan (Adachi, 1998) and in Korea (Lee et al., 2002) but this may result from shared pheromone components

(the chemical communication system of *H. mista* has not been studied to date) rather than *H. mista* using the aggregation pheromone of *P. stali* as a kairomone. The possibility of one herbivorous species using the aggregation pheromone of another, sympatric one, to locate suitable host plants merits further attention for truth. The multi-species management systems could be developed, such as using E2HE2H to control both *R. clavatus* and *P. hybneri*.

Abstract—Male *Galerucella californiensis* and *Galerucella pusilla* (Coleoptera: Chrysomelidae) emit an aggregation pheromone while feeding on host foliage. Isolation of the compound from collected volatiles was guided by comparisons of gas chromatograms of extracts from males and females and by gas chromatography–electroantennographic detection. The compound was identified by a combination of spectrometric methods and microchemical tests as the novel dimethylfuran lactone, 12,13-dimethyl-5,14-dioxabicyclo[9.2.1]-tetradeca-1(13),11-dien-4-one. The structure was confirmed by synthesis, and the synthetic compound attracted males and females of both species in field bioassays. These beetles were previously introduced into North America as biological control agents for the invasive wetland weed, purple loosestrife *Lythrum salicaria*, and the pheromone could become a tool for monitoring populations. A new method is described for distinguishing the two species based on the tibial spurs of the males.

INTRODUCTION

Galerucella californiensis (L.) and *Galerucella pusilla* (Duftschmidt) are leaf beetles (Coleoptera: Chrysomelidae) that were introduced into the United States from Europe as biological control agents for the invasive wetland weed, purple loosestrife *Lythrum salicaria* L. (Hight et al., 1995). The adults are small (3.5–5.5 mm) and brownish with dark markings; the species and sexes are nearly identical in appearance. The insects consume the foliage of purple loosestrife, both as adults and as larvae. For biocontrol purposes, methods of monitoring release sites for beetle establishment, abundance, seasonal timing, dispersal rates, and other population properties are required. Pheromone-baited traps could be sensitive and selective tools for acquiring such information. Observations of aggregation behavior in these beetles suggested that a pheromone exists (Grevstad and Herzig, 1997), but none had been chemically identified.

Existing knowledge about chrysomelid pheromones gave little guidance on *Galerucella* spp. because of the considerable chemical and biological diversity within the family. Pheromones of the rootworm beetles (*Diabrotica* spp.) are female produced and attract only males; they consist of esters of methyl-branched secondary alcohols and structurally related ketones (reviewed in Krysan et al., 1989). The more recently identified chrysomelid pheromones are all male produced and attract both sexes. These include a hydroxyketone from the cereal leaf beetle *Oulema melanopus* L. (Cossé et al., 2002; Rao et al., 2003), a dihydroxyketone from the Colorado potato beetle *Leptinotarsa decemlineata* Say (Dickens et al., 2002), a series of himachalene and cadinene sesquiterpenes from *Aphthona* and *Phyllotreta* flea beetles (Bartelt et al., 2001, 2003; Muto et al., 2004; Soroka et al., 2005), and a 7-carbon diene aldehyde and alcohol from *Diorhabda elongata* Brullé (Cossé et al., 2005).

An approach was chosen that would detect pheromone emission by either sex. Volatiles were collected from male and female beetles separately and analyzed for sex-specific compounds that elicited strong antennal responses in gas chromatography–electroantennographic detection (GC–EAD) studies as possible pheromone components. Only one such compound was found from *G. californiensis* (from males), and it was subsequently found from *G. pusilla* males also. We report here the identification, synthesis, and field testing of the pheromone, which was attractive to both sexes of each species. Structurally, the compound is unlike any of the previously identified chrysomelid pheromones.

METHODS AND MATERIALS

Insects. *G. californiensis* were reared on potted purple loosestrife plants in a greenhouse at the Illinois Natural History Survey. Adults for volatile-collection efforts in early spring were obtained from a stock of beetles that had diapaused in cold storage over the winter, and in late spring or summer, adults were collected as they emerged from pupation in the soil. The sexes of *G. californiensis* were separated based on the characteristic tibial spurs on the meso- and metathoracic legs of males (Cossé, 2004). Early in the project, when it was unknown which sex emitted a long-range pheromone, adults were placed individually into vials as they emerged from overwintering diapause or from pupation to increase the likelihood that they were unmated when used for collection of volatiles. This precaution was taken because in another chrysomelid, *Diabrotica virgifera*, emission of the female-produced sex pheromone ceased upon mating (Bartelt and Chiang, 1977). Once evidence emerged for a male-produced pheromone in *G. californiensis*, the time-consuming procedure of isolating beetles as they emerged was discontinued. In chrysomelids with male-produced pheromones (e.g., *Phyllotreta cruciferae*, *Aphthona* spp., and *Diorhabda elongata*), pheromones were collected from freely mating, field-collected males (Bartelt et al., 2001; Cossé et al., 2005).

During summer of 2003, *G. pusilla* became available from a population in Minnesota, allowing collection of volatiles and electrophysiology to be conducted for this species also. *G. pusilla* were also studied under the microscope for sexually dimorphic characters and differences from *G. californiensis* that would allow identifications to be made without injuring the beetles. Additional field-collected *G. pusilla* were obtained during summer of 2005 for volatile collections.

Collection of Volatiles. Volatiles were collected from *G. californiensis* during 2002–2004 at the National Center for Agricultural Utilization Research (NCAUR). Initial collections were made from both males and females feeding on purple loosestrife foliage and from foliage alone. Once it became clear that a male-produced pheromone was probable, subsequent collections were made almost entirely from males, accumulating material for identification. In 2002, 122 1- to 3-d collections were made from feeding males, 60 were made from feeding females, and 8 were made from plants only. In 2003, 567 1-d collections were made from males, and 23 from females. In 2004, 117 1-d collections were made, all from males. For *G. pusilla*, 50 1-d collections from males and 21 from females were made during 2003, and 100 1-d collections from males and 40 from females were made during 2005.

The conditions and apparatus for collecting beetle-produced volatiles evolved during the course of this study. Details for the most successful procedure (used in 2004 for *G. californiensis*) are described here: The body of

the collector apparatus was a 45-cm-long by 3-cm-diameter straight glass tube with a female 24/40 ground glass joint on each end. A glass adapter was fitted into each end. (These 9-cm-long adaptors, suitable for holding thermometers or objects of similar diameter, have a male 24/40 joint on one end and a threaded fitting with an airtight O-ring seal on the other, Ace Glass, Vineland, NJ, USA #5028-30). Glass filter tubes (6 mm O.D. by ca. 8 cm length) containing a 1-cm plug of Super-Q were prepared as described previously (Cossé et al., 2002) and inserted into each adapter.

Each aeration chamber contained a shoot of purple loosestrife foliage about 30 cm in length after the growing tip was removed, obtained from potted plants maintained in the NCAUR greenhouse. Leaves were detached from the shoot until only three or four remained, each about 5–8 cm in length, well spaced along the stem. The base of the stem was placed in a 5-ml glass vial containing water. A Teflon seal in the ring-shaped cap of the vial kept the water from spilling. Beetles (usually 5–10) were added to the collector, which was then oriented horizontally. This configuration provided ample, but not excessive, food for the beetles for 1 d; using only this amount of foliage helped minimize the background levels of plant-related chemicals in the volatile collections. The beetles were not overcrowded and were able to move about on the plants in a natural manner.

Clean air was pulled through the aeration chamber and volatile trap at 300 ml/min. This rate was rapid enough that transpired water from the leaves did not condense on the walls of the tubes (the target compound was almost never detected when water droplets were visible). An inlet filter cleaned the entering air, and the outlet filter captured the volatiles emitted by the insects and plants. The collectors were located in an environmental chamber at 27°C, ~50% RH, and with a 17:7 (L:D) photoperiod, chosen to maintain the beetles physiologically in a reproductive state (Velarde et al., 2002). Light was provided by four 40-W fluorescent tubes about 1 m above the collectors.

Traps were changed each morning, eluting the traps with 400 µl methylene chloride. The beetles were transferred to clean collectors with fresh foliage, and the collection process was restarted. Maintenance was done daily because amounts of the target compound decreased if foliage was not fresh, and the chemical “background” in the samples increased when the glassware was not cleaned frequently. This procedure was repeated as long as the beetles survived (usually > 30 d). Each collection was analyzed by gas chromatography–mass spectrometry (GC–MS) and then stored in a freezer (–70°C) until it was processed further.

For *G. pusilla*, the procedure in place during 2003 (when the initial collections were made from this species) employed groups of up to 50 males or females held in glass tubes of ca. 8 cm diam and 100 cm length, and the foliage amounts were greater. However, the 2005 collections from *G. pusilla* used the optimum procedure described above for *G. californiensis*.

Electrophysiology. Samples from feeding male or female beetles of both species were analyzed by GC–EAD. The effluent from the GC column was split to a flame ionization detector (FID) and to the antenna of a male or female beetle. A glass pipette Ag/AgCl grounding electrode was inserted into the back of an excised beetle head. A second pipette serving as the recording electrode was placed in contact with the distal end of one antenna. Both pipettes were filled with physiological saline. GC and EAD data were analyzed by Syntech (Hilversum, the Netherlands) software, using previously described methods and equipment (Cossé and Bartelt, 2000).

Gas Chromatography–Mass Spectrometry. Coupled GC–MS was used to analyze all extracts (EI mode, 70 eV), using a Hewlett Packard 5973 mass selective detector, interfaced to an HP 6890 GC, controlled with Agilent ChemStation software (Release C.00.00), and with the Wiley spectral library with 275,000 spectra. A DB-1 column (30 m length, 0.25 mm ID, 0.25 μ m film thickness, J&W Scientific, Folsom, CA, USA) was used, programmed from 50°C/1 min, 10°C/min to 280°C, hold 5 min at 280°C. Other column types were also used. Injections were made in splitless mode, with He carrier gas and inlet and transfer line temperatures of 280°C. Positive chemical ionization (CI) mass spectra were acquired on the same instrument, with either methane or isobutane reagent gas. The high-resolution EI mass spectrum was obtained at the University of Illinois on a VG 70SE instrument with a GC inlet.

Gas Chromatography. Selected samples were analyzed by GC to estimate amounts of material present, using an HP 5890 Series II instrument with FID and column and parameters similar to those used for GC–MS. Quantitation was by the external standard method, relative to alkanes.

Preparation of NMR Sample by HPLC. The *G. californiensis* compound was purified in one step by HPLC, using a Waters 515 pump with a Supelcosil LC-SI silica column (25 cm by 0.46 cm ID, 5 μ m particle size), eluting with 5% ethyl ether (redistilled) in hexane (1 ml/min). The LDC/Milton Roy Spectro-Monitor D variable-wavelength UV detector was operated at 229 nm and was interfaced to an HP 3396 Series III integrator. Volatile collections were combined and concentrated under a stream of argon (three batches, each concentrated to about 500 μ l). HPLC injections were 100 μ l. The target compound eluted between 10 and 11 min and was essentially free of impurities, by GC–MS. Finally, the combined fractions were taken to dryness under a stream of nitrogen, and the compound was quickly taken up in 200 μ l deuterobenzene. The sample for NMR contained 17 μ g.

NMR Spectroscopy. NMR spectra were acquired at NCAUR on a Bruker Avance 500-MHz instrument with a 5-mm inverse broadband probe with a Z-gradient. Samples were run in a Bruker Microbore capillary-end tube (Wilma-Labglass, Buena, NJ, USA #520-1A). The experiments conducted included 1D 1 H NMR and 2D 1 H COSY and HMBC.

Additional NMR spectra were acquired on this sample at Pfizer on a Bruker 500-MHz instrument equipped with a Bruker Dual CryoProbe™. The sample was transferred to a Shigemi tube, and 1D ¹H NMR, ¹³C proton decoupled, DEPT135, and DEPT90 experiments and the 2D HMBC, HSQC, and HSQC-TOCSY experiments were conducted.

UV Spectroscopy. The UV spectrum was obtained on an HP 1040A diode array detector, using the Waters HPLC system described above. A quantitated sample was also run in a 1-cm cuvette on a Shimadzu UV-1601PC spectrophotometer to measure the extinction coefficient.

Microchemical Tests. Hydrogenation was conducted over Adam's catalyst (PtO₂) and over 10% palladium on carbon. Samples were dissolved in methylene chloride (ca. 1 μg in 100 μl) in a conical vial, and a small amount of catalyst was added (1 mg or less, barely visible in the vial). Hydrogen was bubbled through the solution from a fine needle for 5 min at room temperature, and then the sample was analyzed by GC-MS.

An aliquot was also reduced with LiAlH₄. The reagent (1 M in ether, Aldrich Chemical Co., Milwaukee, WI, USA) was diluted further with dry ether, and a drop was added to a sample of the beetle compound (ca. 500 ng) in ether. After several minutes, the reaction was quenched with a minimal amount of water and analyzed by GC-MS. Treatment with diazomethane was done essentially as described by Levitt (1960) on the beetle compound and on the standards, heptanoic acid and γ-decalactone.

Synthesis. The synthetic scheme is summarized in Figure 1. Briefly, the strategy was to prepare 3,4-dimethylfuran (**7c**), construct hydroxyl and acyl side chains at the 2 and 5 positions, and then close the lactone ring.

To make 3,4-dimethylfuran, 3,4-bis-(acetyloxymethyl)furan **6** was first prepared by a Diels-Alder reaction between butynediol diacetate **3** (obtained by acetylating diol **2**) and 4-phenyloxazole **5** (made from phenacyl bromide **4** and ammonium formate). The Diels-Alder adduct decomposed spontaneously to **6** and benzonitrile. All of the above reactions were done as described by Hutton et al. (1979). Diacetate **6** was converted to diol **7a** by transesterification with MeOH/MeONa (Christie, 1993). Diol **7a** was converted to dichloride **7b** with thionyl chloride, which was reduced to 3,4-dimethylfuran **7c** with LiAlH₄ (see Rawson et al., 1979, for both of these reactions).

The precursor for the 5-carbon side chain was prepared by converting 1,5-pentanediol **8** to iodohydrin **9a** by refluxing with HI in a two-phase system (Kang et al., 1985). The hydroxyl group of **9a** was protected as the tetrahydropyranyl (THP) ether **9b** (Miyashita et al., 1977). Furan **7c** was smoothly alkylated with **9b** after the 2 position was lithiated with butyllithium, giving trisubstituted furan **10** (Nolan and Cohen, 1981). To prepare the 3-carbon acyl side chain, **10** was first carbonylated to **11** by lithiation of the 5 position, followed by reaction with *N,N*-dimethylformamide (Koenig, 2002). Aldehyde

FIG. 1. Synthesis of *Galerucella* furan lactone (**1**). (a) Ac₂O, PTSA, 110–115°C, 3 hr; quant.; (b) ammonium formate, isobutyl formate, formic acid, azeotropic removal of water at 92–94°C, 7 hr; 51%; (c) Na₂CO₃, 205–206°C, 24 hr; 64%; (d) (i) NaOMe (0.2 equiv.), MeOH, rt, 1 hr; quant.; (ii) SOCl₂, pyridine, CH₂Cl₂, –5°C, 15 min; 60%; (iii) LiAlH₄, ether, addition at 0°C, then reflux, 4 hr; 70%; (e) (i) concentrated HI, hexane (two phases), reflux, 4 hr; 35%; (ii) dihydropyran, pyridinium *p*-toluenesulfonate (PPTS), CH₂Cl₂, rt, 4 hr; 86%; (f) addition of BuLi to **7c**, THF, –15°C, 2 hr, followed by addition of **9b**, –15°C, 1 hr, then rt, 1 hr; 62%; (g) BuLi, THF, 0°C, 2 hr, then dimethylformamide, 0°C, 1 hr; 40%; (h) triethyl 2-phosphonoacetate, BuLi, THF, 0°C, 45 min; 40%; (i) (i) 10% Pd on carbon, hexane, H₂ (1 atm), rt, 5 min; 95%; (ii) PPTS, EtOH, 55°C, 2.5 hr; quant.; (iii) KOH, 1:1 MeOH/H₂O, 45°C, 2 hr, by GC reaction complete; (j) 2,4,6-trichlorobenzoyl chloride, Et₃N, THF, rt, 2 hr, then 4-(*N,N*-dimethylamino)pyridine, toluene, reflux, addition over 3.5 hr; 75%.

11 was elaborated to unsaturated ester **12** by a Wittig–Horner condensation with triethyl 2-phosphonoacetate (Boutagy and Thomas, 1974). The side-chain double bond was selectively reduced by hydrogenation over 10% Pd on carbon in hexane to give **13a** (Lie Ken Jie, 1981).

Compound **1** was completed by deprotecting the hydroxyl (Miyashita et al., 1977, giving **13b**) and acyl functions (KOH in aqueous MeOH) and closing the ring. Hydroxy acid **13c** was activated by conversion to the mixed anhydride with 2,4,6-trichlorobenzoyl chloride, followed by cyclization under high-dilution conditions using 4-(*N,N*-dimethylamino)pyridine as the catalyst (Sinha et al., 1993). Purification on silica gel (10% ether in hexane, after 5% ether in hexane) yielded 30 mg of **1** (91% pure).

The synthesis is described in detail in the online supplementary information available for this article, at <http://dx.doi.org/10.1007/s10886-005-9026-3> and is accessible for authorized users.

Field Lures. Red rubber septa (Aldrich) were cleaned by Soxhlet extraction with CH₂Cl₂, and loaded with synthetic **1** (500 µg in 100 µl of hexane). Loaded septa were stored at –20°C until used. One freshly prepared septum was placed into a laboratory volatiles-collection apparatus to determine the emission rate of **1**. Volatiles were collected continuously for 31 d and were quantitated every 1–4 d by GC, using heptadecane as internal standard.

Field Tests. Field tests of synthetic **1** were conducted on May 10, 17, and 18, 2005, in two wetlands in northeastern Illinois (Cook County) known to have infestations of purple loosestrife and populations of *Galerucella* spp. The field sites were at Hyde Lake (41°39.9'N, 87°33.1'W) and Powderhorn Lake (41°38.6'N, 87°32.0'W). The three test days were mostly sunny, with maximum temperatures of ca. 20°C. Beetles were observed on plants at both locations, but the season was slightly more advanced at Hyde Lake: Eggs were easily found at Hyde Lake on May 17, but none were apparent at Powderhorn Lake on that date.

Traps were 15 × 15-cm yellow sticky cards with adhesive on both sides (“Sticky Strips,” Olson Products, Medina, OH, USA, cut in half). These were attached near the tops of bamboo stakes (1.2 m in length). Lures were fastened to the tops of the sticky cards with wire.

Experiments were organized as paired *t* tests, with a treated and a control trap in each pair. Traps were placed near purple loosestrife, but not necessarily in dense stands. Trap positions of a pair were separated by 3–4 m and were chosen to be as similar as possible with respect to height, density, and type of vegetation. Assignment of treatments within trap pairs was randomized. Spacing between pairs was at least 10 m. Overall, 15 pairs of traps were run at Hyde Lake (on May 10 and 17), and 20 pairs were run at Powderhorn Lake (on May 17 and 18).

Traps were deployed in midmorning, before beetles became active, and the experiment was terminated between 3:00 PM and 5:00 PM. Beetle numbers were recorded at the end of the experiment, and all specimens were examined under the microscope for tibial spurs. Samples of males (five of each species from each field site) were dissected to examine genitalia (Manguin et al., 1993).

RESULTS AND DISCUSSION

Identification and Sexing of Beetles. As was found previously with *G. californiensis* (Cossé, 2004), the males of *G. pusilla*, but not the females, have spurs on their mesotibiae. However, analogous spurs were not found on the metatibiae of male *G. pusilla*, as they had been on males of *G. californiensis*. These characters allowed males of the two species to be distinguished from each other and from females. Moreover, these determinations could be done without causing injury (compare to Manguin et al., 1993). Species determinations made using the spur characters were subsequently verified by examination of genitalia at NCAUR and by submission to experts at other institutions. We were unable to confidently separate females of *G. californiensis* and *G. pusilla* from mixed populations using the criteria of Manguin et al. (1993).

Male-Specific Compound. GC–MS comparison of volatiles from feeding male and female *G. californiensis*, supplemented by GC–EAD analysis, revealed a likely pheromone. Figure 2 (top) shows example GC traces from feeding males and females. Most of the peaks in these samples were from the plant material. However, one compound was found only from males, and it elicited an intense response from the antennae of both sexes (lower part of Figure 2). The amount of the male-specific compound depended on the conditions during collections and tended to be low early in the project when techniques were still evolving. Some early samples that elicited the characteristic EAD response had such a small amount of the male-specific compound that it was not detected by GC–FID. As the beetle-handling and volatile-collecting procedures were improved, the compound became more prominent in chromatograms (e.g., Figure 2), and it amounted to as much as 5–10% of the total GC peak area in some samples. Males produced a maximum 30–50 ng per male per day. Production typically began within a week of setting up collectors and then continued for a month or more. In the final collection effort during 2004, the compound was detected in 69 of the 81 samples, and all of those not showing it were from the initial 9 days. There was no evidence for other sex-specific compounds that elicited antennal responses.

For *G. pusilla*, 36 of the 50 collections from males in 2003 had detectable amounts of the same compound, but none was found in 21 collections from

FIG. 2. GC comparison of volatiles from male and female *G. californiensis* feeding on purple loosestrife foliage, showing key male-specific compound (top), and GC-EAD responses of antennae of males and females to the volatile collection from males.

females. In 2005, the compound was present in 94 of the 100 collections from males but not in any of the 40 collections from females. The antennae of both sexes responded to the compound (GC-EAD) in the same way as did *G. californiensis*. For *G. pusilla* also, there was no evidence for other sex-specific compounds that elicited antennal responses.

Mass Spectrometry, UV Spectroscopy, and Microchemical Tests. The EI mass spectrum of the male-specific compound (Figure 3, top) had an “aromatic”

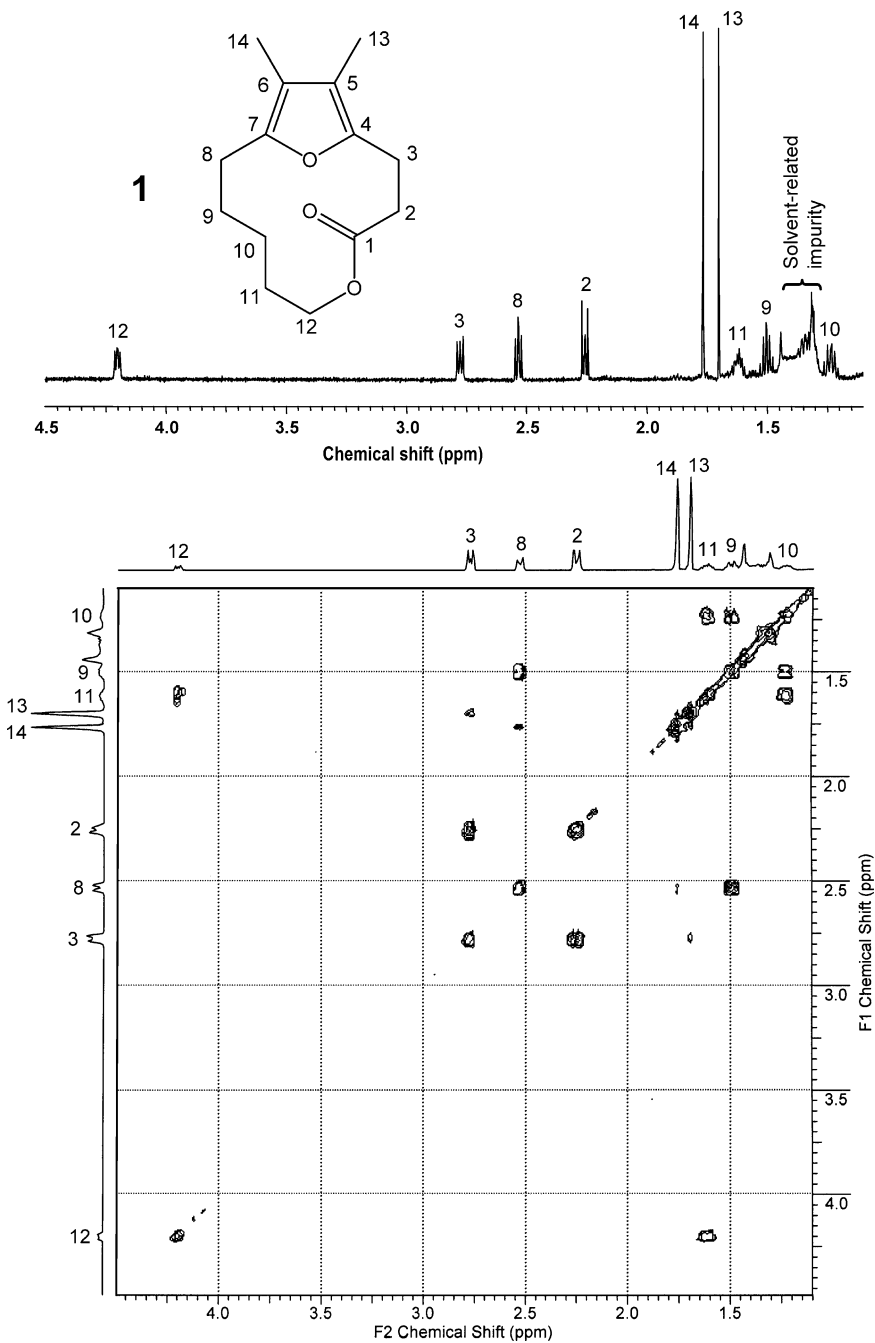

FIG. 3. EI mass spectra of the male-specific compound before and after hydrogenation.

appearance but did not match any spectra in the data system library. The apparent molecular weight of 236 was supported by positive ion CI mass spectra. With methane reagent gas, the base peak was m/z 237 $[(M + H)^+]$, and typical adduct peaks were seen at m/z 265 (15% of the base peak, $M + 29$) and m/z 277 (2%, $M + 41$). With isobutane reagent gas, the base peak was again m/z 237, and adduct peaks were seen at m/z 275 (3%, $M + 39$) and m/z 293 (2%, $M + 57$). The high-resolution EI mass spectrum was consistent with a molecular formula of $C_{14}H_{20}O_3$ (observed m/z : 236.1424; calculated m/z for $C_{14}H_{20}O_3$: 236.1412). This molecular formula indicates five degrees of unsaturation. Hydrogenation over palladium and platinum catalysts suggested that two of the degrees of unsaturation were due to carbon-carbon double bonds. With both catalysts, GC-MS revealed two products (probably diastereomers) with nearly identical spectra and apparent molecular weight of 240 (uptake of four hydrogen atoms). The mass spectrum of the more abundant, later-eluting one is shown in Figure 3, bottom. Thus, three degrees of unsaturation remained to be accounted for with rings, carbonyls, or other features.

The beetle-derived compound had a UV maximum at 229 nm (extinction coefficient 7000), suggesting that there were two double bonds in conjugation but not three.

Other microchemical reactions and liquid chromatography results gave useful structural information. The beetle compound reacted with LiAlH_4 , indicating that a carbonyl or other reducible group was present, although the product from this reaction was not recovered. The compound did not react with diazomethane, indicating no acidic protons. The polarity of the beetle compound on silica (HPLC) was lower than would be expected if a free hydroxyl group were present; the compound eluted with 5% ether in hexane, rather than requiring 25–50% ether in hexane, typically needed to elute an alcohol.

NMR Spectroscopy. NMR analysis was conducted on the purified compound (17 μg). The 1D proton spectrum is shown in Figure 4 (top), and the proton shifts and coupling information are summarized in Table 1. The proton spectrum accounted for all 20 of the protons expected from the high-resolution mass spectrum. The most downfield resonance (signal 12, two protons) suggested a methylene attached to an oxygen, and three midfield signals (2, 3, and 8, all with two protons) suggested methylenes adjacent to unsaturated carbons. The methyl groups (13 and 14) had shifts suggesting attachment to unsaturated carbons. The three remaining resonances (9, 10, and 11, each with two protons) were consistent with methylenes attached only to saturated carbons. Importantly, there was no evidence for olefinic protons.

The COSY spectrum (Figure 4, bottom) indicated two spin systems that were isolated from each other, consisting of two and five methylene units (signals 2 and 3 and 8–12, respectively). In addition, there was evidence for long-range, homoallylic coupling of the methyl groups into the main spin systems (specifically, between methyl 13 and methylene 3 and between methyl 14 and methylene 8). The methyl signals were broadened by this coupling but were not obviously split.

There were two other interesting features of the ^1H data. First, both protons of each methylene pair apparently had the same chemical shift, which would be extremely unlikely if one or more asymmetric centers were present in the molecule. Second, four of the methylenes (2, 3, 8, and 12) were nominally triplets but had second-order character (appearing as $aa'bb'$ multiplets). This was probably due to restricted rotation, perhaps because of a ring structure.

FIG. 4 Proton NMR spectrum of the male-specific compound from *G. californiensis* and assigned structure (top) and the proton COSY spectrum for the compound (bottom). A solvent-related impurity is evident in the proton spectrum; it does not correlate to any of the numbered signals in the COSY spectrum, indicating that it is unrelated to the beetle compound.

TABLE 1. SUMMARY OF ^1H AND ^{13}C NMR DATA FOR THE MALE-SPECIFIC *Galerucella* COMPOUND

Carbon position	^1H : shift (multiplicity), J	^{13}C : shift, ^a (multiplicity)	2D $^{13}\text{C}/^1\text{H}$ (protons observed)

^aUnless otherwise indicated, carbon shifts were observed directly and numbers of attached protons were confirmed by DEPT135 experiment; associations between particular carbons and protons based on HSQC experiment.

^bMixing time was 17 msec; the protonated carbons were correlated to their own protons and also to protons on immediately adjacent carbons.

^cShifts and assignments determined from HMBC experiment.

^dApparent aa'bb' systems; coupling constants are not directly observable.

^eRedundant carbon shifts (δ 114.4) make assignment of cross peak ambiguous.

At this point, the chains of two and five methylenes and the two relatively isolated methyls accounted for 9 of the 14 carbons indicated by high-resolution mass spectrometry (HRMS), but there was little information as to how these protonated groups were connected through the five remaining, unprotonated carbons. The 2D heteronuclear multiple bond correlation (HMBC) experiment (for observing 2- and 3-bond proton/carbon correlations) gave the needed information.

