after another 6 hr, three flies fed with fluorine analog I died. GC-MS analysis of the rectal glands of all 20 *B. dorsalis* males fed with I (including dead flies) showed three main peaks, one of which was easily identified as (*E*)-coniferyl alcohol (III) matching with the standard by retention time (13.46 min) and mass spectrum. The other two (RT 12.70 and 12.97 min) had almost identical mass spectra with a strong ion at 212 *m/z* that could have been attributed to a molecular ion of *E* and *Z* fluoroolefinic phenols because of similarities with the mass spectrum of IV (Nishida

^aTen flies were presented with 10 μl ME and analog I.

^bFound in rectal glands.

^cTotal in other body parts.

^dMeans followed by different letters are significantly different at the 0.05 level, PROC GLM, Tukey's test (SAS Institute, Version 8.2).

et al., 1988a,b). Having synthesized the targeted products, we identified these peaks as II-E and II-Z. In addition to three main peaks, there were some minor products in these rectal gland extracts but no starting I. However, unmetabolized I was found in fairly large quantities in the abdomen of the flies. In the total 17 males dissected, we found 2948 µg starting fluorinated benzene I (or in average 173 µg per fly) indicating an intense feeding. Finally, there were no phenylpropanoids found in other body parts of the flies fed with fluorine analog I. All 20 flies exposed to ME accumulated phenol IV and coniferyl alcohol III in their rectal glands as expected (Nishida et al., 1988a,b), in some cases in fairly large quantities (15–20 µg). There were no phenylpropanoids found in control flies.

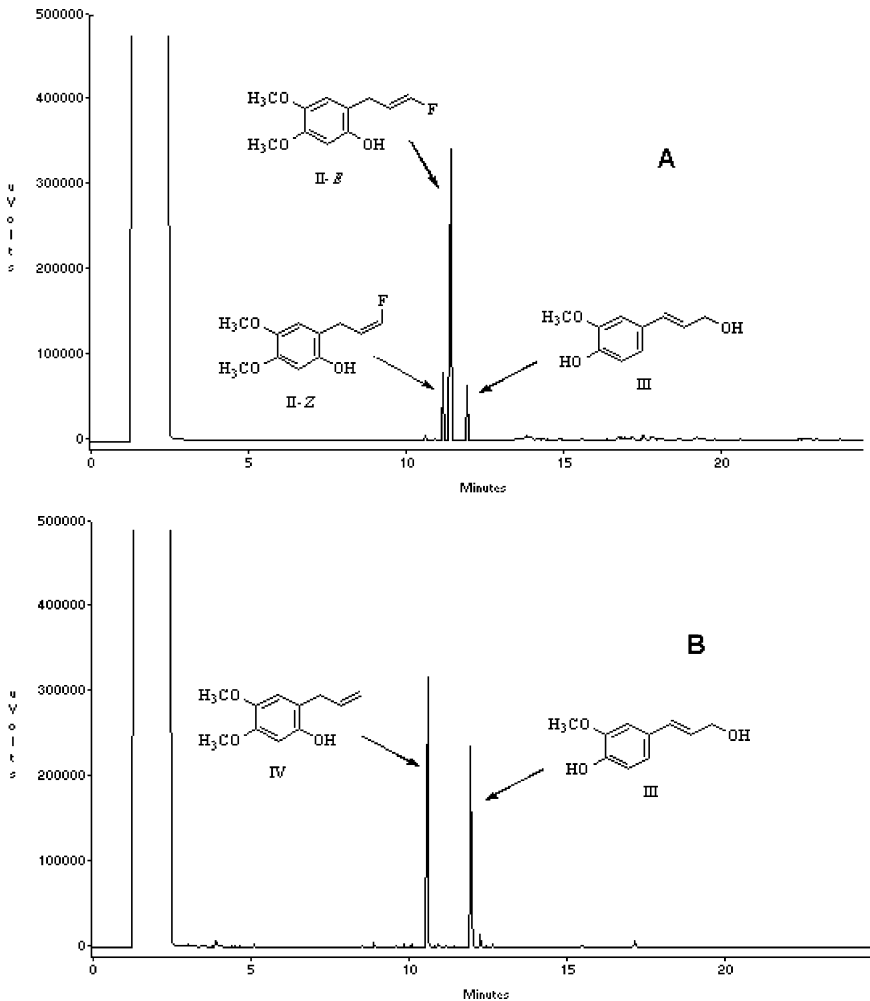

Fig. 1 Gas chromatograms (HP-5, 30 m × 0.25 mm × 0.25 µm, FID) of gland extracts of individual oriental fruit fly males fed with: (A) fluorine analog I (Table 1, species no. 3, II + III = 19.7 µg; II/III = 7.1, mol/mol) and (B) methyl eugenol (Table 1, species no. 1, IV + III = 18.9 µg; IV/III = 1, mol/mol)

In test no. 2, we repeated the experiment with 10 μl of each ME and benzene I and ran the feeding for 40 min. In both treatments, five to six flies initially landed on filter papers; then after 15–20 min, all flew away. In the last 15 min, some flies returned to feeding sources, but we had no knowledge whether all flies touched the filter papers. Dissection of rectal glands was conducted after 24 hr. Quantitative analyses of metabolites as well as unmetabolized ME and fluorine analog I in individual flies are presented in Table 1. With the exception of two species (nos. 2 and 4) that apparently did not touch the source, the rest of fluorine analog-fed *B. dorsalis* males contained large amounts of unmetabolized material in their abdomens, ranging from 28 μg up to ~ 1 mg. Remarkably, a total of 10 flies consumed the fluorinated benzene I (4769.2 ± 99.5 μg) in more than twice the amount of ME (2083.3 ± 250.3 μg), but produced about half the amount of metabolites (99.5 vs. 250.3). The other striking difference was the ratio of metabolites derived from ME and fluorinated benzene I. The average molar ratio of phenol IV and coniferyl alcohol III (Table 1) was 0.8 (± 0.1 SEM), whereas the average ratio II/III was 6.1 (± 0.4 SEM). Gas chromatograms of the rectal gland extracts of two males (one fed with ME and another with benzene I) that produced about the same total amounts of metabolites are presented in Figure 1.

In test no. 3 with 1.0 μl of ME and fluorine analog I, with the exception of one fly fed with analog I, there were no unmetabolized starting materials after 24 hr. The amounts and ratios of metabolites are presented in Table 2. Analogous to the previous test, a total of 10 flies consumed nearly twice as much the fluorine analog I as ME (9.10 vs. 4.58 μg). But in this low-dose consumption, both test compounds

were almost completely metabolized. Again, the mean ratio IV/III was significantly lower than the mean ratio II/III.

Discussion

Formation of coniferyl alcohol III as one of two main metabolites produced by *B. dorsalis* males after feeding on fluorine analog I indicated the occurrence of a side-chain enzymatic hydroxylation, analogously to a biotransformation of ME in the oriental fruit fly. Although mechanistic aspects of ME metabolism in *B. dorsalis* have not been articulated, there is ample information in literature on metabolism of ME in rodents (Solheim and Scheline, 1976; Smith et al., 2002) and even humans (Smith et al., 2002 and references therein). In rats, dimethoxyphenol IV was reportedly one of the major metabolites, but coniferyl alcohol III had not been found (Solheim and Scheline, 1976). In a recent review, Smith et al. (2002) outlined three major metabolic pathways of ME and related phenylpropanoids in mammals: *O*-demethylation to phenols, epoxidation of the double bond followed by hydration, and 1'-hydroxylation to form a benzylic alcohol, which often undergoes allylic rearrangement to a more stable primary alcohol. There was no mention of coniferyl alcohol even as a by-product. Surprisingly, ring hydroxylation leading to phenol IV had been overlooked. At any rate, it appears that coniferyl alcohol is a unique metabolite of ME in *B. dorsalis* and related complex sibling species (Wee et al., 2002), destined to perform a significant pheromonal and allomonal role in fruit-fly biology and ecology (Nishida et al., 1988a,b; Tan and Nishida, 1998, 1996; Wee and Tan, 2001). Mechanistically, the formation of III from ME in *B. dorsalis* could be rationalized as a combination of two major pathways: 1'-hydroxylation with further allylic isomerization and *O*-demethylation in whichever order (Scheme 2). In fact, one product in the 1'-hydroxylation pathway, *cis*-3,4-dimethoxycinnamyl alcohol, was isolated by Nishida et al. (1988b). From this standpoint, metabolism of fluorinated analog I in *B. dorsalis* would lead to a cinnamic aldehyde intermediate VIII (hypothetically through elimination of HF from a 1-fluorocinnamic alcohol) followed by a reduction and further demethylation to coniferyl alcohol III (Scheme 2). The proposed scheme explains the loss of fluorine during metabolic transformation of I to III. However, the aldehyde VIII or its *O*-demethylated analog is yet to be found in the *B. dorsalis* rectal gland extracts. An alternative route includes an enzymatic defluorination of I to form ME, which then follows 1'-hydroxylation–isomerization pathway described above leading to III. Further research will focus on finding evidence supporting either of these hypotheses.

Whether or not the death of three flies in test no. 1 after feeding on fluorine analog I could be associated with a partial metabolic loss of fluorine (in the form of HF or any other) is yet to be determined. In test no. 2 conducted with the same load of I, but even longer feeding, all flies seemed healthy. It seems also possible that feeding on large quantities of I and the inability to efficiently metabolize sicken *B. dorsalis* males, as the consumption of large amounts of even natural product ME reportedly caused the death in the oriental fruit fly (Steiner, 1952). More dose-response studies should be conducted to see whether the fitness of *B. dorsalis* males could be compromised by the intake of fluorine analog I.

Scheme 2 Suggested metabolic transformations of methyl eugenol and fluorine analog I in *B. dorsalis*

Clearly, *B. dorsalis* males perceive the analog I as strong as ME. In two experiments (test nos. 2 and 3), *B. dorsalis* males consumed even total larger quantities of I than the parent molecule. Although not all flies directly contacted the filter papers, they still consumed appreciable amounts of material through a vapor phase. Under our experimental setting, individual *B. dorsalis* males consumed up to 1 mg of I. The highest number for ME intake in *B. dorsalis* was reportedly 2.2 μl , and the average quantity was 700 μg (Wee et al., 2002). The fact that *B. dorsalis* males voraciously feed on fluorine analog I might have a practical implication because eradication programs, by and large, rely on reducing the populations of wild oriental fruit fly males by exposure of ME mixed with toxicants.

Two important observations seem interconnected. At high feed (test no. 2), 10 oriental fruit fly males metabolized after 24 hr only 2.0% of the fluorine analog I they consumed, whereas flies fed with ME metabolized 10.7% of their intake, indicating that incorporation of the fluorine atom overall impeded the metabolism. As a result, total amount of metabolites from ME was higher than from analog I. At low feed (test no. 3), the flies were still able to efficiently metabolize almost the entire intakes of the analog I (and not surprisingly, ME), which resulted in the reversal of metabolite quantities. However, in both test nos. 2 and 3 run at different doses, the fluorination unmistakably redirected the metabolism in favor of ring-hydroxylation pathway. Introduction of fluorine (as an isosteric replacement for hydrogen) in the biologically active substances including insect semiochemicals has long been pursued for altering volatility and lipophilicity, as probes for studying the insect communication mechanism, enhancing metabolic stability, and as enzyme inhibitors (for a recent review, see Pesenti and Viani, 2004). Whatever the mecha-

nism, the introduction of fluorine at the terminal atom of the double bond of ME appears to overall retard the oxidative biotransformation of this important plant phenylpropanoid in *B. dorsalis* and specifically influenced side-chain hydroxylation. It is intriguing whether the metabolism of fluorine analog I in mammals will follow the same path.

Abstract The effect of brief pheromone exposures on responses of codling moth (*Cydia pomonella* L.) males was tested by flight-tunnel and electroantennogram (EAG) studies. Males were preexposed to pheromone for up to 3 min as they sat in release cages or for shorter times (a few seconds to several min) upon initiating flights or orienting in plumes. Brief exposures to Isomate-C Plus dispensers nearly eliminated moth orientations to 0.1 mg codlemone [(*E,E*)-8,10-dodecadien-1-ol] and 0.1 mg three-component (codlemone/12OH/14OH, 100:20:5 ratio) lures 15 min later. However, there was no associated change in EAG responses between preexposed and control moths. Behavioral responses of Isomate-C Plus-exposed males were normal 24 hr following exposure. The reduced sexual responsiveness observed following exposure to Isomate dispensers appeared to be associated with an elevation of response threshold. Brief preexposure to 0.1 mg codlemone and three-component lures also reduced orientational behavior of males 15 min later, but to a lesser degree than when preexposed to Isomate-C Plus dispensers. Male behavior following preexposure to a 0.1 mg codlemone/pear ester [(*2E,4Z*)-2,4-decadienoate] lure (1:1 ratio) was no different from exposure to codlemone only. Orientational disruption in plots treated with 10 dispensers of Isomate-C Plus per tree was 88.3 and 95.9% for 1.0 and 0.1 mg codlemone lures, respectively. Some males did orient to 0.1 mg codlemone lures so we caution that flight-tunnel experiments on preexposure may overestimate the actual pheromone exposure dosage received by feral moths in treated orchards. Importantly, this work documents that a portion of feral males within a population has the capacity to overcome communicational disruption by high densities of Isomate-C Plus dispensers.

Introduction

The codling moth, *Cydia pomonella* (L.), is a worldwide pest of pome fruit (Vickers and Rothschild, 1991). The identification of (*E,E*)-8,10-dodecadien-1-ol (codlemone) as the major pheromonal component (Roelofs et al., 1971) led to attempts to control it by mating disruption (Cardé et al., 1977; Mani et al., 1978; Moffit, 1978). Although a number of studies report successful mating disruption of codling moth and associated crop protection, failures have also been documented, and improvements are called for (Vickers and Rothschild, 1991; Minks, 1997).

A number of laboratory and field experiments have attempted to determine the dosage of pheromone required for effective codling moth mating disruption. A 65% reduction of mating was observed when females were caged with males in 1.2-l containers with 1.0 mg of codlemone (Fluri et al., 1974), whereas by exposing males and females to air moving over one or three 1.0 mg lures of codlemone, there was only a 38% mating reduction (Charmillot et al., 1976). More recently, Judd et al. (2005) established that exposures of male codling moths to ca. 35 µg codlemone/l of air in static air chambers for 10–30 min nearly eliminated response to otherwise attractive lures in a flight tunnel and reduced electroantennogram (EAG) responses. Normal behavioral responses returned after >4 hr and EAG sensitivity after >1 hr. However, caging male codling moths for 30–34 hr in an orchard treated with 1000 Isomate-C dispensers per hectare had no measurable impact on behavioral responses to pheromone in a flight tunnel (Judd et al., 2005). Similar results were obtained by Schmitz et al. (1997) and Rumbo and Vickers (1997) for the European grape moth, *Lobesia botrana* (Denis and Schiffermüller), and the Oriental fruit moth, *Grapholita molesta* (Busck), respectively. Judd et al. (2005) suggested that if male codling moths landed near Isomate-C Plus dispensers for several minutes, they might receive a sufficiently high dose of pheromone to reduce behavioral responses as seen in their preexposure laboratory experiment.

Thirteen minor compounds have also been identified from the sex pheromone gland of female codling moths (Witzgall et al., 2001); dodecanol (12OH) and tetradecanol (14OH) were quantitatively most significant, enhancing behavioral responses of males to codlemone (Einhorn et al., 1984; Arn et al., 1985). Consequently, these two compounds and codlemone are the active ingredients in Isomate-C and -C Plus polyethylene tube dispensers (Pacific Biocontrol Co., Vancouver, WA, USA), which are widely used for mating disruption of codling moth (Thomson et al., 1998).

Codling moth males have been captured in traps baited with Isomate-C dispensers (Barrett, 1995), and they land within a few centimeters of similar dispensers placed directly in untreated (Witzgall et al., 1999) and pheromone-treated (Stelinski et al., 2005a) orchards. Although attracted moths departed within <60 sec (Stelinski et al., 2005a), as seen with three other tortricids (Stelinski et al., 2004a), it is possible that such pheromone exposure contributes to mating disruption.

The purpose of this study was to quantify the effects of brief (seconds to 3 min) preexposures of male codling moths to various pheromone treatments in a flight

tunnel where moths had the capability of flying from release cages during the preexposure treatment. This context approximated the level of pheromone exposure males could receive during brief and close encounters with pheromone dispensers in the field (Stelinski et al., 2005a). In addition, a field experiment was conducted in which high densities (10/tree \approx 5000/ha) of Isomate-C Plus dispensers were deployed throughout tree canopies in an effort to maximize exposure of feral moths to pheromone. Captures of moths in traps baited with lure loadings assayed in the flight tunnel were used to relate flight-tunnel data to field responses of feral moths.

Methods and Materials

Insect Colonies

Codling moth males were drawn from 1- and 5-yr-old laboratory colonies established with pupae from untreated apple orchards in Michigan and North Carolina, USA, respectively. Moths from North Carolina were supplied by Benzon Research (Carlisle, PA, USA). Moths were reared at 24°C and 60% RH on pinto-bean-based diet (Shorey and Hale, 1965) under a 16:8 (L/D) photoperiod. Pupae were sorted by sex, and adults emerged in 1-l plastic cages containing 5% sucrose in plastic cups with cotton dental wicks protruding from their lids.

Chemicals and Release Devices

Polyethylene tube pheromone dispensers (Isomate-C Plus containing 205 mg of 53.0% codlemone, 29.7% 12OH, 6.0% 14OH, and 11.3% inert ingredients) were used to preexpose moths. The lures were red rubber septa (The West Company, Linville, PA, USA) loaded with 0.1, 1.0, or 10.0 mg of codlemone (Bedoukian Co, Danbury, CT, USA) that was >98% isomerically pure. Three-component red septa lures were loaded with 0.1 mg of codlemone, 12OH, and 14OH in a 100:20:5 ratio (El-Sayed et al., 1999). Codlemone + pear ester lures were loaded with 0.1 mg of each component in a 1:1 ratio into gray halobutyl septa (Trécé Inc, Adair, OK, USA). Pheromone blends were prepared in HPLC-grade hexane and stored at -18°C. All lures were aged in a fume hood for at least 48 hr prior to use in flight-tunnel assays, whereas Isomate dispensers were aged under the same conditions for 2 wk to allow dissipation of excess pheromone that might have built up on their surfaces during shipping and freezer storage. For EAG recordings, stimulus cartridges used to deliver pheromone to insect antennae were prepared according to Stelinski et al. (2003a,b) by using the codlemone described above.

Flight-Tunnel Assays

Behavioral assays were conducted in a Plexiglas flight tunnel (Stelinski et al., 2004b, 2005b). The flight-tunnel assay procedures were a slight modification of those described by Stelinski et al. (2005b). Male codling moths, 2–3 d-old, were collected 0.5 hr prior to the end of a 16 hr photophase and placed into cylindrical (8 cm long \times 8 cm diam.) release cages made from aluminum window screening. Each cage, containing two moths, was placed into the flight tunnel for 0.5 hr of acclimation prior

to assays. Subsequently, bioassays ran for a maximum of 1.5 hr. At the upwind end of the tunnel, pheromone dispensers (lures or Isomate dispensers) were placed 1 cm above a horizontal 7.5×12.5 cm yellow card (American Scholar, Bay Shore, NY, USA) attached to a horizontally clamped, 9-cm glass rod attached to a steel ring stand 25 cm above the tunnel floor. Release cages holding male moths were placed at the downwind end of the tunnel at a height matching that of the pheromone dispenser.

Males were allowed a maximum of 3 min to respond to an inserted pheromone dispenser, as this was the longest time feral moths remained in close proximity of Isomate-C Plus dispensers in treated orchards (Stelinski et al., 2005a). However, the majority (>80%) of preexposed males left release cages within 1 min and, thus, did not receive the full 3 min of exposure. Following preexposure, males were assayed to various lures described below. During assays following preexposure, males were allowed 3 min to respond. The behaviors recorded were wing fanning, non-anemotactic flight from the release cage, anemotactic flight in the pheromone plume without touching the release device, upwind anemotactic flight followed by landing on the platform and touching the release device. Also, the numbers of individuals with no detectable behavioral change were recorded.

Experiment 1

For preexposures, moths were released in plumes generated by a rubber septum loaded with 0.1 mg of codlemone or an Isomate dispenser and then, regardless of the behaviors exhibited during preconditioning, were subsequently assayed 15 min later to a 0.1 mg codlemone lure. Two types of controls were conducted. “Naive” moths had no prior exposure to pheromone or the flight tunnel prior to assay. “Control” moths were preexposed to clean air in the flight tunnel and otherwise handled identically to pheromone-exposed moths.

The experiment was conducted as a randomized complete block design; 47 replicate groups of two moths were assayed for each treatment. To avoid any possibility of pheromone contamination in control and naive moths, pheromone preexposed, air preexposed, and naive moths were assayed on different days. This protocol was used in all other flight-tunnel experiments.

Experiment 2

Males exposed to either 0.1 mg codlemone lures or Isomate-C Plus dispensers were assayed to 0.1 mg codlemone lures 24 hr after the preexposure treatment. Following preexposure, moths were kept in an environmental chamber under the temperature and light cycle conditions described above for the interval prior to testing. Thirty-seven replicate groups of two moths were assayed per treatment.

Experiments 3 and 4

In these assays, males were exposed to 0.1 mg three-component lures as preexposure treatments. We chose to assay the effect of preexposure to these three-component lures in addition to the codlemone-only lures given that Isomate-C

Plus dispensers also contain the 14 and 12 alcohols. In addition, these experiments tested the hypothesis that males preexposed to Isomate dispensers would respond differently to three-component vs. codlemone-only lures. Seventy-three and 61 replicate groups of two moths were assayed per treatment for the 15 min and 24 hr postexposure intervals, respectively.

Experiment 5

Here we tested the hypothesis that preexposure to Isomate-C Plus dispensers raises the response threshold of male codling moths to subsequent presentations of codlemone. Forty-eight, 34, and 39 replicate pairs of treated and control groups of two moths were assayed to 0.1, 1.0, or 10 mg lures, respectively, 15 min after preexposure to codlemone.

Experiment 6

Males were preexposed to a 1:1 mixture of codlemone + pear ester and subsequently assayed to 0.1 mg codlemone lures. Forty-one and 40 replicate groups of two moths were assayed per treatment for the 15-min and 24-hr postexposure intervals, respectively.

Experiment 7 (Electroantennograms)

The EAG system and test protocols were identical to those of Stelinski et al. (2003a,b). EAGs were conducted on male codling moths 15 min or 24 hr after a preexposure to a 0.1 mg codlemone lure, a 0.1 mg codlemone/pear ester lure (1:1 ratio), a 10.0 mg codlemone lure, or an Isomate-C Plus dispenser in the flight tunnel. EAGs performed on pheromone-exposed moths were alternated with assays of unexposed, naive moths. Ten moths were assayed per treatment for each preexposure treatment and time interval combination tested.

Experiment 8

Oriental disruption of male codling moth by high densities of Isomate-C Plus dispensers was measured in the field. They were hung 10 per tree such that all possible points within the canopy were <1.5 m from a dispenser. The density of dispensers used (5000/ha) was five times the recommended dose to ensure that feral males were exposed to very high levels of pheromone. The paired treatment and control plots of 16 trees (0.07 ha) were at least 15 m apart in a two-by-two design and the five replicates separated by at least 35 m. The treatments were applied at the onset of the second codling moth generation in Michigan, USA, and the experiment ran from 15 July through 30 August 2004. Each plot was monitored with two delta traps (LPD Scenturian Guardpost, Suterra, Bend, OR, USA); one had a 0.1 mg lure and the other a 1.0 mg lure. Traps were hung ca. 2–3 m above ground level in the upper third of the tree canopy in two of the four central trees of each plot. Traps were positioned as far away as possible from Isomate dispensers (at least 60 cm). Moths captured in traps were counted and removed twice weekly.

Statistical Analyses

The numbers of moths contacting lures, orienting without source contact, flying out of release cages without orienting, wing fanning without flight, or exhibiting no detectable behavioral change for each treatment were transformed [$\log(x + 1)$] and submitted to analysis of variance (ANOVA), followed by Tukey's test (SAS Institute, 2000) for separation of means. EAG data were subjected to ANOVA (SAS Institute, 2000). Captures of moths in traps in treated and control orchards were compared by using paired *t* tests. The significance level was $\alpha < 0.05$. Percent orientational disruption for the field experiment (experiment 8) was calculated as $1 - (\text{mean moth catch per trap in the Isomate-treated plot} / \text{mean moth catch per trap in the control plot}) \times 100$. Data in Tables 1, 2, 3, and 4 are presented as proportions of the total number of moths responding in the flight tunnel.

Results

Experiment 1

The responses of naive and control moths were virtually indistinguishable for each behavioral category (Table 1). After preexposure to Isomate-C Plus dispensers, significantly more males either remained in their release cage or exhibited nonoriented flight than the control; only 2 out of 74 moths oriented anemotactically to 0.1 mg lures and none contacted the source (Table 1). Significantly fewer males reached the source after preexposure to 0.1 mg lures, but there was no difference in the proportion orientating without source contact (Table 1).

Table 1 Behaviors of naive, control (air preexposed), and pheromone-exposed codling moths 15 and 24 hr after preexposure to 0.1 mg codlemone lures

	Proportion of males exhibiting				
	No behavioral change	Wing fanning only	Fly out without orientation	Orientation without source contact	Source contact
15 min postexposure					
Naive (no exposure)	0.00b	0.01a	0.13b	0.28a	0.56a
Control (clean air)	0.00b	0.03a	0.11b	0.33a	0.53a
Codlemone lure exposed	0.02b	0.00a	0.46a	0.30a	0.19b
Isomate-C Plus exposed	0.54a	0.06a	0.37a	0.02b	0.00b
24 hr postexposure					
Naive (no exposure)	0.02a	0.00a	0.14a	0.28b	0.56a
Control (clean air)	0.01a	0.20a	0.24a	0.27b	0.46a
Codlemone lure exposed	0.00a	0.00a	0.16a	0.58a	0.26b
Isomate-C Plus exposed	0.00a	0.00a	0.11a	0.36b	0.52a

Numbers in the same column followed by the same letter are not significantly different (ANOVA followed by Tukey's test, $\alpha < 0.05$).

Experiment 2

Twenty-four hours postexposure, there were no significant differences among responses of Isomate-dispenser-exposed, control, or naive moths to 0.1 mg codlemone lures (Table 1). In contrast, significantly more males preexposed to 0.1 mg lures oriented without source contact, although significantly fewer reached the source than in the other treatments (Table 1).

Experiment 3

Significantly fewer males preexposed to Isomate dispensers or three-component lures contacted 0.1 mg three-component lures 15 min postexposure (Table 2). In addition, significantly fewer Isomate-dispenser-exposed males oriented without source contact, whereas more exhibited no behavioral change than control moths (Table 2).

Experiment 4

After 24 hr, the only effect of preexposure was that significantly fewer Isomate-dispenser-exposed males flew out of release cages without orienting compared with the other treatments (Table 2).

Experiment 5

Significantly more Isomate-exposed moths remained in the release cage and exhibited nonoriented flight than control moths; consequently, fewer oriented to and contacted

Table 2 Behaviors of control (air preexposed) and pheromone-exposed codling moths in response to three-component (Codlemone/12OH/14OH, 100:20:5 Ratio) lures

	Proportion of males exhibiting				
	No behavioral change	Wing fanning only	Fly out without orientation	Orientation without source contact	Source contact
15 min postexposure					
Control (clean air exposed)	0.01b	0.00a	0.24b	0.13a	0.61a
3-Component lure exposed	0.04b	0.01a	0.47a	0.24a	0.24b
Isomate-C Plus exposed	0.47a	0.00a	0.47a	0.04b	0.02c

Control (clean air exposed)	0.01a	0.05a	0.16a	0.11a	0.66a
3-Component lure exposed	0.04a	0.00a	0.22a	0.16a	0.58a
Isomate-C Plus exposed	0.00a	0.00a	0.04b	0.18a	0.78a

Numbers in the same column followed by the same letter are not significantly different (ANOVA followed by Tukey’s test, $\alpha < 0.05$).

Table 3 Behaviors of air preexposed versus Isomate-C plus dispenser-exposed codling moths in response to 0.1, 1.0, OR 10.0 mg codlemone lures 15 min postexposure

	Proportion of males exhibiting				
	No behavioral change	Wing fanning only	Fly out without orientation	Orientation without source contact	Source contact
0.1 mg codlemone lure					
Clean air exposed	0.00b	0.02b	0.19b	0.23a	0.56a
Isomate-C Plus exposed	0.44a	0.12a	0.40a	0.04b	0.00a
1.0 mg codlemone lure					
Clean air exposed	0.26a	0.07a	0.37a	0.27b	0.03a
Isomate-C Plus exposed	0.00b	0.05a	0.30a	0.58a	0.05a
10.0 mg codlemone lure					
Clean air exposed	0.87a	0.01a	0.09b	0.03b	0.00a
Isomate-C Plus exposed	0.21b	0.08a	0.46a	0.29a	0.00a

Numbers in the same column followed by the same letter are not significantly different (ANOVA followed by Tukey's test, $\alpha < 0.05$).

the 0.1 mg lure (Table 3). In contrast, more preexposed males took flight and significantly more oriented to both 1.0 and 10.0 mg lures than controls. However, at both concentrations, there were no differences in the number reaching the source in treated and control treatments (Table 3). For the 10 mg lure, significantly more control males remained in the release cage than the preexposed ones (Table 3).

Experiment 6

At 15 min following preexposure to a 0.1 mg codlemone + pear ester lure, significantly more males remained in the release cage and significantly fewer contacted the lure than in the control (Table 4). However, responses were not different from controls 24 hr after preexposure (Table 4).

Experiment 7

Mean EAG responses of naive males were indistinguishable, and not statistically different, from those assayed either 15 min or 24 hr after flight-tunnel preexposure

Table 4 Behaviors of air preexposed versus 0.1 mg codlemone: pear ester lure (1:1 ratio) preexposed codling moths in response to 0.1 mg codlemone lures

	Proportion of males exhibiting				
	No behavioral change	Wing fanning only	Fly out without orientation	Orientation without source contact	Source contact
Clean air	0.06b	0.04a	0.32a	0.06a	0.59a
15 min postexposure	0.22a	0.04a	0.26a	0.19a	0.28b
24 hr postexposure	0.09b	0.06a	0.43a	0.09a	0.51a

Numbers in the same column followed by the same letter are not significantly different (ANOVA followed by Tukey's test, $\alpha < 0.05$).

to a 0.1 mg codlemone, 0.1 mg codlemone + pear ester, or 10 mg codlemone lure or an Isomate-C Plus dispenser (data not shown).

Experiment 8

Significantly more males were captured in traps baited with either 1.0 mg (99.1 ± 21.8 vs. 11.6 ± 4.2) or 0.1 mg (58.2 ± 13.3 vs. 2.4 ± 1.1) lures in control plots than those treated with 10 Isomate-C Plus dispensers per tree. Orientational disruption was 88.3 and 95.9% for the 1.0 and 0.1 mg lures, respectively.

Discussion

Brief (seconds to 3 min max) exposures of codling moth males to Isomate-C Plus dispensers in a flight tunnel drastically reduced the proportion of successful orientations to otherwise highly attractive codlemone or three-component (codlemone/14OH/12OH) lures. The effect appeared to be dose dependent; exposure to 0.1 mg lures with codlemone only or with codlemone and the 14 and 12 alcohols did not reduce behavioral responses of males 15 min later to the same degree as did exposure to Isomate dispensers, which release pheromone at ca. 20 $\mu\text{g/hr}$ (Knight, 1995). The effect is likely habituation, given that EAG responses to codlemone were normal in preexposed moths exhibiting reduced behavioral responsiveness. This habituation appears to be a classic threshold elevation (Mafra-Neto and Baker, 1996), as more preexposed moths oriented to elevated dosages of codlemone (1 and 10 mg) than did control moths (Table 3). Conversely, normally attractive dosages of codlemone (0.1 mg) elicited little behavioral response from moths exposed to Isomate dispensers. In field trials, more males are captured in pheromone-treated orchards using higher loadings of codlemone (10.0 mg) compared with lower loadings (1.0 mg), whereas the converse is true in untreated orchards (Charmillot, 1990; Barrett, 1995). Our flight-tunnel data support the hypothesis that pheromone pre-exposure in pheromone-treated orchards raises the behavioral response threshold of codling moth males to subsequent encounters with pheromone plumes (Vickers and Rothschild, 1991). However, the majority of preexposed moths resumed normal behavioral responsiveness within 24 hr of the initial preexposure in the current study. This suggests that a pheromone-induced elevation of response threshold could be reversed in feral males capable of moving to and remaining for some time in pheromone-free air.

An exception was that 24 hr following initial exposure, fewer moths preexposed to 0.1 mg codlemone contacted identical lures compared to those preexposed to Isomate-C Plus (Table 1). This difference is likely due to the type of pheromone preexposure received, as <2% of moths touched the Isomate source during preexposure, compared with >50% of those preexposed to 0.1 mg codlemone (Table 1). It is possible that codlemone was adsorbed onto the insects' cuticle during contact and, thus, exerted a longer-lasting effect. If true, then dispensers, such as hollow fibers (Moffitt and Westgard, 1984; Knight, 2003), that elicit direct source contacts could impact male responsiveness for longer periods than dispensers that do not.

Preexposure of caged male codling moths to an Isomate dispenser for 24 hr increased their behavioral responsiveness to the pear ester [(2*E*,4*Z*)-2,4-decadienoate] in flight-tunnel assays (Zhihua et al., 2005). In addition, captures of both male and female codling moths in pear-ester-baited traps were higher in pheromone-treated vs. untreated orchards (Zhihua et al., 2005). In the current investigation, brief preexposure of males to a low dose of codlemone + pear ester did not affect their subsequent behavioral responses any more than preexposure to codlemone alone. This does not rule out the possibility of habituation at higher dosages of pear ester.

Codling moth males exhibit a prolonged reduction of EAG responses following 10–30 min exposures to codlemone, lasting ca. 1–1.5 hr (Judd et al., 2005; Stelinski et al., 2005c). Similar “long-lasting” adaptation has been reported for other moths, including polyphemus moth, *Antheraea polyphemus* (Cramer) (Kaissling, 1986), the obliquebanded leafroller, *Choristoneura rosaceana* (Harris) (Stelinski et al., 2003a), and the Pandemis leafroller, *Pandemis pyrusana* Kearfott (Stelinski et al., 2005c). In cases where the airborne concentration of pheromone has been quantified (Stelinski et al., 2003b; Judd et al., 2005), micrograms per liter of air are required to induce long-lasting adaptation. In field trials, long-lasting antennal adaptation in male obliquebanded leafrollers following 24 hr of exposure to Isomate dispensers was seen if males were held 1–2 cm from dispensers but not if the distance was increased to 2 m. Given that long-lasting adaptation was not recorded following any of the preexposure treatments in the current study, males probably did not receive the $\approx 355 \mu\text{g min}^{-1} \text{l}^{-1}$ dose required to induce long-lasting adaptation (Judd et al., 2005). Stelinski et al. (2005c) questioned the importance of long-lasting adaptation as a contributing factor to mating disruption, as airborne concentrations of pheromone to induce the phenomenon are much higher than those recorded in pheromone-treated orchards (Koch et al., 1997, 2002).

Since exposure of codling moth males to Isomate-C Plus dispensers strongly reduced subsequent responsiveness to codlemone in the flight tunnel, we postulated that feral males, landing near such dispensers in the field would be effectively eliminated from an olfaction-based search for females on that night, given the short diel window of male and female sexual activity (Castroville and Cardé, 1979). However, some feral males were captured in traps baited with 0.1 mg lures despite having 10 Isomate-C Plus dispensers hung throughout tree canopies. This spotlights a vulnerability of polyethylene tube dispensers for pheromonal control of codling moth under high population densities. Given that delta traps limit the importance of close-range visual cues, it is possible that disruption of feral females may have been even lower.

The data from our field experiment suggest that some feral males may receive a pheromone exposure below that imparted by our flight-tunnel preexposure treatments. Thus, we suggest that disruption outcomes in the laboratory, where male moths have been carefully preexposed to microgram per liter dosages of pheromone for several minutes and subsequently shown to exhibit reduced sexual response, may need to be interpreted with caution. These exposures are likely higher than those received by feral males under disruption protocols in the field. Additionally, feral males may actively modulate their exposure by flying to pheromone-free air or to areas of lower pheromone concentrations. Alternatively, those males captured in traps with 0.1 mg codlemone lures in our field experiment

might represent a tolerant phenotype selected by years of pheromone application at this study site.

Acknowledgments We thank Krista Buehrer, Elizabeth Steere, and Lech Stelinski for diligent maintenance of insect colonies and assistance with flight-tunnel work. Thanks to Rachael Mallinger, Krista Buehrer, and Kevin Vogel for assistance with the field experiment. The manuscript was improved by comments from Juan Huang.

Abstract Females of the parasitic wasp *Glyptapanteles flavicoxis* (Hymenoptera: Braconidae) deposit a close-range sex pheromone from their abdominal tip that attracts conspecific males and elicits wing-fanning behavior. In this study, we isolated the pheromone components and determined their role in the males' behavior. In coupled gas chromatographic–electroantennographic detection (GC-EAD) analyses of the females' body extract, four components (below GC detection) elicited strong responses from male antennae. Monitored by GC-EAD, the components were separated by flash silica gel and high-performance liquid chromatography. Y-tube olfactometer experiments with one or more components revealed that all are necessary to elicit short-range attraction and wing-fanning responses by males. These components remained below detection threshold of the mass spectrometer (~10 pg) even when 4500 female equivalents were analyzed in a single injection, which attests to the potency of the pheromone and the insects' sensitivity to it.

Introduction

Sex pheromones in hymenopteran parasitic wasps are typically produced by females. They have been reported in seven families [Aphelinidae, Chalcididae, Cynipidae, Pteromalidae, Scelionidae, Braconidae, and Ichneumonidae (Kainoh, 1999)], but have been identified in only a few species, including *Itopectis conquisitor* (Robacker and Hendry, 1977), *Syndipnus rubiginosus* (Eller et al., 1984), *Macrocentrus grandii* (Swedenborg and Jones, 1992a,b), *Ascogaster reticulatus* (Kainoh et al., 1991), *Cardiochiles nigriceps* (Syvertsen et al., 1995), and *Ascogaster quadridentata* (DeLury et al., 1999).

In the Braconidae, sex pheromones have been reported in *Opius alloeus* (Boush and Baerwald, 1967), *Apanteles medicaginis* (Cole, 1970), *Apanteles medicaginis glomeratus* (Obara and Kitano, 1974), *Apanteles medicaginis melanoscelus* (Weseloh, 1976, 1980), *Cotesia rubecula* (Field and Keller, 1994), *Cotesia flavipes* (Kimani and Overholt, 1995), *Praon volucre* (Nazzi et al., 1996), and *Fopius arisanus* (Quimio and Walter, 2000). Most are long-range attractants.

Substrate-borne sex pheromones in parasitoids are rare. Female *Aphelinus asychis* (Hymenoptera: Aphelinidae) appear to have a trail pheromone, but do not exhibit specific trail-marking behavior (Fauvergue et al., 1995). In *Trichogramma brassicae* (Hymenoptera: Trichogrammatidae), a substrate-borne pheromone induces male searching in an area previously explored by females and attracts males from short distance (Pompanon et al., 1997). Female *As. reticulatus*, egg-larval parasitoids of the smaller tea tortrix, *Adoxophyes* sp., employ short-range pheromones that activate searching by males and increase the probability of mating (Kamano et al., 1989).

Some parasitic wasps have multiple-component pheromones. For example, male *M. grandii* are attracted to the female-produced components (*Z*)-4-tridecenal and (*Z,Z*)-9,13-heptacosadiene (Swedenborg and Jones, 1992a,b). The behavioral activity of both compounds is enhanced by (3*R*,5*S*,6*R*)-3,5-dimethyl-6-(methyl-ethyl)-3,4,5,6-tetrahydropyran-2-one as a third component that is biosynthesized in mandibular glands of both males and females (Swedenborg et al., 1993). In the ichneumonid *Eriborus terebrans*, the nonpolar pheromone component by itself is inactive, but when added to the polar component provokes the male's behavioral response (Shu and Jones, 1993).

Glyptapanteles flavicoxis (Hymenoptera: Braconidae) is a gregarious, koinobiont endoparasitoid of larval Indian gypsy moth, *Lymantria obfuscata* (Lepidoptera: Lymantriidae) (Marsh, 1979). In 1981, it was imported from India and released into North America as a potential biological control agent for larvae of the European gypsy moth, *Lymantria dispar* (Krause et al., 1990). Female *G. flavicoxis* press their abdominal tip to the substrate, apparently depositing pheromone that elicits wing fanning by males (J. Fuest, personal communication). This interpretation of the females' behavior is supported by reports of abdominal pheromone glands in other braconid females, including *Ap. glomeratus* (Tagawa, 1977), *Ap. melanoscelus* (Weseloh, 1980), *Ap. plutellae*, *Ap. liparidis*, *Ap. baoris*, *Ap. ruficrus*, and *Ap. kariyai* (Tagawa, 1983). Female *G. flavicoxis* also emit an airborne component (ethyl dodecanoate) that, by itself, is not effective in attracting conspecific males (J. Fuest, personal communication).

Our objectives were to investigate whether female *G. flavicoxis* use sex pheromone components, and, if so, to isolate them and determine their behavioral role.

Methods and Materials

Experimental Insects

The rearing colonies of experimental insects in the Global Forest Quarantine Facility at Simon Fraser University (SFU) were started and augmented with specimens obtained from the Beneficial Insects Introduction Research Laboratory, United States Department of Agriculture, Agricultural Research Service, Newark, Delaware. To facilitate mating in *G. flavicoxis*, 10 females and 30 males were placed in plastic mesh cages (10 × 10 × 6 cm) (Hu et al., 1986), and provisioned with cotton wicks (1 × 10 cm; Richmond Dental, Charlotte, NC, USA) soaked in sugar water solution. Oviposition cages (18 × 18 × 12 cm) contained 10–15 mated females, five *L. dispar* larvae (3–4 instar) (Fuester et al., 1987), and artificial diet for the larvae (Bell et al., 1981). After 1–2 d, parasitized host larvae were removed and placed on artificial diet in plastic cups (192 ml) with tight-fitting paper lids (Sweetheart Plastics, Wilmington, MA, USA). Every second day, larval frass was removed, diet replenished if needed, and parasite cocoons with insects to be used in bioassays transferred individually to capped plastic cups (30 ml) provisioned with sugar-water-soaked cotton wicks. Cocoons of insects to be used for mass rearing were placed in plastic Petri dishes (14 cm diam.) and food provisioned as described above. Rearing took place under a 16L:8D photoregime at 22–25°C and 50–70% RH.

Acquisition of Volatiles

Unmated, 1- to 2-d-old females (5–10) were placed into vertical cylindrical Pyrex glass chambers (10 ID × 6 cm), and were provisioned with a sugar-water-soaked cotton wick. Control chambers contained the same food source but no parasitoids. A water aspirator drew humidified, charcoal-filtered air at a rate of 1.5–2 l/min for 2 d through the chambers and a glass column (14 × 1.3 cm OD) filled with 150 mg of Porapak Q (50–80 mesh, Waters Associates Inc., Milford, MA, USA). Volatiles were eluted from the Porapak Q volatile traps with redistilled pentane (2 ml). The extract was concentrated under a stream of nitrogen such that 10 µl of extract contained one female hour equivalent (FHE) of volatile acquisition (= amount of volatiles released by one female during 1 hr).

Acquisition of Pheromone Extracts

Females (1- to 3-d-old) were macerated in vials containing hexane (ca. 10 µl per female) placed on dry ice. The extract was kept at room temperature for ~15 min. The supernatant was withdrawn, filtered through a small amount of glass wool in a pipette, and quantified to determine the volume representing one female body extract (FBE).

Video-recording of Trail-following Behavior by Males

To test the hypothesis that males follow a pheromone trail, their behavioral response was video recorded (Sony Digital Video Camera Recorder, DCR-VX 1000). Into each of 10 Pyrex glass dishes (9 × 2 cm high), 1 FBE was pipetted in trail-like pattern (Fig. 1). Additional 10 Pyrex glass dishes served as a control stimulus, with solvent

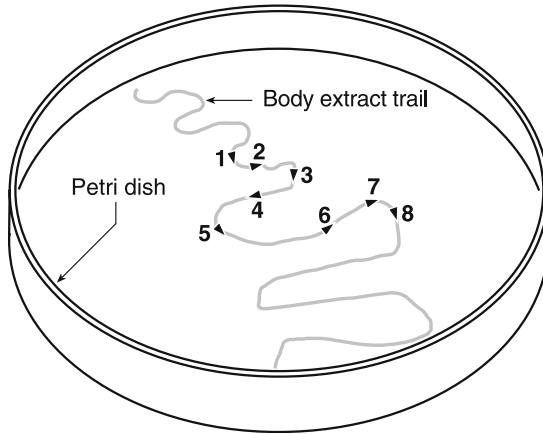

Fig. 1 (Top) Time spent by male *G. flavicoxis* ($n = 10$) on line drawings of a trail treated with one female body extract equivalent or a solvent control. Single-factor analysis of variance, $P < 0.05$. (Bottom) Representative example of “trail-following behavior” by a male (depicted as arrow head), with the position recorded every 2 sec

applied in the same way as the treatment. After the solvent had evaporated (~10 sec), a virgin 1- to 3-d-old male was released and video-recorded for 5 min. Recordings were analyzed for the time a male had spent on the trail and for other characteristic behavioral responses, such as wing fanning.

Y-tube Olfactometer Bioassays

All experiments were conducted during hours 2 to 6 of the insects' photophase (16L:8D). Anemotactic responses of males to odor sources were tested in vertical Pyrex glass Y-shaped olfactometers (stem: 20×2.5 cm ID; side arms at 120° : 18 cm long) positioned vertically 15 cm below a light source, consisting of one tube of fluorescent “daylight” (F40DX, H118; Osram Sylvania Ltd., Ontario, Canada) and one tube of “wide-spectrum grow light” (F40GRO/WS, H658; Osram Sylvania Ltd., Ontario, CA).

Treatment or control (solvent) stimuli were pipetted on white strips of paper (15×1 cm) placed in side arms of the Y-tube (experiments 1–28) or on filter paper discs (4.3 cm diam., Whatman No. 1, Whatman International Ltd., Maidstone, England, UK) placed near the orifice of side arms (experiments 29 and 30).

In experiment 31, two live 2- to 3-d-old females served as a test stimulus. They were transferred 10–15 min before experimental replicates into mesh-covered glass

tubes (6 × 2 cm ID) and provisioned with a sugar-water-soaked cotton wick. Treatment and control tubes (lacking females) were placed at the orifice of side arms of the Y-tube olfactometers.

In all experiments, a water aspirator drew air at ~1 l/min through the Y-tube to test anemotactic responses of parasitoids released individually into the stem of the Y-tube. An insect was classed a responder when it traversed the entire paper strip up to the orifice of the side arm within 10 min (experiments 1–28) or contacted the filter paper discs (experiments 29 and 30), or glass tube housing two females (experiment 31). All others were classified as nonresponders. For each replicate, a new insect, paper strip, filter paper disc, and clean (Sparkleen-washed and oven-dried) Y-tube or glass tube were used, with test stimuli randomly assigned to side arms.

To compare the attractiveness of test stimuli most rigorously, two to four experiments were often run in parallel over 2–4 d, alternating between replicates for each experiment. To gauge the relative attractiveness of two or more test stimuli, parallel experiments proved to be more effective than head-to-head comparisons of stimuli in the same Y-tube olfactometer.

Experiment 1 tested the “trail-following” response by males. Experiments 2 and 3 determined whether the females’ body extract in combination with the females’ effluvia, or synthetic effluvium component ethyl dodecanoate, were similarly effective in attracting males. Experiments 4 and 5 determined whether males or females respond to the pheromone. Experiments 6–8 explored the relative attractiveness of body extract, ethyl dodecanoate, or both.

Experiments 9–12 tested whether silica fraction 4 (containing candidate close-range pheromone components) and female body extract (containing candidate close-range pheromone components plus traces of ethyl dodecanoate and possibly other components) were equally attractive, at a low dose (1 FHE plus 1 FBE) or medium dose (5 FHE plus 5 FBE). Taking into account that silica fraction 4 at the medium dose was effective in attracting males, experiments 13 and 14 retested whether ethyl dodecanoate enhances the attractiveness of silica fraction 4. Although ethyl dodecanoate did not seem critical for male attraction, it was retained in subsequent experiments (15–27, 30) to ensure the best possible response of males to all test stimuli, and to allow the best comparison of results in all experiments.

Experiments 15 and 16 tested silica fraction 4 at the medium dose vs. the combination of all HPLC fractions that contained candidate close-range pheromone components (= effective blend). Considering the strong attractiveness of the effective blend, follow-up experiments 17, 19, 21, and 23 explored whether one or more of the candidate close-range pheromone components 1 (HPLC fractions 25–28), 2 and 4 (HPLC fractions 21–24), or 3 (HPLC fractions 16–20) could be deleted from the effective blend without affecting the males’ attraction or wing-fanning response. Experiments 25–27 tested the males’ attraction and wing-fanning responses to ethyl dodecanoate (experiment 27) alone, or in combination with either the effective blend (experiment 25) or most EAD-active pheromone component 3 (experiment 26).

Placement of test stimuli near (~1 cm) the junction of Y-tubes in experiments 1–28 was appropriate to test close-range anemotactic and wing-fanning responses of males, but not suitable to determine whether ethyl dodecanoate, or other female-produced components, might enhance the active space (mate-recruiting distance) of the entire pheromone blend. Thus, final experiments 29–31 tested the response of males to stimuli [silica fraction 4 on filter paper disc (experiment 29); silica fraction 4 plus ethyl dodecanoate on filter paper disc (experiment 30); two caged live females (experiment

31)] that were placed at the orifice of side arms >10 cm apart from the junction of the Y-tube.

Analyses of Pheromone Extracts

Aliquots of 1 FHE or 1 FBE were analyzed by coupled gas chromatographic–electroantennographic detection (GC-EAD) (Arn et al., 1975; Gries et al., 2002), employing a Hewlett Packard (HP) 5890A gas chromatograph equipped with a GC column (30 m × 0.25 or 0.32 mm ID) coated with DB-5, DB-17, DB-210, DB-23, or FFAP (J & W Scientific, Folsom, CA, USA). For GC-EAD recordings, a male's head was severed and placed into the opening of a glass capillary electrode filled with saline solution (Staddon and Everton, 1980). One antenna with its tip removed by spring microscissors (Fine Science Tools Inc., North Vancouver, British Columbia, CA) was placed into the opening of a second (indifferent) electrode.

EAD-active compounds were analyzed by (1) full-scan electron-impact and chemical ionization (CI, acetonitrile) mass spectrometry (MS) with a Varian Saturn 2000 Ion Trap GC-MS fitted with the DB-5 column referred to above; (2) retention index calculations (Van den Dool and Kratz, 1963); and (3) microanalytical treatments (hydrogenation, oxidation, reduction, acetylation, deacetylation) followed by renewed GC-EAD and GC-MS of the extract.

Aliquots of 100 FBEs with EAD-active components were fractionated through silica gel (0.5 g) in a glass column (14 × 0.5 cm ID). After the silica was prerinsed with pentane, the extract was applied, allowed to impregnate the silica gel, and then eluted with six consecutive rinses (1 ml each) of pentane/ether, with increasing proportion of ether, as follows: (1) 100:0; (2) 100:0; (3) 90:10; (4) 75:25; (5) 50:50; and (6) 0:100. This procedure generated fractions containing analytes of increasing polarity.

To determine silica fractions with candidate pheromone components, fractions were concentrated to the corresponding number of female equivalents processed in the initial extract and analyzed by GC-EAD, co-injecting as an internal standard ethyl dodecanoate (1 ng), which eluted 4–8 min earlier on the different GC columns than any of the four components. Fractions with more than one EAD-active compound (= candidate pheromone component) were fractionated further into 40 fractions (one fraction/25 sec) by HPLC, followed by renewed GC-EAD analyses of all HPLC fractions. HPLC fractionation employed a Waters LC 626 HPLC equipped with a Waters 486 variable-wavelength UV visible detector set to 210 nm, HP Chemstation software (Rev. A.07.01), and a reverse-phase Nova-Pak C18 column (60 Å, 4 µm; 3.9 × 300 mm) eluted with 1 ml/min of 100% acetonitrile.

Results

In experiment 1, 1 FBE induced wing-fanning and “trail-following behavior” by males (Fig. 1). Males also spent more time on trails of body extract of females than on solvent control trails (Fig. 1).

Effluvium (1 FHE) and body extract (1 FBE) of females in combination attracted more males than did the solvent control (Fig. 2, experiment 2). Similarly, ethyl dodecanoate plus female body extract attracted males (Fig. 2; experiments 3, 5, and 8), but not females (Fig. 2, experiment 4). Unlike female body extract, ethyl

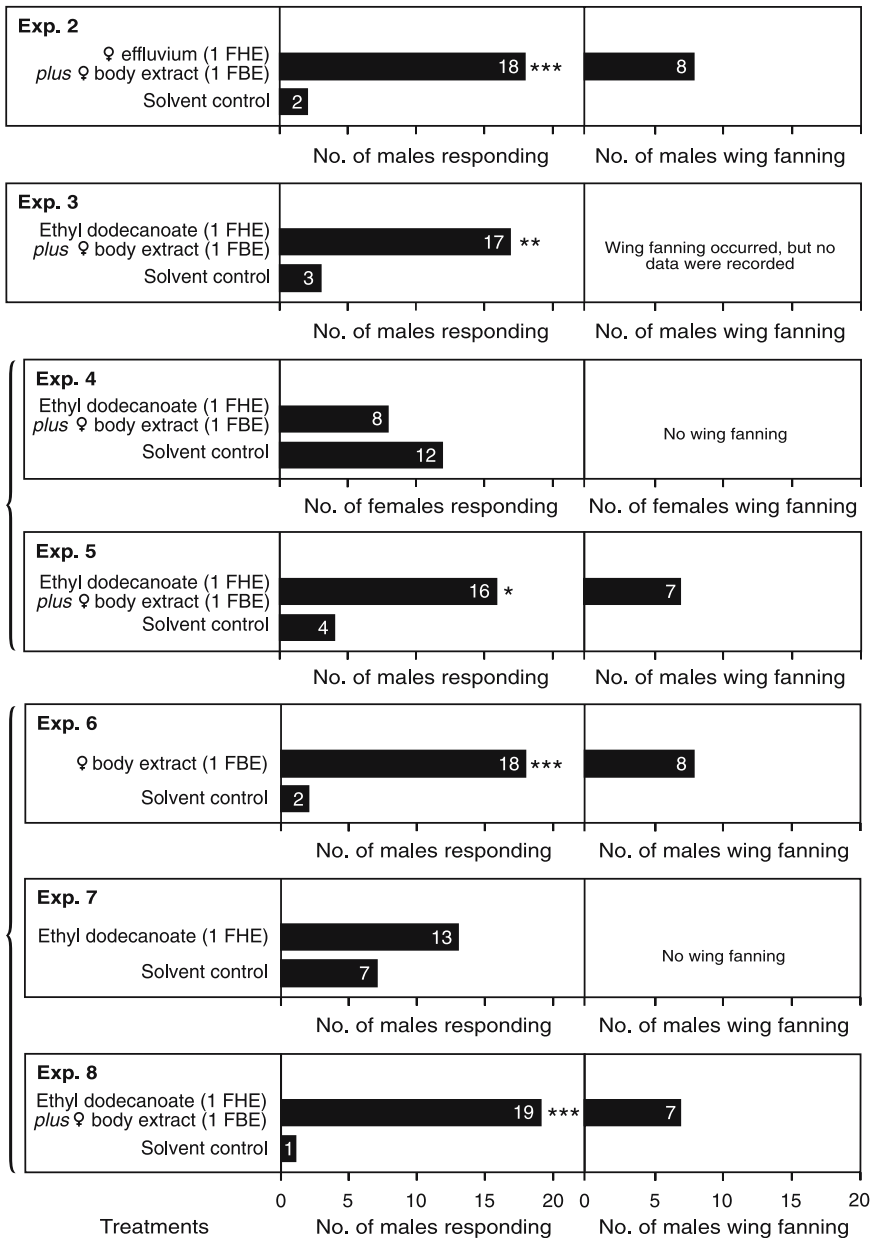

Fig. 2 Number of male or female *G. flavicoxis* that were attracted, or wing fanned, in response to test stimuli tested in Y-tube olfactometer experiments 2–8. 1 FHE = one female hour equivalent = pheromone component(s) released by one female during 1 hr; 1 FBE = one female body extract equivalent = pheromone component(s) contained in extract of one macerated female body. In each experiment, bars with asterisks indicate a significant response to a particular treatment; χ^2 test (experiments 2 and 3), heterogeneity χ^2 test with Yates' correction for continuity, treatment vs. control (Zar, 1996); * $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$. Note: (1) Experiments grouped by brackets were run in parallel; (2) only after completion of experiment 3 did we realize that we should have recorded wing fanning as a response criterion

Fig. 3 Flame ionization detector (FID) and electroantennographic detector (EAD: male *G. flavicoxis* antenna) responses to aliquots of female body extract (top), silica fraction 4 (middle), and HPLC fractions 16–20, 21–24, and 25–28 (bottom). Chromatography: Hewlett Packard 5890A equipped with a DB-23-coated column (30 m × 0.25 mm ID); linear flow velocity of carrier gas: 35 cm/sec; injector and FID detector temperature: 220°C; temperature program: 1 min at 100°C, 10°C/min to 220°C

dodecanoate by itself failed to attract males or to provoke wing fanning (Fig. 2; experiments 6, 7).

GC-EAD analyses of female body extracts revealed four components that elicited antennal responses from males (Fig. 3; Table 1). Although these components appeared to be abundant in the corresponding flame ionization detector (FID) trace, their mass spectra suggested that they were not pheromone components, but superimposed on them. GC-EAD analyses of all six silica fractions of female body extract revealed that fraction 4 contained the four EAD-active components, and that they indeed occurred below FID detection threshold (Fig. 3).

In Y-tube olfactometers, female body extract (at 1 FBE) combined with ethyl dodecanoate was attractive, whereas silica fraction 4 (at 1 FBE) with ethyl dodecanoate was not (Fig. 4, experiments 9, 10), suggesting that some active material had been lost during fractionation. However, silica fraction 4 at 5 FBE, together with ethyl dodecanoate, attracted males (Fig. 4, experiment 11), indicating that all essential components of the close-range pheromone were present in silica fraction 4. Female body extract at 5 FBE plus ethyl dodecanoate was not attractive (Fig. 4, experiment 12), suggesting that this dose might have exceeded a biologically relevant threshold. In experiments 13 and 14, silica fraction 4 with or without ethyl dodecanoate appeared equally attractive to males.

In GC-EAD analyses of HPLC fractions of silica fraction 4, component 3 was present in fractions 16–20 (elution time: 4–5 min), components 2 and 4 (not separable)

Table 1 Retention indices (relative to alkane standards) of pheromone components 1–4 in body extracts of female *Glyptapanteles flavicoxis* (Fig. 3), and ability of microanalytical treatments of silica or HPLC fractions of body extracts to alter the molecular structure of components 1–4, as determined by the presence or absence of respective antennal responses in GC-EAD recordings of such fractions

Abbreviations as in caption of Fig. 2; effective blend = combined HPLC fractions 16–20, 21–24, and 25–28 (see Fig. 3). In each experiment, bars with asterisks (*) indicate a significant response to a particular treatment; heterogeneity χ^2 test with Yates' correction for continuity, treatment vs. control; * $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$. Note: (1) Experiments grouped by brackets were run in parallel; (2) one male in experiment 12 did not respond to test stimuli

Fig. 5 Number of male *G. flavicoxis* that were attracted, or wing fanned, in response to test stimuli in Y-tube olfactometer experiments 17–24. Abbreviations as in caption of Figs. 2 and 4. In each experiment, bars with asterisks (*) indicate a significant response to a particular treatment; heterogeneity χ^2 test with Yates' correction for continuity, treatment vs. control; * $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$. Note: (1) Experiments grouped by brackets were run in parallel; (2) one male in experiment 17 did not respond to test stimuli

Fig. 6 Number of male *G. flavicoxis* that were attracted, or wing fanned, in response to test stimuli in Y-tube olfactometer experiments 25–31. Abbreviations as in caption of Figs. 2 and 4. In each experiment, bars with asterisks (*) indicate a significant response to a particular treatment; heterogeneity χ^2 test with Yates' correction for continuity, treatment vs. control; * $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$. Note: (1) Experiments grouped by brackets were run in parallel; (2) one male in each of experiments 30 and 31 did not respond to test stimuli. ¹Test stimuli placed at the orifice of the Y-tube's side arms

were present in fractions 21–24 (elution time: 5–6 min), and component 1 was present in fractions 25–28 (elution time: 6–7 min) (Fig. 3). In Y-tube olfactometers, all fractions with one or more EAD-active components recombined at 5 FBE, together with ethyl dodecanoate, attracted males (Fig. 4, experiment 15; Fig. 6, experiment 25). This effective blend was no longer attractive to males, when fractions 16–20 (containing component 3), 21–24 (containing components 2 and 4), or fractions 25–28 (containing component 1) were lacking (Fig. 5; experiments 17–22). Ethyl dodecanoate by itself, or in combination with HPLC fractions 16–20, failed to consistently attract males or to elicit wing-fanning responses (Fig. 2, experiment 7; Fig. 5, experiments 23, 24; Fig. 6, experiments 26, 27).

In experiment 28 (Fig. 6), silica fraction 4 applied on a paper strip (15 × 1 cm) in a Y-tube's side arm prompted strong anemotactic and wing-fanning responses by males (see also experiment 14), but failed to do so, with or without ethyl dodecanoate, when pipetted on a filter paper disc (4.3 cm diam.) at a side arm's orifice in parallel experiments 29 and 30. In contrast, two live females caged at a side arm's orifice were significantly attractive to males (experiment 31).

Discussion

Our data support the conclusion that female *G. flavicoxis* use a four-component pheromone blend that provokes strong close-range anemotactic attraction and wing-fanning responses by conspecific males (Fig. 4, experiment 14; Fig. 6, experiment 28). Response of males but not females to the pheromone (Fig. 2; experiment 4, 5) indicates that it is a sex rather than aggregation pheromone. Failure of these four components to attract males over a distance of 10 cm (Fig. 6, experiment 29), coupled with attraction of males to live females over the same distance (Fig. 6, experiment 31), suggests that females use one or more additional pheromone components for long-range attraction of males. Similarly complex sexual communication has been reported for the parasitic wasp *Aphidius nigripes* (Hymenoptera: Aphididae) (McNeil and Brodeur, 1995; Marchand and McNeil, 2000). Body extracts of females provoked wing fanning but not upwind flight by males, suggesting that female *A. nigripes* use both short- and long-range pheromone components.

Ethyl dodecanoate in the effluvia of female *G. flavicoxis* was a potential long-range pheromone component, but it did not affect the males' behavioral response in our experiments (Fig. 4, experiments 13, 14; Fig. 6, experiments 29, 30), and thus cannot be considered a pheromone component.

Video footage (graphical illustration not shown) revealed that females deposit, and males respond to, pheromone on substrate. It is, however, not likely that females deposit a continuous trail, as bioassayed in experiment 1. Males of the braconid *As. reticulatus* respond sporadically to substrate that females have frequented before, suggesting that females deposit traces rather than trails of pheromone (Kamano et al., 1989). Similarly, in *G. flavicoxis*, substrate-borne pheromone may signal the presence of, rather than provide long-range directional cues toward, females (Fig. 6; experiments 29, 30).

Intriguingly, the close-range pheromone blend of *G. flavicoxis* is bifunctional, also eliciting wing-fanning responses by males. The males' strong wing-fanning response, however, was dependent upon their close distance to the pheromone source (e.g., Fig. 4, experiment 14; Fig. 6, experiment 28). Even caged live females (and their

potential pheromone depositions on substrate) that remained inaccessible to males hardly elicited wing-fanning responses (Fig. 6, experiment 31). A strong wing-fanning response was also dependent upon the composition of the pheromone blend. It required the presence of component 3 and component(s) 1, or 2 and 4 (Fig. 5).

Wing fanning has been interpreted as a behavior that facilitates the males' orientation toward females. As demonstrated with fine chalk dust in the ichneumonid *Campoletis sonorensis*, wing fanning pulls air from front to rear, allowing directional orientation of males toward females (Vinson, 1972). This interpretation, however, does not explain completely why male *G. flavicoxis* were so discerning in their wing-fanning response to test stimuli (Fig. 5). Males wing fanned mostly in the presence of the complete pheromone blend, suggesting that they were motivated more by the quality of the female-produced signal than prospects of improved anemotactic orientation toward females. If true, the males' wing fanning could produce sound, possibly so specific that the female could use it to recognize conspecific males and discern between prospective mates (Sivinski and Webb, 1989).

Identification of the close-range sex pheromone components was attempted but failed despite the large sample size (4500 FE) that was analyzed. Nonetheless, numerous microanalytical treatments of, and electrophysiological recording with, pheromone extract (Table 1) suggested that all close-range sex pheromone components are unsaturated molecules of medium polarity, most likely esters. That these compounds remained below detection threshold of the mass spectrometer (~10 pg) even when 4500 FE were analyzed in a single injection, attests to the potency of the pheromone and the insects' sensitivity to it. Alternatively, the components are heat labile (as suggested by an anonymous reviewer), and defy identification by techniques involving gas chromatography.

Acknowledgments We thank Carl Lowenberger for review of the manuscript, Susan Barth, Kenneth Swan, Philip Taylor, and Roger Fuester for supplying experimental insects, Bob Birtch for graphical illustrations, and two anonymous reviewers and Jeremy McNeil for constructive comments. This research was supported, in part, by a graduate fellowship from Simon Fraser University to A.D. and by a Discovery Grant and Industrial Research Chair from the Natural Sciences and Engineering Research Council of Canada (NSERC) to G.G., with Phero Tech. Inc., SC Johnson Canada, and Global Forest as industrial sponsors. Experimental insects were maintained in SFU's Global Forest Quarantine Facility, construction of which was completed through financial support from Global Forest (GF-18-2000-SFU-8).

Abstract Foragers of many species of stingless bees guide their nestmates to food sources by means of scent trails deposited on solid substrates between the food and the nest. The corresponding trail pheromones are generally believed to be produced in the mandibular glands, although definitive experimental proof has never been provided. We tested the trail following behavior of recruits of *Trigona recursa* in field experiments with artificial scent trails branching off from natural scent trails of this stingless bee. First-time recruits (newcomers) did not follow these trails when they were laid with pure solvent or mandibular gland extract. However, they did follow trails made with labial gland extract. Chemical analyses of labial gland secretions revealed that hexyl decanoate was the dominant component ($72.4 \pm 1.9\%$ of all volatiles). Newcomers were significantly attracted to artificial trails made with synthetic hexyl decanoate, demonstrating its key function in eliciting scent-following behavior. According to our experiments with *T. recursa*, the trail pheromone is produced in the labial glands and not in the mandibular glands. Hexyl decanoate is the first component of a trail pheromone identified and proved to be behaviorally active in stingless bees.

Introduction

Foragers of many species of stingless bees guide their nestmates to food sources using a scent trail deposited on solid substrates between the food and the nest (Lindauer and Kerr, 1958, 1960; Kerr and da Costa Cruz, 1961; Kerr et al., 1963; Kerr, 1969; Blum et al., 1970; Johnson, 1987; Jarau et al., 2003; Schmidt et al., 2003; Nieh et al., 2003, 2004; Sánchez et al., 2004). Many textbooks report that the pheromones involved in trail marking originate from the bees' mandibular glands (e.g., Wilson, 1971; Michener, 1974; Free, 1987; Roubik, 1989; Alcock, 2001; Wyatt, 2003). Definitive experimental proof of this assumption, based on conclusive trail-following bioassays of gland extracts or of synthetic compounds identified from mandibular glands, has never been provided (for a more detailed discussion see Jarau et al., 2004). In fact, Lindauer and Kerr (1958, 1960) reported in their pioneering investigations on stingless bee recruitment communication that recruits of *Scaptotrigona postica* never followed artificial scent trails made of mandibular gland secretions when these trails were laid in a direction other than that of the bees' natural scent trail.

Recently, Jarau et al. (2004) demonstrated that in *Trigona recursa*, a species that effectively recruits nestmates to food sources by means of scent trails (Jarau et al., 2003), mandibular gland extract had a repellent effect on both newcomers that arrived at a test feeder and on bees already sitting on the feeder to take up sugar solution. More importantly, however, feeders baited with labial gland extract clearly attracted the newcomers (Jarau et al., 2004). Labial gland secretions are released from the base of the glossa (Snodgrass, 1956; da Cruz Landim, 1967), and a forager rubs her extended glossa over exposed substrates like twigs, leaves, or blades of grass to deposit a scent mark on the feeder or along the way back to the nest (Jarau et al., 2004). From this observation and from the attractive effect of labial gland extract at the feeder, Jarau et al. (2004) concluded that the trail pheromone of *T. recursa* is produced in the labial glands and not the mandibular glands. This conclusion, however, was based on the behavior of newcomers at the food source and not on observations of trail-following behavior.