Because of the small sample size, the NCAUR instrument showed only the most intense HMBC cross peaks, those related to the methyl group protons, but these were informative. Methyl protons 13 (δ 1.70) were correlated to carbon resonances at δ 114.4 and 146.1, and methyl protons 14 (δ 1.77), to carbon resonances at δ 114.4 and 147.6. Because three cross peaks were anticipated for each methyl, it was postulated that there were really two carbons at δ 114.4 and that both of these were coupled to both of the methyl

groups. The furan ring in **1** would meet these criteria, and the observed carbon shifts were consistent with a furan (Glass et al., 1975; Levy et al., 1980). The furan structure also accounted for the two double bonds revealed by hydrogenation. Tetrasubstituted furans have been shown to be reactive to catalytic hydrogenation (Glass et al., 1975). Furthermore, a substituted furan could explain the observed UV maximum at 229 nm (Scott, 1964; Glass et al., 1975). The ring of the furan would also account for one of the three remaining, unexplained degrees of unsaturation.

The initial HMBC result was confirmed on the more sensitive instrument at Pfizer, and additional information was obtained as well. Nearly all of the possible HMBC correlations for **1** involving the unprotonated carbons were observed, as were many of those involving the protonated carbons (summarized in Table 1). The experiment showed the attachment of the methylene chains to the furan ring and also gave evidence for the lactone function. In particular, carbon 1 was attached to methylene 2 and, through an oxygen, to methylene 12, and the shift of carbon 1 (δ 172.0) was consistent with a lactone carbonyl (Levy et al., 1980). The lactone group accounted for the two remaining degrees of unsaturation. Other evidence supporting the lactone was the reactivity with LiAlH_4 (ester reduction), failure to react with diazomethane (no free carboxyl), and the relatively low polarity by silica gel chromatography.

The ^{13}C spectrum acquired at Pfizer (30,000 scans) showed peaks for all of the protonated carbons (shifts summarized in Table 1). The DEPT135 experiment confirmed which carbons were methyls and which were methylenes. No peaks were observed in the DEPT90 experiment, consistent with no methine protons. The HSQC experiment showed all of the possible one-bond proton/carbon correlations, and these were used to assign the carbon shifts to the particular positions listed in Table 1. The HSQC–TOCSY experiment (Table 1) supported the proton/carbon and proton/proton correlations obtained from the HSQC and COSY experiments, respectively. Taken together, the data fully determined the structure of the beetle compound **1**, 12,13-dimethyl-5,14-dioxabicyclo[9.2.1]tetradeca-1(13),11-dien-4-one. The beetle-derived and synthetic **1** were identical with respect to GC retention, mass spectrum, proton NMR spectrum, and GC–EAD analysis (males and females of both species).

Septum Emissions. Over a period of 31 d, the mean emission rate of **1** from a septum treated with 500 μg of this compound was 30 (\pm 7 SD) ng/hr (N = 17). The rate remained stable over the 31-d period (linear regression of release rate over time not significant, t = -1.67 , P = 0.12). Calculated from collected amounts and septum load, less than 5% of the applied compound actually volatilized during the test. The release rate was approximately 15 times the maximum observed daily average per live male in the laboratory. However, if the beetles only produce pheromone during certain periods of the day (rather than throughout the day), or if not all of the males in the aeration tubes were

actually emitting, or both, then the peak emission rate from males could approach or exceed the release rate from septa.

Field Tests. Traps baited with synthetic **1** caught more beetles (10.3 ± 9.9 SD) than controls (1.8 ± 2.6 ; $N = 35$, $t = 10.3$, $df = 34$, $P < 0.001$; paired t test after $\log(X + 1)$ transformation). The control catch never exceeded that of the treated trap for any pair, although no beetles were caught in 2 of the 35 blocks.

Examination of the trapped beetles gave the results summarized in Table 2. Species determinations based on tibial spurs were fully supported by dissections of genitalia. By a chi-square test, the overall difference between the pheromone and the control was again highly significant ($P < 0.001$), but the treatment by beetle-category interaction was not significant ($P = 0.16$). Thus, the effect of the pheromone, expressed as the percentage of the catch found in pheromone traps, was reasonably consistent over all six beetle categories (involving species, sexes, and locations).

The overall captures of males (Table 2, totals for pheromone plus control) suggested that *G. californiensis* is the minor species at the Hyde Lake site (24% of the captured males) but is the major species at Powderhorn Lake (88% of the captured males). Based on a 2 by 2 contingency table with the trap totals for males, these percentages of *G. californiensis* at the two locations were

TABLE 2. SUMMARY OF *Galerucella* TRAPPING RESULTS, CHICAGO, IL, MAY 2005 (DATA ARE TOTALS OVER REPLICATIONS FOR INDIVIDUAL TREATMENTS, BEETLE CATEGORIES, AND LOCATIONS)

Beetle category	Trap catch			Percent on pheromone
	Pheromone	Control	Total (pheromone + control)	
Hyde Lake (15 replications)				
Male <i>G. californiensis</i>	25	8	33	76
Male <i>G. pusilla</i>	86	21	107	80
Female <i>Galerucella</i> spp.	150	25	175	86
Powderhorn Lake (20 replications)				
Male <i>G. californiensis</i>	51	8	59	86
Male <i>G. pusilla</i>	7	1	8	88
Female <i>Galerucella</i> spp.	33	1	34	97
Overall totals (35 replications)	352	64	416	85

Chi-square tests: (1) Using the two overall totals for pheromone and control, test of pheromone effect (H_0 : Pheromone and control trap catches are equal): $\chi^2 = 199$, 1 df , $P < 0.001$. (2) Using the 12 treatment totals for the individual beetle categories (6 for pheromone and 6 for control), test of treatment by beetle-category interaction (H_0 : Pheromone trap catch, as % of total, is the same for all beetle categories): $\chi^2 = 7.88$, 5 df , $P = 0.16$.

significantly different ($\chi^2 = 76.3$, 1 *df*, $P < 0.001$). Given that substantial numbers of females were caught in both places, we suggest that females of both species were caught during the study, although the actual numbers of each were not determined. An important question for future research would be whether trap catches reflect actual species compositions around the trap sites. Establishing a correlation of this sort would enhance the value of the pheromone as a monitoring tool. A final pattern in the trap data was that females represented a significantly smaller percentage of the trap catch at Powderhorn Lake (34%) than at Hyde Lake (56%) ($\chi^2 = 14.7$, 1 *df*, $P < 0.001$). The reason for this difference is unknown, but may reflect the slightly later phenology at Powderhorn Lake.

Biological Activity and Future Research. A surprising finding was that both *G. californiensis* and *G. pusilla* produce and respond to the same compound. The two species often occur at the same location and at the same time of year in their native Europe (Manguin et al., 1993). It was suggested by Manguin et al. (1993) that the species might have different pheromones, but the evidence so far is the opposite. It is unclear how interspecific competition/confusion is avoided, whether there are subtle differences in diel activity periods of each species, additional pheromone components that have yet to be discovered, or still other mechanisms for long-range species recognition and reproductive isolation.

Related Compounds from the Literature. Several other furan-containing fatty acids derivatives that are structurally related to pheromone **1** have been reported. The example shown in Figure 5 is found in minor amounts in grasses,

A "furan fatty acid"

Furan fatty acid metabolite

FIG. 5. Natural compounds chemically related to **1**: A "furan fatty acid" and the product obtained from it after metabolism by a rat (see text).

potato leaves, and birch tree leaves (Hannemann et al., 1989) and in olive oil (Boselli et al., 2000). The same compound is also a major lipid in the testes of a fish, the northern pike (*Esox lucius* L.) (Glass et al., 1975). Related lipids in these and other organisms have different numbers of methylenes in the side chains, unsaturation in a side chain, and/or have one of the ring methyls replaced by hydrogen. When fed to rats, furan fatty acids were partially metabolized and excreted in the urine; one such example is shown in Figure 5 (Sand et al., 1983). Interestingly, this metabolite differs from **1** only in the oxidation state at the end of the 5-carbon side group and in the absence of a closed lactone ring.

Other insects with macrocyclic lactone pheromones are known. Examples include the beetle *Oryzaephilus surinamensis* (L.) (Pierce et al., 1985), the beetle *Cryptolestes ferrugineus* (Stephens) (Wong et al., 1983), and the true bug *Piezodorus hybneri* (Gmelin) (Leal et al., 1998). Insect macrolides have a range of ring sizes, may have double bonds or branches, and may be chiral or achiral. However, none was previously found that includes the furan structure. Compound **1** is unique as a natural product and further extends the known chemical diversity of pheromones within the Chrysomelidae.

Acknowledgments—Dr. Luke Skinner, Minnesota Department of Natural Resources, St. Paul, MN, and Dr. A. S. Konstantinov of the USDA-ARS Systematic Entomology Laboratory, Beltsville, MD, verified the species identifications. Dr. Skinner also provided *G. pusilla* adults used for collection of volatiles and GC-EAD studies in 2003 and 2005. We are grateful to Professor James Gloer, Department of Chemistry, University of Iowa, for helpful discussions about NMR techniques and possible structures. We also thank Dr. James Oliver, USDA-ARS, Beltsville, MD, for thoughts about structures and future syntheses. The high-resolution mass spectrum was acquired by Mr. Furong Sun, Mass Spectrometry Laboratory, School of Chemical Sciences, University of Illinois, Champaign, IL.

Abstract Large-scale implementation of transgenic crop varieties raises concerns about possible nontarget effects on other organisms. This study examines the effects of genetic modification on plant volatile production and its potential impact on arthropod population dynamics. We compared herbivore-induced volatile emissions from *Bacillus thuringiensis* Berliner (Bt) maize plants to those from a non-transformed isolate following exposure to various types of leaf damage. When equal numbers of *Helicoverpa zea* Boddie (Lepidoptera: Noctuidae) larvae fed on Bt and non-Bt maize, volatile emissions were significantly lower in the transgenic plants, which also exhibited less leaf damage. When damage levels were controlled by adding more larvae to Bt plants, the plants' volatile emissions increased but displayed significant differences from those of nontransgenic plants. Significantly higher amounts of linalool, β -myrcene, and geranyl acetate were released from transgenic maize than from non-Bt plants. Manipulating the duration of feeding by individual larvae to produce similar damage patterns resulted in similar volatile profiles for Bt and non-Bt plants. Controlling damage levels more precisely by mechanically wounding leaves and applying larval regurgitant likewise resulted in similar emission patterns for Bt and non-Bt maize. Overall, changes in the herbivore-induced volatile profiles of Bt maize appeared to be a consequence of altered larval feeding behavior rather than of changes in biochemical plant defense pathways. The implications of these findings for understanding the impacts of plant-mediated cues on pest and natural enemy behavior in transgenic crop systems are discussed.

Introduction

Genetically modified (GM) crops designed to resist insect herbivores are rapidly being adopted in many parts of the world. Transgenic maize (*Zea mays* L.) engineered to express delta-endotoxins from the soil bacterium *Bacillus thuringiensis* Berliner (Bt) has been commercially available since 1996 and now accounts for 35% of all maize grown in the US (National Agricultural Statistics Service, 2005). Large-scale implementation of transgenic crop technology has sparked substantial debate over the social, economic, and ecological implications of GM agriculture. Concerns about the ecology of insect-resistant transgenic crops have often focused on resistance development by pests and potential negative effects on natural enemies (Gould, 1998; Shelton et al., 2002). These issues are intricately linked to one another because natural enemies can influence the rate that pest populations adapt to resistant plants (Gould et al., 1991). The mechanisms underlying possible unintended ecological effects of transgenic crops warrant increased research attention.

One way in which GM crops might affect pest and natural enemy population dynamics is by altering plant defense mechanisms, including herbivore-induced plant volatiles. Volatile compounds released by plants can influence the behavior of herbivores searching for oviposition sites (Anderson and Alborn, 1999; De Moraes et al., 2001) and foraging natural enemies (Dicke et al., 1990; Dicke and van Loon, 2000; Turlings et al., 1990; De Moraes and Mescher, 2004). The ecological interactions mediated by these induced plant volatiles are often complex and can be quite sophisticated; for example, volatile blends can be keyed to particular herbivore species and attract species-specific parasitoids (De Moraes et al., 1998). Thus, these interactions may be sensitive to any changes in plant biochemistry that alter plant responses.

Volatile responses might be altered in GM crops through unanticipated phenotypic changes in plant defense systems because of pleiotropic effects or insertional mutations caused by incorporating a foreign gene (Schuler et al., 1999a). Significant phenotypic changes induced by genetic modification are not without precedent: the production of lignin, a major structural component of plants, increased in vascular tissues by 33–97% in Bt maize over non-Bt isolines (Saxena and Stotzky, 2001). Similar changes to complex biochemical pathways involved in plant defense might disrupt or alter the ability of plants to recognize and respond to herbivores, leading to significant differences between crop lines.

Induced volatile responses in transgenic crops might also be influenced by changes in interactions between herbivores and plants. The presence of Bt toxin changes the behavior of some insects. Lepidopteran larvae, for example, can detect and avoid plant parts or artificial diet containing varying forms of the toxin (Ashfaq et al., 2001; Gore et al., 2002, 2005). Such behavioral changes may alter herbivore feeding patterns, changing patterns and intensity of plant tissue damage and the exposure of the plant to oral secretions of herbivores. Plant volatile emissions are likely to be affected by such changes (Schmelz et al., 2003; Pare et al., 2005).

Whereas qualitative and quantitative changes in volatile emissions have been shown for undamaged Bt cotton and mechanically damaged GM tomatoes (Smith et al., 1996; Yan et al., 2004), the effects of genetic engineering on herbivore-induced plant volatiles remain largely unexplored. No change in parasitoid attraction was

found between Bt and non-Bt oilseed rape plants equally damaged by Bt-resistant herbivores, suggesting a similarity in the volatiles produced by each plant, but no mechanism was elucidated (Schuler et al., 1999b). Further understanding of these effects will be accomplished most readily in plant species, such as maize, where the molecular and biochemical bases of induced volatile production are well understood. In response to herbivore feeding on maize, specific blends of compounds from the lipoxygenase, terpenoid biosynthesis, and shikimic acid pathways are released both locally and systemically (Turlings and Tumlinson, 1992). Whereas many of these compounds are not released in response to mechanical damage, the application of herbivore regurgitant induces a volatile response that closely resembles actual feeding (Turlings et al., 1990).

In this study, we investigated how induced volatiles varied between GM maize with the Bt *cryIA(b)* gene inserted and a nontransformed isoline. The endotoxin produced by the modified gene is targeted toward the European corn borer (*Ostrinia nubilalis* Hübner), but is also effective at increasing developmental times and mortality rates in other lepidopteran larvae, including the corn earworm (*Helicoverpa zea* Boddie) (Wiseman et al., 1999). *H. zea* is an economically important pest of maize kernels, but can also cause damage to whorl-stage maize plants by foliar feeding (Capinera, 2000). We first compared volatiles from undamaged plants to determine if Bt and non-Bt maize plants differed in their constitutive release of chemicals. Then, we performed several experiments comparing volatile induction by *H. zea* feeding on Bt and non-Bt maize plants, manipulating larvae numbers, damage amounts, and feeding patterns. To further control damage levels and patterns, we mimicked herbivore feeding by mechanically wounding leaves and applying regurgitant collected from larvae fed either with Bt or non-Bt maize.

Methods and Materials

Plants and Insects

Both Bt and non-Bt maize seeds were obtained from Dekalb (Monsanto Co., St. Louis, MO, USA). The Bt maize DKC61-25 contains the Monsanto Event 810, with the *cryIA(b)* gene. The nearest isoline of the Bt hybrid, DKC61-24, was used for the non-Bt plants. Plants were grown in a growth chamber (14-hr photophase; 25:22°C day/night, 65% RH) in pots (16 × 17-cm diam) filled with a peat-based general-purpose potting soil with micronutrients added.

H. zea larvae were reared from eggs (USDA/ARS, Tifton, GA, USA) on an artificial casein-based diet in plastic diet cups (30 ml, Solo Cup Co., Urbana, IL, USA) in incubators (14-hr photophase, 25°C, 60% RH). Larvae were starved for 24 hr before experiments. Third instar larvae were placed on plants for all experiments.

Volatile Collection and Analysis

We collected volatiles in a greenhouse from potted, intact 2- to 3-wk-old maize plants using a closed push/pull system (Analytical Research Systems, Gainesville, FL, USA). About 3 in. above the soil line, a Teflon® base consisting of two sliding

plates (that when pushed together left a hole for the stalk to pass) was secured around the plant. A cotton ball was wrapped around the stalk to fill space between the base and plant and to allow air to exit. A cylindrical glass chamber (46 cm tall, 8-cm diam) was placed over the plant, resting on the Teflon[®] base. Air was pumped into the chamber (3.0 l/min) through Teflon[®] tubing and pulled out of the chamber (1.0 l/min) through side ports and across traps containing 40 mg SuperQ[®] (Alltech, Deerfield, IL, USA). Two separate volatile collections were made daily: one during the light phase for 12 hr, and the other during the dark phase for 8 hr.

Traps were eluted with 150 μ l of dichloromethane, and *n*-octane (80 ng) and nonyl acetate (400 ng) were added to each sample as internal standards. Volatiles were analyzed by gas chromatography with a Hewlett-Packard model 5890 GC. Samples were injected in 1- μ l aliquots with a splitless injector held at 240°C. The column (15 m \times 0.25 mm i.d., HP-1) was maintained at 60°C for 2 min, and then increased 4°C/min to 180°C, where it was held for 10 min. Quantifications of compounds were made relative to the internal standard using Enhanced Chem-Station software (Agilent Technologies, Palo Alto, CA, USA). Identifications were confirmed with mass spectrometry and by comparing retention times with those of known standards.

Undamaged Plants

Volatiles were collected from undamaged Bt and non-Bt maize to determine baseline emissions. Collections were made from four plants of each type. Means for Bt and non-Bt maize for this and all other experiments were compared with Student's *t* test using Minitab v. 14.1 (State College, PA, USA) (Sokal and Rohlf, 1995).

Equal Number of Larvae Per Plant

We tested the induced responses of maize when exposed to an equal number of larvae on each plant type to approximate likely field conditions. Two third instars were added to each chamber containing individual Bt or non-Bt plants and allowed to feed freely on plants during 4 d of volatile collecting. Each day, dead or molting larvae were replaced with ones that had been starved for 24 hr. These comparisons were made on six Bt and six non-Bt plants.

To avoid disturbing the plants while larvae were feeding, we assessed herbivore damage while plants remained inside volatile collection chambers. Each morning during the 4-d feeding experiment, we estimated the size of damage holes on unfurled leaf blades and through the enumerated layers of the whorled cylinder by comparison with a guide composed of five different-sized circles of known area. From the number and estimated size of holes, we calculated the total leaf area removed.

Equal Amount of Herbivore Damage

To determine if the amount of larval feeding affects induced responses of Bt and non-Bt maize, we added *H. zea* larvae to Bt plants daily to achieve equivalent damage on both plant types. On the first day of the experiment, 8–10 third instars were added to each Bt maize plant, and one or two larvae were added to each non-Bt plant. Each day, more third instars (~5) were added to Bt maize through the tops

of chambers to replace ones that had died. By the end of the 4-d sampling period, most larvae had reached their fourth instar. As a control, the tops of the non-Bt chambers were vented for an equal time. Each day, we assessed and estimated the amount of plant damage as above. Three plants of each type were used for comparisons.

Equal Pattern and Amount of Herbivore Damage

Individual larvae on non-Bt plants feed longer and cause greater localized damage. Because the feeding pattern (i.e., the number and size of damage holes) may influence induced responses, we manipulated the duration of larval feeding, resulting in the consumption of an equal amount of leaf tissue in a similar pattern on each plant type. Third instars placed on Bt and non-Bt maize plants were monitored continuously as they fed, and individual larvae were removed once they consumed an area of leaf tissue equivalent in size to the damage a Bt plant would typically incur from one larva ($\sim 5 \text{ mm}^2$). The number of larvae on each plant was manipulated to achieve similar amounts of damage across plants ($\sim 60 \text{ mm}^2$). After all larvae were removed, usually about 3 hr after the first larvae were placed on the plants, we collected volatiles in a growth chamber for the next 3 d by using a collection system similar to the one used in the other experiments (Analytical Research Systems). Air was pumped into the chambers at 2 l/min and pulled out through traps at 0.8 l/min. A total of five Bt plants and four non-Bt plants were used as replications in this experiment. When volatile collections were finished, we cut plants at the base and digitally scanned leaves to quantify leaf area removed (SigmaScan Pro v. 5.0, SPSS Inc., Chicago, IL, USA).

Mechanical Damage and Regurgitant Application

To control the pattern and amount of damage more precisely than was possible using natural herbivory, we artificially simulated herbivory by mechanically damaging leaves and applying larval regurgitant. We collected regurgitant from fourth instar *H. zea* by probing the preoral cavity with a pipette tip and drawing in the fluid released from the mouth. Larvae in diet cups had either been fed with foliage from non-Bt maize for 24 hr or foliage from Bt maize for 6 hr after having been starved for 18 hr prior to collecting. The shorter feeding time was necessary for those fed with Bt maize because the larvae would become inactive soon after eating the transgenic leaves, at which point regurgitant could not be obtained. Regurgitant was kept on ice while being collected and boiled for 3 min to stop enzyme activity (Mori et al., 2001). Samples were stored at -80°C until needed. Preliminary experiments showed no clear differences between the volatile profiles of Bt or non-Bt plants induced by regurgitant collected from larvae fed with either Bt leaves or non-Bt leaves (data not shown). Because of this similarity in responses and the difficulties involved in collecting regurgitant from larvae exposed to the Bt toxin, regurgitant collected from non-Bt fed larvae was used to compare volatiles from Bt and non-Bt plants with artificial herbivory.

Volatiles were collected from mechanically damaged plants with and without regurgitant. Plants were damaged by scraping leaf tissue from the upper side of

leaves with a razor blade in a 1 × 2 cm rectangle. Each day, the glass volatile collection chambers were temporarily removed, and three leaves on each plant were damaged, with regurgitant (10 µl) applied to each damaged spot. The chambers were replaced, and volatiles were collected. Three Bt and three non-Bt plants were used for each experiment (with and without regurgitant).

Results

Undamaged Plants

We found no differences in the total amount of volatiles released or in quantities of individual compounds in the emissions from undamaged Bt and non-Bt maize (Table 1).

Equal Numbers of Larvae Per Plant

When equal numbers of *H. zea* larvae were fed on both maize isolines, non-Bt plants suffered 4 to 22 times more damage by the end of the experiment (Student's *t* test, $t_6 = -3.53$, $P = 0.012$). By the third day, the amount of damage as well as the amount of volatiles released was significantly greater on non-Bt plants (Table 1). Damage to Bt maize typically occurred only on the first day larvae that were placed on the plants, because after initial feeding, larvae often would be inactive but still alive for one or two more days. On non-Bt plants, larvae would continue to feed for the 4 d of the experiment, causing extensive damage.

Equal Amount of Herbivore Damage

When we equalized the amount of herbivory each day, there was a significant difference in the total amount of volatiles released by day 3 (Table 1). Four

Table 1 Total volatiles (Mean ± SE) released during and damage incurred (mm²) preceding day 3 from Bt and non-Bt maize

Treatment	Type	Total volatiles (ng/hr)	<i>P</i> value	Total damage (mm ²)	<i>P</i> value
Undamaged control	Bt	180.7 ± 41.6	0.834	0	n/a
	Non-Bt	193.5 ± 41.7		0	
Equal number of larvae per plant	Bt	652.7 ± 236.7	0.003	39.4 ± 23.3	0.006
	Non-Bt	3118.6 ± 482.9		302.4 ± 59.8

Unknown 4	35.4 ± 6	23.2 ± 5	0.231
(<i>Z</i>)-3-Hexenyl acetate	83.7 ± 19	21.6 ± 10	0.066

^a Values represent means ± SE in ng/hr.

Bolded numbers signify statistically significant differences between Bt and non-Bt values (Student’s *t* test, *P* < 0.05).

compounds constituted a major proportion of this difference: (*Z*)-3-hexenyl acetate, linalool, β-myrcene, and geranyl acetate (Table 2). The pattern of damage inflicted by each larvae differed between plant lines, however, with larvae on Bt plants feeding in short bouts and leaving many small, scattered holes, whereas larvae on non-Bt plants fed more or less continuously, creating large areas devoid of leaf tissue (Fig. 1).

Fig. 1 Sample of feeding patterns created by *Helicoverpa zea* larvae on Bt and non-Bt maize leaves

Table 3 Characteristics of damage holes created by *Helicoverpa zea* larvae while controlling duration of feeding to achieve an equal amount and pattern of damage

	Bt	Non-Bt	<i>P</i> value
Number of holes	15.5 ± 3.6	17.0 ± 3.7	0.789
Area (mm ²)	62.1 ± 6.2	61.0 ± 7.3	0.913
Perimeter (mm)	122.6 ± 11.0	126.9 ± 9.4	0.793

Equal Pattern and Amount of Herbivore Damage

Manipulating the amount of time larvae were allowed to feed resulted in plants with similar numbers of damage holes, leaf area removed, and perimeters of damaged areas (Table 3). In this case, the two maize isolines emitted similar blends in terms of total volatiles released and proportions of individual compounds (Table 1).

Mechanical Damage and Regurgitant Application

The volatiles released by Bt and non-Bt plants after applying larval regurgitant did not differ substantially from one another quantitatively or qualitatively (Table 1).

Fig. 2 Chromatograms of volatile compounds emitted on day 3 from non-Bt maize plants subjected to feeding by *H. zea* larvae, mechanical damage, mechanical damage with regurgitant applied, and no damage. Major compounds (with a threshold emission of 2 ng/hr) are labeled as follows: (1) unknown 1; (2) β -myrcene; (3) (*Z*)-3-hexenyl acetate; (4) linalool; (5) (*E*)-4-8-dimethyl-1,3,7-nonatriene; (6) unknown 2; (7) indole; (8) unknown 3; (9) unknown 4; (10) geranyl acetate; (11) bergamotene; (12) (*E*)- β -farnescene; (13) (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene; IS and IS₂, internal standards (*n*-octane and nonyl acetate)

The volatile profile of maize plants with artificial herbivory closely approximated that of plants exposed to actual larvae damage (Fig. 2). However, regurgitant-treated plants did not release some “green leafy volatiles” (Turlings et al., 1998) and had a weaker induction of β -farnescene and bergamotene (Fig. 2). Plants that were wounded with a razor blade appeared to release fewer volatile compounds and smaller quantities of the ones that were emitted relative to those damaged by herbivores.

Discussion

In our experiments, genetic modification did not appear to alter the volatile profile of undamaged maize (Table 1). However, undamaged Bt cotton plants emitted unique compounds and different proportions of typical compounds when compared to non-Bt cotton (Yan et al., 2004), hinting at the diversity of effects genetic modification can have on different plant species.

Undamaged Bt maize plants do not appear to influence the ovipositional preferences of some Lepidopteran pests (Hellmich et al., 1999; Liu et al., 2002), suggesting that an equal number of larvae would initially be expected on each plant type. When we allowed equal numbers of larvae to feed on plants continuously for 4 d, non-Bt maize received up to 22 times more damage and emitted significantly more volatiles than Bt maize (Table 1). In the field, similar reductions in induced volatile emissions could cause areas planted with Bt maize to be less attractive to natural enemies that rely on herbivore-induced plant cues to find suitable hosts. Sked (2003) showed that fields sown with Bt maize had one third the numbers of *Macrocentrus cingulum*, a parasitoid specialist on the European corn borer, as non-Bt plots. Such reductions in population size could conceivably lead to local extirpation of natural enemies. At the same time, reduced volatile emissions could attract herbivores seeking a suitable oviposition site. For example, *O. nubilalis* oviposits in the field preferentially on undamaged maize plants compared to those infested with conspecific larvae (Harmon et al., 2003). More pest egg masses laid on Bt plants emitting fewer volatiles than severely damaged non-Bt maize could increase the possibility of resistance emerging within pest populations (Hellmich et al., 1999).

If an ovipositional preference for Bt plants did arise in the field, the greater numbers of larvae might produce an amount of damage closer to that incurred by non-Bt plants. Our results indicate that even with an equal amount of damage, volatile emissions still varied between Bt and non-Bt plants (Table 2). Linalool, β -myrcene, and geranyl acetate were released in significantly greater quantities from Bt maize. These compounds have been implicated in natural enemy attraction through behavioral studies and antennal electrophysiological responses (Turlings et al., 1991; Rose et al., 1998; Gouinguene et al., 2005).

Although damage amounts were equalized by increasing the number of larvae on Bt plants, these larvae exhibited a different feeding behavior, and thus created a different pattern of damage than larvae feeding on non-Bt plants. Damage holes were more numerous but smaller on Bt maize, increasing the perimeter of damaged areas and maximizing the contact zone of oral secretions and exposed plant tissue. When the feeding of individual larvae was manipulated to achieve similar damage

patterns, differences in volatile emissions between Bt and non-Bt maize were no longer evident, suggesting that these differences resulted from the altered feeding behavior of larvae on Bt plants, rather than physiological changes in plant response resulting from genetic modification.

When the damage pattern and amount were standardized, either by manipulating the feeding duration of larvae or by applying larval regurgitant to mechanically damaged leaves, the induced volatile emissions of Bt and non-Bt maize were similar. These results suggest that Bt and non-Bt fields subjected to similar amounts and patterns of feeding damage, as might occur if pest populations developed resistance to the Bt maize, would be equally attractive to natural enemies. Similarly, the parasitic wasp *Cotesia plutellae* was found to be equally attracted to Bt oilseed rape plants fed upon by Bt-resistant hosts (*Plutella xylostella*) and wild-type plants equally damaged by the same herbivore, suggesting no change in the composition of the induced volatiles (Schuler et al., 1999b).

In summary, observed differences in induced volatile profiles between Bt and non-Bt maize appear to result from different amounts and patterns of feeding damage inflicted. Individual larvae on transgenic plants fed in short bouts, causing less damage and leaving distinctive damage patterns relative to conventional plants. When we controlled for these differences in the amount and pattern of feeding damage inflicted, differences in the volatile profiles of Bt and non-Bt plants disappeared, suggesting that these differences are a consequence of altered larvae feeding behavior on Bt plants rather than of changes in biochemical plant defense pathways. As reduced herbivory is the goal of insect-resistant transgenic crops, the consequent reductions in volatile emissions may have important implications for sustainable pest management.

Abstract Induced volatile terpenes have been commonly reported among diverse agricultural plant species, but less commonly investigated in odorous plant species. Odorous plants synthesize and constitutively store relatively large amounts of volatiles, and these may play a role in defense against herbivores. We examined the effect of herbivory and methyl jasmonate (MeJA) exposure on the release of volatile organic compounds (VOCs) in the marsh elder, *Iva frutescens*, which contains numerous constitutive VOCs, mainly mono- and sesquiterpenes. Our specific goal was to test for the presence of inducible VOCs in a naturally occurring plant already armed with VOCs. The abundant, native specialist leaf beetle *Paria aterrima* was used in herbivore induction trials. VOCs were sampled from herbivore wounded and unwounded, and from MeJA treated and untreated *I. frutescens*. Total VOC emissions were significantly greater in response to herbivory and MeJA treatment compared to unwounded controls. Herbivore wounding caused a substantial shift in the emission profile (42 VOCs from wounded, compared to 8 VOCs from unwounded *I. frutescens*), and MeJA had a similar yet less substantial influence on the emission pattern (28 VOCs from MeJA treated compared to 8 VOCs from untreated *I. frutescens*). Constitutive VOC emissions predominated, but some VOCs were detected only in response to herbivory and MeJA treatment, suggesting *de novo* synthesis. Several VOCs exhibited a delayed emission profile in contrast to the rapid release of constitutive VOCs, and principal components analysis revealed they were not associated with constitutive emissions. While *I. frutescens* contains many constitutive VOCs that are released immediately in response to herbivory, it also produces novel VOCs in response to feeding by the specialist *P. aterrima* and MeJA treatment.

Introduction

Many plants from diverse lineages synthesize secondary metabolites that accumulate in specialized secretory cells, or whose production is induced by herbivory (Karban and Baldwin, 1997). Terpenoids are a diverse group of secondary compounds that serve a variety of functions in plants, ranging from heat stress resistance (Sharkey and Singaas, 1995) to serving as cell membrane components, plant hormones, membrane-bound sugar carriers, and photoprotective pigments (Gershenzon and Croteau, 1993). Terpenoids may also play a direct defensive role in plant species that produce these compounds, as well as an indirect defensive role, by attracting natural enemies of herbivores (Paré and Tumlinson, 1999; Theis and Lerdau, 2003). Stored volatile organic compounds (VOCs) may be volatilized into the atmosphere by a healthy unwounded plant depending on their concentration and physiochemical properties (Niinemets et al., 2004). These stored VOCs are volatilized in greater quantity into the atmosphere upon tissue breakage during herbivore attack (Karban and Baldwin, 1997). While many plants contain large amounts of stored VOCs, others do not synthesize and emit them until a stimulus (such as herbivory) is perceived. Here, we use the term “constitutive” to refer to VOCs that are stored in the leaf and can be immediately released by mechanical wounding, “induced” to refer to VOCs that are increased in response to herbivory (which may include up-regulated constitutive VOCs), and “novel” to refer to unique induced VOCs that are not normally stored by the plant, but whose synthesis is up-regulated in response to herbivory.

Induced VOCs may be emitted hours or days after an attack, both from the site of wounding as well as systemically from undamaged plant leaves (Paré and Tumlinson, 1997a; 1999; Mattiacci et al., 2001). The synthesis of novel compounds not normally produced and accumulated may also be induced by herbivore oral secretions (Alborn et al., 1997; Paré et al., 2005). $^{13}\text{CO}_2$ pulse-labeling experiments have demonstrated the *de novo* biosynthesis of novel VOCs emitted from herbivore-wounded plants (Paré and Tumlinson, 1997b).

Numerous studies have shown that third-trophic-level members use novel VOCs as indicators of prey location, thus facilitating a tritrophic interaction and an indirect defense to the wounded plant (Dicke et al., 1990; Drukker et al., 2000; De Boer and Dicke, 2004). For instance, the C_{11} homoterpene, (*E*)-4,8-dimethyl-1,3,7-nonatriene (herein referred to as nonatriene), and the C_{16} homoterpene, (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (herein referred to as TMTT), among other terpenes, are induced by a broad spectrum of herbivores feeding on their host plants, and these induced VOCs are attractive to foraging predators and parasitoids (Dicke et al., 1990; Turlings et al., 1991; Vanpoecke et al., 2001).

Novel VOCs induction has been a focal point for research in tritrophic interactions and indirect defense, while constitutive VOCs have garnered relatively less attention. Constitutive VOCs have been mainly studied for their roles in direct defense as toxins and herbivore deterrents (Wittstock and Gershenzon, 2002). However, herbivory may up-regulate the production of constitutive VOCs, and due to their volatility they may also play a role in indirect defense. In many coniferous trees, constitutive terpene synthase enzymes are up-regulated in response to herbivory (Litvak and Monson, 1998), and specialist bark beetle predators are attracted to both constitutive and induced VOCs from conifers (Raffa and Smalley, 1995). In angiosperms, constitutive VOCs from *Zea maize*, in addition to novel

VOCs, enhance the ability of predators and parasites to find herbivore hosts (Fukushima et al., 2002). These findings suggest that constitutive VOCs may play a similar ecological role to induced VOCs.

Emission of VOCs in response to herbivory, as well as attraction of third-trophic-level members, has been documented in many systems, most of which are crop species lacking large amounts of constitutive VOCs. While much progress has been made in understanding the function of VOCs and the mechanisms regulating VOC emissions, less emphasis has been placed on understanding herbivore stimulated VOCs in natural plant systems that can store relatively large amounts of constitutive VOCs compared to agricultural species. Baldwin and coworkers have pioneered efforts to elucidate the function of VOCs in nature by using native populations of tobacco (*Nicotiana attenuata*) and the odorous sagebrush (*Artemisia tridentata*) (Kessler and Baldwin, 2001). Southeastern salt marsh plant communities have a high occurrence of many largely constitutive VOC producing species such as the marsh elder, *Iva frutescens* (Asteraceae), and (southern) wax myrtle, *Myrica cerifera* (Myricaceae). The role of herbivore-induced VOCs in plant assemblages containing large amounts of constitutive VOCs is not known.

The objective of this research was to examine herbivore-induced VOC emissions in a native coastal plant, *I. frutescens*, which is armed with an array of constitutive VOCs (mainly mono- and sesquiterpenes). Our specific goal was to determine the potential for induced VOC emission in response to herbivory by a native herbivorous beetle, *Paria aterrima* (Chrysomelidae) (Wilcox, 1957). Plants containing a high amount of constitutive VOCs may immediately release stored VOCs, up-regulate constitutive VOCs, and may synthesize and emit novel VOCs in response to herbivory. We also tested for potential VOC induction by treating unwounded *I. frutescens* with the volatile methyl jasmonate (MeJA). VOC emissions (and other defense responses) are induced by the plant hormone jasmonic acid (JA), and its volatile methyl ester, MeJA (Dicke et al., 1999; Koch et al., 1999). Jasmonates are products of the octadecanoid pathway, which has been identified as one of the major signaling pathways in plant defense (Farmer and Ryan, 1990). Jasmonates may play a role in the up-regulation of VOCs, since treatment of plants with this compound can enhance both constitutive and novel VOC emissions (Martin et al., 2003). If *I. frutescens* contains herbivore-inducible VOC emissions, application of MeJA should stimulate the production and subsequent emission of novel VOCs, and potentially up-regulate constitutive VOC emissions.

Methods and Materials

Plants and Insects

Iva frutescens occurs naturally along the forest edge of salt marshes in southeastern North America. The salt marsh plant community shows a distinct zonation pattern with the grass, *Spartina alterniflora*, dominating the lower elevations, and rushes (*Juncus* sp.) occurring on the landward border. At higher elevations, the marsh transitions to a shrub zone that is dominated by *Borrchia frutescens*. *I. frutescens* occurs as scattered individuals throughout the shrub zone but dominates the landward edge. A *M. cerifera* zone occurs on the landward side of *I. frutescens*, and borders an inland oak–pine forest. A combination of physical stress and biotic

interactions are thought to limit the distribution of salt marsh plants, with physical stress playing a primary role at low elevations and competition playing a larger role on the landward edge (Pennings and Callaway, 1992; Bertness and Yeh, 1994; Pennings and Moore, 2001).

I. frutescens plants approximately 2 m in height were collected in June 2000 from the marsh edge of the forest transition zone on Goat Island, at the North Inlet Marsh, Belle W. Baruch Marine Laboratory in Georgetown, SC, USA. Plants were pruned to approximately 1 m in height, and transplanted into 3-gal pots in the field using a 3:1 soil/sand mixture (Baccto lite™ potting soil: play sand), transported back to the University of South Carolina (USC) (Columbia, SC, USA), where they were fertilized using Peter's® 20/20/20 (5 ml of fertilizer per 3.78 l water) and maintained in a greenhouse. Plants were pruned to a height of approximately 1 m, and fertilized on an annual basis. Plants were moved in early May 2002 to a growth chamber where environmental conditions could be controlled. All herbivore wounding and MeJA treatment experiments took place in June 2002.

Paria aterrima beetles were collected in June 2002 from *I. frutescens* plants at Goat Island and transported back to USC. Beetles were maintained in plastic storage containers fitted with a mesh screen on the lid in the same growth chamber as experimental *I. frutescens* plants. Beetles were offered cotton balls saturated with water and branches of *I. frutescens* leaves as a food source. Branches were collected from the coastal site and stored in a cold room at 4°C in sealed plastic bags with moist paper towels to maintain freshness. New branches were placed in the beetle containers daily.

Growth Chamber Conditions

Growth conditions were maintained on a 14-hr photoperiod from 7:00 A.M. to 9:00 P.M., with a daytime temperature of 22°C and a nighttime temperature of 16°C. These conditions were maintained throughout the course of the experiments. The light regime was chosen to allow all volatile measurements to be made under daylight conditions when volatile emissions are greatest (Loughrin et al., 1994). *I. frutescens* approximately 1 m in height were used for experiments. These plants were in the original pots in which they were initially transplanted in the field, and appeared to be root-bound to some extent. Plants were watered every 2 d to saturation.

Herbivore Wounding Trials

For the herbivore wounding trials, the volatile collection system was placed over a selected branch and loosely fastened around the stem with a cable tie. Twenty beetles were inserted into the collection system through a small hole in the top of each bag, which was subsequently sealed with a cable tie. Insects were randomly chosen for each replicate, and no insects were reused. Beetles designated for a wounding trial were placed in a separate container with water, but without food for 24 hr prior to each trial. Once beetles were placed inside the collection bag, VOC emissions were collected in 1-hr intervals for 4 hr, with the traps changed every hour. After the first four collections, beetles were removed and VOC emissions were collected in 4-hr sampling periods at 4–8, 20–24, 32–36, 44–48, 56–60, and 68–72 hr. This sampling scheme was chosen to characterize any rapid changes in VOC emission during herbivory, as well as changes following herbivory. New traps were used for each

sampling period. An unwounded plant was simultaneously sampled with a wounded plant. All wounding experiments were replicated with seven different plants, and initiated at the same time of day (11:00 A.M.).

Plant Volatile Collection

A push–pull volatile collection system was designed using Reynolds[®] oven bags. One top corner of a bag was fitted with a straight connector to serve as the inlet, while another straight connector was fitted to the opposite side of the bag at the base near the opening to serve as the exhaust. Connectors were fastened to the bags with cable ties. Compressed medical grade air was used as the inlet air supply. A gas regulator was connected to the gas cylinder to control the flow rate into the collection bag at 1.1 l min^{-1} . An SKC, Inc. Aircheck sampler (model # 224-44XR) was used to pull headspace air through the bag and onto a 250-mg Tenax TA (Alltech, Inc.) trap fitted to the exhaust line on the bag. Headspace VOCs were sampled at 1 l min^{-1} . Therefore, 90.9% of the air was sampled during each sampling period. A frame was constructed out of chicken wire and placed inside the bag to maintain a rigid structure around the branch being sampled to minimize VOC emissions due to artificial damage. For each wounding trial, the frame and bag were baked prior to use at 160°C for 30 min to eliminate any potential volatile contaminants. Control collections (bag and frame only) showed two artificial peaks from the bag and frame system (data not shown). These peaks were not included in *I. frutescens* VOC data analysis. For the herbivore wounding experiments, one branch from a plant was selected for wounding as described below. The frame and bag were placed over the branch, and volatiles were collected at intervals described above. VOC collections from collection bags containing only beetles revealed no detectable beetle-associated VOCs (data not shown).

Chemical Analysis

Each volatile trap was eluted with 2 ml of gas chromatography/mass spectroscopy (GC/MS) analytic grade pentane and stored in 2-ml auto sampler vials. Pentane was added in 1-ml aliquots and allowed to elute by gravity. A light stream of air was used to push the remaining pentane through the trap. The eluate was concentrated to 300 μl under a stream of compressed nitrogen. The concentrated sample was fractionated into two 150- μl samples. All samples were analyzed by using a Hewlett Packard 5890 series II gas chromatograph equipped with an HP-5 methyl-silicone capillary column (30 m \times 0.25 mm) with helium as a carrier gas at a rate of 1.22 ml min^{-1} . The injector temperature was set at 275°C . All injection volumes were 2 μl . The temperature program consisted of an initial hold at 50°C for 3 min, followed by an increase to a final temperature of 220°C at a rate of 5°C/min , followed by a hold at maximum temperature for 20 min. Samples were subsequently analyzed by mass spectroscopy with a Hewlett Packard 5971 series Mass Selective Detector. Volatile compounds collected from headspace emissions were identified by comparison of retention time and mass spectra to those contained in the National Bureau of Standards essential oil database, as well as the database of essential oil components identified by GC/MS (Adams, 1995). All VOCs were quantified by an external standard method based on two major constitutive VOCs from *I. frutescens*, the monoterpene limonene, and the sesquiterpene β -caryophyllene. Six-carbon volatiles,

termed “green leaf volatiles” are produced from the catalytic activity of hydroperoxide lyase when cell membranes are damaged. They are among the most ubiquitous and earliest volatiles released in response to herbivory, and may have VOC-inducing capabilities (Frag and Paré, 2002). Green leaf volatiles, while presumably emitted in *I. frutescens* in response to herbivory, were not detected due to contamination from an unknown source in the portion of the chromatogram where these volatiles would have been detected.

Identification of Constitutive Leaf VOCs

Five g of fresh leaf material were collected from undamaged plants, and lipophilic components were extracted from the leaves in 20 ml GC/MS grade pentane by using a mortar and pestle to crush the leaves. Ten ml of the leaf extract were collected into a 50-ml polypropylene tubes and centrifuged for 10 min at 3600 rpm. One hundred and fifty μ l aliquots were collected and analyzed by the GC/MS protocol described above. The volatiles obtained from the leaf extraction were used as a reference for preformed VOCs contained within *I. frutescens*, and also to generate reliable mass spectra for the identification of VOCs emitted in smaller quantities. Tentative identification of the compounds was carried out as described above.

Methyl Jasmonate Treatment

Five *I. frutescens* plants were exposed to exogenous MeJA based on the protocol described by Rodriguez-Saona et al. (2001). Briefly, 50 μ l of a 9:1 (ethanol/MeJA) mixture were applied to two cotton-tipped applicators (100 μ l total) and placed at the base of a single *I. frutescens* branch without physically touching any leaf material. Branches to be exposed to MeJA were enclosed in collection bags. Control plants were maintained in a separate growth chamber, and exposed to 100 μ l of ethanol. Following an overnight 18-hr exposure period, cotton applicators were removed, new collection bags were placed over the treatment branch, and VOCs were immediately sampled for 1 hr.

Statistical Analyses

The experimental design consisted of a series of repeated measures on individual plants over time. Therefore, we used multivariate analysis of variance (MANOVA) and repeated-measures analysis of variance (ANOVA) to test for main effects on emissions of multiple or single VOCs, respectively. Individual VOCs with significant main effects ($P < 0.05$) were compared across time using Tukey tests to correct for multiple comparisons. VOC emissions in response to MeJA treatment were analyzed using a *t* test. All statistical tests were carried out using SAS V8.2 (SAS Institute, Cary, NC, USA). We also compared VOC emissions across time and treatment by using principal components analysis of VOC emissions. Twenty-two individual VOCs, comprising >0.5% at any sampling time, were used in the analysis. Principal components analysis reduces multivariate data to a smaller set of orthogonal, uncorrelated components that account for the maximum amount of variability. The first principal component accounts for the greatest amount of variation in the data, while additional components account for successively smaller amounts of variation.

Results

Constitutive VOCs

Iva frutescens leaves contain a complex mixture of secondary compounds dominated by monoterpenes and sesquiterpenes (Table 1). Sixty-one compounds comprising $63.2 (\pm 5.5) \mu\text{g g fr wt}^{-1}$ of material were recovered by pentane extraction. Fifty-three compounds were identified either to a specific compound or, at the least, a class of terpene based on molecular ions in mass spectra, while eight compounds could not be reliably identified to any class. Sesquiterpenes and oxygenated sesquiterpenes were the most diverse class recovered, followed by the monoterpenes. The major constituents (each >5%) of the total mixture in order of decreasing concentration were limonene, germacrene D, unknown sesquiterpene 3, β -caryophyllene, and α -pinene (Table 1).

Herbivore-Induced VOC Emissions

Unwounded *I. frutescens* plants constitutively emitted a mixture of eight detectable VOCs consisting of the monoterpenes α -pinene, sabinene, β -pinene, limonene, and the sesquiterpenes β -caryophyllene, α -humulene, germacrene D, and *cis*- β -guaiene, all of which occur in high concentration within leaf material (Table 1). The production of these VOCs in unwounded plants did not differ over the 72-hr sampling period. Table 1 also contains the mean for all compounds recovered in response to herbivory across the sampling periods, which on average were higher than unwounded plants.

Statistical analysis of the dataset by MANOVA and repeated-measures ANOVA yielded similar results (Table 2). Herbivore wounding has a significant effect on the emission of VOCs over time ($P < 0.001$) (Table 2, Fig. 1). Significant interactions between treatment and sampling period were detected in repeated-measures ANOVA, indicating that the treatment effect varied significantly with time (Table 2). No significant nested effects of plant within treatment were observed (Table 2). Beetles feeding on *I. frutescens* caused total VOC emissions to increase in

^aForty-two VOCs from seven wounded and unwounded plants used in analysis. Individual VOCs determined significant by repeated-measures ANOVA were analyzed for differences over time using Tukey multiple comparisons.

Fig. 1 Total emissions collected from herbivore wounded and unwounded *Iva frutescens* over 72 hr in response to 4 hr of herbivory by *P. aterrima*. Sample periods 1–4 collected during wounding. Sample periods 5–10 collected after wounding. Data points represent mean \pm SE of seven plants. Asterisk (*) indicates significantly increased emissions in the herbivore wounded treatment (Tukey, $P < 0.05$)

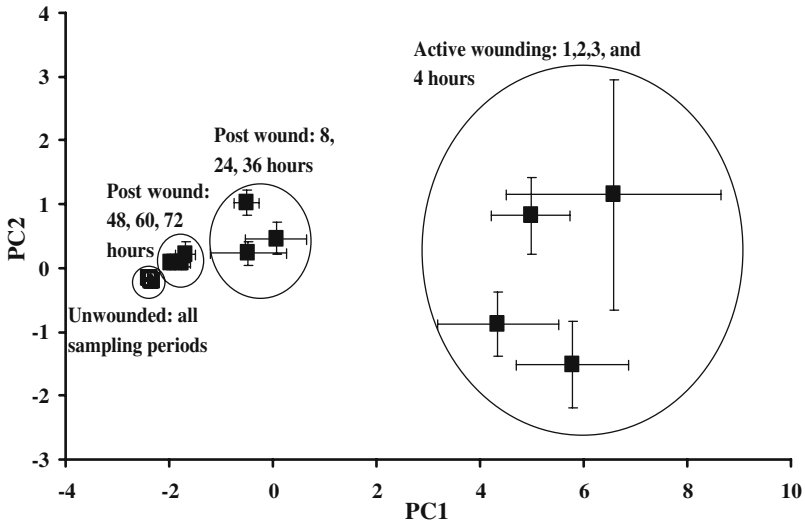

Fig. 2 Clustering pattern of sampling periods for wounded and unwounded *I. frutescens* in principal component space. Data points are mean \pm SE of principal component scores for seven wounded and unwounded plants at each time period

Fig. 3 Volatile organic compound (VOC) blend emitted from wounded (closed bars) and unwounded (open bars) *I. frutescens* during the first hour of herbivory (A), 24 hr (B), 48 hr (C), and 72 hr (D) after initial wounding by *P. aterrima* beetles. Twenty-two VOCs greater than 5% of the total blend are plotted. Values are mean ± SE of seven plants. Identities of compounds are listed numerically in Table 1. Asterisk (*) indicates significant difference from unwounded controls (Tukey, $P < 0.05$)

the first 4 hr during feeding compared to unwounded controls ($P < 0.05$) (Fig. 1). Herbivory caused a 22-, 14-, 16-, and 14-fold increase in total VOC emissions during hours 1, 2, 3, and 4, respectively. Following the 4hr feeding period, total VOC emissions declined dramatically, but remained elevated up to 48 hr after initial wounding ($P < 0.05$) (Fig. 1).

The influence of herbivory on VOC emissions over time is also displayed in principal component space (Fig. 2). Mean principal component scores at each sampling period are plotted for wounded and unwounded *I. frutescens*, and describes the influence of time and wounding on the variation in VOC emissions. Principal component 1 accounts for 61% of the total variation in the data, while component 2 accounts for 10%. Wounded plants show a steady relaxation toward unwounded plants, and four distinct clusters are seen over time (Fig. 2). The clusters indicate sampling periods with similar variation in VOC emissions. Active herbivore wounding sampling periods 1–4 hr, postwounding sampling periods 8, 24, and 36 hr, postwounding samplings periods 48, 60, 72 hr, and all unwounded principal component scores show distinct associations over time in principal component space (Fig. 2).

Herbivory caused a distinct compositional change in the total blend by stimulating the emission of 42 compounds including most constitutive VOCs. VOCs comprising greater than 0.5% of the total blend are displayed in Fig. 3 (22 total compounds). With the exception of the monoterpenes α -pinene, sabinene, β -pinene, and limonene and the sesquiterpenes β -caryophyllene and Germacrene D, all other VOCs were present in extremely small quantities (all less than 1% of the total blend). However, most of these VOCs remained significantly elevated 2 d after wounding, and persisted for the 72hr duration of the experiment. Two novel compounds were detected in the herbivore treatment, *p*-cymene, and an unidentified oxygenated sesquiterpene 3 (Figs. 3 and 4). These two compounds were unique in that they were not detected in *I. frutescens* leaf extracts, nor in MeJA-induced emissions (discussed below). Significant emissions of the unique oxygenated sesquiterpene 3 were immediately detected in response to herbivory (Tukey, $P < 0.05$), and these emissions remained significantly elevated 24 hr after herbivory (Fig. 4).

p-Cymene, nonatriene, and unidentified sesquiterpene 3 exhibited a delayed emission pattern that was distinct from VOCs released immediately upon wounding (Fig. 4). These compounds were not detected in wounded *I. frutescens* plants during the initial 2 hr of herbivory. Beginning at the third hour, they were detected in only one *I. frutescens* plant, which accounts for the large amount of variability in emission at that collection period. Significant emissions of unidentified sesquiterpene 3, *p*-cymene, and nonatriene were not detected until 4, 24, and 36 hr, respectively (Tukey, $P < 0.05$) (Fig. 4). Nonatriene and *p*-cymene emissions rapidly waned 48 hr after herbivory, but remained detectable throughout the experiment (Fig. 4). Unidentified sesquiterpene 3 emissions were not detected in *I. frutescens* after 24 hr (Fig. 4). The relationship between the constitutive and novel VOCs in *I. frutescens* is also shown in the plot of VOC loading factors in principal component space 1 and 2 (Fig. 5). Loading factors indicate the similarity between individual VOCs and the principal components on which they are plotted. All 22 VOCs used in the analysis have positive loadings on principal component 1, and most of the major constitutive mono- and sesquiterpenoids are closely associated in principal component space (Fig. 5). The herbivore novel compounds [*p*-cymene (10) and oxygenated

Fig. 4 Delayed volatile organic compound (VOC) emissions [*p*-cymene, oxygenated sesquiterpene 3, and (*E*)-4,8-dimethyl-1,3,7-nonatriene], and unique VOC emissions (*p*-cymene, and oxygenated sesquiterpene 3) from herbivore wounded *I. frutescens*. Asterisk (*) indicates significant difference from untreated controls (Tukey, $P < 0.05$). Values are mean \pm SE of seven plants

Fig. 5 Relationship of 22 major individual VOC loadings ($\geq 0.5\%$ of total blend) in principal component space. Numbers correspond to compounds listed in Table 1. The intersection of the dotted lines represents the origin of the VOC loading factors. VOC loadings were obtained from the factor pattern matrix of the principal components analysis, and represent the correlations between VOCs and the principal components on which the values are plotted. Thus, the distance between any two VOCs is an indication of the relationship between them. Similar shapes represent a class of terpenoid. Squares = monoterpenoids, triangles = sesquiterpenoids, diamonds = homoterpenes. Closed shapes = constitutive VOCs. Open shapes = delayed/herbivore specific VOCs

sesquiterpene 3 (**61**)] and the delayed VOC, nonatriene (**12**), do not cluster with any of the major constitutive terpenoids (Fig. 5).

MeJA-Induced VOC Emissions

Exposure of *I. frutescens* to MeJA caused a 10-fold increase in total VOC emissions compared to untreated controls ($P < 0.01$) (Fig. 6). MeJA-elicited VOC emissions were similar to, yet distinct from, VOC blends emitted from herbivore-treated *I. frutescens*. The blend of VOCs emitted in response to MeJA was less complex compared to the blend released in response to herbivory. MeJA-treated plants emitted a total of 28 compounds compared to 42 released in response to herbivory (Table 1). Some compounds were unique to the MeJA-treated plants including (*E*)- β -ocimene, hexenyl butyrate, methyl butyrate, *cis*-jasnone, and methyl salicylate (Table 1). While MeJA elicited the emission of novel VOCs, it also stimulated significant emissions of constitutive VOCs (Fig. 7). MeJA stimulated the release of nonatriene, and caused a 14-fold increase in α -pinene emissions, a 5-fold increase in sabinene, and an 8-fold increase in limonene emissions (Fig. 7). The herbivore wounding and MeJA treatment results can not be statistically compared because they were conducted as separate experiments; however, it is interesting to observe the similarities in some of the VOCs emitted from *I. frutescens* 24 hr after wounding, and after 18 hr of MeJA exposure (Figs. 6 and 7).

Fig. 6 Total volatile organic compound (VOC) emissions from methyl jasmonate treated and untreated; herbivore wounded and unwounded (24 hr after initial wounding) *I. frutescens*. Herbivore and methyl jasmonate experiments were not simultaneously conducted, preventing statistical comparison of the two treatments. Methyl jasmonate treated and untreated bars represent mean \pm SE of five plants. Asterisk (*) indicates significant difference from untreated controls (*t* test, $P < 0.05$). Herbivore wounded and unwounded bars represent mean \pm SE of seven plants

Fig. 7 Individual constitutive and nonconstitutive volatile organic compounds (VOCs) emitted from methyl jasmonate treated and untreated *I. frutescens*, and herbivore wounded and unwounded (24 hr after initial herbivory) *I. frutescens*. Methyl jasmonate treated and untreated bars represent the mean ± SE of five plants. Herbivore wounded and unwounded bars represent the mean ± SE of seven plants. Asterisk (*) indicates methyl jasmonate treatment is significantly different from methyl jasmonate untreated plants (*t* test, ****P* < 0.05)

Discussion

Many plants respond to insect attack by releasing VOCs that are known to attract natural enemies of herbivores (Paré and Tumlinson, 1999). A short 4-hr feeding period by *P. aterrima* on *I. frutescens* caused a dramatic quantitative and qualitative change in VOC emissions over time. Herbivory induced the emissions of both constitutive and novel VOCs, and dramatically changed the composition of the total blend released. Unwounded *I. frutescens* emitted a mixture of eight components that were detected by gas chromatography. Wounded *I. frutescens*, however, emitted a mixture of 42 compounds most of which are stored constitutively in the plant and only released in significant quantities in response to herbivory. Principal components analysis by treatment and time also shows the effect of wounding on VOC emissions. Sampling periods grouped into four main clusters, indicating the similarity in variation of VOC emissions at those time periods. The aggregation of postwounding sampling periods 8, 24, and 36 hr, separate from active wounding sampling periods, and the remaining postwounding sampling periods (Fig. 2), may be the result of the release of novel and delayed VOC emissions that persisted mainly during these sampling periods.

VOCs are produced by two main biochemical pathways. The cytosolic mevalonic acid pathway produces the sesquiterpenes, and the plastidal methyl erythritol phosphate pathway produces the monoterpenes (Lichtenthaler et al., 1997). Both pathways result in the formation of precursors that react with specific terpene synthases

to produce a wide variety of VOCs. Upon formation, VOCs are typically localized to specialized secretory cells where they may be stored. In this system, the quantitative and qualitative increase in VOC emissions in response to herbivory may be the result of several mechanisms. (1) The release of novel induced VOCs may be the result of *de novo* synthesis. (2) The increased emissions of constitutive VOCs may be the result of increased synthesis due to herbivore/MeJA up-regulation of constitutive terpene synthases. (3) Increased emission of constitutive VOCs may be the result of passive release from stored pools upon tissue breakage. The high emission during active feeding suggests mechanical release can be an important means for herbivore-stimulated VOC emissions. Casual observation of *I. frutescens* leaves indicates an abundance of nonglandular stellate trichomes. No obvious specialized storage structures were detected in cross sections of leaf material; however, it was observed that simple abrasion of the leaves results in no release of odorous compounds. Mechanical disruption of the lamina (breaking leaves), however, produces an immediate burst of odorous material, suggesting internal storage of compounds. Therefore, when cells are disrupted, an immediate burst of odor indicates that mechanism (3) may be in operation. While all three mechanisms may be operating to some degree during herbivory, the results of the MeJA-treated plants suggest that mechanisms (1) and (2) are responsible for the sustained increase in VOC emissions. Constitutive as well as novel VOC emissions were significantly elevated in undamaged leaf tissue exposed to MeJA, suggesting that the elevated emissions are not simply due to passive volatilization from ruptured storage structures.