In the present study we used mandibular or labial gland extract to lay artificial scent trails branching off from the bees' natural scent trails to test whether newcomers follow such trails. In addition, we analyzed the components of mandibular and labial gland secretions and tested whether hexyl decanoate, which was found to be the dominant compound in the labial glands, releases trail-following behavior in recruited bees.

Methods and Materials

Study Site and Bee Nests

The experiments were carried out in March and April 2004 at the Ribeirão Preto Campus of the University of São Paulo with two nests (A and B) of *T. recursa* (Smith 1863) that naturally occurred there. Colonies of *T. recursa* usually consist of

about 3000 to 5000 adult individuals (Jarau et al., 2003). The two nests were separated from each other by approximately 900 m, and no additional nests were found near the test colonies. Bees marked with color during the experiments with one nest never showed up at the feeder during experiments with the other nest, nor were marked bees ever observed at the entrance of the wrong nest. Thus, it is highly unlikely that recruits from the nests would have been mixed in our experiments.

Test Substances for Bioassays

We tested whether one or more of the following substances release trail-following behavior in *T. recursa* recruits: (i) mandibular gland extract; (ii) labial gland extract; (iii) synthetic hexyl decanoate, the main compound identified from labial gland secretions (see “Results”); and (iv) pure solvent (pentane).

Gland extracts were prepared from *T. recursa* that had been collected during foraging at sugar solution feeders. The bees were sacrificed by freezing at -8°C and their glands dissected in saline solution under a microscope by carefully separating them from any tissue other than the respective glandular epithelia and reservoirs. Gland extracts from foragers of one nest were only used for bioassays with bees of the same nest. For all extracts, the amount of pentane was adjusted to 100 μl per pair of glands (i.e., nest A: 20 mandibular glands in 1000 μl pentane and 36 labial glands in 1800 μl pentane; nest B: 10 mandibular glands in 500 μl pentane and 18 labial glands in 900 μl pentane). Thus, 100 μl of extract corresponded to the gland content of one individual bee. The glands were left in the solvent for 24 hr at room temperature and the extracts subsequently stored in a freezer (-8°C) unless they were in use for the bioassays. For the tests with hexyl decanoate we diluted the synthetic ester in pentane (1 $\mu\text{g}/100 \mu\text{l}$).

Artificial Scent Trail Bioassays: Experimental Procedure

For each experiment we trained five marked foragers by stepwise moving a feeder with unscented 15% (w/w) aqueous sugar solution to a distance of 30 m from the nest. *T. recursa* recruits very well to food sources at this distance (Jarau et al., 2003). The location of the feeder relative to the nest was varied by experiment to exclude the possibility of a site preference by the bees. Recruitment never occurred during the training phase. Thus, recruited bees had not already been in the field searching for food when the artificial scent trails were installed. At its final location the training feeder was replaced with a clean feeder (henceforth the *recruitment feeder*) containing an unscented 40% (w/w) sugar solution, at which free recruitment (Jarau et al., 2003) was allowed. Unscented food was used to exclude an attraction of recruits to the feeders due to food volatiles, which they might have potentially encountered from the foragers inside the nest. As soon as the first forager began to lay a scent trail and to recruit nestmates from inside the nest, we installed an experimental scent trail between the nest and the recruitment feeder. The experimental trail branched off from the natural trail 20 m away from the nest, and led to a *test feeder* that was identical to the recruitment feeder in appearance and food supply (Fig. 1). The experimental trail consisted of 10 short branches of a Pitanga tree, *Eugenia uniflora* L., put into the ground at 1-m intervals and with their leaves baited with pentane (control experiments) or with one of the three test substances. To the leaves at each branch we applied 10 μl of the solvent control or

Fig. 1 Experimental setup for the behavioral assay of recruited *T. recursa* bees to artificial scent trails. Shaded circles represent baited and open circles represent unbaited short branches from a Pitanga tree, *E. uniflora*; RF, recruitment feeder; TF, test feeder; $d = 10$ m, distance between the two feeders

the test substance (corresponding to 0.1 bee equivalent mandibular or labial gland extracts or 0.1 μg hexyl decanoate). We used 0.1 bee equivalents because this concentration has been shown to be behaviorally active (Jarau et al., 2004). In addition, three scent marks (a total of 30 μl) were applied to the test feeder, because it was reported for several species of *Trigona* that the concentration of scent marks deposited by foragers is highest at the feeding table itself (Kerr et al., 1963; Johnson, 1987; Nieh et al., 2003, 2004). Untreated branches of *E. uniflora* were placed along the last 10 m towards the recruitment feeder (Fig. 1) in order to provide equal structural conditions for the 10-m test trail and for the corresponding route between the nest and the recruitment feeder. Five experiments (three with nest A, two with nest B) were carried out with each test substance and the control. On a particular day, a nest was used for only one experiment and the order of the substances tested on different days was randomized. Each trial with a substance lasted for 40 min, and the marks were renewed once after 20 min.

All bees arriving at the recruitment feeder for the first time were marked with colors that durably adhered to their thoraces and allowed to shuttle between the feeder and the nest without any interference. The bees that followed the experimental trail and arrived at the test feeder were captured, color marked, and only released when the experiment had ended. Thus, they were not allowed to return to the nest to report the location of the test feeder to nestmates during the experiment. Only unmarked recruits, which had never visited a feeder during a preceding experiment (henceforth called *newcomers*), were considered for the analyses. Thus, in order to minimize the impact of pseudoreplication in our experimental design, each individual bee was tested only once throughout the entire series of experiments. The percentage of bees that followed the experimental trail to the test feeder was calculated from the total number of newcomers that were counted at both feeders during an experiment.

Chemistry

For quantitative analyses, the labial glands of seven foragers and the mandibular glands of another seven foragers were dissected and extracted individually in 200 μl pentane (24 hr at room temperature). Prior to gas chromatographic analysis (Thermo Finnigan Trace GC, Rodano, MI, Italy) each extract was concentrated

to 30 μl , and 1 μg *n*-eicosane was added as an internal standard. The GC was equipped with a DB5 capillary column (30 m \times 0.32 mm, J&W Scientific, Folsom, CA, USA), and helium was used as carrier gas (constant linear flow rate 42 cm/sec). The GC was operated splitless at 50°C for 1 min, followed by a programmed increase to 310°C at a rate of 4°C/min and held at the final temperature for another 9 min.

For qualitative investigations, pooled extracts of the labial glands and the mandibular glands of 15 foragers were used. The samples were analyzed by using a Fisons Instruments gas chromatograph series 8000 linked to a Fisons MD 800 mass spectrometer (Fisons Instruments, Ismaning, Germany); 70 eV mass spectra were taken in EI mode. Separations were performed with a 30 m \times 0.25 mm fused silica column coated with DB5-MS, 0.25- μm thickness (J & W Scientific, Folsom, California, USA). The temperature was initially held at 60°C for 5 min, then increased by 10°C/min to 300°C and held at this temperature for 30 min. Helium served as the carrier gas. Identification of compounds was based on comparisons of mass spectra with the literature (McLafferty and Stauffer, 1989), as well as by comparing retention times and mass spectra using authentic reference substances. Esters that were not commercially available were synthesized from the corresponding acid chlorides and alcohols according to standard laboratory protocols. Mass and NMR spectra were in accordance with expected data (Francke et al., 2000). Racemic 2-octanol was purchased from Aldrich, whereas (*S*)-2-octanol was synthesized by Grignard reaction of pentyl magnesium bromide and commercially available (*S*)-methyloxirane (Aldrich). A mixture of diastereomeric derivatives of 2-octanol was prepared by reaction with (*S*)-2-acetoxypropanoic acid chloride (Aldrich). The corresponding derivative of (*S*)-2-octanol served as the reference. The derivatization was carried out as follows: To a natural extract containing one to two bee equivalents was added 100 μl carbon disulfide and a solution of 10 μl of diethylether and 1% of pyridine and 1 μl of (*S*)-2-acetoxypropanoic acid chloride. In a screw-capped 1-ml vial, the mixture was kept at 40°C for 12 hr. After cooling to room temperature, the mixture was diluted with 500 μl pentane and washed with two, 200- μl aliquots of water. The organic layer was filtered over 300 mg silica (Merck silica 60, 230-40 mesh). After additional elution with 2 ml diethylether, the resulting mixture was concentrated and submitted to GC/MS analysis. Separation conditions were the same as given above.

Statistical Analyses

Bioassay data were normally distributed with homogeneous variances. We therefore applied parametric statistical tests. One-way analysis of variance (ANOVA) was used to check for a significant effect of artificial trail treatment on the percentages of bees that landed on the test feeder during the experiments. Multiple comparisons between the single groups were carried out by using the Student–Newman–Keuls method to reveal significant differences among the mean percentages of bees following the control or various test substance trails.

Absolute amounts of the compounds detected in the gland extracts were determined by comparison of their peak areas with the peak area of the internal standard. The relative amount of a compound was calculated as the percentage of the total amount of all volatile gland constituents detected. For both variables we calculated the mean \pm SD ($N = 7$).

Results

Behavioral Bioassays

The total numbers of recruits reaching the two feeding tables in the single experiments proved to be similar for the different test substances (five experiments with each substance, mean \pm SD: mandibular gland extract: 42.8 ± 27.9 , range 23–91; labial gland extract: 48.4 ± 30.2 , range 18–94; hexyl decanoate: 35.8 ± 15.1 , range 19–54; pentane: 54.0 ± 21.1 , range 29–87). In all test series, the majority of the newcomers followed the natural scent trails made by the recruiting foragers. There was a highly significant difference, however, in the percentage of newcomers following the four different types of artificial scent trails [Fig. 2; one-way ANOVA: $F(3,16) = 45.599$, $P < 0.001$]. In the control experiments, only $1.4 \pm 1.7\%$ (mean \pm SD) of the bees arrived at the test feeder at the end of the pentane trail. This percentage is not significantly different (SNK method: $q = 0.407$, $P = 0.778$) from the $0.4 \pm 1.1\%$ of newcomers that reached the test feeder during the experiments with mandibular gland extract trails. In contrast, significantly more bees followed the labial gland extract trails ($35.4 \pm 9.7\%$; $q = 14.098$, $P < 0.001$) and the hexyl decanoate trails ($10.8 \pm 4.2\%$; $q = 3.867$, $P = 0.015$) than the control trails. Similarly, there were significant differences in the percentage of bees reaching the test feeders in the experiments using labial gland extracts and hexyl decanoate ($q = 10.231$, $P < 0.001$), labial gland and mandibular gland extracts ($q = 14.504$, $P < 0.001$), and hexyl decanoate and mandibular gland extracts ($q = 4.273$, $P = 0.021$).

Fig. 2 Mean (\pm SD) response ($N = 5$ experiments per trail substance) to artificial scent trails measured as the percentage of newcomers of *T. recursa* that reached the test feeder (100% = newcomers at recruitment feeder + newcomers at test feeder). Numbers above or in the bars are the total numbers of the individuals tested; NS, not significant; P values for significant differences between groups (Student–Newman–Keuls method) are given

Table 1 Volatiles from labial gland secretions of *T. recursa* foragers^a

Number ^b	Compound name	Absolute amount (μg)	Relative amount (%)
1	Hexyl decanoate ^c	0.02 ± 0.01	0.50 ± 0.07
2	Hexyl decanoate	3.44 ± 1.02	72.38 ± 1.94
3	Octyl decanoate	0.22 ± 0.07	4.55 ± 0.27
4	Hexyl dodecanoate	0.09 ± 0.03	1.83 ± 0.06
5	Methyl octadecenoate ^c	0.03 ± 0.01	0.64 ± 0.23
6	Unidentified	0.09 ± 0.04	1.80 ± 0.42
7	Unidentified	0.26 ± 0.08	5.54 ± 1.30
8	Ethyl octadecenoate ^c	0.03 ± 0.02	0.58 ± 0.23
9	Isopropyl octadecenoate ^c	0.05 ± 0.03	1.06 ± 0.33

^a Components that make up at least 0.5% of the total gland content were quantified (mean ± SD, *N* = 7).

^b Numbering follows increasing retention times and is identical to peak numbering in Fig. 3. Trace components eluting before hexyl decanoate were identified to be decanoic acid, ethyl decanoate, isopropyl decanoate, propyl decanoate, methyl dodecanoate, isobutyl decanoate, hexyl octanoate, butyl decanoate, ethyl dodecanoate, isopropyl dodecanoate, and propyl dodecanoate. After ethyl octadecenoate, traces of decyl decanoate, octyl dodecanoate, hexyl tetradecanoate, and hexyl hexadecanoate also eluted.

^c Double bond position not identified.

Chemistry

The mean total amount of volatile constituents found in the labial glands was $4.76 \pm 1.39 \mu\text{g}$ (*N* = 7). Among the compounds that occurred in relative amounts of at least 0.5%, seven carboxylic acid alkyl esters were identified, whereas two substances remained unknown (Table 1). Hexyl decanoate was by far the dominant compound (Table 1, Fig. 3), comprising almost three quarters of all volatiles. The mass spectrometric fragmentation pattern of wax-type esters has been described from stingless bees (Francke et al., 2000). In addition to the seven quantified esters, trace amounts of decanoic acid and 14 additional esters were identified (see legend to Table 1). Traces of hexyl decanoate were also found in the extracts of mandibular

Fig. 3 Gas chromatogram of an extract of the labial glands from a *T. recursa* forager. The dominant compound (peak 2) is hexyl decanoate. See Table 1 for the remaining compound names

glands—possibly as a contaminant transferred from the labial glands during preparation. Volatiles of the mandibular glands were dominated by 2-octanol ($99.67 \pm 0.19\%$ of gland contents, $N = 7$). The diastereomeric (*S*)-acetyl lactic acid derivatives of 2-octanol were separated by GC, revealing that the natural product was 96% (*S*).

Discussion

Our experiments show that naïve recruits of a stingless bee can be misled by artificial scent trails during the natural process of recruitment to a food source. In contradiction to the prevailing opinion in the literature, however, the bees did not follow trails scented with substances from the mandibular glands. Instead, they followed trails made with labial gland extract, confirming our earlier hypothesis (Jarau et al., 2004) that the trail pheromone of *T. recursa* is produced in the labial glands. The effectiveness of the artificial scent trails made with natural extracts is even more remarkable because the bees had to leave their straight flight path towards the recruitment feeder and turn at an angle of 60° to follow the experimental trail. The nonnatural situation of a bent trail may explain why the majority of the recruits still arrived at the recruitment feeder instead of being equally distributed at the two feeders. It may also be possible, however, that additional information, such as guidance of recruits by the forager, is involved in the recruitment system of *T. recursa*. In *S. postica* (Lindauer and Kerr, 1958, 1960) and *T. corvina* (Aguilar et al., 2005), guiding flights most likely play an important role in addition to scent trails. On the other hand, information could have been lost or jammed in the extracts due to the work-up and application procedure.

The effectiveness of trails made with synthetic hexyl decanoate in releasing trail-following behavior clearly demonstrates that this substance is a key compound of the trail pheromone in *T. recursa*. Therefore, hexyl decanoate is the first trail pheromone component identified and proved to be behaviorally active in stingless bees. Its reduced attractiveness as compared to the labial gland extract indicates, however, that the complete pheromone contains additional substances that may specify and enhance the activity of the signal that is dominated by hexyl decanoate. In *T. recursa*, octyl decanoate and hexyl dodecanoate, along with two unidentified substances, are the next most abundant volatiles in the labial glands. These compounds along with various minor components might add species and/or nest-specific information, i.e., they “fine tune” the signal. Such details could be important in an environment shared with other species of stingless bees competing for the same resources and communicating by means of scent trails as well. Hexyl decanoate was also detected in the cephalic secretions of *Trigona hyalinata* and *Trigona hypogea* (Francke et al., 2000), which are partially sympatric with *T. recursa*. In order to keep the information about the food location “private,” the trail pheromone should contain a species-specific blend of different compounds or of the same compounds in different relative proportions. The gland secretions might also contain interspecifically active repellents. The activities of additional compounds in the trail pheromone of *T. recursa* and its species specificity will be investigated in future studies.

Many diverse chemical structures have been identified to function as trail pheromones in social insects, mainly in ants and termites (Moore, 1974; Hölldobler

and Wilson, 1990; Morgan, 1990; Keeling et al., 2004), but hexyl decanoate was not known as a trail pheromone in any species before. The compound (MW 256) is a typical low molecular weight wax-type ester, representing a structure that is particularly widespread among secondary metabolites produced by bees. It shows medium to low polarity and boils at about 300°C at atmospheric pressure. The compound has been described as a volatile component of the cephalic secretions of two other *Trigona* species, *T. hyalinata* and *T. hypogea* (Francke et al., 2000), but no biological significance has been reported. Future investigations with the aim to identify trail pheromones of other species of stingless bees should be performed in order to better understand the role of esters as marking substances in this group of insects.

The presence of 2-octanol in cephalic secretions of stingless bees has been reported for several *Trigona* spp. and *Frieseomelitta* spp. (Francke et al., 2000; Cruz López et al., 2002), but neither the enantiomeric composition of the compound nor its biological significance is known in these species. We did not test synthetic 2-octanol in our bioassays with *T. recursa*, but the failure of mandibular gland extracts in eliciting trail-following behavior demonstrates that 2-octanol, its almost exclusive component, does not act as a trail pheromone.

Acknowledgments We are very grateful to Sidnei Mateus and Geusa de Freitas for their help in locating the bee nests on the University Campus. This study was supported by grant P-14328 of the Austrian Science Foundation (FWF) to F.G.B. and by money made available by the “Fonds der Chemischen Industrie” to W.F.

Abstract *Hogna helluo*, *Pardosa milvina*, and *Trochosa ruricola* are co-occurring species of wolf spiders within agricultural fields in the eastern USA. The largest species, *H. helluo*, is a common predator of the two smaller species, *P. milvina* and *T. ruricola*. *H. helluo* frequently resides within soil fissures where *P. milvina* and *T. ruricola* may be attacked when they enter or walk near these fissures. We tested the ability of *P. milvina* and *T. ruricola* to avoid *H. helluo*-containing burrows by detecting airborne enemy-avoidance kairomones associated with *H. helluo*. To simulate soil fissures and control for visual and vibratory means of predator detection, we baited funneled pitfall traps with one of the following ($N = 20$ traps/treatment): (1) blank (empty trap); (2) one house cricket (*Acheta domesticus*); (3) one adult female *H. helluo*; and (4) one adult male *H. helluo*. Over two separate 3-d periods, we measured pitfall capture rates of *P. milvina* and *T. ruricola* as well as other incidentally captured ground-dwelling arthropods. During the day, male *P. milvina* showed significant avoidance of pitfall traps baited with *H. helluo* of either sex but showed no avoidance of empty traps or those containing crickets. At night, male *T. ruricola* showed a qualitatively similar pattern of avoiding *H. helluo*-baited traps, but the differences were not statistically significant. We found no evidence that other ground-dwelling arthropods either avoided or were attracted to *H. helluo*-baited traps. This study suggests that an airborne enemy-avoidance kairomone may mediate behavior among male *P. milvina* in the field.

Introduction

Semiochemicals among insects have been studied extensively, but comparable studies among spiders have received less attention (Francke and Schulz, 1999; Dicke and Grostal, 2001; Schulz, 2004). Of the studies documenting behavioral responses to chemical cues among spiders, the vast majority (reviewed in Schulz, 2004) have examined pheromones rather than kairomones or other types of semiochemicals. Spider kairomones documented so far are of two types: foraging kairomones used to locate prey and enemy-avoidance kairomones used by prey species to avoid predators (Ruther et al., 2002). Foraging kairomones are known among ant-hunting spiders (Zodariidae) (Allan et al., 1996), jumping spiders (Salticidae) (Clark et al., 2000; Jackson et al., 2002), and wolf spiders (Lycosidae) (Persons and Uetz, 1996; Punzo and Kukoyi, 1997; Persons and Rypstra, 2000; Hoeffler et al., 2002). Enemy-avoidance kairomones have been found in bowl-and-doily spiders (Linyphiidae) (Suter et al., 1989), but have been studied more extensively in the Lycosidae (Punzo, 1997; Persons et al., 2001).

Pardosa milvina (Araneae, Lycosidae, Hentz, 1844) is a small wolf spider that exhibits a range of antipredator behaviors, such as freezing, vertical climbing, and reduced activity, when exposed to silk and excreta from the larger syntopic wolf spider *Hogna helluo* (Araneae, Lycosidae, Walckenaer, 1837) (Persons and Rypstra, 2001; Persons et al., 2001, 2002; Barnes et al., 2002; Lehmann et al., 2004). In these studies, *P. milvina* was in direct contact with substrates containing deposits from *H. helluo*, and, therefore, the methods allowed for the possibility that *P. milvina* gained information about *H. helluo* via tactile cues. However, one of the experiments revealed that *P. milvina* avoids substrates that have been occupied by *H. helluo* even before coming into physical contact with them (Persons and Rypstra, 2001). This finding suggests that *P. milvina* may be able to detect an airborne cue released by *H. helluo*.

Pardosa milvina can be expected to gain significant benefits by being able to detect airborne enemy-avoidance kairomones of *H. helluo*. *H. helluo* is a common ground-dwelling spider in agricultural systems in the eastern USA (Marshall et al., 2002) and a facultative burrower that often hides in soil fissures during the day when *P. milvina* is most active (Walker et al., 1999; Marshall et al., 2002). Many members of the genus *Pardosa*, including *P. milvina*, are active diurnal foragers that range widely across the ground surface and use soil fissures similar to those used by *H. helluo* as temporary retreats (Walker et al., 1999; Samu et al., 2003). Thus, it would be advantageous for *P. milvina* to detect volatiles emitted either directly from *H. helluo* or the material it leaves behind so that it could avoid entering burrows or soil fissures occupied by *H. helluo* as it navigates the landscape.

Trochosa ruricola (Araneae, Lycosidae, De Geer, 1778) is also a co-occurring agrobiontic wolf spider species intermediate both in size and abundance relative to *P. milvina* and *H. helluo*. Anecdotal field observations suggest that *T. ruricola*, unlike *P. milvina*, prefers burrowing or hiding under objects during the day and actively forages at night. Field and laboratory observations of *T. ruricola* indicate that they are also commonly preyed upon by *H. helluo* (personal observation) and may also benefit substantially from early detection of *H. helluo* via an airborne cue.

In an open plot field study, we tested the ability of *P. milvina* and *T. ruricola* to detect airborne enemy-avoidance kairomones associated with *H. helluo*. By

enclosing *H. helluo* in traps that allowed volatiles to escape but prevented free-ranging *P. milvina* and *T. ruricola* from having any direct contact cues, we were able to use differences in the rates at which these smaller wolf spider species were captured in the traps as evidence of either or both species using airborne information to avoid the predator. We also measured trapping frequencies of other incidentally captured ground-dwelling arthropods to assess if these other species can detect airborne volatiles from *H. helluo* and to control for the possibility that these other captured arthropods might serve as an attractant or deterrent for *P. milvina* and *T. ruricola*.

Methods and Materials

Adult male and female *H. helluo* were collected in late May 2003 from mixed corn and alfalfa fields in White Deer Township, Union County, PA, USA. They were maintained in individual opaque plastic containers (10.5-cm diam \times 7.5 cm deep) with a 1-cm-deep layer of moistened peat moss covering the bottom. Prior to being used as stimuli within pitfall traps, *H. helluo* were maintained at 22°C with a 14:10 hr light/dark cycle. When in the laboratory, spiders were fed with two to four adult house crickets *Acheta domesticus* (L.) (Orthoptera: Gryllidae) each week.

In an 8-ha fallow cornfield at Susquehanna University Ecology Research Center, Selingsgrove, Snyder County, PA, USA, a grid of 96 live-fall pitfall traps was established (12 columns \times 8 rows). This site was selected because of the high population density of *P. milvina* and *T. ruricola*. The rows and columns of traps were 12.5 m from each other. An individual trap consisted of a vertically oriented 0.7-cm-thick polyvinyl chloride (PVC) pipe (10.1-cm diam \times 18 cm deep) that was inserted into the soil flush with the ground surface. A plastic cup (9.8-cm diam \times 17 cm deep) was then inserted within the PVC sleeve and pushed to the bottom of the hole. Each pitfall trap was then capped with a small smooth plastic funnel (10-cm diam at top, tapering to an opening 2-cm diam at the bottom). The lip of the funnel was flushed with the ground and with the edge of the cup making it possible for wolf spiders and other small crawling arthropods to get in but not get out of the trap. This design also prevented spiders from viewing the contents of the cup prior to being trapped. Seismic detection of *H. helluo* from outside the trap was also highly unlikely because there was a small gap between the inner cup and outer PVC sleeve that would have impeded transmission of *H. helluo* movement across the barrier. Seismic information was further limited by restricting *H. helluo* to small containers that minimized their movement during the testing period. The relatively small funnel opening effectively prevented large predatory species from physically entering the trap and potentially preying on the smaller spiders.

We checked the empty traps in the grid for 3-d prior to the experiment to determine baseline trapping rates of *P. milvina* and to test for possible trap site effects. Traps remained open for an 8-hr sampling period (0900–1700 hr). A χ^2 analysis was performed on the 80 traps with the highest capture rates by using individual trap as the treatment. We found no significant difference in the total number of captured *P. milvina* spiders across traps ($\chi^2 = 84.683$, $df = 79$; $C_v = 100.749$, $P = 0.25$; $N = 670$). We caught 503 males, 153 females, and 14 unsexed juveniles. All 80 traps were then paired (highest and lowest, second highest and

second lowest, third highest and third lowest, etc.) to further minimize potential trap bias effects. We sequentially assigned each of these 40 paired pitfall traps to each of the assigned treatments and ran a second χ^2 test by using each of the 40 pairs of traps as a separate treatment. We found no significant difference in capture rates of *P. milvina* among these pairs, indicating no confounding trap bias among unbaited traps by treatment pairing ($\chi^2 = 9.317$, $df = 39$; $C_v = 54.572$, $P > 0.999$; $N = 670$).

The experiment was begun with one of the following stimuli placed in the bottom of each pitfall trap: (1) no added stimulus (negative control, $N = 20$); (2) one adult *A. domesticus* (positive control, $N = 20$); (3) one adult female *H. helluo* ($N = 20$); and (4) one adult male *H. helluo* ($N = 20$). The traps were baited by placing the stimulus arthropod in a plastic vial (4.5-cm diam \times 8 cm deep) that contained a folded moist paper towel as a water source. We then covered the vial with two layers of fiberglass screening and secured it with a rubber band. Each vial was placed in its assigned treatment trap. The fiberglass screening allowed any volatiles present to emanate and simultaneously served to further obscure visual detection of the stimulus from directly above. Each negative control trap contained a vial, moist paper towel, rubber band, and fiberglass screening, but was otherwise empty. All traps were live traps and devoid of preservatives or other chemicals.

The experiment was carried out from June 17 to 23, 2003. There was no rain during this period. Traps remained open daily during an 8hr period (0900–1700 hr). All traps were checked and emptied of arthropods three times daily during the daylight hours of June 17–19. Traps were checked at 1100, 1400, and 1700 hr. For June 21–23, traps were checked three times at night during an 8-hr sampling period from 1900 to 0500 hr. Traps were checked at 2300, 0200, and 0500 hr, primarily to assess *T. ruricola* trap catch rates, but all arthropods found in the traps were recorded during this period. One-way analyses of variance (ANOVAs) were used to analyze the differences in the total number of *P. milvina* and *T. ruricola* captured among the four trap treatments during the day and night, respectively. We then used a Tukey *post hoc* comparison of means test to compare significant differences among treatments. Additional arthropods caught incidentally in the traps were recorded and identified at least to class and, in some cases, to species. When sample sizes permitted, these taxa were also subjected to statistical analysis across treatments. For all arthropods other than *P. milvina* and *T. ruricola*, sample sizes were insufficient for ANOVA. Instead, captures from individual traps were pooled by treatment and subjected to a χ^2 analysis when possible. When sample sizes allowed, we also used binomial tests to compare the total number of spiders caught across all treatments during the day vs. the night for each age and sex category of *P. milvina* and *T. ruricola*. Using a binomial test, we also compared the number of males vs. the number of females captured for both diurnal and nocturnal testing periods.

Results

There was a significant effect of treatment on the total number of *P. milvina* per trap during the day (ANOVA, $F = 9.549$, $P < 0.001$, $N = 519$, $\beta = 0.998$; Tables 1 and 2). Fewer males were captured in traps with *H. helluo* (ANOVA, $F = 11.084$, $P < 0.001$, $N = 374$, $\beta = 1.00$; Table 1), but there was no difference in female *P. milvina* captures among treatments (ANOVA, $F = 1.548$, $P = 0.209$, $N = 140$, $\beta = 0.383$; Table 1).

^a Treatments were empty trap (negative control), *Acheta domesticus* house crickets (positive control), female *H. helluo*, and male *H. helluo*.

^b Letters after means indicate significant differences between treatments based on Tukey *post hoc* test. Numbers in parentheses indicate sample size.

Sample sizes for *P. milvina* at night (Table 3) were too small to analyze statistically for age and sex effects by using ANOVA; however, by using a χ^2 test, we did find that significantly fewer *P. milvina* were captured at night in traps baited with *A. domesticus* compared to all other groups (Table 3), but we found no significant avoidance of traps baited with *H. helluo*.

A total of 597 *P. milvina* were captured during diurnal and nocturnal sampling periods (Tables 2 and 3). Significantly more (519 vs. 78) spiders were captured during the day than during the night (binomial test; $P < 0.001$) supporting our general field observations that *P. milvina* is active diurnally. Over the entire diurnal sampling period, 519 *P. milvina* were caught (374 males, 140 females, and 5 juveniles too young to accurately determine sex; Table 2). In comparison, over the entire nocturnal sampling period, 78 *P. milvina* were caught (12 males, 26 females, and 40 juveniles; Table 3). Although *P. milvina* is generally diurnal, we found significant differences in capture rates among adult males, adult females, and juveniles during the day and night. We captured significantly fewer juveniles during the day than at night (binomial test; $P < 0.001$). Significantly fewer females were captured than males during the day (binomial test; $P < 0.001$), but at night, this trend was reversed with significantly fewer males captured than females (binomial test; $P = 0.05$).

There was no significant effect of treatment on the total number of *T. ruricola* per trap during the night (ANOVA, $F = 1.186$, $P = 0.314$, $N = 217$, $\beta = 0.310$; Table 1). Adult male capture rates did not vary significantly among treatments (ANOVA, $F = 2.238$, $P = 0.083$, $N = 187$, $\beta = 0.558$; Tables 1 and 3), but fewer males were found in the *H. helluo*-baited traps. Fewer female *T. ruricola* were caught during the trapping period, and we found no difference in female trapping rates among treatments (ANOVA, $F = 0.725$, $P = 0.548$, $N = 27$, $\beta = 0.175$; Tables 1 and 3).

^aTreatments were empty trap (negative control), *A. domesticus* house crickets (positive control), female *H. helluo*, and male *H. helluo*.

^b χ^2 tests were completed only for taxa where the expected frequencies of the treatments were greater than 5.

A total of 220 *T. ruricola* were captured during diurnal and nocturnal sampling periods (Tables 2 and 3). The species was caught in higher numbers during the night than during the day (binomial test; $P < 0.001$; Tables 2 and 3). Only three *T. ruricola* were caught over the entire 3-d diurnal period (Table 2), quantitatively supporting our hypothesis that *T. ruricola* is largely nocturnal. Over the entire nocturnal sampling period, 217 *T. ruricola* were caught (187 adult males, 27 adult females, and 3 late-instar juvenile females; Table 3). During nocturnal sampling, we captured more males than females (binomial test; $P < 0.001$).

A number of other arthropods were captured in the pitfall traps (Tables 2 and 3). In most cases, there were too few individuals to analyze statistically by treatment. Of those species with sufficient sample size for analysis, we found no differences in trapping rate across treatments (Tables 2 and 3). However, in males of the crab spider *Xysticus gulosus* (Keyserling, 1880), there appeared to be a nonsignificant trend to avoid *H. helluo*-baited traps (Table 3).

Discussion

Our results suggest that both sexes of *H. helluo* release an airborne kairomone that enables male *P. milvina* to detect and avoid *H. helluo* during the day, but we found no evidence that *P. milvina* or *T. ruricola* avoid *H. helluo* at night. Our data indicate that the detection by *P. milvina* is not very fine-tuned. Although we found significantly fewer male *P. milvina* in traps baited with *H. helluo*, *P. milvina* did not discriminate between male and female predators. In addition, they were not attracted to or repulsed by whatever cues might be released by adult crickets during the day. Although *T. ruricola* showed no statistically significant trap avoidance, the number of males found in *H. helluo*-baited traps was 19–40% lower than the number in cricket-baited or control traps, respectively.

Our finding that male, but not female, *P. milvina* detect and avoid *H. helluo* may be a statistical artifact because, throughout the study, male capture frequency was much higher than females and resulted in greater statistical power ($\beta = 1.00$ for males vs. 0.383 for females). This higher capture frequency suggests that males of *P. milvina* tend to be more active than females overall, as may be true of most wolf spiders (Hallander, 1967; Cady, 1984; Persons, 1999; Persons and Uetz, 1999). However, in laboratory studies, no differences in male and female *P. milvina* activity were detected (Walker and Rypstra, 2003), suggesting that pitfall traps may be an indicator of *P. milvina* space use rather than activity level *per se*, or that laboratory findings are not representative of movement patterns of spiders under field conditions. Notably, other studies have shown that an airborne pheromone attracts *P. milvina* males to female conspecifics (Searcy et al., 1999). In addition, males use pheromones to identify the mating status of females, whereas females assess male quality by using primarily visual cues (Rypstra et al., 2003). Thus, it may be that males are more sensitive to chemical cues in general and, specifically, more sensitive to airborne cues than are females.

Female *H. helluo* show significantly higher attack frequencies on *P. milvina* than male *H. helluo* (Walker and Rypstra, 2002; Lehmann et al., 2004); therefore, females pose a much greater predation risk. It was therefore surprising that *P. milvina* was unable to discriminate between male and female *H. helluo*. If an airborne sex

^aTreatments were empty trap (negative control), *A. domesticus* house crickets (positive control), female *H. helluo*, and male *H. helluo*.

^b χ^2 tests were completed only for taxa where the expected frequencies of the treatments were greater than 5.

pheromone of *H. helluo* were used as an enemy-avoidance kairomone by *P. milvina*, sex discrimination would appear to be readily achievable. Because volatiles from adult male or adult female *H. helluo* elicited similar avoidance responses by *P. milvina*, this suggests that the kairomone is not a sex pheromone.

Although it has been shown that *P. milvina* can recognize substrate-borne cues from prey items (Hoeffler et al., 2002), we uncovered no evidence that *P. milvina* responded either positively or negatively to the crickets contained in our traps during the day. We did find a significant tendency for *P. milvina* to avoid cricket-baited traps at night. The adult crickets that we used were much larger than those consumed by *P. milvina*. If *P. milvina* detected the crickets, and was able to determine their size, then they may have avoided them based on this criterion alone. Previous studies have demonstrated that *P. milvina* can estimate the size of *H. helluo* based on substrate-borne chemical cues alone by responding to the quantity of silk and excreta produced (Persons and Rypstra, 2001). Alternatively, *P. milvina* may not have had sufficient experience with crickets of this size and species to respond strongly to their emissions one way or another. Previous studies have found that *H. helluo* are attracted to volatiles from *P. milvina* but apparently not *A. domesticus* (Persons and Rypstra, 2000).

Although male *T. ruricola* and male *X. gulosus* showed the same general pattern as *P. milvina* with respect to trap capture rates, differences did not reach the level of statistical significance. This could be attributable to low statistical power. As an alternative hypothesis, *T. ruricola* and *H. helluo* are both nocturnally active and are closer in size to one another. As such, *H. helluo* may not present as great of a predation risk to *T. ruricola* as it does to *P. milvina*. *Xysticus gulosus* is smaller than *T. ruricola* and well within the prey size range of *H. helluo*. However, unlike *T. ruricola*, we have never observed *X. gulosus* predation by *H. helluo* in the field. Although we found no evidence that *Xysticus* spp. respond to *H. helluo* volatiles, there is field evidence that some *Xysticus* species are capable of detecting volatile chemicals (Aldrich and Barros, 1995).

Pardosa milvina failed to show significant avoidance of *H. helluo* at night. This also could have been attributable to a lack of statistical power because far fewer *P. milvina* were captured at night. Alternatively, diurnal and nocturnal conditions may have influenced kairomone production and persistence by *H. helluo*. Previous studies have found that *P. milvina* antipredator responses are reduced when they encounter *H. helluo* silk and excreta that have been wetted, but that subjecting *H. helluo* silk and excreta to heat has no effect on *P. milvina* response (Wilder et al., 2005). Based on these findings, dew at night may have reduced the effectiveness of any volatile kairomone produced by *H. helluo* resulting in less effective avoidance by *P. milvina* males, whereas the higher temperatures and sunlight during the day likely had no negative effect on *P. milvina* responsiveness to this kairomone. However, our use of moist paper towels in this study likely minimized extreme differences in ambient trap humidity levels during the day vs. the night, but humidity levels outside of the trap probably varied considerably.

We cannot completely rule out the hypothesis that *P. milvina* could have been attracted to insects or spiders captured in the traps other than *H. helluo*. Another alternative hypothesis is that differential predation by trapped larger spiders or ground beetles could have skewed the capture frequencies across treatments. However, both of these alternative interpretations of biased trap capture rates are

unlikely. First, we found no evidence for differential trapping rates by treatment for species other than *P. milvina*. Second, because the traps were designed to capture small wolf spiders, few larger potential predators were able to physically enter the traps. Third, because we cleared the traps frequently, arthropod densities never were sufficiently high to encourage predation. We also visited traps with sufficient frequency to observe any predation when it did occur. Only two instances of predation were found. This occurred twice in the control traps, and these were omitted from the analysis because the spiders could not be positively identified with respect to age, sex, or *Pardosa* species. Only six species found in the traps were capable of preying upon *Pardosa*: one beetle species, the carabid *Scarites subterraneus* (Fabricius, 1775); two species of crab spider, *Xysticus ferox* (Hentz, 1847) and *X. gulosus* (Keyserling, 1880); and three wolf spiders, *H. helluo* (Walckenaer, 1837), *Schizocosa avida* (Walckenaer, 1837), and *T. ruricola*. *Trochosa ruricola* and *S. subterraneus* occurred in sufficiently low numbers during the day as to be unlikely to have had a significant predation effect (three *Trochosa* during the day and 12 *Scarites* during the day). *Schizocosa avida* also occurred only in very low numbers during the day and night, and only a single *H. helluo* was captured making both unlikely to bias the results. The crab spiders, although numerous, were never larger than *Pardosa*, and, more importantly, they were either equally distributed across all treatment groups or showed trends toward the same capture bias as *Pardosa*, and thus, if anything, would underestimate the magnitude of the capture bias effect because predation would skew it in the opposite direction as what the results indicate. Furthermore, during trap checks, we found no evidence of intraguild predation occurring between *P. milvina* and either of the *Xysticus* spp.

Research on airborne chemical communication in spiders is in its infancy. Currently, there are few studies of communication among spiders via airborne pheromones (Tietjen, 1979; Watson, 1986; Willey and Jackson, 1993; Searcy et al., 1999; Papke et al., 2001; Becker et al., 2005) and even fewer that test for airborne chemical cues among different species of spider (Persons and Rypstra, 2000; Jackson et al., 2002; Li and Lee, 2004; Kasumovic and Andrade, 2004). Our study provides evidence that wolf spiders can and do use an airborne enemy-avoidance kairomone within an ecologically relevant context. We suggest that future studies of interspecific interactions among spiders should consider volatile cues as a possible mediator of observed behavioral responses.

Acknowledgments We thank Ashley Boyer and Daisy Conduah for their help in setting up pitfall traps and collecting spiders used in this study. This research was funded by NSF grants DBI 0216776 to M. Persons and DBI 0216947 to A. Rypstra.

Abstract The kairomonal activity of the sex pheromones of three pine bast scales, *Matsucoccus feytaudi*, *Matsucoccus josephi*, and *Matsucoccus matsumurae*, as well as a new analog of the *M. feytaudi* sex pheromone, were investigated in pine forests of France, Portugal, and Italy. The response of the maritime pine bast scale predators, *Elatophilus* spp. and *Hemerobius stigma*, was used to test the influence of trapping methods, kairomone composition, and dose. Both predators showed significant attraction to all compounds except to the sex pheromone of *M. josephi*. Significant increase in captures was observed as a function of dose, and within the studied dose range, up to 2200 µg, no threshold saturation limits were observed for any of the attractive compounds. Trap design and size did not significantly influence predator captures, except for high population levels of *Elatophilus crassicornis*, when plate traps were more efficient than delta traps. Geographic variations were found in the kairomonal responses patterns of both predators, with the *M. matsumurae* sex pheromone being more attractive to the oriental populations from Corsica and Italy, whereas the western populations in Aquitaine and Portugal were more attracted to the *M. feytaudi* sex pheromone.

Introduction

Pheromones represent one of the major components of ecologically based insect pest management (Howse et al., 1998). Effectively, the use of these semiochemicals for monitoring, mass trapping, mating disruption, or lure-and-kill has been investigated or developed during recent decades (e.g., Taschenberg et al., 1974; Brockerhoff and Suckling, 1999; Millar et al., 2002). However, although pheromones are generally viewed as environmentally sound, some practical problems regarding their safety could arise from their kairomonal activity. In effect, there is increasing evidence that these pheromones attract natural enemies (e.g., Bakke and Kvamme, 1981; Hendrichs et al., 1994; Boo et al., 1998; Millar et al., 2001; Mendel et al., 2004). This is of importance, as catching large numbers could impact negatively the densities of these beneficial insects, and potentially result in increases in pest populations. However, this aspect has not been studied in great detail to date. The analysis of response patterns by natural enemies to the different compounds can further elucidate the role of these infochemicals in the behavioral mechanisms related to kairomonal attraction, prey detection, prey preference, and functional response.

In this work, we undertook an international study to determine if there is dose response to sex pheromones of hosts by natural enemies, by using the responses of *Elatophilus* spp. and *Hemerobius stigma*, to the pheromones of three pine bast scales, *Matsucoccus feytaudi* Ducasse, *Matsucoccus matsumurae* Kuwana, and *Matsucoccus josephi* Bodenheimer and Harpaz, and also to a new analogue of the *M. feytaudi* sex pheromone. We also examined the specific responses of these natural enemies to different types of traps in order to develop an optimal trapping method to monitor or attract natural enemies of *M. feytaudi* and to evaluate the adverse effect of trapping with *M. feytaudi* pheromone on its natural enemies.

Methods and Materials

The experiments were repeated in four European regions: Aquitaine and Corsica in France, Península de Setúbal in Portugal, and Liguria in Italy. In each region, a trapping line was set up at two different sites, with traps separated by about 25 m. At each site, we tested four compounds (synthetic sex pheromones of *M. feytaudi*, *M. josephi*, and *M. matsumurae*, as well as a new analogue of the *M. feytaudi* pheromone, Fig. 1) at four concentrations (400, 800, 1400, and 2200 µg), using two trap types (delta and plate) and two sticky surface areas (15 × 15 cm vs. 30 × 30 cm), for a total of 64 traps. In addition, there were four control traps (a delta and plate trap with either a 15 or 30 trapping surface). Traps were made of white polypropylene and covered with a sticky material. The active compounds were used in the form of racemic mixtures: 56:44 *EE*/*ZE* ratio for *M. josephi* sex pheromone and 65:35 *EE*/*ZE* ratio for the other three compounds.

Pheromones were synthesized at the UPMC, INRA-Versailles. The new analogue was synthesized by using a procedure similar to that used for the synthesis

Fig. 1 Chemical structure of the four semiochemical compounds tested for attractiveness toward predator species of *M. feytaudi*

of *M. matsumurae* pheromone (Watanabe et al., 1997). Lures for *M. feytaudi*, *M. feytaudi* analogue, and *M. matsumurae* pheromones were loaded in caps of rubber septa (OD 8 mm, purchased from Sigma-Aldrich) in France (INRA-Versailles), and those for *M. josephi* were prepared in Israel (Volcani Center).

Trials were carried out between April and May, 2000. Sticky surfaces of traps were replaced twice a week, and the lures (rubber septa) replaced every 2 wk. In all sites, we recorded the number of brown lacewing, *H. stigma* Stephens. We also collected predaceous bug adults: *Elatophilus nigricornis* Zetterstedt in France and Italy and *Elatophilus crassicornis* Reuter in Portugal.

Data were analyzed by ANOVA, following logarithmic of $x + 1$ transformation and subject to *post hoc* Student–Newmann–Keuls multiple-range tests ($\alpha = 0.05$).

The *M. josephi*, *M. feytaudi*, and *M. matsumurae* pheromones have different relative volatiles (Dunkelblum et al., 1996). Therefore, to test lures with similar release rates, we compared the kairomonal response of the predators 400 and 800 μg of *M. feytaudi* sex pheromone with that of 1400 and 2200 μg of *M. matsumurae* sex pheromone. In this experiment, the data were analyzed using independent sample *t* tests.

Results

Kairomone Composition and Dose

There was significant region \times kairomone interaction for both *E. nigricornis* and *H. stigma* [$F(6,204) = 10.51$, $P < 0.001$ and $F(9,2720) = 7.13$ $P < 0.001$, respectively], so separate ANOVAs were conducted for each region. In the four regions, and for both groups of predators, the two main factors kairomone type and dose were significant (Tables 1 and 2). The mean catches increased with increasing dose of all pher-

omones, except for that of *M. josephi*, which never differed from the control. The dose responses showed no clear saturation limit within the tested range (Figs. 2 and 3).

The highest *Elatophilus* species captures were in traps baited with the *M. feytaudi* pheromone, followed by the *M. feytaudi* analogue and *M. matsumurae* pheromone at all sites (Fig. 3). Similarly, in Aquitaine and Portugal populations, *H. stigma* were mostly attracted by *M. feytaudi* pheromone, followed by *M. feytaudi* analogue (Fig. 2). In contrast, especially at the higher doses, *H. stigma* from Corsica and Italy were mostly attracted by *M. matsumurae* pheromone (Fig. 2).

Fig. 2 Effect of kairomone and dose on *H. stigma* captures in Portugal, Corsica, Italy, and Aquitaine ($N = 8$), in relation to the compounds *Matsucoccus feytaudi* analog, *M. feytaudi*, *M. josephi*, and *M. matsumurae*

The comparison 400 and 800 µg of *M. feytaudi* sex pheromone with 1400 and 2200 µg of *M. matsumurae* sex pheromone, gave different results depending on the region. The western populations of the brown lacewing were equally attracted to both semiochemicals, whereas the eastern populations showed a significantly higher attraction to the *M. matsumurae* pheromone (Table 3). Furthermore, the eastern populations of *Elatophilus* species showed no preference for either kairomone, whereas the western populations were more attracted to the *M. feytaudi* pheromone.

Trap Size and Design

Captures of *H. stigma* were higher in Corsica and Portugal than in Aquitaine and Italy (Fig. 4). In Liguria, delta traps captured significantly more brown lacewings than plate traps (Fig. 4, Table 1), whereas no differences were observed in the other three regions. As for Portugal, where the *Elatophilus* spp. catches were two to three times higher than in the other three regions (Fig. 5), plate traps captured more bugs

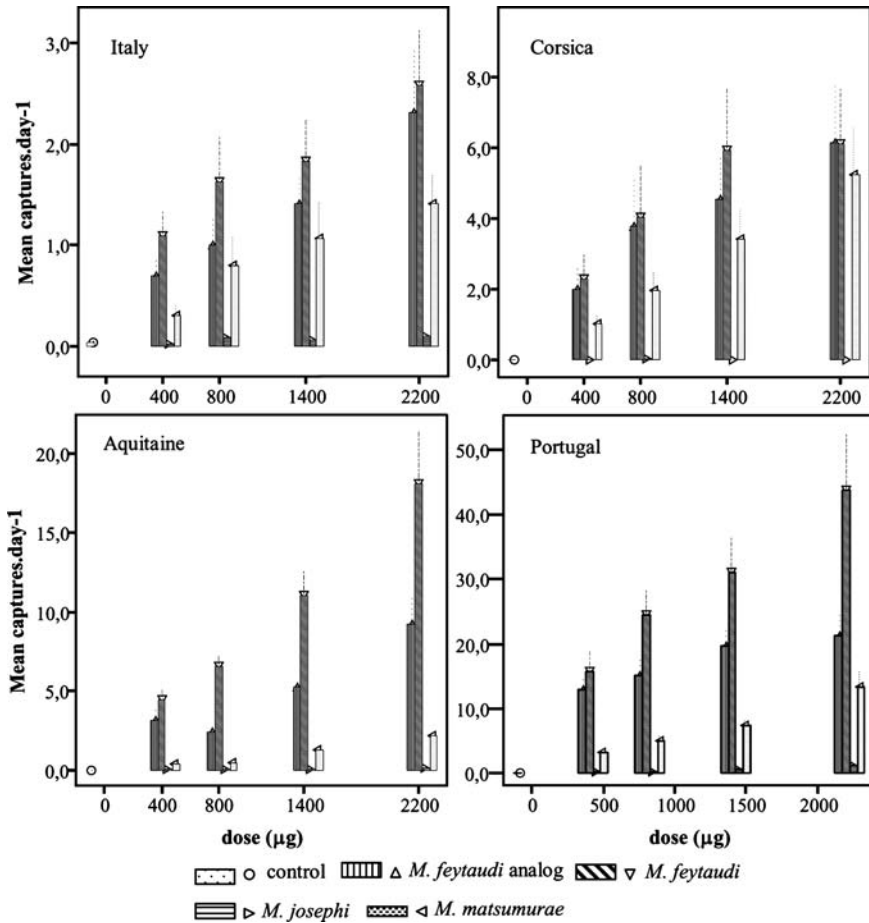

Fig. 3 Effect of kairomone and dose on *E. nigricornis* (Aquitaine, Italy, and Corsica) and *E. crassicornis* (Portugal) captures ($N = 8$), in relation to the compounds *Matsucoccus feytaudi* analog, *M. feytaudi*, *M. josephi*, and *M. matsumurae*

Values are log(mean captures per trap) ± SE. Mm, *M. matsumurae*; Mf, *M. feytaudi*.

^a $P < 0.05$; significantly different from the other treatments (independent sample *t* test).

Fig. 4 Effect of region, trap type, and trap size on the mean catches of *H. stigma* ($N = 34$). Within each site, means with the same letter are not significantly different (SNK test, $\alpha = 0.05$)

than delta traps, thus explaining the observed trap type effect for this species (Table 2). Differences caused by trap size were not significant at any site.

Discussion

The results provide new evidence that predators respond to the sex pheromones of several scale species in several different geographic locations, suggesting that they play a role in host location. This kairomonal activity was previously demonstrated in Europe (Mendel et al., 2003, 2004) and Israel, where *E. hebraicus* responded to the same *Matsucoccus* pheromones (e.g., Dunkelblum et al., 1996; Mendel et al., 1997, 2003). Pine bast scales occupy an inconspicuous location under the bark of the trunk where they feed on the phloem, and in their native environment they generally

Fig. 5 Effect of region, trap type, and trap size on the mean catches of *E. nigricornis* (Aquitaine, Italy, and Corsica) and *E. crassicornis* (Portugal) ($N = 34$). Within each site, means with the same letter are not significantly different (SNK test, $\alpha = 0.05$)

occur in extremely low densities. Therefore, the use of the host sex pheromone would provide a reliable cue to locate prey, and the fact that they respond to the pheromones of several different scales would improve their ability to locate different host species. Predators require higher concentrations to locate the pheromone source than male pine scales, suggesting that scales may only be extensively exploited when densities are abundant enough to sustain natural enemy populations. However, the high kairomonal response of predators suggests that sex pheromone may also be used to draw natural enemies into the habitat and increase the local population of natural enemies. Further studies are needed to evaluate this possibility.

There are several nonmutually exclusive explanations for the observed intersite differences that are noted above: (i) the effect of prevailing climate on both the effectiveness/longevity of lures, as well as the behavior of the target species, (ii) the actual population densities of prey/predator populations, (iii) the relative importance of the scales as prey to these predators in each habitat, and (iv) the time that prey and predators have been in association at the different sites (Jonsson and Anderbrant, 1993; Sharov et al., 1996; Mendel et al., 1997; Krips et al., 1999). Although several examples of different geographic variation in intraspecific sex pheromones have been reported (McElfresh and Millar, 2001; Anderbrant et al., 2000; El Sayed et al., 2003), we believe that the marked differences in response of both *H. stigma* and *Elatophilus* spp. to different host pheromones is the first example of geographic variation in response to kairomones. These differences are possibly related to the fact that the western regions correspond to the original geographical range of *M. feytaudi*, whereas this species was only introduced into Italy and Corsica in the 1970s and 1990s, respectively (Covassi and Binazzi, 1992; Jactel et al., 1998; Burbán et al., 1999). Prior to the introduction of *M. feytaudi*, *M. pini* was the only pine bast scale present in these eastern regions (Rieux, 1976; Tranfaglia et al., 1985). The sex pheromone of *M. pini* is not known, but our results suggest that it may resemble the sex pheromone of *M. matsumurae*. This is also consistent with the observation that *Sympherobius fuscescens*, another potential predator of *M. pini* in the eastern areas, also responded to the sex pheromone of *M. matsumurae* but not to that of *M. feytaudi* (Mendel et al., 2004). The observation that the predators of *M. pini* responded to the *M. matsumurae* pheromone emphasizes the need to clarify the taxonomic status of these two species, as suggested by Kosztarab and Kozár (1988).

Dunkelblum et al. (2000) reported that the species specificity of the pheromone was dependent on the structure of the side chain, whereas the kairomonal effect was dependent on the ketodiene moiety. However, as all compounds tested in this study had a common ketodiene moiety yet differed markedly in kairomonal activity, this indicates that changes in the side chain also affect the response of natural enemies.

There are significantly different dose-dependent responses by scale predators. When sex pheromones are used as a pest management strategy, then the potential negative effects on the populations of natural enemies must take this into consideration when determining the most effective dose to use. Furthermore, no saturation level was observed by predators over the dose range tested, which contrasts with the observed response of *M. feytaudi* males to increasing dose of sex pheromone (Branco et al., 2004). The present results indicate that generally the size and type of trap did not influence efficiency, except for large plate traps, which

caught more *E. crassicornis* when there were high densities of this predator. A preference for vertical objects, as observed elsewhere among other groups of insects that use trees for shelter or feeding (e.g., Willis et al., 1994; Gross et al., 2001), may explain this result.

In summary, the present study provides information on the kairomonal responses of these entomophagous insects that could be useful in the pest management strategies against the pine bast scale. Additional research is required to determine the relative importance of biotic and abiotic factors affecting the responses of natural enemies to scale pheromones, and how these may differ at different geographic locations.

Abstract In many animals, chemical signals play an important role in species recognition and may contribute to reproductive isolation and speciation. The Iberian lizards of the genus *Podarcis*, with up to nine currently recognized lineages that are often sympatric, are highly chemosensory and provide an excellent model for the study of chemically mediated species recognition in closely related taxa. In this study, we tested the ability of male and female lizards of two sister species with widely overlapping distribution ranges (*Podarcis bocagei* and *P. hispanica* type 1) to discriminate between conspecific and heterospecific mates by using only substrate-borne chemical cues. We scored the number of tongue flicks directed at the paper substrate by each individual in a terrarium previously occupied by a conspecific or a heterospecific lizard of the opposite sex. Results show that males of *P. bocagei* and *P. hispanica* type 1 are capable of discriminating chemically between conspecifics and heterospecifics of the opposite sex, but females are not. These results suggest that differences in female, but not male, chemical cues may underlie species recognition and contribute to reproductive isolation in these species. The apparent inability of females to discriminate conspecific from heterospecific males, which is not because of reduced baseline exploration rates, is discussed in the context of sexual selection theory and species discrimination.

Introduction

The evolution of prezygotic reproductive isolation remains a central issue in the study of speciation and one of the least well-understood questions in evolutionary biology (Eady, 2001). Results from several taxa suggest that behavior plays a major role in preventing interspecific mating (so-called “ethological isolation mechanisms”): differences in mating signals between species or populations are often much more pronounced than morphological differences and provide an important barrier to gene exchange (e.g., Butlin and Ritchie, 1994; Ptacek, 2000; Shine et al., 2002). Furthermore, behavioral characters are increasingly recognized as useful tools for phylogenetic reconstruction (de Queiroz and Wimberger, 1993; Gittleman and Decker, 1994). Thus, behavioral assays of species recognition may provide important clues to the elucidation of the taxonomic status in complex groups.

In many animals, chemical signals play an important role in species recognition and speciation: the detection of species-specific chemical cues allows individuals to recognize each other as potential mates and promotes assortative mating (reviewed in Wyatt, 2003). This phenomenon has been widely studied, although with a strong taxonomic bias toward invertebrates, mainly moths (e.g., Phelan and Baker, 1987), and also flies (e.g., Mas and Jallon, 2005), beetles (Symonds and Elgar, 2004), spiders (e.g., Roberts and Uetz, 2004), and polychaetes (Sutton et al., 2005). Squamate reptiles have well-developed chemosensory systems and are among the most chemosensory of vertebrates: for many lizards and snakes, chemical stimuli are important sources of information about several aspects of the environment crucial to fitness (Halpern, 1992; Schwenk, 1995). Chemicals released at the time of reproduction may provide the basis for species recognition and avoidance of interspecific mating among closely related sympatric species (Cooper and Vitt, 1987; Mason, 1992; Labra et al., 2001) or between different populations of the same species (LeMaster and Mason, 2003). Among lizards, the discrimination of conspecifics from heterospecifics based on chemical cues alone has been reported in a few scincid (Cooper and Vitt, 1987), iguanian (Labra et al., 2001), and lacertid species (Gómez et al., 1993; Cooper and Pérez-Mellado, 2002; Barbosa et al., 2005).

The lizards of the genus *Podarcis* are the predominant lacertid group in southern Europe, and their taxonomy has remained unstable and controversial until recently. In the Iberian Peninsula, the combination of nuclear and mitochondrial molecular markers has allowed the identification of several cryptic forms, probably with specific status, confirmed also by morphological studies (Harris and Sá-Sousa, 2002; Sá-Sousa, 2001; Sá-Sousa et al., 2002; Pinho et al., 2003, 2006; Kaliontzopoulou et al., 2005).

Although the chemosensory abilities of *Podarcis* lizards have been previously studied (e.g., López and Martín, 2001; Font and Desfilis, 2002; Desfilis et al., 2003), only a few studies have dealt with the issue of species recognition. Gómez et al. (1993) provided the first evidence of chemically mediated species recognition in a lacertid: male *Podarcis hispanica* (*sensu lato*) were capable of detecting and discriminating conspecific from heterospecific (*Psammotromus algirus*) chemicals. However, the two species used in this study were not even congeneric. More recently, Cooper and Pérez-Mellado (2002), working also with *P. hispanica* (*sensu lato*), reported that males of this species have the ability to discriminate among conspecifics and sympatric female congeners (*Podarcis carbonelli*) based on chemical cues alone. These findings point to a possible role of chemoreception as an ethological isolating mechanism in this complex genus.

In a previous study (Barbosa et al., 2005), we tested the ability of males of two closely related species, *P. bocagei* and *P. carbonelli*, to discriminate between substrates labeled by conspecific and heterospecific females. Our results demonstrated the existence of reciprocal chemical discrimination between these two species. In the present study, we focused on *P. hispanica* type 1 and *P. bocagei*, a monophyletic and closely related species pair (in fact, sister taxa) within this genus, (Pinho et al., 2006), and tested the ability of individuals of either sex to discriminate between conspecifics and heterospecifics of the opposite sex. Because they are sister species, have largely overlapping distributions that includes contact even at a microscale (personal observation), no introgression events have been detected so far, and no extrinsic barriers to hybridization have been described, this species pair presents an interesting case study for research on the role of chemical cues in species discrimination and reproductive isolation.

Methods and Materials

Study Species

Podarcis hispanica type 1 and *P. bocagei* are small-sized lizards, which have a widely overlapping distribution in the NW Iberian Peninsula, living in sympatry over large areas. *P. hispanica* type 1 is a rock-dwelling lizard found in Galicia (Spain), northern Portugal, and the western Castilian plateau and Central System (Spain). *P. bocagei* is a ground-dwelling lizard occurring in western Asturias, Cantabria, Galicia (Spain), and northwestern Portugal (Galán, 1986; Sá-Sousa, 2000). Although very closely related, the two species can be easily identified by their morphological characteristics (for details, see Sá-Sousa, 2001; Sá-Sousa et al., 2002).

Animal Capture and Maintenance

Lizards were collected at the beginning of the reproductive season (February 2005) in the coastal area of Moledo do Minho (northern Portugal), where both species occur syntopically. They were transported to and housed at the laboratory in Valencia, Spain. Lizards were transported in individual plastic terraria (20 × 12 × 16 cm) with damp paper to avoid dehydration and then housed in glass terraria (40 × 20 × 25 cm for females and 35 × 20 × 20 cm for males), with a permanent supply of water and a rock for basking and shelter. Incandescent (40-W) bulbs placed above each terrarium provided light and heat. Lights were scheduled to provide a 12-hr light/12-hr dark photoperiod cycle. Terraria were kept in a temperature-controlled room (temperature cycle of 24–6 hr: 19°C; 6–11 hr: 23°C; 11–20 hr: 28°C; 20–22 hr: 23°C; 22–24 hr: 22°C) at ambient humidity (2–45%). Lizards were fed daily with mealworm (*Tenebrio molitor*) larvae dusted with vitamins.

Experimental Design

The experimental trials were conducted during March and April 2005. Trials consisted of gently picking up a lizard and transferring it to a test terrarium (40 × 20 × 25 cm) for a 10-min observation period. The test terrarium was kept in the same room where lizards were housed and had a 40-W incandescent bulb suspended

ca. 20 cm above the floor of the terrarium as a source of heat and light. The floor of the test terrarium was covered with a paper substrate. The stimulus conditions were prepared by placing an odor donor inside the test terrarium in the evening preceding an experimental trial and allowing it to remain there until 15 min before the trial. Shed skin, feces, and other obvious visual stimuli left by the donor were removed prior to the trial. For control trials, the test terrarium was fitted with a clean paper substrate. At the end of each trial, the paper substrate was discarded, and the terrarium was washed thoroughly with water and alcohol to eliminate residual chemical traces. Trials were conducted between 11:00 and 13:30 hr GMT, when the lizards were fully active. Room temperature at the time of testing was maintained between 26 and 29°C to minimize variability arising from thermal dependence of tongue flick rates (Cooper and Vitt, 1986a).

Each trial was video-recorded, and the lizards' behavior was later analyzed with the aid of a portable computer equipped with JWatcher event-recording software (Blumstein et al., 2000). As we were interested in the lizards' chemosensory responses, we focused our behavioral observations on tongue flicks. Tongue flicking functions to acquire chemicals for analysis by the vomeronasal organ and provides an observable index of the chemosensory investigation of a stimulus (Cooper and Burghardt, 1990; Halpern, 1992). We scored the number of tongue flicks directed at the substrate, which is indicative of chemosensory investigation of traces left by other individuals, and the number of tongue flicks directed at the air (air licks). Although results were similar for both variables, based on our previous work (Font and Desfilis, 2002; Barbosa et al., 2005), we restricted further analyses to the number of tongue flicks directed at the substrate in each experimental condition. Moreover, it has been suggested that air licks may be more influenced by stress than specific stimuli, at least in other lizards (Greenberg, 1985).

In the first set of experiments, we tested the ability of *P. hispanica* type 1 and *P. bocagei* males to chemically discriminate conspecific from heterospecific females. Thirteen females (five *P. hispanica* type 1 and eight *P. bocagei*) acted as donors of chemical stimuli for the trials (no female was used more than five times as a donor). Males were tested three times: once in a clean test terrarium (control), once in a test terrarium bearing chemical stimuli from a conspecific female, and once in a test terrarium bearing chemical stimuli from a heterospecific female. Each individual was tested only once per day with an intertrial interval of 2 d. The order of stimulus presentation was partially counterbalanced to avoid sequence effects. Eleven *P. hispanica* type 1 and 11 *P. bocagei* males were tested.

In the second set of experiments, we tested the ability of females of both species to discriminate chemical stimuli of conspecific and heterospecific males. The procedure was identical to that described for the first experimental set, except for the sex of donors and experimental lizards. Thirteen males (six *P. hispanica* type 1 and seven *P. bocagei*) acted as donors of chemical stimuli for the trials (no male was used more than five times as a donor). Twelve *P. hispanica* type 1 and 11 *P. bocagei* females were tested.

Statistical Analyses

We fitted a robust partly nested analysis of variance (ANOVA) model to rank-transformed data using SPSS 11.5. We used a group \times trials repeated-measures design with responses to each of the three stimulus conditions as the repeated

measure and with individual males/females (random factor) nested within species (Quinn and Keough, 2002). The sphericity assumption was tested with Mauchly’s test. In those cases in which significant departures from sphericity were detected, we tested the significance of treatment effects and of the treatment × species interaction using adjusted univariate *F* ratios and multivariate ANOVA statistics (Pillai Trace). Following detection of significant treatment effects, we conducted pairwise comparisons between the different stimulus conditions. Power analyses were performed using *R*.

To compare the rate of tongue flicks of males and females in control conditions (which indicates the level of baseline chemosensory investigation by each sex), we used a Mann-Whitney nonparametric test for two independent samples (Siegel and Castellan, 1988).

Significance level for rejection of the null hypothesis was set at 0.05, and all tests were two-tailed. Data are presented as mean ± SEM.

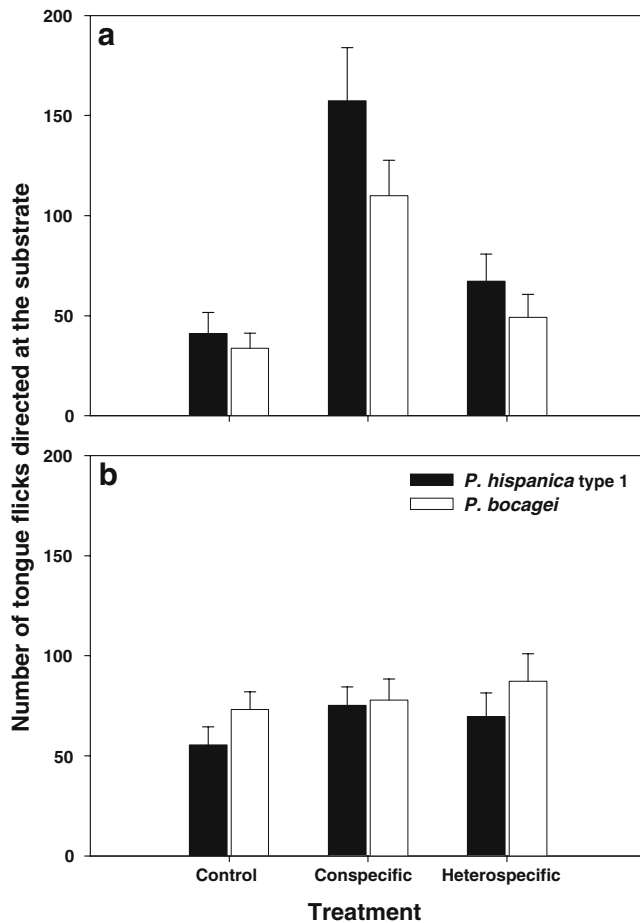

Fig. 1 Number (mean ± SEM) of tongue flicks of *P. hispanica* type 1 and *P. bocagei* males (a) and females (b) directed at the clean substrate (control) or at the substrate labeled by a conspecific or a heterospecific of the opposite sex

Results

Five *P. bocagei* (two males and three females) exhibited persistent escape attempts during the trials and were discarded from the analyses.

The males' responses to the treatments are illustrated in Fig. 1a. Table 1 shows *F* ratios adjusted by means of two commonly used types of correction (Quinn and Keough, 2002), although sphericity could be assumed (Mauchly's test: $W = 0.939$; $df = 2$; $P = 0.587$). All tests indicate a highly significant treatment effect. Lizards of both species directed more tongue flicks at substrates bearing chemical stimuli from conspecific females than to clean (control) substrates ($F = 65.68$, $df = 1$, $P < 0.001$) or substrates labeled by heterospecific females ($F = 36.706$, $df = 1$, $P < 0.001$). Moreover, lizards directed more tongue flicks to substrates labeled by heterospecifics than to clean substrates ($F = 5.079$, $df = 1$, $P = 0.037$). In no case was the species and treatment \times species interaction term significant.

The females' responses to the treatments are depicted in Fig. 1b. Table 1 shows adjusted *F* ratios (as in the case of males). As we could not assume sphericity (Mauchly's test: $W = 0.507$; $df = 2$; $P = 0.003$), we tested for treatment and treatment \times species interaction effects on the number of tongue flicks directed at the substrate using adjusted univariate and multivariate statistics. There were no significant species, treatment, or treatment \times species interaction effects. This test had sufficient power (0.883) to detect a difference of the same magnitude as that found in the males' experimental set.