Jasmonates are potent regulators of several defense pathways in plants, and both JA and its methyl conjugate, MeJA, have been directly implicated in the regulation of VOCs in plants (Reymond and Farmer, 1998; Walling, 2000; Farmer et al., 2003). Our results indicate that *I. frutescens* responds to MeJA treatment by emitting several VOCs, some of which were detected from the herbivore-wounded *I. frutescens*, and some that were unique to the MeJA treatment. MeJA-induced multiple biosynthetic pathways in *I. frutescens* including the shikimic acid pathway (producing methyl salicylate), the octadecanoid pathway (producing *cis*-jasmonone), as well as the mevalonate-dependent and -independent terpenoid pathways (producing mono- and sesquiterpenes). MeJA stimulates these same pathways in agricultural species such as tomato, lima bean, and corn (Thaler et al., 1996; Dicke et al., 1999; Schmelz et al., 2003). Martin et al. (2003) recently demonstrated that MeJA application induced the activities of both constitutive and novel terpene synthases in Norway spruce. The up-regulation of constitutive and novel VOCs suggests that *I. frutescens* invests in the production of both constitutive and novel VOCs following herbivore attack.

The function of VOCs has been debated ever since their discovery. Terpenes may function as direct defenses by deterring herbivores (Karban and Baldwin, 1997). They may also protect vital photosynthetic material from oxidative stress, or provide thermal tolerance and UV-B protection to leaf material (Niinemets et al., 2004). VOCs can influence the behavior of herbivores as well as predators and parasitoids (Paré and Tumlinson, 1999; Heil, 2004). A large quantitative and qualitative increase in VOC emissions was detected in response to a short 4-hr feeding period. In nature, *P. aterrima* occur in high abundances. Larvae emerge in early spring (April), develop into adults by late spring (May), and continue feeding through midsummer (July). Because of these extended feeding periods by *P. aterrima*, field emissions of constitutive and induced VOCs may be even more dramatic than those detected in this laboratory assay. We speculate that while the production of large

amounts of constitutive VOCs may provide some direct defensive and/or physiological functions, the large variation in VOC emissions in response to herbivory provides a basis for trophic interactions in this system. How effective VOCs may be at serving as infochemicals to higher trophic levels has yet to be determined in this setting. However, it has been shown that constitutive VOC emissions play an important role in increasing the effectiveness of foraging parasitoid wasps (Fukushima et al., 2002). Many studies aimed at understanding the ecological function of VOCs in nature have focused on agricultural species planted in monoculture field plots. In these settings, the chemical landscape is relatively homogenous compared to a native plant assemblage. *I. frutescens* coexists with several odorous plant species that contain their own unique VOC profiles (Wang, 2001), and the background levels of VOCs in the atmosphere may be considerably more heterogeneous relative to an agricultural field. Whether herbivores and predators/parasitoids can exploit VOC emissions in this chemically complex landscape remains to be determined. *P. aterrima* specializes on *I. frutescens* (Wang, 2001), and may exploit components of *I. frutescens* VOC mixture to locate host-plant material.

While most compounds were immediately detected upon herbivory, some constitutive compounds (nonatriene) as well as the novel VOCs (*p*-cymene) exhibited a delayed emission pattern. Our results showed that nonatriene and *p*-cymene were not detected in significant quantities until 24 hr after herbivory, and peak emissions occurred 36 hr after initial herbivory. While we did not assay enzyme activity, the results suggest that novel compounds, and those showing delayed emissions may be the result of a herbivore-specific response, whereas the immediate release and increased emission of constitutive VOCs may indicate a general wound response. In some systems, herbivore oral secretions are required to stimulate emissions of novel VOCs, and these emissions are typically induced hours or days after herbivory (Alborn et al., 1997; Boumeester et al., 1999; Degenhardt and Gershenson, 2000). Furthermore, nonatriene, *p*-cymene, and oxygenated sesquiterpene 3 were not associated with the major constitutive VOC emissions in principal component space (Fig. 3). The placement of these compounds away from the major constitutive mono- and sesquiterpenes may be the result of a difference in the dynamics or regulation of their emissions. While many constitutive VOCs were released immediately in response to herbivory and rapidly waned thereafter, some constitutive and novel VOCs had a different dynamic, with prolonged sustained emissions following herbivory.

Acknowledgments We thank the Belle W. Baruch Institute for access to the field site. Special thanks to Dr. Min Wang and Dr. Randi Hansen for their assistance with transplanting of *I. frutescens*.

Abstract Experience of nonhost plants by phytophagous insects may alter their foraging and oviposition responses to these plants. Using the diamondback moth (DBM) *Plutella xylostella* (L.), its host-plant Chinese cabbage, and a nonhost-plant *Pisum sativum* (pea) as a model system, we examined whether experience of the nonhost plant by adults can induce oviposition on the nonhost plant. Naive DBM females did not accept pea for oviposition in either no-choice or choice conditions, whereas females with prior experience of pea laid up to 20% of their eggs on this plant. Naive females reduced their oviposition, but experienced females did not refrain from laying eggs in a nonhost-plant environment. Such habituation to nonhost plants could lead to host range expansion in phytophagous insects and increase mortality of pest insects in diversified crop systems.

Host range expansion · *Plutella xylostella* · *Pisum sativum*

Introduction

The modification of host selection behavior by experience is a widespread phenomenon in phytophagous insects (Papaj and Prokopy, 1989; Bernays, 1995) and insect parasitoids (Turlings et al., 1993). The experience-altered behavior allows the insects to maintain a rigid, genetically determined rank of hosts, with retained flexibility to more successfully deal with uncertainty in the environment (Papaj and Prokopy, 1989; Turlings et al., 1993; Cunningham et al., 2001). In phytophagous insects, experience-induced changes in host selection behavior by larvae, such as habituation to feeding deterrents, have been well documented (Jermy, 1987; Bernays, 1995); but experience-induced changes of oviposition behavior have been reported only in a few species (e.g., Liu et al., 2005). Using the diamondback moth

(DBM), *Plutella xylostella* L., its host-plant Chinese cabbage, and a nonhost-plant *Chrysanthemum* as a model system, Liu et al. (2005) showed that experience of a nonhost-plant extract by DBM adults resulted in a higher attraction of moths to host plants treated with the nonhost-plant extracts. These females laid more eggs on host plants treated with the extract. They speculated that this kind of habituation or induced preference for chemicals from nonhost plants may increase the tendency of insects to accept nonhost plants for oviposition and thus play a key initial role in host range expansion and the evolution of insect–plant relationships. Experiments presented here demonstrate that adult experience of a nonhost plant by a specialist herbivore can alter its oviposition behavior to accept the nonhost plant for oviposition.

Methods and Materials

Insects and Plants

The DBM culture was established from a field collection on a cabbage farm in a suburb of Hangzhou, China, and maintained on common cabbage (*Brassica oleracea* L. var. *capitata*, cultivar Jing-feng no. 1) in a temperature-controlled room at $26 \pm 1^\circ\text{C}$, 60–70% RH, and 14-hr light/10-hr dark photoperiod. The host-plant Chinese cabbage (*Brassica campestris* L. ssp. *pekinensis*, cultivar Zao-shu no. 5) and the nonhost-plant pea (*Pisum sativum* L. var. *arvense*, cultivar Qiwangyiji) were used in the oviposition tests. All experiments utilized potted Chinese cabbage grown to the fifth to sixth fully extended true leaf stage and potted pea grown to the 20th–25th fully extended true leaf stage in greenhouses. In oviposition choice tests, care was taken to use host plants and nonhost plants that had similar leaf areas.

Survival of DBM on Host and Nonhost Plants

Two hundred DBM eggs, deposited on plastic sheets, were randomly taken from the DBM culture. They were randomly divided into two cohorts of 100 each. Eggs of one cohort were placed onto four plants of Chinese cabbage, and those of the other onto four plants of pea. The two cohorts were reared in a temperature-controlled room at $26 \pm 1^\circ\text{C}$, 60–70% RH, and 14-hr light/10-hr dark photoperiod. Daily observations were made on the development, feeding, and survival of the two cohorts.

Experience Treatments

We used the following three types of experience treatments for test insects:

- (1) No experience. Insects were reared on common cabbage from egg to pupation. Pupae were collected 2–3 d after pupation and placed in a clean, ventilated cage ($55 \times 55 \times 55$ cm) for adult emergence and mating. Adults were provided with 15% honey-water as food. We collected mated females at 2–3 d postemergence for oviposition tests.
- (2) Experience after emergence. Insects were reared the same way, and adults were collected at the same age as that in (1), except that 8 hr prior to the

oviposition tests, five potted pea plants were placed into the emergence cage for the adults to experience. We collected mated females directly from the cage for oviposition tests.

- (3) Experience during and after emergence. Insects were reared on common cabbage from egg to late fourth instar, and then the mature larvae were moved manually onto pea plants to force them to pupate on the nonhost plants. Insects were left to emerge naturally on the nonhost plants. Adults were provided with 15% honey-water and enclosed with the nonhost plants in a cage. We collected mated females at 2–3 d postemergence from the cage for oviposition tests. As only chemicals experienced during and after emergence can affect adult foraging and oviposition in DBM (Liu and Liu, 2006), the treatment here was termed “Experience during and after emergence,” despite the fact that insects were placed on pea from late fourth instar onward.

Oviposition Tests

We tested oviposition by DBM females from each of the three experience treatments in two no-choice tests and one choice test:

- (1) No-choice test using host plant. One plant of Chinese cabbage was placed in the center of a ventilated cage. The cage was constructed with a frame of metal wires covered on all sides with black plastic sheets. The cage had an internal volume of $40 \times 40 \times 40$ cm with two 15×15 cm screened windows on the front and back sides for ventilation. At 19:00 hr, four females were released into each cage (no food was provided). After 12 hr in darkness at 26°C, the moths were removed, and all eggs deposited on each plant, pot, and the inner surface of the cage were counted.
- (2) No-choice test using nonhost plant. The same procedure as in (1) was used, except that pea was used as test plant.
- (3) Choice test using host and nonhost plants. One Chinese cabbage and one pea were placed in diagonally opposite corners of a ventilated cage ($55 \times 55 \times 55$ cm), so that the foliage of the two plants was approximately 20 cm apart at the closest point. At 19:00 hr, four females were released into the center of each cage. After 12 hr in darkness at 26°C, the moths were removed, and the eggs deposited on each of the two plants, the pots, and inner surface of the cage were counted.

In all, there were nine experience \times plant treatments as shown in Table 1. Ten replicates (four moths per replicate) were conducted for each treatment.

Data Analysis

Proportional data were transformed by arcsine square root for analysis of variance (ANOVA) and were back-transformed to percentages for presentation. The mean number of eggs in the nine plant (three levels) \times experience (three levels) treatments was analyzed by a two-factor ANOVA. The mean proportions of eggs deposited on host or nonhost plants were compared between the three experience treatments by using one-way ANOVA. Means were compared pairwise using the least significant difference procedure.

Table 1 Mean number of eggs laid by diamondback moths (*Plutella xylostella*) in each of the nine plant × experience treatments

Plant	Level of experience of pea			Mean ± SE of three experience treatments
	No experience	After emergence	During and after emergence	
Cabbage	120.3 ± 17.8 a ^a	103.2 ± 13.3 a,b	68.6 ± 7.4 d,e	97.4 ± 8.7 a ^b
Pea	45.9 ± 7.6 e	105.3 ± 11.4 a	61.5 ± 8.8 d,e	70.9 ± 8.7 b
Cabbage and pea	83.3 ± 8.8 b,c,d	98.7 ± 8.2 a,b,c	71.7 ± 8.6 c,d,e	84.3 ± 8.7 a,b
Mean ± SE of three plant treatments	83.1 ± 8.7 b ^c	102.4 ± 8.7 a	67.2 ± 8.7 b	

^a Means ± SE of the nine plant × experience treatments followed by the same letter do not differ significantly ($P < 0.05$).

^b Means ± SE of this column followed by the same letter do not differ significantly ($P < 0.05$).

^c Means ± SE of this line followed by the same letter do not differ significantly ($P < 0.05$).

Results

Survival of DBM on Host and Nonhost Plants

On Chinese cabbage, 95 of the 100 eggs hatched, the larvae were fed and pupated normally, and in 17 d, 68 moths in total emerged. On pea, 96 of the 100 eggs hatched but all died as first instar larvae within 2 d of hatching, although there was some feeding on the leaves by the larvae.

Number of Eggs Laid

Both test plant and experience had significant effects on the number of eggs laid (plants: $F = 4.57$, $df = 2,81$, $P = 0.013$; experiences: $F = 8.09$, $df = 2,81$, $P < 0.001$), as did the interactions of plants × experiences ($F = 3.90$, $df = 4,81$, $P = 0.006$). Females provided with Chinese cabbage laid the highest number of eggs, followed by females provided with both Chinese cabbage and pea, and then by those provided with only pea (Table 1). As for the effects of experience, females in the “After emergence” treatment laid significantly more eggs than females of the “No experience” or those of the “During and after emergence” treatments (Table 1).

The number of eggs laid on Chinese cabbage by females of the “No experience” treatment can be regarded as the normal level of oviposition by the test insects. When provided with Chinese cabbage, females of the “After emergence” treatment laid a similar number of eggs to the normal level, but the females of the “During and after emergence” treatment laid significantly fewer eggs (Table 1). When provided with pea, females in the “No experience” treatment laid only one third of the eggs, and the females of the “During and after emergence” treatment also laid significantly fewer eggs compared to the normal level; in contrast, females in the “After emergence” treatment laid a similar number of eggs to the normal level (Table 1). When provided with both Chinese cabbage and pea, females in both the “No experience” and “During and after emergence” treatments laid significantly fewer

eggs, but the females in the “After emergence” treatment again laid a similar number of eggs compared to the normal level (Table 1).

Egg Locations

In nonchoice tests using Chinese cabbage, females in the “No experience,” “Experience after emergence,” and “Experience during and after emergence” treatments laid on average 88, 77, and 82% of their eggs on the host plants, with the remainder on pots and cage surface (Fig. 1A). The proportions of eggs laid on cabbage did not differ among the three treatments ($F = 1.200, df = 2, P = 0.317$).

In nonchoice tests using pea, females in the “No experience,” “Experience after emergence,” and “Experience during and after emergence” treatments laid on average 4, 26, and 18%, respectively, of their eggs on the nonhost plants, with the remainder on pots and cage surface (Fig. 1B). The proportions of eggs deposited on pea differed among the three treatments ($F = 4.046, df = 2, P = 0.029$). The proportion of eggs laid on pea by females in the “Experience during and after emergence” treatment was higher than that of the “No experience” treatment ($P = 0.009$; Fig. 1B). The proportion of eggs laid on pea by females in the “Experience

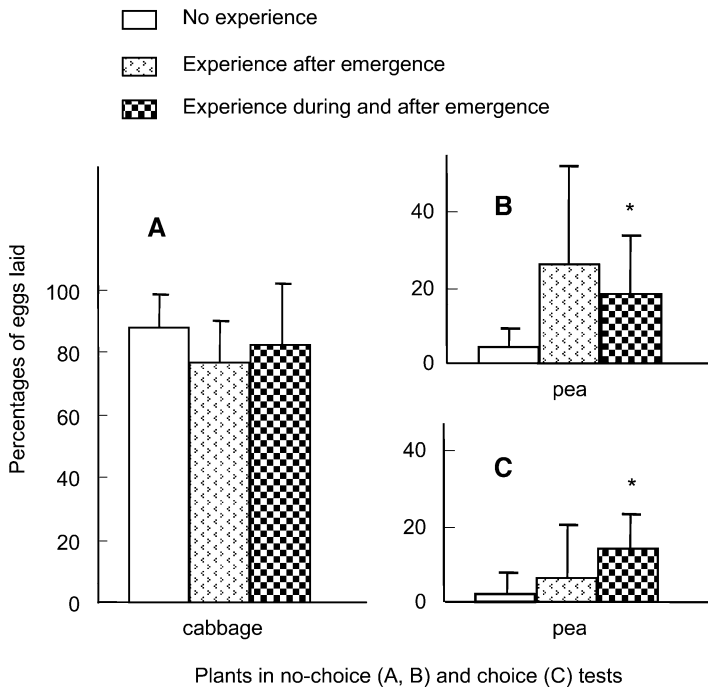

Fig. 1 Oviposition by naive and experienced *Plutella xylostella* females on host and nonhost plants in no-choice and choice tests. (A) Percentages of eggs laid on Chinese cabbage (of the total number of eggs laid on the plants and cages) in no-choice test. (B) Percentages of eggs laid on pea (of the total number of eggs laid on the plants and cages) in no-choice test. (C) Percentages of eggs laid on pea (of the total number of eggs laid on the Chinese cabbage and pea plants) in choice test. Error bars indicate standard deviation, and an asterisk above the column in a diagram indicates significant difference between that treatment and no experience ($*P < 0.05$)

after emergence” treatment was apparently higher than that of the “No experience” treatment, but the difference between the two treatments was not significant because of large variation among replicates ($P = 0.081$; Fig. 1B).

In choice tests using Chinese cabbage and pea, females in the “No experience,” “Experience after emergence,” and “Experience during and after emergence” treatments laid on average 83, 79, and 80%, respectively, of their eggs on the two plants, with the remainder on pots and cage surface. Of the eggs laid on the two plants, the average proportions of eggs laid on pea were 2, 6, and 14% for females in the three experience treatments, respectively, (Fig. 1C; $F = 3.457$, $df = 2$, $P = 0.046$). Compared to the proportion of eggs laid on pea by females of “No experience” treatment, the proportion of the “Experience during and after emergence” treatment was significantly higher ($P = 0.015$), but that of the “Experience after emergence” treatment was not ($P = 0.364$).

Discussion

Survival of DBM on the two plants indicated that the pea cultivar used in this study is a nonhost plant of the local DBM population. Naive DBM females generally did not accept pea for oviposition in either no-choice or choice conditions, whereas females with prior experience of pea laid a significant proportion of eggs on this nonhost plant (Fig. 1). Thus, experience of a nonhost plant by adults of a phytophagous insect can produce significant habituation and alter its foraging/oviposition responses to lay eggs on the plant.

The females in the “During and after emergence” treatment laid a lower number of eggs than those of the other two experience treatments. Pupae and adults were apparently smaller, but we missed the opportunity to take measurements of body size and lifetime fecundity of the test insects. The reduction in size and subsequently fecundity were apparently caused by insufficiency of food during the late fourth instar. Because of the experimental procedure, we had to move the fourth instars from cabbage onto pea before they completely stopped feeding. Thus, mature larvae were imposed to food limitation. It is possible that the negative impact of the partial food limitation on fitness of the test insects might have also contributed to the change of oviposition preference and the increased acceptance of the nonhost plant for oviposition. The effect of larval food availability and/or quality on fitness parameters, such as body size, fecundity, and survival, has been extensively studied for insects (Honěk, 1993; Boggs and Freeman, 2005). However, to our knowledge, the effect of larval food limitation on oviposition preference between plants has not been examined for DBM or any other insects. The latter effect warrants experimental investigation. In nature, pupation on nearby nonhost plants may occur. We have occasionally encountered pupae of DBM on pea and cucurbit plants next to a cabbage field, especially when all cabbage plants in a large plot surrounded by noncrucifer crops are suddenly harvested (unpublished data).

When provided with only the nonhost-plant pea, naive females drastically reduced their oviposition, whereas experienced females did not. They laid 26% of their eggs on the nonhost plant (Table 1, Fig. 1). These results indicate that females with prior experience of a nonhost plant are less likely to refrain from laying eggs in

a nonhost-plant environment than naive females, which constitutes part of the experience-induced physiological/behavioral changes conducive to oviposition on nonhost plants.

Many phytophagous insects are capable of including new plant species within their diets, although the causes and rates of host-plant range expansion are poorly understood (Strong, 1979; Schoonhoven et al., 1998; Liu et al., 2005). In nature, adult females may repeatedly encounter nonhost plants during host foraging, depending on the distribution and abundance of plants in the landscape and their movement behavior. The results from this study suggest that experience may induce some females to lay large number of eggs on nonhost plants. There is often substantial individual variability in larval survival (Zalucki et al., 2002), and in many species, larvae can feed and survive on plants that are not usually accepted as oviposition substrates by adult females (Schoonhoven et al., 1998; Janz et al., 2001). If some of the offspring show an increased acceptance for the novel host plants as a result of either an inherited or a conditioned behavior, further oviposition on novel hosts could be the first step of a host range expansion (Larsson and Ekblom, 1995). Numerous studies of insect–plant associations have provided a general pattern of strong predominance of specialists over generalists and a strong taxonomic conservatism in host-plant utilization (Schoonhoven et al., 1998). However, studies on the issue of directionality in host range evolution have produced mixed results (Termonia et al., 2001; Janz, 2002). Evidence has been accumulating to suggest that host range is dynamic, evolving through repeated phases of expansion and contraction (Janz et al., 2001; Janz, 2002). Learning in oviposition, including habituation to nonhost plants as demonstrated in this study, may play an important role in assisting insects to explore new host plants when the herbivores are in the evolutionary phase of host range expansion.

The ability of the Hangzhou DBM population to survive on pea was tested with a limited number of individuals of both insects and plants. The variation of survival among individuals of the local DBM population needs to be investigated with large number of field-collected individuals and a range of cultivars of pea. Gupta and Thorsteinson (1960) recorded a low level of survival on pea in a Canadian DBM population in the laboratory. Recently, Löhr and Rossbach (2004) found a field DBM population on pea crops in Kenya and demonstrated that this population could survive well on both pea and kale.

This study suggests that even the so-called specialist phytophagous insects may show strong experience-induced responses to nonhost plants, and it also questions the conserved nature of oviposition preference, which is fundamental to weed biological control. Experience-altered foraging and oviposition behavior must be carefully considered in host specificity tests for selecting weed biological control agents (Bellows and Headrick, 1999).

In agricultural ecosystems, increase of vegetation diversity has often resulted in reduction of abundance of monophagous insect pests (Andow, 1991). In polyculture crop systems, insect pests may lay large number of eggs on nonhost crops, and large number of eggs laid on nonhost crops can contribute to increased mortality of monophagous insect pests (Ampong-Nyarko et al., 1994). Depending on the spatial arrangement of plants, the scale of the intercrops, and the movement ambit of the insects, intercropping may lead to repeated encounter of nonhost plants by the insects. Experience-induced habituation or preference for nonhost plants may be an

important mechanism contributing to oviposition on nonhost plants in these circumstances. To reduce the likelihood of host range expansion by insect pests, different nonhost plants may be alternated between seasons to suppress any survival on the nonhost crops.

Abstract Recognition of cabbage as a host plant for the diamondback moth (DBM) has previously been shown to depend on compounds that are extracted by soaking intact foliage in chloroform. Analysis of such chloroform extracts by open column chromatography has now resulted in the isolation of highly active fractions that elicit oviposition on treated filter papers. Further separation of these fractions by high-performance liquid chromatography revealed the presence of two distinct groups of active compounds that may be classified as volatile and non-volatile. The two prominent volatile components were separated and identified by mass spectrometry as the isothiocyanates, iberin (3-methylsulfinylpropyl isothiocyanate) and sulforaphane (4-methylsulfinyl-3-butenyl isothiocyanate). Subsequent bioassays of a range of isothiocyanates showed that iberin and sulforaphane were the most active of those tested. Other isothiocyanates with sulfur in the side chain were also active, whereas alkyl and phenyl isothiocyanates had only limited activity. In electrophysiological experiments, electroantennograms (EAGs) indicated positive responses of moth antennae to the isothiocyanates that were most active in behavioral assays. Since sulforaphane has been identified as a major inducer of anticarcinogenic activity in mouse tissue, a synthetic analog (exo-2-acetyl-5-isothiocyanatonorbornane) that shows similar inducer activity was tested on DBM. This bicyclic analog was highly active in both behavioral and EAG assays, suggesting similarity in receptor sites for the two types of biological activity.

Introduction

The diamondback moth (DBM), *Plutella xylostella* L. (Lepidoptera: Plutellidae), is a major pest of cruciferous crops on a worldwide basis and has developed resistance to most insecticides, including *Bacillus thuringiensis* (Talekar and Shelton, 1993). Efforts to find new natural approaches to control this insect have focused on understanding the plant chemistry that plays a major role in acceptance or rejection of potential host plants. The involvement of glucosinolates in host recognition has been suggested by several studies (Gupta and Thorsteinson, 1960; Reed et al., 1989; Renwick and Radke, 1990). Furthermore, a synergistic effect of leaf waxes with a glucosinolate or with cabbage homogenates was demonstrated by Spencer (1996) and Spencer et al. (1999). Also, the involvement of plant volatiles in attracting moths to their host plants was shown by Palaniswamy et al. (1986) and by Pivnick et al. (1990), but no attempts to identify active compounds were reported.

More recent studies have shown that potent oviposition stimulants for the DBM are extracted from cabbage foliage by soaking the intact leaves in chloroform (Hughes et al., 1997). A bioassay was developed whereby thousands of eggs were laid on filter papers treated with the extracts or with active fractions from an open column separation. However, sufficient separation was not obtained for identification of the active constituents at that time. Here, we report on the identification of two volatile compounds that account for much of the activity. Tests were performed to examine structure–activity relationships, and electrophysiological studies were conducted to determine the sensory mode of detection of these compounds by the moths.

Methods and Materials

Plants and Extracts

Cabbage plants, *Brassica oleracea* L. var. Golden Acre (Agway, Inc., Syracuse, NY, USA) were grown from seed in an air-conditioned greenhouse at 23/19°C day/night with a 16 hr photophase. Supplemental lighting was provided by 400-W multivapor, high-intensity discharge lamps (General Electric MV 400/VBU). Plants were generally 4–5 wk old when used for extraction. One kg of intact leaves was immersed in approximately 3 l of chloroform for a period of 1.5 hr. The resulting extract was separated from leaf water and evaporated to a small volume for chromatography.

Insects

P. xylostella moths used for behavioral assays were from a laboratory colony maintained in Ithaca, NY, as previously described (Hughes et al., 1997). For the

electrophysiological recordings in Switzerland, the insects came from the laboratory culture at Wädenswil that was established with approximately 200 individuals during spring of 2000 and reared as described by Marazzi and Städler (2004). Briefly, an equal number of male and female mature moths (approximately 100 per cage) was placed in mesh cages (50 × 45 × 45 cm) in a climate-controlled room (21 ± 1°C, 70% RH and 16 hr photophase), where they were allowed to mate and oviposit only on the leaves of potted *B. napus* cv CC-Cross F1 at the prebolt stage. The moths had access to a source of water and to 10% sugar water.

Behavioral Assays

Extracts and fractions were tested for activity using recently emerged moths (approximately 150 mixed sexes) in 31 × 31 × 31 cm screened cages. Moths in each cage were provided with a 10% sucrose solution. Test material representing 1 g leaf equivalent (gle) was applied in chloroform solution to 5.5-cm-diam. filter paper disks, and chloroform alone was applied to control disks. After air drying, the treated filter papers were weighed (±0.0001 g), and two treated and two control disks were placed on small plastic supports in opposite corners of each cage. After overnight exposure to the moths (approx. 15 hr), test filter papers were weighed to provide an estimate of the number of eggs laid, based on an average weight of 0.0000195 g per egg. Active fractions generally received more than 3000 eggs in this time period.

Known isothiocyanates were tested in the same way, using 250 µl of a 0.1 µg/µl chloroform solution to deliver 25 µg of test compound per disk. Relative activity of each isothiocyanate was determined in choice assays, using allyl isothiocyanate (ANCS) as control. Based on these comparative assays, activity was expressed as an oviposition preference index (OPI), where $OPI = 100 (T - ANCS) / (T + ANCS)$, where *T* is the number of eggs laid on the test compound and ANCS is the number of eggs laid on the control.

Chemicals

All of the common aliphatic and aromatic isothiocyanates for behavioral studies (Fig. 1) were obtained from Sigma-Aldrich Corp (St. Louis, MO, USA). Iberin and sulforaphane were from LKT Laboratories (St. Paul, MN, USA) and the sample of bicyclic ketal (Posner #23) was a gift from Dr. Gary H. Posner of Johns Hopkins University, Baltimore, MD, USA. For electroantennograms recorded in the Wädenswil Laboratory, analytical quality allyl (2-propenyl) as well as benzyl, butyl, and methyl isothiocyanates were obtained from Fluka Chemicals, Basel, Switzerland.

Isolation and Identification of Active Compounds

Chloroform extracts of cabbage were separated by open column and medium pressure chromatography on silica gel as previously described (Hughes et al., 1997). Using stepwise elution with increasing concentrations of chloroform in hexane, followed by methanol in chloroform, two active fractions, A and B, were obtained.

Fig. 1 Structures and common names of compounds tested for activity in stimulating oviposition and for electrophysiological responses of DBM. *: Not included in EAG experiments

Fraction A eluted in 30:70 chloroform/hexane, whereas B eluted in 4:96 methanol/chloroform. The active fractions were subjected to high-performance liquid chromatography (HPLC) using a Waters instrument fitted with a Phenomenex analytical column, Luna 5 μ silica, 1.0 \times 250 cm, with a flow rate of 1.0 ml/min. A diode array detector was used to monitor elution at 254 nm and to provide UV spectra of detected compounds. A solvent gradient of methanol in chloroform was used as follows: 0% methanol from 0 to 5 min, 3.0% MeOH at 17 min, 10.0% MeOH at 35 min, and 10.0% MeOH at 45 min.

The high-resolution electron impact mass spectra (HREIMS) and MS–MS were recorded on an AutoSpec (VG Analytical Instruments, Manchester, UK) instrument. The sample was introduced through a direct probe insert, and mass spectral data were collected at a temperature gradient of 70–350°C. The positive low-resolution electron spray ionization mass spectra (LRESIMS) and MS–MS were recorded on a VG Quattro (Micromass UK) instrument. The sample was introduced directly through a syringe pump at a flow rate of 200 $\mu\text{l/hr}$.

Electrophysiological Recordings

All isothiocyanates were dissolved in hexane (Fluka, GC grade, Buchs) to prepare six concentrations (1×10^{-5} , 1×10^{-4} , 1×10^{-3} , 1×10^{-2} , 0.1, 1 mg/ml).

Freshly emerged females were cooled in a refrigerator (5.5°C) for 15 min to reduce their activity. The wings and legs of the cooled insects were amputated, and the body was mounted ventral side up in the groove of a Plexiglas® holder and positioned so that the antennae were attached to a sticky wax layer, using strips of adhesive tape. The preparation was mounted under a stereomicroscope and continuously humidified with a water-saturated air stream (1 m s^{-1} , room temperature $\approx 22^\circ\text{C}$). These preparations showed good longevity, and it was possible to obtain strong responses for over 1.5 hr, allowing plenty of recording time. For the stimulation, we basically used the same method described by Guerin and Visser (1980). In brief, the airflow was split into continuous and stimulatory air streams in a 9:1 ratio, which converged prior to reaching the preparation. The stimulatory air stream passed through a Pasteur pipette (20 mm tip diam) containing the test compound in 100 μl paraffin oil spread on a folded filter paper ($15 \times 50 \text{ mm}$, from Schleicher and Schuell). The amount of an individual isothiocyanate in the air stream reaching the antenna is dependent on its partial vapor pressure, but this value can be kept constant by dissolution in paraffin oil (Kafka, 1970). It was injected into the continuous air stream upon activation of a valve. The indifferent electrode, filled with a saline solution (Kaissling, 1995), was inserted into the head, and the recording electrode, containing saline was brought into contact with the antennal tip. The EAG signal was recorded using a lab-built amplifier with high input impedance ($10^{13} \Omega$) and low bias current ($<10 \text{ pA}$). The signals were filtered (electronic high-pass with cornering frequency of 0.001 Hz), amplified (100 times), and digitized using Superscope II 3.0 Software (GW Instruments, Somerville, MA, USA) on a Macintosh computer. The EAG amplitudes were determined using PowerChrom v2.2.4 software (AD Instruments, Colorado Springs, CO, USA). Responses to the concentration series of each isothiocyanate were measured, from the lowest to the highest concentration; isothiocyanates were presented in a randomized order. We also tested the pure solvent to check that it did not elicit a strong olfactory response. Before and after running each concentration series, we recorded the response to 100 μg (*E*)-2-hexenal on filter paper (as described above). The data were analyzed by calculating the mean amplitude of the five responses to each tested combination of compound and concentration, then dividing this value by the average amplitude of the associated response to (*E*)-2-hexenal. This standardized the data to control for changes in preparation sensitivity over time.

Results

As previously reported, medium-pressure silica gel chromatography yielded two major active fractions that eluted with 30% chloroform in hexane (A) and 4% MeOH in chloroform (B). When these fractions were further separated by HPLC, fraction A revealed the presence of two major groups of UV-absorbing compounds that could not be completely separated, and, thus, no meaningful spectral data could be obtained. However, fraction B yielded clear peaks that were well separated (Fig. 2). Collection and assay of individual compounds and groups of compounds showed that the combined compounds eluting at 20.5–22.0 min as well as compounds **1** and **2** at 24.3 and 24.9 min were highly active in stimulating oviposition. Since the other groups of compounds could not be easily separated, further studies focused on compounds **1** and **2**.

High vacuum separation using a sublimation apparatus showed that compounds **1** and **2** are volatile, whereas other constituents of fraction B remained in the nonvolatile residue. The UV spectra of **1** and **2** were similar, with absorption maxima at 227 and 245 nm, which is typical of isothiocyanates. The positive HREMS of compound **1** gave a quasimolecular ion at m/z 164.020383 ($M + H$)⁺ and its sodium adduct at 186.002327 ($M + Na$)⁺, suggesting a molecular formula (MF) of C₅H₉S₂ON. The presence of sulfur was confirmed by a peak at m/z 166 ($M + 2 + H$)⁺ and its abundance in relation to m/z 164. In MS–MS, a molecular ion m/z 164 gave daughter ions at m/z 132, 130, 105, and 100. Similarly, the ion m/z 166 gave peaks at 134, 107, and 100. This suggested that fragments at 132 and 105 still retained at least one sulfur atom. On the basis of the fragmentation results, we identified this compound as iberin. This was further substantiated by comparing its NMR (in CDCl₃) spectrum with reported literature values (Kore et al., 1993) and by comparing its retention times on GC and HPLC with those of an authentic sample of iberin. The MS fragmentation pattern also matched that of the authentic sample.

Fig. 2 HPLC separation of active fractions A and B from open column chromatography. Volatile compounds with strong activity are designated as **1** and **2**

The mass spectrum of compound **2** gave a quasimolecular ion at m/z 178.02 for $(M + H)^+$ in LRESIMS, and had a similar fragmentation pattern to that of **1**. The combined MS and UV spectral properties suggested that this compound was sulforaphane. The identity of compound **2** was confirmed by comparing its MS, as well as retention times, on HPLC and GC with those of authentic sulforaphane.

When authentic samples of iberin and sulforaphane were tested in bioassays, both isothiocyanates were highly active as stimulants. Comparative assays of a range of isothiocyanates were then conducted using allyl isothiocyanate (ANCS) as a standard. Tests of ANCS showed that this representative had limited activity when compared to iberin and sulforaphane. The comparative assays showed that methyl, ethyl, propyl, and phenyl isothiocyanates were considerably less active than ANCS (Fig. 3). Butyl and benzyl isothiocyanates had activity that was similar to that of ANCS, but sulforaphane, iberin, and iberberin were much more active than the standard (Fig. 3). Sulforaphane was previously identified as a major inducer of anticarcinogenic activity in mouse tissue (Zhang et al., 1992), and several isothiocyanate analogs with additional functional groups were subsequently found to have similar anticarcinogenic activity (Posner et al., 1994). One representative of these analogs, *exo*-2-acetyl-5-isothiocyanatonorbornane, was included in our oviposition assays, and this bicyclic ketal (referred to as Posner #23) also showed high activity when compared with ANCS (Fig. 3).

Electrophysiological recordings from DBM antennae provided EAGs that were in good agreement with behavioral responses. When tested at a medium dose of 10^{-3} to 10^{-2} mg, the most active isothiocyanates were the sulfur-containing iberin,

Fig. 3 Stimulation of DBM oviposition by isothiocyanates relative to that by allyl isothiocyanate (ANCS). Preference indices were calculated from egg distribution in separate choice tests between ANCS and each compound

Fig. 4 EAG responses of DBM antennae to 10- μ g samples of isothiocyanates, in relation to a standard response to *trans*-2-hexenal

Fig. 5 Responses of DBM antennae to increasing doses of tested isothiocyanates

sulforaphane, iberverin, and the bicyclic keto analog (Posner # 23). The least-active representatives were methyl and allyl isothiocyanates, whereas phenyl isothiocyanate gave an intermediate response, and phenethyl isothiocyanate was highly stimulatory (Fig. 4). However, at higher doses of 10^{-1} to 10^{-0} mg, saturation of olfactory neurons by some compounds was apparent (Fig. 5). The almost perfectly linear relationship of EAG response to increasing concentrations of Posner # 23 was particularly striking, although the highest dose (1 mg) of this compound was not available and could not be tested.

Discussion

Recognition of cabbage as a host plant by ovipositing DBM females is dependent on perception of a combination of chemicals at or near the surface of foliage. However, the results of this study show that highly active individual constituents may be just as effective as total extracts. Although nonvolatile constituents are involved (Renwick and Radke, 1990; Spencer, 1996), volatile compounds apparently play a key role in stimulating oviposition, either before or after contact with the leaf surface. Our identification of the volatile isothiocyanates, iberin and sulforaphane, as the most prominent volatile compounds in active fractions provides additional evidence to support the idea that these moths may already recognize host plants while in flight (Bukovinszky et al., 2004).

The involvement of isothiocyanates in host recognition is not surprising. However, the presence of these compounds at the leaf surface or their release from intact foliage has not been reported previously. Isothiocyanates are released as hydrolysis products of glucosinolates, which are characteristic glycosides in crucifers. However, this hydrolysis is believed to occur only when foliage is disrupted by insect feeding or mechanical damage (Städler, 2002). The concentrations of isothiocyanates in the headspace above undamaged crucifer plants are known to be extremely low (Finch, 1978; Tollsten and Bergström, 1988). However, host recognition by another crucifer specialist, the cabbage root fly, has been shown to involve detection of these low levels of volatiles (De Jong and Städler, 1999). The presence of iberin and sulforaphane in chloroform extracts of intact foliage would now suggest that they are readily available at or near the leaf surface and may in fact be released in small quantities from foliage in the field. However, we cannot discount the possibility that compounds may leak from the cut petioles of the leaves, or that some kind of chloroform-induced tissue damage occurs.

The apparent synergy between a glucosinolate and wax in stimulating oviposition by DBM (Spencer, 1996; Spencer et al., 1999) may now be explained by the likely presence of small quantities of isothiocyanate from spontaneous degradation of the glucosinolate, sinigrin. The allyl isothiocyanate released might be adsorbed to the wax, which could then act as a slow release substrate and result in increased oviposition. On a test substrate, in the absence of wax, the stimulatory isothiocyanate would evaporate before significant oviposition could occur.

Preliminary behavioral assays of authentic isothiocyanates indicated intermediate activity for allyl isothiocyanate. When this representative was used as a standard for comparison, it was clear that iberin, sulforaphane, and iberverin were extremely active, whereas the alkyl representatives, methyl, ethyl, and propyl, were less active

than the standard. The most active compounds are characterized by the presence of sulfur, as thio, sulfinyl, or sulfonyl, in the side chain. When the bicyclic keto-isothiocyanate (Posner #23) was tested, this analog had high activity that was comparable to that of the sulfur-containing representatives. This compound is one of several bifunctional analogs of sulforaphane that were found to be potent inducers of anticarcinogenic detoxication enzymes in mouse tissues and murine hepatoma cells (Posner et al., 1994). These authors found that the most potent anticarcinogenic analogs were those isothiocyanates in which the isothiocyanate group was separated from a methyl sulfonyl or an acetyl group by three or four carbons. It appears, therefore, that the structure–activity relationship for DBM stimulation and for anticarcinogenic activity is remarkably similar.

EAG recordings in response to the various isothiocyanates verified the fact that olfaction is the mode of perception of these stimulants. Independent experiments have shown that volatiles from differently fertilized *Brassica* plants play an important role in host selection of ovipositing DBM females (Marazzi and Städler, 2004). Furthermore, the most active stimulants in our study evoked the highest levels of electrophysiological activity. The high activity of sulforaphane, iberin, iberberin, and Posner #23 mirrored the behavioral responses to these compounds. The response to phenyl isothiocyanate, which was relatively inactive in behavioral assays, and to phenethyl isothiocyanate (not available for behavioral assays) may be explained by the fact that EAG responses may be positive or negative. In addition, EAG responses are likely to be higher in response to more volatile members of the series. No attempt was made to compensate for differences in volatility of the different compounds. The most active compounds in behavioral tests are actually among the least volatile of the group. It is likely, therefore, that the EAG results would be more dramatic if the actual dose reaching the antenna were to be more precisely controlled. Lower activity of the most volatile compounds in behavioral assays might be expected as a result of rapid dissipation during the test period, but no evidence of reduced activity after a 15 hr exposure was observed.

The correlation between structural features required for oviposition stimulating activity and anticarcinogenic activity is remarkable. The extensive structure–activity experiments for anticarcinogenic activity that were conducted by the Johns Hopkins Group (Posner et al., 1994) showed the superiority of the sulfur-containing compounds that, we now find, are most active as oviposition stimulants. Although only one of the synthetic bicyclic analogs was available for our experiments, the behavioral and electrophysiological responses to this compound appear to confirm that the same molecular characteristics are required for activity. The close similarities in requirements for the two types of biological responses suggest that the receptors involved have features in common.

Our study was restricted to a continuation of previous work on cabbage, *B. oleracea*. However, subsequent investigations have shown that similar soaking of foliage of several other crucifers in chloroform provides highly stimulatory extracts. Extracts of those species that produce glucosinolates with sulfur in the side chain appear to be particularly active (Renwick, unpublished data). Since the glucosinolate composition of crucifers varies widely, it is likely that other isothiocyanates are responsible for most of the activity in other plants. Recent studies on the attractiveness of *Barbarea vulgaris* to DBM have focused on the possible use of this plant as a trap crop, since the hatching larvae do not survive (Badenez-Perez et

al., 2005). Although the involvement of volatiles has been suggested (Lu et al., 2004), the compounds responsible for high levels of oviposition and the types of isothiocyanates released from this plant have yet to be determined. Glucosinolate analyses of *Barbarea vulgaris* have shown that phenethyl is the only glucosinolate that would yield an isothiocyanate upon hydrolysis (Agerbirk et al., 2001; Windsor et al., 2005), and autolysis of foliage results in the release of traces of phenethyl as well methyl thioalkyl and allyl isothiocyanates (Cole, 1976). However, we have no evidence to indicate that the isothiocyanates released into chloroform are dependent on the glucosinolate composition of the plant.

The involvement of sulfur-rich compounds in DBM oviposition has been further indicated by fertilization experiments. *Brassica napus* plants that received higher rates of sulfur fertilization were preferred for oviposition by the moths. Methanolic surface extracts of the *B. napus* foliage produced EAG responses that were higher in the case of fertilized plants (Marazzi et al., 2004), although isothiocyanates were not detected within the threshold limits of the GC-MS system that was used.

Future studies on chloroform extracts of foliage from *Barbarea vulgaris* and other highly attractive crucifers are likely to reveal additional isothiocyanates that play a role in host recognition by the DBM. However, the involvement of sulforaphane and related compounds that have important physiological activity in mammals would suggest that comparative results from assays might reveal structure–activity relationships that could have wider biological applications. Additional work on the DBM will be required to identify nonvolatile constituents of host plants involved in the sequence of events leading to host selection by this important worldwide pest.

Acknowledgments We are indebted to Gary H. Posner of the Johns Hopkins School of Medicine for providing a sample of the bicyclic ketone. We thank Athula Attygalle for help with mass spectral analyses. We also thank two anonymous reviewers for helpful comments. Abstract The subsocial tenebrionid *Parastizopus armaticeps* Pér. is parasitized by the closely related *Eremostibes opacus* Koch (Coleoptera: Tenebrionidae). We found that the pygidial defensive secretions of both species are similar and contain a mixture of 1,4-benzoquinones, 1-alkenes, and monoterpene hydrocarbons. The 1-alkenes are dominated by 1-undecene, with admixtures of 1-tridecene in both species and 1-pentadecene in *P. armaticeps* only. Methyl- and ethyl-1,4-benzoquinone are the major quinones of the secretions of both species. The monoterpene fractions consist of (–)- α -pinene, (–)-camphene, sabinene, (–)- β -pinene, and (–)-limonene. Volatiles trapped with Porapak Q at the entrance to the breeding burrows of *P. armaticeps* were identified as components of the defensive secretion. However, in contrast to the secretion, the 1,4-benzoquinones were almost completely absent in the volatiles. Bioassays investigating attraction showed that the cleptoparasite *E. opacus* was drawn to the monoterpene hydrocarbons, produced by *P. armaticeps*, and deterred by the 1,4-benzoquinones. The 1-alkenes had no effect. Among the monoterpenes, only (–)-camphene was attractive to *E. opacus*. This is one of the rare cases of chemical exploitation of defensive allomones, and the first based on odor homology. We have drawn an evolutionary scenario

Introduction

“...predatory and parasitic arthropods are able to intercept the sex [and aggregation] pheromone signals of their prey or hosts” (Stowe et al., 1995), and there are a few cases where less specific allomones (e.g., defensive secretions) are known to be used as kairomones (Eisner et al., 1991; Mattiacci et al., 1993; Aldrich and Barros, 1995; Krell et al., 1997). Defensive secretions of arthropods, however, may have various additional functions in intra- and interspecific communication (Blum, 1996) and could, therefore, be eavesdropped by predators or parasites.

The nocturnal detritivorous desert tenebrionid *Eremostibes opacus* Koch lives in close association with the larger subsocial *Parastizopus armaticeps* Pér. of the same subtribe Stizopina (Rasa, 1994). During the dry season, both species are found together in burrows that the bigger *P. armaticeps* has excavated. The smaller *E. opacus* has either no effect or a positive effect on *P. armaticeps* by reducing the average transpiration rate per beetle in the burrow (Helsberg, 1994). During the breeding season of *P. armaticeps*, however, which starts after heavy rainfalls, *E. opacus* becomes a cleptoparasite (Rasa, 1996). This is based on the specific reproduction behavior of the host species.

P. armaticeps shows biparental brood care and division of labor (Rasa, 1990). A pair digs a breeding burrow together, and, after larval hatch, the female collects detritus at night and deposits it at the entrance to the burrow. The male stays in the burrow and pulls the food down into the burrow to form a food cache on which the larvae feed and continues to excavate the burrow and guard the entrance. The individuals of *E. opacus* gain admittance to breeding burrows by chemical mimicry based on cuticular hydrocarbons Geiselhardt et al., (in press). They feed on the food cache, and invading females lay their eggs there. The larvae inhabit the sand layer under the food cache and pull down items into the sand to feed.

E. opacus is specific to the host *P. armaticeps* and must find the burrows of *P. armaticeps* among the burrows of other fossorial arthropods, such as scorpions, millipedes, or other tenebrionids (Rasa, 1994). Choice experiments have shown that *E. opacus* is attracted to the odor of *P. armaticeps*, but *E. opacus* is unable to distinguish between the odor of *P. armaticeps* and conspecifics, whereas the odor of the sympatric tenebrionid *Gonopus agrestis* is avoided (Rasa, 1994). Rasa (1994) hypothesized that *E. opacus* host specificity is based on an odor homology within the tribe Opatrini.

To test this hypothesis as a basis for the cleptoparasitic relationship, we (1) analyzed and compared the defensive secretions of *P. armaticeps* and *E. opacus*, (2) adsorbed the volatiles from breeding burrows of *P. armaticeps* using Porapak Q, and (3) conducted a choice experiment to test the response of *E. opacus* to synthetic

blends and single volatiles of the *P. armaticeps* defensive secretion to identify the host-finding kairomone.

Methods and Materials

Beetles

P. armaticeps and *E. opacus* originated from Twee Rivieren, Kalahari Gemsbok National Park, South Africa, and were bred in the laboratory. Each species was kept in a separate terrarium containing Kalahari sand, hiding places, and a water source. They were fed with oat flakes or *Lebeckia linearifolia* (Fabaceae), which is their natural food plant.

Collection of Defensive Secretion

Defensive secretions were milked from beetles by holding a small piece of filter paper against the junction of the elytra and the anal sternite (Brown et al., 1992). The filter papers were extracted in 0.5 ml *n*-pentane.

Chemical Analysis

Samples for quantification were analyzed on an HP 6890 gas chromatograph (GC) equipped with a split/splitless injector (300°C) and an autosampler (injection of 1 μ l). A fused silica column (DB-1, 30 m \times 0.25 mm ID, 0.25 μ m, J&W Scientific, Folsom, CA, USA) was used with a helium flow of 1 ml/min. The oven temperature was programmed as follows: 2 min at 50°C, to 250°C at 6°C/min, to 300°C at 20°C/min. The FID was operated with 40 ml H₂/min and 450 ml air/min at 300°C.

Chemical identifications were performed on a coupled gas chromatography–mass spectrometer system (HP 6890 series GC-HP 5973 MSD) under the same GC conditions. Electron impact ionization was 70 eV.

To determine the configuration of the monoterpenes, authentic standards of (+)- or (–)-enantiomers [all from Fluka, except (+)-camphene from Merck] were added to the defensive secretions of *P. armaticeps* and *E. opacus*. Each standard was adjusted to the equivalent of the corresponding monoterpene in the defensive secretion. A β -DEX™120 fused silica column (30 m \times 0.25 mm ID \times 0.25 μ m, Supelco, D-Deisendorf) was used for enantiomeric separation. The oven temperature program was 2 min at 35°C, to 270°C at 5°C/min, held for 15 min.

Collection of Volatiles

Glass terraria (30 \times 20 \times 20 cm) were equipped with PVC inserts (27 \times 17 \times 10 cm) so that a 1-cm gap was left at each side. This gap was filled with moist Kalahari sand, and a thin layer of sand was spread on the top of the roof of the insert to provide an area over which the beetles could walk. A pair of *P. armaticeps* was placed in each terrarium and sprayed with water to stimulate them to dig a breeding burrow. The beetles were supplied with *Lebeckia ad libitum*.

The collection of volatiles was started once the beetles had dug a burrow at least 10 cm long or when larvae were present. A glass tube (2 mm ID, 9 cm long), packed with 1 cm Porapak Q (80/100 mesh, Waters Corporation, Milford, MA, USA 01757), was placed at the burrow entrance, as near as possible without disturbing the beetles. Each tube was connected to a vacuum pump (DC12/08NK, Fürgut, D-Aichstetten), and the airflow was adjusted to 100 ml/min. Volatiles were collected for 23 hr, and 10 samples were obtained for each burrow over a period of 30 d. For quantification, we used the mean total amounts of the 10 samples from each burrow. To determine the amount evaporated during the bioassays, we adsorbed the volatiles with the same method as for breeding burrows, but this time at the entrance of the bioassay boxes ($N = 10$). The rubber septa in the boxes were spiked with defensive secretion of *P. armaticeps* at the concentration equivalent to that of one beetle. Collection time was 6 hr (duration of bioassay). All experiments were conducted in an environmental chamber (GEA AG, D-Bochum) with a constant temperature of 30°C and a 14:10 hr light/dark regime.

Trapped volatiles were eluted by dripping 0.5 ml of *n*-pentane through the tubes. To each sample, 10 μ l of an internal standard [*n*-tetradecane (Fluka), 100 μ g/ml] were added, which was then concentrated to 50 μ l in a N_2 stream.

Synthetic Blends for Bioassays

“Terpene blend”: (–)- α -Pinene, (–)-camphene, (–)- β -pinene, and (–)-limonene (all from Fluka, purity >99%) were mixed in a ratio of 1:5:8:21, respectively, and 35 μ l of the mixture were added to 965 μ l of *n*-pentane. The concentrations of individual monoterpenes were 1 μ l/ml for (–)- α -pinene, 5 μ l/ml for (–)-camphene, 8 μ l/ml for (–)- β -pinene, and 21 μ l/ml for (–)-limonene.

“Alkene blend”: 1-Undecene (Sigma), 1-tridecene (Sigma), and 1-pentadecene (Fluka) were mixed in a ratio of 10:1:1, respectively, and 175 μ l of the mixture were added to 825 μ l of *n*-pentane.

“Quinone blend”: 1,4-Benzoquinone (Fluka), methyl-1,4-benzoquinone (Merck), and ethyl-1,4-benzoquinone (synthesized according to Peschke and Metzler, 1982) were mixed in a ratio of 1:3:5, respectively, and 120 mg of the mixture were dissolved in 1 ml of *n*-pentane.

In 5 μ l of each of the above blends, each component has the equivalent amount as in the defensive secretion of one *P. armaticeps*.

Bioassays

Choice experiments were conducted in glass terraria (50 \times 50 \times 20 cm) kept in an environmental chamber at 26–34°C and a 12:12 hr light/dark regime. Dusk and dawn (30 min) were simulated by an additional 40-W bulb. The terraria contained two inverted circular black plastic boxes (6 cm OD; 2 cm high), each with a small entrance, positioned in the corners 3 cm away from the walls. These hiding places contained water, food, and a rubber septum (violett 11 mm, Analyt, D-Müllheim) onto which the substances to be tested or the solvent for the control was applied. In the middle of the terraria, a dish filled with moist gravel provided high humidity. Trials were run with individual beetles. Five microliters of extract or solvent (*n*-pentane) were added to each rubber septum 4 hr before the beginning of the

photophase, and the beetles' choices were registered 6 hr after treatments were applied to the septa.

Results

Chemical Composition of the Defensive Secretions

The defensive secretion of *P. armaticeps* was composed mainly of 1-alkenes, 1,4-benzoquinones, and monoterpene hydrocarbons (Table 1; Fig. 1a). The 1-alkenes were dominated by 1-undecene, followed by 1-tridecene and 1-pentadecene. The most abundant quinones were ethyl-1,4-benzoquinone, methyl-1,4-benzoquinone, and 1,4-benzoquinone. Small quantities of vinyl-, isopropyl-, and propyl-1,4-benzoquinones were also identified. The major monoterpene hydrocarbons, in order of greatest abundance, were (–)-limonene, (–)- β -pinene, (–)-camphene, and (–)- α -pinene. Sabinene was only detectable in traces.

Table 1 Chemical composition (median, % total peak area) of extracts of the pygidial defensive secretion, and of volatiles trapped with porapak Q at the entrances to breeding burrows of *P. armaticeps* or bioassay boxes spiked with defensive secretion of *P. armaticeps*

Peak no.	Substance	Defensive secretion extracts		Breeding burrows (<i>N</i> = 6)	Bioassay boxes (<i>N</i> = 10)

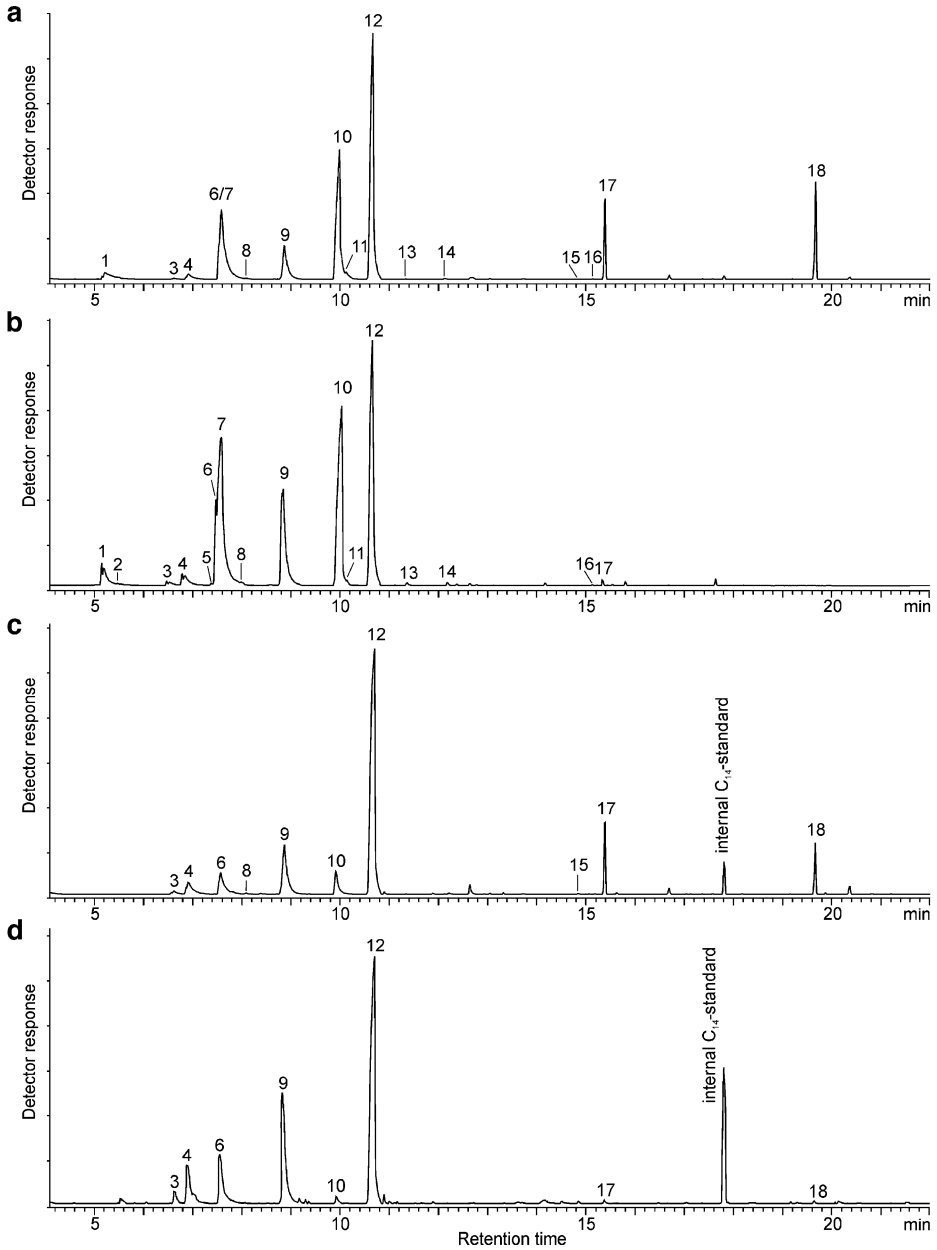

Fig. 1 Total ion chromatograms of pygidial defensive secretion extracts of (a) *P. armaticeps* and (b) *E. opacus*, and of volatiles trapped with Porapak Q at the entrances of (c) breeding burrows of *P. armaticeps* or (d) bioassay boxes with spiked defensive secretion of *P. armaticeps*. Key to peak numbers is given in Table 1

The composition of the defensive secretion in *E. opacus* was similar to that of *P. armaticeps*, except that the secretion of *E. opacus* contained no 1-pentadecene, and 1-tridecene was present only as a minor component (Table 1, Fig. 1b). The quinones and monoterpenes were the same in both species. The proportion of the monoterpenes in *E. opacus* (24.1%) was higher than in *P. armaticeps* (9.8%), based on the higher proportions of (–)-β-pinene and (–)-limonene.

Source and Chemical Composition of Burrow Volatiles

The comparison of the volatiles trapped with Porapak Q at the entrance to burrows with the defensive secretion of *P. armaticeps* showed that all volatiles derived from the defensive secretion (Table 1, Fig. 1c), the major 1-alkenes, and all monoterpene hydrocarbons were present. No volatiles were detected that might have come from the food or any other source. The main difference between the composition of volatiles from breeding burrows and defensive secretions was the low proportion of the 1,4-benzoquinones in the volatiles, with ethyl-1,4-benzoquinone being the only detectable quinone. The volatiles trapped at the entrance to breeding burrows and bioassay boxes (Table 1, Fig. 1d) showed a similar composition; only the quantities of 1-tri- and pentadecene were somewhat higher in breeding burrows.

Quantification of Burrow Volatiles

The total amount of volatiles adsorbed with Porapak Q at the entrance to breeding burrows of *P. armaticeps* was 167 ng/hr (median, range 42–1599 ng/hr, *N* = 6). The amounts measured from the same burrow varied considerably during the collection period, but there was no obvious dependency on the age of the larvae or pupae. For example, the total amounts of volatiles from one burrow varied between 5 and 5451 ng/hr, with a mean of 1599 ng/hr. When a rubber septum was spiked with one beetle equivalent of defensive secretion, the amounts trapped at the entrance of the bioassay boxes showed a smaller range of variation (median 428 ng/hr, range 174–

Fig. 2 Bioassay responses of *E. opacus* to solvent and different blends of volatile classes or single monoterpene hydrocarbons emitted from breeding burrows of *P. armaticeps*. The bars show the percentage of individuals choosing a bioassay box. The asterisks indicate significant attraction/avoidance to treatments (two-tailed binomial test, **P* < 0.05, ***P* < 0.01)

905 ng/hr, $N = 10$). The median was somewhat higher than that adsorbed from breeding burrows (Mann–Whitney U test, $U = 10.0$, $P = 0.03$), but the amounts were all within the range of variability of the latter.