There was a statistically significant difference in the number of tongue flicks performed in control conditions between sexes in *P. bocagei* (females perform more tongue flicks than males: Mann-Whitney's test, $U = 8.5$, $P = 0.008$); in the case of *P. hispanica* type 1, no differences were detected between sexes (Mann-Whitney's test, $U = 44.5$, $P = 0.185$).

Table 1 ANOVA table for the number of tongue flicks directed at the substrate (after rank transformation) by *P. hispanica* type 1 and *P. bocagei*

Sex	Males			Females		
	<i>F</i>	<i>df</i>	<i>P</i>	<i>F</i>	<i>df</i>	<i>P</i>
Source of variations						
Between subjects						
Species	0.819	1	0.378	0.957	1	0.341
Within subjects						
Treatment						
Sphericity assumed	33.024	2	<0.001	–	–	–
Greenhouse-Geiser	33.024	1.885	<0.001	1.846	1.339	0.187
Huyn-Feldt	33.024	2	<0.001	1.846	1.488	0.184
Pillai Trace	37.685	2	<0.001	5.63	2	0.013 ^a
Treatment \times Species						
Sphericity assumed	0.144	2	0.866	–	–	–
Greenhouse-Geiser	0.144	1.885	0.855	0.683	1.339	0.458
Huyn-Feldt	0.144	2	0.866	0.683	1.488	0.472
Pillai Trace	0.109	2	0.897	1.827	2	0.191

^a Note that the multivariate adjustment (Pillai Trace) indicates a significant treatment effect. However, because there is a disagreement between the univariate and multivariate adjusted results, we conclude, following Quinn and Keough (2002), that there is a lack of treatment effect.

Discussion

The results show that *P. hispanica* type 1 and *P. bocagei* males respond differentially to chemical cues of conspecific and heterospecific females, exhibiting more chemosensory behaviors in response to conspecifics. These results clearly indicate the males' ability to discriminate between conspecific and congeneric females of a sympatric, closely related species using only substrate-borne chemical cues. Thus, differences in female chemical cues may underlie specific recognition in these species. The lack of significant species or treatment \times species interaction effects further indicates that males of the two species show consistent responses to the paper substrates. Moreover, the difference between the number of tongue flicks directed at substrates labeled by heterospecific females and controls indicates that the males also respond to heterospecific cues, which may suggest their detection as a biologically relevant stimulus. These findings are in agreement with previous results of reciprocal chemical discrimination in *P. carbonelli* and *P. bocagei* (Barbosa et al., 2005) and underscore the importance of chemical cues in species discrimination by *Podarcis* males, even in closely related lineages. These results also suggest that the chemicals deposited by females on the paper substrate vary in composition. These differences may be related to the genetic differences between the two species, as has been reported in mammals (Bininda-Emonds et al., 2001; Heth et al., 2001), although this hypothesis is still to be tested in lacertids.

Cooper and Pérez-Mellado (2002) showed that *P. hispanica* (*sensu lato*) males are capable of discriminating between chemicals of conspecific females and those of sympatric *P. carbonelli* presented on cotton swabs. However, these authors did not test the ability of *P. carbonelli* males to discriminate between chemical cues of their own females and those of the other species. In closely related sympatric species, an ability to distinguish between conspecifics and heterospecifics may be important for reducing energy costs of finding potential mates (Labra et al., 2001; Cooper and Pérez-Mellado, 2002) or sexual rivals (Cooper and Garstka, 1987) and for preventing interspecific courtship or fighting. Although vision and chemoreception have been recognized as important sensory modalities in courtship and mating in lacertids (Verbeek, 1972; López and Martín, 2001), the fact that *Podarcis* females belonging to different species are generally more similar in morphology and coloration than males (Sá-Sousa, 2001; Sá-Sousa et al., 2002) suggests that there may be a selective pressure for chemical recognition mechanisms to take precedence over visual recognition when a male is searching for a potential mate.

Chemical species recognition has been reported in other squamates, particularly in complex groups such as tropidurids of the genus *Liolaemus* and scincids of the genus *Eumeces*. *Liolaemus jamesi* and *L. bellii* are capable of discriminating conspecifics from sympatric heterospecifics (*L. alticolor* and *L. nigroviridis*, respectively) based on chemical cues, manifested by higher chemical exploratory behavior in enclosures previously occupied by conspecifics (Labra et al., 2001). In the species of the *Fasciatus* group of the genus *Eumeces*, lizards exhibit higher tongue flick rates to conspecifics than to members of closely related species (Cooper and Vitt, 1987). In addition, the sympatric sibling species of sea snakes *Laticauda colubrina* and *La. frontalis*, so similar in morphology that they were considered conspecific until recently, are reproductively isolated because of species-specific chemical cues (female skin lipids acting as pheromones) that elicit courtship by males of their own species (Shine et al., 2002).

Contrary to males, females of *P. hispanica* type 1 and *P. bocagei* did not respond differentially to conspecific and heterospecific male chemical cues. The contrasting discrimination by males and apparent lack thereof by females require an explanation. It could be argued that, compared to males, females have reduced chemosensory exploration rates when placed in a novel environment. However, this hypothesis is not supported by our results because a comparison of the basal rate of tongue flicks (number of tongue flicks performed in control conditions) of males and females revealed that females explore as much or even more than males.

Tongue flicks provide a convenient assay of the ability to respond differentially to biologically relevant stimuli and have been extensively used in the study of chemoreception in squamates (Cooper and Burghardt, 1990). Whereas significant results are usually taken as a *bona fide* evidence for discrimination, the interpretation of nonsignificant results in experiments where tongue flick rates are the dependent variable is not straightforward. In a thoughtful review of methodological issues relating to the study of squamate chemoreception, Cooper (1998) argued that, although differential tongue flick rates may indicate discrimination, their absence does not necessarily indicate a lack of discriminatory ability. On the other hand, several authors have suggested that the discrimination of individual characteristics of conspecifics, such as sex (Mason, 1993), body size and shape (Shine et al., 2003), or recent reproductive history (Shine et al., 2000), may require only a few tongue flicks. According to this interpretation, the differential tongue flicking rates would not indicate semiochemicals' discrimination but rather an interest in pursuing a scent trail and locating its source, as suggested by Cooper and Vitt (1986b). Thus, females may detect differences through vomerolfaction, but not respond by differential tongue flicking.

An alternative explanation is that species discrimination in females is based on sensory modalities other than vomerolfaction. Lacertids have well-developed olfactory systems (Gabe and Saint-Girons, 1976), and it is conceivable that olfaction alone may be sufficient to make adaptively significant discriminations (Halpern, 1992). This type of discrimination would not be detectable through varying tongue flicking rates, although other behaviors, such as buccal pulsing, could serve as observable indices indicating olfactory discrimination (Dial and Schwenk, 1996; Desfilis et al., 2003). The role of visual stimuli may also be important and cannot be discarded, especially considering that *Podarcis* males are, in general, more colorful and display much more interspecific variation in coloration patterns than females (Sá-Sousa, 2001; Sá-Sousa et al., 2002). Because males and females undergo different selective pressures to optimize different aspects of reproduction, it is conceivable and even likely that they use different criteria to assess potential mates and, thus, use different sensory modalities in mate choice/recognition (for an example in spiders, see Rypstra et al., 2003).

The apparent inability of females to discriminate substrate-borne chemical cues of males of their own and of a closely related species could be due to a lack of species specificity of semiochemicals released by males. According to this hypothesis, male-produced semiochemicals would have not diverged sufficiently to allow females to discriminate conspecific from congeneric males by using substrate-borne chemicals alone. This hypothesis seems unlikely for two reasons: (1) males are capable of species chemical discrimination of congeneric females (which suggests that female chemicals do have diverged), and (2) several studies with lizards have revealed the

presence of variability in the chemical composition of male-produced semiochemicals, even among closely related species (Alberts, 1991; Labra et al., 2001).

Differences in discriminatory abilities of males and females have been reported in other studies. For example, Verrell (2003) found that males of the salamander *Desmognathus ocoee* discriminate conspecific from heterospecific and heterotypic females based on chemical cues, but females cannot make a similar discrimination. Similarly, studies of sex recognition in lizards and snakes have reported differences in the discriminating abilities of males and females. Females of *Eumeces laticeps* (Cooper and Vitt, 1984) and *Eublepharis macularius* (Steele and Cooper, 1997) do not discriminate sexes by differential tongue flicking, while males of these species do. In garter snakes, *Thamnophis sirtalis*, males discriminate and follow female trails during the breeding season, whereas females, in general, do not trail either sex (Mason, 1992; LeMaster et al., 2001). These findings may reflect the lack of a selective pressure for females to locate mates by scent tracking (Cooper and Vitt, 1986b). Likewise, it is conceivable that in the species studied here, there has not been a selection pressure for the evolution of female chemical discrimination.

Although a naive interpretation of sexual selection theory would lead to the expectation of female mate choice and, thus, discrimination, the apparent lack of chemically based species recognition shown by female *Podarcis* would seem to agree with reports that female lizards are generally indiscriminate and lack mate choice based on male quantitative traits (Olsson and Madsen, 1998; Tokarz, 1995; LeBas and Marshall, 2001). However, the evidence regarding female mate choice in lizards is controversial (see, for example, Hamilton and Sullivan, 2005), and studies of the mating systems of autarchoglossans, and lacertids in particular, are scarce.

Although chemically mediated species discrimination may not function as a complete reproductive barrier, our study demonstrates the contribution of chemical stimuli in species discrimination and reproductive isolation in a complex and diverse genus. The relative roles of chemoreception and of other sensory modalities in species discrimination by males and, especially, females are still not clear. Further studies are clearly necessary to clarify the role of different sensory systems in specific recognition between *Podarcis* species leading to the maintenance of reproductive isolation between lineages.

Acknowledgments This work was financially supported by project POCTI/BSE/45664/2002 of Fundação para a Ciência e a Tecnologia (FCT, Portugal). D.B. was funded by a Ph.D. grant (SFRH/BD/14084/2003) and M.A.C. by a postdoctoral grant (SFRH/BPD/3596/2000), both also from FCT. We thank two anonymous reviewers for helpful advice and comments and R. Ribeiro, R. Vasconcelos, and D. J. Harris for helping in fieldwork. Animals were collected under permits provided by the Instituto da Conservação da Natureza (ICN, Portugal) and were maintained and treated in accordance with Spanish Law (Real Decreto 223/1988) and Animal Behavior Society Guidelines for the Treatment of Animals in Behavioral Research and Teaching.

Pheromone-Induced Priming of a Defensive Response in Western Flower Thrips

Abstract The Western flower thrips *Frankliniella occidentalis* produces conspicuous anal droplets that function as a direct defense against various predators. These droplets also function in pheromonal communication in that they contain a mixture of decyl acetate and dodecyl acetate, which acts as an alarm. Exposure of thrips to synthetic pheromone is known to promote takeoff or refuge seeking, but the effect of the natural pheromone has not yet been studied. Here, we not only studied the response to natural pheromone, but also tested the new hypothesis that the alarm pheromone primes a defensive response in thrips. This test was carried out by measuring the reaction time to a simulated predator attack after exposure to synthetic or natural alarm pheromone (against a control with no pheromone at all). The reaction was quantified in terms of the time it takes a thrips larva to produce a droplet after attack. We found that thrips larvae produce droplets of alarm pheromone faster when cues associated with danger are present. There were no significant differences in reaction times of responses to synthetic pheromone, natural pheromone, or odors from a patch with a predator attacking a thrips larva. This implies that the synthetic pheromone mimics the natural pheromone, and that other cues emanating from the predator play a minor role. We conclude that the alarm pheromone increases the vigilance of the thrips, and this may promote its survival.

Introduction

Much intraspecific communication in insects involves chemical messengers, called pheromones, which elicit attraction of the other gender, aggregation, or alarm.

Alarm pheromones are animal-produced chemicals that intentionally or inadvertently communicate danger. Their release usually results in conspecifics showing antipredator behavior, such as fleeing, hiding, remaining motionless (e.g., in cryptic species), aggregating, changing group structure, or even mobbing predators (Lima and Dill, 1990). This behavior is generally assumed to promote survival.

The Western flower thrips *Frankliniella occidentalis* produces conspicuous droplets that are excreted anally. Upon encounter with a predator, thrips quickly move their abdomen from side to side (swing), trying to hit the predator, and they produce droplets when the threat of predation persists. Predators contaminated with such a droplet retreat to groom, and in this way, the droplets serve as a defense (Bakker and Sabelis, 1987, 1989). The droplets contain a solution of decyl acetate and dodecyl acetate (Teerling et al., 1993a,b) in a ratio that varies with the age of the larva (Macdonald et al., 2003). When a synthetic formulation of these compounds is present, thrips will increase their movements, reduce oviposition, decrease landing rates, increase takeoff rates, or hide (Teerling et al., 1993a,b; Macdonald et al., 2002), suggesting that the chemicals function as an alarm pheromone.

Although the behavior of thrips toward the synthetic alarm pheromone is well documented, there are no reports on the response of thrips to natural pheromone. It is also not known whether the alarm pheromone primes defensive responses. For instance, upon exposure to alarm pheromone, a thrips larva may become alerted and may produce an anal droplet faster upon actual attack. This hypothesis on priming of the defensive response was tested by assessing the effect of synthetic pheromone as well as natural alarm pheromone on the time elapsed from a simulated attack of a thrips larva until it produced an anal droplet. This effect is taken as a measure for the vigilance of thrips larvae because it demonstrates the degree to which they are prepared to defend themselves.

Methods and Materials

Thrips

Thrips were collected from cucumber plants in a commercial greenhouse in Pijnacker, The Netherlands, in May 1994. They were reared in the laboratory under constant climatic conditions (25°C and 60% humidity at 16-hr light/8-hr dark) on a cucumber leaf provided with cattail pollen (*Typha latifolia*). The leaf was cut to fit in a Petri dish with a layer of wet cotton wool on the bottom. Cohorts of thrips were obtained by introducing thrips pupae, allowing the emerging adults to oviposit and the larvae to develop until the pupal stage, after which this process was repeated.

Predatory Bugs

Orius laevigatus (Fieber), obtained from Koppert BV, was reared by using eggs of the flour moth *Ephestia kuehniella* (Zeller) as prey and bean pods as an oviposition substrate. Bean pods with *Orius* eggs were regularly collected from cages with adults in the reproductive phase, replaced by fresh ones, and used to start new age cohorts (van den Meijracker, 1994; Venzon et al., 1999).

Synthetic Alarm Pheromone

According to Macdonald et al. (2003), the alarm pheromone of Western flower thrips contains decyl acetate and dodecyl acetate in a molar ratio ranging from 0.4:1 (first instar) to 1.5:1 (second instar). Because we used second instars in our behavioral experiments, we used 0.05 μl of the 1.5:1 mixture dissolved in 500 μl pentane following the procedure described by Teerling et al. (1993a). Decyl acetate (98.1% pure), dodecyl acetate (95%+ pure), and pentane (98% pure) were obtained from Sigma-Aldrich, Los Angeles, CA, USA.

Pheromone Production after Simulated Attack

Five treatments were applied to test the response of thrips larvae to attacks simulated by the experimenter with the aid of a wooden toothpick. Four second instars were transferred to a leaf disk (24-mm diam) cut from the cotyledons of a cucumber plant. Per replicate and per treatment, one focal individual larva was challenged repeatedly by contacting it with a toothpick until it responded by producing an anal droplet. In the first three treatments, the toothpick was dipped in synthetic alarm pheromone (dissolved in pentane) or solvents (water or pentane) as controls. Each focal thrips larva was challenged with a toothpick that had received one treatment only. Per treatment, 15 larvae on 15 different leaf disks were challenged. These tests were performed “blind,” i.e., without the observer knowing which liquid was applied to the toothpick. Therefore, variation in the way the thrips were challenged was independent of the treatment of the toothpick. In a fourth treatment, the toothpick was put in the anal droplet released by a thrips larva upon challenge with a toothpick. Subsequently, this toothpick was used to challenge another thrips larva, of which the response was recorded. For obvious reasons, this treatment could not be performed blind. In the fifth treatment, the focal thrips larva was challenged with a water-dipped toothpick, while one of the other three thrips was being attacked simultaneously by a predatory bug (*O. laevigatus*) and usually produced an anal droplet. Results of this treatment were compared with the controls with a toothpick dipped in water prior to challenge (see above).

All observations were performed with a binocular microscope with magnification 6.3. The time elapsed between challenge with a toothpick and the production of a droplet by the focal thrips larva was measured and subjected to a one-way analysis of variance (ANOVA). Multiple comparisons among treatments were made using a Tukey’s honestly significantly different *post hoc* test.

Results and Discussion

The time elapsed between challenging thrips larvae with a toothpick and droplet production varied among treatments (Fig. 1; ANOVA: $F_{4,70} = 13.7$, $P < 0.001$). Compared to the controls (pentane, water), the response time was significantly shorter in treatments involving natural pheromone (pheromone droplet collected from another thrips larva), synthetic pheromone (decyl acetate and dodecyl acetate dissolved in pentane), and signals released nearby during the attack of another thrips larva by a predator (Fig. 1). However, Tukey tests reveal no difference among

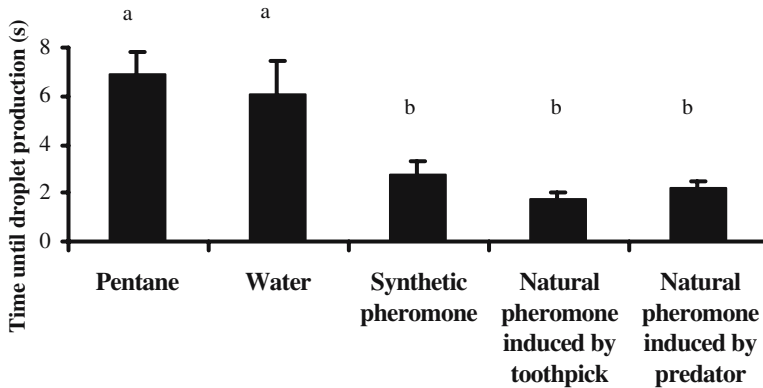

Fig. 1 Response time of thrips larvae to a simulated attack, expressed as the number of seconds between attack and the production of an anal droplet containing the putative alarm pheromone. See text for explanation of the treatments; each treatment involves 15 replicates. Vertical bars represent standard errors. Bars with different letters differ significantly

these three treatments. Hence, other cues emanating from the predator appear to play a minor role in inducing vigilance in thrips larvae. Furthermore, the synthetic pheromone elicits responses similar to those elicited by the natural pheromone, indicating that the concentrations are in the same range. These results provide additional evidence that decyl acetate and dodecyl acetate act as an alarm pheromone. Our results also demonstrate that the response of a simulated attack with a toothpick is context dependent; whereas attacks with a toothpick dipped in water elicit a slow response, attacks with a similarly treated toothpick elicit a fast response when nearby thrips larvae produce a droplet.

If the anal droplet contains alarm pheromone, the response of the thrips larvae to the pheromone is expected to result in increased survival. We think this is the case for two reasons. First, thrips larvae with a fast response were observed to escape more often from an attack by the predatory mite *Iphiseius degenerans* (personal observation, PJAdB). Second, females of other predatory mite species have been reported to retreat upon contamination with the anal droplet (Bakker and Sabelis, 1987, 1989). However, releasing a pheromone also makes the thrips larvae more conspicuous to predators because predatory bugs (*Orius tristicolor*) and predatory mites (*Neoseiulus cucumeris*) are attracted to a source of pheromone (Teerling et al. 1993a,b). Thus, we hypothesize that the release of pheromone-containing droplets upon predator attack depends on: (1) the probability to escape because of increased alertness or predator retreat; (2) the increased vigilance induced in conspecifics; and (3) the increased conspicuousness to predators other than the attacker. It remains to be investigated whether the balance of these costs and benefits explains the behavior of thrips larvae.

Abstract—The chemical and ecological function of cross-attraction of *Piezodorus hybneri* (Pentatomidae) to the *Riptortus clavatus* (Alydidae) pheromone (a mixture of three components) was studied. In a field attraction test using traps with synthetic pheromone components, *P. hybneri* was attracted to (*E*)-2-hexenyl (*E*)-2-hexenoate, a component of the *R. clavatus* pheromone. Other components had neither an additive nor a synergistic effect on the attraction of *P. hybneri*. Neither (*E*)-2-hexenyl (*E*)-2-hexenoate nor other components of the *R. clavatus* pheromone were detected in volatiles or whole-body extracts of *P. hybneri* adults by gas chromatographic analysis. In addition, (*E*)-2-hexenyl (*E*)-2-hexenoate could not be found in volatiles of soybean plants. Therefore, it appears that *P. hybneri* responds to a component of the *R. clavatus* pheromone that is not emitted by *P. hybneri* itself. We discuss this interspecific pheromone cross-attraction of the soybean bug and hypothesize that *P. hybneri* utilizes the pheromone of its competitor as a kairomone for host location.

Key words—*Piezodorus hybneri*, *Riptortus clavatus*, Pentatomidae, Alydidae, aggregation pheromone, kairomone, cross-attraction, soybean, (*E*)-2-hexenyl (*E*)-2-hexenoate, host finding.

INTRODUCTION

A complex of bugs (Heteroptera) often threatens soybean production in Japan. The most important species are the bean bug *Riptortus clavatus* (Thunberg) (Alydidae) and the stink bug *Piezodorus hybneri* (Gmelin) (Pentatomidae) (Wada et al., 2006). Pheromone-based monitoring is a significant component of the integrated pest management of these bugs in soybean.

The adult male of *R. clavatus* releases an aggregation pheromone to which conspecific adults and nymphs are attracted (Leal et al., 1995). The pheromone is a mixture of three components: (*E*)-2-hexenyl (*Z*)-3-hexenoate, (*E*)-2-hexenyl (*E*)-2-hexenoate, and tetradecyl isobutyrate in a ratio of 1:5:1 (Leal et al., 1995). These compounds have been synthesized, and the synthetic pheromone is now commercially available (Fuji Flavor Co., Ltd.).

Endo et al. (2003) revealed that the synthetic pheromone of *R. clavatus* attracts not only conspecifics but also *P. hybneri*, which is one of the major competitors of *R. clavatus* in terms of consuming soybean resources. Among the three pheromone components, (*E*)-2-hexenyl (*E*)-2-hexenoate seemed to be responsible for attracting *P. hybneri*. The male-produced sex pheromone of *P. hybneri* has also been identified as a mixture of β -sesquiphellandrene, (*R*)-15-hexadecanolide, and methyl (*Z*)-8-hexadecenoate (Leal et al., 1998). No components in the *P. hybneri* pheromone system are identical with those of the *R. clavatus* pheromone system.

In addition, *Ooencyrtus nezarae*, one of the dominant egg parasitoids of *R. clavatus*, is attracted to the synthetic pheromone of *R. clavatus* (Leal et al., 1995). However, another pheromone component, (*E*)-2-hexenyl (*Z*)-3-hexenoate, was responsible for the attraction in this case (Mizutani et al., 1997). It was suggested that the egg parasitoid utilizes this component of the host pheromone as a kairomone to find host eggs (Leal et al., 1995; Mizutani et al., 1997).

The objectives of the present study were (1) to determine whether or not (*E*)-2-hexenyl (*E*)-2-hexenoate is the only component responsible for attracting *P. hybneri* and (2) to confirm the absence of the pheromone components of *R. clavatus* in body extracts and volatiles emitted from *P. hybneri*. On the basis of our findings, we discuss the ecological significance of this interspecific cross-attraction among soybean bugs.

METHODS AND MATERIALS

Chemical. The pheromone components of *R. clavatus* and *P. hybneri* were synthesized as described previously (Leal et al., 1995, 1998).

Field Experiment. A field experiment using traps baited with the pheromone components of *R. clavatus* was conducted in soybean fields of the National Agricultural Research Center for Kyushu Okinawa Region (KONARC), Kumamoto, Japan. Synthetic (*E*)-2-hexenyl (*E*)-2-hexenoate (EE), (*E*)-2-hexenyl (*Z*)-3-hexenoate (EZ), and tetradecyl isobutyrate (14iBu) were incorporated into plastic pellets (4- to 5-mm diam, containing 5 mg chemical) made of a copolymer of polyethylene and ethyl acetate and used as bait for the traps. Treatments were EE (50 mg), EZ (10 mg) plus 14iBu (10 mg), *R. clavatus* pheromone blend (EZ/EE/14iBu = 1:5:1, total 70 mg), and an empty (blank) trap. A plastic bottle (4 × 3.3 cm ID) with plastic pellets containing the chemicals was placed 5 cm above the water surface of a water-pan trap (16 × 35 cm ID). One set of traps was spaced 20 m apart and placed randomly around the soybean field. The numbers of adults and nymphs of *P. hybneri* and *R. clavatus* captured in traps were counted and removed every 3 d (15 October to 26 November 2004, a total of 14 replicates). Pheromone lures were renewed every 2 wk.

Insects. Adults of *P. hybneri* and *R. clavatus* were caught in soybean fields of the KONARC, and their progenies were kept in the laboratory (25 ± 1°C, 16-hr light/8-hr dark photoregime). Both species were reared on a diet of soybean seeds, red clover (*Trifolium pratense*) seeds, and water. After molting to the adult stage, the bugs used for experiments were transferred and kept individually in plastic containers to prevent sexual contact.

Extracts. Whole-body extracts of *P. hybneri* and *R. clavatus* were prepared by immersing five mature adults (15 d old) in hexane for 3 min. Airborne volatiles from *P. hybneri* (10 bugs) were collected on a Tenax TA (GL Sciences Inc., Japan) column as follows. Cohorts of 10 virgin adults (15 d old) and five soybeans were placed in individual 250-ml glass vessels. Activated charcoal-filtered, humidified air (100 ml/min) was pulled through the system by vacuum, over the insect, and out through the Tenax TA (60/80 mesh, 100 mg) column. Bugs were aerated for 24 hr, and then the column was eluted with hexane (1 ml × 3). Volatiles from soybean plants (leaves and pods) were collected in the same way as for the bugs.

Analysis of Extracts. Hexane extracts of bugs and soybean plants were concentrated and, subsequently, analyzed by gas chromatography–mass spectrometry (GC-MS). GC was performed on a Hewlett-Packard 5890 Series II Plus instrument equipped with an Equity-5 column [30 m × 0.25 mm × 0.25 µm; split mode (41:1); Supelco Inc., Bellefonte, PA, USA] with helium carrier gas. The column temperature was held at 50°C for 1 min, increased to 180°C (5°C/min) and held for 1 min, and increased to 230°C (10°C/min) and held for 5 min. MS spectra were recorded on JMS-600W (JEOL, Japan) in the electron impact (EI) mode (70 eV). Compounds were identified by comparison of retention times and mass spectra with those of authentic standards.

^aEach numeral shows the mean of the bugs caught per 3 d (14 replicates from 15 October to 26 November).

^bEZ: (*E*)-2-hexenyl (*Z*)-3-hexenoate; EE: (*E*)-2-hexenyl (*E*)-2-hexenoate; 14iBu: tetradecyl isobutyrate.

^cMeans (±SE) followed by the same letter are not significantly different at 5% level by ANOVA and Tukey-Kramer test. The data were analyzed after $\log(x + 0.5)$ transformation.

RESULTS

Field Experiment. Trap catch data indicated that the *R. clavatus* pheromone blend (EZ/EE/14iBu = 1:5:1, total 70 mg) and EE (50 mg; equal to the amount in the pheromone blend) attracted adults and nymphs of *P. hybneri* (Table 1). The mean catch of *P. hybneri* did not differ significantly between EE and the *R. clavatus* pheromone blend. A few bugs were caught in the trap baited with the mixture of 14iBu (10 mg) and EZ (10 mg), but these values were not significantly different from that of the control.

The *R. clavatus* pheromone blend (70 mg), as well as the mixture of 14iBu (10 mg) and EZ (10 mg), attracted adults and nymphs of *R. clavatus*. EE

FIG. 1. Gas chromatograms of extracts from *Riptortus clavatus* (top) and *Piezodorus hybneri* (bottom) males. EE: (*E*)-2-hexenyl (*E*)-2-hexenoate; 1: (*E*)-2-hexenyl (*Z*)-3-hexenoate; 2: tetradecyl isobutyrate; 3: β -sesquiphellandrene; 4: (*R*)-15-hexadecanolide; 5: methyl (*Z*)-8-hexadecenoate.

(50 mg) alone did not attract *R. clavatus*, consistent with previous reports (Mizutani et al., 1997; Endo et al., 2003)

Chemical Analysis. The presence of the three pheromone components, EE, EZ (**1**), and 14iBu (**2**), in the extract from *R. clavatus* males, as reported by Leal et al. (1995), was confirmed (Figure 1, top). In *P. hybneri* males, EE was not detected in either the body extracts (Figure 1, bottom) or headspace volatiles (not shown). The three pheromone components of *P. hybneri* (Leal et al., 1998) were detected: β -sesquiphellandrene (**3**) (R_t 26.26 min), (*R*)-15-hexadecanolide (**4**) (R_t 35.26 min), and methyl (*Z*)-8-hexadecenoate (**5**) (R_t 35.26 min; Figure 1, bottom). In addition, neither EE nor the other two components of the *R. clavatus* pheromone were found in any of the extracts from *P. hybneri* females or from soybean plants (not shown).

DISCUSSION

Interspecific pheromone attraction has been reported for some true bugs. Such cross-attraction has been observed between species of the same genus (Aldrich et al., 1991) and even among species in different families (Borges et al., 1998; Zhang and Aldrich, 2003). These cross-attraction phenomena have been attributed to common pheromone components shared by the species involved (pheromone sharing). For example, synthetic pheromone of the milkweed bug *Oncopeltus fasciatus* (Lygaeinae) attracts males of the plant bug *Phytocoris difficilis* (Miridae). This phenomenon has been explained in part by the coexistence of (*E*)-2-octenyl acetate in both pheromone systems (Zhang and Aldrich, 2003). In the Brazilian soybean stink bug complex, *Piezodorus guildinii* is attracted to a synthetic racemic mixture of methyl 2,6,10-trimethyltridecanoate, which is a pheromone component of *Euschistus heros* (Borges et al., 1998). Further study (Borges et al., 1999) revealed that *P. guildinii* has the same chemical compound in its pheromone.

Interspecific pheromone attraction among *R. clavatus* and *P. hybneri* seems to be a phenomenon that differs from the pheromone sharing described above. Our field data clearly indicated that *P. hybneri* was attracted to (*E*)-2-hexenyl (*E*)-2-hexenoate, a component of the *R. clavatus* pheromone. Other components had neither additive nor synergistic effects on the attraction to *P. hybneri*. However, (*E*)-2-hexenyl (*E*)-2-hexenoate was not detected in volatiles or extracts from *P. hybneri* adults, despite the detection of the three pheromone components from *P. hybneri* males. In addition, the chemical structure of (*E*)-2-hexenyl (*E*)-2-hexenoate is quite different from the structures of the *P. hybneri* pheromone components. Thus, it is unlikely that *R. clavatus* and *P. hybneri* share a common compound in their pheromone blends, as exemplified by

pheromone sharing. One likely possibility is that *P. hybneri* is attracted by a pheromone component of *R. clavatus*, which is a competitor in soybean fields.

A possible explanation for the interspecific attraction found between *R. clavatus* and *P. hybneri* is that *P. hybneri* utilizes the *R. clavatus* aggregation pheromone as a kairomone to search for food plants. Both species have similar host ranges, feeding mainly on leguminous plants including soybean (Kono, 1991). Males of *R. clavatus* release a pheromone only when food is available (Leal et al., 1995). Therefore, if *P. hybneri* responds to a component of the *R. clavatus* pheromone, an individual can increase its probability of finding food. Thus, the response to the component of the *R. clavatus* pheromone is adaptive for *P. hybneri*.

Further studies will be needed to verify the hypothesis that *P. hybneri* utilizes the pheromone component of its competitor as a kairomone. However, our finding of interspecific cross-attraction between soybean bugs provides new insights into the diverse communication systems of heteropteran bugs.

Acknowledgments—We thank Dr. Tetsuya Yasuda, National Agricultural Research Center, for critical reading of the manuscript. We also thank Kunio Sakamoto for planting and maintaining our study fields and Masayo Hashimoto for her assistance in the experiments. We also appreciate and extend our thanks to two anonymous reviewers for their valuable comments.

A recent article by Curran et al. [*J. Chem. Ecol.* vol. 31(7); 1607–1619, 2005] describes the collection and chemical analysis of “human scent.” Contrary to the authors' claims, a great deal is known about the chemical constituents of human scent and its measurement. Here we clarify what is known about human scent and highlight several shortcomings concerning the authors' analysis related to (1) the definition of human scent, (2) chemical analysis of human scent, and (3) conclusions about individual differences.

Human Scent

More than 15 years of research has presented both organoleptic and analytical evidence that a mixture of C₆–C₁₁ normal, branched, hydroxy- and unsaturated acids present in axillary sweat constitutes the characteristic axillary odor (Zeng et al., 1991, 1992, 1996a,b; Natsch et al., 2003). In addition to this mixture of major odor constituents are trace amounts of thioalcohols (Hasegawa et al., 2004; Natsch et al., 2004; Troccaz et al., 2004) with high odor impact (low olfactory threshold). The details of the chemical identification, exact structures, and synthesis (of noncommercially available compounds), as well as biogenesis of many of these compounds, have been described in the above cited manuscripts.

Importantly, these characteristic axillary odorants are volatile organic compounds. Thus, we read with dismay the authors' comments that there is “limited understanding of how the body produces the volatile organic compounds present in human odor.” Furthermore, their comment on the bottom of page 1608 to the top of 1609, “Although the components of human sweat have been studied extensively, comparatively little work has been carried out

to determine the volatile organic compounds (VOC's) present in human odor," is also incorrect. The compounds that give the underarm its characteristic odor are volatile organic compounds (VOC's).

We have previously demonstrated that the characteristic odor components are not the most abundant compounds found in underarm extracts (see Figure 2 in Zeng et al., 1991). Hence, their definition of "human scent" as the most abundant VOC's is inconsistent with past studies and unfounded. It also contradicts numerous studies of food, beverages, plants, and malodors that have used the nose as a detector to determine which compounds have the greatest odor impact. The "scent" is often found in the minor constituents of complex mixtures from natural products. Likewise, Zeng et al. (1991) used gas chromatography olfactometry (GC-O) to identify the characteristic "human scent" constituents, which turned out not to be the most abundant compounds.

Analytical Techniques to Measure Scent

To measure scent, Curran et al. used gauze pads to swipe armpits of subjects following exercise, and then used solid phase microextraction (SPME)–gas chromatography/mass spectrometry to sample the headspace above the gauze pads. It is possible that many of the compounds identified by this approach have no relevance to human odor for at least three reasons.

First, and the most serious, the characteristic axillary odorants are predominately a variety of polar, acidic compounds that will bind to the gauze material used for collection. Therefore, SPME headspace analysis over the gauze pads would not be adequate to sample and detect these types of compounds, which offers one possible explanation for their nondetection of 3-methyl-2-hexenoic acid (3M2H). We demonstrated more than 25 years ago (Labows et al., 1979) that the major compounds collected by sweeping and collecting the headspace above either cotton pads worn in the underarm or the underarm itself are not characteristic of axillary odor. In model experiments, we also noted that aliphatic acids were not readily transferable from cotton pads to headspace collection devices. In that study, most compounds observed in the headspace were exogenous constituents because of residual VOCs from cosmetic products. The important odor constituents are polar molecules that tend to bind to pad material. In Curran et al. (2005), dodecanoic and tetradecanoic acid were found only in the axillary volatiles of one subject (out of eight). In a previous study (Zeng et al., 1996a), these acids were found in each gender. The authors do not comment on the sensitivity of their instrumentation, but it is likely that the nondetection of these two compounds is an example of polar compounds remaining on absorbent surfaces.

Second, the sampling procedure of wiping the underarm after exercise is more likely to collect eccrine sweat than apocrine secretions, the well-documented source of axillary odor precursors (Shehadeh and Kligman, 1963; Zeng et al., 1992, 1996b). In an eccrine-enriched sample, odorants derived from the interaction of axillary bacteria and apocrine secretions are not given time to form. To this point, the absence of 3M2H in their analysis, one of the most abundant characteristic axillary odorants, should have been an immediate indication that something was amiss with their measurement technique, and that the measured compounds might not be characteristic of human scent.

Third, prior to sampling, subjects were instructed to discontinue use of deodorants, lotions, and perfumes for at least 48 hr. This "washout" period is likely too short to prevent collection of exogenous compounds, so that many of the compounds detected might actually be artifacts of cosmetic products. Labows et al. (1979) showed that the less volatile components of some

cosmetic products may still be found in axillary headspace analyses 10–14 days after subjects stop using them.

Individual Differences

In their abstract, Curran et al. state, “Qualitative differences noted between the males and females studied, along with differences in chemical ratio patterns among the common compounds, demonstrated the ability to differentiate between the individuals through the examination of VOC’s,” which is an apparent overgeneralization of their reported data. Any conclusion about differences between individuals needs to account for intrasubject variability, i.e., variability between samples from the same subject collected on different days or conditions. This is illustrated in Figure 2 of the paper, but no data were provided, nor were they factored into statements about individual differences. [The authors cite a previous study in their lab comparing two samples from one subject with one sample from another subject as evidence for repeatable individual differences.] Beyond statistical significance—which is not demonstrated—is the task of accurately discriminating individuals from each other, which is generally more difficult to accomplish, and again not demonstrated by the authors.

For these data, it seems the best we can do is look for qualitative or quantitative differences between *genders*. Four males and four females were used in the study. Table 2 in Curran et al. provides *qualitative* comparisons between the eight subjects, showing which of the 47 compounds were detected for each subject. No compounds show statistically significant qualitative differences between genders.

Table 3 in Curran et al. shows the relative ratios of 22 compounds (relative to decanal) for all eight subjects. Some of these ratios are reported as 0 where the compound was not detected, which can complicate quantitative comparisons: it is possible that the compound is present in trace amounts below detection limit but greater than 0. With this in mind, and using two standard two-sample comparison techniques (*t*-test and Wilcoxon nonparametric test based on ranks), we found only one compound to be marginally significant (nonanoic acid–methyl ester; *t*-test, $P = 0.09$; Wilcoxon, $P = 0.11$), but after adjusting for the large number of hypothesis tests, no compound is significant.

In summary, it is possible, perhaps even likely, that people have distinct genetically determined odor profiles—or *odorprints*. Sweat contains a complex mixture of compounds whose expression is influenced by a person’s genetic makeup. The profile of volatile metabolites is also likely to reflect, in part, a person’s genotype. Because it is difficult to determine whether a VOC profile is really measuring “scent” without behavioral confirmation (e.g., perception tests using GC-O), the authors may have been a bit overzealous in their definition of “scent.” From a forensics perspective, however, it does not really matter whether the VOC profile measures “scent” or something else, as long as it can be used to differentiate individuals. Similarly, it might not matter which secretions the profile of constituents is obtained from, although, again, the “scent” moniker is not justified for all chromatographable constituents.

Whatever the definition, the individuality of human scent as measured by VOC’s has yet to be demonstrated.

Many of the concerns raised by Preti et al. in their letter to the editor of *JCE* entitled “On the definition and measurement of human scent” appear to be the result of misunderstandings regarding the objectives of the published work as well as the different terminology used in this multidisciplinary research project. Perhaps, we could have been clearer in describing the overall goals of the project. However, the purpose of the paper (Curran et al., 2005b) was not to identify the components of perspiration, nor to differentiate subjects, but rather to provide a limited qualitative and semiquantitative population study of the volatile components above collected axillary samples via headspace solid phase microextraction-gas chromatography/mass spectrometry (SPME-GC/MS), and to analyze the pattern differences among primary odor compounds.

Although we recognize that it is important not to be overzealous in using the terms odor or scent, to limit these terms to only those chemicals eliciting responses from an animal severely restricts their use. For example, Preti’s use of the term “characteristic axillary odor” should be restricted to discussions of human perception of malodor since insects and canines may not use the same chemicals for detection. When referring to human odor, many of the studies referenced by Preti et al. mistakenly interchange the terms human odor and “characteristic axillary odor.” This is illustrated in the Letter to the Editor itself when citing a paper by Zeng et al. (1991) that used GC olfactometry “to determine which of the chromatographic effluents had odors resembling axillary extract” (p. 1474), and was not intended to identify the characteristic “human scent” constituents as claimed. The papers cited by Preti et al. are focused on studies intended to determine the specific compounds

that contribute to human axillary malodor and are, therefore, limited in application to the broader research field of human scent detection that includes canines and machines.

In law enforcement, as well as the forensic science community, the terms human scent and human odor are commonly used and often interchanged. The Locard exchange principle is fundamental to the field of forensic science, and proposes that a person can not enter or leave an area or come in contact with an object without an exchange of materials. In the case of human scent evidence, the suspect leaves scent in the location of the crime scene itself or on objects found therein. Because our research interests entail the use of human scent for forensic purposes, our paper (Curran et al., 2005b) states “The authors have defined *human scent* to be the most abundant volatile organic compounds (VOCs) identified in the headspace above *scent* samples; however, other substances that have a relatively low volatility or are present in low concentrations may make contributions to *human odor*.” In our paper, human odor was used as a general term to describe overall body odor, and not region-specific. Although axillary sweat was collected, and thus a scent sample from the axillary region, the purpose of our study was never to analyze “characteristic axillary odor.”

Human Scent

The 15 years of research conducted and cited by the authors of the Letter to the Editor pertain to compounds that are characteristic of axillary odor as described by humans. It is known that human secretions and emanations contain a vast number of compounds as stated in the previously referenced papers as well as by Bernier et al. (1999, 2000). The elucidation of how the body produces a handful of these (as described in the papers referenced by Preti et al.), which have been determined to be characteristic of axillary odor, does not translate into a complete understanding of how the human body produces all of the volatile organic compounds in human odor. Thus, our statements pertaining to “a limited understanding in how the body produces the volatile organic compounds in human odor” are founded.

Another point of contention by Preti et al. is the statement in our paper (Curran et al., 2005b) on pp. 1608–1609, “Although the components of human sweat have been studied extensively, comparatively little work has been carried out to determine the VOCs in human odor.” The compounds that give the body its detectable odor are anticipated to fall into the volatile to semivolatile range; yet, the majority of work conducted in the arena of determining the VOCs present in human odor has been carried out with emphasis on the components of sweat. Consequently, our manuscript goes on in the next sentence to say: “Knowing the contents of human sweat may not accurately represent the nature of what volatile compounds are present in the headspace above such samples, which would comprise the odor.” This is not a new concept, as it was stated as the reasoning for not conducting solvent extractions of sweat in *Analytical Chemistry* by Bernier et al. (1999). While investigating the volatile compounds emitted by humans that function as mosquito attractants, they reported that “these volatiles may not be present in the perspiration aqueous phase.”

Advances in the field of machine olfaction or mimicking the sense of smell further complicate the use of the terms odor and scent. Instruments that are capable of distinguishing odors via electronic detection (including arrays of sensors) and suitable signal processing (typically a statistical system based on multivariate analysis) units are commonly referred to as electronic noses. This instrumental “olfaction” of chemicals capable

of differentiating individuals may utilize different chemicals from those utilized by biological systems. It is well established that different organisms may utilize distinct targets with invertebrates capable of both excitatory and inhibitory responses to odors via multiple transduction pathways. In addition, the number of detectable odors may exceed 100,000 depending on the training of the organism to discriminate odors and on the physical chemistry, which acts as a limiting factor on an odor chemical's ability to act on olfactory systems based on volatility, solubility, and stability (Firestein, 2001).

Olfactory studies of food, beverages, plants, and studies of the compounds with the greatest human determined odor impact may have no bearing on the differentiation of humans by scent identification canines. In addition, the study of chemicals that have been used by human beings as odor judges may not be applicable to studies relating to the ability of canines to differentiate humans based on scent. Previous headspace studies that compare volatile profiles have demonstrated pattern differences among individuals (Sommerville and Gee, 1987; Sommerville et al., 1994). In addition, pattern matching recognition software has been applied to the volatile patterns obtained from the headspace analysis of collected axillary sweat among people. This research has determined that both qualitative and quantitative differences are important factors when evaluating identity through sweat analysis (Sommerville et al., 1994). We have extended this work to identify specific chemical components that may be important in identifying individuals.

Analytical Techniques

Sample Collection on Cotton Sorbents

Human scent evidence collected from a crime scene can be evaluated through the use of specially trained canines to determine an association between the evidence and a suspect (Sommerville and Gee, 1987; Stockham et al., 2004a; Curran et al., 2005a). Canines can successfully utilize human scent collected on a cotton material to differentiate among individuals (Kalmus, 1955; Settle et al., 1994; Schoon and De Bruin, 1994; Schoon, 1996, 1998; Harvey and Harvey, 2003; Stockham et al., 2004a,b). If what the authors of the Letter to the Editor are proposing by stating that nondetection of acids is “an example of polar compounds remaining on absorbent surfaces” is that the acids are binding to cotton materials rendering them unavailable in the headspace, then it is reasonable to infer that these compounds are also unavailable to canines and, thus, possibly not utilized for human scent discriminations.

It has been shown that males can be distinguished through human evaluation of odors collected on cotton from both the torso and axillary area based on the number of matching major histocompatibility complex (MHC) alleles (McClintock et al., 2005); the odors evaluated were described by the female odor judges as “mild scents” and seldom associated with human malodor. In 1979, when Labows and Preti published their report, suggesting that polar compounds cannot be determined through headspace analysis with a Tenax Trap from cotton materials, it is possible that their technique was not as sensitive as those available today. A recent study by a group from the Federal Bureau of Investigation in collaboration with Oak Ridge National Labs has shown that cotton gauze pads have the ability to trap and release isovaleric acid as well as hexanoic acid, as detectable through headspace GC/MS analysis (Eckenrode et al., 2006). Preti et al. also state that “the important odor constituents are polar molecules that tend to bind to the (cotton) materials,” referring to a previous study into characteristic axillary odors, which we (again) emphasize was not the subject of our study, and, thus, compounds deemed to be “important odor constituents” may have no consequence.

Non-Detection of 3-Methyl-2-Hexenoic Acid

A study conducted by Munk et al. (2000) to determine the compounds present in residual axillary odor on cotton (polar backbone) and polyester (nonpolar backbone) after wearing and then washing failed to detect acid compounds. The study utilized human odor judges, and was followed by subsequent liquid extraction of swatches deemed to contain an axillary odor quality and these swatches did not contain organic acids. The compound classes identified in the extract were esters, ketones, and aldehydes, thus suggesting that human perception of axillary malodor may not be limited to the acid class. Direct sampling of the volatile organic compounds released by the skin through SPME-GC/MS, without the use of a collection material, has been conducted by various groups in which 3-methyl-2-hexenoic acid (3M2H) has not been reported (Ostrovskaya et al., 2002; Zhang et al., 2005). Nondetection of 3M2H by the headspace SPME/GC-MS method employed in our research (Curran et al., 2005b) does not mean the compounds are not present, but rather, that they are minor components of the headspace and may be below the detection limit of the instrument. Likewise, nondetection by an animal does not necessarily mean that the compounds are not odor compounds or scent components, but rather, the delivered amount may be below—or in some cases, above—the range of detection for the animal. Our definition of human scent acknowledges the fact that some components, due to low volatility and or concentration, which are not detected, may contribute to human odor.

Sampling Procedure

Preti et al. cite a study by Labows and Preti (1979) and state that most compounds observed in the headspace of cotton pads worn in the axillary area were exogenous. However, the sampling method used by Labows and Preti lends itself to the collection of exogenous compounds, as the cotton pads were worn overnight, thus coming into contact with various types materials (bedding, sheets, clothing, etc.), which would contribute exogenous or “tertiary odor” components to the collection materials. With the sampling procedure followed in our experiment (Curran et al., 2005b), the axillary area is wiped for sample collection, thus limiting the opportunity for tertiary odors to influence the sample. We acknowledge that the influence of deodorants may not have been completely removed through discontinued use; however, other studies (Sommerville et al., 1994) on the volatile components of human sweat also used the same method of no deodorant for a 48-hr period. It was suggested by Preti et al. that, because our samples were eccrine-enriched, adequate time was not given for the interaction of axillary bacteria and apocrine secretions to allow for these types of odorants to be formed. The samples collected in our study were allowed to sit for 24 hr at room temperature prior to extraction, and no attempt was made to control microbial activity inside the vials. This was modeled from the fact that suspect samples are generally kept no longer than 48 hr before canine human scent lineup evaluations by most law enforcement agencies in Europe, including the Netherlands National Police Agency. The sampling method was also created for the purpose of collecting a concentrated sweat sample by using the materials and storage techniques employed for collecting human scent evidence for canine evaluation, which was discussed on p. 1611 (Curran et al., 2005b).

As described in our introduction (Curran et al., 2005b), canines have the ability to differentiate human odors (Kalmus, 1955; Sommerville and Gee, 1987; Settle et al., 1994; Schoon and De Bruin, 1994; Schoon, 1996, 1998; Hepper, 1998; Harvey and Harvey, 2003; Stockham et al., 2004a,b). By utilizing human scent collected from objects and/or people,

canines have also demonstrated the ability to generalize odors (Settle et al., 1994) collected from different regions of the body with an 85% accuracy. These studies suggest that there are common elements to human odor produced and/or released among the various body regions that contain differing types and/or quantities of secretion glands. The purpose of our study was not to analyze apocrine sections, but the secretions of the axillary region as a whole, which is composed of apocrine, eccrine, and sebaceous secretion. As has been presented elsewhere (Curran et al., 2006), in the United States more than 70% of items from which human scent is collected for forensic purposes have been handled by people and, thus, contain odor imparted from the secretions of eccrine and sebaceous glands. Since our primary interest lies in being able to apply the information gained from our study to forensic science and the canine community, it was expected that the samples would be eccrine-enriched and, thus, not an oversight or a flaw in experimental design.

Individual Differences

The focus of our study (Curran et al., 2005b) was neither to determine differentiation between subjects nor to determine stability of a profile for an individual over time. Rather, our study demonstrates that through the use of SPME as an extraction method, it is possible to analyze human scent and measure ratio pattern differences among subjects. The 23 compounds compared for ratio differences among the eight individuals were selected because of their probability as being “primary odor” components, as their presence was detected in weekly scent samples for an individual, thus reducing the chance of selecting an exogenous, “tertiary odor” components for comparison. The primary odor of an individual is the portion of the odor that is most likely to be stable over time, and is not influenced by external factors. To be considered a primary odor component, a compound must be present in all samplings for that individual, and it may differ among subjects (Curran et al., 2005a).

While Preti et al. were unsuccessful in differentiating individuals by applying a *t*-test and Wilcoxon nonparametric test to our data, if one utilizes nonparametric Spearman ranking correlation to our data, there is a statistically significant difference between the individuals in the study. Comparing the results of eight subjects in the possibility of 28 pairs and at a correlation threshold value of 0.9, there are no Type II errors (100% distinguished), whereas a threshold of 0.8 results in two Type II errors at correlation values of 0.81 and 0.83 (92.8% distinguished). Preti et al. correctly state that intrasubject variability is important when discussing the significance of intersubject differences, and this was qualitatively displayed in Figure 2 of our paper. However, quantitative comparisons were not presented, as this was not the focus of the presented work.

In summary, the concerns stated by Preti et al. in their Letter to the Editor appear to be the consequence of differences in terminology and misinterpretation regarding the objectives of the published work. We consider the study of human scent to be a multi-disciplinary field; if relevant research is restricted only to those studies on human perceived malodorous axillary substances, then there will be no occasion for comprehensive understanding of the compounds that emanate from the human body as a whole. Preti et al. draw conclusions from our study that are beyond the scope of the paper. While interpretive differences exist between Preti et al. and our group, there are agreements as well. This may represent a convergence between research groups addressing different aspects of this important subject. We agree with Preti et al. that it is likely that people have distinct genetically determined odor profiles made up of a complex mixture of volatile metabolites reflecting, in part, a person’s genotype. We also agree that, from a forensic science perspective, it does not matter whether the VOC profiles measure “scent” or something else, as

long as it can be used to differentiate humans. We disagree, however, that a VOC profile cannot be referred to as measuring “scent” without a human perception test such as GC-O and, rather, describe this as one measure of scent. Finally, while “the individuality of human scent as measured by VOCs has yet to be demonstrated,” this was not our intention. The reevaluation of the data through statistical analysis as presented here supports the hypothesis of the uniqueness of human scent. Larger-scale studies are ongoing to evaluate the differentiation of human scent samples by using precleaned collection materials, an optimized SPME-GC/MS method and multivariate statistical analysis.

Abstract Previous investigations of *Aedes aegypti* response to human odor components have revealed a number of compounds that attract host-seeking females. However, such studies have utilized only a small number of long-term laboratory *Ae. aegypti* colonies. Using laboratory y-olfactometers, we studied the attraction of four different *Ae. aegypti* populations (North Queensland, Australia; Florida, USA; Singapore; and Minas Gerais, Brazil) to a key attractant compound from human skin, lactic acid. Combinations of lactic acid with ammonia and a fatty acid (caproic acid) were also investigated. The aims were to determine the extent of variation in lactic acid dose response among populations and to see whether all four populations responded equally to combinations of human odor components. Although all *Ae. aegypti* populations were attracted to lactic acid, there were differences in the threshold dose: Florida 0.03 $\mu\text{g}/\text{min}$, Singapore 0.17 $\mu\text{g}/\text{min}$, North Queensland 1.92 $\mu\text{g}/\text{min}$, and Brazil 10.27 $\mu\text{g}/\text{min}$. Attraction to lactic acid alone

(maximum <40%) was significantly lower than for human odor (>87% for all populations). Significant increases in attraction were observed when lactic acid was combined with ammonia or caproic acid, although not for all populations. In addition, the highest doses of caproic acid tested decreased attraction when combined with lactic acid. The divergent responses to host kairomones seen here may be evidence of adaptation to locally available hosts in different parts of the geographic range of *Ae. aegypti*.

Introduction

The yellow fever mosquito *Aedes aegypti* (L.) is a prominent vector of dengue viruses throughout tropical regions, resulting in human illnesses ranging from mild fever to fatal hemorrhagic disease (Gubler and Kuno, 1997). The role of *Ae. aegypti* as a dengue vector is related to its ability to breed in water-filled habitat associated with human habitation and its preference for human blood hosts (Gubler and Kuno, 1997). This host preference is facilitated by strong olfactory responses to human skin emanations (Skinner et al., 1965; Schreck et al., 1990; Geier and Boeckh, 1999).

The surveillance of *Ae. aegypti* populations has traditionally relied on labor-intensive methods, such as the sampling of immature stages from breeding sites, and on the use of ovitraps that sample the egg-laying portion of the population. However, some of the indices obtained lack epidemiological sensitivity (Focks, 2003). Sampling techniques for adult *Ae. aegypti*, such as human-biting catch and aspiration samples, can be unsafe and labor intensive for operators (Focks, 2003). Hence, there is a need to develop efficient sampling methods for adult *Ae. aegypti* that can be readily related to dengue epidemiology. The development of traps that specifically attract host-seeking *Ae. aegypti* through the use of kairomone lures would provide a more efficient and epidemiologically relevant alternative, and possibly augment current population reduction methods.

A number of compounds identified from human skin emanations attract host-seeking *Ae. aegypti*. Lactic acid was identified as a key kairomone for *Ae. aegypti* host finding (Acree et al., 1968; Geier and Boeckh, 1999), given that the addition and removal of this compound from human skin extracts respectively increases and decreases attraction in laboratory olfactometers (Geier et al., 1996; Steib et al., 2001). However, it is much less attractive alone than whole human odor extracts (Eiras and Jepson, 1991; Geier et al., 1996), indicating that other kairomones are important in *Ae. aegypti* host finding. The combination of lactic acid with carbon dioxide creates a powerful attractive synergism (Acree et al., 1968; Smith et al., 1970; Eiras and Jepson, 1991) as do other compounds from human skin, namely ammonia (Geier et al., 1999a), fatty acids of various chain length (Bosch et al., 2000), dimethyl disulfide, and acetone (Bernier et al., 2003). The response to lactic acid alone or when combined with other kairomones is dose dependent (Geier et al., 1996, 1999a; Bosch et al., 2000). However, the importance of such compounds in nature is not as certain, so extrapolation from laboratory studies must be performed with caution, especially as all research to date has been carried out with a single *Ae. aegypti* strain that has been reared in the laboratory for several decades.

To develop attractive kairomone blends for global use in *Ae. aegypti* trapping, the response of different populations to key kairomones should be assessed to evaluate

geographic variability in responses and to determine whether specific blends are needed for different populations. Furthermore, such a study may detect differences in the sensory physiology of *Ae. aegypti* throughout its geographic range. Given that genetic differentiation may exist between *Ae. aegypti* populations only a few kilometers apart (Tabachnick and Powell, 1978; Paupy et al., 2004), and that other mosquito species show heterogeneity in odor-mediated host preferences throughout their geographic range (e.g., Williams et al., 2003), it seems likely that *Ae. aegypti* populations could become adapted to particular kairomones exuded by locally available resources (i.e., humans). Any geographic variability in human odor profiles could facilitate such adaptation, which would be manifested in divergent responses to certain kairomones.

The aims of this study were to describe the response of host-seeking *Ae. aegypti* from four populations of distinct geographic origin to host kairomones, using laboratory y-olfactometers. The response of each population to increasing doses of lactic acid alone as well as in combination with ammonia or a fatty acid (caproic acid) was to be established. A combination of all three compounds forms a proprietary blend (Geier and Eiras, 2003; BioGents GmbH, Regensburg, Germany) and is the focus of a subsequent study.

Methods and Materials

Mosquito Rearing Methodology

Four populations of *Ae. aegypti* mosquitoes, which varied in their laboratory colonization history, were used in these studies at the University of Regensburg (September–November 2004; Table 1). Although it would have been ideal for all populations to be tested as field F_1 generations, this was not practical. Larvae were fed with Tetramin fish food. Adults were maintained in plastic containers (50 × 40 × 25 cm) at 26–28°C, 60–70% relative humidity, light/dark 12:12 hr, and with continuous access to a 10% glucose solution.

Olfactometers

A series of four identical, Plexiglas[®], y-olfactometers (Geier and Boeckh, 1999) on white tables was used (Fig. 1). Eighty l/min of charcoal-filtered, heated ($27.6 \pm 0.1^\circ\text{C}$), and humidified ($63.7 \pm 0.6\%$ relative humidity) air was passed through two parallel stimulus chambers, in which test compounds mixed with the air. These two parallel airstreams (0.2 m/sec) then passed through the common rectangular branch of the olfactometer and into the stem (0.4 m/sec) that was attached to the release chamber holding the mosquitoes. Rotating screens in the release chamber and in both arms of the upwind end enabled the release and recapture of mosquitoes.

Table 1 Summary data for *Ae. aegypti* populations used in this study

Population	Source	Length of time in laboratory
North Queensland, Australia	Cairns	Nil (F_1 generation)
Florida USA	Orlando	Since ca. 1960 (regularly supplemented with field material until ca. 1992)
Minas Gerais, Brazil	Belo Horizonte	Nil (F_1 generation)
Singapore	Singapore	ca. 20 generations

Fig. 1 Schematic drawing of the y-olfactometer design used to test geographically disparate populations of *Ae. aegypti* (Geier and Boeckh, 1999). Dimensions are given in millimeters

Volatile Stimulus Delivery

For each test, volatile stimuli were introduced into one of the two parallel stimulus chambers, with the other remaining as a blank control. Air was passed through a 200-ml Erlenmeyer flask containing 20 ml of the compound under study, and carried the headspace volatiles to ports immediately proximal to the treatment arms of the olfactometers by Teflon tubing (Geier et al., 1999a; Bosch et al., 2000). The delivery rate of volatile compounds to the olfactometers was determined by the airflow rate through the flask. When combinations of compounds were tested, each was delivered through separate flasks and tubing that met at a single release point in the olfactometer.

Bioassay and Statistical Analyses

Previously published methods (Geier et al., 1999a; Bosch et al., 2000) were used. Groups of 17–25 avid female *Ae. aegypti* (10–20 d postemergence, not blood fed, nulliparous) were lured from their holding cages by human odor, thereby selecting host-seeking mosquitoes for tests. This was achieved by fitting the y-olfactometer release cage onto a specially designed fitting on the holding cage, and creating airflow with a small fan that carried human odor from a hand through the release cage into the holding cage. Attracted mosquitoes then entered the release cage, which was then removed.

Before tests, the release cage containing mosquitoes was attached to the olfactometer. Mosquitoes were allowed 20 min to acclimatize, with clean air flushing through. When odor stimuli were introduced, mosquitoes were released from their chamber and allowed 30 sec to respond, after which the rotating screens were closed, trapping those in the treatment and control arms, and in the release cage. Odor stimuli were tested in balanced, randomized block designs. Each experiment involved the use of all four *Ae. aegypti* strains,

allocated to y-olfactometers in a randomized block design. Those captured in the treatment arm of the olfactometer were deemed to have been attracted to the stimulus. The small numbers captured in the control arm were also recorded. Mosquitoes were lured back into their release cage in response to human odor (hand of CRW) by reversing the air flow. Groups of mosquitoes were retested up to five times in this manner, with a 30-min “rest” period between tests, during which clean air continued to flow through the olfactometer. This method verified that mosquitoes would readily respond to natural human odors in between each trial. Previous studies with this apparatus have demonstrated that there are no carryover effects of contamination or behavioral conditioning in between replicate trials (Geier 1995; Geier and Boeckh, 1999).

Furthermore, previous studies have shown that a single laboratory strain of *Ae. aegypti* will respond in a consistent manner to a variety of kairomones (M. Geier and C. Aigner, unpublished data, University of Regensburg, 2001). This was demonstrated by testing cohorts from the same colony repeatedly over 5 mo in the same y-olfactometers used here.

Percentage data (number of mosquitoes in the test arm as a percentage of those released) were arcsine-transformed to normality before ANOVA with least significant difference (LSD) *post hoc* tests performed using SPSS statistical software (Release 11.0.1, 2003, SPSS, Inc., Chicago, IL, USA).

Experiment 1: Lactic Acid

Lactic acid (analytical reagent grade, Merck, Germany) dose was manipulated by adjusting flow rate through the Erlenmeyer flask. Five flow rates ranging from 0.2 to 300 ml/min were used. The size of the lactic acid dose (in $\mu\text{g}/\text{min}$) was determined by using calibration values taken from Geier et al. (1999b).

Human odor was tested as a gold standard control to determine the optimal behavioral response of each population in the y-olfactometers. This was introduced into stimulus chambers by inserting an index finger (always that of CRW) through a snug-fitting hole. A 20 ml water control (air flow: 10 ml/min) was also used to ascertain the baseline level of upwind flight. A minimum of 10 replicate trials was performed for each population for each treatment. Human odor was used despite the risk of subtle variations in kairomone output. The balanced, randomized block design used here ensured that all four *Ae. aegypti* populations would be subject to the same variations in output from the human hand, thereby controlling for this factor. Human hands have been previously used as an odor source in similar experiments (e.g., Geier and Boeckh 1999; Geier et al. 1999b).

The lowest lactic acid dose required to cause attraction significantly greater than the water control is hereafter termed the “attraction response threshold” dose. Means were separated using LSD *post hoc* tests.

Experiment 2: Lactic Acid + Ammonia, and Experiment 3: Lactic Acid + Caproic Acid

The attraction of a fixed dose of lactic acid (determined from experiment 1) with four 10-fold increasing flow rates of ammonia (experiment 2) or caproic acid (experiment 3) ranging from 0.3 to 300 ml/min was investigated. Unlike for lactic acid, we could not determine the ammonia and caproic acid doses in micrograms per minute because of a lack of calibration data. Ammonia (analytical reagent grade, Merck, Germany) was a 25% solution of ammonium hydroxide further diluted 1:100 in water. Caproic acid (Fluka Chemika, Germany) was also of analytical reagent quality.

Results

Experiment 1

All four mosquito populations responded to both lactic acid and human odor (Fig. 2). In all cases, the responses to human odor were significantly higher than to any concentration of lactic acid tested. Mean percentage capture in the control arm was $\leq 6.4\%$ for the lactic acid treatments.

Each of the populations demonstrated different attraction response thresholds. These varied from 0.03 $\mu\text{g}/\text{min}$ for Florida USA ($F = 68.86$, $d.f. = 6$, $P < 0.001$) to 0.17 $\mu\text{g}/\text{min}$ for Singapore ($F = 35.964$, $d.f. = 6$, $P < 0.001$), 1.92 $\mu\text{g}/\text{min}$ for North Queensland Australia ($F = 57.04$, $d.f. = 6$, $P < 0.001$), and 10.27 $\mu\text{g}/\text{min}$ for MG Brazil *Ae. aegypti* ($F = 66.42$, $d.f. = 6$, $P < 0.001$; Fig. 2).

There is no one common flow rate that is more attractive than others for all populations. Therefore, a dose of 50 ml/min (10.27 $\mu\text{g}/\text{min}$) was chosen for experiments 2 and 3, because it was greater than or equal to the attraction response threshold dose for all groups.

Experiment 2

For the North Queensland Australia population, there was no statistically significant increase in attraction when ammonia was added to lactic acid ($F = 1.86$, $d.f. = 4$, $P = 0.131$; Fig. 3), in contrast to the marked increase in attraction seen with the Florida USA population ($F = 12.97$, $d.f. = 4$, $P < 0.001$). For the MG Brazil and Singapore populations, lactic acid and ammonia combined provided greater attraction than lactic acid alone ($F = 2.59$, $d.f. = 4$, $P = 0.048$ for both) although only at the lower ammonia concentrations (Fig. 3).

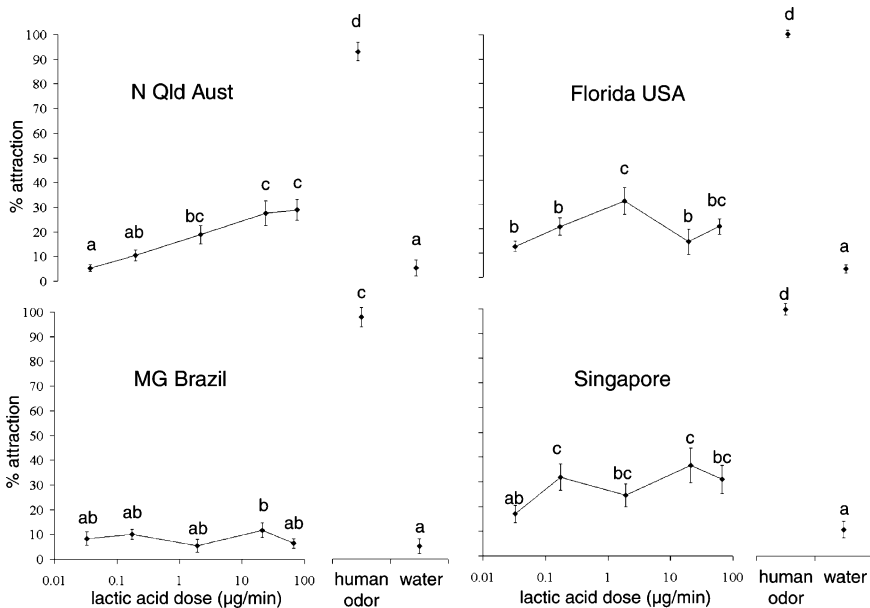

Fig. 2 Mean percentage attraction (\pm SE) of four populations of *Ae. aegypti* to various doses of lactic acid, as well as human odor and water. Different letters indicate significant differences within a population

Fig. 3 Mean percentage attraction (\pm SE) of four *Ae. aegypti* populations to mixtures of lactic acid (LA) at 10.3 μ g/min and ammonia (NH₃) in y-olfactometers. Different letters indicate statistically significant differences within a population

When tested alone (0.3 ml/min), ammonia proved slightly attractive to some populations: North Queensland Australia $28.3 \pm 3.9\%$, Florida USA $19.7 \pm 6.2\%$, Singapore $23.1 \pm 3.9\%$, and MG Brazil $8.1 \pm 2.7\%$. These data enabled calculation of the expected additive attraction (E) for lactic acid and ammonia (Colby 1967). These values were then compared with the observed attraction percentage ($O \pm 95\%$ confidence interval) to determine the presence of synergistic attraction. Comparisons were not performed for North Queensland Australia *Ae. aegypti*, as ammonia did not improve attraction for this group (Fig. 3). Singapore ($E = 51.1\%$, $O = 54.8 \pm 11.7\%$), Florida USA ($E = 41.3\%$, $O = 48.7 \pm 8.1\%$), and MG Brazil ($E = 17.1\%$, $O = 23.4 \pm 9.6\%$) *Ae. aegypti* all showed slightly greater attraction (O) than the expected additive effect (E). However, overlapping 95% confidence intervals were suggestive of an additive rather than synergistic effect.

Fig. 4 Mean percentage attraction (\pm SE) of four populations of *Ae. aegypti* to lactic acid (LA) at 10.3 μ g/min and caproic acid (CA) in y-olfactometers. Different letters indicate significant differences within a population

Experiment 3

Lactic acid plus caproic acid (30 ml/min) significantly increased attraction over lactic acid alone or with caproic acid at 0.3 or 3 ml/min, in all populations except Singapore (Fig. 4). Increasing the concentration of caproic acid to 300 ml/min caused a significant decline in attraction, compared with lactic acid plus caproic acid (30 ml/min) in all populations, and was less attractive than lactic acid alone for Florida USA and Singapore populations. ($F = 11.19$, $df = 4$, $P < 0.001$).