Bioassay for Attraction

The response of *E. opacus* toward the different blends (Fig. 2) showed that the “terpene blend” attracted the beetles significantly ($N = 42$, two-tailed binomial test, $z = 2.01$, $P < 0.05$). The “quinone blend” deterred *E. opacus* ($N = 42$, $z = 2.62$, $P < 0.05$), whereas the “alkene blend” produced no effect ($N = 43$, $z = 0.00$, n.s.). Of the monoterpene hydrocarbons, only (–)-camphene was attractive to *E. opacus* ($N = 47$, $z = 2.04$, $P < 0.05$); (–)- α -pinene ($N = 44$, $z = -0.15$, n.s.) and (–)- β -pinene ($N = 40$, $z = -0.47$, n.s.) showed no effects, and (–)-limonene was avoided by the beetles ($N = 40$, $z = -2.37$, $P < 0.05$).

Discussion

“...it is impossible for a species to completely avoid emitting chemical signals” (Stowe et al., 1995). In the case of *P. armaticeps*, chemical signals originate from the secretion of the pygidial gland and mediate the interspecific communication with its cleptoparasite. Besides the primary function as defensive secretion, the compounds adopt secondary functions in the different stages of its lifetime. We developed an evolutionary scenario of these functional changes, leading to the kairomonal exploitation of the secretion by the cleptoparasite *E. opacus*.

Composition of the Defensive Secretion

Our chemical investigations on the defensive secretions of *P. armaticeps* and *E. opacus* agreed with the results on many tenebrionid beetles (Happ, 1968; Tschinkel, 1975; Markarian et al., 1978; Gnanasunderam et al., 1981; Attygalle et al., 1991; Brown et al., 1992). The secretions of all these species contained methyl- and ethyl-1,4-benzoquinone, in most cases together with 1-alkenes. Besides the two major 1,4-benzoquinones, the secretions of *P. armaticeps* and *E. opacus* comprised 1,4-benzoquinone and other substituted 1,4-benzoquinones, of which vinyl-1,4-benzoquinone was identified here for the first time in tenebrionids. Tschinkel (1975) has analyzed the defensive secretion of *Parastizopus balneorum* Pér. (= *P. armaticeps* Pér.) and detected only methyl- and ethyl-1,4-benzoquinone, together with 1-alkenes. As those beetles originated from a different population, this could be the reason why we found no 1-heptadecene and a lower proportion of 1-pentadecene in the secretion of *P. armaticeps*. In contrast to previously studied tenebrionid species (Tschinkel, 1975), the defensive secretions of *P. armaticeps* and *E. opacus* contained substantial proportions of monoterpene hydrocarbons. Monoterpenes have been detected in defensive secretions of numerous insects, e.g., termites (Moore, 1968; Gush et al., 1985), ants (Brand et al., 1974), and bugs (Aldrich et al., 1990). They have also been reported in defensive secretions of some Australian and New Zealand tenebrionids from different subfamilies (Gnanasunderam et al., 1981; Brown et al., 1992). As yet, only α -pinene, limonene, and α -phellandrene have been

reported in the defensive secretions of tenebrionids. Camphene, sabinene, and β -pinene are new to the family. Although Tschinkel (1975) found no monoterpene hydrocarbons in the defensive secretion of *P. balneorum*, the presence of (–)- α -pinene, (–)-camphene, sabinene, (–)- β -pinene, and (–)-limonene seems to be typical for defensive secretions of Stizopina, as all investigated species, except *Psammogaster malani* Koch, contained these monoterpenes (unpublished data).

Burrow Volatiles and Possible Functions

The volatiles adsorbed on Porapak Q from burrows of *P. armaticeps* are components of the defensive secretion. This contradicts a study of odor profiles of undisturbed *P. armaticeps* and *E. opacus*, which rejected the pygidial defensive secretion as a source of volatiles in resting odor profiles (Hein et al., 1996). The peaks were only described by their retention times, and no information was given about relative amounts or mass spectra, limiting further comparison with our results. However, we found no evidence for a source of volatiles other than the defensive secretion.

The main difference between the composition of emitted defensive secretion and volatiles trapped with Porapak Q was the low proportion of 1,4-benzoquinones in the volatiles, regardless of whether they were collected at the entrances of breeding burrows or bioassay boxes. We concluded that the low amounts of 1,4-benzoquinones were not a result of a reduced production of quinones during breeding; rather, they were the result of the physical conditions during the experiment. 1,4-Benzoquinones are polar substances and soluble in water, in contrast to 1-alkenes and monoterpene hydrocarbons. Therefore, their adsorption on the moist sand could be the reason for their underrepresentation.

The adsorbed 1,4-benzoquinones might have a secondary function as antimicrobial agents during breeding. We did not observe any microbial infection in the food caches of breeding burrows if parent beetles were present, but an infection occurred within 1 or 2 d after a pair was removed (unpublished data). Prendeville and Stevens (2002) have shown that 1,4-benzoquinones from the defensive secretion of the tenebrionid *Tribolium* inhibit the growth of yeast and bacteria. In addition to the 1,4-benzoquinones, monoterpene hydrocarbons are known to have antimicrobial activities. For example, in the termite genus *Nasutitermes*, the frontal gland secretion, containing α -pinene, β -pinene, and limonene, reduces fungal infection of soldiers and spore germination in the nests (Rosengaus et al., 2000). The 1-alkenes not only serve as solvents for the 1,4-benzoquinones, but they may also have a repellent effect on insects, e.g., the ant *Monomorium pharaonis* (Peschke and Eisner, 1987). Therefore, 1-undecene could prevent ants or other insects from entering breeding burrows of *P. armaticeps*.

Exploitation of Defensive Secretion as a Kairomone

The use of kairomones for host or prey location is a widespread phenomenon in arthropods (Weseloh, 1981; Vinson, 1984; Stowe et al., 1995; Aldrich, 1999; Powell, 1999). Besides the numerous examples of parasitoids and predators exploiting the pheromone system of their victims (Bowers and Borden, 1992; Teerling et al., 1993; Kielty et al., 1996; Zuk and Kolluru, 1998; Zhu et al., 1999), there are a few cases of

kairomonal exploitation of allomones. For example, Eisner et al. (1991) found that cleptoparasitic milichiid flies are attracted to defensive secretion of bugs caught by orb-weaving spiders. Moreover, the use of heteropteran defensive secretions for host or prey location has been shown by Mattiacci et al. (1993) for the egg parasitoid *Trissolcus basalus* (Hymenoptera) and by Aldrich and Barros (1995) for crab spiders. Fresh carcasses of juliform millipedes attract necrophagous *Onthophagus* dung beetles. Krell et al. (1997) have demonstrated that 1,4-benzoquinones from the defensive secretion were responsible for the attraction. In addition, Schmitt et al. (2004) have shown that only the mixture of the two major 1,4-benzoquinones, methyl- and 2-methoxy-3-methyl-1,4-benzoquinone, was attractive to *Onthophagus* dung beetles, but not the individual components. In all these cases, whether exploitation of pheromones or allomones, the species had to “decipher the language of their hosts or prey” before they could exploit them.

On the other hand, in *E. opacus*, the exploitation of (–)-camphene as a host-finding kairomone could have evolved as a consequence of “misinterpreting” their own aggregation pheromone. Rasa (1994) has shown that *E. opacus* are unable to distinguish between the odor of conspecifics and *P. armaticeps*, and that they are attracted to high odor concentrations. The larger *P. armaticeps* probably emit greater amounts of volatiles than *E. opacus*, so that *E. opacus* are more likely to be attracted to aggregations of *P. armaticeps* than to those of their own species. All Stizopina that have been investigated, except *Ps. malani*, which is lacking monoterpenes, form intraspecific aggregations (unpublished data). Therefore, (–)-camphene might be a basal aggregation pheromone within the Stizopina. This hypothesis remains to be proved. If it is true, it could be the reason why interspecific aggregations have evolved several times independently in this subtribe (Rasa and Endrödy-Younga 1997).

An additional function of defensive secretion components as aggregation pheromones is known from the tenebrionid genus *Blaps* (Tannert and Hien 1973). Low concentrations of the defensive secretion led to the formation of aggregations in this species. However, the components have not yet been identified. The deterrence of *E. opacus* by 1,4-benzoquinones could be the result of high concentrations in the bioassay boxes. However, 1,4-benzoquinones are universal within defensive secretions of Tenebrionidae (Tschinkel, 1975) and, therefore, they cannot be responsible for the discrimination of *E. opacus* between its host and other burrowing tenebrionids in the Kalahari, such as *Gonopus* (Rasa, 1994).

In summary, the subsocial *P. armaticeps* and its cleptoparasite *E. opacus* exhibit defensive secretions that are typical for tenebrionid beetles, except for high proportions of monoterpene hydrocarbons. As these monoterpenes characterize the defensive secretions of all members of the subtribe Stizopina, to which both species belong, they can be considered as a homologous feature. During the breeding period of *P. armaticeps*, defensive chemicals might adopt different secondary functions. Both monoterpenes and 1,4-benzoquinones are known for their antimicrobial properties, which prevent the food cache from bacterial or fungal infections, and the volatiles, monoterpenes as well as 1-alkenes, are repellents for potential arthropod intruders. However, *E. opacus* exploits just these monoterpenes as the host-finding kairomone. The evolution of cleptoparasitism by *E. opacus* might originate from mistaking volatiles from *P. armaticeps* aggregations for their own aggregation pheromone, (–)-camphene, leading to interspecific aggregations. During drought, such interspecific aggregations would be beneficial for both

partners by reducing their transpiratory water loss. At this evolutionary stage, (–)-camphene probably functioned as a synomone. After *E. opacus* was able to mimic its host's cuticular hydrocarbon pattern, and thus gained access to breeding burrows, (–)-camphene may have become a kairomone. This would represent the first case of volatile semiochemical exploitation based on odor homology.

Acknowledgments We are grateful to Thomas Schmitt for synthesis of isopropyl- and propyl-1,4-benzoquinone as reference standards and to Sonia Whitlow, Stefanie Geiselhardt, and two anonymous reviewers for helpful comments on the manuscript. Abstract Ethanol and α -pinene were tested as attractants for large wood-boring pine beetles in Alabama, Florida, Georgia, North Carolina, and South Carolina in 2002–2004. Multiple-funnel traps baited with (–)- α -pinene (released at about 2 g/d at 25–28°C) were attractive to the following Cerambycidae: *Acanthocinus nodosus*, *A. obsoletus*, *Arhopalus rusticus nubilus*, *Asemum striatum*, *Monochamus titillator*, *Prionus pocularis*, *Xylotrechus integer*, and *X. sagittatus sagittatus*. *Buprestis lineata* (Buprestidae), *Alaus myops* (Elateridae), and *Hylobius pales* and *Pachylobius picivorus* (Curculionidae) were also attracted to traps baited with (–)- α -pinene. In many locations, ethanol synergized attraction of the cerambycids *Acanthocinus nodosus*, *A. obsoletus*, *Arhopalus r. nubilus*, *Monochamus titillator*, and *Xylotrechus s. sagittatus* (but not *Asemum striatum*, *Prionus pocularis*, or *Xylotrechus integer*) to traps baited with (–)- α -pinene. Similarly, attraction of *Alaus myops*, *Hylobius pales*, and *Pachylobius picivorus* (but not *Buprestis lineata*) to traps baited with (–)- α -pinene was synergized by ethanol. These results provide support for the use of traps baited with ethanol and (–)- α -pinene to detect and monitor common large wood-boring beetles from the southeastern region of the USA at ports-of-entry in other countries, as well as forested areas in the USA.

Keywords Cerambycidae · *Xylotrechus* · *Monochamus* · *Acanthocinus* · Curculionidae · *Hylobius* · *Pachylobius* · Elateridae · *Alaus* · Ethanol · α -Pinene · Kairomone · Exotics

Introduction

Introductions of bark and wood-boring beetles via the movement of solid wood packing materials used in crating and securing cargo for shipping are common (Hoebcke, 1994; Haack and Cavey, 2000; Haack, 2001). From 1996 to 1998, most

interceptions of beetles at ports-of-entry in the USA were associated with solid wood packing material (USDA APHIS and Forest Service, 2000). Coleoptera accounted for 94% of all pest interceptions with the Cerambycidae accounting for 37% of all beetle interceptions. The risk of invasive species of Cerambycidae moving between continents and countries is particularly high because of the cryptic nature of adults and larvae (Allison et al., 2004).

The impacts of Cerambycidae can be varied, ranging from beneficial as primary agents of nutrient recycling within forested stands (Hanks, 1999; Allison et al., 2004) to damaging in terms of social, economic, and environmental values (Liebholt et al., 1995). The mining activities of larvae result in large-diameter holes and tunnels in wood that can translate into significant levels of degrading damage to forestry products (Safranyik and Raske, 1970; Cerezke, 1977). Several species of long-horned beetles (*Monochamus* spp.) are known vectors of a wilting disease caused by the pine wood nematode *Bursaphelenchus xylophilus* (Steiner and Buhner) Nickel (Tylenchida: Aphenlenchoididae) (Wingfield et al., 1982; Linit, 1988). Introduction of the pine wood nematode into Japan in the early 1900s resulted in numerous epidemics of pine wilt on 28% of the pine forests by 2000 (Mamiya, 2003). Since 1996, the Asian long-horned beetle *Anoplophora glabripennis* (Motschulsky) has killed thousands of high-value urban trees in Illinois, New York, New Jersey, and Ontario with the cost of eradication and tree restoration expected to exceed US\$300 million by 2009 (USDA Forest Service, 2005). Similarly, the brown spruce borer *Tetropium fuscum* (Fabricius) has become established in Nova Scotia, killing significant numbers of red spruce *Picea rubens* Sargent in park lands near Halifax (Natural Resources Canada, 2005). It is likely that even more introductions will occur because of increases in the movement of solid wood packing material associated with expected increases in international trade (USDA APHIS and Forest Service, 2000).

One common trapping protocol used for wood borers at ports-of-entry and forest monitoring sites in the USA employs multiple funnel or intercept traps baited with devices releasing ethanol and (–)- α -pinene at fairly high rates (1–2 g/d at 20–25°C; USDA Forest Service, 2001). In Ontario, traps baited with ethanol and (±)- α -pinene were attractive to various species of Cerambycidae, including *Monochamus scutellatus* (Say) and *Xylotrechus undulatus* (Say) (Chénier and Philogène, 1989). In British Columbia, *Xylotrechus longitarsis* Casey was attracted to traps baited with ethanol and (–)- α -pinene (Morewood et al., 2002), whereas *Monochamus notatus* (Drury) and *M. scutellatus* were attracted to traps baited with ethanol and a blend of seven monoterpenes that included (–)- α -pinene (Allison et al., 2001).

My objective was to assess the efficacy of standard commercially available ethanol and (–)- α -pinene lures used with multiple-funnel traps in capturing the following common large (>8 mm in length) Cerambycidae in the southeastern USA: *Monochamus titillator* (Fabricius), *Xylotrechus sagittatus sagittatus* (Germar), *X. integer* (Haldeman), *Acanthocinus nodosus* (Fabricius), *A. obsoletus* (Olivier), *Arophalus rusticus nubilus* (LeConte), *Asemum striatum* (L.), and *Prionus pocularis* Dalman. The goal was to verify that traps baited with the combination of the two lures were as effective as, if not better than, traps baited solely with one lure over a broad range in the South: eight National Forests in five Southern states. Previous studies on the attractiveness of ethanol and monoterpenes to Cerambycidae in the USA have largely been restricted to Florida with some recent tests in South Dakota.

In Florida, Fatzinger (1985), Fatzinger et al. (1987), and Phillips et al. (1988) found that the combination of ethanol and turpentine was attractive to various species of

pine Cerambycidae; however, these studies did not incorporate blank controls. Moreover, the use of turpentine in these studies is a concern because the monoterpene composition of turpentine can vary widely depending on the species and location of pines used in producing turpentine (Mirov, 1961; Smith, 2000). The main monoterpene in one of the Florida studies (and likely the other two as well) was α -pinene (Phillips et al., 1988). In South Dakota, Costello (2005) found that traps baited with ethanol and α -pinene were attractive to the cerambycids *Acanthocinus obliquus* (LeConte), *A. spectabilis* (LeConte), *Acmaeops proteus* (Kirby), and *Monochamus clamator* (LeConte); however, traps baited solely with α -pinene were not tested.

I also monitored the responses of the following species of saproxylic beetles commonly found in southern pine stands: *Buprestis lineata* Fabricius (Buprestidae), *Alaus myops* (Fabricius) (Elateridae), and the root weevils (Curculionidae) *Hylobius pales* Herbst and *Pachylobius picivorus* LeConte. Larval *Alaus myops* prey upon the larvae of pine woodborers, whereas larvae of the weevils *Hylobius pales* and *Pachylobius picivorus* feed in the roots and stumps of stressed or dying pines, often feeding on seedlings after removal of mature trees in plantations (USDA Forest Service, 1985). Ethanol synergized attraction of *Pachylobius picivorus* to turpentine in Wisconsin (Hunt and Raffa, 1989), whereas in Florida, ethanol synergized attraction of *Hylobius pales* but not *Pachylobius picivorus* to turpentine (Phillips et al., 1988). Erbilgin et al. (2001) found that *Hylobius pales* and *Pachylobius picivorus* were attracted to flight traps baited with α -pinene and ethanol in Louisiana and Wisconsin, although neither compound was tested alone.

Methods and Materials

Chemicals and Release Devices

Phero Tech Inc. (Delta, British Columbia, Canada) supplied sealed ultrahigh-release (UHR) plastic pouches containing either ethanol (150 ml) or α -pinene (200 ml; chemical purities >95%). The enantiomeric purity of α -pinene was >95% (-). The release rates of ethanol and α -pinene from UHR pouches were approximately 1 and 2 g/d, respectively, at 25–28°C (determined by weight loss).

Experimental Design

Eight experiments were conducted in 2002–2004 to evaluate the attractiveness of ethanol and (-)- α -pinene to large bark- and wood-boring beetles in the southeastern region of the USA. All eight experiments used the same design with one experiment conducted in mature pine stands on each of seven National Forests (NF) and one Experimental Forest (EF) in the South (Table 1). Disturbances occurred in stands used in experiments 1–3 and 6–8 during the 6-mo period preceding trap deployment but not in stands used in experiments 4–5. Prescribed fire was the disturbance agent in experiments 1–3 and 8, whereas salvage logging was used to remove a spot infestation of *Dendroctonus frontalis* Zimmerman in stands used in experiment 6; stands in experiment 7 were thinned with removal of woody material.

I employed a behavioral choice type of design in all experiments with treatments within a block grouped within the same area and traps spaced 10–15 m apart. My expectation was that the plumes of volatiles from each treatment would blend

Table 1 National forest (NF) and experimental forest (EF) locations, forest types, and trapping dates for experiments (2002–2004)

Experiment	Location	Tree species	Trapping dates

5	Bankhead NF near Grayson AL	<i>P. taeda</i> and <i>Tsuga canadensis</i> (L.)	28 April–10 July 2003
6	Nantahala NF near Murphy NC	<i>P. strobus</i> and <i>P. echinata</i> Miller	1 May–14 August 2003
7	Sumter NF near Union SC	<i>P. taeda</i>	15 April–16 July 2003
8	Apalachicola NF near Tallahassee FL	<i>Pinus palustris</i> and <i>P. elliotii</i>	30 March–16 June 2004

together and spread over a single catchment area. In all experiments, 16 8-unit multiple-funnel traps (Phero Tech Inc.) were set in four linear blocks of four traps per block at each of the two sites. Blocks within site, and traps within blocks, were spaced 10–15 m apart, whereas sites were spaced 50–500 m apart. Each trap was suspended between trees by rope such that the bottom of each was 0.2–0.5 m above ground level. No trap was within 2 m of any tree. Collection cups contained 150–200 ml of pink propylene glycol solution (Peak RV and Marine Antifreeze, Old World Industries Inc., Northbrook, IL, USA) as a killing and preservation agent. Voucher specimens were deposited in the Entomology Collection, Museum of Natural History, University of Georgia (Athens, GA, USA). In each of the eight experiments, four treatments were randomly assigned to traps within each of eight replicate blocks as follows: (1) blank control; (2) ethanol alone; (3) α -pinene alone; and (4) ethanol + α -pinene. In all experiments, lures were replaced at intervals of 50–60 d.

Statistical Analyses

Data were analyzed only for locations where sufficient numbers of the following species were captured: *Acanthocinus nodosus*, *A. obsoletus*, *Arhopalus rusticus nubilus*, *Asemum striatum*, *Monochamus titillator*, *Prionus pocularis*, *Xylotrechus integer*, *X. s. sagittatus*, *Buprestis lineata*, *Alaus myops*, *Hylobius pales*, and *Pachylobius picivorus*. The data were analyzed with the SYSTAT (ver. 11.00.01) and the SigmaStat (ver. 3.01) statistical packages (SYSTAT Software Inc., Point Richmond, CA, USA). Trap catch data were transformed by $\ln(Y + 1)$ to remove heteroscedasticity (Pepper et al., 1997). Where possible, trap catch data in all experiments were subjected to two-way analysis of variance (ANOVA) using the following model components: (1) replicate, (2) ethanol, (3) α -pinene, and (4) ethanol \times α -pinene. In a number of locations, mean trap catches of some species to one or two treatments (control and traps baited with ethanol alone) were zero with zero variance and a clear violation of the assumption of homoscedasticity (Cobb, 1998). In such

instances, data were subjected to one-sided *t* tests (using a Bonferroni correction for multiple comparisons), testing that individual treatment means were greater than zero (Reeve and Strom, 2004). Trap catch data where variances were homoscedastic for all treatments at all locations were subjected to two-way ANOVA using the following model components: (1) replicate nested within location, (2) location, (3) treatment, and (4) locations × treatment.

In all experiments, the Holm–Sidak multiple comparison procedure was used to compare means within a location for each species when treatment effect was significant at *P* = 0.05. When two treatments had means of zero with zero variance, then the two remaining means were compared by two-sided *t* test at *P* = 0.05.

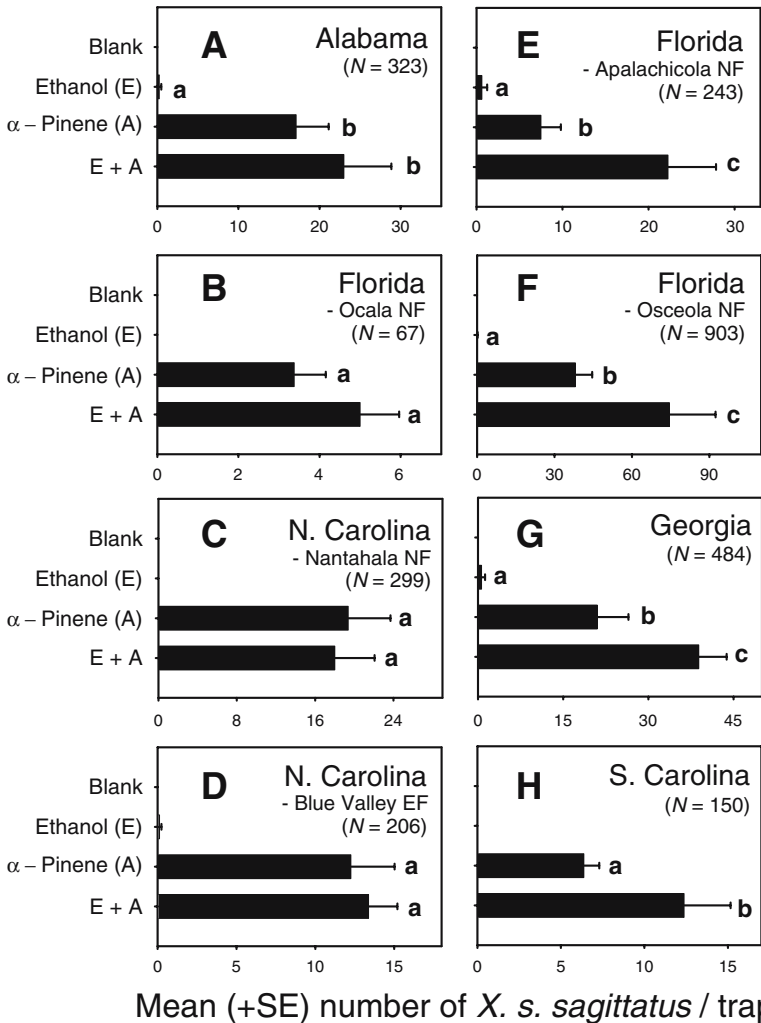

Fig. 1 Effects of ethanol and (–)- α -pinene on trap catches of *Xylocopa s. sagittatus* (Cerambycidae) in southeastern USA. Means followed by the same letter are not significantly different at *P* = 0.05 [Holm–Sidak multiple comparison test for three treatments (A, E, F, and G) or *t* test for two treatments (B, C, D, and H)]. Treatments without a letter had zero catches of beetles

Synergism between ethanol and (–)- α -pinene in attracting beetles was indicated by satisfying two statistical conditions. First, ethanol and/or (–)- α -pinene had to be benign alone in attracting beetles to traps. Second, the combination of ethanol and (–)- α -pinene had to result in higher trap catches than ethanol or (–)- α -pinene alone.

Results

A total of 2675 *Xylotrechus s. sagittatus* (about 66% of all Cerambycidae caught) were captured from all eight locations (Fig. 1). The data for *X. s. sagittatus* could not

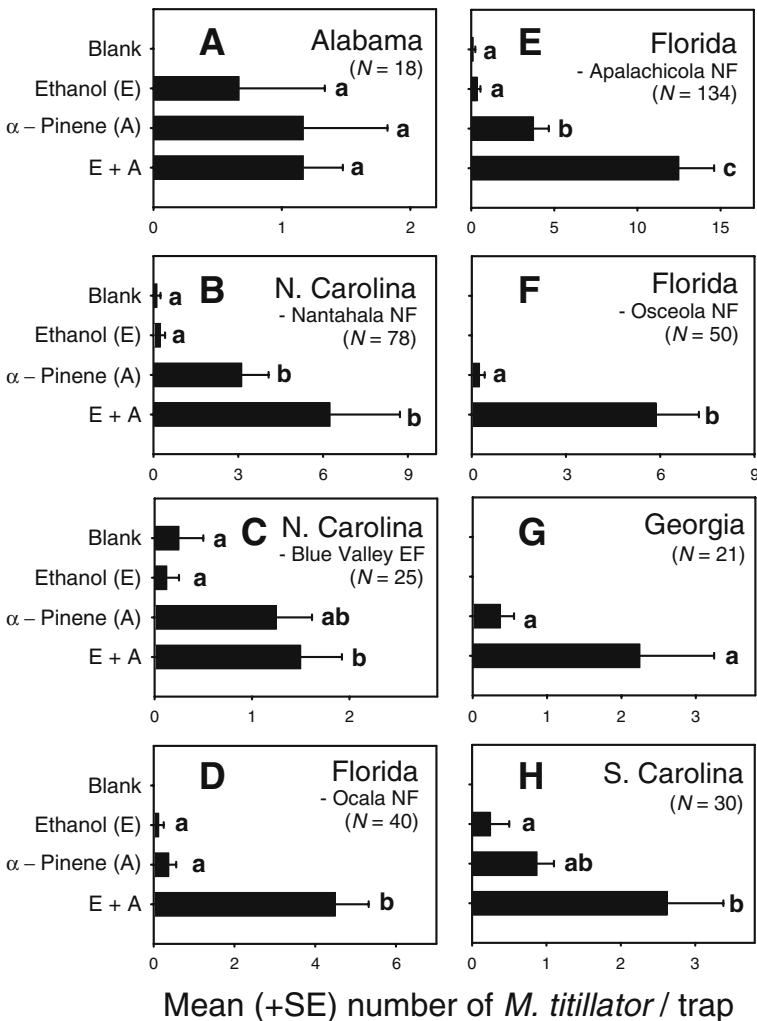

Fig. 2 Effects of ethanol and (–)- α -pinene on trap catches of *Monochamus titillator* (Cerambycidae) in southeastern USA. Means followed by the same letter are not significantly different at $P = 0.05$ [Holm–Sidak multiple comparison test for three to four treatments (A–E and H) or t test for two treatments (F and G)]. Treatments without a letter had zero catches of beetles

be analyzed by two-way ANOVA because no beetles were caught in control traps at any location. Catches of *X. s. sagittatus* in traps baited with (–)- α -pinene (with or without ethanol) were greater than zero at all locations (*t* tests, all *df* = 7, all *P* < 0.01). At some locations, ethanol seemed to affect trap catches of *X. s. sagittatus* as a synergist (Fig. 1). There were no beetles caught in traps baited solely with ethanol at four locations (Fig. 1), whereas catches in ethanol-baited traps at other four locations were not different from zero (*t* tests, all *df* = 7, all *P* > 0.50). However, when ethanol was added to traps baited with (–)- α -pinene, catches of *X. s. sagittatus* were significantly greater than those in traps baited with (–)- α -pinene in four locations: Georgia, South Carolina, and the Apalachicola and Osceola NF in Florida (Fig. 1E–H). At no location, was attraction of beetles to traps baited with (–)- α -pinene interrupted by ethanol.

Monochamus titillator was caught at all eight localities with a total capture of 396 beetles (about 10% of total Cerambycidae catch; Fig. 2). Trap catches of *M. titillator* were significantly affected by (–)- α -pinene but not ethanol in the Nantahala NF and Blue Valley EF in North Carolina, whereas both (–)- α -pinene and ethanol affected catches in the Apalachicola NF in Florida (Table 2). Two-way ANOVA could not be employed for *M. titillator* at the remaining five locations because no beetles were caught in control traps. Catches of *M. titillator* in traps baited solely with (–)- α -pinene were different from zero in South Carolina (*t* test, *df* = 7, *P* = 0.006) but not the remaining four locations (*t* tests, all *df* = 7, all *P* > 0.10). Ethanol had a synergistic effect on catches to traps baited with (–)- α -pinene at six of the eight locations (Fig. 2). Catches of *M. titillator* in traps baited with ethanol and (–)- α -pinene were significantly greater than those baited solely with (–)- α -pinene or ethanol alone at all three locations in Florida (Fig. 2D–F). In Alabama, Georgia, and South Carolina, catches of beetles in traps baited with ethanol and (–)- α -pinene were different from zero (*t* tests, all *df* = 7, all *P* < 0.04), whereas catches in traps

Table 2 Significant levels for ANOVA on effects of ethanol and (–)- α -pinene on beetle trap catches in southeastern USA

baited with ethanol alone were not greater than zero (t tests, all $df = 7$, all $P > 0.50$). At no location, were catches in traps baited with $(-)\text{-}\alpha\text{-pinene}$ interrupted by ethanol (Fig. 2).

We caught a total of 187 *Acanthocinus obsoletus* at four locations (Fig. 3A–D). $(-)\text{-}\alpha\text{-Pinene}$ had a significant effect on *A. obsoletus* in the Osceola NF (Table 2) with catches in traps baited solely with $(-)\text{-}\alpha\text{-pinene}$ greater than those in blank

Fig. 3 Effects of ethanol and $(-)\text{-}\alpha\text{-pinene}$ on trap catches of *Acanthocinus obsoletus* (A–D) and *A. nodosus* (E–H) (Cerambycidae) in southeastern USA. Means followed by the same letter are not significantly different at $P = 0.05$ [Holm–Sidak multiple comparison test for three to four treatments (C–E) or t test for two treatments (A, B, and F–H)]. Treatments without a letter had zero catches of beetles

control traps (Fig. 3C). *Acanthocinus obsoletus* was not captured in control traps at the remaining three locations. Catches of *A. obsoletus* in traps baited with (–)- α -pinene were greater than zero in the Apalachicola NF (*t* test, *df* = 7, *P* = 0.03) but not in the Ocala and Nantahala NF (*t* tests, *df* = 7, *P* = 0.068 and 0.060, respectively). In contrast, catches of beetles in traps baited with ethanol and (–)- α -pinene were greater than zero in all three locations (*t* tests, all *df* = 7, all *P* < 0.04; Fig. 3A, B, D). Catches in traps baited solely with ethanol were not greater than zero in the Nantahala NF (*t* test, *df* = 7, *P* = 0.526); none were caught in ethanol-baited traps in the Apalachicola and Ocala NF (Fig. 3A, B). Catches of *A. obsoletus* in traps baited with (–)- α -pinene were synergized by adding ethanol lures at two of the three Florida locations (Fig. 3B, C).

We caught a total of 198 *Acanthocinus nodosus* at four locations (Fig. 3E–H). No beetles were captured in control traps at all four locations. Catches of *A. nodosus* in traps baited solely with (–)- α -pinene were greater than zero in the Osceola NF (*t* test, *df* = 7, *P* = 0.028) but not at the other three locations (*t* tests, all *df* = 7, all *P* > 0.15). As with *A. obsoletus*, ethanol had a synergistic effect on trap catches of *A. nodosus*. Catches of *A. nodosus* in traps baited with both ethanol and (–)- α -pinene were greater than zero at all four locations (*t* tests, all *df* = 7, all *P* < 0.02). Catches in traps baited solely with ethanol were not greater than zero in the Apalachicola NF (*t* test, *df* = 7, *P* = 0.2566); none were caught in ethanol-baited traps in the Ocala, Osceola, and Nantahala NF (Fig. 3F–H). Catches of *A. nodosus* in traps baited with (–)- α -pinene were increased by adding ethanol lures at two of the three Florida locations (Fig. 3F, G).

Fig. 4 Effects of ethanol and (–)- α -pinene on trap catches of *Arhopalus r. nubilus* (A), *Prionus pocularis* (B), *Asemum striatum* (C), and *Xylotrechus integer* (D) (Cerambycidae) in southeastern USA. Means followed by the same letter are not significantly different at *P* = 0.05 (Holm–Sidak multiple comparison test). Treatments without a letter had zero catches of beetles

Catches of *Arhopalus r. nubilus* and *Asemum striatum* were significantly affected by $(-)\text{-}\alpha\text{-pinene}$ in two separate locations (Table 2). For both species, catches of beetles in traps baited with $(-)\text{-}\alpha\text{-pinene}$ alone caught more beetles than control traps (Fig. 4A, C). Ethanol had a synergistic effect on *A. r. nubilus* with catches in traps baited with both ethanol and $(-)\text{-}\alpha\text{-pinene}$ greater than those in traps baited solely with $(-)\text{-}\alpha\text{-pinene}$; traps baited with ethanol alone were not attractive (Fig. 4A). Catches of *Xylotrechus integer* in traps baited with $(-)\text{-}\alpha\text{-pinene}$ (with or without ethanol) were greater than zero (t tests, all $df = 3$, all $P < 0.002$), whereas catches in traps baited solely with ethanol were not greater than zero (t test, $df = 3$, $P = 0.273$). Catches of *Prionus pocularis* in traps baited with $(-)\text{-}\alpha\text{-pinene}$ were greater than zero (t test, $df = 7$, $P < 0.001$), whereas catches in traps with the remaining treatments were not greater than zero (t tests, all $df = 7$, all $P > 0.059$), both of which were significantly less than catches in traps baited solely with $(-)\text{-}\alpha\text{-pinene}$ (Fig. 4B).

Buprestids were not common with only one species captured in numbers sufficient for analyses. *Buprestis lineata* were represented in trap catches from six locations with a total capture of 348 beetles (Fig. 5). In South Carolina and the Ocala NF in Florida, catches of *B. lineata* were significantly affected by $(-)\text{-}\alpha\text{-pinene}$, but not

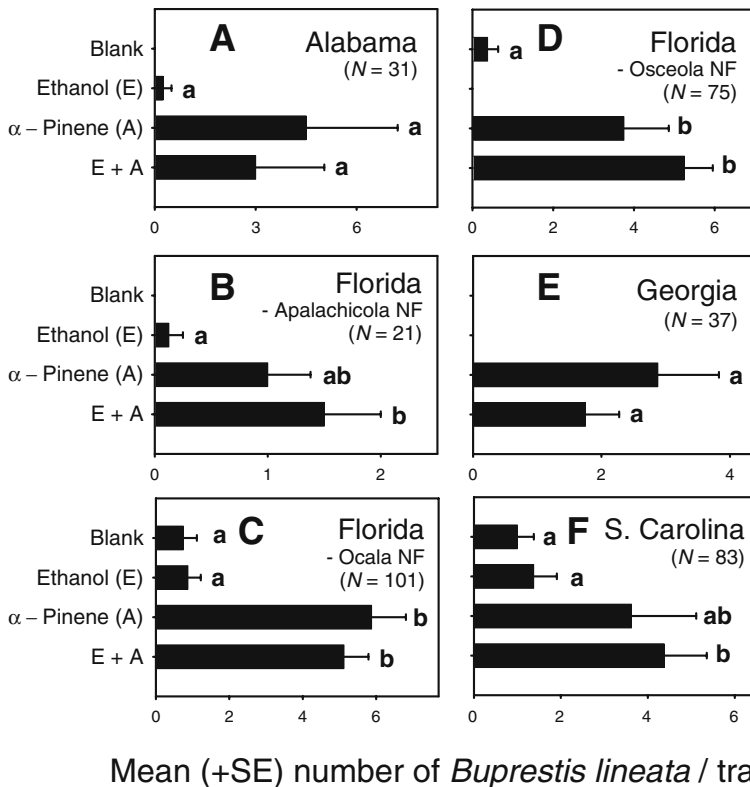

Fig. 5 Effects of ethanol and $(-)\text{-}\alpha\text{-pinene}$ on trap catches of *Buprestis lineata* (Buprestidae) in southeastern USA. Means followed by the same letter are not significantly different at $P = 0.05$ [Holm–Sidak multiple comparison test for three to four treatments (A–D, and F) or t test for two treatments (E)]. Treatments without a letter had zero catches of beetles

ethanol, with no significant interaction between ethanol and (-)- α -pinene (Table 2). In both locations, catches of beetles in traps baited with ethanol and (-)- α -pinene were greater than those in control traps (Fig. 5C, F). In the Apalachicola NF, catches of *B. lineata* in traps baited with ethanol and (-)- α -pinene were greater than zero (*t* test, *df* = 7, *P* = 0.038); the opposite was not true for catches in the remaining two treatments (*t* tests, all *df* = 7, all *P* > 0.056). In the Osceola NF (Florida), catches of *B. lineata* in traps baited with (-)- α -pinene (with or without ethanol) were greater than those in control traps (Fig. 5D). Catches of beetles in traps baited with (-)- α -pinene (with or without ethanol) were greater than zero in Georgia (*t* test, all *df* = 7, all *P* < 0.01) but not Alabama (*t* tests, all *df* = 3, all *P* > 0.17). At no location, was there a difference between catches of *B. lineata* in traps baited solely with (-)- α -pinene and those baited with both (-)- α -pinene and ethanol.

A total of 672 *Alaus myops* were captured in four locations (Fig. 6). Trap catches of *A. myops* in South Carolina and the three locations in Florida were affected by (-)- α -pinene (Table 2). At all four locations, traps baited with (-)- α -pinene (with or without ethanol) caught more beetles than control traps or traps baited solely with ethanol (Fig. 6). There was no significant interaction between location and treatment on catches of *A. myops* (*F* = 0.912, *df* = 9,84, *P* = 0.519). Traps baited with ethanol were not attractive to *A. myops*, although attraction of beetles to (-)- α -pinene was increased by ethanol at two of the Florida locations (Fig. 6A and C).

Two common pine root weevils *Hylobius pales* and *Pachylobius picivorus* were caught in sufficient numbers in Florida for analyses (total of 257 and 1616 beetles, respectively; Fig. 7). (-)- α -Pinene had a significant effect on catches of both species at all three locations in Florida (Table 2). Catches of *Pachylobius picivorus* in traps baited with (-)- α -pinene (with or without ethanol) were significantly greater than those in control traps at all three locations (Fig. 7A–C). The same was true for catches of *Hylobius pales* in the Osceola NF and the Ocala NF but not at the

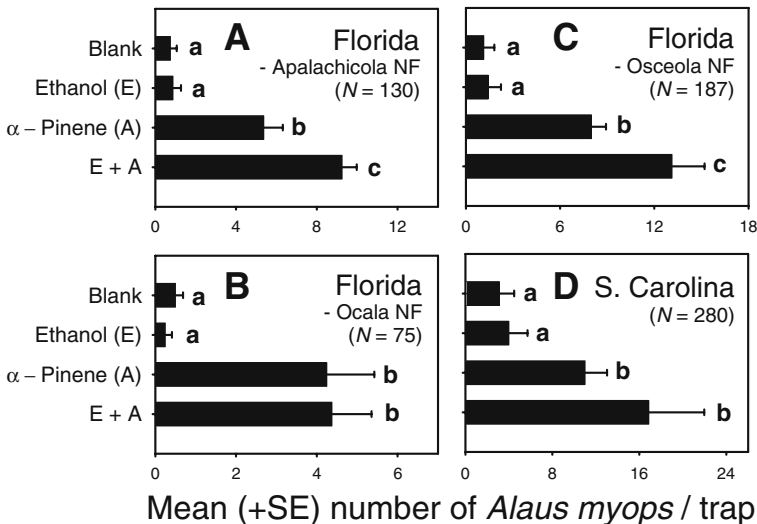

Fig. 6 Effects of ethanol and (-)- α -pinene on trap catches of *Alaus myops* (Elateridae) in South Carolina and northern Florida. Means followed by the same letter are not significantly different at *P* = 0.05 (Holm–Sidak multiple comparison test)

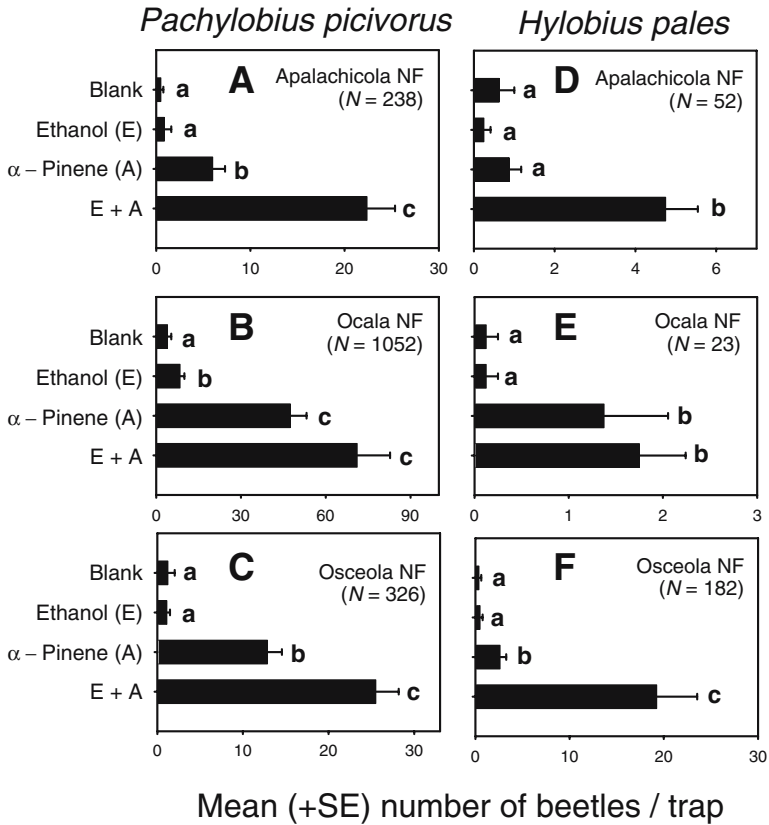

Fig. 7 Effects of ethanol and ($-$)- α -pinene on trap catches of *Pachylobius picivorus* (A–C) and *Hylobius pales* (D–F) (Curculionidae) in northern Florida. Means followed by the same letter are not significantly different at $P = 0.05$ (Holm–Sidak multiple comparison test)

Apalachicola NF (Fig. 7E and F). There was an interaction between treatments and location on catches of *Hylobius pales* in Florida ($F = 6.830$, $df = 6,21$, $P < 0.001$) but not on catches of *Pachylobius picivorus* ($F = 1.704$, $df = 6,21$, $P = 0.135$). At all locations, catches of both species in traps baited with ethanol and ($-$)- α -pinene were greater than those in control traps. However, the effect of ethanol on attraction of both weevils to ($-$)- α -pinene was synergistic in the Apalachicola and Osceola NF but not in the Ocala NF (Fig. 7A–F).

Discussion

Almost all of the wood-boring beetle species caught in this study breed in recently cut, wind-thrown, fire-killed, insect-killed, or dying pines as well as pine logs and stumps (USDA Forest Service, 1985; Yanega, 1996). One commonality to these situations is the release of resin by pines that thwarts further damage or invasions by insects or pathogens (Raffa, 1992; Trapp and Croteau, 2001). α -Pinene is a common and predominant monoterpene in the resin of most southern pines (Smith, 2000).

Xylotrechus integer breeds in stands of balsam fir *Abies balsamea* (L.) and eastern hemlock (Yanega, 1996); one of the sites used in Alabama contained a large component of mature eastern hemlock. However, α -pinene is a common monoterpene in eastern hemlock as well (Broeckling and Salom, 2003). Therefore, it is not surprising that traps baited with (–)- α -pinene were attractive to several species of pine-inhabiting wood borers throughout the southeastern USA. Selection should favor those individuals that capitalize on any cues that facilitate the quick invasion of suitable yet ephemeral and patchy resources (Atkins, 1966).

In many locations, attraction of four species of Cerambycids as well as the weevils *Hylobius pales* and *Pachylobius picivorus* and the wood-borer predator *Alaus myops* to traps baited with (–)- α -pinene was increased by the addition of ethanol (Figs. 1E–H, 2D–F, H, and 3B, C, F, G). The exceptions were *Prionus pocularis* (Fig. 4B), *Asemum striatum* (Fig. 4C), and *Xylotrechus integer* (Fig. 4D). Ethanol concentrations of woody tissues can rise dramatically in stressed or damaged trees because of anaerobic respiration (Moeck, 1970; Kelsey, 1996; Kelsey and Joseph, 2001). In cases such as those arising from fire damage, such cues are likely short lived and may be important for species that invade trees soon after injury (Kelsey and Joseph, 2003).

The synergistic effect of ethanol on the attraction of many of the species to traps baited with (–)- α -pinene was evident in many but not all locations. The apparent lack of synergy at some locations may be random events because of low numbers of beetles captured at these locations. Alternatively, it may represent geographical variation in the use of host attractants for these species, reflecting some variation in host preferences. Our studies were conducted in forests that varied widely in species composition (Table 1), and there is considerable variation in chemical and enantiomeric composition of resin among pine species in North America (Smith, 2000). The addition of other components, such as β -pinene or 3-carene, may be important in some locations. Enantiomeric composition of α -pinene may also be important (Allison et al., 2004). Erbilgin et al. (2001) found that *Pachylobius picivorus* were attracted equally to traps baited with ethanol and (+)- α -pinene as to traps baited with ethanol and (–)- α -pinene in Louisiana. However, they also found that catches of *H. pales* were lower in traps baited with ethanol and (+)- α -pinene than in traps baited with ethanol and (–)- α -pinene.

Managers of agencies responsible for interceptions of exotic species at ports-of-entry face a dilemma in choosing between general lures that attract a broad array of bark and wood-boring beetles and species-specific lures for a trapping program. Traps baited with commercial lures releasing ethanol and (–)- α -pinene at high rates are attractive to many common large wood-boring beetles from the southeastern USA (Figs. 1, 2, 3, 4, 5, 6, and 7) and other regions of North America (Phillips et al., 1988; Chénier and Philogène, 1989; Hunt and Raffa, 1989; Erbilgin et al., 2001; Allison et al., 2001; Morewood et al., 2002; Costello, 2005). Ethanol does not seem to interrupt attraction of these species to traps baited with (–)- α -pinene.

Species-specific attractants, such as pheromones, may be much more attractive than ethanol and (–)- α -pinene albeit to a smaller number of species (Billings and Cameron, 1984; Allison et al., 2003). The bark beetle pheromones ipsenol and ipsdienol are attractive to bark beetles as well as various species of sawyer beetles (*Monoctonus* spp.) in North America, but few other cerambycids (Billings and Cameron, 1984; Billings, 1985; Miller and Borden, 1990; Allison et al., 2001, 2003; De Groot and Nott, 2004; Miller and Asaro, 2005). However, as the absolute

efficiency of such lures in trapping populations of any species of bark- and wood-boring beetles is largely unknown, the relative increase in attraction to species-specific lures may not be that significant in forested areas. The relative increase in efficiency may be more important at ports-of-entry than in forested areas simply because of the lack of competing sources of attractants on average. Therefore, adding bark beetle pheromone lures to the combination of ethanol and (–)- α -pinene may provide an optimal solution by maintaining a low level of attraction to broad range of wood borers while maintaining a high level of attraction to some key species, such as bark beetles and sawyer beetles.

The issue of trap efficacy is an important one for risk assessments of exotic invasive species. We need to determine the proportion of a population caught by baited funnel traps to predict the real risk at that moment. We also need to know the variation in trapping efficacy caused by various environmental parameters, such as population levels, competing sources of attractants, and the lack of vertical silhouettes. Resolution of all these issues should lead to an increased ability in assessing risk and directing containment operations in an efficacious and timely manner.

The knowledge obtained by our work provides quarantine officials and forest managers in other countries with support for using traps baited with ethanol and (–)- α -pinene for capturing Cerambycidae native to the southeastern USA that may be inadvertently transported to other countries. In addition, such knowledge can be used at processing plants and ports-of-departure within the USA to ensure certification of products free of wood borers. Finally, such knowledge supports the use of traps baited with ethanol and (–)- α -pinene in monitoring the ecological impacts of wildfire and silvicultural treatments in southern forests (Hanula et al., 2002).

Acknowledgments I thank J. D. Allison, J. L. Hanula, W. D. Morewood, and J. F. Negrón for reviews of the original manuscript, C. M. Crowe, C. Asaro, D. Johnson, and R. Brantley for field and laboratory assistance, and the staff at the Apalachicola, Bankhead, Nantahala, Ocala, Oconee, Osceola, and Sumter National Forests and the Blue Valley Experimental Forest for their assistance and permission to conduct these studies on their respective lands. Funding for this research was provided by the USDA Forest Service.

Abstract Poison frogs contain an alkaloid-based chemical defense that is derived from a diet of certain alkaloid-containing arthropods, which include mites, ants, beetles, and millipedes. Variation in population-level alkaloid profiles among species has been documented, and more than 800 different alkaloids have been identified. In the present study, we examine individual alkaloid variation in the dendrobatid poison frog *Dendrobates pumilio* among seven populations and between two seasons on Isla Bastimentos, located in the Bocas del Toro archipelago of Panama. Alkaloid profiles vary among populations and between seasons, illustrating that chemical defense in this species can vary on a small spatial and temporal scale. Alkaloid variation among populations is marginally correlated with geographic distance, and close populations have profiles more similar to each other than to distant populations. Individuals within populations also vary in alkaloid profiles. Differences are attributed to both spatial and temporal variations in the availability of alkaloid-containing arthropods. Many of the alkaloids present in the skin of *D. pumilio* appear likely to be of ant origin, supporting the importance of myrmecophagy in chemical defense among poison frogs. However, a variety of frog skin alkaloids was recently detected in mites, suggesting that mites may also play an important role in chemical defense.

Introduction

Chemical defense in animals generally involves the manufacture or acquisition of defensive compounds from other organisms (Mebs, 2001). Although manufacturing defensive compounds is more common among animals, their acquisition from other organisms has convergently evolved in numerous lineages (Termonia et al., 2001). Animals commonly acquire defensive compounds from other organisms through the uptake, accumulation, in some cases modification, and storage of compounds (or precursors) that were originally present in other organisms, including microorganisms, plants, or other animals (Mebs, 2001; Termonia et al., 2001). Animals that employ this type of defensive strategy are dependent on symbiotic relationships with organisms capable of manufacturing defensive chemicals or a particular diet of chemically defended prey (Mebs, 2001).

Arthropods represent the largest group of animals known to acquire defensive compounds through diet, and this ability is known for lepidopterans, orthopterans, hemipterans, coleopterans, and hymenopterans (Boppre, 1990; Hartmann and Witte, 1995; Hartmann and Ober, 2000; Klitzke and Trigo, 2000). In addition to arthropods, flatworms (Kubaneck et al., 1995), nudibranch mollusks (Cimino and Ghiselin, 1998; Fahey and Garson, 2002), birds (Dumbacher et al., 2000, 2004), amphibians (Daly et al., 1994a,b, 2000, 2002, 2005; Jones et al., 1999; Saporito et al., 2003, 2004; Clark et al., 2005), and possibly snakes (Mori and Burghardt, 2000) have also been reported to acquire defensive compounds from dietary sources.

Poison frogs represent a group of organisms that are chemically defended from predation and possibly microorganisms by the dietary uptake of lipophilic alkaloids from arthropod prey (Daly and Myers, 1967; Daly et al., 1994a,b, 2000, 2002; Jones et al., 1999; Saporito et al., 2003, 2004; Clark et al., 2005; Macfoy et al., 2005). More than 800 alkaloids, representing at least 24 different structural classes, have been isolated from the skin of brightly colored poison frogs from four different anuran families (Dendrobatidae from Central and South America; Bufonidae from South America; Mantellidae from Madagascar; Myobatrachidae from Australia; Daly et al., 2005). The ability to uptake certain alkaloids through diet has been experimentally demonstrated in dendrobatid frogs of the genera *Dendrobates*, *Phyllobates*, and *Epipedobates* (Daly et al., 1994b), and mantellid frogs of the genus *Mantella* (Daly et al., 1997). It seems likely that bufonid toads of the genus *Melanophryniscus* will share a similar ability to uptake alkaloids (Garraffo et al., 1993a). Myobatrachid frogs of the genus *Pseudophryne* appear to biosynthesize pseudophrynamine alkaloids, yet are able to accumulate dietary provided pumiliotoxin alkaloids (Smith et al., 2002). Frogs of the genus *Dendrobates* have been shown to efficiently convert a dietary pumiliotoxin alkaloid (**251D**) to a more toxic allopumiliotoxin alkaloid (**267A**; Daly et al., 2003), and one species of the genus *Pseudophryne* appears to be able to metabolize a dietary pumiliotoxin (**307A**) by both reduction and hydroxylation (Smith et al., 2002), representing the only known incidents of alkaloid modification in poison frogs.

A variety of alkaloids are present in arthropods (for a review see, Jones and Blum, 1983; Numata and Ibuka, 1987; Braekman et al., 1998 and references within), and the ability of poison frogs to accumulate alkaloids through diet suggests that sequestration of these compounds from arthropod prey accounts for their presence in the skin of these frogs (with the exception of the pseudophrynamines of

myobatrachid poison frogs). Several alkaloid classes found in the skin of poison frogs have been identified in arthropods such as oribatid mites (Takada et al., 2005; Saporito et al., unpublished data), myrmicine, formicine, and ponerine ants (Daly et al., 1994a, 2000; Jones et al., 1999; Saporito et al., 2004; Clark et al., 2005), siphonotid millipedes (Saporito et al., 2003; Clark et al., 2005), and coccinellid and melyrid beetles (Ayer and Browne, 1977; Dumbacher et al., 2004). These arthropods represent the likely dietary sources for certain alkaloids found in poison frogs. Therefore, their presence in poison frogs is the result of uptake, accumulation, in certain cases modification, and storage of alkaloids from a diet of alkaloid-containing arthropods.

Alkaloid profiles (a measure of the number, type, and amount of alkaloids) are known to vary spatially and temporally among and within species of poison frogs (Myers and Daly, 1976, 1980; Daly et al., 1987, 1992, 1994a,b, 1996, 2002; Garraffo et al., 1993a,b; Myers et al., 1995; Clark et al., 2005; Mebs et al., 2005; and references within). In most cases, alkaloid variation has been described on a population level, in which samples of frogs collected from a certain population are pooled for chemical analysis (examples include Daly et al., 1987, 1996, 2002; Garraffo et al., 1993a,b; Mortari et al., 2004; and references within). Alkaloid variation among individuals within a population has been reported, but only in a few instances (see Daly et al., 1992, 1994a,b; Clark et al., 2005; Mebs et al., 2005; Myers et al., 1995). Although it is generally assumed that alkaloid variation within populations is less than variation among populations (see Daly et al., 1992), relatively few studies have directly addressed this issue. Changes over time in profiles have also been documented (Daly et al., 1987, 2002; Myers et al., 1995); however, no studies have specifically examined the question.

This study investigated the degree of geographic and temporal variations in alkaloid chemical defense within and among populations of the dendrobatid poison frog, *Dendrobates pumilio*, on Isla Bastimentos, located within the Bocas del Toro archipelago of Panama. The natural geographic range of *D. pumilio* extends from lowland Caribbean rainforests of southern Nicaragua through Costa Rica and into northwestern portions of Panama (Myers and Daly, 1983). Population-level alkaloid profiles have been shown to vary among populations of *D. pumilio* in the northwestern portions of Panama within and among islands in the Bocas del Toro archipelago, on the mainland bordering the archipelago, and in a few cases over time (Daly et al., 1987, 2002, unpublished data). In this study, we take a multivariate statistical approach to examine differences in individual alkaloid profiles within and among populations of *D. pumilio* over a small geographic range and between two different seasons.

Methods and Materials

Frog Collections

A total of 70 *D. pumilio* were collected from seven different populations located on Isla Bastimentos, Bocas del Toro Province, Panama (Fig. 1 and Table 1). Five *D. pumilio* were collected at each of the seven populations during the dry and wet seasons of 2003 (February 2–8 and August 20–23, respectively), for a total of 10

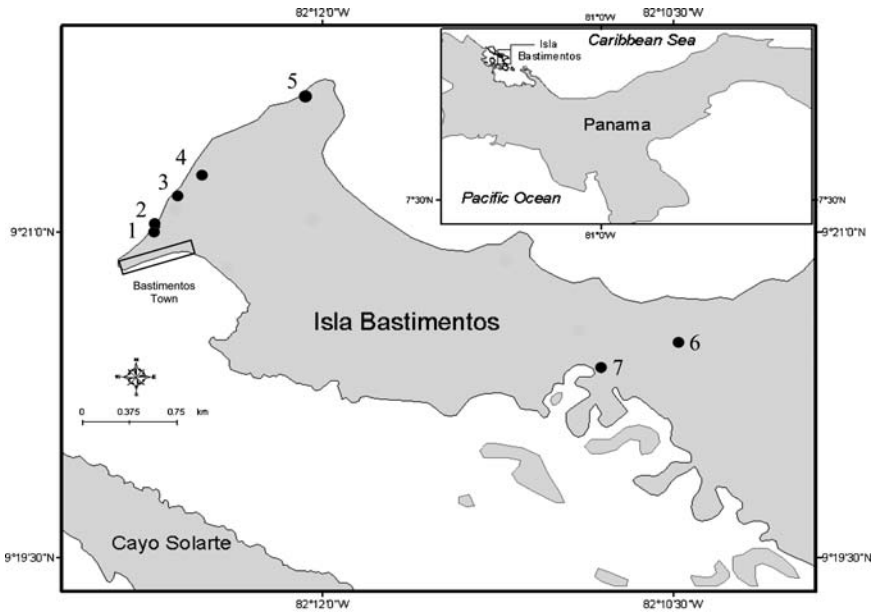

Fig. 1 Map of research sites on Isla Bastimentos, Bocas del Toro, Panama

frogs per population. At each of the seven sites, one 45×45 m plot was established. Frogs were captured by hand and the same plots were used in both seasons. Individuals were measured snout to vent (SVL) to the nearest 0.5 mm, and sex was determined. Only adult frogs were used (>20 mm SVL). All frogs were euthanized in the field laboratory, and individual *D. pumilio* skins were stored in uniquely marked 1.7-ml plastic vials containing 100% methanol at ambient temperature. All

voucher specimens were deposited in the herpetological collection at Florida International University.

Alkaloid Extraction and Isolation

Individual alkaloid fractions were generated for all 70 *D. pumilio*; however, the protocol for preparing the individual fractions differed between seasons. Alkaloid fractions for the dry season samples was prepared as described by Daly et al. (1994b), whereas alkaloid fractions for the wet season samples were obtained from a modified version of this protocol (see below). The modified version was used to reduce analysis time.