Caproic acid alone (0.3 ml/min) showed little or no attraction for *Ae. aegypti*: North Queensland Australia $16.2 \pm 7.8\%$, Florida USA $3.2 \pm 1.9\%$, Singapore $7.8 \pm 5.9\%$, and MG Brazil $6.5 \pm 2.6\%$. Furthermore, caproic acid did not improve the attraction of lactic acid at this flow rate (0.3 ml/min, Fig. 4) and no synergism calculations were possible.

Discussion

Geographically disparate populations of *Ae. aegypti* responded to lactic acid but differed in their sensitivities. The attraction response threshold dose for Florida USA and Singapore strains was below the lowest rate of lactic acid emission from human hands ($0.38 \mu\text{g}/\text{min}$; Smith et al., 1970). Human individuals differ in their level of emission of L-lactic acid from their skin by at least a factor of 5 (Acree et al., 1968; Smith et al., 1970; Steib et al., 2001). However, we do not know how big the differences in the lactic acid emission rates are between different geographic subpopulations of human hosts. MG Brazil mosquitoes showed a much lower response to lactic acid at any dose when compared with other populations. Given the avid response to human odor by this population (Fig. 4), the low response to lactic acid cannot be attributed to some behavioral anomaly hampering y-olfactometer flight. Rather, it indicates that other kairomones may be more important in host finding for this population.

The results presented here concur with those of Geier et al. (1996), who demonstrated that increasing the dose of lactic acid past the attraction response threshold does not significantly increase the attraction of *Ae. aegypti* (Bayer strain). The level of attraction (ca. 25%) reported in Geier et al. (1996) was similar to the level reported for three of the four populations studied here. Also, a similar mean level of attraction (20.5%) was reported by Bernier et al. (2003) for *Ae. aegypti* from the same Florida USA laboratory population by using similar apparatus. This finding demonstrates consistency in response of this *Ae. aegypti* strain to lactic acid when tested in different laboratories. This consistency is further illustrated by similar responses to a human hand in both laboratories (this study; Kline 1998).

The greater attraction of the lactic acid–ammonia combination compared with lactic acid alone, first described for the Bayer strain of *Ae. aegypti* by Geier et al. (1999a), has been confirmed here. An exception is the North Queensland Australia population in which the lack of effect may reflect the good response of North Queensland Australia *Ae. aegypti* to lactic acid alone, or that ammonia is not an important attractant for this population. A significant combination effect was demonstrated for the MG Brazil population, although its attraction both to lactic acid and the lactic acid–ammonia combination was poor. This possibly reflects a poor response to lactic acid in general. The attraction to ammonia when presented alone, up to ca. 28% (North Queensland Australia), is much greater than the ca. 5% presented by Geier et al. (1999a). This may be attributed to behavioral variability between *Ae. aegypti* populations. The increased attraction of lactic acid with the addition of

caproic acid, first described by Bosch et al. (2000), has been confirmed here for at least three *Ae. aegypti* populations, although too much caproic acid may cause reduced attraction.

Because of the varied colonization history of the populations studied here, and the significant genetic differentiation that exists even between *Ae. aegypti* populations separated by just a few kilometers (Tabachnick and Powell, 1978; Paupy et al., 2004), conclusions about naturally occurring heterogeneity in response to attractants throughout the geographic range of *Ae. aegypti* must be made with caution. Nor can generalizations be made about *Ae. aegypti* response to kairomones from particular regions, as population genetic studies would be needed to determine how representative these laboratory populations are for each region.

Groups of *Ae. aegypti* may respond differently to the same volatile compounds, and statements concerning responses to kairomone combinations must be specific to the population in question. The divergent responses to host kairomones seen here may be evidence of adaptation to locally available hosts in different parts of the geographic range of *Ae. aegypti*. However, a study of human odor components in different regions (particularly lactic acid emission levels), paired with population genetic studies and behavioral responses of mosquito strains from different regions, is needed to address such a hypothesis. The results presented here indicate that the development of trapping lures for host-seeking *Ae. aegypti* may require some specialization for the region of use. The validity of laboratory olfactory studies in terms of field behavior has been demonstrated directly for at least one mosquito species (*Culex annulirostris* in Australia; Williams et al., 2003). Nonetheless, we report here the response of *Ae. aegypti* to human odorants over a very short range in an artificial environment. It follows that field trials are required to validate the attraction of *Ae. aegypti* to these odorants. Last, it is clear that human odor is significantly more attractive to *Ae. aegypti* than any of the odorants tested here, confirming that a complex suite of kairomones is required to maximize the attraction of this species.

Acknowledgments Ulla Kroeckel, Thomas Hoerbrand, Sebastian Haas, and Margit Lindner provided technical assistance at the University of Regensburg. Carl Baptista from the Origin Exterminators PTE, Ltd., Singapore provided the Singapore mosquito colony. These experiments adhered to James Cook University guidelines for the use of human subjects in experimentation. This work was funded by Australian National Health and Medical Research Council grant 279401 (to SAR and RCR).

Abstract Although several studies have examined the effect of human odor on kin recognition and mate choice, few have focused on the impact of familiarity on recognition of nonrelatives by olfactory cues. As part of a program designed to engage students in scientific research, 53 high school students researched, planned, and implemented a project to analyze the effect of odor on human recognition of, and preference for, friends, sex, and self. A total of 37 students, including friends of their choosing, wore T-shirts for three consecutive nights. During that time, subjects were controlled for exposure to extraneous perfumes, household odors, and other humans. The students were then asked to smell a series of five shirts and evaluate them with respect to pleasantness. Students were also asked to identify the shirts belonging to themselves and their friend, and determine the sex of the person who wore each shirt. Although subjects were unable to distinguish sex by olfactory cues alone, a significant percentage of subjects were able to identify their own odor (51.6%), as well as distinguish the odor cue of their friend (38.7%). Additionally, subjects who could not identify their friend's cue were apt to choose the odor of a member of the opposite sex as their friend. This result was not believed to rely on odor preference as neither individual, friend, nor stranger odors were rated significantly different with respect to odor pleasantness. The ability to recognize friends via odor cues lends credence to the hypothesis that association and familiarity are important aspects of conspecific olfactory recognition in humans. Furthermore, this study augments evidence that olfaction may supplement visual and auditory cues used in human conspecific and kin recognition.

Keywords Kin recognition · Human social behavior · Association · Familiarity

This research was designed and implemented by 53 high school General Biology and Advanced Placement students who contributed as fellow authors to this project. Refer to Acknowledgments for a full list of names.

Introduction

“Reason is sight. Instinct is touch. Intuition is smell.” Mason Cooley (2001)

Humans are creatures of sight and sound. Yet, of all the human senses, olfaction is considered the most ancient, possessing links to several areas of the brain, including those responsible for cognitive, visceral, emotional, and homeostatic behaviors (Purves et al., 2001). Moreover, although it is often assumed that humans have a poor sense of smell, we possess an amazingly acute sensitivity to some chemicals, such as vanillin and 2-bromophenol (sensitivity thresholds of $10^{-5.6}$ and $10^{-4.5}$ ppm, respectively; Devos et al., 1990; Jacob et al., 2002). In fact, humans can recognize at least 10,000 different odors (Prasad and Reed, 1999).

Humans may also use olfactory cues for conspecific recognition and communication (see Hays, 2003; Wysocki and Preti, 2000, 2004 for recent reviews). With its persistence and complexity, the olfactory cue is suitable for producing highly individualized and long-lasting signals. Even with voices and faces, olfaction may function throughout life to supplement these cues. Furthermore, olfactory cues learned in the first few hours of life, or even prenatally, might impact our earliest lessons of whom kin and non-kin are (refer to Porter, 1999).

Odor-mediated recognition of conspecifics is ubiquitous throughout the animal kingdom. However, the mechanisms for discrimination can be diverse. For example, *Polistes metricus* paper wasps use the scent of hydrocarbons from their nest to recognize kin (Espelie et al., 1990). Salmonid fishes, well known for their use of olfaction in kin recognition, potentially use odors mediated by major histocompatibility complex (MHC) alleles (immunoresponse genes) to determine kin (Olsen et al., 1998; Rajakaruna et al., 2001). However, another fish, the Trinidadian guppy (*Poecilia reticulata*), uses odor to identify and school with *familiar* conspecifics, whether they are genetically related or not (Griffiths and Magurran, 1999).

In mammals, there are several examples of conspecific recognition via olfaction. Golden hamsters (*Mesocricetus auratus*) appear to use self-referent phenotype matching of odors (the “armpit effect”) to determine kin (Mateo and Johnston, 2000a). Belding’s ground squirrels (*Spermophilus beldingi*) respond toward littermate odors even after hibernation (Mateo and Johnston, 2000b). These squirrels can also discriminate degrees of relatedness through odor alone (Mateo, 2002). In this species, precise recognition may be mediated by both kin association and self or kin phenotype matching (Mateo and Johnston, 2000b).

There is a growing body of evidence that humans can also recognize each other via olfactory cues. Several studies have shown evidence for odor-mediated self-recognition (Russell, 1976; Hold and Schleidt, 1977; Schleidt, 1980; Schleidt et al., 1981; Lord and Kasprzak, 1989; Platek et al., 2001). Mothers can recognize olfactory cues from their infants within a few hours of birth (Porter and Cernoch, 1983; Russell et al., 1983; Kaitz et al., 1987). Likewise, infants will preferentially orient their heads toward maternal odors (Cernoch and Porter, 1985; Porter et al., 1992). There is also evidence that siblings and other relatives can recognize each other using odor cues (Porter and Moore, 1981; Porter et al., 1986).

The mechanisms underlying human odor recognition have not been elucidated. A number of studies have suggested that odor is influenced by the MHC, a series of genes also involved in immune response (see Penn, 2002 for review). In addition, both phenotype matching and association have been suggested to play a role in human kin recognition (Weisfeld et al., 2003). However, few studies have examined odor-mediated recognition of nonrelatives. Studies of relatives show that we can recognize conspecifics, but are unable to

distinguish the mechanisms behind this recognition. Genetically related individuals might employ both association and phenotype matching to identify each other. Tests of non-relatives are imperative to understand the impact of familiarity on human odor recognition, as phenotype matching is impossible where no genetic relatedness exists. Wallace (1977) found that subjects could distinguish between the hand odor of two different individuals. Kaitz and Eidelman (1992) showed that nonparturient strangers with little infant experience could distinguish a newborn's undershirt from other infants' after holding them for only 45 min. Verron and Gaultier (1976) found that 4- to 5-yr-old children were able to identify peers to some extent, although it was unclear how they controlled for extraneous scents due to foods, perfumes, and other sources. In 1998, Mallet and Schaal also found that young school children (average age of 9.5 yr) were able to identify nonrelative peers. However, the authors were not interested in purely biological odors and did not control for any extraneous scents. The majority of other studies that have tackled human odor recognition have concentrated their efforts on the recognition of partners (Hold and Schleidt, 1977; Schleidt, 1980; Schleidt et al., 1981). These studies are insufficient to examine effects of familiarity because subjects were also influenced by sexual attraction. Weisfeld et al. (2003) might have examined nonrelatives other than partners; however, because they did not separate the two in their presentation, no conclusions can be drawn.

In the present study, we investigated the impact of familiarity and association on human odor recognition by testing the hypothesis that humans can recognize familiar nonrelatives by odor cues. As part of a program designed to engage students in scientific research, 53 General and Advanced Placement biology students (ages 15–18 yr) implemented a project to analyze the effect of odor on human recognition of, and preference for, friends, sex, and self. Thirty-seven students wore T-shirts for three consecutive nights. During that time, subjects were controlled for exposure to an extensive list of extraneous odors.

Methods and Materials

The study was approved by the Cornell University Committee on Human Subjects (Institutional Review Board) and the Geneva Central School District Administration for use of data collected for research purposes.

Subjects

A total of 37 Geneva High School students (Geneva, NY, USA; 26 females, 11 males), ages 15–18 yr ($\bar{X} = 16.77$), volunteered to participate in a study to examine human odor recognition of, and preference for friends, sex, and self. This population was diverse on both racial and socioeconomic levels. Students were asked to choose one friend to participate in the experiment with them. They were also asked to choose only friends with whom they had a platonic relationship. Of the pairings used for data analysis, 2 were male/male, 12 were female/female, and 7 were male/female.

Thirty-one students were members of classes participating in a university and National Science Foundation–sponsored program designed to engage students in scientific research. The two class instructors participated in the program and coordinated with S. Olsson to integrate inquiry research into their General and Advanced Placement Biology curriculum. As such, the entire class designed and implemented all aspects of this project as part of the curriculum and was informed of the testing procedures. The six students from other classes

were informed both by written and oral instructions from the student friend participating in the program. All class members were educated on the ethics of human subject research both for research training and to inform them of their rights as potential subjects. All information and case studies for the education were taken directly from The Cornell University Committee on Human Subjects Training Program for Researchers in the Use of Human Subjects, and The National Institutes of Health Human Participant Protections Education for Research Terms on-line tutorial. Students were assessed through in-class discussions of case studies for their understanding of autonomy, beneficence, and justice as regards the use of human subjects in research. Although participation in planning and data analysis was a mandatory aspect of the education, participation as experimental subjects was strictly voluntary. Students were informed that any assessment for grading purposes was based solely on participation in planning and analysis of the study. Furthermore, students who did not volunteer as subjects were identical to subjects in their participation in all other aspects of the project. Thus, only 31 of the 52 total class members and six friends from other classes chose to participate. All student information was kept confidential through the use of identification numbers, and students were presented only these numbers during the data analysis phase. Consequently, data records could not be traced to specific students.

Odor Collection and Storage

Subjects were provided with 100% cotton T-shirts to wear to bed on three consecutive nights with clean pajama or alternative bottoms. Before wearing the shirts, subjects were instructed to wash all bed sheets in an unscented laundry detergent provided to them. The 37 shirts as well as one unworn T-shirt used as a control were laundered together in the same detergent before wearing. Subjects were also presented with the same lightly scented shampoo, conditioner, and soap (Zoto International, Inc.) to use *each* night immediately before donning the shirt.

Subjects were instructed to use only the items provided to them, and avoid other soaps, lotions, deodorants, etc. Although they were not required to alter daytime activities, subjects were cautioned to avoid smoking, eating, and strenuous activity while wearing the shirts. Finally, they were instructed to wear the shirts at least 6 hr each night, and prevent other humans/pets from sleeping on or using the bed during the testing period. Each morning, subjects placed their shirts in a plastic zip-lock bag to store in the freezer during the day to minimize loss of odor. Upon collection, all sealed bags, including the unworn control in a sealed bag, were stored together in the same freezer at approximately -5°C .

Testing Procedure

Subjects were tested by S. Olsson on 3 consecutive days in January 2004, approximately 6–8 d after wearing the shirts. They were first asked to complete a questionnaire concerning the study, providing data such as age, sex, information about their friendships (length, number of days a week they met their friend, etc.), compliance with testing procedures, information about potential impediments to the study such as allergies or illness that could create olfactory deficits, and exposure to pets smoke and strong food odors that could facilitate identification of specific individuals.

Upon completion of the questionnaire, subjects were screened for olfactory deficits by identifying a sequence of three scents [orange, vanilla, and almond extracts (McCormick and Co., Inc., Hunt Valley, MD, USA)] diluted 50% in water, similar to screening methods described in another human odor recognition study (Kaitz et al., 1987). Subjects were asked

to identify the three correct scents from a list of 10 odor choices. Then, wearing latex or nitrile gloves, they were asked to open and smell the contents of five numbered zip-lock bags containing shirts worn by themselves, their friend, an unworn control, and two strangers from the opposite sex. The unworn control had been laundered and stored at -5°C with the worn T-shirts. The two “strangers” were subjects randomly chosen from classes other than the test subject. Strangers of the opposite sex were used to aid in testing odor recognition of sex. Bags and shirts were of similar size and color with no identifying marks. The bags were numbered 1–5 and presented in random order. Subjects were allowed to smell the contents as long as necessary and repeat if needed to complete a test.

In the first test, subjects rated the pleasantness of each shirt’s odor on a scale from 1–5 (1, very unpleasant; 2, somewhat unpleasant; 3, neutral; 4, somewhat pleasant; 5, very pleasant). They were then asked to determine the sex of each of the five shirt owners (including the unworn control shirt). Finally, each was asked to identify the two shirts belonging to self and friend.

Statistical Analyses

χ^2 Tests (StatXact-4 and StatXact-6, Cytel Software Corporation, 1998 and 2004) were used to compare pleasantness ratings for each type of shirt (Pearson’s with Monte Carlo estimates of exact P values using 10,000 samples) as well as compare frequencies of shirts chosen as self and friend to the 20% expected by chance (goodness-of-fit with exact P values). All χ^2 P values reported are exact. A Kolmogorov–Smirnov Z test was used to compare distributions of pleasantness ratings for the tested shirt types (SPSS Version 12.0, SPSS, Inc., 2001). For recognition of sex, a logistic model was fitted to the number of correct and incorrect selections for each individual using STATA (v.7, StataCorp, 2001) with a Huber–White robust variance estimator to obtain 95% confidence intervals, which accounted for positive correlation with individual. Finally, logistic regression (STATA v. 7, StataCorp, 2001) was used to determine the influence of a number of factors answered in the questionnaire (see testing procedure, above) on identification of self and friend.

Results

Olfactory Screening

Subjects were initially screened for olfactory deficits through identification of three odors: orange, vanilla, and almond. Only those who correctly identified at least two of three odorants were considered for further analysis. However, 20/37 subjects (54.0%) identified orange odor as lemon. Because of this, lemon was accepted as an alternate response to orange. Most of the subjects ($n = 31$, 83.8%) identified at least two of three odorants correctly, including those who chose lemon.

Human Odor Qualitative Comparisons

Each subject rated the pleasantness of five T-shirts (self, friend, male stranger, female stranger, and an unworn, blank shirt) on a scale of 1–5. Figure 1 depicts the distribution of pleasantness ratings for each of the five types of shirts. All distributions are similar with the exception of the unworn, blank shirt, which was considered neutral more frequently. According to a χ^2 test, the distribution of pleasantness ratings did not differ among the shirt

Fig. 1 Distributions of pleasantness for each of the five shirt types. Each shirt was rated 1–5, as follows: 1, very unpleasant; 2, somewhat unpleasant; 3, neutral; 4, somewhat pleasant; 5, very pleasant

types, ($df = 16, n = 155$) = 24.09, $P = 0.08$, nonsignificant (NS). These distributions were also similar when male and female subjects were analyzed separately [data not shown; males: χ^2 ($df = 16, n = 40$) = 22.81, $P = 0.110$, NS; females: χ^2 ($df = 16, n = 115$) = 23.28, $P = 0.109$, NS. A Kolmogorov–Smirnov Z test also did not find any difference between any paired rating distributions ($Z = 0.254 - 1.143, P > 0.1$).

Recognition of Sex via Odor Cues

Subjects were asked to identify the sex of the owner for each of the five shirts presented. A logistic model was fitted to these data with a robust variance estimator accounting for

Fig. 2 Percentage of T-shirts chosen by the subjects as their (a) own shirt and (b) friend’s shirt ($n = 31$)

positive correlation with individual. On average, subjects identified $54.8 \pm 8\%$ shirts correctly (95% confidence interval), which does not differ significantly from chance. The unworn, blank shirt was identified male as frequently as it was identified female (15/31 or 48.4%, and 16/31 or 51.6%, respectively). However, males were 1.67 times more likely to identify the blank shirt as male (5:3), whereas females were 1.30 times more likely to identify it as female (13:10).

Self-Recognition via Odor Cues

Figure 2a shows the distribution of shirts identified by the subjects as their own. A total of 51.6% of the subjects identified their own shirt correctly, which is significantly greater than the 20% expected by chance, $\chi^2 (1, n = 31) = 19.36, P < 0.001$. Females identified their own shirt significantly greater than chance, $\chi^2 (1, n = 23) = 14.88, P < 0.001$, and males were marginally significant (MS), $\chi^2 (1, n = 8) = 4.5, P = 0.056, MS$. During testing, four shirts were identified by at least two to three subjects as having a “nonhuman” odor, such as food or cigarette smoke. Removal of these shirts from all aspects of the data pool (self, friend, and stranger) did not effect this significance, $\chi^2 (1, n = 14) = 12.07, P = 0.002$. Likewise, Table 1 shows that subjects could still identify their own shirt even when controlling for several factors that could have impacted result accuracy. This table was compiled from subjects’ questionnaire answers filled out the day of testing (see [Methods and Materials](#)). Subjects who answered “yes” to any factor such as allergies, sickness, or

Table 1 Recognition of self and friend odor cues as a function of specific conditions or situations

Condition controlled	No. subjects who answered “no” on questionnaire	Self-recognition		No. subjects whose friends answered “no” on questionnaire	Friend recognition	
		χ^2	<i>P</i> value		χ^2	<i>P</i> value
Pet owners	9	12.25	0.003	8	0.12	1.000, NS
Smokers ^a	24	10.01	0.004	25	4.00	0.074, NS
Allergies	23	14.88	<0.001	23 ^b	7.92	0.009 ^b
Strong foods consumed during testing	23	24.01	<0.001	24	7.04	0.013
Odorants used (i.e., perfumes, lotions, deodorant)	28	19.72	<0.001	27	4.90	0.033
Illness while wearing shirt or during olfactory trials	22	16.41	<0.001	22 ^c	3.68	0.063, MS ^c
Directions not followed (e.g., proper soaps not used, shirt not worn three nights, etc.)	20	15.31	<0.001	23	5.26	0.033

^a Subjects or friends with household members who smoke are also excluded.

^b Includes only subjects who answered “no” on questionnaire, but does not exclude any friends.

^c Includes only subjects who answered “no” to illness during trials and whose friends answered “no” to illness while wearing shirt.

exposure to smoke and strong food odors were removed from that analysis. A χ^2 test was performed using only those subjects who stated they were not affected by that factor. The table lists the number of remaining subjects for each condition considered (i.e., those who answered “no” on questionnaire). Additionally, logistic regression found no influence of any of these factors on choice of self ($P > 0.2$).

Recognition of Friends via Odor Cues

Based on questionnaire answers, most of the subjects (34/37, 91.9%) considered their chosen partner to be a friend rather than simply a classmate. Nevertheless, only 19/37 (51.4%) considered this person to be a close friend. All but one subject indicated that they met their friend at least three times a week, and 26/37 (70.3%) stated that they had known their friend at least 3 yrs.

A total of 38.7% of the subjects identified their friend’s shirt correctly, which is significantly greater than the 20% expected by chance, $\chi^2(1, n = 31) = 6.78, P = 0.014$ (Fig. 2b). This was only true for friends who knew each other at least 3 yr, $\chi^2(1, n = 21) = 6.86, P = 0.014$. Friends who knew each other less than 3 yr could not distinguish each other by odor, $\chi^2(1, n = 10) = 0.62, P = 0.698$, NS. However, logistic regression found no influence of friendship length on subjects’ ability to distinguish their friends’ odor ($P > 0.2$).

Removal of the four shirts identified two to three times as having a “nonhuman” odor from the data pool did affect the significance, $\chi^2(1, n = 14) = 2.16, P = 0.174$, NS. Nevertheless, Table 1 shows that subjects could still identify their friends even when their friends were controlled for most factors obtained from the questionnaire filled out the day of testing (i.e., only subjects whose friends stated they were not affected by that factor were included). The use of logistic regression found no influence of these factors on choice of friend ($P > 0.2$).

Finally, there was a sex difference in the ability of subjects to identify their friend’s shirt. Although females could identify their friends, $\chi^2(1, n = 23) = 11.13, P = 0.002$, males could not, $\chi^2(1, n = 8) = 0.28, P = 0.706$, NS. However, the low sample size could have contributed to the lack of significance among male subjects. Additionally, if subjects selected incorrectly, males were four times more likely to identify the female stranger as their friend than the male stranger (4:1), whereas females were seven times more likely to identify the male stranger (7:1). The propensity to identify a member of the opposite sex as the friend was not dependent on the pairing of the subjects (male/male, female/female, and male/female). Indeed, in the 11 cases where female/female pairs identified the incorrect shirt, subjects selected the male stranger in seven of the cases (64%). Likewise, in the three cases where male/male pairs identified friends incorrectly, they chose the female stranger once and their own shirt twice.

Discussion

Our results indicate that subjects, when presented with several different stimuli, could recognize both their own and their friend’s odor cue. However, subjects could not reliably distinguish the sex of the wearer nor did they prefer the scent of any particular individual (i.e., self, friend, stranger, or unworn). Apparently, the ability to recognize odor in this context did not require a preference for that scent. All shirt odors were rated similarly for

pleasantness, and although male stranger shirts were considered slightly less pleasant on average, this distinction was not significant.

Subjects were not only unable to distinguish sex via odor cues, but, as shown above, male and female odors were considered equally pleasant, indicating that neither sex possessed qualitative differences in odor. Furthermore, the unworn, blank control shirt was identified to be male as often as female, showing that subjects had no overall bias to choose one sex over the other. Nonetheless, both males from females were slightly more likely to choose their own sex for the unworn shirt. These results are in disagreement with previous studies (Hold and Schleidt, 1977; Schleidt, 1980; Schleidt et al., 1981). In these experiments, subjects (20–64%) were not only able to discriminate males from females, but many deemed female odor to be “more pleasant” than male. However, shirts were worn for a longer period of time (seven nights) and fewer controls were taken (i.e., subjects’ bed sheets not washed in same detergent, same shampoo not used by all subjects, shirts not stored under isolated, cold conditions, and ownership of pets not considered). Consequently, there was a greater potential for extraneous and unnatural odors to accumulate on the shirts and affect the results. Several studies reviewed in Doty (1981) also suggest the discrimination of sex via olfactory cues, and in these studies shirts/gauze pads were worn for 18–24 hr. In our study, subjects might have been able to distinguish sex had they worn the shirts for an extended period of time. It is also possible that the odor cues responsible for distinguishing men from women are less prominent during young adulthood than for adults used in the previous research. Lord and Kasprzak (1989) found that age was a significant factor in subjects’ ability to recognize self via olfaction. In fact, many of the subjects who failed the test were under 20 yr, similar to our subjects. Mallet and Schaal (1998) also found that 9-yr-old children were unable to determine the sex of their peers by smell alone. Finally, a study of volatiles emitted from subjects ages 26–75 yr found a positive correlation in the concentration of 2-nonenal with age, with detectable amounts only found in persons age 40 yr and above (Haze et al. 2001). Perhaps our subjects neither produce sufficient quantities of, nor are adequately familiar with the odor cues responsible for distinguishing sex.

In both recognition tests, our subjects were able to distinguish their own and their friend’s odor cue. Subjects could identify their own scent 51.6% of the time, and their friend’s 38.7%. The ability to recognize self via odor cues was not affected even when separately controlling for factors that might influence shirt odor, e.g., pets, smoking, allergies, strong foods eaten, odorants used, illness, and experimental error. The ability to recognize friends via odor cues was affected only when nonhuman-scented shirts, friends who were pet owners, or friends who were smokers were removed from the data set.

These results are in congruence with previous studies that confirm the ability of humans to recognize self via olfactory cues (Russell, 1976; Hold and Schleidt, 1977; Schleidt, 1980; Schleidt et al., 1981; Lord and Kasprzak, 1989; Mallet and Schaal, 1998; Platek et al., 2001). Furthermore, the percentage of subjects able to recognize their own scent (51.6%) falls well within values obtained in other studies [25% in Schleidt et al. (1981) to ~75% in Russell (1976) and Lord and Kasprzak (1989)].

Individuals were able to identify their friend’s odor although only half (51.4%) stated that their partner was a close friend. Furthermore, the result that only friends who knew each other longer than 3 yr could identify each other may indicate that a longer period of association is necessary to learn olfactory cues. However, because of the small sample size in relation to this question ($n = 10$ for friends <3 yr), and the lack of statistical relation to length of friendship, this conclusion must be made with caution. Additional studies with larger sample sizes may elucidate the validity of this claim.

Subjects who did not identify their friend's odor correctly were apt to choose the odor of a member of the opposite sex. This was true even for same-sex pairings, showing that individuals who chose incorrectly were not merely searching for odors of the same sex as their friend. This agrees with the conclusion that our subjects could not distinguish sex. Although subjects did not express a conscious preference for the odor of the opposite sex, this result indicates that they may consider the odor of the opposite sex to be a "friendly" odor. Implications of this on the role of odor in human mate preference are beyond the scope of this investigation and are not discussed here.

The ability to recognize friends via odor cues lends credence to the idea that association and familiarity are important aspects of conspecific olfactory recognition in humans. Further tests are necessary to determine the extent to which humans utilize association vs. phenotype matching for kin and conspecific recognition. Potentially, a study with adopted children and unknown relatives could address this concern. Adopted children, although lacking a coefficient of genetic relatedness, are kin in the human social context. Recognition of adopted children could occur purely through association. However, a recent study found that although mothers and siblings could identify odor of their biological children and siblings, they were unable to identify the odor of their stepchildren or stepsiblings (Weisfeld et al., 2003). Alternatively, relatives whom the subject has never met could only be identified through phenotype matching. These tests are essential to understand the mechanisms by which we use odor as a means for identification.

Although this examination uses indirect cues (i.e., T-shirts), there remains significant support for the recognition of nonrelatives via odor cues. Olfaction, particularly if operational *in utero*, may be important for identifying individuals early in life by supplementing newly developed senses. Furthermore, odor can function throughout life to enhance other visual, auditory, and tactile cues. Our sense of smell may have more impact on our life than we realize.

Acknowledgments We thank Zoto's International, Inc., for their donation of soap, shampoo, and conditioner; Graphic Connections of Geneva for their assistance in obtaining T-shirts; Dr. Jan Nyrop and the Cornell University Office of Statistical Consulting for assistance with statistical calculations; Dr. Charles E. Linn, Jr., Dr. Wendell Roelofs, Dr. Robert Johnston, Prof. Elaine Wethington, and Sarah Demo for comments on the manuscript; and the Cornell Science Inquiry Partnerships, Geneva High School, the NYS Agricultural Experiment Station, and Dr. Wendell Roelofs' laboratory for their support and assistance. How an Ant Manages to Display Individual and Colonial Signals by Using the Same Channel

Abstract Cuticular hydrocarbons are used by some ants to discriminate nestmates from nonnestmates. Every member of the colony bears the same pattern because they are continuously exchanged among nestmates. The postpharyngeal gland (PPG) stores the blend of hydrocarbons and is involved in the distribution of this common mixture. However, some individuals might display individual information on the cuticle (such as a chemical signal of fertility) that must not be mixed within the common pool. We investigated how this paradox is solved in the ant *Pachycondyla goeldii* by analyzing the nature and localization of colonial and fertility signals. Workers in a queenless condition showed a dominance hierarchy that was correlated with ovarian development. Hydrocarbons from the cuticle and the PPG analyzed by gas chromatography (GC) and identified by GC-mass spectrometry showed a clear discrimination among colonies, supporting the involvement of the PPG in the colonial identity signal. We identified and selected 11 cuticular hydrocarbons that permitted us to discriminate ovarian development classes and that might function as a fertility signal. They allowed clear colony discrimination as well, which suggests that the two signals (the individual signal of fertility and the common signal of colony identity) can be conveyed by the same compounds. However, the hydrocarbons in the PPG did not discriminate among ovarian developmental classes, suggesting that the portion of variation in the cuticular hydrocarbons constituting the fertility signal is superimposed on the signal of colony identity.

Keywords *Pachycondyla* · Ants · Cuticular hydrocarbons · Colonial odor · Ovarian status · Fertility signaling

Introduction

In colonies of most social insect species, individual workers are able to discriminate between nestmates and nonnestmates. They are usually aggressive against nonnestmates, especially in the vicinity of the nest. They limit their altruistic behavior to members of their colony and protect it against intruders. According to Gestalt theory, each colony has a unique odor that is a blend of all individually produced odors (Crozier and Dix, 1979;

Crozier, 1987), which allows for nestmate discrimination. In ants, this model implies the existence of a Gestalt organ where chemicals involved in nestmate discrimination are mixed before being displayed by the individual (Carlin and Hölldobler, 1986, 1987; Stuart, 1988; Crosland, 1989; Tsuji, 1990; Dahbi and Lenoir, 1998). This organ should contain chemicals from all colony members in order to develop a colonial odor.

In ants, it has been demonstrated that cuticular hydrocarbons are involved in the nestmate discrimination process (Bonavita-Cougourdan et al., 1987; Lahav et al., 1999; Thomas et al., 1999; Wagner et al., 2000). Cuticular hydrocarbons are synthesized in tissues from the abdomen (epidermis, fat body, oenocytes) (Soroker and Hefetz, 2000) and are likely transported by high-density lipophorin (an internal hydrocarbon carrier) through the hemolymph to the postpharyngeal gland (PPG) (Lucas et al., 2004). Hydrocarbons are exchanged between the PPG and the cuticle during self-grooming, and between nestmates during trophallaxis, allogrooming, and physical contact. This mutual redistribution of hydrocarbons between all colony members might allow the formation of a colonial odor (Lenoir et al., 1999; Soroker et al., 2003; Lucas et al., 2004). Thus, the PPG is considered as the Gestalt organ (Soroker et al., 1994; Lahav et al., 1999). Indeed, most of the hydrocarbons present on the cuticle are also present in this gland (Bagneres and Morgan, 1991; Do Nascimento et al., 1993; Lucas et al., 2004). In *Pachycondyla* ants, newly synthesized hydrocarbons are chiefly transported from the hemolymph to the basitarsal brushes of the front legs (Hefetz et al., 2001). These are licked during self-grooming, and cuticular hydrocarbons are transferred to the PPG. PPG hydrocarbons are then dispatched on the other parts of the same individual's cuticle or on its nestmates' cuticles during grooming (Meskali et al., 1995). Because *Pachycondyla* ants do not perform trophallaxis, hydrocarbons are only exchanged between nestmates during body contact and allogrooming.

All members of a colony bear a common odor, the colonial odor, but some members may display individual chemical signals on their cuticle that are not mixed in the common pool. For example, such signals are compounds yielding information about fertility, dominance status, or caste, in different social insects. Recent studies suggest that cuticular hydrocarbons are involved in fertility signaling in ants. In queenright ants, the queen displays the fertility signal (Liebig et al., 2000; Heinze et al., 2002). When several queens cooccur in the same colony, the cuticular hydrocarbons provide information on the degree of fecundity, and workers are able to discriminate among queens with different fecundities (Hannonen et al., 2002). In some species, the queen caste does not exist and workers (called gamergates) mate and reproduce (Peeters, 1991). The gamergate, often only one per colony, can be considered as a functional queen, and has been shown to bear a fertility signal (Monnin et al., 1998; Liebig et al., 2000; Cuvillier-Hot et al., 2004a). However, in queenless species, unmated egg layers tend to develop a fertility signal (Cuvillier-Hot et al., 2001, 2004b). In *Harpegnathos saltator*, where both queens and gamergates occur, the fertility signal is the same in both castes (Liebig et al., 2000). In many queenright species, the workers have retained the ability to lay unfertilized eggs that produce males. In these species, the loss of the queen is usually followed by a burst of worker reproduction. Moreover, workers compete to access reproduction, and form a dominance hierarchy (reviewed in Cuvillier-Hot et al., 2004a). Once the hierarchy is established, dominant workers may display a chemical signal of fertility and/or dominance that limits costly competitive interactions. Similarity between the fertility signal of queens and fertile workers has been shown (Heinze et al., 2002). Such dequeened systems are especially good models to study fertility signaling because morphological caste does not influence the signals studied. Some results suggest that the hydrocarbons involved in colony and fertility signaling belong to different classes (Dietemann et al., 2003).

The neotropical ant *Pachycondyla goeldii* (Forel) is an arboreal species that lives in ant gardens. Workers are aggressive to members of other colonies, indicating substantial society closure (D.D., personal observation). As in many poneromorphs, *P. goeldii* workers have retained the ability to lay unfertilized eggs that develop into males in the absence of the queen. This provides an opportunity to study the consequences of orphaning on reproductive conflict. The aim of our study was to investigate how ants manage to display at the same time a colonial signal that must be homogenized among nestmates and an individual signal of fertility that should not be transferred to nestmates. We first verified whether workers in orphaned groups display dominance hierarchy and whether it is related to reproductive activity. We then checked whether the cuticular and PPG hydrocarbon profiles are consistent with the Gestalt model. Then, we attempted to identify a fertility signal on the cuticle and determine how this signal is combined with the colonial odor.

Methods and Materials

Collection and Rearing of Colonies

Three entire queenright colonies of *P. goeldii* were collected in September 2002 near the dam of “Petit Saut,” French Guiana (colonies A, B, and C: 160, 225, and 198 workers, respectively). Mature colonies of this species usually contain about 200 workers. They were maintained in the laboratory in artificial nests made of plaster connected to an outside arena. Colonies were kept at $28 \pm 2^\circ\text{C}$ and $80 \pm 2\%$ RH. They were fed twice a week with crickets and diluted honey. Worker behavior was investigated in eight dequeened groups of 16 workers each (without brood). Three, two, and three dequeened groups were formed out of queenright colonies A, B, and C, respectively.

Behavioral and Physiological Observations

Ants were individually marked with dots of enamel paint on their gaster. To characterize dominance hierarchies, each dequeened group was observed at a rate of 10 hr/wk for several weeks, until more than 200 antennal boxing behaviors were observed (approximately 80 hr of observation). Antennal boxing is a ritualized behavior characteristic of dominance relationships between ants (Ito and Higashi, 1991; Heinze et al., 1996; Cuvillier-Hot et al., 2004a), during which a dominant worker makes a rapid lunge for a subordinate worker and aggressively pummels its head with the vibrating antenna. The frequency of antennal boxing varies considerably among groups, but is the most conspicuous and frequent dominance interaction in many ant species, and particularly in *P. goeldii*. It is the only quantifiable behavioral expression of dominance available to the observer. We recorded all antennal boxing behaviors (the only type of aggression observed), and workers were ranked according to the proportion of workers they dominated.

At the end of the period of behavioral observation, we dissected all surviving workers (102 ants). We noted the number of developing ovarioles for each individual. An ovariole was considered as developed if it contained at least one oocyte >0.5 mm. Pearson's correlation coefficient (see below) was computed between worker rank and the number of developing ovarioles for each of the eight dequeened groups. Individuals were assigned to three ovarian developmental classes: (1) undeveloped ovaries (no developing ovarioles); (2) moderately developed ovaries (between one and four developing ovarioles); (3) fully

developed ovaries (more than five developing ovarioles). Workers of *P. goeldii* normally have eight ovarioles.

Extraction and Analysis of Hydrocarbons from the Cuticle and Postpharyngeal Gland

Hydrocarbons extraction was performed on the two highest, the two lowest, and the two middle ranking workers in each group from colonies A and C, and three workers of each rank class in each group from colony B, giving a total of 54 individuals with 18 of each rank class. For each individual, the thorax and PPG were each soaked in 50 μl pentane with 1.5 μg *n*-nonadecane as an internal standard. Thoraces were removed after 10 min, and PPG were left in the tube. The relative proportions of cuticular hydrocarbons in ants can differ among body parts (Bonavita-Cougourdan et al., 1993). We chose the thorax instead of other body parts to characterize the individual odor because previous observations revealed that antennal boxing was elicited when the antennae of the focal individual touched the head or the thorax, but never the abdomen, of another ant. Furthermore, we needed the head to extract the PPG. Moreover, the abdomen is rich in chemical-producing glands that could have contaminated extracts of individual odor. Five μl of each sample were analyzed by gas chromatography with flame ionization detection (GC-FID) on a Varian 3900 (Varian, Palo Alto, CA, USA) instrument equipped with a split/splitless injector and a DB-5 fused silica capillary column (30 m \times 0.32 mm, 0.25 μm film thickness; J&W scientific column, Agilent Technologies, Palo Alto, CA, USA) with helium as carrier gas at a flow rate of 28.57 cm/sec. The temperature was maintained at 100°C for 5 min, with the split valve closed for the same interval. Next, the temperature was raised at 3°C/min to 300°C, and held constant for 10 min. In pilot tests, we could not detect additional compounds when the temperature was raised to 320°C instead of 300°C. The injector port was maintained at 200°C, and the FID was kept at 320°C. Peak areas were computed with Varian system control (version 6.20). Identification of hydrocarbons was performed on 30 workers from three orphaned colonies by GC/MS (VGM250Q) with a DB-5 fused silica capillary column (30 m \times 0.32 mm, 0.25 μm film thickness; J&W scientific column, Agilent). The temperature program was 120°C to 270°C at 5°C/min with a hold at 270°C for 30 min, and then heated to 295°C at 20°C/min with helium as the carrier gas at a flow rate of 28.57 cm/sec, the injector port was kept at 200°C. The mass spectrometer detector was a Fisons MD 800 (Foremost Equipment, Rochester, NY, USA) operated at 70 eV. The eluting hydrocarbons were identified by their fragmentation patterns.

Data Analysis

Compounds that were not present in all three colonies were excluded from the analysis. Four of the remaining compounds that were present on the cuticle but absent from the PPG were excluded: two of them were volatile (*n*-pentadecane and *x*-pentadecene), and two occurred irregularly (they were displayed by a few individuals and were not related to colony or ovarian development, suggesting they that were contaminants). Peak areas were transformed according to $Z = \ln[A_p/g(A_p)]$, where Z is the standardized peak area, A_p is the peak area, and $g(A_p)$ is the geometric mean of all peak areas in the respective individual (Aitchison, 1986), in order to correct for the high dependence of this type of data. However, the compounds were still too redundant to allow a discriminant analysis (DA) to be performed. We computed the correlation matrix and removed the compound that had the highest mean coefficient of correlation (*x,y*-tricosadiene; mean coefficient of correlation \pm SD: 0.49 \pm 0.2). This compound also had the highest number of significant correlations (17

out of the 19 coefficients of correlation computed). Thus, a total of 19 peaks were retained for the analysis.

Statistical analyses were performed with Statistica 6 software (Statsoft France 2003, Maisons-Alfort, Val-de-Marne, France), and standard DAs were performed on the standardized peak areas of hydrocarbons from cuticle and PPG to determine whether variation in hydrocarbons allows discrimination among individuals according to their colony of origin and ovarian development. For each compound, we computed the Pearson's correlation coefficient between standardized peak areas from cuticle and PPG profiles. A stepwise DA was performed on cuticular profiles to identify which combination of compounds allowed the best discrimination among ovarian development classes; at each step, the least discriminating compound was removed and a new DA was performed until only one compound remained. Thus, we obtained 18 DA models. Potential for discrimination was evaluated by the percentage of correct classifications under each model, and then, by their P value. The best model was selected. We then compared the values of

Fig. 1 Correlation between rank of worker and number of developed ovarioles in workers from each of eight queenless groups of *Pachycondyla goeldii*

the Pearson's correlation coefficient (see above) among the compounds included in and excluded from the model, by using a Mann-Whitney test. A new DA was performed with the compounds included in the model to see whether these compounds allowed us to discriminate colonies. Another DA was performed with these compounds in the PPG to test whether they allowed us to discriminate between ovarian classes in this gland. Finally, four principal component analyses (PCA) were computed with the cuticular compounds from the model: one with workers from all colonies to check whether these compounds differentiated colonies, and one with workers from each of the three colonies to test whether they differentiated ovarian development.

Results

Behavior and Ovarian Development

Each group displayed agonistic behaviors (mean \pm SE: 237.62 \pm 14.11 over 35–68 d) and showed a significant correlation between ovarian development and rank (Figure 1). High-ranking individuals had more developed ovarioles.

Hydrocarbon Analysis

The hydrocarbons identified from the three colonies ranged from C₁₅ to C₂₉ in chain length and were *n*-alkanes, alkenes, and alkadienes (Table 1). Cuticular and PPG hydrocarbon profiles of *P. goeldii* lacked methyl branched alkanes. Among the hydrocarbons, the relative quantities of linear *n*-alkanes showed less correlation between the thoracic cuticle and PPG (Table 2). Moreover, for each colony, we found that each linear *n*-alkane that we identified was present in a higher proportion on the thoracic cuticle than in the PPG (Table 1).

Chemical analysis of the thoraces revealed that the hydrocarbon phenotypes of the colonies were qualitatively similar: 82.75% (*N* = 29) of the hydrocarbons detected were present in all three colonies. Only five compounds did not occur in all three colonies. *x*-Tetracosene, *y*-pentacosene, *y*-heptacosene, and *x*-nonacosene were detected only in colony B, whereas *x*-hexacosene was detected in colonies B and C. Those compounds may have been present in the other colonies, but our analysis did not detect them. For each colony, the cumulative relative proportion of these five hydrocarbons was small (mean % over workers ± SD: 0.00 ± 0.00, 4.52 ± 2.99, and 0.56 ± 0.46 for colony A, B, and C, respectively). Two compounds were abundant on thoracic cuticle: *n*-tricosane and *x*-pentacosene represented more than 40% of total hydrocarbon (Table 1).

The qualitative hydrocarbon content of the PPG was similar among colonies: 90.90% (*N* = 22) of the compounds were present in all three colonies. *y*-Heptacosene and *x*-nonacosene occurred only in PPG from colony B but represented only 0.50 ± 0.62% (mean ± SD) of the total amount of hydrocarbons. All compounds from the PPG were also detected on the cuticle. The two most abundant hydrocarbons from the cuticle, *n*-tricosane and *x*-pentacosene, were also the most abundant in the PPG (they also represented more than 40% of the total).

^aHydrocarbon names in italics represents compounds that when included in the model allowed the best discrimination among ovarian development classes.

Discriminant Analysis

Discriminant analyses were performed on all compounds of cuticular and PPG hydrocarbon profiles (19 variables; Figure 2, Table 2). They showed a clear discrimination among colonies on cuticular (Figure 3A; $F_{(38,66)} = 83$, $P < 0.001$; 100% of all the individuals are correctly classified) and PPG profiles (Figure 3B; $F_{(38,66)} = 4$, $P < 0.001$; 91% of all the individuals are correctly classified). However, DAs on all variables did not discriminate

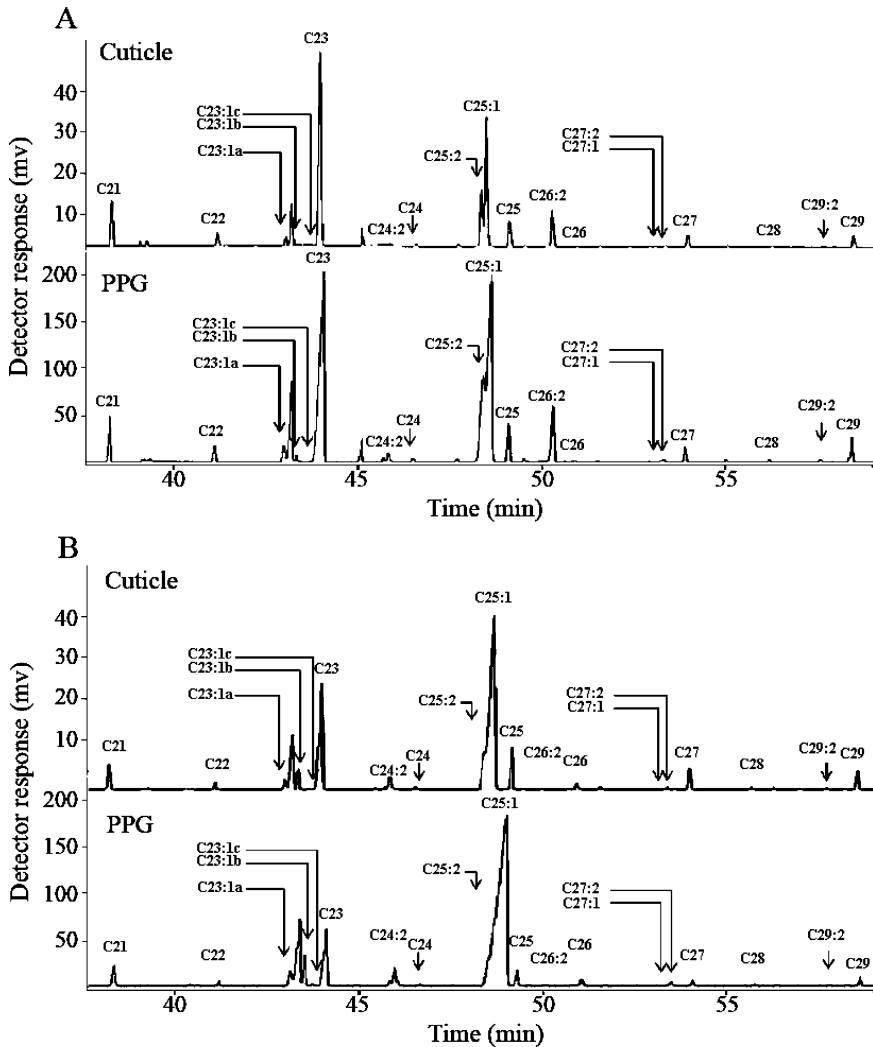

Fig. 2 Total ion chromatograms of cuticular and PPG hydrocarbons extracted from a worker of *P. goeldii* with fully developed (A) and undeveloped (B) ovaries. C21 = *n*-heneicosane; C22 = *n*-docosane; C23:1a = *x*-tricosene; C23:1b = *y*-tricosene; C23:1c = *z*-tricosene; C23 = *n*-tricosane; C24:2 = *x,y*-tetracosadiene; C24 = *n*-tetracosane; C25:2 = *x,y*-pentacosadiene; C25:1a = *x*-pentacosene; C25 = *n*-pentacosane; C26:2 = *x,y*-hexacosadiene; C26 = *n*-hexacosane; C27:1 = *x*-heptacosene; C27:2 = *x,y*-heptacosadiene; C27 = *n*-heptacosane; C28 = *n*-octacosane; C29:2 = *x,y*-nonacosadiene; C29 = *n*-nonacosane. The prefixes *x*, *y*, and *z* indicate different and undetermined positions of the double bond

among classes of ovarian development (cuticle: $F_{(38,66)} = 1.5$, $P = 0.063$; PPG: $F_{(38,66)} = 1$, $P > 0.05$), indicating that the fertility signal is likely encoded in only a subset of compounds. Thirteen compounds out of 19 were significantly correlated between cuticle and PPG (Table 2).

To identify the substances with the highest discriminatory power, we conducted a stepwise DA on cuticular profiles. Out of the 18 models, the one containing 11 compounds was the best for discriminating among the classes of ovarian development (Table 3). The 11 compounds retained in the model have correlation coefficients between cuticle and PPG that are significantly greater than the eight compounds excluded from the model (Table 2, $U = 20$, $P = 0.047$), suggesting that these 11 compounds are also involved in the colony identity signal. Standard DA on cuticular profiles of these 11 compounds allowed us to discriminate among classes of ovarian development ($F_{(22,82)} = 2.9$, $P < 0.001$; 78% of all the individuals are correctly classified). The three classes of ovarian development were segregated (Figure 4; 1: undeveloped ovaries, 2: moderately developed ovaries, 3: fully developed ovaries; Mahalanobis distances, 1–3 = 7.2, $F_{(11,42)} = 4.2$, $P < 0.001$; 1–2 = 3, $F_{(11,42)} = 2.3$, $P = 0.03$; 2–3 = 5.1, $F_{(11,42)} = 2.6$, $P = 0.01$). Moreover, this DA model correctly classified 92% of the individuals with undeveloped ovaries, 59% of the individuals with moderately developed ovaries, and 75% of the individuals with fully developed ovaries. The “moderately developed ovaries” class is intermediate between the two other classes, and this explains this class’s relatively low percentage of correct classification. The standard DA on the 11 compounds discriminated among colonies as well ($F_{(22,88)} = 88$, $P < 0.001$; 100% of all the individuals are correctly classified). However, the standard DA on the 11 compounds in the PPG did not discriminate among classes of ovarian development ($F_{(22,82)} = 1.2$, $P > 0.05$).

Principal Component Analyses

A PCA on the 11 cuticular hydrocarbons of workers from all colonies showed a distinction among the three colonies (Figure 5A). The first two factors explained a high proportion of the variance (60.29%). Factor 1 differentiated colonies A and C from colony B, and factor 2 differentiated colonies A and B from colony C. Principal component analyses on each colony illustrated the differentiation between workers with fully developed and undevel-

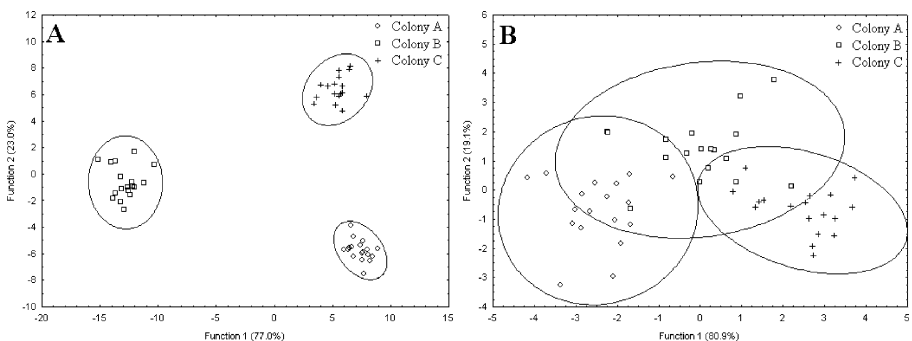

Fig. 3 Discriminant analysis of the cuticular (A) and PPG (B) hydrocarbon profiles from three colonies of *Pachycondyla goeldii* ($N = 18$ for each colony). Ellipses represent 95% confidence limits. The percentages of variance explained by each of the two factors are provided parenthetically

Discussion

In the ant *P. goeldii*, the patterns of cuticular and PPG hydrocarbons vary strongly among colonies, and many compounds are correlated between the cuticle and the PPG. However, ovarian development in workers from queenless groups were best discriminated on the basis of 11 cuticular hydrocarbons. These compounds still allow a clear discrimination between colonies. Moreover, these compounds are among the most correlated between cuticle and PPG. Thus, workers bear two signals—colonial identity and reproductive state—on their cuticle. A striking result is that the two signals can be potentially conveyed by the same set of compounds. Although this insights may lead to a new understanding of ant communication, our results are purely correlational at this point. Indeed, we still need to prove that the ants actually perceive and react to these signals.

Numerous studies have suggested the importance of hydrocarbons in nestmate recognition (Vander Meer and Morel, 1998; Lenoir et al., 1999; Ozaki et al., 2005). They have shown that workers from the same colony present a similar hydrocarbon pattern on their cuticle, which is considered to be a colonial signature (Bonavita-Cougourdan et al., 1987; Vander Meer and Morel, 1998). According to Gestalt theory (Crozier and Dix, 1979), nestmates blend their hydrocarbons to form a common colonial odor. The hydrocarbons involved in nestmate discrimination appear to be mixed in the PPG (Meskali et al., 1995; Lenoir et al., 1999; Soroker et al., 2003; Lucas et al., 2004), consequently the hydrocarbon

content of the PPG should more or less match the cuticular profile. In our focal species, we observed that two-thirds of the compounds have relative proportions that are significantly correlated between PPG and cuticle. Moreover, colonies could be discriminated on the basis of all hydrocarbons from both cuticle and PPG, providing arguments in favor of the Gestalt model of nestmate discrimination in *P. goeldii*. However, one-third of the compounds was not correlated between PPG and cuticle. A probable reason is that they are involved in preventing desiccation, the primary function of the cuticular hydrocarbons in insects. The higher the melting point of a hydrocarbon, the better its capacity to prevent water loss. At a given chain length, linear *n*-alkanes are better candidates for this function than alkenes (Hadley, 1994). We observed in our study that linear *n*-alkanes tended to have a low correlation between PPG and cuticle. A surprising result was the absence of methyl branched alkanes in the *P. goeldii* profiles. This class of hydrocarbons is common on the cuticle of other ants, and we do not know why they do not occur in our focal species.

In addition to conveying information about colonial identity, the cuticular hydrocarbons of queenless *P. goeldii* workers bear another signal: 11 compounds allow discrimination of ovarian development classes, suggesting a chemical signal of fertility that could allow subordinates to recognize breeders. Several studies have shown that fertility signals in social Hymenoptera can be conveyed by cuticular hydrocarbons. However, the quality and quantities of compounds potentially involved vary across species. In some species, the signal can be composed of few compounds. This is the case in the ants *Dinoponera quadriceps* (Monnin et al., 1998; Peeters et al., 1999), *H. saltator* (Liebig et al., 2000), *Myrmecia gulosa* (Dietemann et al., 2003), and *Pachycondylainversa* (Heinze et al., 2002). In contrast, in the ants *Diacamma ceylonense* (Cuvillier-Hot et al., 2001), *Streblognathus peetersi* (Cuvillier-Hot et al., 2004a), and *Formica fusca* (Hannonen et al., 2002), the signal varied in multiple hydrocarbons. In *P. goeldii*, the optimal signal is composed of 11 compounds. Thus, even within the same genus, species may display different signals. Our data suggest that this signal has a different nature in *P. goeldii* than in the other species studied to date. We could not identify a single or a few compounds that were simply more abundant on individuals with more developed ovaries, but we identified a group of compounds whose relative proportions were characteristic of the degree of ovarian development. The fertility signal could thus be potentially more complex than previously thought. These studies draw some correlation between cuticular hydrocarbons and fertility. However, we do not know, except in a few cases (Dietemann et al., 2003; D'ettore et al., 2004), whether the ants perceive these compounds, and, assuming they do, whether they use the entire signal. Future investigations should address these possibilities.

Cuticular hydrocarbons are known to vary according to colony, reproductive status, age, and caste (Hölldobler and Wilson 1990; Peeters et al., 1999; Kaib et al., 2000; Cuvillier-Hot et al., 2001). Thus, the same channel can convey various types of information. It is unknown, however, whether the same chemicals are involved in the different signals. As the cuticle bears many compounds, we might expect different signals to be conveyed by different hydrocarbons. However, we found that the cuticular hydrocarbons responsible for the best discrimination among ovarian development classes also yielded a clear discrimination among colonies and had significantly higher correlation coefficients between cuticle and PPG than the other hydrocarbons. This suggests that these compounds are among the most important for colonial identity. Our interpretation is that the two signals, colony identity and reproductive status, can be potentially conveyed by the same compounds. Moreover, in addition to a sharp difference between colonies, there is a fine-tuned variation accounting for ovarian development. Two facts explain the high correlation between the relative proportions of compounds in the PPG and in the cuticle: the PPG is

involved in the formation of the colony identity signal displayed on the cuticle, and this signal is different among colonies. Variations in cuticular hydrocarbons related to fertility are much weaker. Thus, even if they do not occur in the PPG, these variations have little influence on the correlation between PPG and cuticle.

If colony identity and fertility signals are conveyed through the same compounds, one signal must be shared between nestmates and the other must remain individual. Body contacts and nestmates grooming (and trophallaxis in some species) lead to the homogenization of the cuticular and PPG hydrocarbons within the colony (Soroker et al., 1994, 1998). The presumed function of the PPG is to store a blend of hydrocarbons from all the nestmates that can be more easily spread on the cuticle. To remain individual-specific, the fertility signal must not be involved in this circulation scheme. Therefore, the PPG should not contain this signal. Indeed, our analysis of the PPG showed that the 11 compounds that allow for discrimination of reproductive status on the cuticle do not do so in the PPG. In contrast, Dietemann et al. (2003) showed that workers of the ant *M. gulosa* discriminate between the PPG hydrocarbons of reproductive and nonreproductive workers. Their results suggest that the fertility signal follows the same pathway as the colony identity signal, i.e., through the PPG. The two signals should then be made of different compounds. The model we propose in *P. goeldii* is not a general one, and more information is needed in other species to draw broader conclusions. How is the fertility signal of *P. goeldii* prevented from being in the PPG? Our results suggest that the hydrocarbons are transferred from the PPG to the cuticle and not in the opposite direction. How does the fertility signal persist after the spread of compounds from the PPG then? The fine-tuned variation responsible for the discrimination between ovarian development classes seems to be superimposed on the colony identity signal on the cuticle. The hydrocarbons displayed on the cuticle would result from two different regulating pathways: one responsible for the colonial identity signal involving the PPG, and another responsible for the fertility signal, perhaps involving the gaster.

One way the hydrocarbon pathways of the colony identity and the fertility signal could be kept separate is by lipophorin, the internal hydrocarbon carrier. This molecule is known to bind hydrocarbons relatively unselectively, but the unloading mechanism might depend on body tissue and on the hydrocarbon transported, and thus provide target tissue specificity (Schal et al., 1998, 2001). The unloading of the compounds that are involved in colony identity and the fertility signal could be slightly different between the PPG and the cuticle. Thus, because of differences in biosynthesis, the relative proportions of these compounds would be roughly similar between PPG and cuticle, accounting for the colony identity signal, but the slightly different unloading specificity close to the cuticle would account for the fertility signal, only present on the cuticle. The frequent hydrocarbon exchanges between PPG and cuticle and between nestmates would dilute the fertility signal, which would, therefore, have to be updated continuously. This could be achieved through the tissue-specific loading/unloading mechanism of hydrocarbons on the lipophorin. A strongly marked difference between PPG and cuticle in the unloading mechanism of certain hydrocarbons could explain the fact that some of them have relative proportions that are not correlated between these two body sites. Hydrocarbons whose function is to prevent desiccation would thus only be displayed on the cuticle.

Our results suggest that there is a functional relationship between the PPG and the cuticular hydrocarbons involved in the colonial odor, but that the fertility signal remains independent of the PPG. Each ant can display two signals at the same time and with the same compounds, a rough signal of colony identity that is common to all nestmates, and a fine-tuned individual signal of fertility. However, it remains to be seen whether the fine-

tuned variation that allowed us to discriminate between classes of ovarian development is perceived as a fertility signal by ants.

Acknowledgments We are grateful to Pr. A. Hefetz for identification of hydrocarbons by GC/MS and to Jeremy Bono for correcting the English text. The experiments were conducted in accordance with the current laws of France to the best of the authors' knowledge.

Abstract The cranberry root grub *Lichnanthe vulpina* (Hentz) (Coleoptera: Glaphyridae) is a pest of cranberries in Massachusetts, reducing yield and vine density. (*Z*)-7-Hexadecenol and (*Z*)-7-hexadecenal were identified from the female effluvia collection by gas chromatographic–electroantennographic detection and gas chromatography–mass spectrometry. The double-bond position was confirmed by dimethyl disulfide derivatization. Both compounds were tested in the field, each alone and as blends of the two. Each compound alone captured males; however, (*Z*)-7-hexadecenol alone captured significantly more males than did (*Z*)-7-hexadecenal alone. The addition of varying amounts of (*Z*)-7-hexadecenal to (*Z*)-7-hexadecenol did not statistically affect male capture. Flight activity of the cranberry root grub may be monitored with traps baited with rubber septa containing 300 µg of (*Z*)-7-hexadecenol. A test of trap vane colors indicated that traps with green or black vanes maximized target male catch while minimizing nontarget catch of important cranberry pollinators.

Keywords (*Z*)-7-Hexadecenol · (*Z*)-7-Hexadecenal · Gas chromatography–mass spectrometry · Electroantennogram · Scarab beetle · Glaphyridae

*Deceased May 15, 2001. He is dearly missed by his family, friends, and colleagues.

Introduction

The cranberry root grub (CRG) *Lichnanthe vulpina* (Hentz) (Coleoptera: Glaphyridae) is a native scarab beetle species whose immature stages have a long history as root-feeding pests of cranberry beds in Massachusetts, first being reported in 1911 (Franklin, 1950). Dunn and Averill (1996) found that of the 38 Massachusetts cranberry beds sampled, 61% were infested with CRG larvae. Currently, the only control strategy for the CRG is renovation. Bog renovation, the removal and disposal of the top 25–30 cm of the bog (including the cranberry plants and associated CRG larvae), is an extreme and expensive solution for a problem that may eventually recur. The identification and commercial availability of the CRG sex pheromone of this species could provide a useful tool for monitoring or managing this pest.

The objective of this study was to identify the sex pheromone of *L. vulpina* as well as to determine a trap color that would maximize target capture while minimizing capture of honeybees and bumblebees, important pollinators of cranberries.

For more information on the taxonomy, behavior, and distribution of the *Lichnanthe*, see Westcott (1976), Carlson (1980), and O'Donnell (1996).

Methods and Materials

Pheromone Collections

Third instar larvae of CRG were collected in mid-April by digging them from the soil in an infested cranberry bog in Carver, MA. Recovered larvae were kept individually in ~30-ml plastic cups in a 3:1 mix of greenhouse sand and screened peat moss raised to ca. 12% moisture. They were housed in a controlled environment room at 25°C during the 16-hr photophase and 20°C during the 8-hr scotophase. After pupation and adult emergence, individuals were separated by sex, and up to 15 females were placed together in an all-glass collection vessel during the photophase because the species is diurnal (Zhang et al., 1994; O'Donnell, 1996). Twelve female collections were made during the course of the study. During the photophase, pump-drawn air was filtered through charcoal, bubbled through distilled water, passed over and among the females, and finally through a glass tube filled with adsorbent Super Q polymer material (Alltech, Deerfield, IL, USA). Volatiles were eluted from the Super Q using ca. 2 ml of dichloromethane before condensing under a nitrogen stream to a volume of ca. 20 μ l.

Instrumentation

The coupled gas chromatograph–electroantennogram detector (GC-EAD) system used was as previously described in Zhang et al. (1997, 1999, 2003). A Hewlett Packard (HP) 5880 gas chromatograph equipped with a 30 m \times 0.25 mm ID, 0.25- μ m film-thickness nonpolar SE-30 capillary column (Alltech Associates) in the splitless mode with nitrogen as carrier was used for GC-EAD analysis (150°C for 2 min, then programmed to 250°C at 10°C/min and held for 25 min) or a 30 m \times 0.25 mm ID, 0.25- μ m film-thickness polar Stabilwax capillary column (Restek Corp., 150°C for 2 min, then programmed to 220°C at 10°C/min and held for 25 min). The capillary column effluent and nitrogen makeup gas (10 ml/min) were split (~1:1) by a Y GlasSeal capillary column connector (Supelco, Inc.) to the flame ionization detector (FID) and EAD. After removing an antenna from the beetle, one lamella

tip and the scape were positioned between two gold wire electrodes, which were immersed in saline-filled (0.9% NaCl) wells in a small acrylic plastic holder. This holder held the antennal club open, exposing the sensilla to the airstream (see photo in Robbins et al., 2003). The output recording electrodes were connected to a high-impedance 1:100 amplifier with automatic baseline drift compensation. The airstream flowing over the antennae (about 500 ml/min) was humidified by bubbling through distilled water before entering the EAD interface. The antennal preparation was cooled to ~5°C inside a condenser by circulating near 0°C water from a bench-top refrigeration unit (RTE-100, NESLAB instruments, Inc., Portsmouth, NH, USA) through the insulation layer of the modified condenser containing the acrylic plastic holder mounted on top of the GC. An HP 3390A integrator was used for EAD recording.

Electronic impact gas chromatography–mass spectrometry (GC-MS) was conducted on an HP 5890 GC coupled to an HP 5970B mass selective detector using an identical SE-30 capillary column [150°C for 2 min, then programmed to 250°C at 10°C/min and held for 25 min for regular analysis; 180°C for 2 min, then programmed to 230°C at 15°C/min and held for 50 min for analysis of dimethyl disulfide (DMDS) adducts] or a DB-5 capillary column (60 m × 0.25 mm ID, 0.25- μ m film thickness, J&W Scientific Inc.; 50°C for 2 min, then programmed to 300°C at 15°C/min and held for 50 min) but with helium as carrier gas. A 70-eV electron beam was employed for sample ionization.

Chemicals

Synthetic (*Z*)-7-hexadecenol (Z7-16:OH) and (*Z*)-7-hexadecenal (Z7-16:Ald) were purchased from Pheromone Bank, Wageningen, The Netherlands. Purities of the chemicals, as determined on 30-m polar Stabilwax and nonpolar SE-30 GC capillary columns, were > 98%.

Microderivatization

Dimethyl disulfide derivatives of extracts and synthetic standards were prepared according to standard procedures (Buser et al., 1983; Dunkelblum et al., 1985). Dichloromethane solutions of effluvia extracts or hexane solutions of synthetic monounsaturated standards (10 μ l, 20 ng/ μ l) were treated with 50 μ l of DMDS (Aldrich Chem. Co., 99+%) and one drop of an iodine solution (60 mg/ml diethyl ether). The mixtures were kept at 60°C for 4 hr. After cooling to room temperature, one drop of 5% aqueous sodium thiosulfate (Na₂S₂O₃) was added, and the solutions were shaken vigorously to reduce the iodine. The organic phase was removed, and the aqueous phase was extracted with 100 μ l hexane. The combined extracts were then dried over anhydrous sodium sulfate (Na₂SO₄) and concentrated to ~20 μ l under nitrogen for GC-MS analysis.

The effluvia collection, synthetic Z7-16:OH, and synthetic Z7-16:Ald (30 ng in hexane) were each treated separately in a conical glass vial with 5 μ l of acetic anhydride–pyridine (10:1, v/v), sealed with a Teflon lined screw cap, and heated at 40°C in a GC oven for 30 min. After 1 μ l water was added to destroy the excess anhydride, the organic layer was removed for GC-MS analysis.