Dry Season Samples

Each skin was cut into small pieces and macerated (with a mortar and pestle) \times 3, each time with 5 ml methanol. The combined methanol extract was diluted with 15 ml water and extracted \times 3, each time with 15 ml chloroform. Combined chloroform layers were concentrated to a small volume (\sim 5 ml) *in vacuo* at 35°C with a rotary evaporator. Following concentration, 20 ml *n*-hexane were added to the concentrated chloroform layer. This solution was extracted \times 3, each time with 15 ml of 0.1 N HCl. The combined 0.1 N HCl fractions were adjusted to pH 9.0 with 2 N aqueous ammonia, followed by extraction \times 3, each time with 15 ml chloroform. The combined chloroform extract was dried with anhydrous Na₂SO₄ and evaporated to dryness at 35°C *in vacuo* with a rotary evaporator. The resulting alkaloid residue was dissolved in sufficient methanol so that 100 μ l of this alkaloid fraction corresponded to 100 mg of the original wet weight of the skin. In the dry season samples, it appeared that the recovery of alkaloids was less than expected, although there was no apparent explanation for the poor yield.

Wet Season Samples

Each skin was cut into small pieces and macerated (with a mortar and pestle) \times 2, each time with 4 ml methanol. The combined methanol extract was immediately mixed with 8 ml of 0.1 N HCl and extracted \times 5, each time with 20 ml hexane. The pH was adjusted to 9.0 with 2 N aqueous ammonia, followed by extraction \times 3 with 15 ml chloroform. This solution was dried with anhydrous Na₂SO₄ and evaporated to dryness at 35°C *in vacuo* with a rotary evaporator. Following the original protocol, the resulting alkaloid residue was dissolved in sufficient methanol so that 100 μ l of this alkaloid fraction corresponded to 100 mg of the original wet weight of the skin.

Alkaloid Identification (GC-MS)

All alkaloids within each fraction were identified by using gas chromatography in conjunction with mass spectrometry (GC-MS). Identification of individual alkaloids was based on comparison of retention times and mass spectral data with expected data for known anuran alkaloids. Anuran alkaloids have been assigned a code name, consisting of a bold-faced number corresponding to the nominal mass and a bold-faced letter for identification of individual alkaloids with the same nominal mass

(Daly et al., 1999). A revised, updated tabulation with code names for over 800 anuran alkaloids is now available (Daly et al., 2005).

GC-MS analysis for all dry season samples was performed on a Finnigan GCQ instrument with a 25 m × 0.25 mm i.d. Rtx-5 amine fused-silica column (Restek). GC-MS analysis for all wet season samples was performed on the same Finnigan GCQ instrument, however with a 30 m × 0.25 mm i.d. DB-1 fused-silica column (J&W Scientific). GC separation of alkaloids was achieved by using a temperature program from 100 to 280°C at a rate of 10°C per min with helium as the carrier gas. Each extract was analyzed with both electron impact-mass spectrometry (EI-MS) and chemical ionization-mass spectrometry (CI-MS) with ammonia as the reagent

gas. An injection volume of 2 μ l was used for each frog alkaloid fraction, corresponding to 2 mg wet weight frog skin.

Alkaloid Quantification (GC-FID)

All alkaloids within each fraction were assessed quantitatively by using gas chromatography in combination with a flame-ionization detector (GC-FID). GC was performed on a Hewlett Packard 5890 with a 6-ft 1.5% OV-1 packed column (2 mm i.d.). GC separation of alkaloids was achieved by using a temperature program from 150 to 280°C at 10°C per min with helium as the carrier gas. An injection volume of 2 μ l was used for each alkaloid fraction, corresponding to 2 mg wet weight frog skin.

In order to quantitatively assess the amount of alkaloids within individual frogs, a calibration curve for GC-FID was constructed by using a standard of the alkaloid, decahydroquinoline (DHQ) **195A**. Decahydroquinoline **195A** is the most common alkaloid found in all frog populations from the northwest coast of Isla Bastimentos. Each alkaloid within an individual frog was assigned to one of the following quantitative categories: (1) major alkaloid (present in an amount greater than or equal to 50 μg per 100 mg frog skin), (2) minor alkaloid (present in an amount between 5 and 50 μg per 100 mg frog skin), or (3) trace alkaloid (present in an amount less than 5 μg per 100 mg frog skin). Using this quantification scheme allows for the direct comparison of data from this study to those of previous and current studies conducted on other lipophilic alkaloid-containing frogs and toads.

Statistical Analyses

Variation in individual alkaloid profiles within and among populations of *D. pumilio* were graphically visualized for both seasons by using nonmetric multidimensional scaling (nMDS). Statistical differences in individual alkaloid profiles among populations for each season were detected with a one-way analysis of similarity (ANOSIM). Statistical differences in individual alkaloid profiles among the same populations between seasons were examined with a two-way ANOSIM. Both nMDS plots and ANOSIM results are based on Bray–Curtis dissimilarity matrices. A Mantel test was performed to examine the relationship between geographic distance and alkaloid profile variation among populations for the wet season data. All statistical analyses were performed with the software program PRIMER (version 5) and the PopTools add-in function in Microsoft Excel (written by G. Hood; available at <http://www.cse.csiro.au/poptools>).

Results

Alkaloids Present in *D. pumilio*

A total of 153 alkaloids, representing 16 different structural classes, were identified from *D. pumilio* skin extracts. Individual frogs contained an average of 17 different alkaloids (range 6–31 alkaloids). Populations also contained an average of 17

different alkaloids (range 9–31 alkaloids). Decahydroquinoline **195A** was found in all frog skin extracts from each of the seven sites during both seasons, and represents the most common and widespread alkaloid among populations of *D. pumilio* on Isla Bastimentos. Decahydroquinoline **195A** is thought to be obtained from myrmicine ants that are found microsympatrically with dendrobatid frogs containing this alkaloid (Daly et al., 2000, 2002). Based on the presence of an

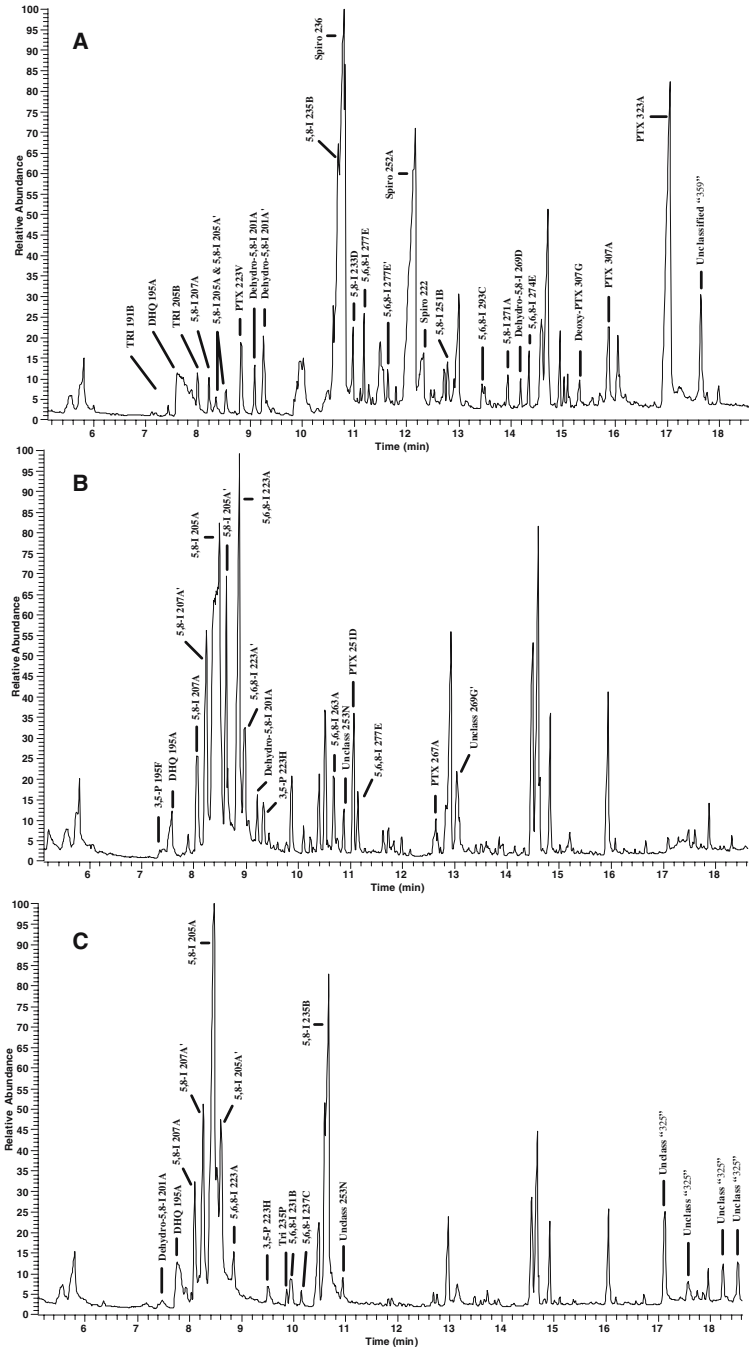

Fig. 4 Nonmetric multidimensional scaling (nMDS) plot of *D. pumilio* alkaloid profiles among seven populations on Isla Bastimentos during the wet season. nMDS plot is based on major, minor, and trace alkaloids. alkaloid in at least three out of the five frogs sampled from each site (excluding alkaloids present in trace amounts), the other most abundant alkaloids in populations of *D. pumilio* were 5,8-disubstituted indolizidines (5,8-Is) **205A**, **207A**, and **235B''**, pumiliotoxins (PTXs) **307A** and **323A**, tricyclics (TRIs) **205B** and **191B** (propyleine), spiropyrrrolizidines (Spiros) **236** and **252A**, a 5,6,8-trisubstituted indolizidine (5,6,8-I) **223A**, a 3,5-disubstituted pyrrolizidine (3,5-P) **223H**, and two unclassified alkaloids of apparent molecular weight “321” and “325.” Chemical structures for these are shown in Fig. 2 (structures have not yet been proposed for the two unclassified alkaloids).

The 5,8-Is **205A** and **207A** were detected as major or minor alkaloids in most frog skin extracts from sites 2, 5, 6, and 7, whereas the 5,8-I **235B''** was a major or minor alkaloid in most frog skin extracts from sites 1, 2, 3, 4, and 7. The PTXs **307A** and **323A** were detected as major or minor alkaloids in frog skin extracts from sites 1, 2, 3, and 4. The tricyclic **205B** was a major or minor alkaloid in most frogs from sites 1, 2, 3, and 4, whereas the tricyclic **191B** was a major or minor alkaloid in most frogs from sites 1, 2, and 3. The Spiros **236** and **252A** were the major or minor alkaloids in most frogs from sites 1 and 2. The 5,6,8-I **223A** was a major or minor alkaloid in most frogs from sites 3, 5, and 7. The 3,5-P **223H** was a major or minor alkaloid in most frogs from sites 3 and 4. Two unidentified alkaloids, “321” and “325,” were detected as major alkaloids in all frogs from site 7, but only during the wet season. Site locations and descriptions are in Table 1 and Fig. 1. The above information is summarized in Table 2.

Alkaloid Variation—Dry Season

Alkaloid profiles for individual frogs during the dry season were significantly different among the seven sites (Global $R = 0.77$, $P < 0.001$). Pairwise comparisons of the seven sites showed no statistical difference in alkaloid profiles between frogs from sites 3 and 4 (Global $R = 0.19$, $P < 0.063$). Differences within and among sites are graphically displayed with nMDS (Fig. 3). Due to low recoveries, profiles for individual frogs during the dry season were statistically analyzed based on untransformed presence/absence of alkaloids.

Alkaloid Variation—Wet Season

Alkaloid profiles for individual frogs during the wet season were significantly different among all seven sites (Global $R = 0.83$, $P < 0.001$). Differences within and among sites are graphically displayed with nMDS (Fig. 4). Profiles for individual frogs during the wet season were statistically analyzed based on untransformed categorical (i.e., major, minor, or trace) alkaloid data. Representative alkaloid profiles for an individual frog from sites 2, 5, and 6 are presented in Fig. 5. Alkaloid

Fig. 5 Gas chromatographs of alkaloid profiles of individual *D. pumilio* from three different populations on Isla Bastimentos, illustrating variation in alkaloids among populations. Only major and minor alkaloids are identified in the chromatographs. Peaks that are not identified represent trace alkaloids or nonalkaloid compounds (i.e., plasticizers, fatty acid methyl esters, etc. that were not removed during the fractionation process). (A) Individual *D. pumilio* from site 2, (B) individual *D. pumilio* from site 5, (C) individual *D. pumilio* from site 6. Site numbers correspond to map in Fig. 1

Fig. 6 Nonmetric multidimensional scaling (nMDS) plot of *D. pumilio* alkaloid profiles for individual frogs in seven populations on Isla Bastimentos between the dry and wet season. nMDS plot is based on the presence/absence of alkaloids. Each symbol represents an individual frog from a specific population and season. Site numbers correspond to map in Fig. 1

profiles were positively correlated with geographic distance among all seven sites ($R = 0.51$, $P < 0.001$).

Alkaloid Variation—Dry vs. Wet Season

Alkaloid profiles for individual frogs among the seven sites between the dry and wet season were significantly different (Global $R = 0.502$, $P < 0.001$). Differences in alkaloid profiles among sites and between seasons are graphically displayed with nMDS (Fig. 6). Due to low recoveries in the dry season samples, alkaloid profiles for individual frogs among sites and during both seasons were statistically analyzed based on untransformed presence/absence of alkaloids.

Discussion

Alkaloid profiles of *D. pumilio* examined in this study varied significantly among populations and between seasons on Isla Bastimentos, Bocas del Toro, Panama. The seven populations are located in the northwestern region of Isla Bastimentos and no two populations are more than 3.5 km in distance from each other (with most populations being less than 1 km apart; see Fig. 1), demonstrating that chemical defense can vary considerably over a relatively small geographic range. Our results are consistent with a previous study (Daly et al., 2002), which showed that population-level alkaloid profiles varied among five of the same populations. Alkaloid profiles in this study also varied between populations sampled during the dry and wet season, illustrating that chemical defense in *D. pumilio* can vary across short periods of time. Although differences in alkaloid profiles have been documented among

years in certain populations of *D. pumilio* (Daly et al., 1987, unpublished data), changes have never been described for a time period as brief as two seasons.

Variation in alkaloid profiles among populations of *D. pumilio* within a season is related to geographic proximity, and close populations tend to have more similar profiles than distant ones. Myers and Daly (1976) have shown that geographically close populations of *D. histrionicus* share more alkaloids than do distant populations. Myers et al. (1995) reported that sympatric populations of *D. pumilio* and *D. granuliferus* contain more alkaloids in common with each other than with geographically distant populations of *D. granuliferus*. Daly et al. (1992) illustrated that introduced populations of *D. auratus* in Hawaii have alkaloid profiles more similar to each other than those of their ancestral population from Panama. In our study, geographic distance accounted for 51% of the difference in alkaloid profiles among populations of *D. pumilio*, suggesting that the distribution of certain alkaloid-containing arthropods in this region is also related to geographic distance.

Variation in profiles among individuals within populations is less than variation among populations. Daly et al. (1992) stated that there is variation in the amounts of alkaloids found in individuals within populations of *D. auratus*, and suggested that these differences were less than differences among populations. Daly et al. (1994a,b) illustrated that although alkaloid compositions are similar within populations of *D. auratus*, the relative amounts of a given alkaloid are variable. Our study with *D. pumilio* supports these findings. Myers et al. (1995) described individual alkaloid variation within two populations of *D. granuliferus* and one population of *D. pumilio* from Costa Rica, and concluded that there were differences among individual frogs. Clark et al. (2005) recently reported that individual alkaloid profiles varied within populations for three species of *Mantella* from Madagascar. Mebs et al. (2005) recently reported variable levels of alkaloids (particularly the pumiliotoxin **251D**) in individuals of *Melanophryniscus montevidensis* from Uruguay. In our study, individual frogs within a population differed in overall alkaloid profiles (differences in the number of alkaloids present in individual frogs are illustrated in Fig. 7). In some cases, alkaloids that were predominant in one frog were completely absent in another frog from the same population. Clark et al. (2005) suggested that individual variation within populations of *Mantella* represents the possibility that some alkaloid-containing arthropods are rare. Based on the degree of individual alkaloid variation observed here, we agree that certain alkaloid-containing arthropods are rare, and further suggest that in some cases, the distribution of arthropods is confined to small areas and may be the result of localized hatches or migrations (Daly et al., 2002). Differences in alkaloid profiles among *D. pumilio* individuals within a population likely represent local small-scale geographic differences in the availability of certain alkaloid-containing arthropods.

The presence of an alkaloid-based chemical defense in poison frogs (including *D. pumilio*) is a result of the dietary accumulation of alkaloids from a variety of arthropod prey items. Coccinellid beetles contain coccinelline alkaloids as well as some of the structurally related tricyclic alkaloids (Ayer and Browne, 1977), and an oribatid mite contains two coccinelline alkaloids (Takada et al., 2005). Batrachotoxin alkaloids have been identified in melyrid beetles (Dumbacher et al., 2004) and spiropyrrolizidine alkaloids in siphonotid millipedes (Saporito et al., 2003; Clark et al., 2005). Ants appear to be the largest presumed source of alkaloids in poison frogs. In particular, 2,5-disubstituted pyrrolidines, 2,6-disubstituted piperidines, 3,5-disubstituted pyrrolizidines, 3,5-disubstituted indolizidines, 4,6-disubstituted quinoli-

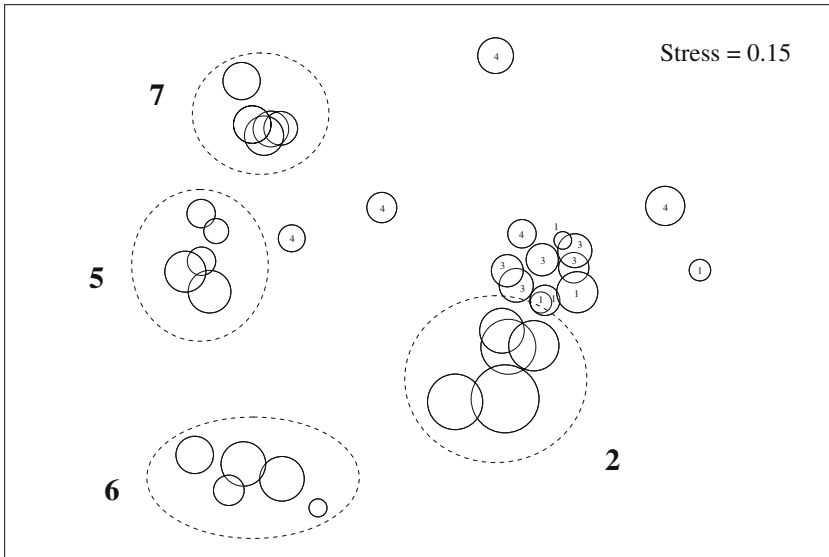

Fig. 7 Nonmetric multidimensional scaling (nMDS) plot of *D. pumilio* alkaloid profiles for individual frogs in seven populations on Isla Bastimentos during the wet season. nMDS plot is based on major, minor, and trace alkaloids. Each symbol represents an individual frog from a specific population. Site numbers correspond to map in Fig. 1. The size of each circle is proportional to the total number of alkaloids in that individual

zidines, and 2,5-disubstituted decahydroquinolines have been identified in ants of the subfamily Myrmicinae (Daly et al., 1994a, 2000; Jones et al., 1999; Clark et al., 2005). These alkaloids contain unbranched carbon skeletons. In addition, 3,5-disubstituted lehmizidines, histrionicotoxins, and gephyrotoxins are alkaloid classes that share certain structural features (i.e., unbranched carbon skeletons) with those of known myrmicine ant alkaloids, and it is expected that they will prove to be of myrmicine ant origin as well (Daly et al., 2005). 5,8-Disubstituted indolizidines have been identified in a mixed collection of leaf-litter arthropods from Isla Bastimentos, Panama (Daly et al., 2002), and recently in ants of the subfamily Myrmicinae from Madagascar (Clark et al., 2005). 2,5-Disubstituted pyrrolidines and 3,5-disubstituted pyrrolizidines were recently reported in ants of the subfamilies Formicinae and Ponerinae from Madagascar (Clark et al., 2005). A 5,6,8-trisubstituted indolizidine has been identified in ants from Panama; however, the sample included several ant species, and the specific ant taxon that contains the compound could not be determined (Saporito et al., 2003). In addition, a 5,6,8-trisubstituted indolizidine and a 1,4-disubstituted quinolizidine have been identified in an oribatid mite (Takada et al., 2005). Pumiliotoxin alkaloids have been identified in ants of the subfamily Formicinae from Panama (Saporito et al., 2004) and more recently in oribatid mites (Takada et al., 2005).

Poison frogs' dependence on arthropods for chemical defense suggests that much of the geographic and temporal variation observed in alkaloid profiles is the result of variation in availability of alkaloid-containing arthropods. In tropical regions, arthropod abundances are known to vary spatially and temporally (Janzen and Schoener, 1968; Janzen, 1973; Lieberman and Dock, 1982; Levings and Windsor,

1984; Levings, 1983), suggesting that the availability of alkaloid-containing arthropods is variable. On Isla Bastimentos, the spiropyrrolizidine alkaloid **236** and the pumiliotoxin alkaloids **307A** and **323A** are major alkaloids in certain populations of *D. pumilio*. Recently, arthropod sources for these two classes of alkaloids have been shown to occur sympatrically with the same populations of *D. pumilio* examined in this study (Saporito et al., 2003, 2004). The spiropyrrolizidine **236** is a major alkaloid in two of the seven populations of *D. pumilio* on Isla Bastimentos; however, in 1972 it was not detected in these populations (Daly et al., 1987, 2003). The appearance of this alkaloid in populations of *D. pumilio* today is most likely due to a recent introduction and current availability of the millipede *Rhinotus purpureus* (Family: Siphonotidae) as a dietary source (Saporito et al., 2003). The presence of **236** in certain populations of *D. pumilio* supports the idea that spatial and temporal differences in arthropod availability plays an important role in alkaloid variation of these dendrobatid frogs. Recently, a variety of different spiropyrrolizidine alkaloids, including **236**, have also been discovered in *R. purpureus* millipedes from Madagascar, which occur sympatrically with alkaloid-containing mantellid frogs (Clark et al., 2005). These findings suggest that variation in alkaloids within the same species of arthropod may also be responsible for alkaloid variation among poison frogs. The pumiliotoxins **307A** and **323A** are present in variable amounts in certain populations of *D. pumilio* on Isla Bastimentos. Dietary sources for these have been identified in two different genera of ants in the Subfamily Formicinae (*Paratrechina* and *Brachymyrmex*) in regions where *D. pumilio* populations are known to contain variable amounts of these alkaloids (Saporito et al., 2004). Interestingly, their presence in *Brachymyrmex* is also variable. The pumiliotoxins **307A** and **323A** were not detected in all *Brachymyrmex* samples collected within a site, and certain ant samples contained only one of the two pumiliotoxins (Saporito et al., 2004). The pumiliotoxins were not detected in ants from the dry season (Saporito et al., 2004). The variable presence of pumiliotoxins in *Brachymyrmex* suggests the possibility of a dietary source or microsymbiont as the ultimate source for these alkaloids in ants (Saporito et al., 2004). Recently, the pumiliotoxins **237A** and **251D** and the deoxypumiliotoxin **193H** were identified in two different species of scheloribatid mites (*Schelorbates azumaensis* and *Schelorbates* sp.), suggesting that mites may be the ultimate source for some of the pumiliotoxin alkaloids (Takada et al., 2005). However, ants in the genus *Solenopsis* are known to be caste-specific in the production of alkaloids (Deslippe and Guo, 2000; Torres et al., 2001), and it remains possible that alkaloid variation in *Brachymyrmex* is attributable to differences among castes. Regardless of the source of alkaloid variation in *Brachymyrmex*, the variable presence of pumiliotoxins in these ants suggests that alkaloid variability of certain arthropod prey items may contribute to alkaloid profile variation in *D. pumilio*.

Other factors may also contribute to alkaloid variation within and among populations of *D. pumilio*. Some poison frogs possess the ability to modify certain dietary pumiliotoxin alkaloids (Smith et al., 2002; Daly et al., 2003). One species in the genus *Pseudophryne* is able to convert the pumiliotoxin **307A** to a significant extent into reduced and/or hydroxylated pumiliotoxins of molecular weights 309, 323, and 325 (Smith et al., 2002). Frogs in the genus *Dendrobates* are able to convert over 70% of the natural dietary (+)-enantiomer of pumiliotoxin **251D** (by stereoselective hydroxylation) into the natural (+)-allopumiliotoxin **267A** (Daly et al., 2003). Frogs of the genus *Dendrobates* did not hydroxylate the unnatural (–)-en-

antimer of pumiliotoxin **251D** (Daly et al., 2003). The presence of such a hydroxylase raises the likelihood that poison frogs are able to convert other pumiliotoxin alkaloids (i.e., side-chain hydroxylated analogs) into allopumiliotoxins. Both of these processes are likely mediated by enzymes and are under some genetic control, and a differential ability to modify certain alkaloids would influence variability in profiles. Pumiliotoxin **251D** is always accompanied by **267A** in populations of *D. pumilio* that have been examined (this study; Daly et al., 1987, 2003, and unpublished data), and, therefore, the data do not suggest a difference in the ability to convert **251D** within and among populations of *D. pumilio*. However, differences among genera of poison frogs in the ability to modify certain pumiliotoxins appear to contribute to alkaloid variation among species (Daly et al., 2003). For instance, frogs of the genera *Phyllobates* and *Epipedobates* did not hydroxylate dietary pumiliotoxin **251D** (Daly et al., 2003). The ability to uptake and sequester certain alkaloids is also likely under genetic control (Myers et al., 1995), and variation in alkaloid profiles of *D. pumilio* may be in part due to genetic variation in the uptake/sequestration process. Although not intended to address genetic differences in alkaloid uptake, Summers et al. (1997) demonstrated that there were low degrees of mitochondrial DNA divergence among populations of *D. pumilio* in the Bocas del Toro region of Panama, including populations on Isla Bastimentos. This study illustrates that there are no prominent genetic differences among populations, at least as revealed by mitochondrial markers, suggesting that genetic factors are not responsible for the variation observed in alkaloid profiles. In addition, genetic factors would not solely explain differences in alkaloid profiles between seasons. Finally, it remains possible that differences in prey selectivity may explain alkaloid variation. If different populations and individuals within populations are differentially utilizing prey, alkaloid profiles could reflect variable prey consumption. In a study of *D. pumilio* diet in Costa Rica, Donnelly (1991) suggested that frogs change their diet over time in response to natural fluctuation in the availability of food. It is likely that differences in diet of *D. pumilio* within and among populations are also attributable to differences in the availability of arthropod prey. Although differences in selectivity may account for some of the alkaloid variation observed among different species of poison frogs, it is unlikely that individuals of *D. pumilio* confined to a small area exhibit such marked geographic and seasonal differences in dietary selectivity. Donnelly (1991) also reported differences in diet between juveniles and adults as well as between sexes of *D. pumilio*. Here, we only examined adults. However, both males and females were examined, and it is possible that some of the individual variation within populations is related to sexual differences in diet. Although males and females were collected from each population in this study, sample sizes were not large enough to statistically examine differences between sexes.

The natural diet of *D. pumilio* consists mainly of ants and mites (Donnelly, 1991; Caldwell, 1996; Saporito et al., unpublished data). In general, dendrobatid frogs of the genera *Dendrobates*, *Epipedobates*, and *Phyllobates* consume a large proportion of ants as part of their diet, and members of the genus *Dendrobates* (including *D. pumilio*) and some members of the genus *Epipedobates* have been referred to as “ant-specialists” (Donnelly, 1991; Toft, 1995; Caldwell, 1996). Frogs of the genera *Mantella*, *Melanophryniscus*, and *Pseudophryne* have also been shown to consume large amounts of ants (Pengilley, 1971; Filipello and Crespo, 1994; Vences et al., 1998). These findings have led many researchers to suggest that myrmecophagy has

played a major role in the evolution of alkaloid sequestration in poison frogs (Toft, 1995; Caldwell, 1996; Vences et al., 1998, 2003; Summers and Clough, 2001; Daly et al., 2002; Santos et al., 2003; Saporito et al., 2004; Clark et al., 2005; Darst et al., 2005). Interestingly, although myobatrachid frogs of the genus *Pseudophryne* consume a large proportion of ants, they do not appear to accumulate myrmicine ant alkaloids (see Smith et al., 2002). Instead, these frogs synthesize unique indolic pseudophrynamine alkaloids (Smith et al., 2002). Therefore, their uptake system may be designed to retain the pseudophrynamines and also to accept certain dietary pumiliotoxins for uptake and storage (see Smith et al., 2002). In our study, many of the alkaloids are from classes known or suspected to be of ant origin, suggesting that myrmecophagy plays a dominant role in chemical defense in these frogs. However, certain tricyclic, indolizidine, quinolizidine, spiropyrrolizidine, and pumiliotoxin alkaloids were recently detected in mites (Takada et al., 2005; Saporito et al., unpublished data), suggesting that mites represent another major source of alkaloids in poison frogs.

In summary, individual alkaloid profiles of *D. pumilio* are shown to vary among populations and between the dry and wet season on Isla Bastimentos, Bocas del Toro, Panama. Variation in profiles among populations is related to geographic proximity, and it is likely that the availability of alkaloid-containing arthropods in this region share a similar distribution. Individual frogs within a population have alkaloid profiles more similar to each other than to frogs from different populations. Individual variation within a population is attributed to small geographic differences in the distribution of alkaloid-containing prey. Overall, alkaloid variation in *D. pumilio* is likely the result of spatial and temporal variation in the availability of certain alkaloid-containing arthropods and the presence of alkaloids in these arthropods. Many of the alkaloids found in *D. pumilio* appear to be from ant sources, further indicating the importance of ants in chemical defense among poison frogs. Recent findings that certain frog skin alkaloids are also known in mites, suggests that mites may also play an important role in the chemical defense of poison frogs.

Acknowledgments We thank the República de Panamá and the Autoridad Nacional del Ambiente for permission to conduct this research (permits SEX/A-15-03 and SEX/A-45-03), the Smithsonian Tropical Research Institute for assistance with logistics and the map in Fig. 1, Adam L. Edwards for assistance in the field, Lisa Addington for assistance with GIS, Jenise M. Snyder, the Florida International University Herpetology Group and two anonymous reviewers for valuable comments on this manuscript, and the Environmental Protection Agency (Fellowship No. U-91608001-0), Explorers Club, National Institute of Diabetes and Digestive and Kidney Diseases, and the intramural research program of NIDDK for supporting this research. The Institutional Animal Care and Use Committee of Florida International University approved the methods utilized in this study. This paper is contribution number 102 to the program in Tropical Biology at Florida International University.