Field Evaluation of Synthetic Lures

The following protocol was used for field testing in all years. Lures were formulated by dissolving Z7-16:OH and Z7-16:Ald in hexane, dispensing appropriate amounts into

5-mm rubber stopper septa (Thomas Scientific, Swedesboro, NJ, USA), and allowing the hexane to evaporate in a fume hood. Lures were deployed in the field in cross-vane traps. Traps were placed ca. 20 m apart along the cranberry bog edge and were randomized at deployment. The bottom of the trap was hung ca. 60 cm from the ground. Dates in parentheses at the end of each section indicate the dates that the traps were checked and rerandomized.

Effect of Different Proportions of the Pheromone Constituents on CRG Trap Catches

In 1999, treatments tested in the field included eight blends of Z7-16:OH and Z7-16:Ald at a dose of 1000 $\mu\text{g}/\text{septa}$ in the ratios of 100:0, 90:10, 80:20, 60:40, 40:60, 20:80, 10:90, and 0:100 and a solvent-only control treatment. One set of the nine treatments was deployed at each of three Massachusetts cranberry bogs during the flight period in July (July 6–13, 15, 16, and 19).

Effect of Different Doses of a 90:10 Blend of the Alcohol and Aldehyde on Trap Catches

In 2000, a test was deployed to compare doses of a 90:10 blend of Z7-16:OH and Z7-16:Ald. The doses included 100, 300, 600, and 1000 $\mu\text{g}/\text{septa}$ and a solvent-only control septa. One set of five treatments was deployed at each of four Massachusetts cranberry bogs during the flight period in July (July 3–9, 14, 18, and 25).

Effect of Trap Vane Color on CRG and Nontarget Insect Catches

A test was deployed in 2000 to test the effect of vane color on CRG adult male catch and honeybee and bumblebee catches. Honeybee and bumblebee catches are of concern to growers because they are essential for crop pollination. This test was conducted to determine a color that would maximize CRG male catches while reducing bee catches. All traps were baited with lures consisting of a 90:10 blend of Z7-16:OH and Z7-16:Ald at a dose of 1000 $\mu\text{g}/\text{septa}$. Vanes for the lab-constructed cross-vane traps were fabricated from 4-mm corrugated plastic of six different colors (white, red, yellow, blue, black, and green) purchased from KIVA Container Corporation, Taylors, SC, USA. One set of six treatments was deployed at each of four Massachusetts cranberry bogs during the flight period in July (July 3–9, 14, 18, and 25).

Effect of the Presence of Different Amounts of the Aldehyde on the Optimum Dose of the Alcohol on Male Catches

In 2004, a test was deployed to compare male CRG capture when various amounts of Z7-16:Ald were added to 1000- μg doses of Z7-16:OH. This test was initiated because the results of the 1999 test (see Fig. 2) did not resolve the role of Z7-16:Ald in male capture. The six treatments tested included 1000 μg of Z7-16:OH alone, 1000 μg of Z7-16:OH + 10% (111 μg) of Z7-16:Ald, 1000 μg of Z7-16:OH + 20% (250 μg) of Z7-16:Ald, 1000 μg of Z7-16:OH + 40% (666 μg) of Z7-16:Ald, 1000 μg of Z7-16:Ald, and a solvent-only control. One set of the six treatments was deployed at each of two Massachusetts cranberry bogs, and two sets were deployed at separate locations on a third bog during the flight period (June 28, July 1, 5, and 8).

In 2005, a test was deployed to compare male CRG capture when various amounts of Z7-16:Ald were added to 300- μg doses of Z7-16:OH. In this test, the dose of Z7-16:OH was

reduced from 1000 $\mu\text{g/septa}$ (see 2004 test above) to 300 $\mu\text{g/septa}$ to provide a more sensitive assay of male CRG response to added amounts of the Z7-16:Ald. The three treatments tested included 300 μg of Z7-16:OH alone, 300 μg of Z7-16:OH + 10% (33 μg) of Z7-16:Ald, and 300 μg of Z7-16:OH + 20% (75 μg) of Z7-16:Ald. Four sets of the three treatments were deployed at separate locations on a large Massachusetts cranberry bog during the flight period (July 3, 5, 8, 11, 16, and 19).

Fig. 1 Simultaneous EAD and FID responses of a male CRG antenna to (A) synthetic Z7-16:Ald and Z7-16:OH (10 ng, 1:3 ratio, v/v); (B) effluvia trapped from 15 virgin female CRG (3–13 days old) on an SE-30 capillary column

Statistics

Using the Levene test for homogeneity of variance, data sets were tested for homogeneity of variance and log-transformed ($x + 1$) as necessary. Data were analyzed using a one-way analysis of variance, F at $P < 0.05$, with *post hoc* comparisons using Fisher's least significant difference (LSD) test.

Results and Discussion

Pheromone Identification

Coupled GC-EAD analyses of female effluvia extracts demonstrated that male beetle antenna consistently responded to two compounds (Fig. 1B). Two EAD-active peaks from 12 female effluvia collections were observed at 10.39 and 11.14 min on a 30-m SE-30 capillary column and at 10.82 and 14.27 min on a 30-m Stabilwax column at about a 1:3 ratio. The MS of the active component corresponding to the later EAD response in the effluvia extracts exhibited a comparatively strong ion at m/z 222 (5%) as the highest mass fragment and matched spectra of monounsaturated C_{16} derivatives retrieved from the Wiley 275 mass spectral database. In addition, the MS of the earlier component showed the largest fragment at m/z 220 (3%), 2 amu less than the later compound, indicating that it could possess an additional unsaturation.

The identity of the EAD-active compounds was determined by capillary GC-MS analysis of DMDS derivatives of the female effluvia extracts. Pairs of diagnostic sulfide fragments were observed at m/z 161 (81%) and 173 (100%) with the molecular ion at m/z 334 (52%). Pairs of diagnostic fragments were also observed at m/z 159 (18%) and 173 (100%) with molecular ion at m/z 332 (44%). These observations indicated that $\Delta 7$ -16:OH and $\Delta 7$ -16:Ald, respectively, were likely candidates for the natural pheromone. The $\Delta 7$ -16:OH was also verified by a pair of diagnostic sulfide fragments observed at m/z 173 (94%)

Fig. 2 Average capture/treatment (mean \pm SE) of male CRG beetles in traps baited with various 1000- μ g blends of Z-7:16:OH and Z-7:16:Ald, 1999. Data were transformed using $\log(x + 1)$ before analysis. Bars with the same letter are not significantly different ($P < 0.05$, Fisher's LSD test)

Fig. 3 Average capture/treatment (mean ± SE) of male CRG beetles in traps baited with various doses of a 90:10 blend of Z7-16:OH and Z7-16:Ald, 2000. Data were transformed using $\log(x + 1)$ before analysis. Bars with the same letter are not significantly different ($P < 0.05$, Fisher’s LSD test)

and 203 (75%) with the molecular ion at m/z 376 (30%) from the microacetylation preparation of the female effluvia collection. To confirm the above conclusion, and to determine pheromone geometry, synthetic standards of the (*E*) and (*Z*) isomers of Δ 7-16:OH, Δ 7-16:Ald, and Δ 7-16:Ac were then subjected to the corresponding analysis. The MS spectra and GC retention times of synthetic Z7-16:OH, Z7-16:Ald, Z7-16:Ac, and their DMDS adducts were indistinguishable from those of natural products on both SE-30 and Stabilwax capillary columns. The natural pheromone in each case corresponded to the later-eluting isomers (monounsaturated C_{16} derivatives) with an SE-30 capillary column and earlier-eluting isomers (DMDS adducts) on a Stabilwax capillary column, which established

Fig. 4 Average capture/treatment (mean ± SE) of honeybees in traps of various vane colors, 2000. Bars with the same letter are not significantly different ($P < 0.05$, Fisher’s LSD test)

Fig. 5 Average capture/treatment (mean \pm SE) of bumblebees in traps of various vane colors, 2000. Data were transformed using $\log(x + 1)$ before analysis. Bars with the same letter are not significantly different ($P < 0.05$, Fisher's LSD test).

these components to be the (Z) isomers. The strong antennal responses to Z7-16:OH and Z7-16:Ald were confirmed with authentic standards (Fig. 1A).

Effect of Different Proportions of the Pheromone Constituents on CRG Trap Catches

Traps baited with Z7-16:OH only captured significantly more males than did traps baited with Z7-16:Ald. Male captures decreased steadily in response to increasing amounts of Z7-16:Ald relative to the Z7-16:OH, but in all cases, baited treatments captured more males than the control ($F_{8,18} = 8.18$; $P < 0.001$; Fig. 2).

Fig. 6 Average capture/treatment (mean \pm SE) of male CRG beetles in traps baited with blends of Z7-16:OH and Z7-16:Ald, 2004. In treatments containing Z7-16:OH, the Z7-16:OH was held constant at 1000 µg/septum. Data were transformed using $\log(x + 1)$ before analysis. Bars with the same letter are not significantly different ($P < 0.05$, Fisher's LSD test).

Effect of Different Doses of a 90:10 Blend of the Alcohol and Aldehyde on Trap Catches

Traps baited with the 100- μg dose captured a smaller number of males than did traps baited with the 300, 600, or 1000- μg doses ($F_{4,15} = 13.32$; $P < 0.001$; Fig. 3).

Effect of Trap Vane Color on CRG and Nontarget Insect Catches

In the 2000 vane color trial, color of the trap vanes did not affect the number of males captured when traps were baited with lures loaded with 1000 μg of a 90:10 ratio of Z7-16:OH and Z7-16:Ald ($F_{5,18} = 0.35$; $P = 0.87$; data not shown). However, the numbers of honeybees ($F_{5,18} = 4.67$, $P < 0.05$; Fig. 4) and bumblebees ($F_{5,18} = 11.64$, $P < 0.001$; Fig. 5) caught were affected by trap color, being captured most frequently in traps with white or blue vanes. These findings are similar to those reported for *Hoplia equina* LeConte, another scarab pest of cranberry (Weber et al., 2005). Based on the findings of these two studies, it is recommended that green or black vanes be used, thereby ensuring effective male capture while reducing the negative impact on beneficial insects.

Effect of the Presence of Different Amounts of the Aldehyde on the Optimum Dose of the Alcohol on Male Catches

In 2004, there were no significant differences among baited treatments ($F_{5,18} = 5.98$, $P < 0.05$; Fig. 6). The high averages in the treatments testing 10% Z7-16:Ald and 20% Z7-16:Ald were caused by two large capture events that grossly inflated the averages in those treatments. In 2005, there were no significant differences among the treatments ($F_{2,11} = 0.096$, $P = 0.91$; data not shown).

Although the female-produced sex pheromone of the CRG contains both Z7-16:OH and Z7-16:Ald, and each compound alone captures males, the Z7-16:Ald, when combined in various ratios with the Z7-16:OH, did not increase male capture. We conclude that although both compounds can be classified as pheromone components, Z7-16:OH alone is sufficient for monitoring or management programs.

Acknowledgments Financial support was provided by the Cape Cod Cranberry Growers Association, the Cranberry Institute, and Ocean Spray Cranberries, Inc. We thank Pam Connor, Jessica Dunn, Revel Gilmore, and Jay O'Donnell of the UMASS Cranberry Experiment Station, East Wareham, MA, and Harald Abrahamson of SUNY Cobleskill, Cobleskill, NY, for field assistance, and several cranberry growers for providing access to their premises.

Abstract The Paulownia bagworm, *Clania variegata* Snell. (Lepidoptera: Psychidae), is one of the most significant forest defoliators in China. In gas chromatographic (GC)–electroantennographic detection analyses of pheromone gland extracts of female *C. variegata* on three GC columns (DB-5, DB-23, DB-210), two compounds (**A** and **B**) elicited strong responses from male antennae. The more abundant component **B** was isolated by high-performance liquid chromatography and identified as 1-ethyl-2-methylpropyl 3,13-dimethylpentadecanoate by transesterification, GC-mass spectrometry (MS), and comparison of its spectral and GC retention characteristics with those of synthetic compounds. In field trapping experiments in China, racemic and (1*S*)-1-ethyl-2-methylpropyl 3,13-dimethylpentadecanoate [but not the (1*R*)-stereoisomer] attracted male *C. variegata*. The absolute configuration of **B** (a molecule with three chiral centers) and the structure of component **A** remain to be determined.

Introduction

The Paulownia bagworm, *Clania variegata* Snell. (Lepidoptera: Psychidae), occurs in China, Japan, Korea, Vietnam, Thailand, and India (Zhang, 1997). In China, *C. variegata* is one of the most important pest insects in managed forests. The polyphagous larvae defoliate mainly empress trees, *Paulownia* spp., and false acacia trees, *Robinia pseudacacia*, but also feed on a variety of other tree species (e.g., walnut, chestnut, ginkgo, elm, oak, mulberry, pear, peach, apple), and agricultural crops (e.g., maize, cotton, peanuts, soybean; Zhang, 1997).

Like other bagworms, *C. variegata* has an unusual life history. Upon encountering a suitable host, wind-dispersed neonate larvae envelop themselves in a self-constructed bag, which they enlarge throughout their development. Following eclosion, vermiform apterous females stay within their pupal case and await the arrival of winged males. To attract males, females release sex pheromone from a gland in the dorsal mesothorax, and expel pheromone-impregnated scales (hairs) out of the pupal case into the lower part of the bag (Zhao, 1981, 1984). Conspecific males attracted by the pheromones alight on the bag, insert their extensible abdomen through the bag into the female pupal case, and mate with the adult female.

Despite this intriguing system of sexual communication and mating, and the ecological and economic significance of bagworms, the sex pheromones of only three species of bagworms have been identified. (1*R*)-1-Methylbutyl decanoate is the major sex pheromone component of both *Thyridopteryx ephemeraeformis* (Leonhardt et al., 1983) and *Oiketicus kirbyi* (Rhainds et al., 1994). In *O. kirbyi*, the *R* but not the *S* enantiomers of 2-pentyl octanoate, 2-pentyl nonanoate, 2-hexyl decanoate, and 2-pentyl dodecanoate enhance the attractiveness of the major pheromone component (Rhainds et al., 1994). 1-Methylethyl octanoate is the main sex pheromone component of *Megalophanes viciella* in Bulgaria and Romania (Subchev et al., 2000).

Previous analyses of the major sex pheromone component of *C. variegata* by gas chromatography (GC), GC–mass spectrometry, and GC–infrared spectroscopy suggested that it was an ester with the molecular formula $C_{16}H_{33}COOC_6H_{13}$, and with a methyl branch in both the acyl and the alcohol portions (Tan et al., 1987). Here we report the identification of (1*S*)-1-ethyl-2-methylpropyl 3,13-dimethylpentadecanoate as the major component of the sex pheromone of *C. variegata*.

Methods and Materials

Experimental Insects

Late instar larvae or pupae were collected in a forest near the city of Qidong (Jiangsu Province, P. R. China) and sent under import permit from Agriculture and Agri-Food Canada (Food Production and Inspection Branch) to Simon Fraser University. They were kept in mesh cages at 24°C under a photoperiod of 13L:11D. Eclosed males were transferred to and kept individually in filter-paper-lined Petri dishes. Females were removed from their bag and pupal case, and their mesothoracic pheromone gland (plus surrounding tissue) was excised with a razor blade and extracted with hexane for 15 min.

Aliquots of one female equivalent (FE) of this extract, and other pheromone extracts previously prepared in China, were analyzed by coupled gas chromatography–electro-

antennographic detection (GC-EAD) and GC–mass spectrometry (Saturn 2000 Ion trap GC-MS), with procedures and equipment previously described in detail (Arn et al., 1975; Gries et al., 2002). To isolate the major candidate pheromone component, crude pheromone extract was fractionated by high-performance liquid chromatography (HPLC), employing a Waters LC 625 chromatograph equipped with a Waters 486 variable-wavelength UV–visible detector set at 210 nm, HP Chemstation software (Rev.A.07.01), and a reverse-phase Nova Pak[®] C₁₈ (3.9 × 300 mm) column (Waters) eluted with acetonitrile (1 ml/min).

To isolate **B** for transesterification, a pheromone gland extract from 600 female moths was evaporated to dryness, 50 μl of acetonitrile were added, and the solution was injected into the HPLC column. Eighty 0.2-min (200 μl) fractions were collected between 20 and 36 min [the elution time range (± 6 min) of synthetic esters referred to below], concentrated and analyzed by GC-MS. The three HPLC fractions (retention times: 26.8–27.4 min) containing **B** (as determined by GC-MS) were combined, extracted with pentane (500 μl), and evaporated to dryness.

Component **B** was then transesterified by adding a solution of 2 mg KOH in 100 μl methanol and keeping the sample at 40°C for 3 hr.

Syntheses

13-Methyl-1-tetradecene (1a, Fig. 1, Scheme 1). CuI (1.22 g, 6.4 mmol) in THF (150 ml) was added to a freshly prepared and cooled (−23°C) solution of isobutylmagnesium bromide [from 7.0 ml (64 mmol) of isobutyl bromide and activated Mg (3.10 g, 128 mmol)]. After 10 min stirring, 11-bromo-1-undecene (4.71 g, 20.2 mmol; Aldrich) in THF (50 ml) was slowly added. The mixture was stirred at −20°C for 30 min, then warmed to room temperature, quenched with aqueous, saturated NH₄Cl, extracted with hexane (3 × 75 ml), washed with water and brine, and dried (MgSO₄). Solvents were removed *in vacuo*. Purification by flash chromatography (hexane) afforded 13-methyl-1-tetradecene (**1a**, 3.1 g, 14.7 mmol, 73%), which had been previously characterized (Trivedi and Mamdapur, 1986).

12-Methyl-1-tetradecene (1b, Fig. 1, Scheme 1). Compound **1b** was synthesized by the same procedure (see **1a**), starting with 2-bromobutane (10.5 ml, 96 mmol), Mg (4.65 g, 191 mmol), CuI (1.82 g, 9.6 mmol) and 11-bromo-1-undecene (4.71 g, 20.2 mmol). The yield of **1b** was 3.40 g (16.2 mmol, 80%). ¹H NMR (CDCl₃): δ 0.84 (d, 3H, *J* = 6.7 Hz), 0.86 (t, 3H, *J* = 7.3 Hz), 1.19–1.42 (m, 19H), 2.04 (m, 2H), 4.93 (tdd, 1H, *J* = 1.2, 2.3, 10.2 Hz), 5.00 (tdd, 1H, *J* = 1.6, 2.3, 17.2 Hz), 5.82 (tdd, 1H, *J* = 6.7, 10.2, 17.1 Hz). ¹³C NMR (CDCl₃): δ 11.40, 19.23, 27.13, 28.98, 29.18, 29.52, 29.54, 29.65, 29.73, 30.05, 33.84, 34.43, 36.67, 114.06, 139.24. Anal. calcd. for C₁₅H₃₀ (%): C, 85.63; H, 14.37; found C, 85.82; H, 14.10.

11-Methyl-1-tetradecene (1c, Fig. 1, Scheme 1). Compound **1c** was synthesized by the same procedure (see **1a**), starting with 2-bromopentane (10 g, 66 mmol), Mg (3.17 g, 130 mmol), CuI (1.25 g, 6.6 mmol) and 10-iodo-1-decene (6.65 g, 25 mmol). The 10-iodo-1-decene was obtained in 95% yield by mesylation of 9-decen-1-ol (Aldrich) with methanesulfonyl chloride and triethylamine in dichloromethane at room temperature, and subsequent replacement of the methanesulfonate group by iodide (7 hr stirring with 5-fold excess of NaI in DMSO at 50°C). Yield of **1c** was 4.10 g (19.5 mmol, 78%). After chromatographic purification, the by-product 4,5-dimethyloctane was removed by vacuum distillation (room temperature, 1–2 mm Hg, 3 hr). ¹H NMR (CDCl₃): δ 0.84 (d, 3H, *J* = 6.6 Hz), 0.88 (t, 3H, *J* = 7.2 Hz), 1.20–1.42 (m, 19H), 2.05 (m, 2H), 4.93 (tdd, 1H, *J* = 1.2, 2.4, 10.2 Hz), 4.99 (tdd, 1H, *J* = 1.6, 2.4, 17.0 Hz), 5.82 (tdd, 1H, *J* = 6.7, 10.2, 17.0 Hz). ¹³C NMR (CDCl₃): δ 14.42, 19.67, 20.15, 27.09, 28.97, 29.19, 29.54, 29.68, 30.03, 32.50,

Fig. 1 Schemes for the syntheses of 3,12-, 3,13-, and 3,14-dimethylpentadecanoic acid methyl esters (**6a–c**), 1-ethyl-2-methylpropyl 3,13-dimethylpentadecanoate (**8**), and for the syntheses of (3*S*)-2-methyl-3-pentanol (**14**) and (3*R*)-2-methyl-3-pentanol (**15**)

33.85, 37.10, 39.44, 114.07, 139.25. Anal. calcd. for $C_{15}H_{30}$ (%): C, 85.63; H, 14.37; found C, 85.44; H, 13.99.

1,2-Epoxy-13-methyltetradecane (**2a**, Fig. 1, Scheme 1). 3-Chloroperoxybenzoic acid (12.0 g, 52 mmol, 75% pure; Aldrich) was added at 0°C in two portions to **1a** (3.10 g, 14.7 mmol) in dichloromethane (100 ml). The reaction mixture was stirred for 4 hr, warmed to room temperature, and quenched with 150 ml of 2N NaOH. The mixture was extracted with hexane (2 × 100 ml). Extracts were washed twice with water and brine, and dried ($MgSO_4$). After filtration and removal of solvents *in vacuo*, flash chromatography afforded

2.25 g (9.9 mmol, 67% yield) of 1,2-epoxy-13-methyltetradecane (**2a**) that had been previously characterized (Trivedi and Mamdapur, 1986).

1,2-Epoxy-12-methyltetradecane (2b, Fig. 1, Scheme 1). Compound **2b** was synthesized by oxidation of **1b** (3.30 g, 15.8 mmol) with 3-chloroperoxybenzoic acid (6.0 g, 26 mmol, 75% pure) under the same conditions as for **2a**. After work-up and flash chromatography, 3.55 g (99% yield) of **2b** was obtained. $^1\text{H NMR}$ (CDCl_3): δ 0.83 (d, 3H, $J = 6.5$ Hz), 0.85 (t, 3H, $J = 7.3$ Hz), 1.19–1.36 (m, 16H), 1.38–1.48 (m, 3H), 1.52 (m, 2H), 2.45 (dd, 1H, $J = 2.8, 5.1$ Hz), 2.74 (dd, 1H, $J = 4.0, 5.1$ Hz), 2.90 (ddt, 1H, $J = 2.8, 4.0, 5.7$ Hz). $^{13}\text{C NMR}$ (CDCl_3): δ 11.39, 19.20, 25.96, 27.08, 29.43, 29.47, 29.55 (2), 29.66, 29.49, 32.48, 34.37, 36.61, 47.10, 52.37. Anal. calcd. for $\text{C}_{15}\text{H}_{30}\text{O}$ (%): C, 79.58; H, 13.36; found C, 79.50; H, 13.00.

1,2-Epoxy-11-methyltetradecane (2c, Fig. 1, Scheme 1). Compound **2c** was synthesized by oxidation of **1c** (4.00 g, 19.0 mmol) with a 1.5 molar excess of 3-chloroperoxybenzoic acid under the same conditions as for **2a**. Yield of **2c** was 4.20 g (18.6 mmol, 98%). $^1\text{H NMR}$ (CDCl_3): δ 0.83 (d, 3H, $J = 6.6$ Hz), 0.87 (t, 3H, $J = 7.4$ Hz), 1.19–1.36 (m, 16H), 1.39–1.48 (m, 3H), 1.50 (m, 2H), 2.46 (dd, 1H, $J = 2.8, 5.1$ Hz), 2.74 (dd, 1H, $J = 4.0, 5.1$ Hz), 2.90 (ddt, 1H, $J = 2.8, 4.0, 5.7$ Hz). $^{13}\text{C NMR}$ (CDCl_3): δ 14.39, 19.64, 20.19, 25.96, 27.03, 29.44, 29.55, 29.58, 29.96, 32.45, 32.48, 37.09, 39.39, 47.12, 52.41. Anal. calcd. for $\text{C}_{15}\text{H}_{30}\text{O}$ (%): C, 79.58; H, 13.36; found C, 79.81; H, 12.99.

13-Methyl-2-tetradecanol (3a, Fig. 1, Scheme 1). Epoxide **2a** (2.30 g, 10.2 mmol) was slowly added to a stirred suspension of lithium aluminum hydride (LAH; 2.38 g, 70.0 mmol) in THF (150 ml). After 45 min at room temperature, the mixture, with vigorous stirring, was slowly quenched with 2N NaOH until a white precipitate formed on the flask bottom. The organic layer was decanted, the solids were washed with ether (2 \times 75 ml), and the wash was combined with the decanted solution. The mixture was stirred with anhydrous MgSO_4 , filtered, and concentrated to afford 1.70 g (7.40 mmol, 74% yield) of pure **3a**. $^1\text{H NMR}$ (CDCl_3): δ 0.85 (d, 6H, $J = 6.4$ Hz), 1.17 (d, 3H, $J = 6.4$ Hz), 1.22–1.31 (m, 16H), 1.37–1.46 (m, 4H), 1.50 (m, 1H), 3.78 (m, 1H). $^{13}\text{C NMR}$ (CDCl_3): δ 22.63 (2), 23.45, 25.76, 27.40, 27.95, 29.59, 29.61, 29.65 (2), 29.69, 29.92, 39.05, 39.38, 68.14. Anal. calcd. for $\text{C}_{15}\text{H}_{32}\text{O}$ (%): C, 78.87; H, 14.12; found C, 79.12; H, 13.96.

12-Methyl-2-tetradecanol (3b, Fig. 1, Scheme 1). Compound **3b** was obtained from **2b** (3.50 g, 15.5 mmol) by reduction with LAH (3.7 g, 109 mmol) under the same conditions as **3a**. Yield of **3b** was 2.75 g (12.0 mmol, 77%). $^1\text{H NMR}$ (CDCl_3): δ 0.82 (d, 3H, $J = 6.4$ Hz), 0.84 (t, 3H, $J = 7.3$ Hz), 1.17 (d, 3H, $J = 6.2$ Hz), 1.19–1.34 (m, 16H), 1.35–1.46 (m, 4H), 1.51 (m, 1H), 3.77 (m, 1H). $^{13}\text{C NMR}$ (CDCl_3): δ 11.38, 19.19, 23.45, 25.76, 27.08, 29.46, 29.59, 29.61, 29.63, 29.68, 29.99, 34.36, 36.61, 39.35, 68.11. Anal. calcd. for $\text{C}_{15}\text{H}_{32}\text{O}$ (%): C, 78.87; H, 14.12; found C, 78.48; H, 13.79.

11-Methyl-2-tetradecanol (3c, Fig. 1, Scheme 1). Compound **3c** was obtained from **2c** (4.10 g, 18.1 mmol) by reduction with LAH (4.0 g, 126 mmol) under the same conditions as **3a**. Yield of **3c** was 3.61 g (15.8 mmol, 87%). $^1\text{H NMR}$ (CDCl_3): δ 0.83 (d, 3H, $J = 6.6$ Hz), 0.86 (t, 3H, $J = 7.2$ Hz), 1.17 (d, 3H, $J = 6.2$ Hz), 1.19–1.48 (m, 21H), 3.78 (m, 1H). $^{13}\text{C NMR}$ (CDCl_3): δ 14.39, 19.64, 20.12, 23.45, 25.77, 27.04, 29.62, 29.63, 29.65, 29.99, 32.45, 37.06, 39.36, 39.40, 68.14. Anal. calcd. for $\text{C}_{15}\text{H}_{32}\text{O}$ (%): C, 78.87; H, 14.12; found C, 78.83; H, 13.90.

13-Methyl-2-tetradecanone (4a, Fig. 1, Scheme 1). Pyridinium chlorochromate (PCC; 2.13 g, 9.88 mmol) was added in one portion to a stirred solution of **3a** (1.50 g, 6.57 mmol) in dichloromethane (15 ml). The reaction mixture was stirred for 1 hr, then 30 ml of hexane/ether (1:1) were added. Filtering the mixture through silica (15 g) and washing the silica with hexane/ether (100 ml) afforded a clear solution of **4a**. After removal of solvents *in*

vacuo, the yield of **4a** was 1.45 g (6.40 mmol, 97%). ^1H NMR (CDCl_3): δ 0.85 (d, 6H, $J = 6.4$ Hz), 1.21–1.30 (m, 16H), 1.50 (m, 1H), 1.56 (m, 2H), 2.12 (s, 3H), 2.41 (t, 2H, $J = 7.6$ Hz). ^{13}C NMR (CDCl_3): δ 22.64 (2), 23.88, 27.39, 29.18, 29.39, 29.46, 29.59, 29.66, 29.80, 29.91, 39.05, 43.81, 209.24. Anal. calcd. for $\text{C}_{15}\text{H}_{30}\text{O}$ (%): C, 79.58; H, 13.36; found C, 79.84; H, 13.09.

12-Methyl-2-tetradecanone (4b). Compound **4b** was synthesized from **3b** (2.60 g, 11.4 mmol) and PCC (3.69 g, 17.1 mmol). Yield of **4b** was 2.51 g (11.1 mmol, 97%). ^1H NMR (CDCl_3): δ 0.82 (d, 3H, $J = 6.4$ Hz), 0.84 (t, 3H, $J = 7.3$ Hz), 1.19–1.40 (m, 17H), 1.55 (m, 2H), 2.12 (s, 3H), 2.40 (t, 2H, $J = 7.5$ Hz). ^{13}C NMR (CDCl_3): δ 11.38, 19.19, 23.84, 27.06, 29.16, 29.38, 29.45, 29.46, 29.62, 29.81, 29.96, 34.36, 36.60, 43.79, 209.32. Anal. calcd. for $\text{C}_{15}\text{H}_{30}\text{O}$ (%): C, 79.58; H, 13.36; found C, 79.89; H, 13.19.

11-Methyl-2-tetradecanone (4c, Fig. 1, Scheme 1). Compound **4c** was synthesized from **3c** (3.40 g, 14.9 mmol) and PCC (4.83 g, 22.4 mmol). The yield of **4c** was 3.30 g (14.5 mmol, 97%). ^1H NMR (CDCl_3): δ 0.82 (d, 3H, $J = 6.6$ Hz), 0.86 (t, 3H, $J = 7.2$ Hz), 1.19–1.40 (m, 17H), 1.56 (m, 2H), 2.12 (s, 3H), 2.41 (t, 2H, $J = 7.5$ Hz). ^{13}C NMR (CDCl_3): δ 14.39, 19.63, 20.11, 23.85, 27.01, 29.17, 29.39, 29.49, 29.82, 29.92, 32.44, 37.03, 39.38, 43.80, 209.35. Anal. calcd. for $\text{C}_{15}\text{H}_{30}\text{O}$ (%): C, 79.58; H, 13.36; found C, 79.31; H, 13.28.

Methyl 3,14-dimethylpentadecanoate (6a, Fig. 1, Scheme 1). Trimethyl phosphonoacetate (1.10 ml, 7.0 mmol; Aldrich) was added in one portion under argon to a stirred solution (-25°C) of lithium diisopropylamide (LDA; 8.0 mmol; Aldrich) in dry THF (120 ml). The solution was stirred 1 hr, warmed to room temperature, and **4a** (1.40 g, 6.18 mmol) in THF (10 ml) was added. The reaction mixture was refluxed for 4 hr, cooled, quenched with water (150 ml), and extracted (3×75 ml) with hexane/ether (1:1). The combined extracts were washed with water and brine, dried (MgSO_4), and concentrated. The crude mixture (**5a**, 1.3 g), containing >95% unsaturated esters ($E/Z = 3:1$, GC), was hydrogenated for 3 hr with 10% Pd/C catalyst (0.40 g) in hexane under H_2 atmosphere. Filtering and flash chromatography (60 g SiO_2 , 5% ether in hexane as eluent) afforded **6a** (1.20 g, 4.22 mmol, 68% yield based on **4a**). The overall yield of **6a** was 24%. ^1H NMR (CDCl_3): δ 0.85 (d, 6H, $J = 6.6$ Hz), 0.92 (d, 3H, $J = 6.7$ Hz), 1.21–1.32 (m, 20H), 1.51 (m, 1H), 1.94 (m, 1H), 2.10 (dd, 1H, $J = 8.2$, 14.7 Hz), 2.30 (dd, 1H, $J = 6.0$, 14.7 Hz), 3.66 (s, 3H). ^{13}C NMR (CDCl_3): δ 19.72, 22.64 (2), 26.90, 27.41, 27.96, 29.61, 29.63, 29.67, 29.70, 29.74, 29.93, 30.34, 36.72, 39.04, 41.66, 51.31, 173.80. Anal. calcd. for $\text{C}_{18}\text{H}_{36}\text{O}_2$ (%): C, 76.00; H, 12.76; found C, 75.64; H, 12.37.

Methyl 3,13-dimethylpentadecanoate (6b, Fig. 1, Scheme 1). Compound **6b** was synthesized analogous to **6a**, starting with LDA (12 mmol), trimethyl phosphonoacetate (1.45 ml, 10 mmol), and **4b** (1.90 g, 8.40 mmol). The resulting mixture of isomers was hydrogenated with 10% Pd/C catalyst (0.40 g). Yield of **6b** was 1.21 g (4.25 mmol, 51% based on **4b**). Overall yield was 30%. ^1H NMR (CDCl_3): δ 0.83 (d, 3H, $J = 6.5$ Hz), 0.84 (t, 3H, $J = 7.3$ Hz), 0.91 (d, 3H, $J = 6.7$ Hz), 1.18–1.35 (m, 21H), 1.93 (m, 1H), 2.09 (dd, 1H, $J = 8.2$, 14.7 Hz), 2.29 (dd, 1H, $J = 6.0$, 14.7 Hz), 3.65 (s, 3H). ^{13}C NMR (CDCl_3): δ 11.40 (C-15), 19.20 (Me-13), 19.72 (Me-3), 26.90, 27.10 (C-5, C-11), 29.48, 29.62, 29.64, 29.70, 29.73 (C-6 to C-10), 30.01 (C-14), 30.34 (C-3), 34.38 (C-13), 36.63 (C-12), 36.72 (C-4), 41.66 (C-2), 51.30 (OMe), 173.79 (C-1). Anal. calcd. for $\text{C}_{18}\text{H}_{36}\text{O}_2$ (%): C, 76.00; H, 12.76; found C, 75.73; H, 12.74.

Methyl 3,12-dimethylpentadecanoate (6c, Fig. 1, Scheme 1). Compound **6c** was synthesized analogous to **6a**, starting with LDA (21.4 mmol), trimethyl phosphonoacetate (2.60 ml, 18 mmol), and **4c** (3.20 g, 14.1 mmol). The resulting mixture of isomers was hydrogenated with 10% Pd/C catalyst (0.80 g). Yield of **6c** was 2.46 g (8.65 mmol, 61%

yield based on **4c**). Overall yield was 48%. ^1H NMR (CDCl_3): δ 0.83 (d, 3H, $J = 6.6$ Hz), 0.87 (t, 3H $J = 7.2$ Hz), 0.92 (d, 3H, $J = 6.7$ Hz), 1.18–1.41 (m, 21H), 1.93 (m, 1H), 2.10 (dd, 1H, $J = 8.2, 14.7$ Hz), 2.30 (dd, 1H, $J = 6.0, 14.7$ Hz), 3.66 (s, 3H). ^{13}C NMR (CDCl_3): δ 11.40, 19.65, 19.73, 20.13, 26.90, 27.06, 29.63, 29.67, 29.74, 30.03, 30.34, 32.46, 36.72, 37.07, 39.41, 41.67, 51.31, 173.80. Anal. calcd. for $\text{C}_{18}\text{H}_{36}\text{O}_2$ (%): C, 76.00; H, 12.76; found C, 75.84; H, 12.58.

3,13-Dimethylpentadecanoic acid (**7**). Ester **6b** (1.1 g) was stirred overnight in a mixture of ethylene glycol (10 ml), 95% ethanol (10 ml), and KOH (0.5 g). The mixture then was acidified with 10% HCl and extracted three times with ether. The extract was washed with H_2O and brine, dried (MgSO_4), and evaporated to afford crude acid **7** (1.0 g, 95% crude yield).

(3S)- and (3R)-2-Methyl-3-pentanol (**14** and **15**, Fig. 1, Scheme 2). 4-Methyl-1-penten-3-ol (**9**) was synthesized from propenal and isopropylmagnesium bromide (Georgoulis et al., 1984; Harayama et al., 1997). Kinetic resolution of 3.95 g of pure **9** (Martin et al., 1981) with D-(-)- and L-(+)-tartrate reagents [under argon and vigorous stirring at -25°C , racemic **9** (19.7 mmol) in CH_2Cl_2 (5 ml) and *t*-BuOOH (36.0 mmol; 3 M solution in toluene) were added to 150 ml of a solution of $\text{Ti}(\text{O}-i\text{Pr})_4$ (20 mmol) and D-(-)- or L-(+)-diisopropyl tartrate (21 mmol) in CH_2Cl_2 ; reaction mixtures were kept at -25°C for 7 d, followed by usual work-up] led to, respectively, 55% and 53% enantioselective conversion to the epoxides **10** and **12** (Jung and Jung, 1989) and alcohols **11** and **13**. The latter were separated from the epoxides by column chromatography (20% ether in pentane as eluent), and then hydrogenated with 5% Pd/C to (3*S*)- and (3*R*)-2-methyl-3-pentanol **14** and **15** (Grundon et al., 1971) in 0.5 and 0.4 g (25% and 20%) yields, respectively. The enantiomeric purity was determined by converting 10 mg of each alcohol to its corresponding lactate by overnight esterification in ether, using excess of (*S*)-lactic acid chloride in the presence of pyridine at room temperature (Slessor et al., 1985). The diastereomeric excess—monitored by GC (DB-5, 115°C isothermal)—was 98.7% for the ester derived from the *R*-alcohol, and 97.2% for the one derived from the *S*-alcohol.

1-Ethyl-2-methylpropyl 3,13-dimethylpentadecanoate (**8**) (Fig. 1, Scheme 1). A solution of acid **7** (0.5 g) in CH_2Cl_2 (5 ml) was stirred 0.5 hr with trifluoroacetic anhydride (0.45 g; Bolton et al., 1971). Then racemic 2-methyl-3-pentanol (0.2 ml) was added. After 1 hr, the mixture was diluted with ether/hexane (75 ml), washed with water and brine, dried (MgSO_4), and concentrated to yield ester **8** (0.35 g). After purification on silica gel (60 g; 5% ether in hexane as eluent), 100 mg of **8** as a mixture of four diastereomers was obtained. ^1H NMR (CDCl_3): δ ^1H : 4.68 (m, 1H), 2.31 (dd, 1H, $J = 6.1, 14.5$ Hz), 2.11 (dd, 1H, $J = 8.1, 14.5$ Hz), 1.93 (m, 1H), 1.83 (qdd, 1H, $J = 6.7, 6.7, 13.5$ Hz), 1.55 (m, 2H), 1.18–1.35 (m, 21H), 0.94 (d, 3H, $J = 6.7$ Hz), 0.83–0.90 (m, 15H). ^{13}C NMR (CDCl_3 ; carbons numbered as in Fig. 1): δ 9.87/9.88 (C-5'), 11.42 (C-15), 17.63/17.64 (C-1'), 18.59 (Me-2'), 19.22 (Me-13), 19.75/19.77 (Me-3), 23.97 (C-4'), 26.92, 27.11 (C-5, C-11), 29.49, 29.64, 29.71, 29.79 (C-6 to C-10), 30.02 (C-14), 30.39 (C-3), 30.84/30.86 (C-2'), 34.39 (C-13), 36.63 (C-12), 36.72/36.74 (C-4), 42.26 (C-2), 79.40 (C-3'), 173.33 (C-1). Spectral editing by the DEPT pulse sequence confirmed the ^{13}C peak assignments and revealed the presence of diastereomers (two signals for C-5', C-1', Me-3, C-2' and C-4, respectively). Anal. calcd. for $\text{C}_{23}\text{H}_{46}\text{O}_2$ (%): C, 77.90; H, 13.08; found C, 78.05; H, 12.91. Esterifications of acid **7** with optically active alcohols **14** and **15**, respectively, were conducted under the same conditions with comparable yields, and resulted in NMR data consistent with those of racemic ester **8**.

Methyl 3-, 4-, and 14-methylpentadecanoate standards were synthesized as described above by coupling, respectively, 2-tetradecanone, 2-methyltridecanal, and 12-methyltride-

canal with trimethyl phosphonoacetate, and by hydrogenating (H_2 and 10% Pd/C) the resulting unsaturated esters.

Field Experiments

Field experiments were conducted in forests of Yishui County (Shandong Province, P. R. China; 118.64 east longitude and 35.78 north latitude) with 18- to 25-m tall *Paulownia tomentosa* trees. Experiments employed a randomized complete block design with 7–10 replicates each. Delta-like traps were made from 2-l milk cartons (Gray et al., 1984), coated with Tanglefoot (The Tanglefoot Company, Grand Rapids, Michigan, PA, USA), and suspended from trees 15 m above ground at ~30-m spacings. Traps were baited with a gray sleeve stopper (West Pharmaceutical Services, Lionville, PA, USA) impregnated with candidate pheromone components in HPLC-grade hexane. Every day the numbers of moths captured were recorded and treatment positions were re-randomized.

Experiment 1 (6–25 June 1998) consisted of four treatments: (1) racemic 1-ethyl-2-methylpropyl 3,13-dimethylpentadecanoate (**8**) (280 μg); (2) (1*S*)-1-ethyl-2-methylpropyl 3,13-dimethylpentadecanoate (140 μg); (3) (1*R*)-1-ethyl-2-methylpropyl 3,13-dimethylpentadecanoate (140 μg); and (4) an unbaited control. Experiment 2 (31 May to 8 June 2000) tested racemic 1-ethyl-2-methylpropyl 3,13-dimethylpentadecanoate at 0, 1, 10, 100, and 1,000 μg doses. Trap catch data were subjected to nonparametric analyses of variance (Friedman's test) followed by comparison of means by the Scheffé test (Zar, 1984; SAS/STAT, 1988). In all analyses, $\alpha = 0.05$.

Results and Discussion

GC-EAD analyses of pheromone gland extracts from female *C. variegata* revealed two components (**A** and **B** in Fig. 2) that elicited strong responses from male *C. variegata*

Fig. 2 Representative recording ($N = 5$) of flame ionization detector (FID) and electroantennographic detector (EAD: male *C. variegata* antenna) responses to one female equivalent of *C. variegata* pheromone gland extract. Chromatography: DB-210 column; 100°C/1 min, 15°C/min to 180°C, then 2°C/min to 220°C; **A** = unknown; **B** = (1*S*)-1-ethyl-2-methylpropyl 3,13-dimethylpentadecanoate

antennae. Component **B** appeared to be the major candidate pheromone component because it elicited the strongest responses and occurred in quantities greater than those of **A**. In this manuscript we have focused on the structural elucidation of **B**.

Retention indices (RI, relative to alkane standards; Van den Dool and Kratz, 1963) of **B**, and intercolumn RI differentials of **B** and of known ester pheromones (Table 1), suggested that **B** had an ester functionality. Mass spectral data of **B** in electron impact (Fig. 3) and chemical ionization mode (Tan et al., 1987) supported an ester functionality and disclosed that **B** had an unusually high molecular weight (354) (Tan et al., 1987; molecular ion not visible in Fig. 3) for a (candidate) lepidopteran sex pheromone component. Based on the strong fragment ion m/z 84 (the alkyl portion of the ester), the acylium ion m/z 253, and the m/z 271 ion [the fragment formed by transfer of a hydrogen atom from the alkyl portion to the carbonyl oxygen (McLafferty and Tureček, 1993)], we hypothesized that the ester had 17 carbon atoms in the acyl portion and six carbon atoms in the alkyl portion. We thus esterified (Nieses and Steglich, 1978) heptadecanoic acid with primary, secondary, and tertiary 6-carbon alcohols, including 1-hexanol, 2-hexanol, 3-hexanol, 2-methylpentan-2-ol, 3-methylpentan-2-ol, 4-methylpentan-2-ol, 2-methylpentan-3-ol, 3-methylpentan-3-ol, 2,3-dimethylbutan-2-ol, and 3,3-dimethylbutan-2-ol (all from Sigma-Aldrich). The resulting esters, however, had RIs on all three GC columns that were 70 to 200 RI units higher than those of **B**. Considering that the RIs of methyl-branched molecules are ca. 40–70 units lower than those of straight-chain molecules (Jennings and Shibamoto, 1980), we hypothesized that the acyl portion of **B** must have at least two methyl branches. Considering further that methyl esters, unlike other alkyl esters, are most likely to reveal GC-MS fragment ions indicative of methyl-branch positions in the acyl portion (McLafferty and Tureček, 1993), we decided to isolate **B** by HPLC and to transesterify it to a methyl ester.

Table 1 Retention indices (RI) and intercolumn RI differentials of components **A** and **B** in pheromone gland extracts of female *C. variegata* and of synthetic standards

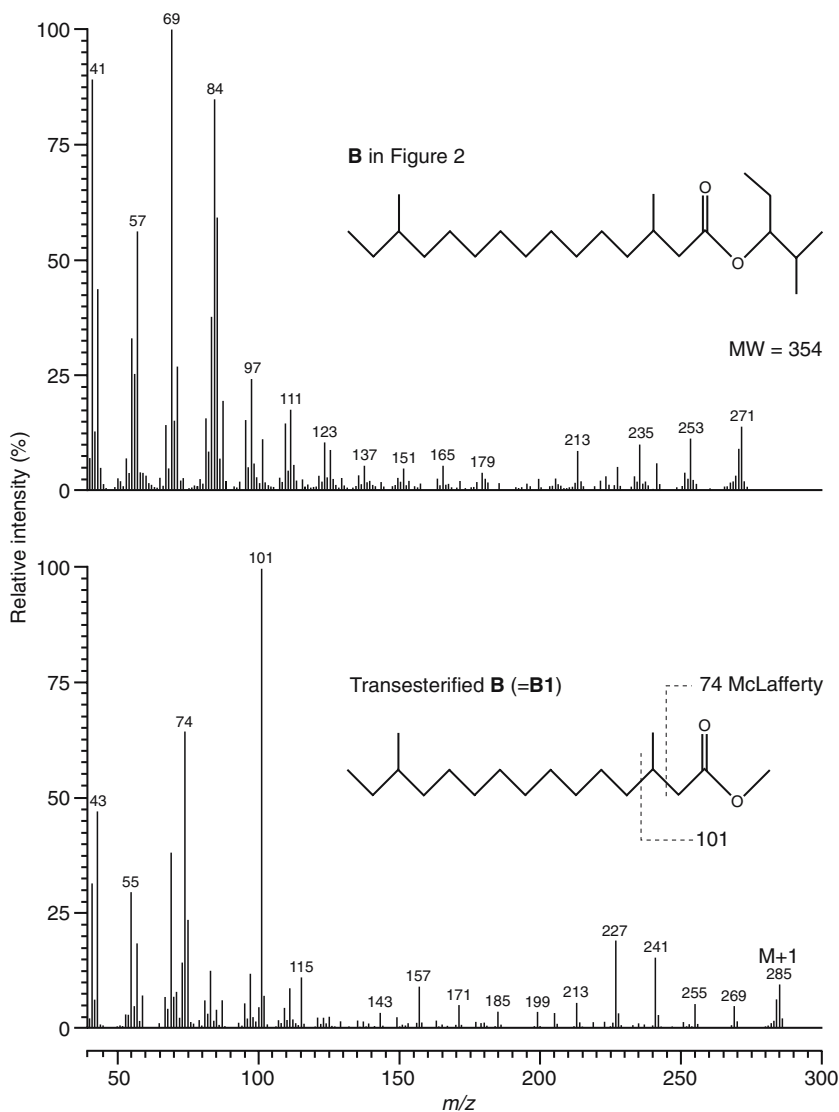

Fig. 3 Ion trap mass spectra (top) of (1*S*)-1-ethyl-2-methylpropyl 3,13-dimethylpentadecanoate (**B** in Fig. 2) from pheromone gland extracts of female *C. variegata* and (bottom) of methyl 3,13-dimethylpentadecanoate (**B1**) prepared by transesterification of HPLC-isolated **B**. Fragment ions in **B1** indicate a methyl branch at C3 in the acyl portion of the molecule

GC-MS analysis of the transesterified sample revealed **B** (75%) and a new compound (**B1**) with fragment ions m/z 74, indicative of a methyl ester, and m/z 101, indicative of a methyl branch at C3 (Fig. 3). To infer the second methyl-branch position in **B**, we synthesized and studied the mass spectra of pentadecanoic acid methyl esters with methyl branches near (e.g., C3, C4, C5) or widely separated (e.g., ω -1, ω -2, ω -3) from the carboxylate carbon. Whereas the mass spectrum of methyl 4-methylpentadecanoate indicated a methyl branch at C4 (data not shown), the mass spectrum of methyl 13-

methylpentadecanoate did not reveal the methyl branch at C13 (data not shown). Considering that the mass spectra of **B** and **B1** (Fig. 3) also did not reveal the second methyl branch position, we hypothesized that it might be at ω -1, ω -2, or ω -3.

We thus synthesized 3,12-, 3,13-, and 3,14-dimethylpentadecanoic acid and esterified each of the three acids (scheme 1 in Fig. 1) with each of ten 6-carbon alcohols (see above). Of all the resulting esters, only 1-ethyl-2-methylpropyl 3,13-dimethylpentadecanoate had mass spectral and GC retention characteristics (diastereomers not resolved on DB-5, DB-23, or DB-210 columns) entirely consistent with **B** in pheromone gland extracts. Moreover, synthetic 1-ethyl-2-methylpropyl 3,13-dimethylpentadecanoate and **B** elicited similar antennal responses from male antennae in GC-EAD analyses (data not shown). Finally, identical GC and GC-MS characteristics of methyl 3,13-dimethylpentadecanoate and of transesterified **B1** provided supporting evidence for the correct identification of **B**.

In field experiment 1, traps baited with (1*S*)-1-ethyl-2-methylpropyl 3,13-dimethylpentadecanoate attracted male moths, whereas the (1*R*)-stereoisomer was neither attractive by itself, nor did it reduce attractiveness of the (1*S*)-isomer in the racemic mixture (Fig. 4). In field experiment 2, only traps baited with the highest dose of racemic pheromone captured male moths (a total of 17).

Consistent with other psychid moths (Leonhardt et al., 1983; Rhainds et al., 1994; Subchev et al., 2000), female *C. variegata* produce an ester sex pheromone. This ester, however, has a molecular weight (MW = 354) 84–214 daltons heavier than that of pheromone components in congeners. Indeed, to our knowledge only three sex pheromone components identified to date in the Lepidoptera have higher molecular weights (Arn et al., 1992; El-Sayed 2005). (*Z,Z,Z*)-11,14,17-Icosatrienyl 4-methylvalerate (MW 390) and (*Z,Z,Z*)-11,14,17-icosatrienyl isobutyrate (MW 362) synergistically attract male *Euproctis pulverea* (Lymantriidae) (Wakamura et al., 2001), and (*Z,Z,Z,Z*)-7,13,16,19-docosatetraen-1-ol isobutyrate (MW 404) attracts male *E. chrysorrhoea* (Lymantriidae) (Leonhardt et al., 1991). Interestingly, these three pheromone components are also esters.

To fully characterize the sex pheromone blend of *C. variegata*, the molecular structure of candidate pheromone component **A** (Fig. 2) needs to be identified. Similar intercolumn RI differentials of **A** and **B** (Table 1), coupled with lower RIs of **A** than **B**, suggested that **A** might be another ester with lower molecular weight, possibly 340. Moreover, the relative and absolute configurations at the additional chiral centers C3 and C13 of the acyl portion of **B** need to be determined. Conceivably, any of the eight possible stereoisomers of **B** could be pheromone components, or pheromone inhibitors. Should the synthetic material field-

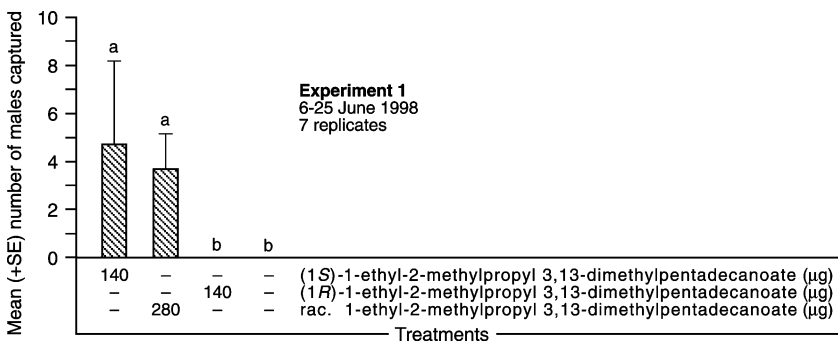

Fig. 4 Mean captures per night of male *C. variegata* in field experiment 1 in sticky traps baited with racemic or optically active candidate pheromone components, Yu Shan Forest Farm, Yu Shui County, Shandong Province, P. R. China. Bars with different letter superscripts are significantly different, $\alpha = 0.05$

tested in experiments 1 and 2 have contained one or more inhibitors, it might explain the relatively moderate trap captures. Alternatively, component **A** in Fig. 1 may be an important synergist that is required in the pheromone blend for strong attraction of male *C. variegata*.

Acknowledgments We thank Keith N. Slessor and Jianxiong Li for provision of laboratory space and contributions at a very early stage of this project, Sadao Wakamura for a reference sample, Eberhard Kiehlmann for constructive comments and critical review of the manuscript, Mei-Keng Yang for elemental analyses, Derek Vance Steel, Sharon Oliver, and Renee Picard for word processing, and Bob Birtch for graphical illustrations. Abstract Males of the parasitoid *Nasonia vitripennis* (Walker) (Hymenoptera: Pteromalidae) show a characteristic courtship behavior. We demonstrate that male arrestment and key behavioral elements of the courtship sequence are mediated by a female-derived contact sex pheromone. Males were arrested on paper disks treated with female extracts but not on those treated with male extracts. Male responsiveness was influenced by the surface to which female extracts were applied. Extracts applied to an extracted beetle elytron arrested males more strongly than those applied to filter paper of comparable size. However, more complex behavioral elements, such as head nodding and copulation attempts, were shown only when extracts were applied to extracted male cadavers, suggesting that tactile or visual cues synergize the male response. The chemicals involved are stable, of low volatility, and nonpolar. Dead females arrested males and elicited courtship behavior for at least 8 d. Males showed no sign of attraction to live females at a distance of 3 cm in an olfactometer. Fractionation of female extracts demonstrated that the activity was exclusively located in the nonpolar fraction. Analysis of the active fraction by gas chromatography–mass spectrometry revealed that cuticular hydrocarbons with chain lengths between 25 and 37 carbon units were present. Comparison of hydrocarbon profiles from males and females showed qualitative and quantitative differences. These results suggest that sex-specific cuticular hydrocarbons are the key signals mediating the male courtship behavior in *N. vitripennis*.

Introduction

Sex pheromones are assumed to play a major role in the sexual communication of parasitic wasps (Godfray, 1994; Quicke, 1997). Depending on the function of the

pheromones, the range of activity varies: highly volatile compounds released by females are used by males for long-range orientation during mate finding (Eller et al., 1984; Swedenborg and Jones, 1992a,b; Swedenborg et al., 1994; McNeil and Brodeur, 1995; Jewett and Carpenter, 1999), whereas chemicals of relatively low volatility mediate male courtship behavior at close range (Simser and Coppel, 1980; Mohamed and Coppel, 1987; Shu and Jones, 1993; Syvertsen et al., 1995; Sullivan, 2002). Sex pheromones have been demonstrated in several families of the parasitic Hymenoptera, e. g., in Braconidae, Chalcididae, and Ichneumonidae (reviewed by Kainoh, 1999). Within the Pteromalidae, little is known. The sex pheromones hitherto demonstrated in this taxon are exclusively those eliciting courtship behavior at close range (van den Assem and Povel, 1973; Yoshida, 1978; Ruther et al., 2000; Sullivan, 2002). Studies on *Roptrocercus xylophagorum* (Sullivan, 2002) and *Lariophagus distinguendus* (Steiner et al., 2005) indicated that the active compounds are cuticular hydrocarbons. Interestingly, the female sex pheromone of *L. distinguendus* is already present in pupae of both sexes. However, males actively decompose the chemicals involved immediately after emergence (Steiner et al., 2005).

Nasonia vitripennis (Walker) (Hymenoptera: Pteromalidae) is a gregarious parasitoid attacking pupae of several fly species, including blowflies, flesh flies, and houseflies. The parasitoid has been intensely investigated in studies addressing genetic (Reed, 1993), ecological (King and D'Souza, 2004), behavioral (Baeder and King, 2004), developmental (Rivers et al., 1999), and evolutionary (van den Assem and Jachmann, 1982) aspects of its biology. As with many other parasitoids, the mating system of *N. vitripennis* is characterized by protandry, i.e., males emerge first and females follow shortly after. When male density is low, single dominant individuals aggressively defend the escape hole in the host puparium against competitors to ensure that they mate with the emerging females. Inferior males may wander away and find other puparia in the vicinity. At high density, however, competition degenerates into scramble competition, and the territorial system breaks down (van den Assem et al., 1980a).

Males of *N. vitripennis* perform a characteristic courtship behavior that has been studied in detail (Barras, 1960; van den Assem and Vernel, 1979; van den Assem and Werren, 1994). When encountering a female, the male immediately mounts. Subsequently, the male shows regular movements of the wings. These movements are slight lifts rather than the high-frequency wing-fanning as described from other pteromalids (e.g., Ruther et al., 2000). Wing movements may be accompanied by a characteristic head nodding consisting of rapid raising and lowering of the head in combination with chewing movements of the mouthparts. It has been hypothesized that head nodding serves to transfer a male aphrodisiac to the female (van den Assem et al., 1980b). As a result of the male courtship behavior, the female signals sexual receptivity by lowering her antennae and synchronously raising the abdomen to expose her genitalia. Subsequently, copulation may occur. It has been suggested that male courtship behavior in *N. vitripennis* is induced by a female-derived sex pheromone (van den Assem et al., 1980b), but the chemicals involved are unknown.

The present study was initiated to investigate more thoroughly the role of female sex pheromones in the sexual communication of *N. vitripennis*. We characterized the chemicals involved by studying their longevity, range of activity, and polarity. We also analyzed fractions eliciting behavioral activity. Finally, we investigated the possible influence of additional physical cues on male responsiveness and studied whether the pheromone is already present in the pupal stage.

Methods and Materials

Insect Rearing

Laboratory cultures were kept at 25°C and 60% relative humidity with a daily light/dark cycle of 16:8 hr. Thirty to 40 freshly emerged *N. vitripennis* were placed in petri dishes with 50 freeze-killed puparia of the green bottle fly *Lucilia caesar* and kept there until their death. After a development time of 14–15 d, adult parasitoids from the next generation emerged and were collected every second day.

General Methods for Experiments

To obtain virgin individuals for bioassays, parasitoid pupae were removed from host puparia 1–2 d before eclosion and sexed in the pupal stage according to the different-sized wing pads (van den Assem and Jachmann, 1999). Pupae were kept individually in 1.5-ml microcentrifuge tubes until emergence.

Freshly emerged parasitoids were held for 1–2 d in single-sex groups of 10–15 individuals in petri dishes lined with moistened filter paper and provided with one split raisin. One hr before experiments, parasitoids were transferred individually into microcentrifuge tubes.

All experiments except for experiment 4 were performed in a bioassay chamber (10 mm diam × 3 mm high) described elsewhere (Ruther et al., 2000). Behaviors were observed with a stereo microscope with illumination from a microscope light and recorded using The Observer 3.0 computer software (Noldus Information Technology, Wageningen, the Netherlands). Parasitoids were used only once in bioassays.

Experiment 1: Activity of Pheromone Extracts

Ten freshly emerged females were killed by freezing (1 hr, -20°C) and extracted for 30 min with 60 µl dichloromethane at room temperature. The resulting extracts were concentrated to one-third individual equivalent per microliter under nitrogen. Two female equivalents of the extract were applied on a filter paper disk (diam 5 mm, Melitta, Germany), and the solvent was allowed to evaporate for 15 min. The paper disk was offered to a male in the observation chamber, and arrestment time on the disk as well as key elements of the courtship sequence (head nodding, copulation attempts) were recorded for 5 min. Paper disks treated with pure solvent or male extract were used as controls ($N = 15$ for each treatment). Extract samples were changed after every five parasitoids.

Experiment 2: Influence of the Release Matrix on Male Courtship Behavior

This experiment was carried out to study whether male responsiveness was influenced by the matrix to which female extracts were applied. Extracts were prepared as described in experiment 1 and applied (two female equivalents) to (1) a piece (3 × 2 mm) of filter paper, (2) a piece (3 × 2 mm) of a solvent extracted elytra of the garden chafer *Phyllopertha horticola* (model insect cuticle), or (3) a solvent-extracted dead *N. vitripennis* male. Treated objects and solvent-treated control objects were presented to a male and arrestment time, head-nodding behavior, and copulation attempts were recorded for 5 min ($N = 25$ for each treatment).

Experiment 3: Stability of the Biologically Active Chemicals

This experiment investigated the time that dead females remained active to verify literature data suggesting that activity ceases within 2 d. For this purpose, freshly emerged females were killed by freezing and stored throughout the test period at a constant temperature of 25°C and a relative humidity of 60%. The cadaver was presented daily to a male during the first 6 d and finally 8 d after killing. Arrestment time on the cadavers, head-nodding behavior, and copulation attempts were recorded for 5 min. Solvent-extracted females were used as controls ($N = 10$ for each treatment).

Experiment 4: Test for Attraction of Males to Females

This experiment was performed in a static four-chamber olfactometer, which has been used successfully to study the long-range orientation of pteromalids (Steidle and Schöller, 1997; Ruther and Steidle, 2000). No airflow was generated. Ten freshly emerged virgin *Nasonia* females were placed in a petri dish (5.5 cm diam \times 1.2 cm high) covered with gauze (mesh 0.5 mm) and transferred into one chamber of the olfactometer. The remaining three chambers contained empty petri dishes as controls. The olfactometer was covered with a walking arena made from gauze (distance to the volatile source: 3 cm) and finally with a glass plate to prevent test animals from escaping. The olfactometer was placed on the bottom of a white bucket (29 cm diam, 36 cm high) and illuminated from above (2050 lux). A single male was introduced in the center of the walking arena, and the time the parasitoid spent in the area above the four chambers was recorded for 10 min. Males that rested more than 5 min of the total observation time were assumed to be unmotivated and excluded from statistical analysis. Virgin females were replaced after every five males ($N = 22$).

Experiment 5: Production of the Sex Pheromone During Pupal Development

To investigate whether *N. vitripennis* begins producing the sex pheromone during pupal development as shown for other pteromalids (Yoshida, 1978; Steiner et al., 2005), male and female pupae were dissected from host puparia and classified according to pigmentation. Behavioral responses of adult males to single male and female pupae from three stages (yellowish pupae, pupae with red mouthparts, and totally melanized pupae) were observed for 5 min in a bioassay chamber. Extracted male and female pupae were used as controls. Pupae used as odor sources were tested only once ($N = 20$ for each pupal stage of both sexes).

Experiment 6: Activity of Pheromone Fractions

Dichloromethane extracts of *N. vitripennis* females were fractionated by liquid chromatography, and the resulting fractions were bioassayed. Batches of 10 freshly emerged females were extracted with 60 μ l dichloromethane as described in experiment 1. The extracts were concentrated to 15 μ l under nitrogen, applied to 25 mg silica gel cartridges for solid phase extraction (IST, Mid-Glamorgan, UK), and eluted sequentially with 120 μ l each of hexane, 10% dichloromethane in hexane, dichloromethane, and methanol. Four female equivalents of the fractions were applied onto extracted male cadavers, and the behavioral responses of males (arrestment time, head nodding, and copulation attempts) to the treated dead males were recorded for 5 min ($N = 27$ for each fraction). Extracted male cadavers treated with pure solvent were used as controls ($N = 24$ for each fraction).

Chemical Analysis

Hexane fractions from females and males ($N = 7$ for each sex) were prepared as described in experiment 6 and analyzed by coupled gas chromatography–mass spectrometry (GC–MS) on a Fisons GC 8060 with a Fisons MD 800 quadrupole MS (Thermo Finnigan, Egelsbach, Germany). Analytical conditions were as follows: injector temperature 240°C, column 30 m \times 0.32 mm ID DB-5 ms, film thickness 0.25 μ m (J & W Scientific, Folsom, CA, USA), carrier gas: helium, and inlet pressure 10 kPa. The temperature program started at 150°C and increased 2°C/min to 280°C. One microliter of each fraction, representing 0.5 wasp equivalent, was injected together with 25 ng of tetracosane as an internal standard. Linear retention indices of methyl-branched and unsaturated hydrocarbons were calculated by coinjection of straight-chain hydrocarbons. Methyl-branched hydrocarbons were identified by diagnostic ions resulting from the favored fragmentation at the branching points (Lockey, 1988; Nelson, 1993) and by comparing linear retention index values with literature data (Carlson et al., 1998). Position of the double bonds of unsaturated hydrocarbons was determined by iodine-catalyzed methylthiolation using dimethyl disulfide (Francis and Velant, 1981; Howard, 1993). Peak areas for each compound were calculated and related to the total peak area for each run.

Statistical Analysis

Statistical analyses were performed with Statistica 4.5 scientific software (StatSoft, Hamburg, Germany). Mean arrestment times of males were analyzed by Kruskal–Wallis H test followed by multiple U tests for individual comparisons. The time parasitoids spent in the areas above the four chambers of the olfactometer (experiment 4) were analyzed by a Friedman analysis of variance. Number of males responding by head nodding and copulation attempts to different odor sources were compared by using a $2 \times 2 \chi^2$ test. Relative abundances of hydrocarbons in male and female hexane fractions were compared by a Mann–Whitney U test. Whenever multiple comparisons were carried out during statistical analysis, a sequential Bonferroni correction was applied (Sachs, 1992).

Results

Experiment 1: Activity of Pheromone Extracts

Males spent more time on filter paper disks treated with two equivalents of a female extract than on disks treated with male extract or pure solvent (Fig. 1). Apart from this arrestment, however, no other behaviors related to courtship (e.g., head nodding or copulation attempts) were observed. Paper disks treated with male extracts did not cause arrestment in responding males when compared with solvent controls.

Experiment 2: Influence of the Release Matrix on Male Courtship Behavior

Males were arrested on all objects treated with female extracts when compared with controls (Fig. 2). However, arrestment on treated beetle elytra was stronger than on filter paper of the same size. Male cadavers treated with female extracts arrested males more strongly than filter paper, whereas the difference between beetle elytra and male cadaver

Fig. 1 Mean arrestment time (\pm SE) of *N. vitripennis* males on differently treated paper disks (Fe: female extract, Ma: male extract, Con: solvent control) during a 5-min observation period. Bars with different lowercase letters are significantly different at $P < 0.05$ (Kruskal–Wallis H test followed by multiple U tests; $N = 15$)

was not significant ($U = 222$, $P = 0.079$). When considering more complex behavioral elements such as head nodding and copulation attempts, only treated cadavers released male responses (head nodding: 28% response, $\chi^2 = 8.14$, $P = 0.004$; copulation attempts: 48% response, $\chi^2 = 12.58$, $P < 0.001$).

Experiment 3: Stability of the Biologically Active Chemicals

Females killed by freezing shortly after emergence and stored at 25°C and 60% relative humidity elicited responses from males for several days. During the first 8 d, males spent significantly more time on female cadavers when compared with controls (Fig. 3A). Head-nodding behavior and copulation attempts were elicited up to the sixth day of the test period (Fig. 3B–C). This shows that the bioactive chemicals are relatively stable.

Fig. 2 Mean arrestment time (\pm SE) of *N. vitripennis* males on differently treated paper disks, extracted beetle elytra (model insect cuticle), and extracted male cadavers of *N. vitripennis* (Con: solvent control, Ext: treated with two equivalents of a female extract) during a 5-min observation period. Asterisks indicate significant differences (*** $P < 0.001$, ** $P < 0.01$, n.s.: not significant, Kruskal–Wallis H test followed by multiple U tests, $N = 25$)

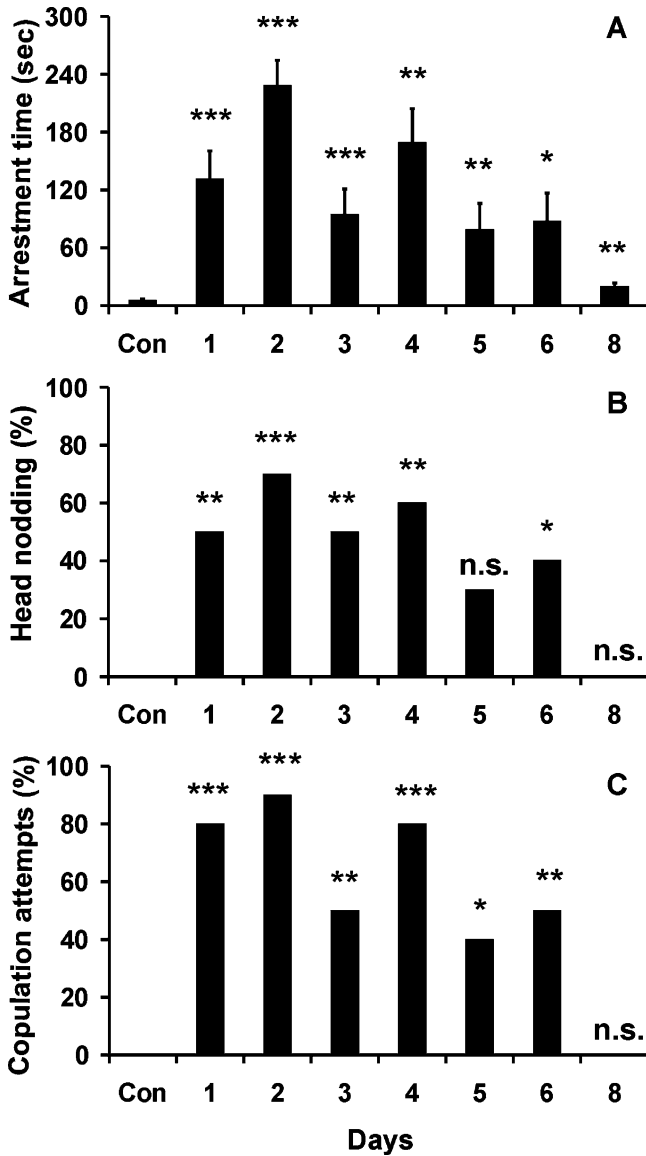

Fig. 3 Response of *N. vitripennis* males to female cadavers presented 1–6 and 8 d after killing. (A) Mean arrestment time (\pm SE). (B) Percentages of males showing head nodding. (C) Percentages of males showing copulation attempts. Asterisks indicate significant preferences for female cadavers when compared with control (***) $P < 0.001$, ** $P < 0.01$, * $P < 0.05$, n.s.: not significant). Mean arrestment times were compared by multiple Mann–Whitney U tests; head-nodding and copulation behavior was analyzed by $2 \times 2 \chi^2$ tests ($N = 10$)

Experiment 4: Test for Attraction of Males to Females

In the four-chamber olfactometer, males did not spend more time in the test field above the 10 virgin females than in the control fields ($\chi^2 = 4.087$, $P = 0.252$). This result indicates that females of this species do not produce a volatile sex pheromone that attracts males from a distance.

Experiment 5. Production of the Contact Sex Pheromone During Pupal Development

Male and female pupae of the three different stages elicited few behavioral responses from males. Males spent more time on totally melanized female pupae when compared with extracted female control pupae (Fig. 4). However, the arrestment time on pupae was smaller when compared with fully developed dead females (Fig. 3A). The arrestment on totally melanized male pupae did not differ significantly from the time spent on extracted male control pupae. Regardless of the sex, yellowish pupae and pupae with red mouthparts did not cause arrestment in responding males. Although head nodding was shown once and copulation attempts in two cases toward totally melanized pupae of either sex, these differences were not significant when compared with the respective control pupae, which elicited no responses at all (head nodding: 5%, $\chi^2 = 1.030$, $P = 0.311$; copulation attempts: 10%, $\chi^2 = 2.110$, $P = 0.147$).

Experiment 6: Activity of Pheromone Fractions

Only the hexane fraction of female extracts elicited arrestment and courtship behavior (head nodding and copulation attempts) in males when applied to extracted male cadavers. The other fractions did not elicit behavioral responses (Fig. 5A–C). This shows that the arrestant pheromone is comprised of nonpolar compounds.

Chemical Analysis

Sixty-seven straight-chain, methyl-branched, or monounsaturated hydrocarbons were identified in the hexane fractions of *N. vitripennis* (Table 1). The chain length varied

Fig. 4 Mean arrestment time (\pm SE) of adult *N. vitripennis* males on female (black bars) and male pupae (white bars) from different stages (Y: yellowish pupae, RM: pupae with red mouthparts, TM: totally melanized pupae, Con: extracted melanized pupae as control). Asterisks indicate significantly increased arrestment compared with control at $P < 0.001$ (Mann–Whitney *U* test, $N = 20$)

Fig. 5 Response of *N. vitripennis* males to extracted male cadavers treated with different fractions of female extracts (H: hexane, D10%: 10% dichloromethane in hexane, D: dichloromethane, M: methanol, Con: solvent control). (A) Mean arrestment time (\pm SE). (B) Percentages of males showing head nodding. (C) Percentages of males showing copulation attempts. Different lowercase letters indicate significant preferences at $P < 0.05$ (mean arrestment times were compared by Kruskal–Wallis H test followed by multiple U tests; head-nodding and copulation behavior was analyzed by multiple χ^2 tests; $N = 27$)

between 25 and 37 carbon units. Most compounds occurred both in male and female parasitoids, but in most cases the relative abundances of the individual hydrocarbons were substantially different between sexes. In both sexes, the majority (>80%) of hydrocarbons consisted of methyl-branched alkanes with one to four methyl groups. All compounds eluting before triacontane (peak 14) occurred in higher relative amounts in the hexane fractions from females than in those from males. The most striking sex-related differences among later-eluting hydrocarbons were found in homologous series of monomethylalkanes

Table 1 Relative composition of hexane fractions from freshly emerged *N. vitripennis* females and males

LRI: linear retention index; DMDS: diagnostic ions after derivatization with dimethyl disulfide.

^a Means ± S.E.

^b Relative amounts were compared by Mann–Whitney *U* test. Significantly higher abundances are shown in boldface (*N* = 7).

^c Not previously reported in *N. vitripennis* by Carlson et al. (1999).

and dimethylalkanes. In hexane fractions from females, there were higher relative abundances of peaks resulting from the coelution of 9-, 11-, 13-, and 15-methylalkanes (peaks 19, 36, 46) and of those belonging to 9,*x*-, 11,*x*-, 13,*x*-, and 15,*x*-dimethylalkanes (peaks 22, 23, 39, 48, 52). Compounds with higher relative abundances in male fractions were some of the 5-methylalkanes and 7-methylalkanes (peaks 20, 21, 37, 47) as well as 3,*x*-, 5,*x*-, and 7,*x*-dimethylalkanes (peaks 26, 40, 41, 44, 49). Alkanes with more than two methyl branches (peaks 30, 32, 42, 45) were more abundant in female extracts, whereas alkenes (peaks 16, 17, 33, 34) were predominantly found in extracts from males.

Discussion

The study demonstrates that arrestment and key elements of the male courtship sequence in *N. vitripennis* are mediated by a female-derived contact sex pheromone. Bioassays of fractions of cuticular extracts revealed that the active compounds are nonpolar. The pheromone components from cuticular extracts were only active at close range, and were shown to be relatively stable because dead females elicited courtship in males for at least 6 d and caused arrestment for at least 8 d. The loss of activity after this period might be explained with residues left by male responders on the surface of the cadavers during previous trials. The only compounds detectable in the biologically active hexane fraction were cuticular hydrocarbons. The relative composition of cuticular hydrocarbons from males and females showed numerous qualitative and quantitative differences. These findings suggest that sex-specific differences in cuticular hydrocarbon profiles form the chemical basis of signals mediating male courtship behavior in *N. vitripennis*. Van den Assem et al. (1980b) assumed the presence of a sex pheromone in *N. vitripennis* after showing that

male courtship behavior toward dead females can be terminated by solvent extraction of the cadavers. However, they concluded that the chemicals involved were relatively unstable because dead females induced mounting responses in conspecific males for less than 2 d.

The primary function of insect cuticular hydrocarbons is to protect insects from desiccation (Lockey, 1988). However, numerous studies have demonstrated that these chemicals are also involved in orientation and recognition processes of insects, such as species, kin, and sex discrimination, as well as chemical mimicry by social parasites or parasitoids to gain access to their hosts (reviewed by Blomquist et al., 1993; Dettner and Liepert, 1994; Singer, 1998; Howard and Blomquist, 2005). Carlson et al. (1999) analyzed the cuticular hydrocarbon profiles of *N. vitripennis* and *Muscadifurax raptorellus* exuviae to develop a tool for discrimination of parasitoid species after these had left the host puparium. For comparison, the authors presented also some preliminary data on adult parasitoids which, however, did not allow for a systematic analysis of gender-specific differences. Our study reports also some additional components which have not been reported in the mentioned paper. This might indicate strain-specific variations or an influence of the host on the hydrocarbon profiles of the parasitoid, because Carlson et al. (1999) used house fly pupae to rear the parasitoids.

Only a few authors have studied the composition of cuticular hydrocarbons of parasitic wasps with regard to their possible role as contact pheromones. Syvertsen et al. (1995) found that some female-derived alkadienes arrested males of the braconid *Cardiochiles nigriceps*. As in the present study, pheromone activity was located in the hydrocarbon fraction of cuticular extracts of two other pteromalids, *R. xylophagorum* (Sullivan, 2002) and *L. distinguendus* (Steiner et al., 2005). In the latter species, as well as in the closely related *Anisopteromalus calandrae* (Yoshida, 1978) and in the braconid *Cotesia glomerata* (Tagawa, 1977), the pheromone was already present in the early pupal stage. It has been suggested that this might enable mating of the females before they leave the site of emergence to search for new host patches (Steiner et al., 2005). Because male pupae and freshly emerged *L. distinguendus* males also contained the courtship pheromone, Steiner et al. (2005) assumed that developing males use the courtship pheromone to fool sexual competitors. The present study shows a different situation for *N. vitripennis*: contact pheromones appear in the cuticular lipids much later, and only totally melanized female pupae are slightly attractive to males. Pheromone activity is fully developed in freshly emerged females but not in males. This explains why males of *N. vitripennis* are arrested on fly puparia containing females that are about to leave the host (King et al., 1969).

Interestingly, the response of *N. vitripennis* males to female extracts was influenced by the release substrate. Pheromone extracts applied to insect cuticles (extracted beetle elytra or male wasp cadaver) arrested males more strongly than those applied to pieces of filter paper. This might be because of differing adsorptive properties of the two matrices influencing the available amounts of the active compounds. Alternatively, physical cues associated with the insect cuticle might affect male responsiveness. More complex behavioral elements such as head-nodding or copulation attempts were shown only toward male cadavers treated with female extracts. In contrast, neither untreated male cadavers nor extracted female cadavers with reapplied male hydrocarbons elicited any responses in males (data not shown). This supports the hypothesis that visual and/or tactile cues synergize the male response to the female courtship pheromone. In other parasitic wasps, physical cues do not seem to play that crucial role because paper disks treated with pheromone extracts not only caused arrestment but also elicited elements of the courtship behavioral sequences (Takahashi and Sugai, 1982; Shu and Jones, 1993; Sullivan, 2002; Steiner et al., 2005).

Nasonia vitripennis females did not attract males from a distance. The present study revealed no apparent change in behavior of males in the four-chamber olfactometer when exposed to virgin females at a distance of only 3 cm. This suggests that this species does not use a volatile sex pheromone, unlike some other parasitic hymenoptera (e.g., Lewis et al., 1971; Field and Keller, 1993; McNeil and Brodeur, 1995). This reflects the natural history and the mating strategy of *N. vitripennis*: the parasitoid is gregarious, and protandrous males mate at the site of emergence with later emerging females. Thus, female-derived sex attractants are not necessary in this species. Males of the gregarious pteromalid *L. distinguendus* have been shown to use volatile cues other than sex pheromones for reaching or being arrested in the habitat of potential mates, orienting toward the host-associated volatiles that females use for host finding. These chemicals are emitted from the larval feces of the host *Sitophilus granarius* (Ruther and Steidle, 2000). Future studies will address the question of whether *N. vitripennis* males also use host-associated cues for long-range orientation during mate finding, and whether this strategy is a general feature among pteromalid wasps. Another challenge of future research is to identify the specific cuticular hydrocarbons that act as contact sex pheromones. However, the complexity of insect hydrocarbon profiles together with the nonavailability of synthetic reference compounds will complicate this undertaking.

Acknowledgments The authors thank Lars Krogmann (University of Hamburg) for providing start-up individuals of *N. vitripennis*. Two anonymous reviewers gave helpful comments on an earlier version of the manuscript.

Abstract We describe the identification and characterization of two new cDNAs encoding pheromone-binding proteins (PBPs) from the male antennae of *Sesamia nonagrioides*, a species where no PBPs have been identified to date. Because PBPs are thought to participate in the first step of odor detection in a specific manner, we focused our investigation on this olfactory protein family using reverse transcription–polymerase chain reaction strategies. The deduced amino acid sequences of SnonPBP1 and SnonPBP2 revealed mature proteins of 142 and 143 amino acids, respectively, with six cysteine residues in conserved positions relative to other known PBPs. The alignment of the two mature *S. nonagrioides* PBPs with other noctuid PBPs showed high sequence identity (70–80%) with other full-length sequences from GenBank. Sequence identity between SnonPBP1 and SnonPBP2 was only 46%, suggesting that the two proteins belong to different classes of PBPs already described from the Noctuidae. Furthermore, analyses of expression patterns of SnonPBP1 and SnonPBP2 were performed by *in situ* hybridization on antennae of both sexes, and these studies revealed the expression of the two PBPs at the bases of olfactory sensilla (basiconica or trichodea) from both sexes. The possible binding properties of these two new PBPs are discussed according to their homologies with other known PBPs and *S. nonagrioides* pheromone components.

Introduction

In insect antennae, odorant-binding proteins (OBPs) are soluble proteins that are thought to participate in the first step of olfactory detection by specific binding with volatile molecules. Well known in insects, OBPs are proposed to be specialized in solubilization, binding, and transport of odorants across the aqueous lymph of the olfactory sensilla (Vogt and Riddiford, 1981), allowing hydrophobic molecules to reach the membrane olfactory receptors. In addition, these proteins may also participate in dendritic odorant receptor activation or odorant signal deactivation (Kaissling, 2004). They are small hydrophilic proteins synthesized by accessory cells that surround the olfactory neuron and are secreted into the sensillar lymph where they are found at high concentrations. OBPs have been identified in a variety of insect species and appear to be present throughout the Neoptera (Vogt et al., 1999; Vogt, 2003). They are divided in two groups according to their potential ligands: the pheromone-binding proteins (PBP) are thought to bind pheromone components, whereas the general odorant-binding proteins (GOBPs) are believed to bind more “general” odorants such as those from plants. Although the designations PBP/GOBP are used to distinguish two lineages of OBPs with high sequence similarity within the Lepidoptera, this designation is also used across all insects to distinguish functional classes of OBPs based on their probable ligands.

Direct cloning and genomic analysis with insects have revealed the occurrence of multiple OBPs within the same species. For example, up to 50 OBP-related genes were identified in the fruit fly *Drosophila melanogaster* and a similar number in the mosquito *Anopheles gambiae* (reviewed in Vogt, 2003). Within OBPs, multiple PBPs are also expressed in a single species. Indeed, three PBPs are known in the silk moths, *Antheraea polyphemus* and *A. pernyi* (Saturniidae) (Raming et al., 1990; Krieger et al., 1991; Vogt et al., 1991; Maida et al., 2000) and the hawkmoth, *Manduca sexta* (Sphingidae) (Györgyi et al., 1988; Robertson et al., 1999), whereas two PBPs are known in different armyworm moths, e.g., *Mamestra brassicae* (Maïbèche-Coisné et al., 1998) and *Heliothis virescens* (Noctuidae) (Krieger et al., 1993; Abraham et al., 2003; direct GenBank submission no. AY301988). The presence of different subtypes of PBPs in the same species, together with the occurrence of different components in the sex pheromone, suggest a possible role of PBPs in specific binding/transport of pheromone components to the receptor neuron. PBPs could then contribute to the specificity of the olfactory system through an initial selective detection of odorant molecules (Leal, 2003). However, only a few studies have provided data suggesting some binding specificity between PBPs and pheromone components. For example, two different *M. brassicae* PBPs showed different binding affinities to the main pheromone component of this moth, (Z)-11-hexadecenyl acetate [(Z)-11-16:Ac] with PBP1, but not PBP2, binding the compound (Maïbèche-Coisné et al., 1997), although it may not be the only compound that PBP1 could bind (Campanacci et al., 2001). Similar results were obtained in *Lymantria dispar* (Vogt et al., 1989; Plettner et al., 2000), *A. pernyi* (Prestwich et al., 1995), and *A. polyphemus* (Du and Prestwich, 1995). In addition, *Bombyx mori* PBP showed binding to the pheromone component bombykol, but not to structurally unrelated chemicals (Wojtasek and Leal, 1999). In a competitive situation, each of the three *A. polyphemus* PBPs preferentially binds one of the pheromone components (Maida et al., 2000, 2003), and responses of the receptor neurons to pheromone appeared to depend on both the pheromone component and the type of PBPs (Pophof, 2002, 2004). Therefore, the PBPs appeared to contribute to the excitation of the receptor cells (Pophof, 2004).

The stemborer *Sesamia nonagrioides* (Lefebvre) (Lepidoptera: Noctuidae), is an important pest of maize in the Mediterranean Basin. Integrated pest management strategies

are being developed against this species, including olfactory-mediated behavioral modification centered on the sex pheromone. This pheromone consists of a blend of (*Z*)-11-16:Ac (main component), (*Z*)-11-16:OH, (*Z*)-11-16:Ald, and 12:Ac (Mazomenos, 1989). Because no OBP have been described to date in *S. nonagrioides*, we investigated its PBP repertoire by polymerase chain reaction (PCR) strategies and compared the PBPs with previously reported sequences from other noctuid moths. This homology-based approach allowed us to describe two new PBPs from antennae of male *S. nonagrioides*, which are expressed in both male and female olfactory tissues.

Methods and Materials

Insect Rearing

A culture of *S. nonagrioides* was established from pupae collected in central Italy and reared with a meridic diet (Giacometti, 1995). Larvae, sexed pupae, and adults were kept inside screened plastic containers in an environmental chamber ($27 \pm 1^\circ\text{C}$, 60–80% relative humidity, 16-hr light/8-hr dark photoperiod).

RNA Extraction and cDNA Synthesis

Total RNA was extracted from 200 antennae from sexually mature *S. nonagrioides* males by using an Rneasy[®] MiniKit (Qiagen, Hilden, Germany). Single-stranded 3'RACE-ready-cDNA and 5'RACE-ready-cDNA were synthesized from 1 μg of RNA with the SMART[™] RACE cDNA Amplification Kit (Clontech, Mountain View, CA, USA) with 200 U of SuperscriptII[™] (Gibco BRL, Invitrogen, Carlsbad, CA, USA) according to the manufacturer's instructions.

Degenerate PCR for Isolation of PBP1 and PBP2 Gene Fragments

Degenerate primers corresponding to amino acid consensus regions of several PBPs from different species of Lepidoptera were used for PCR amplifications of *S. nonagrioides* cDNA templates: PBP1-forward (5'-GAYCAGTGYYAAGAAYGAGCTTAAT-3') and PBP1-reverse (5'-GTGAGGGATCCRTGYTTYWTNGCRAA-3'); PBP2-forward (5'-ATGAAYT TYGCYAAACCWYTA-3') and PBP2-reverse (5'-ACTCCTGAGCCTTCCCGTGATGCA-3'). These primers have already been used successfully for the molecular cloning of PBP1 and PBP2 from *M. brassicae*, a species that also uses (*Z*)-11-16:Ac as its main pheromone component (Maibèche-Coisné et al., 1998). PCR was carried out with 1 U of Taq polymerase (Promega, Madison, WI, USA) and consisted of 40 cycles of 30 sec at 94°C , 30 sec at 40 and 50°C for PBP1 and PBP2, respectively, and 30 sec at 72°C .

3'RACE-PCR

3'RACE amplifications were conducted on 2 μl of the *S. nonagrioides* 3'RACE-ready cDNA, with sense gene-specific primers deduced from the sequences obtained following degenerate PCR amplifications of PBP1 and PBP2 (PBP1Sn-forward: 5'-CTGGCGCGAG GAGTACGAGCTGGT-3'; PBP2Sn-forward: 5'-TGTGCCATACTCTGTCTCTCATCT-3') and with an antisense Universal Primer Mix (UPM, Clontech). The 50- μl amplification mix was prepared according to the SMART[™] RACE cDNA protocol using the Advantage2[™]

polymerase mix (Clontech). Touchdown PCRs were performed in the following conditions: 1 min at 94°C, followed by 5 cycles of 30 sec at 94°C and 1 min at 72°C; 5 cycles of 30 sec at 94°C, 30 sec at 70°C, and 1 min at 72°C; 30 cycles of 30 sec at 94°C, 30 sec at 68°C, and 1 min at 72°C.

5'RACE-PCR

5'RACE amplifications were conducted on 2 µl of the *S. nonagrioides* 5'RACE-ready cDNA using Universal Primer Mix (Clontech) as a sense primer and antisense gene-specific primers (PBP1Sn-reverse: 5'-GCACATCACCATGCATCCCAGGTCGCG-3'; PBP2Sn-reverse: 5'-CTTAAGGTCTGGATCGAGCAGTTCCAG-3'). Touchdown PCRs were performed as described for the 3'RACE-PCR.

Cloning and Sequencing

After gel extraction (Genelute, Sigma, St. Louis, MO, USA), the amplified cDNAs were ligated into the plasmid pCRTM-II using the TOPO cloning kit from Invitrogen. Recombinant plasmids were isolated using the Plasmid Mini kit (Qiagen), and both strands were subjected to automated sequencing by Genome Express (Grenoble, France). Database searches were performed with the BLAST program (NCBI), protein analyses with MWCALC (InfobioGen) and SignalP (Nielsen et al., 1997), and sequence alignment with CLUSTALW (NPS@IBCP).

In Situ Hybridizations

Digoxigenin-labeled RNA sense and antisense probes (200 bp) were obtained for each PBP. The pCRTMII-cDNA plasmids resulting from degenerate PCR amplifications of the internal gene fragments of PBP1 and PBP2 were PCR amplified by using M13 forward and reverse primers. The PCR products were used to generate digoxigenin-labeled RNA probes by *in vitro* transcription using T7 and SP6 RNA polymerase (Promega) following the manufacturer's protocol and in the presence of 1.5 U of Rnasin (Promega).

For hybridization, antennae were removed from the heads of adults of both sexes, cut into pieces, and fixed in 4% paraformaldehyde (PFA) in phosphate-buffered saline (PBS). Fixed tissues were dehydrated in 100% methanol. The hybridization protocol was performed as described (Jacquin-Joly et al., 2000), with a hybridization temperature of 65°C, and digoxigenin was detected using alkaline-phosphatase-conjugated antidigoxigenin Ig (1:4000; Roche, Basel, Switzerland) and revealed colorimetrically with nitro blue tetrazolium chloride/5-bromo-4-chloro-3-indolylphosphate, toluidine salt (Roche). After sufficient staining, specimens were washed in PBS and fixed in 4% PFA, dehydrated, and embedded in Epon (Agar Scientific, Stansted, Essex, UK). Six-micrometer sections were counterstained with acridine orange. Sections were photographed, and pictures were digitized and processed with Adobe Photoshop 5.0.

Phylogenetic Analysis with Other Noctuid PBPs

Several noctuid PBP sequences were retrieved from GenBank for phylogenetic analysis. Amino acid sequences of PBPs without the leader sequence were aligned by using Multalin program (Corpet, 1988). Maximum parsimony was used to build a strict consensus tree in PAUP 4.0b10 software (Sinauer Associates, Sunderland, MA, USA). Branch support was

assessed by bootstrap analysis based on 1000 replications, and the *H. virescens* GOBP1 and 2 (GenBank accession nos. X96862 and X96863, respectively) were used as outgroups.

Results

Molecular Cloning and cDNA Sequencing of *S. nonagrioides* PBPs

By using degenerate PCR and RACE-PCR strategies, two full-length cDNAs, encoding potential PBPs, were cloned in *S. nonagrioides*. They both contained an open-reading

Fig. 1 Nucleotide and deduced amino acid sequences of SnonPBP1 and SnonPBP2 cDNAs from antennae of male *Sesamia nonagrioides* (GenBank accession nos. AY485219 and AY485220). The stop codons are indicated by an asterisk. The positions of the degenerate primers used in PCR for gene fragment amplifications are underlined with a bold line (PBP1-forward and -reverse; PBP2-forward and -reverse), whereas gene-specific primers for 3'RACE (PBP1Sn-forward and PBP2Sn-forward) and 5'RACE (PBP1Sn-reverse and PBP2Sn-reverse) are marked with dotted and dashed lines, respectively. Putative signal peptides at the N-termini are underlined

Fig. 1 (continued)

frame encoding two putative proteins of 165 and 170 amino acids, named SnonPBP1 and SnonPBP2, respectively, according to their high identity with proteins from these classes in BLAST searches. The sequences for SnonPBP1 and SnonPBP2 have been deposited in GenBank under the accession numbers AY485219 and AY485220, respectively. The deduced amino acid sequences for both proteins possess a putative signal sequence of 23 (SnonPBP1) and 27 (SnonPBP2) amino acids (Fig. 1). Mature predicted SnonPBP1 protein consisted of 142 amino acids with a molecular mass of 16,117 Da and a pI of 5.49, whereas SnonPBP2 consisted of 143 amino acids with a molecular mass of 16,039 Da and a pI of 5.00. Thus, the two predicted mature proteins are small, likely soluble, likely secreted, and both have an acidic isoelectric point. Moreover, both contained six cysteines in conserved positions when aligned with other known PBPs: positions C¹⁹, C⁵⁰, C⁵⁴, C⁹⁷, C¹⁰⁸, and C¹¹⁷ (Fig. 2).

The alignment of the two mature *S. nonagrioides* PBPs with other noctuid PBPs showed high sequence identity. *S. nonagrioides* PBP1 showed 83% identity with *M. brassicae* PBP1 (MbraPBP1), 72% with *Spodoptera exigua* PBP1 (SexiPBP1), and 88% with the partial sequence of *H. virescens* PBP2 (HvirPBP2; Fig. 3). Similarities were even higher,

Fig. 2 Comparison of the predicted amino acid sequences of SnonPBP1 and SnonPBP2 from antennae of male *S. nonagrioides* with pheromone-binding proteins from other noctuids. Fig. 3 Percentage identity of pheromone-binding proteins (PBPs) of the Noctuidae based on conserved amino acid residues. Sequences were retrieved from GenBank (accession numbers listed in Fig. 2), and signal peptides were deleted for this comparative analysis. Identities greater than 55% are in bold. Two different groups of PBPs are evident according to level of identity: Grp1 (names not bold) and Grp2 (names in bold), as defined by Picimbon and Gadenne (2002)

e.g., 95% with MbraPBP1. SnonPBP2 presented the highest identities with MbraPBP2 (80%), HzeaPBP1 (79%), and HarmPBP1 (79%). The degree of identity between SnonPBP1 and SnonPBP2 (46%) was much lower than in the interspecific comparisons within a protein (Fig. 3). Sequence similarities of noctuid PBPs were summarized in a neighbor-joining tree (Fig. 4). This analysis revealed two clusters of PBPs from various species, designated as Grp1 and Grp2, according to the two PBP groups already described in noctuids (Picimbon and Gadenne, 2002). Grp2 contained SnonPBP1, whereas Grp1 contained SnonPBP2 (Fig. 4).

PBP Expression Patterns in *S. nonagrioides*

Expression patterns of the two *S. nonagrioides* PBPs were established by *in situ* hybridization to RNA in both male and female antennae (Figs. 5 and 6). *S. nonagrioides* antennae contain about 40 flagellomeres. In males, they are comb-like (bipectinate) and 7.20 mm long and 0.70 mm wide at mid-length (Fig. 5A), whereas in females, they are filiform and 6.60 mm long and 0.15 mm wide at mid-length (Fig. 6A). In both sexes, the

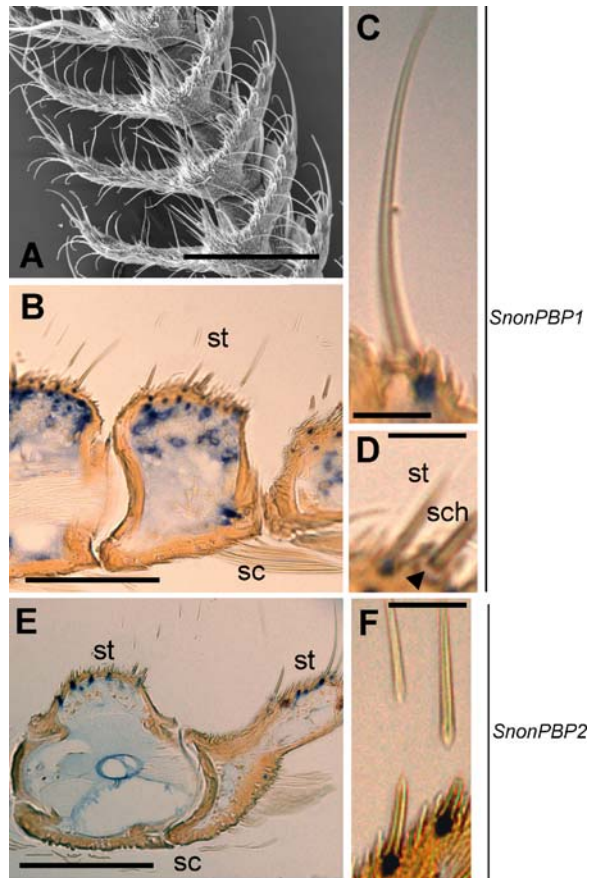

Fig. 4 Phylogenetic analysis of *S. nonagrioides* SnonPBP amino acid sequences with various noctuid PBPs. GenBank accession numbers are listed in Fig. 2. Bootstrap support values (in percent) based on 1000 replicates are indicated. Analysis indicates two groups (Grp1 and Grp2), as defined by Picimbon and Gadenne (2002)

antennae are covered dorsally with overlapping scales. The olfactory hairs, the sensilla trichodea and the sensilla basiconica, are all set on the ventral side of the flagellomere. In males, the olfactory sensilla are distributed across both portions of the lateral processes and in the medial process (Fig. 5A). In particular, the branches of the male antennae carry a great number of long sensilla trichodea, which have been characterized functionally by single cell recording (Quero et al., 2004). Although the number and the distribution of sensilla are quite different in females and males, both sexes share the same types of sensilla (Solinas and Trona, 2002).

Hybridization of male antennae with either SnonPBP1 or SnonPBP2 sense probes showed no signal (data not shown). Hybridization with either SnonPBP1 (Fig. 5B–D) or SnonPBP2 (Fig. 5E and F) antisense probes showed signals restricted to the sensillar side of the antennae (Fig. 5B), with labeling present in both lateral and medial processes (Fig. 5E). No labeling was visible on the dorsal-scaled side of the antennae. On the sensillar side, labeling was observed at the base of olfactory sensilla (Fig. 5C, D, and F), with no labeling at the bases of the sensilla chaetica (Fig. 5D), which are thought to function in gustation in other Lepidoptera (Jørgensen et al., 2006). In some sections (Figs. 5B, C, E, 6B and C), labeling could be clearly associated with numerous long sensilla trichodea. However, it was not possible to exclude expression in sensilla basiconica that differs from sensilla trichodea by their small size because a whole sensillum was rarely visible on a section. In longitudinal sections of female antennae, *in situ* hybridization revealed that both PBP1 and PBP2 are also abundantly expressed in this sex, with labeling observed at the base of the olfactory sensilla with both probes (Fig. 6B and C).

Fig. 5 Expression patterns of SnonPBP1 and SnonPBP2 revealed by *in situ* hybridization to mRNA in longitudinal and transversal sections of *S. nonagrioides* male antennae. Discussion

Heterogeneity of PBPs Expressed in *S. nonagrioides* Antennae

In *S. nonagrioides*, no OBPs had been described prior to our study. In this species, the responses of the olfactory receptor neurons have been recently investigated, defining functional types of long sensilla trichodea distributed on the lateral branches of male antenna (Quero et al., 2004). Deciphering the PBP repertoire in this species provides the opportunity to relate PBP expression with the functional types of sensilla. Here, we have cloned two cDNAs encoding proteins that can be classified in the lepidopteran PBP family. Indeed, both of the deduced amino acid sequences present all of the typical features of OBPs: (1) they are small hydrophilic proteins with acidic isoelectric points; (2) they are destined for secretion, as demonstrated by the occurrence of a signal peptide at the N-termini; (3) they possess six cysteines in positions conserved across OBPs; and (4) their expression is associated with the olfactory sensilla, as revealed by *in situ* hybridization. The two deduced proteins are grouped in the PBP1 and PBP2 families, according to sequence homologies with noctuid PBPs and phylogenetic analyses, and thus have been named SnonPBP1 and SnonPBP2. With only 46% identity, these two PBPs clearly represent divergent proteins.

Fig. 6 Expression patterns of SnonPBP1 and SnonPBP2 revealed by *in situ* hybridization to mRNA in longitudinal sections of *S. nonagrioides* female antennae. (A) SEM of the ventral side of a female antenna. (B) Longitudinal section of female antenna with SnonPBP1 expression pattern. (C) Longitudinal section of female antenna with SnonPBP2 expression pattern. st: sensilla trichodea; sc: scales. Bars: 100 μm (A); 50 μm (B, C)

With the discovery of at least two PBPs in its antennae, *S. nonagrioides* is another example of a moth species expressing multiple PBP-like proteins (Györgyi et al., 1988; Raming et al., 1990; Krieger et al., 1991; Vogt et al., 1991; Maïbèche-Coisné et al., 1998; Robertson et al., 1999; Maida et al., 2000). In particular, noctuid species tend to have PBPs belonging to both the PBP1 and the PBP2 families. Because lepidopteran pheromone blends usually consist of several components, the occurrence of divergent PBPs within a species accounts for a possible role of PBP in specific binding. In particular, *M. brassicae* PBP1 has been shown to bind (Z)-11-16:Ac (Maïbèche-Coisné et al., 1997). As *S. nonagrioides* and *M. brassicae* share this main pheromone component, SnonPBP1 could be the ortholog of MbraPBP1, considering that these proteins share 83% identity. This hypothesis is supported by the establishment of the PBP1 expression pattern in correlation with the functional types of the olfactory sensilla. Indeed, PBP1 appeared to be expressed in association with numerous sensilla distributed on the lateral branches of the male antennae (Fig. 5B). These branches have been shown to carry different functional sensilla types (Quero et al., 2004), and among them, 90% containing at least one olfactory neuron responding to (Z)-11-16:Ac.

Because the sex pheromone of *S. nonagrioides* consists of several different components, SnonPBP2 may bind one or more of these other components. In particular, *S. nonagrioides* female pheromone also contains (Z)-11-16:Ald (Mazomenos, 1989), another common pheromone component between *M. brassicae* and *S. nonagrioides* (Renou and Lucas, 1994), which is detected by *S. nonagrioides* olfactory neurons housed in 48% of the sensilla trichodea located on the branches of male antennae (Quero et al., 2004). High conservation between SnonPBP2 and MbraPBP2 (80% identity), together with PBP2s from other noctuids that also use (Z)-11-16:Ald in their pheromone blend (*H. virescens*, *H. zea*, and *H. armigera*; see the Pherolist: <http://www-pherolist.slu.se/pherolist.php>), further supports the hypothesis that these PBP2s could be involved in (Z)-11-16:Ald binding, although no functional data are available on either SnonPBP1 or SnonPBP2. The correlation between PBP sequence identities and pheromone components has already been investigated, but there is no evidence for convergence of PBP sequences in species that use similar pheromone components (Willett, 2000a). However, when alleles of PBPs were sampled from members of the tortrix moth genus *Choristoneura* (Tortricidae) that use

pheromones with different functional groups, evidence for episodes of selection acting on PBPs was demonstrated (Willett, 2000b). However, it is not clear whether pheromone changes are causing this selection.

Through our neighbor-joining tree analysis (Fig. 4), the two newly identified SnonPBPs were easy to classify in the two previously defined groups of PBPs (Picimbon and Gadenne, 2002; Abraham et al., 2005). Indeed, SnonPBPs segregate into two subclasses. Subclass 1 (Grp1) contains PBPs reported only in noctuid species (Picimbon, 2003) and includes SnonPBP2, HzeaPBP1, HvirPBP1, AsegPBP1, and AipsPBP1. Subclass 2 (Grp2) includes SnonPBP1 together with MbraPBP1, HvirPBP2, AipsPBP2, AsegPBP2, and SexiPBP1, as well as non-noctuid PBPs (Picimbon, 2003). The classification of the two SnonPBPs in the two subgroups confirms the occurrence of two orthologous groups of PBPs in noctuids.

The Two New *S. nonagrioides* PBPs are Expressed in Male and Female Antennae

From our *in situ* hybridization results, we showed that SnonPBP1 and SnonPBP2 were abundantly expressed in both male and female antennae. Moreover, the expression is associated with the olfactory sensilla in both sexes, with no labeling associated with gustatory sensilla (Fig. 5), consistent with a role in olfaction.

Considering their role in pheromone detection, PBPs were first thought to be expressed exclusively in male antennae (Vogt and Riddiford, 1981), in contrast to GOBPs, which were present in both sexes. We now know from several examples that PBPs are expressed in antennae of both sexes (Györgyi et al., 1988; Maïbèche-Coisné et al., 1997; Callahan et al., 2000; Vogt et al., 2002), but with differences according to the insect family. In the Saturniidae, Bombycidae, and Sphingidae, PBPs are present in much higher levels in males than in females (e.g., Györgyi et al., 1988; Steinbrecht et al., 1992, 1995; Vogt et al., 2002), whereas in the Noctuidae, relatively high expression has been observed in female antennae (Maïbèche-Coisné et al., 1997; Callahan et al., 2000; Zhang et al., 2001). Our results on PBP expression in *S. nonagrioides* female antennae are consistent with these previous observations from noctuid moths. However, the function of PBPs in females remains unclear. Although many studies have failed to detect female response to sex pheromone (reviewed in Callahan et al., 2000), electrophysiological recordings from female antennae showed that *Spodoptera littoralis* as well as *M. sexta* females could respond to at least one of their pheromone components (Ljungberg et al., 1993; Kalinova et al., 2001). The behavioral significance of female PBPs and/or female detection of their own pheromone remains unknown.

The molecular characterization of SnonPBP1 and SnonPBP2 are significant not only because olfactory-mediated behavioral modification of the pest is used in integrated pest management strategies, but also because *Telenomus busseolae* Gahan (Hymenoptera: Scelionidae), an egg parasitoid, is being used effectively in crop protection against *S. nonagrioides*. Possible explanations for such efficacy is that *T. busseolae* uses the *S. nonagrioides* sex pheromone component (Z)-11-16:Ac as a host location kairomone and has developed morphofunctional adaptations, behavioral strategies (Conti and Bin, 2000), as well as molecular adaptations of odorant detection. Indeed, like other parasitoids, *T. busseolae* utilizes a semiochemical espionage strategy (Vinson, 1984, 1998). In behavioral laboratory tests, *T. busseolae* are attracted by the *S. nonagrioides* main pheromone component, (Z)-11-16:Ac (Colazza et al., 1997), as well as to contact chemicals from *S. nonagrioides* (Colazza and Rosi, 2001). The long-term goal of this work is to compare the olfactory elements involved in (Z)-11-16:Ac recognition in both the host and its parasitoid.

A molecular analysis of these elements should provide useful information on the coevolution of this host–parasitoid complex.

Abstract The effect of wind on the potato aphid, *Macrosiphum euphorbiae*, male responsiveness to the sex pheromone, and on the calling behavior of virgin oviparae, was studied under constant wind speeds in the laboratory and in the field. A significant proportion of females called at wind speeds up to 4 m/sec, whereas male flight behavior in clean air was inhibited at velocities > 2 m/sec. However, males continued to walk over the range of wind speeds at which females called. Under constant wind velocities in a wind tunnel, males downwind of calling females oriented on the upwind edge of the release stand, and fewer individuals took flight at low constant wind speeds than in a clean air plume. In all cases, whether calling females were present or not, the males that took flight moved downwind. However, when a bridge was available, a significant proportion of males walked upwind to the pheromone source. The same orientation and walking behaviors were observed when males were placed downwind of calling females under variable wind conditions in the field. However, contrary to the laboratory results, 30% of the males tested flew upwind and landed on the source. A more detailed examination found that males orienting toward a source would walk if wind speeds were high but initiated flight in an “upwind” direction if there was a lull in wind velocity. These findings suggest that for the potato aphid, and probably for many other insect species with weak flight capacity, walking behavior is a significant component of pheromone-mediated mate location. This would permit males to continue foraging for calling females in the vicinity when wind velocities inhibit flight.

Introduction

Many abiotic and biotic factors influence chemically mediated reproductive behaviors in insects (McNeil, 1991). Wind is one of the important abiotic factors and may affect reproductive success in two distinctly different ways. The first relates to the temporal and spatial movement of the infochemicals, because wind velocity and the level of turbulence will influence parameters such as the distance the pheromone moves from the source, the plume structure, and the concentration of the message at any given point within the plume (see Elkinton and Cardé, 1984; Murlis et al., 1992; Bell et al., 1995 and references therein). Second, variations in wind speed may directly influence the behaviors of both sexes. Wind speed can influence the proportion of individuals that emit pheromone (Kaae and Shorey, 1972) or change the behavior associated with pheromone release (Conner et al., 1985). In the case of the responding sex, wind speed may influence the proportion of individuals reaching the source, possibly related to the plume characteristics mentioned above. In addition, there will be an upper limit to wind velocity, above which upwind flight is not possible, and this threshold will be determined by the flight capacity of each species.

The sex pheromones of several aphid species have been identified (Dawson et al., 1987, 1989; Campbell et al., 1990; Lilley et al., 1994/1995; Gabry et al., 1997; Boo et al., 2000; Goldansaz et al., 2004) and a few studies of pheromone-mediated behaviors have been carried out under controlled laboratory conditions (Eisenbach and Mittler, 1980, 1987; Guldemond and Dixon, 1994; Thieme and Dixon, 1996). However, there has been little work examining the pheromone-mediated behavior of aphid sexual forms under field conditions in late summer and early fall when these morphs are present in nature. Virgin, apterous female oviparae raise their back legs off the substrate when releasing sex pheromone from glands on the tibia. Fluctuating climatic conditions, including wind velocity, had a marked effect on the expression of this calling behavior in the potato aphid, *Macrosiphum euphorbiae*, in the field (Goldansaz and McNeil, 2003). Aphids are weak flyers, and the speed and direction of flight is usually governed by the wind (Dixon and Howard, 1986). Furthermore, the inhibitory effect of wind speeds >2 m/sec on the flight behavior of parthenogenetic female alate aphids has been documented (Kennedy and Thomas, 1974; Kennedy, 1990; Storer et al., 1999). However, despite the fact that wind velocity could markedly influence the reproductive biology of aphids, no detailed studies have examined the effect of this parameter on alate males. We, therefore, carried out experiments under both laboratory and field conditions to examine the effect of wind speed on the flight behavior of alate male potato aphids and determined how this related to the calling behavior of wingless oviparae under similar conditions.

Methods and Materials

Insects

All aphids used came from a multiclinal laboratory culture, established, and restocked annually with parthenogenetic individuals collected from potato fields around Quebec City, Canada. Colonies were maintained on potato seedlings *Solanum tuberosum* c.v. Norland, at $20 \pm 1^\circ\text{C}$, $60 \pm 10\%$ relative humidity (RH), under a light/dark 16:8 hr photoperiod, conditions that ensure continuous asexual production. In all experiments, aphids were held on four- to six-leaf stage potato seedlings, and new plants were provided every 3 d. To obtain sexual morphs, aphids were reared at $20 \pm 1^\circ\text{C}$, $60 \pm 10\%$ RH, under a light/dark

10:14 hr photoperiod. The gynoparous and androparous females (which produce the sexuals) were produced in the first generation and were held in groups on host plants. Their offspring were collected daily to ensure production of known-age oviparae and males, which were held on potato seedlings under these conditions until used in experiments.

Wind Tunnel Bioassays

Experiments were conducted in a laminar airflow wind tunnel (290 cm long, 120 cm wide, and 100 cm high) with a capacity to generate wind speeds from 0 to 120 cm/sec. The tunnel was located in an environmental chamber maintained at $18 \pm 0.5^\circ\text{C}$ with RH 40–50%, with lighting provided by eight 40-W fluorescent bulbs, placed uniformly above the tunnel ceiling. Light intensity was 150 lux at the points where the potato plants with calling females or male release cages were placed. All assays, using 5- to 6-d-old virgin individuals, were carried out in the 3rd to 6th hr of the photophase because this was the period of maximum calling activity under controlled laboratory conditions (Goldansaz and McNeil, 2003). Individuals were used only once, and all bioassays testing males were terminated after 3 min if the test animal did not respond.

The effect of wind on the calling behavior of oviparae was tested by placing a calling virgin female in the wind tunnel, and classified as either “calling” or “noncalling” after 3 min at wind speeds of 0, 20, 40, 60, 80, 100, and 120 cm/sec. Fifteen oviparae were tested at each wind speed and the entire experiment was replicated $\times 3$, using a randomized block design.

Wind speed is known to affect the probability of take off in parthenogenetic alates (see Kennedy, 1990) so the flight behavior of males was tested over the same range of wind speeds in clean air. Each male was placed downwind in a plastic cage (5 cm long and 3 cm diam) on a metal release platform. The time to take off and flight direction were recorded for 15 males at each wind speed, and the entire experiment was replicated $\times 3$, using a randomized block design.

We then examined the responses of males to the presence of five calling virgin females on a single potato seedling, 40 cm upwind, at wind speeds of 40, 80, and 120 cm/sec, velocities at which $> 80\%$, $< 20\%$, and 0% of males initiated flight in the clean air assays described above. Despite the presence of a pheromone source, any males taking flight still flew downwind, as they did in clean air. Therefore, we repeated the experiment but this time providing a bridge, a single white string connecting the male release platform and the plant with the calling females, which allowed males to reach the source by walking upwind (Goldansaz et al., 2004). We recorded whether males orientated to the pheromone source (moving to the upwind edge of the release cage/platform and exhibiting rapid antennal movement), as well as the time taken to either walk to the source or initiate flight. The experiment was replicated $\times 3$ with 15 males per replicate at each wind velocity, using a randomized block design.

A split plot design was used to test the effect of distance of males from the pheromone source (at 40, 70, and 100 cm) at the same three wind speeds, 40, 80, and 120 cm/sec. There were three replicates, each testing 12 males at all distance/wind speed combinations.

Field Experiments

The distinct female calling posture observed under constant laboratory regimes may be less evident under variable field conditions (Goldansaz and McNeil, 2003), so we examined the effect of wind on female calling and male-searching behaviors under field conditions on the

campus of Laval University, Ste-Foy, Quebec, on September 15 and 27, 2001. These were clear days, and during observation periods temperatures varied between 14–17°C and 12–14°C, respectively. On both days, the calling behavior of 30 oviparae from the laboratory culture, each held on an individual potato seedling placed on a large table around 10:00 hr, was recorded every 30 min from 11:00 to 15:00 hr. Over the same time period, the behavior of males in clean air was also tested hourly on both days. One hundred males, in individual release cages, were placed on the table each morning and two cohorts of 10 individuals were tested each hour. We removed the covers from the release cages, and the behaviors of the 20 males were recorded over a 3-min period, noting if they remained immobile, walked (around the cage and/or the release platform site), or took flight. During each observation period, the wind speed were monitored for 1 min, and because of the variability during the experiment the results were grouped in categories 0– X m/sec, where X was the maximum wind speed observed during a given recording interval.

The behaviors of individual males in the presence of five calling females on a potato seedling were examined under field conditions between 14:00 and 16:00 hr on the October 11 ($N = 29$) and 24 ($N = 17$), 2001. Both days were clear, and during the bioassays air temperatures varied between 17–15°C and 16–13°C, respectively. As in the controlled wind tunnel experiments, females were placed 40 cm upwind of the male, and a string bridge connected the platforms holding the potato plant and the release cage. The cover of the release cage was removed and the behavior of individual males was recorded for 3 min.

Statistics

The proportion of males taking flight in the presence or absence of calling females as a function of wind speed was compared with an analysis of contrasts, using the GENMOD procedure (SAS, 1999). Categorical responses (orient/not orient; reach the source/not reach the source) of males exposed to calling females were compared with a logit model using the GENMOD procedure of SAS (SAS, 1999), whereas the times to reach the source as a function of wind speed were compared with an ANOVA, using the GLM procedure of SAS. The proportions of males taking flight, orienting to, and/or reaching the source at different wind speeds and distances were compared with a logit model.

Results

Laboratory Bioassays

There was no change in the calling behavior of oviparae under the range of constant wind velocities tested in the wind tunnel (Fig. 1). In contrast, the propensity of males to take flight in clean air varied with wind speed ($df = 5$, $\chi^2 = 126.89$, $P < 0.001$: because winds of 120 cm/sec totally inhibited flight, we excluded this treatment from the analysis). The proportion taking flight increased with increasing wind speeds up to 40 cm/sec and then declined at higher wind speeds, with practically 100% inhibition at > 80 cm/sec (Fig. 1).

When a pheromone source was present, $> 80\%$ of males oriented toward the source at all wind speeds tested. However, at a wind velocity of 40 cm/sec, fewer males took flight compared with those tested in clean air ($df = 1$, $\chi^2 = 14.63$, $P < 0.001$; Fig. 2). At wind velocities of 80 ($df = 1$, $\chi^2 = 0.11$, $P = 0.74$) and 120 cm/sec ($df = 1$, $\chi^2 = 1.40$, $P = 0.24$), relatively few males took flight and the proportions were not affected by the presence or absence of pheromone (Fig. 2). In all cases, orienting males moved to the upwind edge of

Fig. 1 Effect of wind speed on the proportion of *M. euphorbiae* oviparae calling and males taking flight ($\bar{x} \pm$ SEM; three replicates of 15 individuals at each wind speed) in a wind tunnel at $18 \pm 0.5^\circ\text{C}$, 40–50% RH

the release cage/platform but, if taking flight, they all flew downwind and not toward the source. However, when there was a bridge available, some males reached the calling females by walking. Wind speed had a significant effect on the proportion of males orienting toward ($df = 2$, $\chi^2 = 11.11$, $P = 0.004$; Fig. 3a), and walking to the source ($df = 2$, $\chi^2 = 16.78$, $P < 0.001$; Fig. 3b), both of which were higher at the higher wind velocities when male flight was inhibited (see Fig. 2). The time taken to reach the source was also influenced by wind speed ($df = 2$, $F = 8.63$, $P = 0.035$), taking longer at 120 cm/sec than at the lower wind velocities (Fig. 3c). Varying the distance to the source did not significantly modify the effect of wind speed on the proportion of males orienting to the source, initiating downwind flight, or reaching the source (Tables 1 and 2). As expected, at any given wind speed, there was an obvious effect of distance on the time to reach the source (Table 1). There was also a significant wind speed \times distance interaction (Table 2), due to the fact that for any given distance between the release site and the calling females, males at

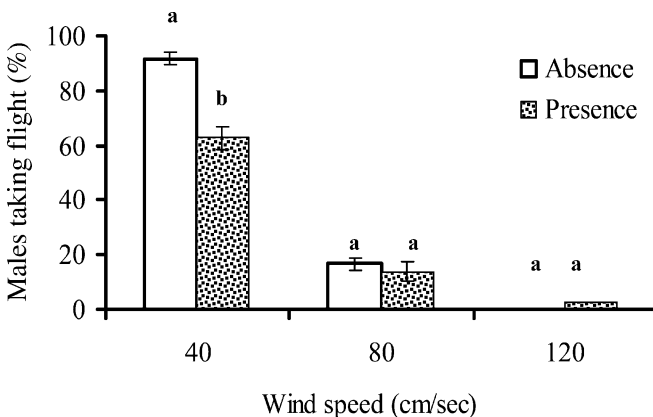

Fig. 2 Effect of wind speed on the proportion of *M. euphorbiae* males ($\bar{x} \pm$ SEM; three replicates of 15 individuals) taking flight in the presence or absence of calling sexual females in a wind tunnel at $18 \pm 0.5^\circ\text{C}$, 40–50% RH

a wind speed of 80 cm/sec took less time to reach the source than those tested at either 40 and 120 cm/sec (Table 1).

Under field conditions, females sustained calling behavior at variable wind speeds up to 4 m/sec, but above this level calling was rarely observed (Fig. 4a,b). A proportion of males exhibited downwind flight behavior if wind speeds did not exceed 2 m/sec, but above this velocity flight was inhibited (Fig. 4a,b). However, some males exhibited active walking behavior at wind speeds up to 4 m/sec, the upper limit at which females called (Fig. 4a,b). When males were tested in the presence of calling females, the behaviors observed in the field differed somewhat from those under laboratory conditions. As before, responding males oriented by moving to the upwind edge of the release cage/platform, and 52% of the 46 males tested still walked to the source. However, about 30% flew upwind to the calling females, with few flying downwind (Fig. 5). Detailed studies of male behaviors during the assay carried out on October 11 (Fig. 6) showed that males walked upwind when there were wind currents, but if the wind dropped to < 25 cm/sec (indicated as 0 in Fig. 6 reading

Fig. 4 Effect of wind speed on the proportion of *M. euphorbiae* oviparae calling and males taking flight ($\bar{x} \pm \text{SEM}$) under variable wind conditions in the field on September 15 (a) and 27 (b), 2001. Thirty females and 20 males were observed at each observation period

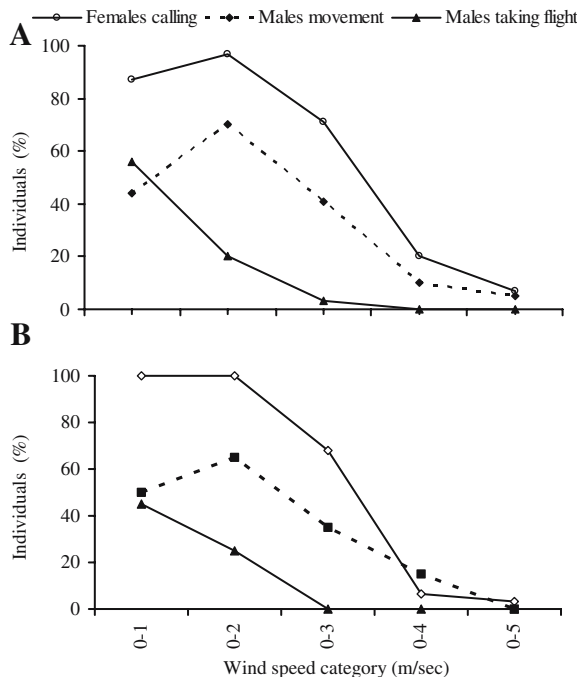

Fig. 5 Responses of *M. euphorbiae* males ($N = 46$; $\bar{x} \pm \text{SEM}$) to calling females located 40 cm upwind under variable wind conditions in the field assays carried out on October 11 and 24, 2001. Males could either fly or walk to the source

because of the sensitivity of the anemometer) during their approach toward the females they profited from the lull to take off and fly to the source. We verified this behavior experimentally in the laboratory by cutting off the wind when walking males were half way across the bridge: within seconds, the males ($N = 12$) took flight and moved in the “upwind” direction toward the calling females.

Discussion

Our results show that the wind speeds prevailing during late summer and fall could have a significant effect on the manner in which *M. euphorbiae* males forage for receptive females. Whether sex pheromone was present or not, male flight was inhibited at constant wind speeds > 1 m/sec in the laboratory, and under variable field conditions, if the maximum velocity exceed 2 m/sec. This is not surprising because many small insects stop flying at relatively low wind speeds (Juillet, 1964; Kring, 1972; Nealis, 1986; Kennedy, 1990; Fink and Völkl, 1995; Messing et al., 1997; Weisser et al., 1997; Marchand and McNeil, 2000). The values observed here for *M. euphorbiae* males are similar to those reported for flight by virginoparous alates of *Aphis fabae* in clean air (Kennedy, 1990), and *Cavariella aegopodii* to plant odors (Chapman et al., 1981).

Although the initiation (Dixon and Mercer, 1983) and termination (Thomas et al., 1977) of flight are active decisions, once in flight aphids are rather clumsy fliers, and movement is generally governed by prevailing wind direction (Dixon and Howard, 1986). Thus, under windy conditions, oriented flight toward a pheromone source may be ineffective and certainly energetically costly (see Keller, 1990). Prevailing environmental conditions

Fig. 6 Temporal pattern of wind velocity during the assay carried out on October 11, 2001, to test the response of *M. euphorbiae* males to calling females located 40 cm upwind under variable wind conditions in the field. The periods identified as W and F represent the conditions under which males either walked or flew to the source

fashion how animals search (Bell, 1991), so the evolution of walking as a major component of mate location in species which are not strong fliers would certainly be beneficial because the inability to fly during strong winds decrease a small insect's reproductive success (Weisser et al., 1997). Our laboratory and field experiments supported this hypothesis in the case of potato aphid males. First, both female calling and male ambulatory behaviors continued at winds approaching 4 m/sec, well above the threshold that inhibited male flight behavior. Second, at lower wind speeds, the proportion of males initiating downwind flight decreased for males orienting toward a pheromone source, which would not be expected if flight were the principal means of locating calling females. However, as seen in the field studies, flight is an integral component of aphid mate searching under appropriate conditions, providing a more rapid means of displacement toward receptive females and facilitating movement from branch to branch when branches are not in direct contact. Kennedy (1990) reported an acceleration in the incidence of “taking off” behavior in black bean aphid parthenogenetic alates following a period when flight was inhibited by winds of 2 m/sec. A similar behavioral postinhibitory rebound by males could play an important role in mate location and merits further investigation. The combined use of ambulatory and flight movement in response to varying environmental conditions has been demonstrated in other insects, such as the Colorado potato beetle (Boiteau, 2001) and parasitic wasps (e.g., Weisser et al., 1997), as well as with male moth responses to pheromone sources (e.g., Willis and Baker, 1987).

We used secondary (summer) rather than primary (fall) host for maintenance of our colonies, so another aspect of the mate location behavior of *M. euphorbiae* males that merits further investigation is the possible role of host plant volatiles. Clean potato plants, or those infested with parthenogenetic aphids, did not induce orientation and walking to the source, but these behaviors were elicited when males were exposed to oviparae on potatoes or just to synthetic pheromone lures (Goldansaz et al., 2004). It is probable that primary plant cues could increase these two responses, but just as the presence of the sex pheromone reduces the incidence of flight (Fig. 2), so the presence of these volatiles might reduce, rather than increase, the probability of take off by males.

It is likely that *M. euphorbiae* males use flight as the primary means of locating habitats where there are receptive females, possibly integrating olfactory cues such as primary host plant volatiles and the female sex pheromone, as suggested for other aphid species (Campbell et al., 1990, Hardie et al., 1994) and phytophagous insects (Landolt and Phillips, 1997). Gynoparae of the black bean aphid, *A. fabae*, appear to have an obligatory “migrant phase” in their maiden flight, flying for a significantly longer time before responding to visual cues that alate virginoparae (Nottingham and Hardie, 1989; Hardie, 1994). Whether male aphids, which also appear in the fall, show a similar tendency with respect to their response to host plant cues remains to be determined. However, prior sustained flight is not a prerequisite for male response to a pheromone source, because the potato aphid males used in our bioassays had no previous flight experience but nevertheless oriented to and approached calling females. However, because many males will be produced by females who are already on primary host plants, extended flight by males in search of receptive ovipare may not be necessary.

Species-specific differences may exist in the respective roles of flight and walking behavior in mate location in aphids. Under seminatural conditions, male hop aphids exhibited upwind flight to a pheromone source (Hardie et al., pers. comm.), but in the present study potato aphid males only flew toward the source during wind lulls. Therefore, comparative research on the behaviors associated with mate location in aphids will be required, within a meaningful ecological framework, to clarify species-specific differences

and to establish whether any generalized trends exist for the Aphididae. This should include detailed studies on the interactions between wind speed and distance from the source affecting male movement, for these relationships certainly are not straightforward (Tables 1 and 2). In addition, there is a need to examine how the complex canopy structure of primary host plants influences plume structure and, thus, the behaviors of aphid sexuals. Such experiments would provide information on the temporal and spatial aspects of the chemical cues actually reaching males and how male aphids respond to such variability, and possibly provide broader insight into the evolution of mate location strategies of insects with poor flight capabilities.

Acknowledgments The research was supported by grants from NSERC and FCAR to J.N.M. and financial support to S.H.G. from the Iranian Ministry of Science, Research, and Technology. We thank L. Pelletier, M. Maury, S. A. Goldansaz, and S. Langevin for technical assistance; G. Daigle for help in statistical analysis; and J. Brodeur for constructive comments on an earlier version of the manuscript.

Abstract The principal sex pheromone component of the whitemarked tussock moth (WMTM), *Orgyia leucostigma*, was recently identified as (Z,Z)-6,9-heneicosadien-11-one (Z6Z9-11-one-21Hy). However, it is thermally unstable and quickly degrades under field conditions so that baited traps are effective for only one night. We have developed a solution to this problem that combines two techniques: (1) the use of a stable pheromone precursor, (Z,Z)-6,9-heneicosadien-11-one ethylene ketal, which is hydrolyzed to the dienone by an acidic aqueous solution (2% *p*-toluenesulfonic acid in 35% aqueous sorbitol), and (2) use of a small, off-the-shelf, autonomous pump (the Med-e-Cell Infu-disk™) to deliver the precursor continuously to a suitable substrate where it is converted rapidly into the attractive dienone pheromone component. The pump and hydrolysis substrate fit inside sticky traps and because generation and release of pheromone is continuous, the instability of the pheromone is not an issue. In electroantennogram bioassays, dose-dependent responses were obtained with 1 to 1000 ng of hydrolyzed ketal on filter paper, but no response was obtained to 1000 ng of the ketal itself. In wind tunnel bioassays, males were attracted to lures emitting the dienone pheromone component generated from 0.1 to 100 ng of the hydrolyzed ketal. Field tests in 2004 and 2005 showed that sticky traps fitted with the pump delivering the ketal (0.1–1 µg/µL in heptane) at 10 µL/hr to a cotton pad soaked with the hydrolyzing solution were attractive to male WMTM. No moths were caught in controls or traps baited with (Z)-6-heneicosen-11-one. An average of 0.51 moths per trap night was caught over an 18-night period in 2005. The

Introduction

The whitemarked tussock moth (WMTM), *Orgyia leucostigma* (J. E. Smith) (Lepidoptera: Lymantriidae), is a serious forest pest in eastern Canada. In 1998, over 5.9 million ha of balsam fir forest were severely defoliated or killed by an outbreak of WMTM in Nova Scotia (van Frankenhuyzen et al., 2002; Grant et al., 2003). Fruit crops were also threatened. In 2004, a new outbreak of WMTM was discovered in the balsam fir forests in the Cape Breton highlands of Nova Scotia (R. Guscott, Nova Scotia DNR, personal communication). This population increased substantially in 2005 and, along with two other balsam fir pests, caused visible defoliation. The infestation is now targeted for research and operational spray programs.

Whitemarked tussock moth populations in the maritime provinces of Canada have been monitored with traps baited with a commercial lure containing (Z)-6-heneicosen-11-one (Z6-11-one-21Hy). Although Z6-11-one-21Hy is produced by the WMTM female (Liu, 1999) and is attractive to males (Grant, 1977; Grant et al., 2003), few WMTM are caught, particularly at low population levels, owing to the lure's low potency. Thus, these monitoring traps were not effective in providing early detection of the aforementioned outbreaks in Nova Scotia.

A substantially more attractive sex pheromone component of WMTM was recently identified as (Z,Z)-6,9-heneicosadien-11-one (Z6Z9-11-one-21Hy; Liu 1999; Grant et al., 2003). It was effective at low doses (1 µg/lure) and low population levels, and it was more than 100-fold more attractive in laboratory bioassays than the minor pheromone component, Z6-11-one-21Hy, currently used for monitoring (Grant et al., 2003). Furthermore, the dienone pheromone component does not appear to attract other tussock moth species in North America, such as the rusty tussock moth, *Orgyia antiqua*, or *Dasychira* tussock moth species, which are attracted by Z6-11-one-21Hy (Daterman et al., 1976; Grant 1977) and which occur in the Maritimes. Hence, Z6Z9-11-one-21Hy would be a superior lure for detecting WMTM outbreaks.

Unfortunately, Z6Z9-11-one-21Hy is thermally unstable and degrades after one night in baited traps (Grant et al., 2003). This compound is also a key pheromone component for another economically important tussock moth species, the painted apple moth, *Teia anartoides*, in New Zealand (El-Sayed et al., 2005; Gries et al., 2005). Thus, a new type of lure is needed to overcome the limitations imposed by the compound's instability, so that baited traps will be effective throughout the flight season without requiring rebaiting. We have developed a solution to this problem that combines two techniques: (1) the use of a stable synthetic precursor or propheromone (Liu et al., 1984; Pickett et al., 1984) that can be readily converted to Z6Z9-11-one-21Hy and (2) the use of a small, off-the-shelf, autonomous pump to deliver the precursor continuously to a suitable substrate where it is converted into the dienone pheromone. Because the generation and release of Z6Z9-11-one-21Hy is continuous, its instability is not an issue. Here, we report the results of experiments that demonstrate the success of this approach.

Methods and Materials

Precursor Chemistry

After preliminary experimentation with two potential precursors of the WMTM dieneone pheromone component, we focused our attention on the ketal (*Z,Z*)-6,9-heneicosadien-11-one ethylene ketal (Fig. 1). Details of its synthesis and purification (>98%) will be described elsewhere (Liu, unpublished data). The ketal is readily converted to *Z,Z*9-11-one-21Hy by acidic hydrolysis (Fig. 1).

Wind Tunnel Bioassays

The effect of ketal concentration on pheromone production and WMTM male behavior was evaluated in a wind tunnel, 2 m long with a 1 × 1 m cross section, and a wind speed of about 0.35 m/sec (Grant et al., 2003). Bioassays were conducted between 10:30 and 13:30 hr, at 23–24°C and ambient relative humidity. Laboratory-reared males from the WMTM colony at the Great Lakes Forestry Centre were held under continuous light and assayed when 1–2-d-old. Males were transferred individually to small screen cages and conditioned in the wind tunnel for at least 1 hr before a test.

Ketal solutions were made up in 10-fold dilutions in hexane at concentrations from 10 to 0.01 ng/μL. Just before the start of a bioassay, 10 μL of a ketal solution were deposited onto a 3-mm-thick, 1 × 1 cm pressed cotton pad (Med-e-Cell, San Diego CA, USA) that had been treated 5–10 min beforehand with 600–700 μL of a 2% solution of *p*-toluenesulfonic acid in 35% aqueous sorbitol (Sigma-Aldrich, Oakville, ON, Canada). Sorbitol was included because it was used in field tests described below to retard evaporation of the solution on the substrate. The pad was then placed in a small nylon screen cage to facilitate handling. The cage was suspended from a wire support about 40 cm above the wind tunnel floor and about 10 cm from the upwind end of the tunnel. Bioassays were started within 10 min of treating the pad with the ketal solution and lasted about 1–1.5 hr.

Caged males were introduced one at a time into the pheromone plume. They were held there until they began wing-fanning behavior and then were released about 20 sec later. If a male failed to become active after 60 sec, a new male was tested. The following behavioral events were recorded: (1) the number of males that began wing fanning when placed in the pheromone plume, (2) the number of males that “locked on” to the plume when released, (3) the number of males that reached (touched) the lure after being released and the time required to do so, and (4) whether or not the male landed on the lure. Thirty males were tested with each dosage of hydrolyzed ketal. To accommodate the small number of males available per day and to simplify the handling of lures, males were tested against only one or two dosages per day until 30 males per dosage had been tested. Controls consisted of cotton pads treated only with ketal at dosages of 1, 10, 50, or 500 ng. Five males were tested against each dosage.

Fig. 1 Hydrolysis of (*Z,Z*)-6,9-heneicosadien-11-one ethylene ketal with an acidic aqueous solution (2% *p*-toluenesulfonic acid in 35% aqueous sorbitol) generates the labile WMTM pheromone component, (*Z,Z*)-6,9-heneicosadien-11-one

Electroantennogram Bioassay

Antennal responses from male WMTM to hydrolyzed ketal (i.e., to Z6Z9-11-one-21Hy) were obtained by electroantennogram (EAG) bioassays. Adults (1–2-d-old) were decapitated and the head and antennae fastened with thin strips of masking tape to a small platform. Glass electrodes filled with 0.9% NaCl were inserted into the distal and proximal segments of an antenna. Gold wires from each electrode were connected to a Syntech portable INR-2 amplifier (Syntech, Hilversum, NL), which was connected in turn to a personal computer containing a Syntech data acquisition interface board (type IDAC-02) and Syntech EAG software for recording and analyzing the EAG responses.

Test stimuli were applied to filter paper strips (1.8×0.8 cm) held in glass tubes (8×0.5 cm id) made from disposable Pasteur pipettes. Pipettes were connected to an airstream (500 mL/min) produced by a tank of high-purity compressed air. A 1.5 sec puff of air, controlled by a solenoid-actuated valve, passed through each glass tube containing a stimulus and over the antenna. The following stimuli were tested: blank filter paper; 15 μ L of the ketal hydrolyzing solution (2% *p*-toluenesulfonic acid in 35% aqueous sorbitol) on filter paper; 1000 ng of the ketal (dry) on filter paper; and filter paper strips dosed first with 1, 10, 100, or 1000 ng of ketal and then treated with 15 μ L of the hydrolyzing solution. The latter were tested successively within 30 sec of applying the hydrolyzing solution. They were reused once with a second antenna some 10–15 min later. A new set of stimuli was prepared for the next set of antennae. Each stimulus was puffed over an antenna at about 1-min intervals in the order given above.

Field Tests

We used a small, commercially available autonomous pump, the Infu-disk™ manufactured by Med-e-Cell (<http://medecell.com/>), to deliver the ketal precursor to a hydrolyzing substrate and generate the pheromone component, Z6Z9-11-one-21Hy. The pump operates by means of an electrochemical cell that is activated manually just before use. The pump forces liquid from a reservoir (5 and 10 mL capacities are available) at a preset rate. Experiments were conducted with the 5 mL Infu-disk (about 4.1 diam \times 1 cm) with a delivery rate of 10 μ L/hr (0.01 mL/hr), which provided an operational life of about 21 d. A few pumps with a higher delivery rate of 30 μ L/hr were also tested to provide a threefold higher level of pheromone for comparison although these pumps had a correspondingly shorter operational life.

A short plastic delivery tube, which emerges from the top of the Infu-disk, terminates with either a metal canula tip or a male luer tip to which a 20- or 22-gauge syringe needle can be attached (Fig. 2A,B). In either case, the end of the delivery tube was attached by means of staples to a 3-mm-thick, 2×7 cm cotton pad (Med-e-Cell) that served as the hydrolysis substrate (Fig. 2A). Care was taken to ensure that the opening of the canula or syringe needle was in contact with the pad but not obstructed by it. When readied for use, the pump reservoir was filled with the ketal solution by means of a syringe, the electrochemical cell was activated, and the pump was then taped into the thin plastic shell used for shipping the pump. The unit was attached to a Pherocon IC sticky trap by passing its wire hanger although the shell before the trap bottom was attached so that the pump and substrate could sit inside the trap (Fig. 2A). When traps were set out, the reaction substrate was soaked with the solution of 2% *p*-toluenesulfonic acid in 35% aqueous sorbitol applied with a syringe. In this initial field trial, we were interested in assessing how long the hydrolyzing substrates remained moist and active, so they were checked for dryness and, if deemed necessary, an aliquot of the solution was added to the pad to remoisten it.

Fig. 2 (A) Pherocon IC sticky trap fitted with a ketal-containing, 5-mL Infu-disk pump connected via a syringe needle to a 1×7 cm cotton pad (hydrolysis substrate), which has been soaked with a solution of 2% *p*-toluenesulfonic acid in 35% aqueous sorbitol. (B) Ketal-containing Infu-disk pump fitted with 6-mL plastic vial containing the cotton pad and several milliliters of hydrolyzing solution. The pump and vial are taped to the thin plastic shell used to ship the pump. The delivery tube from the pump enters the vial through one of the five holes drilled in the cap and is attached to the cotton pad inside. The dienone pheromone component escapes through the perforated cap

The field test in 2004 was conducted late in the WMTM flight season between 24 August and 20 September in four mixed deciduous stands in Sault Ste. Marie, ON, known to harbor low, endemic populations of WMTM. The test was exploratory and designed to determine if our preliminary set of pump parameters and ketal concentrations would produce sufficient pheromone in the traps to attract male moths. Heptane and 2-propanol were tested as ketal solvents because they have a low vapor pressure, reducing the potential for back pressure in the pump, and they were compatible with its plastic components. Ketal concentrations of 0.1 and 1.0 $\mu\text{g}/\mu\text{L}$ (1 and 10 mg/mL) were selected to match the 10 $\mu\text{L}/\text{hr}$ delivery rate of the pump and provide an estimated 0.28 and 2.8 ng/sec , respectively, of Z6Z9-11-one-21Hy on the substrate. Because the test was exploratory, traps were deployed and taken down on different days. They were inspected daily, and moths were counted and removed. This procedure allowed us to confirm that pheromone was being produced continuously during the test. Comparisons were made with unbaited control traps ($N = 3$) and traps ($N = 5$) baited with 200 μg of (*Z*)-6-heneicosen-11-one (Bedoukian Research, Danbury CT, USA) in polyethylene vial closures (caps; no. 60975d-3 Kimball).

By using the results of the 2004 test as a guide, we selected 5 mL Infu-disks containing ketal at a concentration of 0.35 $\mu\text{g}/\mu\text{L}$ in heptane, and a delivery rate of 10 $\mu\text{L}/\text{hr}$ for the 2005 field test. This concentration of ketal was chosen as a reasonable compromise between the 0.1 and 1.0 $\mu\text{g}/\mu\text{L}$ concentrations tested in 2004. Although heptane is immiscible with water (on the hydrolysis substrate), heptane appeared as effective as 2-propanol in the 2004 tests, and hexane was acceptable as the ketal solvent in the flight tunnel bioassays.

In 2005, the cotton pad used as the hydrolysis substrate was enclosed in a 6-mL plastic vial to serve as a reservoir for the hydrolyzing solution to keep the substrate uniformly moist for the duration of the test. Five 5-mm holes were drilled in the vial cap to allow pheromone to diffuse out. The delivery tube of the Infu-disk was threaded through one of the holes in the cap and attached to the cotton pad (about 4.5×1 cm) with staples. The pad was then inserted into an empty vial, which was screwed onto the cap. The pump was activated, placed in its plastic shell, and the vial and pump were taped to the shell. The

entire unit was attached to the wire hanger of the Pherocon IC sticky trap (Fig. 2B). About 4 mL of the hydrolyzing solution were syringed into the vial through a hole in the cap when the trap was hung in the field.

Traps were deployed at seven sites in Sault Ste. Marie on 12 and 13 July 2005. Six sites each received a trap baited with the ketal-loaded Infu-disk matched with a second trap baited with 100 μg of Z6-11-one-21Hy for comparison. Traps were positioned about 25 m apart in each site. The seventh site received two ketal-baited traps and two traps baited with Z6-11-one-21Hy. With one exception, traps were taken down on 30 July. The exception involved one of the ketal-baited traps at the seventh site. This trap had failed to catch any moths between 13 and 26 July in contrast to the other ketal-baited trap at this site. Its pump was not functioning, so the pump was replaced on 26 July with a fresh ketal-loaded pump and allowed to operate until 19 August 2005.

Statistical Analysis

Means are shown with standard errors ($\pm\text{SE}$). The percentages of males successfully reaching different dosages of the lure in the flight tunnel bioassays were compared with the 1-ng dosage with the use of the Fisher exact test (Zar 1984). Mean EAG responses to the nonhydrolyzed ketal and blank filter paper were compared with the paired *t*-test (Zar 1984).

Results

Wind Tunnel Bioassay

Hydrolysis of the ketal at all dosages tested resulted in $>85\%$ of the males initiating wing-fanning behavior, and all but the 0.1 ng dosage induced a high percentage (77–90%) of males to lock on to the plume and fly upwind (Fig. 3). More males (83%, $P < 0.001$, Fisher

Fig. 3 Results of wind tunnel bioassays showing the effect of different dosages of the hydrolyzed ketal on the behavioral responses of male WMTMs

exact test for each comparison with the 1 ng dose) reached the 1 ng dosage lure and landed on it than with the other three dosages tested. The 0.1 ng dose apparently generated too little pheromone because only 30% of the males locked onto the pheromone plume and flew upwind. The two higher ketal doses (10 and 100 ng) apparently generated too high a level of pheromone. Males released into the higher-dose plumes usually locked on to the plume but then remained at or near the release point, casting from side to side before making slow, hesitant progress toward the lure. Otherwise, males in the high-dosage plume drifted slowly backwards from the release point, until they went out the back of the flight tunnel. No males were activated or took flight when exposed to substrate treated only with the ketal.

EAG Bioassay

There was no difference in the mean EAG response to 1000 ng of the dry ketal on filter paper (0.05 ± 0.01 mV, $N = 8$) and the mean EAG response to blank filter paper (0.06 ± 0.01 mV, $N = 8$; $P = 0.65$, paired t -test). In contrast, dose-dependent responses were elicited by the ketal on filter paper when treated with the hydrolyzing solution (Fig. 4). Because no significant EAGs were obtained in response to the ketal by itself or to the hydrolyzing solution (0 ng; Fig. 4), the response to the hydrolyzed ketal was due to the hydrolysis product, Z6Z9-11-one-21Hy.

Field Tests

All ketal-baited traps in the initial trial in 2004 caught WMTM (Table 1). Traps fitted with pumps loaded with a ketal concentration of $1 \mu\text{g}/\mu\text{L}$ delivered at $10 \mu\text{L}/\text{hr}$ caught more moths than similar traps with pumps loaded with $0.1 \mu\text{g}/\mu\text{L}$ ketal delivered at the same rate. Catches in traps fitted with pumps delivering ketal at $30 \mu\text{L}/\text{hr}$ (presumably producing a

higher level of pheromone) were no better than traps with the lower delivery rate of $10 \mu\text{L/hr}$. Also, as expected, their operational life was considerably shorter (6–7 d; Table 1) and, thus, not as practical for monitoring purposes. Heptane and 2-propanol appeared to be equally suitable as solvents for the ketal. All but one trap had catches on more than one night, indicating that Z6Z9-11-one-21Hy was being generated throughout the experiment. The cotton pads in two traps that ran for ≥ 19 d required an additional aliquot of the hydrolyzing solution during the course of the test, whereas the pads in the remaining four traps were almost dry at the end of the test. No WMTM were caught in the unbaited control traps or traps baited with Z6-11-one-21Hy, although rusty tussock moths, *O. antiqua* (0.96 moths/trap night), were caught in the latter.

Fig. 5 Mean (\pm SE) daily catch of WMTMs in sticky traps fitted with Med-e-Cell Infu-disk pumps delivering $0.35 \mu\text{g}/\mu\text{L}$ ketal at the rate of $10 \mu\text{L/hr}$ to a cotton pad substrate treated with 2% *p*-toluenesulfonic acid in 35% aqueous sorbitol. The right-hand axis shows the number of traps per night that successfully caught moths

For the 2005 field test, we selected 5 mL Infu-disks containing ketal at a compromise concentration of 0.35 $\mu\text{g}/\mu\text{L}$ in heptane and a delivery rate of 10 $\mu\text{L}/\text{hr}$. All but one malfunctioning trap caught moths by 19 July and all but this one trap caught moths on three or more nights between 13 July and 30 July (Fig. 5). After the pump in the inactive trap was replaced on 26 July, this trap caught moths on 27 and 30 July when the test ended (except for this trap). A total of 74 WMTM were caught in eight traps over 18 nights, an average 0.51 moths/trap night. All the vials still contained the hydrolysis solution at the end of the trial and the cotton pad substrates inside were still completely wet. None of the traps baited with the Z6-11-one-21Hy caught WMTM, but rusty tussock moths were again caught in these traps.

The trap in which the ketal pump was replaced on 26 July subsequently caught moths on 18 out of the 24 nights between 26 July and 19 August, with an average catch of 4.8 moths/night. On the nights of 3, 4, and 5 August, this trap caught 17, 21, and 17 moths, respectively, suggesting that the peak WMTM flight occurred after the termination of the earlier part of the test on 30 July.

Discussion

Several studies have examined the potential for using pheromone precursors or propheromones to address various types of pheromone instability (Beever et al., 1977; Liu et al., 1984; Pickett et al., 1984; Streinz et al., 1993). Typically, these compounds were converted to the active pheromone by exposure to air or light. Our approach required hydrolysis of a ketal precursor and was dependent on finding a suitable device for delivering the precursor to the hydrolysis substrate, such as the Infu-disk pump. A different version of this device had been used in an experimental trial to emit the antiaggregation pheromone, 3-methyl-2-cyclohexen-1-one, to control attacks of the spruce beetle, *Dendroctonus rufipennis* (Holsten et al., 2003). The appeal of the pump device in that case was its constant delivery rate. In our case, the small size, autonomous operation, the 5 and 10 mL reservoir capacities, and the low delivery rates of the Infu-disk were qualities well suited for use in a monitoring trap. The challenge was to match the ketal concentration to the delivery rate of the Infu-disk pump to provide a level of Z6Z9-11-one-21Hy attractive to WMTM under field conditions.

The 2004 field trials showed that ketal concentrations between 0.1 and 1 $\mu\text{g}/\mu\text{L}$ delivered at a rate of 10 $\mu\text{L}/\text{hr}$ to the hydrolyzing substrate were effective. In that trial, the cotton pad substrates dried out as the trial proceeded. When some of these substrates were dried completely in the laboratory and then retreated with the hydrolyzing solution, they attracted males in the flight tunnel, indicating that not all the ketal reaching the substrate had been converted to the dienone pheromone. The wind tunnel and EAG bioassays indicated that the ketal by itself was not bioactive unless hydrolyzed. We improved the substrate system by enclosing the cotton pad in a perforated 6-mL vial that served as a reservoir for the aqueous solution, thereby keeping the substrate wet throughout the trial.

The seemingly low rate of catch (0.51 moths/trap night) in 2005 with the dienone-baited traps was probably a reflection of the low endemic population of WMTM (no larvae or cocoons were ever visible) and the deployment of the experiment before the usual flight peak in August. The one trap left operating in August had higher catches. Further increases in trap catch might be obtained by optimization of the emission of the dienone from traps through improvements in the pump design or its configuration with the hydrolysis substrate.

Nonetheless, males were caught consistently in the dienone traps on a nightly basis over the test period, and they outperformed traps baited with 100 µg of Z6-11-one-21HY, which caught no moths. In 1975, in the same test area, sticky traps baited with 100 µg of Z6-11-one-21HY in polyethylene caps caught an average of 0.84 moths/trap night, whereas female-baited traps caught 1.95 moths/trap night (Grant 1977). Larvae, cocoons, and egg masses of WMTM were visible on trees and buildings that year (unpublished observations), indicating a much higher WMTM population level than in 2005. This suggests that sticky traps emitting the dienone by hydrolysis of the ketal are a more sensitive method of monitoring WMTM than traps baited with Z6-11-one-21HY.

The response of males in the flight tunnel to hydrolyzed ketal had a narrow dose–response profile with respect to males reaching the lure. This narrow dose–response profile could reflect the absence of the minor pheromone components Z6-11-one-21HY or (*Z,E*)-6,8-heneicosadien-11-one (Liu 1999), although field tests did not show that these components combined with the dienone component increased attraction of males (Grant et al., 2003). The availability of a method for generating the dienone on a continuous basis, however, provides an opportunity to revisit this question with a more stable level of the dienone component. Also, the unstable dienone quickly degrades to several isomers (Gries et al., 1997, 2005; Grant et al., 2003; El-Sayed et al., 2005). Their presence in the pheromone plume could have adversely affected male attraction in the wind tunnel, particularly when the dose of the dienone was high. Finally, the hydrolysis reaction is rapid, because males began wing fanning a few seconds after the ketal was added to the hydrolyzing substrate. Thus, the reaction could produce an initial burst of dienone that for high-dosage lures may be too concentrated for the males. A longer delay before testing the dienone lures to allow for equilibration may improve the male's responses to the high-dosage lures.

Our experiments combining a ketal precursor of the unstable dienone pheromone component, Z6Z9-11-one-21Hy, with an autonomous pump are a first step toward developing a practical monitoring system for WMTM. This system may also prove useful for other species utilizing the same dienone pheromone component. The Infu-disk is also available with a 10-mL reservoir, which has a theoretical life of about 42 d with a 10 µL/hr delivery rate, and which may be more useful for monitoring traps. This slow release system also may offer a potential means of incorporating the unstable diene pheromone component into mating disruption programs for the WMTM (Grant 1978) and the painted apple moth (Suckling et al., 2002).

Acknowledgments The research was supported by the Enhanced Pest Management Methods program, Canadian Forest Service. We thank the National Sciences and Engineering Research Council of Canada for financial support of K.N. Slessor, Henri Maget of Med-e-Cell for helpful discussions on the use of the Infu-disk, and the Insect Rearing Unit at Great Lakes Forestry Centre for the supply of tussock moths. We are grateful to Melanie Coppens for her valuable assistance with the field tests.

Introduction

Oryctes monoceros Oliv. (Coleoptera, Scarabaeidae, Dynastinae) is one of the main pests in the coconut and oil palm plantations of tropical Africa (Lever, 1969; Mariau, 1981), particularly in Ivory Coast (Echimane et al., 1992). The Asian species, *Oryctes rhinoceros* L., which is found throughout the Asia-Pacific area, has a similar ecology and is equally harmful to cultivated palms (Waterhouse and Norris, 1987). Damage is generally caused by adults making feeding galleries in the apical section of young palms, but also of mature palms when populations are large. Larvae develop in decaying dead palm wood. Damage has increased over the last 20 yr as a result of large-scale replanting programs, which leave substantial numbers of felled stems on the ground, multiplying suitable sites for egg laying and larva development (Julia and Brunin, 1974). Periodic surveys carried out in plots at the Marc Delorme research station in Port Bouet (Ivory Coast) have revealed up to 40% damage in 0- to 5-yr-old oil palms (Mariau, 1981). In Africa, damage is worsened through attacks by *Rhynchophorus phoenicis* (Fabr.), which lays eggs in the galleries made by *O. monoceros* and often kills palms.

Removing or burning felled stems, or covering them with a legume, *Pueraria javanica* (Benth.), to prevent larval infestation has been recommended (Mariau and Calvez, 1973); however, these measures are rarely applied because of cost and the high planting density of palms (130–160/ha). Biological control has also been studied, but no pathogen (not even *Baculovirus oryctes*, which is quite active against *O. rhinoceros*) or parasitoid tested has provided long-lasting action against *O. monoceros* (Huger, 1966; Julia and Mariau, 1976a; Purrini, 1998; Seguni et al., 1999). The only control method currently used is manual extraction of adults from feeding galleries and insects (especially larvae) present in decaying old stems. This is highly labor intensive and is impossible in tall standing palms. Frequent insecticide applications are only possible in agroindustrial sectors, but they entail serious environmental risks (Echimane et al., 1992).

Other ways have been explored to control this pest, in particular mass trapping with attractants. Ethyl chrysanthemumate was rapidly abandoned because of insufficient catches (Julia and Mariau, 1976b). More recently, ethyl 4-methyloctanoate (**1**), reported as the male aggregation pheromone of *O. monoceros* (Gries et al., 1994) and *O. rhinoceros* (Hallett et al., 1995; Morin et al., 1996), proved to be a powerful attractant for *O. rhinoceros* (Purba et al., 2000). In a preliminary study, it also showed promise for *O. monoceros* (Allou et al., 2002).

We conducted trials in Ivory Coast to determine if the advances made for *O. rhinoceros* control (Morin et al., 2001a; Sudharto et al., 2001) could be applied to *O. monoceros*. We focused our assessment on: (1) the plant material [oil palm empty fruit bunches (EFB) and coconut wood (CW)] as co-attractants with **1**, (2) the efficiency of two types of traps, and (3) the study of 4-methyloctanoic acid (**2**), an untested molecule regularly emitted by *O. monoceros* males (Gries et al., 1994; Rochat et al., 2004).

Materials and Methods

Attractants

Palm material: About 15 L of plant material were used per trap. We tested the following: (1) 1-wk-old oil palm EFB obtained after processing in the oil mills and (2) CW disks

(6 cm thick and 30 cm diam) from 40- to 60-yr-old trees that we cut and left on the ground under natural conditions for 0.5, 1, 1.5, 2.5, and 3.5 mo before testing. The disks were sprayed with water from time to time during the dry season. For a given age category, three disks were cut into four pieces and placed in the trap. Plant material was not renewed once the trials had started.

Synthetic Chemicals

Ethyl 4-methyloctanoate: *O. monoceros* pheromone (**1**) and 4-methyloctanoic acid (**2**; 99% chemical purity by gas chromatography; racemic mixtures) were synthesized by EGNO-Chimie (Tancarville, France). The dispensers used were sachets made from high-density polyethylene (Alplast, Sainte-Marie-aux-Mines, France). Compound **1** was formulated in model D dispensers (25 × 50 mm, 200- μ m-thick film) containing about 1 mL of pheromone, which emitted 13–14 mg/d under field conditions in an earlier assessment (Allou et al., 2002). Compound **2** was formulated in dispensers made of 100- μ m-thick film. Four models were used: d1, 25 × 50 mm; d2, 12.5 × 50 mm; d3, 12.5 × 12.5 mm; and d4, 6.2 × 12.5 mm. To estimate average daily release rates, all dispensers were filled to last >1.5 mo and were weighed monthly and quarterly in trials 1–5, and 6, respectively.

Traps

Two types of trap were used. One is the pail trap that consisted of a covered 30-L plastic bucket with five holes (diam 5 cm) in the lid. The pheromone dispenser was suspended from the lid. Another type, the tube trap, based on the model described by Morin et al. (2001b), consisted of a vertical polyvinyl chloride (PVC) tube (height 2 m, diam 16 cm) with two apertures (20 × 10 cm) in its upper section 140 cm from the ground. The top of the tube was open while the base stood in a recipient with holes for rainwater drain-off. The dispenser was hung inside the tube, above the two apertures, and protected from direct sunlight with a piece of cardboard.

Trials

The study consisted of six trials conducted by using the same layout and procedure. They comprised eight randomized blocks 100 m apart, and within each block the traps, hung on poles 1.5 m from the ground, were spaced 50 m apart. They were inspected every 3 d and rerandomized every 6 d. Trial 5 compared both types of traps.

The majority of the trials were carried out at the Robert Michaux plantation, in Dabou, 65 km west of Abidjan. The traps were installed in a 19-ha plot, a coconut seed garden, located in the middle of a 4000-ha oil palm estate, planted in 1977 with the Malayan Yellow Dwarf variety. However, trial 3 was conducted in a 12-ha experimental coconut plantation in Assinie (30 km east of Abidjan on the coast) planted in 1999 with PB 121 hybrids combined with tree legumes, *Acacia mangium* and *Acacia auriculiformis*.

- Trial 1 (effect of addition of EFB to **1**) was carried out from 24 January to 21 February 2002, and compared the following three treatments: (1) **1** only, (2) **1** + EFB, and (3) EFB only.
- Trial 2 (comparative effects of EFB and CW with **1**) was conducted from 16 September to 16 October 2002, and comprised six treatments: (1) **1** only, (2) **1** + EFB, (3–6) **1** + 3.5-, 2.5-, 1.5-, and 0.5-mo-old CW, respectively.

- Trials 3 and 4 assessed the effect of 2 with 1 + EFB. Trial 3 was carried out from 2 August to 1 September 2002, with five treatments: (1) 1 + EFB, (2–5) 1 + EFB + 2 emitted from dispensers d1, d2, d3, and d4, respectively. Trial 4 was conducted from 23 January to 22 February 2003, with the same protocol but with an additional treatment, (6) EFB + 2 from dispenser d1.
- Trials 5 and 6 compared the effectiveness of both types of traps (pail and tube) with 1 + either EFB or CW. They comprised four treatments: (1) 1 + EFB in the pail trap, (2) 1 + EFB in the tube trap, (3) 1 + CW in the pail trap, and (4) 1 + CW in the tube trap. Trial 5 took place from 19 September to 22 December 2003, and plant material was not renewed. In trial 6, EFB and CW were renewed each month and every 6 mo, respectively. Pheromone dispensers were renewed every 3 mo in both trials. In trial 6, bait renewal was postponed by ± 10 d on some occasions because of unforeseeable events. Trial 6, started on 7 April 2004, was set up for pest control and served, secondarily, to assess the monthly renewal of EFB (as compared to trial 5), and, as it is ongoing, we present 15 mo of results (last data from 1 July 2005).

Effect of Trapping on Coconut Damage

The coconut seed garden at the Dabou plantation had been planted to produce hybrid seeds but was abandoned in the 1990s. In 2000, it was decided to restore it to its initial function, and new management practices, including monthly inspections, were introduced to monitor the phytosanitary condition of the palms. A report is prepared yearly, including the percentage of palms killed by combined *O. monoceros* and *R. phoenicis* (Coleoptera, Curculionidae) attacks. From January 2000 to December 2001, no special effort was made to control the beetle due to the large size of the palms and the absence of traps. However, damage was high, with surrounding oils palms a constant source of beetles, so it was decided to start pheromone trapping as a control option with trials 1–2 and 4–6 starting in January 2002. At that time, 24–48 traps (1.2–2.5 traps/ha) were installed in the block, on three occasions for 1 mo, in 2002 and early 2003 (trials 1, 2, and 4). Thirty-two traps (1.7 per ha) were installed for another 12 mo, then permanently from April 2004 (trials 5–6). The effect of olfactory trapping was assessed by studying annual trends in coconut palm mortality over a 5-yr period (2000–2004).

Statistical Analyses

In all the trials, the individual in each trap were pooled together over 6-d periods. Trials 1–4: The effect of the treatments was assessed by ANOVAs on values transformed by $(x + 0.5)^{1/2}$. Differences in average catches were assessed by Newman–Keuls multiple comparison tests at 5% (Statitcf Software, 1991). Trials 5–6: Data were analyzed by using a multifactor ANOVA with a GLIM procedure after transformation by $\ln(x + 1)$. The experimental factors were trap type (pail or tube), the kind of palm coactractant (EFB or CW), and the block. The trapping period was an additional factor included in the model, with corresponding interactions for trial 5. The average ages of the baits after installation (EFB, CW, and pheromone dispensers) were introduced as covariables, as catches clearly fluctuated periodically in trial 6 (Fig. 4). Differences in average catches were assessed by Tukey multiple comparison tests (Minitab v12.2, 1998).

Fig. 1 Comparative catches of *O. monoceros* in 30-L pail traps baited with synthetic pheromone: ethyl 4-methyloctanoate (**1**) diffused at a rate of 15 mg/day, 1-wk-old oil palm EFB, or the two combined (trial 1). Treatments with different letters differed significantly (Newman–Keuls test at $\alpha = 0.05$ on $(x + 0.5)^{1/2}$ transformed data)

Results

Compound **1** was emitted at 12.7 ± 1.9 mg/d (mean \pm S.D.; $N = 384$) over all trials, with a minimum of 9.1 mg/d in trial 5 to a maximum of 15.2 mg/d in trial 1. Compound **2** was emitted at 3.8 ± 0.5 , 2.4 ± 0.6 , 1.3 ± 0.4 , and 0.6 ± 0.2 ($N = 16$) from dispensers d1, d2, d3, and d4, respectively.

Fig. 2 Comparative catches of *O. monoceros* in 30-L pail traps using synthetic pheromone: ethyl 4-methyloctanoate (**1**) without plant material (control) or with various palm co-attractants: 1-wk-old oil palm EFB, CW after aging outdoors for 0.5, 1.5, 2.5, or 3.5 mo (trial 2). Treatments with different letters differed significantly [Newman–Keuls test at $\alpha = 0.05$ on $(x + 0.5)^{1/2}$ transformed data]

More males than females were caught in trials 1–4 (64% of 794) and 6 (57% of 4,989), while in trial 5 both sexes were equally represented (51% of 704).

Effect of Addition of Palm Material to Compound 1

A total of 292 beetles was captured in trial 1. The majority were caught in EFB + **1** traps, and while there were significantly fewer in **1** traps, **1** alone was more effective than EFB alone (Fig. 1; Newman–Keuls tests, $P < 0.05$).

A total of 340 beetles was caught in trial 2. Whereas there were no significant differences between the treatments that included a source of palm volatiles, traps baited with

Fig. 3 Effect of 4-methyloctanoic acid (**2**), a volatile emitted by males, assessed at different ratios with synthetic pheromone: ethyl 4-methyloctanoate (**1**) in 30-L pail traps containing 1-wk-old oil palm EFB on *O. monoceros* catches in (a) trial 3, 2002, and (b) trial 4, 2003. Treatments with different letters differed significantly [Newman–Keuls test at $\alpha = 0.05$ on $(x + 0.5)^{1/2}$ transformed data]

the pheromone **1** and either 3.5- or 2.5-mo-old CW captured significantly more than **1** alone (Fig. 2).

Effect of Compound 2

In 2002, the release rate of **2** did not significantly affect the trap catch. However, at the two highest release rates, the number of beetles captured was significantly lower than in traps without **2** (Fig. 3a). In 2003, very few beetles were captured, due in part to heavy rainfall (some traps were flooded). However, as in the previous year, traps with EFB + **1** captured more beetles than EFB + **1** with **2** at the highest release rate although lower rates gave variable results (Fig. 3b). EFB + **2** captured no beetles at all.

Comparison of Trap Types with EFB or CW

Trap type and the kind of palm coacttractant added to **1** significantly affected catches (trap: $F_{1,41} = 21.8$; $F_{1,24} = 141$; palm: $F_{1,41} = 16.1$; $F_{1,24} = 15.0$ in trials 5 and 6, respectively; $P < 0.001$). Tube traps caught more beetles than pail traps, whatever the bait, whereas CW + **1** was more attractive than EFB + **1** regardless of trap type and renewal frequency (Table 1).

A significant “palm × trap” interaction was observed in trial 6 ($F_{1,24} = 4.44$; $P < 0.05$; Table 1) due to the unexpectedly high performance of EFB in tube traps, although globally CW was better than EFB, irrespective of trap type. The presence of a significant interaction in trial 6 but not in trial 5 could be the result of renewing EFB monthly in trial 6, combined with other unknown factors.

Seasonal Variation in Catches in Trial 6

About 5000 beetles were removed from the plot in 15 mo. The sex ratio of the beetles fluctuated from 26% to 70% female, with an average value of 43%. Overall, no significant decrease in catches (C as the mean catch per period) was recorded over time (T as the 6-d period numbered from 1 to 75; $C = -0.008 + 2.38T$; $F_{1,73} = 2.50$; $P = 0.12$). Catches ranged

Table 1 Comparative Captures (Mean ± S.E.) of *O. monoceros* in Traps with Pheromone Bait (**1**) as a Function of Trap Type (Pail or Vertical Tube) and Palm Coacttractant

Trial	No. periods (mo)	Trap	Palm coacttractant ¹		
			EFB	CW	Both
5	15 (3)	30-L pail	0.95 ± 0.10	1.40 ± 0.13	1.18 ± 0.09
		Vertical tube	1.48 ± 0.14	2.04 ± 0.16	1.77 ± 0.10 ²
		Both	1.22 ± 0.08	1.73 ± 0.11 ²	
6	75 (15)	30-L pail	1.28 ± 0.07 ^c	1.69 ± 0.08 ^b	1.48 ± 0.07
		Vertical tube	2.58 ± 0.11 ^a	2.76 ± 0.11 ^a	2.67 ± 0.07 ²
		Both	1.93 ± 0.07	2.22 ± 0.11 ²	

EFB: oil palm empty fruit bunches; CW: coconut stem wood.

¹Catches analyzed by GLIM ANOVAs on Ln($x + 1$) transformed data and means compared using Tukey multiple comparison tests.

²Significant differences between tube and pail traps, and EFB (empty fruit bunches) and CW (coconut wood), irrespective of the bait and trap, respectively ($\alpha = 0.01$). Average catches (per treatment and per 6-d period) with different letters were significantly different ($\alpha = 0.05$) in the case of significant palm × trap interactions (trial 6 only).

Fig. 4 Variation in *O. monoceros* catches at the Robert Michaux Plantation over 15 mo with 32 (16 pail plus 16 tube) traps baited with synthetic pheromone: ethyl 4-methyloctanoate (**1**) and 15 L of either oil palm EFB (renewed monthly) or coconut stem wood (CW renewed quarterly) from April 2004 to July 2005 (trial 6). Arrows indicate actual renewal of CW, EFB, and pheromone (P) and unavoidable run out of most of the pheromone dispensers (Pro)

from 0.2 to 4.8 beetles/trap/6 d, with an average of 2.1 (Fig. 4). These fluctuations were not correlated to the age of the palm material (EFB: $F_{1,24} = 0.40$ and CW: $F_{1,24} = 0.22$; $P > 0.5$) but significantly decreased with pheromone dispenser age ($F_{1,24} = 16.06$; $P < 0.001$). On two occasions, when bait renewal was unavoidably delayed, most of the dispensers ran out and resulted logically in lower catches (Fig. 4).

Fig. 5 Reduction in damage (dead palms) in the 19-ha coconut seed garden at the Robert Michaux plantation (Dabou) after 15 mo of olfactory trapping from January 2002 to December 2004 without any modification to the other plant protection measures. The dotted line indicates when trapping was initiated and the gray bars when trials 1, 2, and 4–6 were run

Effectiveness of Olfactory Trapping in the 19-ha Seed Garden at the Robert Michaux Plantation

Damage (dead coconut palms) caused by *O. monoceros* + *R. phoenicis* in the coconut seed garden at the Dabou plantation was 3.5% in 2000 and 3.8% in 2001 (Fig. 5). No insect control (neither insecticide applications nor particular cultural practice) was carried out in those 2 yr, except the elimination of dead coconut palms. Trapping clearly had an effect as palm mortality dropped to 0.5%, 0.2%, and 0.0% in 2002, 2003, and 2004, respectively (Fig. 5).

Discussion

Synergistic Effects of Decaying Palm Material with Pheromone

Our results show that decaying palm material, either EFB or CW, is a powerful coattractant with the aggregation pheromone **1** of *O. monoceros*, as previously reported for *O. rhinoceros* (Hallett et al., 1995; Alfiler, 1999; Sudharto et al., 2001). The effect of these host plant odors is another similarity of the two *Oryctes* species, which use the same aggregation pheromone. Although both odors are synergistic with **1**, CW was more efficient than EFB. CW can be prepared shortly before trapping starts, and is effective for 6 mo in both trap types. In contrast, EFB only works in a confined environment (straight pipe) and must be replaced each month.

Although the use of readily available plant material will enhance trap efficacy, the need to change it on a regular basis is labor intensive for vast trap networks. For instance, about 1 m³ of EFB is needed to service one trap for 1 yr. However, in using CW that only needs to be changed every 3 mo instead of monthly, one needs a chainsaw to prepare the pieces of CW effectively. Thus, the financial investment of this approach limits the availability to owners of small holdings.

The synergistic effect of plant odors on pheromone communication is common in insects, particularly in long-lived Coleoptera (Landolt and Phillips, 1997). This has been well documented for palm weevils Rhynchophorinae (e.g., *Rhynchophorus* and *Metamasius* spp.; Giblin-Davis et al., 1996; Rochat et al., 2000; Avand-Faghih 2004; Saïd et al., 2005) and certain scarabs, Dynastinae (e.g., *Scapanes australis* Bsdv. and *Oryctes elegans*: Rochat et al., 2002, 2004), where volatiles from freshly cut host plant tissues serve as cosignals with the pheromones for beetle aggregation on sites where both feeding, mating, and egg laying take place.

However, *O. rhinoceros* and *O. monoceros* feed individually rather than in aggregations on fresh tissues of living palms, although a palm may be attacked by several insects in succession (Morin, 1999). Thus, in these species, the synergistic effect of volatiles from decaying palm woody material (CW or EFB) with the pheromones is only important for aggregation at mating and egg-laying sites (Morin and Ollivier, 2001)

Inhibiting Effect of Compound 2

It is clear that when 4-methyloctanoic acid is combined with the aggregation pheromone (~30:70 acid/ester), there is a significant decline in the number of *O. monoceros* captured. This is in marked contrast with the findings for two other *Oryctes* species. In the case of *O. elegans*, 4-methyloctanoic acid serves as an aggregation attractant when combined with odors of freshly cut date palm stem (Rochat et al., 2004), whereas at 30 mg/d, either

evaluated alone or combined with the ethyl ester, it has no effect on *O. rhinoceros* (Hallett et al., 1995). Thus, *Oryctes* species appear to use 4-methyloctanoic acid and the ethyl ester derivative differently.

Interestingly, *O. monoceros* males emit variable amounts and ratios of both compounds (Gries et al., 1994; Morin et al., 1996). Although the origin and meaning of this variability are unknown, males may modulate the amount of acid emitted under certain circumstances and this may act as an antiaggregation signal to regulate densities at breeding sites (decaying woody material). Further research is required to clarify the situation, including the importance of chirality on the responses observed.

Comparison of Trap Types

The tube trap was more efficient than the pail trap for *O. monoceros*, as it was for *O. rhinoceros* (Morin et al., 2001b). The height and shape appear to be more adapted to the flight and approach behavior of the beetle, and insects entering the trap are prevented from escaping, without the need for insecticide or soapy water. The shape also helps keep the plant material moist for longer than in the more aerated pails, thereby lengthening the amount of time the pheromone cocontractants remains effective. Thus, as long as the bait remains active, the tube trap, which is sturdier than the pail trap in field conditions, could stay in the field for a long time without inspection or maintenance, making it suitable for use in coconut small holdings. The disadvantage remains to be its higher initial cost, and the availability of PVC tubes in remote areas.

Effect of Trapping on Damage to Coconut Palms

Despite continuous and stable catches over 3 yr, the damage caused by *Oryctes* (+ *Rhynchophorus*) decreased substantially in the 19-ha plot. The impact of olfactory trapping regimes have generally examined the reduction in a pest populations and this is, to our knowledge, the first comprehensive study showing reduced damage, as earlier reports analyzing 1–2 yr of trapping, reported mitigated effects (Ho 1996; Chung 1997). The insects caught since 2004 probably came from the oil palm plots surrounding the nursery, and the olfactory trapping clearly reduced attacks on palms whose considerable height (>8 m) prevented manual extraction of the insects from the galleries and insecticide applications. Our work has shown that olfactory trapping can be beneficial, and trials are under way to assess whether trapping intensity can be reduced while maintaining the benefit. This could be performed by either decreasing the trap density or by carrying out intermittent trapping at regular intervals. Studies are also in progress to evaluate the effect of trapping in immature crops.

Acknowledgments We are grateful to Peter Biggins from CIRAD for the English revision of the manuscript, and to two anonymous reviewers and Jeremy McNeil for helpful criticism.

Introduction

Plants have innate defense mechanisms that can be differentially activated in response to insect and pathogen attack. For example, plants may contain significant amounts of constitutive secondary metabolites including phenolics, terpenoids, and steroids, which are toxic to invading organisms. In addition to constitutive chemical defenses, there are also compounds that are actively produced or induced after penetration of the tissues has occurred. These inducible defenses are energetically expensive and are only produced upon specific recognition of an invading organism (Ryan and Jagendorf, 1995; Hahn, 1996; Schröder, 1998). Plants that are able to recognize an invading organism activate responses including a rapid localized cell death, also known as a hypersensitive response (HR), at the site of penetration and activation of biochemical defense responses. Biochemical responses include the following: production of reactive oxygen species, structural changes in the cell wall, accumulation of defense-related proteins, and phytoalexin biosynthesis. These chemical defenses can directly affect the development and survival of attacking organisms (Mür et al., 1997). Upon attack, plants may also produce secondary defense chemicals, volatile organic compounds (VOC's), which are released into their immediate airspace. These VOC's are produced by plants in response to attack by herbivores (McCall et al., 1994; Loughrin et al., 1995; Röse et al., 1996; Paré and Tumlinson, 1997) and pathogens (Cardoza et al., 2002; Huang et al., 2003). These VOC's are of great ecological relevance because they have been shown to attract parasitoids of insect pests (Turlings et al., 1991, 1993; Röse et al., 1998; Cardoza et al., 2003a) and to hinder pathogen development (Zeringue and McCormick, 1989, 1990; Zeringue et al., 1996; Cardoza et al., 2002).

While the responses of plants to individual attacks by insects and pathogens have been well studied, regulation of defense mechanisms that help plants cope with multiple stress factors remains to be elucidated. Similarly, it is not yet clear what defense pathways are involved in the production of VOC's by plants in response to combined insect and pathogen attack. Recent studies suggest that activation of plant defenses by pathogens interferes with plant defenses against herbivorous arthropods and *vice versa* (Karban et al., 1987; Bostock, 1999; Felton et al., 1999; Fidantsef et al., 1999; Stout et al., 1999). In light of these possible conflicts, studies on the interactions between insect and pathogen species, and the induced chemical changes that such interactions have on the host plant are needed.

An understanding of the dynamics involved in triggering plant innate defense mechanisms can lead to the development of crop protection based on genetic or chemical manipulation of such responses. The key to exploitation may lie in our ability to decipher the extent to which the biochemical defense cascades triggered within the plant by pathogen and herbivore damage interfere with one another, and to minimize these trade-offs. In this study, we evaluated VOC emissions elicited in bell pepper plants, *Capsicum annuum* L., by compatible and incompatible strains of the leaf spot pathogen, *Xanthomonas campestris* pv. *vesicatoria*, pepper race 1 (XCVP3; compatible) and tomato race 1 (XCVT1; incompatible). We also evaluated the effect of infection by these pathogens on the plants' ability to produce VOC's in response to feeding by beet armyworms (BAW), *Spodoptera exigua* Hübner. VOC

profiles of healthy plants and plants exposed to attack by the insect and the pathogen, individually and in combination, were analyzed and compared. The effect of infection with the two types of bacteria on the insects' feeding preference and larval development, from third instar to pupa, was also evaluated.

Methods and Materials

Plant and Insect Material

Pepper seeds "Early CalWonder" (Grimes, Concord, OH, USA) were sown in pairs in 1-gal pots (16 cm diam) containing Metromix 300 (Scotts-Sierra Horticultural Company, Marysville, OH, USA). Plants were grown in an insect-free greenhouse with natural light, under Florida summer conditions (14:10 light/dark cycle). The greenhouse temperature was kept between 25°C and 30°C. After emergence, seedlings were thinned to 1 individual per pot. Each plant received 100 ml liquid fertilizer [20:20:20 (N/P/K); Peters, W.R. Grace, Fogelsville, PA, USA] every 2 wk starting on the first week after emergence. Six-wk-old pepper plants with eight fully developed leaves were used in all experiments. BAW eggs were obtained from the rearing facilities at the USDA-IBPMRL (Tifton, GA, USA). Larvae were reared on a pinto bean-based artificial diet following the methodology described by King and Leppla (1984). Insects were maintained on a 14:10 L/D cycle and maintained at 28°C. Third instars were used in all experiments.

Bacterial Culture and Plant Inoculation

The initial cultures of *X. campestris vesicatoria*, pepper race 3 (XCVP3; compatible) and tomato race 1 (XCVT1; incompatible), were obtained from Jeffrey B. Jones (Department of Plant Pathology, University of Florida, Gainesville, FL, USA) and were grown on nutrient agar (NA) Petri plates. Subsequent cultures were started by using nutrient broth, and were stored in 15% glycerol at -70°C for later use. Viable cells for plant inoculation were obtained incubating 100 µl of the frozen culture in 50-ml conical centrifuge tubes containing 15 ml nutrient broth. Tubes were placed into a 200-rpm orbital shaker within a biological incubator kept at 28°C for 18 hr. Cells were harvested by spinning at 3000 × g for 10 min, and pellets were resuspended in tap water. Bacterial cell concentration was estimated by measuring absorbance with a spectrophotometer set at 600 nm. Concentration was adjusted to 10⁷ CFU/ml with water and 400 µl/l of Silwett L-77 were added to help cell penetration into the leaf. Plants were inoculated by dipping their aerial portions into the bacterial suspension for 20 sec. Control plants were mock-inoculated by dipping in the water Silwett L-77 mixture without bacterial cells.

Volatile Collections from Pathogen Infected and BAW-Damaged Peppers

Plant treatments consisted of (1) control (uninfected/undamaged) dipped in Silwett L-77 water, as described above; (2) BAW-damaged; (3) XCVP3-infected; (4) XCVT1-infected; (5) XCVP3-infected plus BAW damage; and (6) XCVT1-infected plus BAW damage. Plants were inoculated with bacteria as described above 12 hr before the start of the first sampling period. BAW-damaged plants were also exposed to feeding by six third instars within the volatile collection chambers 12 hr before the start of the first sampling period.

The aerial portion of each intact, nonexcised plant was contained within a cylindrical glass chamber with a guillotine-type Teflon base, which surrounded the plant stems (Röse et al., 1996). Purified air was pushed into the top of the chamber at a rate of 5 l min^{-1} . Samples of air from the whole-plant chambers were collected by pulling air at 1 l min^{-1} through 25 mg Super Q (80–100 mesh) (Alltech, Deerfield, IL, USA) adsorbent traps located around the bottom of each chamber (12). Volatiles were sampled for 4 d in three consecutive periods each day: (1) 6:00 A.M.–12:00 P.M., (2) 12:00–6:00 P.M., and (3) 6:00 P.M.–6:00 A.M. The experiment was set up in single replicates and repeated on different days for a total of six replicates. Data presented as total volatile production are for combined diurnal collection periods (1 + 2). Total volatile production represents the sum of the amounts of all the individual compounds produced by a given treatment.

Sample Extraction and Analysis

Compounds from individual traps in the volatile collection experiments were eluted with $170 \mu\text{l}$ dichloromethane (GC/GC-MS Solvent; B&J, AlliedSignal, Inc, MI, USA), and then 400 ng each of *n*-octane and nonyl acetate were added to each eluted sample as internal standards. Samples were analyzed by gas chromatography with flame ionization detection (HP5890 Gas Chromatograph, HP7673 auto sampler; Hewlett-Packard, Palo Alto, CA, USA) equipped with a $15 \text{ m (H)} \times 0.25 \text{ mm (ID)} \times 0.25 \mu\text{m}$ film thickness DB-1 capillary column (Quadrex, New Haven, CT). The splitless mode injector system was set at 220°C , the column oven was maintained at 40°C for 1 min after injection, and then programmed at $14^\circ\text{C min}^{-1}$ to 180°C . The carrier gas used was helium at an average flow velocity of 19 cm sec^{-1} .

For identification of volatile compounds, selected samples were analyzed via GC/MS (HP 6890/5893) in electron impact mode. Individual compounds were identified by comparing their retention times and mass spectra to those of commercially obtained authentic samples and/or by comparing their mass spectra to those available in a database from the Environmental Protection Agency/National Institute of Standards and Technology.

Effect of Bacterial Infection on BAW Larval Feeding and Performance

To determine if herbivore-induced defenses were compromised in bacterially infected plants, we conducted BAW feeding choice experiments at different times during disease development on the plants. Additionally, the performance of BAW, from third instar to pupa, on healthy and bacteria-infected peppers was evaluated.

To determine the feeding preference of BAW larvae for plants at different times during infection with both bacterial strains, insects were given a choice between leaves from healthy plants and leaves of plants 0, 2, 4, or 6 d after bacterial inoculation. Plants with eight fully developed leaves were used. The fifth oldest leaf of an infected plant was paired with its counterpart from a healthy plant by confining them, while still attached to the plants, side by side within Petri dish clip cages with six third instar BAW larvae (Alborn et al., 1996). Larvae were allowed to feed on the leaves for 24 hr. Leaves exposed to the feeding were photocopied, and the leaf images were scanned and imported into an imaging software program (ImagePC beta version 1; Scion Corporation, Frederick, MD, USA) to calculate leaf area eaten and leaf area remaining for each of the treatments. This experiment was repeated over time for a total of six replicates.

To evaluate larval performance on healthy and infected pepper, plants were individually placed within $46 \times 46 \times 46 \text{ cm}$ plexiglass cages into which 6 third instar BAW were introduced. Although insects were not weighed at the time of introduction, care was taken so that

all larvae used were newly molted third instars. Infected plants had been inoculated 3 d before the beginning of the experiment. Cages were kept in the greenhouse throughout the experiment. One plant provided more than enough food for all insects to develop until pupation. Insects were observed daily and were removed from the plants when they reached the wandering stage and no more feeding activity was observed. All insects from each of the treatments were collectively placed into a Petri plate labeled to indicate plant treatment and replicate number, and kept in the incubator until pupation. At the time of pupation, the number of surviving pupae and their weights were recorded. Eight replicates of this experiment were set up at one time in the greenhouse. This experiment was set up at two different times, by using either the compatible or the incompatible strain of the pathogen to inoculate plants.

Statistical Analyses

Data for total volatile emission were analyzed with ANOVA (SAS Institute, 1996). Significant ANOVAs were followed by Tukey's mean separation test. Data for BAW feeding preference were analyzed by paired *t* test (SAS Institute, 1996) for each day. Data for performance of BAW on healthy and bacteria-infected pepper were subjected to an analysis of variance (ANOVA; SAS Institute, 1996).

Results

Effect of BAW Feeding and Compatible and Incompatible Bacterial Inoculations on Volatile Production

Hypersensitive response symptoms were observed on the XCVT1-infected plants as early as 24 hr after inoculation, whereas chlorotic spots on the leaves in response to XCVP3 were seen only 3–4 d after inoculation. Volatile emission was highest during the second collection period (12:00–6:00 P.M.) and lowest during the third collection period (6:00 P.M.–6:00 A.M.) for the length of the experiment, regardless of plant treatment. Because of the high degree of variability, VOC emissions from the two diurnal collection periods were not different and were combined. The volatile blend emitted by plants under different biotic challenges consisted of mono- and sesquiterpenes, lipxygenase products, and methyl salicylate. However, there were differences in the amounts of each of these compound classes among the different treatments. For instance, total monoterpene release by plants damaged by BAW alone was the highest, followed by plants damaged by combinations of the herbivore and compatible and incompatible bacteria, respectively (Table 1). Monoterpene release by plants infected with the compatible bacterial strain were comparable to those of control plants; however, plants infected with the incompatible bacteria released higher amounts of these compounds on days 3 and 4 compared to controls (Table 1). Sesquiterpene release was significantly higher for plants under the XCVT1/BAW treatment during all 4 d sampled (Table 1). Plants exposed to XCVT1 and XCVT1/BAW had their highest sesquiterpene release on the first day of sampling, decreased on day 2, and remained constant during days 3 and 4 (Table 1). Release of sesquiterpene compounds by BAW damaged plants was equivalent to that released by plants under XCVP3/BAW attack, but higher than those of XCVP3-infected and control plants. Emission of sesquiterpenes by plants under XCVP3 infection alone was equivalent to that of the controls. Production of LOX products was most prevalent in the emissions of plants exposed to BAW damage alone or in combination with either bacterium (Table 1). Methyl salicylate was released by plants exposed to infection by either bacterium alone or

^b Values within days followed by different letters denote significant differences in emission of compound classes between treatments.

in combination with herbivore damage (Table 1). However, plants under the incompatible bacterial treatment started releasing this compound on day 1 (XCVT1/BAW) or day 2 (XCVT1), whereas plants under the XCVP3 treatment started releasing methyl salicylate on day 3 (Table 1). Furthermore, the amounts of methyl salicylate emitted by plants infected with the incompatible *Xanthomonas* were substantially higher than those emitted by plants infected with the compatible strain during the first 2 days of sampling (Table 1). A sharp burst in the release of this compound by plants under the XCVP3/BAW treatment on day 4 is noteworthy (Table 1).

Healthy (uninfected/undamaged; control) plants emitted relatively small VOC amounts throughout the sampling period (Fig. 1, Table 2). In contrast, plants infected with XCVT1, the incompatible strain, released amounts of volatiles that were higher than those emitted by XCVP3-infected plants and healthy control plants starting on the first day of collection

Fig. 1 Mean total volatile emissions from pepper plants for days 1–4 after bacterial inoculation. Bars within treatments headed by different letters denote significant differences between days (Tukey's mean separation test, $P = 0.05$). Error bars denote 1 SE

(Fig. 1). Emission of VOCs by plants exposed to the simultaneous bacterial and BAW challenge were higher than that of healthy plants or plants challenged by either bacterium alone (Fig. 1). Plants exposed to the XCV3/BAW also released higher amounts of VOC than healthy plants exposed to BAW damage starting on the second day of collection, which contrasts sharply with amounts released by XCV1/BAW-treated plants (Fig. 1).

Pepper plants exposed to the different bacteria/BAW treatments emitted distinct blends of compounds consisting of monoterpenes, homoterpenes, lipoxygenase products, linalool, methyl salicylate, and *cis*-jasmones. Pepper plants exposed to BAW feeding alone released a more complex VOC blend and a greater quantity of total volatiles, compared to healthy plants, or plants infected with either bacterium alone, starting on day 2 and persisting throughout the duration of the experiment (Table 1, 2). The VOC blend released by BAW damaged plants consisted of many compounds reported previously as induced by BAW feeding on other plant systems (Turlings et al., 1991; Turlings and Tumlinson, 1991; Röse et al., 1996; Cardoza et al., 2002) in addition to *Z*-3-hexenyl propionate, 2-methyl-hexyl-butyrate, 2-phenyl-ethyl-formate, *Z*-3-hexenyl-valerate, *Z*-3-hexenyl caproate, *Z*-3-hexenyl-hexenoate, β -elemene, α -selinene, and *Z*-3-hexenyl phenyl acetate (Table 2). Emission of VOC by plants infected with XCV3, the compatible strain, was comparable to that of control plants through the third day after bacterial inoculation. However, on day 4 after inoculation, XCV3-infected plants released higher amounts of β -ocimene, methyl salicylate, and α -selinene compared to healthy control plants (Table 2). The VOC profile of XCV1-infected plants was for the most part composed of α -pinene, limonene, β -ocimene, *E*-2-hexenyl butyrate, β -elemene, and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (Table 2). Plants under the simultaneous XCV3/BAW challenge released a blend consisting mainly of *Z*-3-hexenyl acetate, β -myrcene, β -ocimene, *Z*-3-hexenyl propionate, methyl salicylate, and 2-

^a Mean ± SE for 6 replicates per treatment.

^b Underlined boldface within columns indicate the six highest emissions within a treatment.

methyl-hexyl butyrate. The VOC profile of plants under the XCVT1/BAW treatment consisted mostly of β -ocimene, methyl salicylate, Z-3-hexenyl caproate, Z-3-hexenyl hexenoate, β -elemene, and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (Table 2). The relatively large amounts of sesquiterpene compounds released by XCVT1/BAW-treated plants starting on the first day of collection is particularly interesting (Table 1, 2). It is also worth noting that, on the first day of collection, the amounts of sesquiterpenes released by plants under the XCVT1 infection alone were similarly higher than those of other treatments, except XCVT1/BAW.

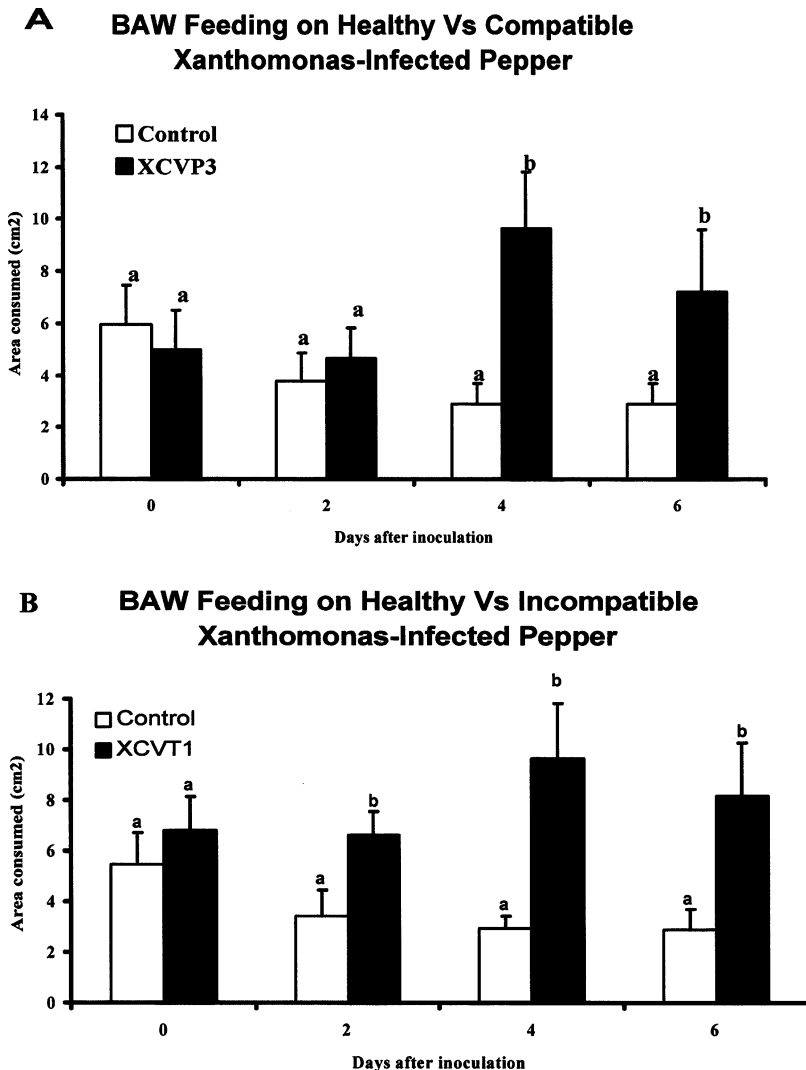

Fig. 2 Mean leaf area consumed by third instar *Spodoptera exigua* larvae in paired-choice tests with healthy (white bars) and *Xanthomonas* (thatched bars) plants at 0, 2, 4, and 6 d after bacterial inoculation. (a) Compatible (XCVP3) infection and (b) incompatible (XCVT1) infection. Error bars denote 1 SE and bars headed by different letters denote significant differences within days (paired *t* test, $P < 0.05$)

Effect of Bacterial Infection on BAW Larval Feeding and Performance

In a choice experiment, feeding by BAW on healthy and XCVP3 plants did not differ significantly on days 0 and 2 after inoculation (Fig. 2a). However, on day 4 and 6 after inoculation, there was a preference by the insects for XCVP3-infected leaves over healthy ones (Fig. 2a). When given a choice between healthy and XCVT1-infected plants, insects showed a significant preference for the latter starting on day 2. This preference was sustained until the end of the experiment (Fig. 2b). Pupal weights and time to pupation did not differ significantly between insects reared on healthy or bacteria-infected plants, regardless of bacterial strain. Combined pupal weights averaged 89.1 ± 16.80 (SD) mg. Mean (\pm SD) developmental time was 5.9 ± 1.24 for the combined treatments. Insects reared on plants infected by the two bacterial strains had significantly higher survival rates than those reared on uninfected plants ($F = 20.4$; $df = 2, 99$; $P = 0.0001$) Mean percent BAW survival (\pm SD) was 61.1 ± 16.01 on controls; 80.7 ± 11.29 on XCVP3 and 82.4 ± 15.67 on XCVT1.

Discussion

Secondary compounds produced by plants in response to insect and pathogen attack include low-molecular-weight VOC released into the plant's immediate air space. Insect herbivore-induced VOC attract natural enemies of the insects and may directly affect the performance of the organism responsible for the attack (Cardoza et al., 2002, 2003a,b). Similarly, pathogen-induced volatile substances may directly hinder pathogen development (Zeringue and McCormick, 1989, 1990; Zeringue et al., 1996; Cardoza et al., 2002). Previously, we reported that different stress factors induced the release of different volatile profiles (Cardoza et al., 2002; Huang et al., 2003). We showed that VOC release by peanut and tobacco plants is specific for compatible and incompatible pathogen infection, and for insect herbivore damage on the same plant system (Cardoza et al., 2002; Huang et al., 2003). Volatile profiles are also affected by the combination of factors afflicting the plant at any given moment (Cardoza et al., 2002). We further our contribution to this subject by evaluating the total volatile emission by pepper plants in response to a compatible and an incompatible pathogen infection alone or in combination with insect damage upon the same host plant. The effect of such pathogen infections on the feeding preference, survival, development, and weight gain of BAW on plants was also evaluated.

Our data show that the pepper plants' VOC emissions in response to damage by a herbivorous insect is significantly, and differentially, affected by inoculation with compatible and incompatible strains of a foliar pathogen. Plants exposed to the incompatible bacterial challenge emitted higher diversity and quantities of sesquiterpenes when exposed to BAW feeding than plants under the compatible bacterial challenge. Furthermore, herbivore-induced volatile emissions by plants are affected by bacterial infection and this interference depends on how soon the plant is able to detect the presence of the pathogen. Pepper plants exposed to the simultaneous XCVT1/BAW damage release a qualitatively different profile and lower amounts of BAW-induced compounds as soon as the second day after inoculation, whereas plants exposed to the XCVP3/BAW treatment released a similar profile, although higher amounts of some VOCs throughout the experiment compared to plants exposed to BAW damage alone (Table 1).

Our results also indicate that physiological changes induced in plants by a pathogen's development result in an increased phagostimulation of the insects. This phagostimulation may be attributable to reduced levels of defensive compounds in the infected plants. This

possibility is reinforced by the fact that the survival of the insects was higher when fed infected *versus* healthy pepper plants. Also, since insects reared on infected plants did not develop significantly faster, nor did they gain more weight, than those reared on healthy plants, the possibility of increased nutritional quality caused by the pathogen infection on the plant tissue is precluded. Our data are similar to previously reported findings, in that plant infection by a pathogen resulted in increased feeding and/or performance by an insect (Cardoza et al., 2002; Cui et al., 2002). The increase in insect feeding and performance on infected plants may have come as a consequence of biochemical changes induced by bacterial infection in the plants.

In recent years, there has been great interest in the potential applications of chemical elicitors to “vaccinate” plants to make them immune to attack or to “prime” them so their defense mechanisms are readily activated upon the first perception of pest damage. While chemical elicitation of plant defenses offers a promising alternative to environmentally harsh conventional pest control methods, caution needs to be exerted for there is a substantial body of evidence showing that the biochemical pathways involved in plant defense against pathogens and herbivores may interfere with one another. For example, recent studies have suggested that the plant pathway leading to jasmonate production and the salicylic acid pathway are involved in direct plant defense against pathogen invasion (Wasternack and Parthier, 1997; Thomma et al., 1998), and that the Jasmonic Acid (JA) and Salicylic Acid (SA) biochemical pathways may interfere with one another (Karban et al., 1987; Fidantsef et al., 1999; Stout et al., 1999; Bostock, 1999; Felton et al., 1999). This theory has been substantiated by findings that some insect species prefer feeding on plants that are either infected by pathogens or induced with SA analog (Felton et al., 1999; Fidantsef et al., 1999; Stout et al., 1999; Thaler et al., 1999; Cui et al., 2002). Another fact supporting this theory is that acetyl salicylic acid and SA inhibit lipoxygenase-induced plant defenses by preventing JA accumulation (Peña-Cortes et al., 1993; Doares et al., 1995). Since we found that plant inoculation with either pathogen enhanced the development and survival of insects fed on infected plant tissue, it appears that the signaling cascade in response to pathogen infection in our system interfered with production of both direct and indirect defenses against the herbivore in this particular system. Additionally, reduction in plant emission of VOCs in response to BAW feeding seem to correlate with the timing of plant detection of each of the pathogen systems tested herein. Plant resistance to pathogens is governed by “gene-for-gene” interactions so that when a pathogen has an avirulence (*avr*) gene and a plant has the corresponding resistance (*R*) gene, the plant can immediately detect the pathogen and respond defensively (Hahn, 1996; Hammond-Kosack and Jones, 1997; Dangl and Jones, 2001). When the interaction ends in pathogen establishment and disease development, the interaction is considered compatible. If the pathogen fails to establish because of resistance from the plant, and no disease develops, the interaction is incompatible. Incompatible pathogen interactions induce defensive responses in plants at a much faster rate than compatible pathogen one. Thus, the reduced amount of BAW-induced VOC in XCVT1-infected plants may be attributable to plant resource allocation to fight off the pathogen.

Although studies addressing the issue of potential conflicts in plant defense responses to pathogens and herbivores now abound, to our knowledge, this is only the second report to evaluate VOC emissions in live plants in response to simultaneous pathogen/herbivore challenge. It is the first one to do so with different pathogen compatibility systems and at different times during the disease development process. We expect that studies such as this will enhance our understanding of the regulation of plant defenses in response to different aggressors and will lead to the development and implementation of methods for plant protection that use defense priming compounds. The hierarchy governing plant defense responses when under

attack by pathogenic and herbivorous organisms merits further attention. Similarly, the potential role of plant hormones and their interactions in biochemical cascades leading to plant volatile induction by multiple herbivorous organisms needs to be investigated.

Acknowledgments The authors thank Hans T. Alborn, Peggy Brennan, and Carolina Briceño (USDA-ARS/CMAVE, Gainesville, FL) for technical support. Our appreciation is extended to Nancy Epsky (USDA-ARS/SAA, Miami, FL) and Claudio Gratton (Department of Entomology, University of Wisconsin, Madison, WI) for comments on a previous version of this manuscript.

phenotypic characters in a concerted way, being an important evolutionary factor for bacterial survival and host infection (Whitehead et al., 2001; Fuqua and Greenberg, 1998). In Gram-negative bacteria, the main signaling substances are the acyl-homoserine lactones (acyl-HSLs). Production of acyl-HSLs is widespread, being present in bacterial species found in different environments, as in *Vibrio fischeri* [*N*-(3-oxohexanoyl)-HSL], a marine bioluminescent bacterium, in *Pseudomonas aeruginosa* [*N*-butanoyl-HSL and *N*-(3-oxododecanoyl)-HSL], a human pathogen, and in *Rhizobium leguminosarum* [*N*-(3-(*R*)-hydroxy-7-*cis*-tetradecenoyl)-(*S*)-HSL], a rhizosphere symbiont (Eberhard et al., 1981; Pearson et al., 1994; Lithgow et al., 2000). The molecular basis of these communication mechanisms involves interaction between the signaling substance and a transcriptional regulator protein. An activated protein then binds to specific DNA regions, regulating the expression of genes important to multicellular behavior (Fuqua and Greenberg, 1998). The main class of genes responsible for acyl-HSL synthesis and detection are called *luxI* and *luxR* homologues, respectively (Engebrecht and Silverman, 1984).

Similar communication mechanisms are also described for plant pathogenic bacteria. In *Pectobacterium carotovorum*, the production of plant-cell-wall degrading enzymes and the antibiotic carbapenem are under the control of the signaling substance (*S*)-(-)-*N*-(3-oxohexanoyl)-HSL (Bainton et al., 1992; Jones et al., 1993). The same signaling substance is produced by the maize pathogen *Pantoea stewartii*, controlling the expression of an exopolysaccharide (EPS) that protects bacterial cells from host defense mechanisms. Also, this EPS obstructs fluid circulation in maize tissues, causing necrosis and cell death in leaves (Bodman and Farrand, 1995). However, in *P. stewartii*, the absolute configuration of the signaling substance was not determined. These examples show the importance of quorum-sensing mechanisms for successful host colonization by phytopathogenic bacteria. Quenching this communication mechanism is considered a promising avenue to control bacterial infections (Suga and Smith, 2003).

The absolute configurations of signaling substances are crucial for their biological activity. In the first work describing the chemical characterization of a signaling substance from a Gram-negative bacterium, the racemic synthetic compound (\pm)-*N*-(3-oxo-hexanoyl)-HSL was less active than the natural product in triggering *V. fischeri* bioluminescence. At that time, the smaller induction capacity was attributed to a less active enantiomer present in the racemic mixture (Eberhard et al., 1981). In *P. carotovorum*, synthetic (*R*)-*N*-(3-oxohexanoyl)-HSL was 90% less active than the natural enantiomer (*S*) during regulation of carbapenem antibiotic biosynthesis (Chhabra et al., 1993). In spite of the relevance of absolute configuration for biological activity and the large number of Gram-negative bacteria studied, the absolute configuration of acyl-HSLs has seldom been directly accessed from the natural products (Lithgow et al., 2000; Bainton et al., 1992; Pomini et al., 2005).

Pantoea ananatis (Serrano, 1928), a phytopathogen encountered worldwide, causes infection and losses in a wide variety of commercially important crops, such as sudangrass (Azad et al., 2000), pineapple (Serrano, 1928), sweet onion (Walcott et al., 2002), eucalyptus (Coutinho et al., 2002), and rice (Cothier et al., 2004), and has been identified as one of the bacteria in “white spot disease” of maize in Brazil (Paccola-Meirelles et al., 2001). In this work, the acyl-HSLs produced by *P. ananatis* CCT 6481^T (=ATCC 33244 type strain) were determined by using gas chromatography-mass spectrometry (GC-MS). The absolute configuration of the major acyl-HSL constituent was established with gas chromatography-flame ionization detection (GC-FID) equipped with a fused silica capillary column with a chiral stationary phase. Bioactivities of extracts, synthetic products, and fractions were qualitatively accessed by using the bioreporter *Agrobacterium tumefaciens* NTL4(pZLR4) in β -galactosidase expression assays.

Methods and Materials

General

Fourier-transform infrared (FTIR) spectra were obtained with a Bomem MB Michelson spectrometer, using KBr (Merck) as sample support. Silica gel for CC (0.035–0.070 mm) was from Merck. Thin layer chromatography (TLC) analyses were done on silica gel 60 F₂₅₄ plates (Merck) and visualized by exposure to UV light (254 nm) or spraying with an acidic *p*-anisaldehyde solution. Nuclear magnetic resonance (NMR) spectra were acquired by using a Varian Inova spectrometer, operating at 499.88 MHz for ¹H NMR and 125.71 MHz for ¹³C NMR or, alternatively, with a Varian Gemini spectrometer operating at 300.07 MHz for ¹H NMR and 75.45 MHz for ¹³C NMR. CDCl₃ was used as solvent and TMS as internal reference (δ_{H} and δ_{C} 0.0). Chemical shifts δ are expressed in ppm and coupling constants *J* in Hz. Optical rotation was measured on a Perkin-Elmer 341 polarimeter.

Bacteria and Media

P. ananatis Serrano CCT 6481^T (= ATCC 33244 type strain) was isolated from pineapple (*Ananas comosus*) 1965, Brazil and maintained on solid nutrient broth (NB, Oxoid, 20 g/l) medium. The indicator strain *A. tumefaciens* NTL4(pZLR4) was maintained on solid Luria–Bertani (LB) medium [1% peptone (Oxoid), 0.5% NaCl, and 0.5% yeast extract (Oxoid)], supplemented with gentamicin (50 $\mu\text{g/ml}$). Solid media were prepared with 2% agar (Oxoid). 5-Bromo-4-chloro-3-indolyl- β -D-galactopyranoside (X-Gal) was purchased from Sigma.

Extraction and Fractionation of Acyl-HSLs

P. ananatis CCT 6481^T was grown in test tubes containing liquid NB medium (10 ml), incubated at 28°C for 24 hr, then transferred to NB medium (1 l) to be incubated at 28°C under shaking at 150 rpm. After 24 hr, the culture medium was centrifuged at 5000 rpm for 20 min at 18°C. The centrifuged medium was extracted with ethyl acetate (3 \times 500 ml). The combined organic phases (1.5 l) were washed with distilled water (1 \times 500 ml) and evaporated under reduced pressure at 40°C. The whole procedure was repeated eight times yielding a crude extract (approximately 0.70 g), which was separated by silica column chromatography (15 g), eluted with hexane, dichloromethane, and ethyl acetate in increasing polarity, recovering 80 fractions of 50 ml, monitored by TLC. Similar fractions were combined and analyzed by GC-MS.

Bioassay with Reporter *A. tumefaciens* NTL4(pZLR4)

Inoculum of *A. tumefaciens* NTL4(pZLR4) was prepared in a test tube with LB liquid medium (2 ml). It was maintained at 28°C for 24 hr, until a cell concentration of 9×10^8 cells/ml, according to McFarland scale. Bioassays were performed in test tubes containing LB liquid medium (2 ml) with 20 μl inoculum of *A. tumefaciens* and 20 μl X-Gal (stock solution at 50 mg/ml in DMF). Biological activities were accessed by using 20 μl of ethanolic solutions (2 mg/ml) of each synthetic product [(\pm)-*N*-hexanoyl-HSL, (*S*)-(-)-*N*-hexanoyl-HSL, (\pm)-*N*-heptanoyl-HSL, and (\pm)-*N*-octanoyl-HSL], ethyl acetate extract from *P. ananatis* cultivation medium and the fractions. Three blanks were performed: (1) with

ethanol (20 μ l), (2) ethyl acetate extract from nutrient broth medium, and (3) with *A. tumefaciens* in the absence of other substances. Tests were performed in duplicate, by incubating the test tubes at 30°C for 24 hr.

GC-MS Analyses of Fractions from *P. ananatis* Cultivation Media

GC-MS analyses were carried out on an HP 6890/5973 instrument, equipped with a 30 m \times 0.25 mm \times 0.25 μ m i.d. HP5 fused silica capillary column. Mass spectra were recorded over the 40–450 amu range at 3.54 scans/sec, with an ionization energy of 70 eV. Helium was the carrier gas at a flow rate of 1 ml/min. The injector temperature was maintained at 250°C. The initial oven temperature was 100°C and was programmed to increase to 290°C at 10°C/min, then held for 10 min. One μ l samples were injected, without splitting.

Acyl-HSL Synthesis

Acyl-HSLs were synthesized as previously described (Chhabra et al., 1993). Briefly, to a round-bottom flask containing distilled water (2.5 ml), triethylamine (1.05×10^{-4} mol), α -amino- γ -butyrolactone hydrobromide [racemic or (*S*)-(-), 1.05×10^{-4} mol], and hexanoic, heptanoic, or octanoic acids (1.57×10^{-4} mol) were added. The reaction medium was stirred at room temperature overnight followed by extract ion with ethyl acetate (3 \times 10 ml). The combined organic phases were washed with aqueous solutions of potassium bisulfate 1 mol/l (2 \times 6 ml), sodium bicarbonate 5% (1 \times 6 ml), and saturated sodium chloride (1 \times 6 ml). The organic layer was dried over anhydrous magnesium sulfate, filtered, and evaporated to dryness under reduced pressure. Pure acyl-HSLs were obtained as white crystals.

Chiral GC-FID Analyses

Chiral gas chromatographic analyses were carried out on an HP 6890 instrument with FID, equipped with a 25.0 m \times 250.0 μ m \times 25.0 μ m chiral capillary column Chrompack CP chiral-sil-dex coating 7502. The initial oven temperature was 50°C and programmed to increase at 2°C/min to 180°C, and then maintained for 5 min. Hydrogen was the carrier gas at a flow rate of 1 ml/min. The injector and detector (FID) temperatures were kept at 220°C and 240°C, respectively. One- μ l samples were injected, with a 1:100 split ratio.

Results

Detection of Natural Acyl-HSLs

Initially, the presence of acyl-HSLs in *P. ananatis* CCT 6481^T extracts was qualitatively evaluated by using the bioreporter *A. tumefaciens* NTL4(pZLR4) (described later). In the present case, extracts from *P. ananatis* provided positive biological activity, stimulating more accurate chemical investigations.

Cell-free extracts from 8 l of *P. ananatis* cultivation medium were obtained and purified by using column chromatography. Similar fractions were grouped based on TLC analysis. Acyl-HSL monitoring usually relies on bioassays that use specific reporters. However, a literature survey indicated that these reporters have limitations for detecting some acyl-HSLs structurally distinct from those produced by the wild-type species from which the

reporter was genetically constructed (Cha et al., 1998; Ravn et al., 2001). To avoid the use of several reporters with different specificities, fractions from *P. ananatis* were analyzed by GC-electron impact mass spectrometry. This is possible because of the standard fragmentation pattern of acyl-HSLs, displaying an intense peak at m/z 143 arising from a McLafferty rearrangement of the acyl moiety. Signals at m/z 100, 101, and 102 are usually present in smaller relative abundance and are derived from the HSL (m/z 100) moiety (Pomini et al., 2005). This methodology allowed the chemical identification of *N*-hexanoyl-HSL (major), *N*-heptanoyl-HSL (traces), and *N*-octanoyl-HSL (traces) from *P. ananatis* (Fig. 1). The presence of *N*-octanoyl-HSL was evaluated with GC-MS operating in the single ion monitoring mode (SIM), for better sensitivity.

N-Hexanoyl-HSL

GC-MS (EI, 70 eV) m/z (%): 199 (M^+ , 2), 170 (5), 156 (12), 143 (100), 125 (21), 115 (7), 102 (12), 101 (15), 100 (10), 99 (25), 57 (62), 43 (51).

N-Heptanoyl-HSL

GC-MS (EI, 70 eV) m/z (%): 213 (M^+ , 3), 170 (5), 156 (15), 143 (100), 125 (22), 113 (16), 102 (11), 101 (15), 85 (19), 57 (59), 43 (47).

N-Octanoyl-HSL

GC-MS (EI, 70 eV, SIM) m/z (%): 227 (M^+ , 4), 170 (4), 156 (18), 143 (100), 128 (8), 127 (10), 125 (19), 102 (12), 101 (12), 85 (6), 57 (48).

Synthesis of Acyl-HSLs

The low amounts of natural acyl-HSLs prevented isolation and/or further NMR spectroscopic investigations. Therefore, identification was carried out by coinjecting the

Fig. 1 Acyl-HSLs identified from *Pantoea ananatis* cell-free extracts

natural products and synthetic substances onto GC-MS. Synthetic products were obtained through a one-step, simple procedure based on the production of an acid anhydride from the corresponding carboxylic acid, in the presence of a water-soluble carbodiimide derivative. α -Amino- γ -butyrolactone hydrobromide was then acylated by these *in situ* generated anhydrides, under mild basic conditions. Purification was facilitated because of the higher affinity of the acyl-HSLs than the reactants for organic solvents (Chhabra et al., 1993). All synthetic products were obtained in reasonable yields (~55%). They were fully characterized by spectroscopy (IR, GC-MS, ^1H NMR, and ^{13}C NMR in one and two dimensions) and by data comparison with the literature (data not shown). IR and ^1H NMR spectral data for *N*-octanoyl-HSL are provided for the first time.

(\pm)-*N*-Hexanoyl-HSL

54% yield. GC-MS (EI, 70 eV) data were identical to the natural product. IR, ^1H NMR, and ^{13}C NMR data were consistent with those previously reported (Chhabra et al., 1993; Lao et al., 1999).

(S)-(-)-*N*-Hexanoyl-HSL

54% yield. IR, GC-MS, ^{13}C NMR, and ^1H NMR data were identical to those obtained for the racemic compound. $[\alpha]_D^{20} -22.86^\circ$ (ca. 0.35 MeOH).

(\pm)-*N*-Heptanoyl-HSL

64% yield. GC-MS (IE, 70 eV) data were identical to the natural product. IR, ^1H NMR, and ^{13}C NMR data were consistent with those previously reported (Pomini et al., 2005).

(\pm)-*N*-Octanoyl-HSL

53% yield. GC-MS (IE, 70 eV) data were similar to the natural product. IR (KBr) 3316 (m), 2954 (m), 2928 (m), 1777 (s), 1644 (s), 1549 (s), 1172 (s), 1013 (m), 946 (w), 656 cm^{-1} (w). ^1H NMR (499.88 MHz, CDCl_3 , TMS) δ /ppm 0.88 (t, 3H, $J = 7.2$ Hz, H-8'), 1.29 (m, 8H, H-4', H-5', H-6', H-7'), 1.64 (quintet, 2H $J = 7.2$ Hz, H-3'), 2.15 (m, 1H, H-4), 2.26 (t, 2H, $J = 7.8$ Hz, H-2'), 2.83 (m, 1H, H-4), 4.28 (ddd, 1H, $J = 5.9, 11.1$ and 9.2 Hz, H-5), 4.46 (t, 1H, $J = 9.0$ Hz, H-5), 4.57 (ddd, 1H, $J = 5.7, 11.6$ and 8.6 Hz, H-3), 6.23 (broad s, NH). ^{13}C NMR data were consistent with those previously reported (Lao et al., 1999).

Bioassays with Reporter *A. tumefaciens* NTL4(pZLR4)

A. tumefaciens is a phytopathogen that causes crown gall tumor disease in several plant species. This bacterium exploits quorum-sensing communication mechanisms to control the expression of genes associated with the infection establishment, including plasmid conjugal transfer regulation (Piper et al., 1993). The mutant NTL4(pZLR4) does not synthesize the cognate signal *N*-(3-oxo-octanoyl)-HSL (Zhang et al., 1993) produced by the wild type strain, but can detect several acyl-HSLs. The detection mechanism consists of a plasmid (for a detailed scheme, see Cha et al., 1998) that contains a *traG::lacZ* fusion and the *traR* gene, which codifies the transcriptional regulator TraR. The protein TraR binds to exogenously added acyl-HSLs present in extracts, fractions, produced by other bacteria *in vivo*, or even synthetic products. The complex acyl-HSL-TraR regulates *lacZ* gene

expression, generating β -galactosidase enzymes that metabolize the added X-Gal reagent. X-Gal enzymatic hydrolysis produces a blue-colored indigo derivative, indicating a positive bioassay.

The ethyl acetate extract from *P. ananatis* cultivation media (1 l) provided positive biological activity. The same procedure was applied to the nutrient broth medium extracts, producing negative results and indicating that active metabolites came from microorganism metabolism. The biological activity of synthetic and natural products with bioreporter *A. tumefaciens* NTL4(pZLR4) was also evaluated, and the positive results corroborated the activity observed with extracts from *P. ananatis* cultivation media.

Absolute Configuration Determination

The optimum analytical conditions for the enantiomeric discrimination of synthetic (\pm)-*N*-hexanoyl-HSL (two peaks in 1:1 ratio) were established with GC-FID equipped with a fused silica Chrompack β -cyclodextrin column. The (*R*)- and (*S*)-*N*-hexanoyl-HSL retention times were accessed by comparing the racemic mixture to the synthetic (*S*)-(-)-*N*-hexanoyl-HSL. The absolute configuration of natural acyl-HSL was determined as (*S*)-(-)-*N*-hexanoyl-HSL by retention time comparison and coinjection with synthetic (\pm)-*N*-hexanoyl-HSL (Fig. 2).

Discussion

The present communication reports the occurrence of three acyl-HSLs for the phytopathogen *P. ananatis*, previously not reported for the *Pantoea* genus. These belong to an important class of signaling substances reported in several other Gram-negative bacteria. Interestingly, the identified metabolites are short-chain acyl-HSLs, similar to those detected in other species of *Pantoea*, *Pectobacterium*, and *Erwinia* genera (Bainton et al., 1992; Bodman and Farrand 1995; Pomini et al., 2005). These three genera are taxonomically closely related and were previously a part of only one genus, *Erwinia* (Hauben et al., 1998). It is now evident that the similarities are not only morphological, but also chemical. For comparison, in distantly related *Rhizobium* and *Sinorhizobium* genera cell communication employs long-chain acyl-HSLs, ranging from dodecanoyl to *N*-octadecanoyl-HSL (Marketon et al., 2002).

Fig. 2 Absolute configuration determination of natural (*S*)-(-)-*N*-hexanoyl-HSL using the GC(chiral)-FID methodology. (a) Enantiomeric discrimination of a synthetic racemic mixture [(*R*) enantiomer at 56.72 min and (*S*) enantiomer at 56.89 min]. (b) Analysis of synthetic (*S*) enantiomer (92% ee), at 56.93 min. (c) Analysis of natural (*S*)-(-)-*N*-hexanoyl-HSL from *P. ananatis* [(*S*) enantiomer at 56.93 min, >99% ee]. (d) Coinjection of natural product and synthetic racemic mixture, with increment in the relative abundance of the (*S*) enantiomer (56.95 min) in comparison with the (*R*) enantiomer (56.78 min)

Another interesting feature observed is the first occurrence of *N*-heptanoyl in the *Pantoea* genus. Odd-chain fatty acid derivatives such as *N*-heptanoyl-HSL are rare in nature. However, this metabolite was previously reported in *R. leguminosarum* (Lithgow et al., 2000) and *Erwinia psidii* (Pomini et al., 2005) using spectroscopic methods. Clues of its occurrence were noted in the fish pathogen *Edwardsiella tarda* (Morohoshi et al., 2004) and in *Serratia marcescens* (Hornig et al., 2002), using biorevelation procedures. Detection of this metabolite in *P. ananatis* increases its importance in quorum-sensing studies, and indicates the necessity of determining if propionate is in fact the acyl side chain biosynthetic initiator, as previously hypothesized (Whithers et al., 2001). However, in all reported cases, this substance was produced by the microorganisms in low amounts, which is an important drawback for accurate biosynthetic studies.

Prospecting of acyl-HSLs signaling substances is usually carried out by using biological reporters. These are genetically constructed microorganisms that contain a transcriptional regulator linking the expression of an observable phenotype to the presence of exogenous acyl-HSLs. The phenotypes include, for example, blue coloration in β -galactosidase assays [as in *A. tumefaciens* NTL4(pZLR4) employed here], bioluminescence, swarm motility, or production of colored antibiotics (Cha et al. 1998; Blosser and Gray 2000; Ravn et al., 2001). The use of bioreporters is crucial to understand the biological mechanisms involved, and is advantageous in high-throughput screenings of acyl-HSL producers. However, this methodology does not accurately identify the signaling substances. Protocols based on bioautography with TLC do not provide conclusive structural information on the acyl-HSLs produced. In addition, the bioreporter response to specific classes of acyl-HSLs (specially those closely related to the cognate signal produced by the wild-type strain from which the reporter was built) is a characteristic that leads to high sensitivity, but also to false negative responses when dealing with unusual acyl-HSLs. Thus, the use of several reporters of different specificities are required during bioguided studies (Cha et al., 1998; Ravn et al., 2001). An interesting example was reported in a study of signaling substances from *Erwinia amylovora*, where highly sensitive bioreporters were crucial to detect acyl-HSLs present in low amounts in infected pea tissues. However, the biorevelation methodology used could not elucidate whether the acyl-HSL produced by the microorganism was a 3-oxo or 3-hydroxy derivative of *N*-hexanoyl-HSL (Venturi et al., 2004). Thus, GC-MS methods seem to be more appropriate for correct identification of natural acyl-HSLs because the sensitivity is reasonable and the technique allows coinjection and mass spectral data comparison with synthetic compounds. The low molar mass and reasonable volatility of acyl-HSLs also makes GC-MS the method of choice for their analysis.

In spite of the great interest in quorum-sensing and the large number of bacteria under investigation, only few acyl-HSLs have been characterized at the absolute configuration level (Bainton et al., 1992; Lithgow et al., 2000). The absolute configuration of the major constituent, (*S*)-(-)-*N*-hexanoyl-HSL, produced by *P. ananatis* was accessed by using on-line GC-FID with a chiral stationary phase. This protocol is efficient when acyl-HSLs are present in complex mixtures (Fig. 2). Absolute configurations of the other two acyl-HSLs identified could not be determined because of their small quantities.

It should be mentioned that, up to now, all natural acyl-HSLs possess (*S*) stereochemistry (Bainton et al., 1992; Lithgow et al., 2000; Pomini et al., 2005). The biosynthetic origin of these metabolites was fully investigated in the marine luminescent bacterium *V. fischeri*, where the acyl-HSL synthesizing protein LuxI was isolated and the substrates were identified. The acyl side chain came from acyl-ACP (acyl carrier protein), whereas the HSL moiety came from *S*-adenosyl-methionine (SAM) (Schaefer et al., 1996). It is likely that the conserved (*S*) configuration is derived from the (*S*) absolute configuration of the SAM

amino acid portion. However, these findings do not exclude the necessity of characterizing the absolute configurations of acyl-HSLs from other producers. Based on the differentiated activity of synthetic (*R*) enantiomers in some quorum-sensing systems (Chhabra et al., 1993) and on the hypothesis that isomerization is one of the possible quorum-quenching (disruption of quorum-sensing) mechanisms (Roche et al., 2004), the detection of an (*R*)-acyl-HSL producing bacterium or a microorganism capable of isomerizing these metabolites would furnish interesting information from the chemical ecology point of view. In this context, the chiral GC-FID protocol could play an important role.

In summary, chemical investigation of the phytopathogen *P. ananatis* allowed the characterization of three acyl-HSLs not previously reported for the *Pantoea* genus. Also, the GC techniques used allowed the chemical characterization and absolute configuration determination of acyl-HSLs produced by *P. ananatis* independent of bioreporter specificities. Further work should be done to understand the roles of these substances in communication systems and gene regulatory networks in this species.

Acknowledgments The authors are indebted to FAPESP for financial support and for a scholarship awarded to A. M. Pomini (process n. 03/09357-7). We wish to express our gratitude to Carol H. Collins (IQ/Unicamp) for revising the manuscript.

Introduction

Most conifer resins are complex mixtures of terpenoids (Sjöström, 1990). Several ecological functions have been attributed to the numerous known conifer terpenoids. For example, they can function as insect-attracting odors in conifers (Vité et al., 1986; Byers et al., 1989; Nordlander, 1991; Almquist et al., *in press*), or as building blocks for *in vivo* syntheses of pheromones by wood-boring beetles (Hendry et al., 1980; Byers, 1995; Martin et al., 2003) and, because of their toxicity, even in defense against insects and pathogens (Raffa et al., 1985; Delorme and Lieutier, 1990; Raffa and Smalley, 1995).

Few species of bark beetles are able to overcome plant-defensive reactions and successfully colonize living trees. These aggressive beetles are normally associated with pathogenic blue-stain fungi (Krokene and Solheim, 1998) that enter the phloem with the tunneling beetles (Francke-Grosmann, 1967). The fungi invade sapwood and kill the tree by blocking water transport (see, e.g., Christiansen et al., 1987; Solheim et al., 1992). A well-studied example of this is the infection of *Picea abies* (L.) Karsten (Norway spruce) by the Eurasian spruce bark beetle, *Ips typographus* L., and associated blue-stain fungi *Ceratocystis* and *Ophiostoma* (Hornqvist et al., 1983; Solheim, 1992; Krokene and Solheim, 1998). *Pinus sylvestris* L. (Scots pine) does not appear to be afflicted by such an aggressive tree killer, although the pine shoot beetle, *Tomicus piniperda* L., may kill weakened trees (Långström, 1983; Långström and Hellqvist, 1991; Annala et al., 1999). *T. piniperda* is associated with the blue-stain fungi *Leptographium wingfieldii* Morelet and *Ophiostoma minus* (Hedgc.) H. and P. Sydow (Lieutier et al., 1989; Gibbs and Inman, 1991; Solheim and Långström, 1991), which are able to kill *P. sylvestris* trees inoculated with doses resembling fungal densities found in beetle attacks (Solheim et al., 1992). In contrast, the lesser pine shoot beetle, *Tomicus minor* Hart., is less aggressive (Långström and Hellqvist, 1993), and its principal associated blue-stain fungus, *Ophiostoma canum* (Münch) H. and P. Sydow, was recently shown to be of low virulence (Solheim et al., 2001).

Conifer defense against insects and pathogens relies on both physical and chemical barriers associated with resinosis (Berryman, 1972; Phillips and Croteau, 1999). In Pinaceae, there are two types of defense reaction: constitutive and induced resinosis. In constitutive defense, preformed resin is exuded in response to attacks by beetles or fungi, whereas in induced defense, resinous compounds are synthesized around the attack site. These processes have been studied in Norway spruce (*Picea abies*) (Evensen et al., 2000) and in *P. sylvestris* (Lieutier et al., 1991a,b, 1995; Långström et al., 1992). The existence of “acquired resistance” following a sublethal challenge (by inoculation of a sublethal dose of fungi) to the defense system was recently demonstrated in *P. abies* (Christiansen et al., 1999a,b; Krokene et al., 1999), in *P. sylvestris* (Krokene et al., 2000), and in Monterey Pine (*Pinus radiata* D. Don) (Reglinski et al., 1998). True firs (*Abies* spp.) synthesize new resin in concretized resin blisters and display a low constitutive production of terpenoids, whereas spruces (*Picea* spp.) and pines (*Pinus* spp.) have well-developed systems of resin ducts (Lewinsohn et al., 1991; Franceschi et al., 1998, 2000; Nagy et al., 2000). *Pinus* species are believed to sustain high levels of constitutive resin production, which is independent of enzyme activity associated with the wounding of tissues (Savage et al., 1994; Phillips et al., 1999). However, *de novo* syntheses of terpenoids and phenols are observed in *P. sylvestris* after insect attack and fungal infection (Lieutier et al., 1991a,b, 1995; Långström et al., 1992; Bois and Lieutier, 1999). *Abies grandis* (Dougl.) Lindl. (grand fir) has been the

subject of extensive research because of its apparent, induced biosynthesis of terpenoids after wounding (Bohlmann et al., 1999; Phillips and Croteau, 1999). The isolation, functional characterization, and gene expression of terpene synthases have contributed to the understanding of mechanisms in the induction of plant defense.

The chemical basis of the conifer defense reactions in response to attacks by bark beetles and associated blue-stain fungi is still not fully understood. Resistance towards virulent pathogens or beetles (where they are the primary killers) can be seen as an accumulation of terpenes, as a simple flushing of resin at the reaction site, or as a change in the constitutive resin composition towards a blend more toxic to invaders. Delorme and Lieutier (1990) have shown that the relative composition of various monoterpenes changes *after* fungal inoculation in resin pockets as well as in reacting phloem in *P. sylvestris*. Various beetle-associated fungi [e.g., *Ophiostoma brunneo-ciliatum* Math.-Käärk, *O. ips* (Rumb.) Nannf. and *L. wingfieldii*] induce resin production, resulting in clear differences between wounded and unwounded phloem. However, the resin in unwounded tissue differs from the preformed resin (Delorme and Lieutier, 1990). *T. piniperda* has been shown to induce resin acid production in *P. sylvestris*, by crystallization of resin acid around the attack area, but no corresponding changes elsewhere in the trunk (Långström et al., 1992).

Previous investigations of monoterpene hydrocarbons that constitute more than 50% of the resin have revealed a wide diversity in *Pinus* species and *Picea abies*, with respect to both enantiomeric compositions and relative amounts. Broad chemical diversity is seen between and within species, as well as in different tissues from the same specimen (Borg-Karlson et al., 1993; Fäldt et al., 2001; Persson et al., 1993, 1996; Sjödin et al., 1993, 1996, 2000). A high level of chemical diversity is argued to be highly beneficial for plants, as variation in terpene composition among trees of the same species probably makes it difficult for a herbivore or phytopathogen to develop resistance to specific compounds (Sturgeon, 1979).

This study is part of our research on chemical markers of resistance in conifers. The biological results related to this study have been published (Krokene et al., 2000) and are discussed below in their chemical context. The aims were: (1) to identify the monoterpenes active within the defense reaction zone against: (a) a highly virulent fungus, (b) a weakly virulent fungus, and (c) a sterile inoculation (wounding only), and thereby to find out how specific the induced defense reaction is; (2) to identify the change in monoterpene compositions after defense responses to the above inoculations in areas beyond the visible reaction zone (induced systemic reaction); (3) to identify the monoterpenes present after defense responses to mass inoculations within as well as beyond the trunk area treated, in order to compare the induced defense reactions in trees with normal and elevated levels of resistance.

Methods and Materials

Biological Material

In spring 1999, 32 pine trees of similar size [85 ± 3 mm (mean \pm SD) diam at a height of 1.3 m] were selected from a single stand at Hökensås in southwestern Sweden. The stand had been severely defoliated (ca. 90–100% of the needle biomass removed) by the pine looper, *Bupalus piniaria* (Lepidoptera, Geometridae) in 1996 (Långström et al., 1999). The trees were estimated to have about 30–50% of full foliage, and had smaller-than-normal shoots of the age classes 1997 and 1998. In addition, four undefoliated trees (60–70 mm in diam) were selected in an adjoining young pine stand.

On May 25–26, 1999, four groups of eight trees each (32 trees in total) were randomly subjected to one of four pretreatments (I to IV). Each pretreatment consisted of a low dosage (50 inoculations m^{-2}) of one of the following inoculants: (I) *L. wingfieldii* (LW) (isolate NISK 89-369/11), (II) *O. canum* (OC) (isolate NISK 97-33/47), (III) sterile agar (W), and (IV) no pretreatment—as a control group (TC). The rationale for these pretreatments is described by Krokene et al. (2000). Inoculations were done with a 5-mm cork borer by using a standard. A bark plug was removed and agar with or without mycelium was inserted into the hole and the bark plug was replaced. Pretreatment inoculations were performed in a 60-cm band around each tree trunk at breast height, and the dose corresponded to 10 plugs per tree. Group IV trees, as well as four extra trees in the same stand were left for use as an extra control group (c) together with the four reference trees from the adjoining stand (c0). In total, 24 trees were used for the chemical analyses.

Four wk after pretreatment, the 32 trees (LW, OC, W, TC) were mass-inoculated with *L. wingfieldii* at a density of 800 inoculations m^{-2} in the same trunk areas as the pretreatment inoculations, in a 60-cm band around each trunk at breast height, in order to assess tree resistance. Trees were felled on September 27, 1999. The lower trunks of half of the trees (16 trees in all) were cut and used for further analyses of defense reactions and fungal performance (see Krokene et al., 2000 for more details).

Chemical Sampling

Four of each pretreatment plus the eight extra trees (c0) and (c) (24 in all) were selected for chemical sampling as described below. All samples were taken with a 5-mm cork borer, which removed a 5-mm sample plug containing cortex, phloem, and some xylem. The cortex and xylem residues in the plug were removed immediately after sampling, before the monoterpenes in the phloem only were extracted with hexane (1 ml, using tetradecane as the internal standard for quantification at a concentration of $0.1 \mu l ml^{-1}$ hexane). At each sampling occasion, ten or five phloem plugs [diam 5 mm, approx. 0.1 g (10 plugs) and 0.05 g (5 plugs)] were taken from each sampling site in each tree. Samples were taken as follows: Day 0 (the pretreatment day): phloem was collected and extracted from 10 plugs per tree in order to have an undisturbed starting sample (constitutive phloem resin, “0” in Fig. 1). No samples were taken from the untreated controls (TC) to avoid triggering any chemical reactions, but the extra controls (c) and the young reference trees were sampled (c0) (see Biological Material; Fig. 1 and Table 1). Day 1: samples were taken 5 mm above the pretreatment inoculation holes in LW, OC, and W trees (“1” in Fig. 1). Again, no samples were taken from the untreated controls (TC) (Table 1). Day 28: (mass inoculation day), new samples were taken 5 mm below the pretreatment inoculation holes, designated area “1” in Fig. 1, and in random positions above the inoculated trunk area (>20 cm above any pretreatment inoculation hole), designated area “2” in Fig. 1, in the LW, OC, and W trees. Samples were also taken from the untreated controls (TC) for the first time, and at random positions in the extra controls (c) and young reference trees (c0) (Fig. 1 and Table 1). Day 124: the 16 mass-inoculated trees were all sampled at random positions within the inoculation area designated “1” in Fig. 1, above the inoculation area (>20 cm) designated area “2” in Fig. 1, and outside the visible phenolic reaction zone, designated area “3” in Fig. 1. Samples were also taken from area designated “2” in Fig. 1 (2) in the extra controls (c) and from reference trees (c0) (Fig. 1 and Table 1).

All samples were extracted in hexane at room temperature for 48 hr. The phloem was removed and the extract was divided into two parts, one of which was filtered through SiO_2

Fig. 1 Schematic representation of the localization of the samples taken on the Scots pine trunk. Trees were pretreated day 0, mass-inoculated on day 28, and harvested on day 124. Phloem samples were obtained (at all occasions) with a cork borer (5 mm diam), and extracted in hexane after removal of xylem and cortex. See also Table 1 for further information

(100 mg) before analysis and the other was stored at -24°C . The residual phloem was dried at 150°C for >3 hr and weighed.

Chemical Analyses

All samples were analyzed with a two-dimensional gas-chromatographic system (2D GC) that employed two Varian 3400 gas chromatographs, as previously described by Borg-Karlson et al. (1993). In the first GC (for nonenantiomeric separation), a DB-WAX column was used (polyethylene glycol column of 30 m length, 0.25 mm inside diam, and 0.25 μm film thickness, J&W ScientificTM). The temperature program started at 42°C for 1 min, increasing to 70°C at a rate of $3^{\circ}\text{C min}^{-1}$, to 160°C at a rate of $10^{\circ}\text{C min}^{-1}$, to 200°C at a rate of $20^{\circ}\text{C min}^{-1}$, and then remaining at 200°C for 20 min. A split/splitless injector (6 s splitless) was used at a temperature of 180°C . The detector temperature was 200°C . Chiral monoterpene hydrocarbon fractions were “cut” by pneumatic valves, controlled by relays. By changing the relays, and, thereby the position of the valve, it was possible to choose a path for the compounds that led either to the detector in the first GC or through the first to

Table 1 Sampling scheme (see also Fig. 1)

Sample	Position	Days	Purpose
Constitutive resin		0(LW, OC, W, c, c0), 28 (TC)	To examine constitutive phloem resin chemistry
(1)	5 mm above pretreatment holes	1, 28, 124	To examine reaction zone chemistry
(2)	>20 cm from the nearest reaction zone	28, 124	To examine chemistry in uninjured phloem
(3)	Outside the visible phenolic reaction zone	124	To examine chemistry outside the visible phenolic reaction zone

the second GC. Two chiral columns were installed in the second GC oven, both of them being used during the same run (operated by the relay control). Column number 1 was a Cyclodex B (permethyl- β -cyclodextrin/DB-1701) column of 30 m length, inside diam of 0.25 mm, and a film thickness of 0.25 μm (J&W ScientificTM), and column 2 was a Chirasil-DEX CB (permethyl- β -cyclodextrin, chemically bound to a polydimethyl siloxane) column of 25 m length, 0.25 mm inside diam, and 0.25 μm film thickness (ChrompackTM). The temperature program started at 55°C for 15 min, increasing to 77°C at 1°C min⁻¹, and then remaining constant for 8 min. The detector temperature was 160°C. The chiral monoterpenes analyzed were α -pinene, camphene (when present in sufficient amounts), β -pinene, sabinene, limonene, and β -phellandrene. The amount of camphene in some of the samples was not large enough to determine the enantiomeric composition. 3-Carene was considered present only as the (+)-enantiomer, being the only enantiomer present in all our previous studies on monoterpene hydrocarbons from Scots pine (Sjödin et al., 1996, 2000; Fäldt et al., 2001).

All samples were analyzed with a gas chromatograph mass spectrometer (GC-MS) (Varian 3400 GC connected to a Finnigan SSQ 7000 MS) for identification and quantification of the monoterpenes. A DB-WAX column was used (J&W ScientificTM; 30 m, 0.25 mm id, and 0.25 μm film thickness). The temperature program was set as follows: 40°C for 4 min, increasing to 200°C at a rate of 4°C min⁻¹, to 220°C at a rate of 20°C min⁻¹, and then remaining constant at 220°C for 10 min. A Finnigan autoinjector was used with a split/splitless injector (6 s splitless) at 210°C for assuring the repeatability. Helium was used as the carrier gas, the transfer line was 250°C, and the ion source 150°C. The compounds were identified by means of their retention times (GC), or by comparison with either natural or synthetic, available reference samples (for (+)-*b*-pinene; see Valterová et al., 1992). The order of elution of monoterpene hydrocarbons on the Chirasil-Dex column was the same as on the Cyclodex B column (Borg-Karlson et al., 1993).

The *absolute amounts* of compounds extracted were calculated according to the formula provided below [Eq. (1)]. The tetradecane concentration used was 0.1 $\mu\text{l ml}^{-1}$ hexane, and the volume of hexane added to each of the samples was 1 ml. Therefore, the mass of the compound could be calculated, by using the following equations:

$$\begin{aligned} n_x(\text{mmol}) &= A_x/A_{C_{14}} * rf * n_{14}; \text{ and } m_x(\text{mg}) \\ &= A_x/A_{C_{14}} * rf * 0.000385 * 136 \end{aligned} \quad (1)$$

where n_x is the molar amount of monoterpene hydrocarbon (x); A_x is the peak area of monoterpene hydrocarbon (x) (GC-MS data); $A_{C_{14}}$ is the area of tetradecane (GC-MS data); rf is the response factor for monoterpene hydrocarbons (acyclic, 1.71; cyclic, 1.53; and bicyclic, 1.72) based on samples injected into the GC-MS containing exactly the same molar concentration of acyclic (myrcene), cyclic (limonene), and bicyclic (α -pinene) monoterpene hydrocarbons as well as tetradecane; n_{14} is the known molar concentration of tetradecane in all samples (0.000385 mmol ml⁻¹); m_x is the calculated mass of the monoterpene hydrocarbon (mg). Standard solutions (with increased concentrations) were injected by the autoinjector. The mass of the compound calculated by means of Eq. (1) was then divided by the dry weight (dw) of each sample to achieve the final expression in mg g dw⁻¹.

The *proportions* (relative amounts) were calculated as the ratio of the area of each peak to the sum of all the areas of monoterpene hydrocarbons in a defined GC fraction (including the enantiomeric ratio of the analyzed chiral constituents) retained from tricyclene to terpinolene, and expressed in percentages. *Enantiomeric composition* was defined as the GC

peak area of the (–)-enantiomer divided by the sum of GC peak areas of both enantiomers, multiplied by 100.

Results

Biological Results

As the biological results have been reported elsewhere (Krokene et al., 2000), we only summarize here that all pretreatments resulted in induced resistance. This reaction was more pronounced after pretreatment with the aggressive fungus (LW) than with OC or the sterile inoculation. Furthermore, we demonstrated that wounding alone produced a small reaction zone, only extending ca. 10 mm vertically from the inoculation point after ca. 11 wk. The corresponding length for inoculations with *O. canum* was ca. 25 and with *L. wingfieldii* ca. 150 mm (Solheim et al., 2001). Lesion size after inoculation with *L. wingfieldii* was 2, 30, and 60 mm after 1, 2, and 4 wk, respectively (Långström et al., 1993). Thus, the samples taken in “area 1” (cf. Fig. 1) were inside the reaction zones on day 28 and day 124, whereas all other samples were taken outside of the reaction zones.

Chemical Results

Absolute Amounts. Day 1. The absolute amounts of the main monoterpene hydrocarbons showed a 3- to 5-fold increase at the site of inoculation as early as 1 d after pretreatment, without any notable differences between the various treatments (Fig. 2). At this early stage,

Fig. 2 Absolute amounts of monoterpene hydrocarbons in the phloem of *Pinus sylvestris* before inoculation (day 0) and 1 d after inoculation (day 1) (mean values from four trees in mg/g dry weight). Generally, there is a 2- to 3-fold increase in the main monoterpene hydrocarbons 1 d after pretreatment. Pretreatment designations: LW, *Leptographium wingfieldii*; OC, *Ophiostoma canum*; W, sterile agar. The numbers in brackets refer to the places of the samplings and are described in Fig. 1 and Table 1

Fig. 3 Absolute amounts of monoterpene hydrocarbons in the phloem of *P. sylvestris* on the day of mass inoculation (day 28) (mean values from four trees in mg/g dry weight). Note that (–)-α-pinene, (+)-α-pinene, and (+)-3-carene increase to 41, 744, and 467 mg/g dry weight, respectively. Samples were taken locally from the reaction zone phloem. Pretreatment designations: LW, *Leptographium wingfieldii*; OC, *Ophiostoma canum*; W, sterile agar

the exudation of resin was caused by generalized wounding, and was not expected to be specific for any of the particular fungal inoculants or wounding techniques. Day 28. After 4 wk, the increase in absolute amounts of monoterpenes was more pronounced in trees inoculated with *L. wingfieldii* (LW) than in trees inoculated with *O. canum* (OC) or wounded only (W) (Fig. 3), measured in the hypersensitive reaction zone of the phloem (at site 28 (1), Fig. 1). Comparing the LW and OC trees, the increase in (+)-α-pinene was more pronounced than the increase in (–)-α-pinene (Fig. 3) for LW trees. By day 124, 3 mo after the first inoculations (pretreatments), there was an obvious accumulation of resin within the area of inoculation [Fig. 4, 124 (1)]. However, the absolute amount of monoterpenes found in the reaction zone of the LW trees were generally lower than those seen on day 28 (Fig. 3) as opposed to the OC and TC trees, where the amounts were higher after 124 d, which can be attributable to leakage through the heavy damage tissues by fungi. When compared with the composition before pretreatment (day 0), the chemical changes in the phloem sampled >20 cm from the nearest reaction zone were more pronounced at day 124 than at day 28 (Fig. 5). The main components, (+)-α-pinene and (+)-3-carene, both decreased in all treatment and control groups. In contrast, the amounts of (–)-β-pinene and (–)-limonene increased in all treatments, but in none of the controls (Fig. 5).

Relative Amounts

The relative amounts of various monoterpenes did not show any marked differences between the constitutive resin (sampled day 0) and the resin sampled in the phloem >20 cm from the nearest reaction zone after 28 d (Fig. 6a and b). There was no clear difference between the treatments. However, after mass inoculation and intense fungal growth, the

Fig. 4 Absolute amounts of monoterpene hydrocarbons in the phloem of *P. sylvestris* on day 124 (after fungal growth) from four trees in mg/g dry weight). Samples were taken locally from the reaction zone phloem. Pretreatment designations: LW, *Leptographium wingfieldii*; OC, *Ophiostoma canum*; W, sterile agar; TC, true controls, no pretreatment. The numbers in brackets refer to the places of the samplings and are described in Fig. 1 and Table 1

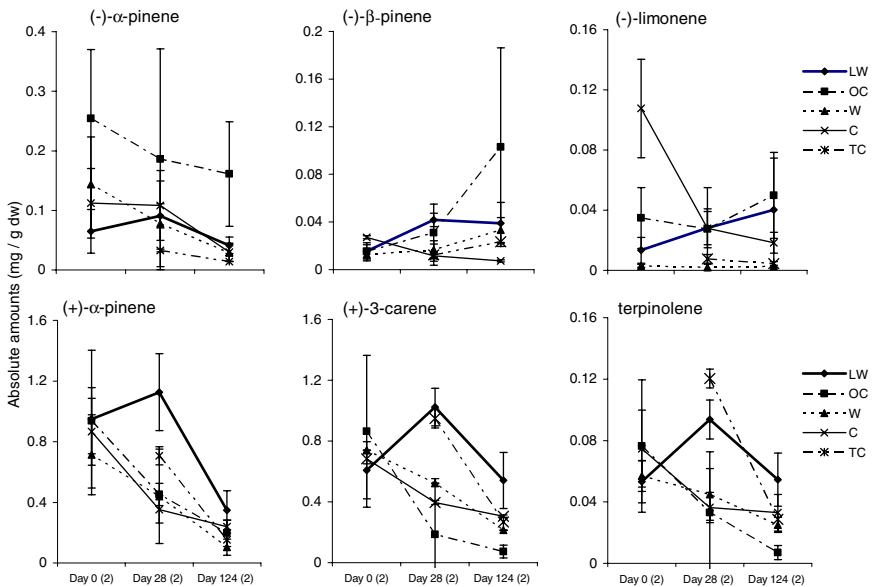

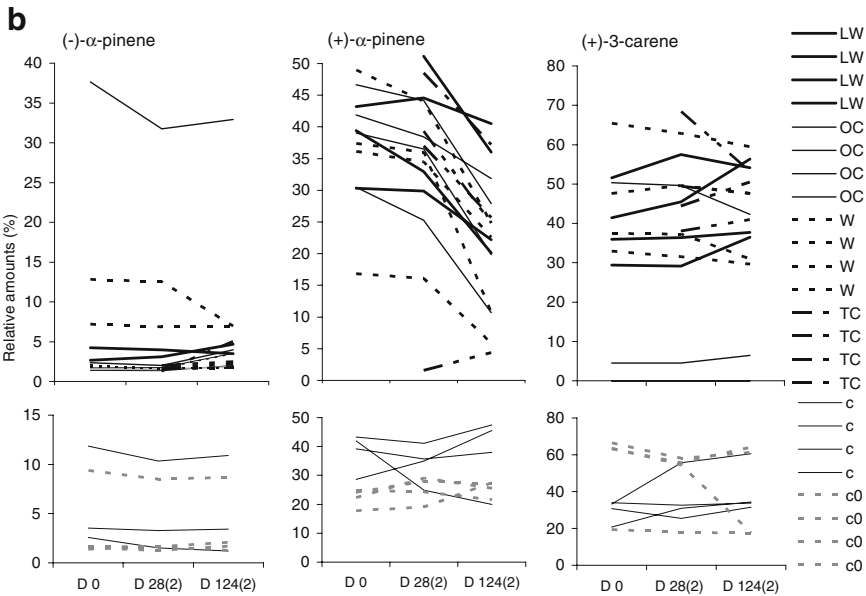

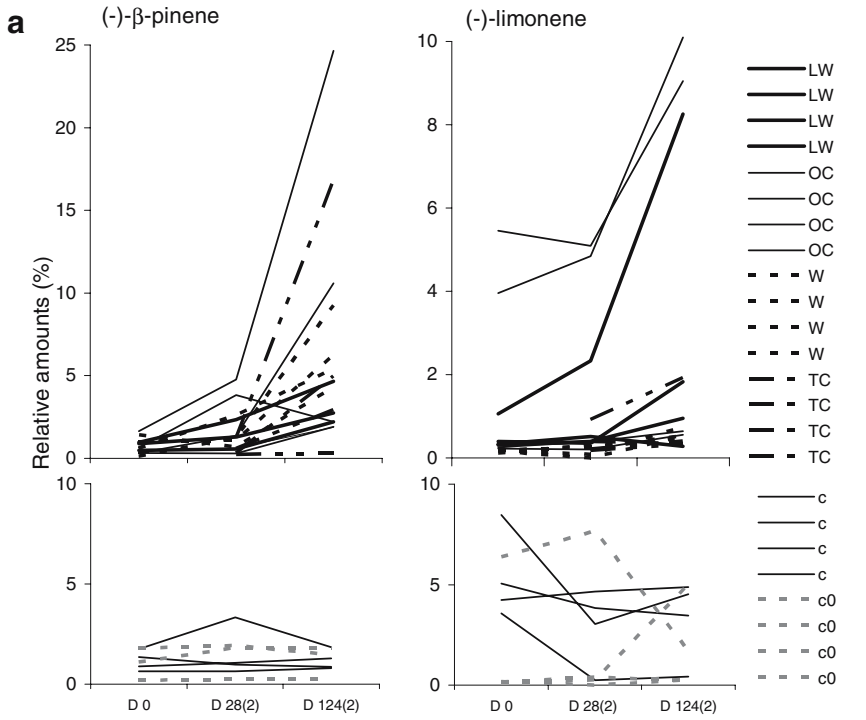

Fig. 5 Absolute amounts of $(-)\alpha$ -pinene, $(-)\beta$ -pinene, $(-)$ -limonene, $(+)\alpha$ -pinene, $(+)\text{-}3$ -carene, and terpinolene in the phloem of *P. sylvestris* before inoculation (day 0), on the day of mass inoculation (day 28), and on day 124 (after fungal growth) (mean values from four trees in mg/g dry weight). Note the difference among the constituents throughout the season as well as after fungal growth. The numbers in brackets refer to the places of the samplings and are described in Fig. 1 and Table 1. The samples (after 28 and 124 d) have been taken >20 cm from the nearest inoculation hole

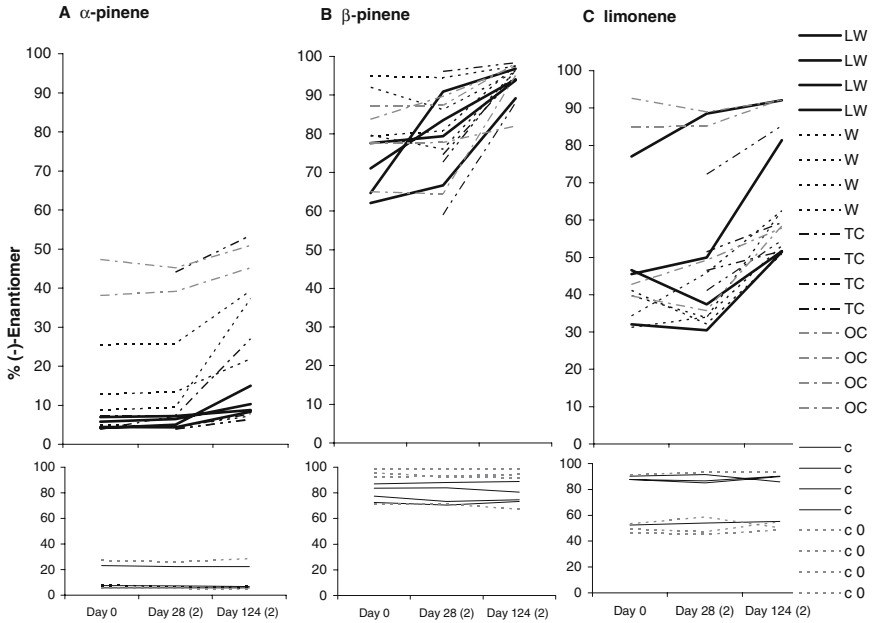

Fig. 7 Changes in enantiomeric compositions of α -pinene (A), β -pinene (B), and limonene (C) for individual trees. Upper diagrams refer to samples taken from treated trees and lower diagrams refer to samples taken from untreated control trees. The (-)-enantiomers increase after pretreatments, but is more obvious after fungal growth of the mass-inoculates. Pretreatment designations: LW, *Leptographium wingfieldii*; W, sterile agar; OC, *Ophiostoma canum*; TC, true controls, trees without any pretreatment. Note that c designates extra controls in the area and c0 designates reference trees outside the test area. The reactions of four trees of each treatment are shown and each tree is connected with a line. The numbers in brackets refer to the places of the samplings on the tree and are described in Fig. 1 and Table 1

relative amounts in the treated groups of trees differed from the control trees as well as from the constitutive resin (day 0) in the treated trees. The most striking differences were found after 124 d with increases in (-)-limonene and (-)- β -pinene (Fig. 6a), and a decrease (or lack of change) in (-)- α -pinene, (+)- α -pinene, and (+)-3-carene (Fig. 6b).

Enantiomeric Composition

Large individual responses on fungal inoculations were observed and, therefore, we present individual reactions in Fig. 7. The (-)-enantiomers of β -pinene and limonene already increased slightly in phloem sampled >20 cm from the reaction zone in the LW trees before mass inoculation, 28 d after pretreatment (Fig. 7), which could be an indication of induced biosynthesis. However, the pronounced increase in the enantiomeric composition of α -

◀ **Fig. 6** Relative amounts of (-)- β -pinene, (-)-limonene (A), and (-)- α -pinene, (+)- α -pinene, and (+)-3-carene (B) in the constitutive resin (day 0) and in the phloem sampled >20 cm from the nearest reaction zone after 28 d (2) and 124 d (2). The relative amounts of (-)- β -pinene and (-)-limonene are increasing after fungal growth, whereas the relative amounts of (-)- α -pinene, (+)- α -pinene, and (+)-3-carene are unchanged, decreasing, or somehow altered, respectively. Pretreatment designations: LW, *Leptographium wingfieldii*; OC, *Ophiostoma canum*; W, sterile agar; TC, true controls, trees without any pretreatment. Note that c designates extra controls and c0 designates reference trees. The reactions of four trees of each treatment are shown and each tree is connected with a line. The numbers in brackets refer to the places of the samplings and are described in Fig. 1 and Table 1

Fig. 8 Enantiomeric compositions of α -pinene (A), β -pinene (B), and limonene (C) in phloem samples sampled at increasing distances from the inoculation. The proportion of (-)-enantiomer increases with distance from the inoculation for β -pinene and limonene (mean value with standard error). See Fig. 7 for the seasonal variation in extra control and reference trees. The numbers in brackets refer to the places of the samplings and are described in Fig. 1 and Table 1

pinene, β -pinene, and limonene was found in the phloem sampled at the same distance on day 124 [see 124 (2) in Fig. 7]. The enantiomeric compositions of the three terpenes increased or changed in phloem from trees stressed by fungal growth, whereas in the phloem extract of the control trees no change in enantiomeric composition of α -pinene throughout the season was found.

With increasing distance from inoculation sites, the proportions of (-)-enantiomers of β -pinene and limonene clearly rose in nearly all of the mass-inoculated trees (Fig. 8). The enantiomeric composition both in the reaction zone [day 124 (1) in Figs. 1 and 8] and in the area near the fungal growth, zone [day 124 (3) in Figs. 1 and 8], exhibited greater variation than the phloem sampled >20 cm from the nearest reaction zone [day 124 (2) in Figs. 1 and 8]. The (-)-enantiomers predominated both in sabinene and β -phellandrene, but the enantiomeric composition remained unchanged (with the exception of low-3-carene-containing trees, which contained low constitutive proportions of (-)-sabinene).

Discussion

This study has shown that mechanical wounding and fungal inoculation both resulted in reduced susceptibility to mass inoculation with LW that was manifested by reduced phloem necrosis and sapwood occlusion. As there was no difference in induced response between the pretreatments, we tend to believe that this is a general, rather than specific, response. It was not possible to determine whether the response was local or systemic as the mass inoculation was done in the same stem area as the pretreatments. In Norway spruce, where this phenomenon was first seen, the enhanced resistance was local (Krokene et al., 1999), but it seems possible that the effect may spread further with increasing time between pretreatment and mass inoculation. The mechanisms responsible for this induced resistance in conifers

are largely unknown, but formation of traumatic resin ducts and activation of phenol-rich parenchyma cells (PP cells) seem to be involved (Franceschi et al., 1998, 2000; Nagy et al., 2000).

Infection-induced responses, in the form of monoterpene production, have been previously investigated in *P. sylvestris* infected by *T. piniperda* (Lieutier et al., 1995) and associated blue-stain fungi (Delorme and Lieutier, 1990). However, an accurate study of the changes in the enantiomeric composition of the chiral constituents has, to our knowledge, not been done to date.

This study shows that the virulence of fungi causes a chemical response in trees that is most obviously close to the inoculation hole, as the quantity of monoterpenes increases up to 800-fold in LW trees, compared to 30-fold in OC trees (see (+)- α -pinene; Fig. 3).

These results, which may be the result of a lower growth rate of OC, are in accordance with the less virulent OC compared to LW (Solheim et al., 2001), and consequently to that of *T. minor* compared to *T. piniperda* (Långström and Hellqvist, 1993).

The presence of an induced systemic reaction and an allocated biosynthesis due to fungal growth is indicated by alteration in the relative amounts of (–)- α -pinene and (–)-limonene, and also by an increase in (–)- β -pinene in samples taken outside of the inoculation zone at day 124 (Fig. 6a and b). This is further confirmed by a change in enantiomeric compositions for the three constituents (Figs. 7 and 8). However, at day 28, before mass inoculation, we could not find any significant difference in the relative amounts or enantiomeric composition between pretreated trees (trees with possibly induced resistance) and trees with a normal level of resistance (TC trees).

The absolute amounts of monoterpenes in the reaction zone samples from day 28 were consistent with amounts found in previous studies on *P. sylvestris* inoculated with blue-stain fungi (Delorme and Lieutier, 1990). They showed marked qualitative and quantitative changes in the monoterpene pattern between unaffected phloem and phloem affected by different fungi (Fig. 3). We found that the most virulent fungus (LW) elicited the largest response in monoterpene production, but the tremendous variation in resin composition and amounts (e.g., low and high (+)-3-carene trees)—not only within each tree, but also between trees in this natural generated forest—prohibited us from finding a monoterpene pattern specific for the two fungal species used.

We found a minor effect of pretreatment on tree chemistry, as the enantiomeric composition in LW and TC treatment groups were in the same range at the start of mass inoculation (day 28). Changes in enantiomeric composition of TC trees to mass inoculation showed the same pattern as changes in LW trees (Fig. 7).

There was high variation in the composition of monoterpenes among trees within each pretreatment group, both before (constitutive) and after the pretreatments. While evaluating changes in relative and enantiomeric monoterpene composition, we found a high variation in the way each tree changed (Figs. 6, 7, and 8). However, there was no specific or distinctive pattern between the chemotypes. The ecological relevance of maintaining high chemodiversity of defense-related constituents in plants has been previously discussed (Sturgeon, 1979; Jones and Firn, 1991), yet susceptibility and resistance among chemotypes is poorly investigated in Scots pine.

Several of the constituents that increased after fungal infection are known to be toxic or growth-inhibiting towards fungi (Delorme and Lieutier, 1990; Klepzig et al., 1996). After the sublethal inoculations (day 28), the monoterpene profiles changed. This was most clearly seen in the enantiomeric composition of some of the chiral monoterpenes. The chemical defense responses elicited by fungal attacks and analyzed via phloem samples

taken beyond the reaction zone suggest that biosyntheses of monoterpenes took place either (1) both locally and at a distance from the reaction zone phloem, or (2) at a distance from the inoculation and reaction zone phloem, and were transported into the reaction zone phloem. Whether this transport is an active or passive process might be a key in the search for chemical markers of resistance.

Induced chemical response due to insect attack and pathogen invasion can be characterized by a change in a plant's chemical profile. This *de novo* production of compounds should benefit the plant by making it more toxic to an invader—herbivore or pathogen—as the induced production of stilbenes observed after inoculation *Ceratocystis polonica* (Viiri et al., 2001), but it may also attract predators or parasitoids of the herbivore. Induced terpene production following wounding or elicitor treatment has been established by enzyme assays (Martin et al., 2002) as well as by gene isolation, characterization, and expression in *A. grandis* (Bohlmann et al., 1999), *Picea sitchensis* (Miller et al., 2005) and *P. abies* (Fäldt et al., 2003; Martin et al., 2004). However, *Pinus* species are believed to rely on their constitutional chemical defense as there is minimal activation of biosynthesis upon wounding (Lewinsohn et al., 1991; Phillips et al., 1999). However, in this study, we have shown that fungi induce a local change in the proportion of monoterpenes, especially in the enantiomeric composition of chiral monoterpenes. In the light of recent knowledge from the products of isolated and cloned terpene synthases, we can understand the correlation between (+)-3-carene and terpinolene, as most probably the (+)-3-carene synthase isolated from Norway spruce by Fäldt et al. (2003) is also present in Scots pine. We hypothesize that a different (–)-pinene synthase is present in pine compared to spruce (Martin et al., 2004). Possibly, a (–)- β -pinene synthase is activated in Scots pine as a result of fungal infection, as the increase in (–)- α -pinene and (–)- β -pinene was not correlated (Figs. 7 and 8). Whether the changes we have observed can be regarded as a systemic induced monoterpene biosynthesis or not, has to be further analyzed, as there is no evidence for systemic enzyme activation in Scots pine.

Acknowledgments The authors thank Chen Peng, Zhao Tao, and Jan Cedervind for assistance in the field. Introduction

Proanthocyanidins (PA) are a class of polymeric, polyphenolic, plant secondary metabolites that are widely distributed in the plant kingdom. These polymers encompass a wide range of structural variants. They consist of chains of flavan-3-ol (Fig. 1) units linked together through C4–C8 and/or C4–C6 linkages (B-type) and may be doubly linked with an additional C2–O–C7 linkage (A-type). In addition to these variations in interflavanoid linkages, PAs can vary in the hydroxylation pattern of the A- and B-rings, stereochemistry at the three chiral centers (C2, C3, and C4) of the C ring, and the degree of polymerization (DP). The most common PAs in forage legumes are procyanidins (PC) with a 3',4'-dihydroxy substitution of B-ring (catechin and epicatechin) and prodelphinidins (PD) with 3',4',5'-trihydroxy substitution (gallocatechin and epigallocatechin).

Proanthocyanidins are not known to play any role in physiological processes of plants. However, they are known to precipitate proteins (Hagerman and Butler, 1981) and have been studied for likely ecological roles. They have been considered as plant defenses against insect (Zucker, 1983; Ayres et al., 1997; Heil et al., 2002) and mammalian herbivores (reviewed in Iason, 2005), but their role in the dynamics of nutrient cycling (Zucker, 1983; Kraus et al.,

Fig. 1 Thiolytic cleavage of proanthocyanidin terminal units released as flavan-3-ols and extension units as flavan-3-ol thioether adducts

2003) and in the photoprotection of plant tissues (Close and McArthur, 2002) has also come into consideration.

In agricultural systems, high concentrations of PA [$>6\%$ of dry matter (DM)] in forage and browse plants reduce voluntary feed intake, digestibility, and animal performance of ruminants (Min et al., 2003), consistent with a defensive role. However, at lower concentrations, the protein-binding effects of PAs protect dietary protein against excessive degradation in the rumen and can have beneficial effects for ruminant herbivores (Min et al., 2003). Low to medium concentrations of PA (2–4% of DM) increase protein utilization, which contributes to increases in lactation, wool growth, and live weight gain (Waghorn et al., 1994; Wang et al., 1996). Other beneficial effects for agriculture include the control of bloat (Chiquette et al., 1988) and improved tolerance against internal parasites (Niezen et al., 1998).

Forage cultivars of *Lotus* spp. are of interest in agriculture, as they combine improved protein supply for animal production through symbiotic nitrogen fixation with the protein-protective action of PAs in the rumen. They exhibit the dichotomy described above of both beneficial and detrimental effects on feed value and animal performance (Waghorn et al., 1998; Aerts et al., 1999). The PA from *L. corniculatus* is associated with better animal performance than that from *L. pedunculatus* (Waghorn et al., 1999), and this cannot be accounted for by the lower PA content of *L. corniculatus* (above half that of *L. pedunculatus*; Terrill et al., 1992). The PA in *L. corniculatus* increased the observed absorption of amino acids from the small intestine of sheep (Waghorn et al., 1987), whereas the PA in *L. pedunculatus* (Waghorn et al., 1994) provided ruminal protein protection, but did not improve absorption.

The primary factor in the difference in activity of the two PAs may be differences in their structure (Min et al., 2003). Structural studies of *L. pedunculatus* and *L. corniculatus* PAs (Foo et al., 1996, 1997; Hedqvist et al., 2000; Meagher et al., 2004) have shown that *L. pedunculatus* PAs have a much higher prodelphinidin (PD) content. The structure of PAs as well as their concentration in the plant are important factors determining their activity and role in both agricultural systems (Min et al., 2003) and the natural environment (Zucker, 1983; Clausen et al., 1990; Ayres et al., 1997; Heil et al., 2002).

The genus *Lotus* contains many species, several of which have been used as a forage for ruminants (Papadopoulos and Kelman, 1999), and the initial motivation for this study was to identify additional *Lotus* species of potential value as forages, which might provide PAs at appropriate concentrations and with desirable properties. *Lotus* spp. are found worldwide, except for cold arctic regions and low land tropical areas of Asia, South and Central America (Kirkbride, 1999a). The largest collection of *Lotus* genetic resources is in New Zealand (Greene, 1999). A number of groupings of *Lotus* spp. have been constructed based on plant morphology (Arambarri, 2000), and within *L. corniculatus*, genotypes have been grouped based on specific characteristics or habitats (Steiner and Garcia de los Santos, 2001). However, relationships between phylogeny and geographical distribution and the phytochemistry of *Lotus* PAs have not been investigated.

In this study, we compare the chemistry of PAs of forage cultivars of *L. corniculatus*, *L. pedunculatus*, and *L. tenuis* with those of 12 additional *Lotus* spp. not currently used in agriculture. Estimates of the concentration of PAs in all 15 species are reported. In addition, the chemical characteristics of PA fractions from *L. pedunculatus* and *L. corniculatus* (including new data on a “creeping” selection of *L. corniculatus*) are compared with new findings on the composition of PAs of four additional *Lotus* species found to have a high PA content in the initial screening: *L. americanus*, *L. angustissimus*, *L. parviflorus*, and *L. suaveolens*.

We applied a number of complimentary and independent approaches to characterize the structure of the *Lotus* PA polymer mixtures. Whereas proanthocyanidin oligomers with DP as high as 5 have been isolated and characterized as single entities (Hemingway et al., 1982; Foo and Karchesy, 1991), the majority of the PA polymer in plants comprises mixtures of oligomers (DP 5–10) and higher polymeric material (DP > 10) that must be characterized collectively. PA polymer fractions prepared by Sephadex LH-20 chromatography have been characterized by acid catalyzed degradation in the presence of benzyl mercaptan coupled with high-performance liquid chromatography–photodiode array (HPLC-PDA) detection to provide information on the nature of the terminal and extension units and the mean degree of polymerization (mDP; Guyot et al., 2001; Gu et al., 2002; Taylor et al., 2003; Sivakumaran et al., 2004). Mass spectrometric methods [liquid chromatography–electrospray ionization–mass spectrometry (LC-ESI-MS) and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS)] have been used to provide further characterization of the PAs in terms of their polydispersity and interflavanoid linkages (A- or B-types), without further isolation or chromatographic separation (Le Roux et al., 1998; Foo et al., 2000a). These estimates of composition are supported by independent nuclear magnetic resonance (NMR) estimates (Porter et al., 1982).

The results are discussed in terms of possible relationships between the concentration and composition of the PAs of *Lotus* spp. and ecological factors.

Methods and Materials

Chemical

Analytical grade acetone and dichloromethane, HPLC grade methanol, acetonitrile, and ascorbic acid were obtained from BDH Ltd., Auckland, New Zealand. Catechin, epicatechin, gallic acid, gallocatechin, and epigallocatechin were obtained from Sigma, St Louis, MO, USA. Benzyl mercaptan was obtained from Merck, Darmstadt, Germany. 2,5-Dihydroxybenzoic acid was obtained from L. Light & Co. Ltd., Colnbrook, UK. Sephadex LH-20 was obtained from Pharmacia, Sweden.

Plant Material

Herbage samples of 15 *Lotus* species were grown in pots at Grasslands Research Centre, Palmerston North, New Zealand; *L. corniculatus* (birdsfoot trefoil, cv. “Grasslands Goldie”), *L. pedunculatus* (big trefoil, cv. “Grasslands Maku”), *L. tenuis* (narrow-leaf trefoil, cv. “Esmeralda”), *L. americanus* (American birdsfoot trefoil), *L. angustissimus* (slender birdsfoot trefoil), *L. arenarius*, *L. crassifolius* (big deervetch), *L. creticus*, *L. decumbens*, *L. edulis*, *L. japonicus* (*L. corniculatus* L. var. *japonicus*), *L. ornithopodioides*, *L. parviflorus* (small-flower birdsfoot trefoil), *L. schoelleri* (*L. corniculatus* L. var. *schoelleri*), and *L. suaveolens* (hairy birdsfoot trefoil) were harvested in July 2000, and regrowth was sampled again in September 2000, freeze-dried, milled, and PA content estimated by the vanillin–HCl assay. The four species with the highest PA content were selected for further investigation, together with the established forage species *L. pedunculatus* and *L. corniculatus*. Herbage samples of 25 individual plants of each of the six *Lotus* species grown in pots were harvested in October 2001, freeze-dried, and milled. The extractable PA content of the individual plants was estimated by the BuOH–HCl assay.

Herbage samples of *L. corniculatus*, *L. pedunculatus*, *L. americanus*, *L. angustissimus*, *L. parviflorus*, and *L. suaveolens* grown in a sand-frame were harvested during December 2001 to January 2002 and were stored at -20°C for extraction. These *Lotus* spp. were grown again in the sand frame and sampled during December 2002 to January 2003 along with two additional *Lotus* spp. in a breeding program: *L. corniculatus* (birdsfoot trefoil, “Grasslands creeping selection”) and *L. tenuis* (narrow-leaf trefoil, cv. “Esmeralda”). Herbage samples harvested in summer 2002–2003 were freeze-dried, milled, and analyzed for PA content by the BuOH–HCl assay.

Colorimetric PA Assay

Plant samples harvested in 2000 were analyzed by the vanillin–HCl assay (Scalbert, 1992). Individual plants harvested in 2001 and bulk plant samples harvested in 2002–2003 were analyzed by the BuOH–HCl assay (Terrill et al., 1992). Freeze-dried plant samples (leaves and stem) were ground in a Wiley mill (1-mm screen). For the 2000 and 2001 samples, “free” PA concentrations were estimated, and for the 2002–2003 samples, a three-step extraction procedure was performed to determine free, protein-bound, and fiber-bound PA. Measurements were performed in duplicate and the mean value reported as a percentage (%) of DM. A purified PA fraction from *L. pedunculatus* was used as a standard for calibration.

Proanthocyanidin Preparative Extraction

Frozen herbage of *Lotus* spp. (600 g/l) were extracted with acetone/water (7:3; v/v) containing ascorbic acid (1 g/l) in a blender (Halldé VCM62 Varning, AB Halldé Maskiner, Kista, Sweden) for 30 min and strained through two layers of cheesecloth to remove plant material. The extract was concentrated *in vacuo* (40°C) to remove acetone and the aqueous solution defatted with dichloromethane (4×11). The aqueous layer was concentrated *in vacuo* and subsequently freeze-dried to yield an aqueous acetone PA extract.

Purification of Proanthocyanidin Fractions

Each freeze-dried aqueous acetone PA extract (6 g) was dissolved in aqueous methanol (1:1, v/v, 50 ml) and centrifuged at $4500 \times g$ for 10 min. The PA solution was applied to a Sephadex LH-20 column (Pharmacia, SR 25/45) preconditioned with aqueous methanol (1:1, v/v) and connected to a Pharmacia GradiFrac system. After loading, the column was washed with aqueous methanol (1:1, v/v; fraction 1 100 ml and fraction 2 500 ml) at a flow rate of 5 ml/min. The PA fractions were eluted with acetone/water (7:3, v/v; fraction 1 100 ml and fraction 2 500 ml) and analyzed by HPLC–PDA at 280 nm. PA fractions were characterized by the observation of a broad unresolved hump at 280 nm in the HPLC trace, combined, and concentrated *in vacuo* (40°C). The aqueous residues were freeze-dried to yield PA fractions.

The initial aqueous methanol (1:1, 100 ml) eluate of *L. americanus* was characterized as containing PAs by the presence of a broad unresolved hump in the HPLC–PDA at 280 nm. The aqueous methanol (1:1) fractions were rechromatographed on a Sephadex LH-20 (Pharmacia, SR 25/45) column. An initial wash with water (100 ml) was followed by elution with aqueous methanol (1:1, 500 ml), which yielded a high molecular weight proanthocyanidin (HMWPA) fraction, and subsequent elution with acetone/water (7:3, v/v, 500 ml) yielded a medium molecular weight proanthocyanidin (MMWPA) fraction.

Thiolysis

A method based on that described by Guyot et al. (1998) was utilized. A PA solution (4 mg/ml in methanol) was prepared for each PA fraction. A subsample (50 μ l) was placed into a vial to which 3.3% (v/v) hydrochloric acid in methanol (50 μ l) and 5% (v/v) benzyl mercaptan in methanol (100 μ l) was added. Each solution was heated to 40°C for 30 min in a heating block and cooled to room temperature. An internal standard, dihydroquercetin in water (100 μ l, 2.5×10^{-2} mg/ml solution), was added and the sample analyzed immediately by reversed phase HPLC. Concentrations of terminal flavan-3-ol units and extender flavan-3-ol thiol adducts were estimated by peak area integration at 280 nm. Responses relative to dihydroquercetin were determined from standards. Response factors to PC and PD flavan-3-ols (0.26 and 0.07, respectively) were the same as the corresponding benzylthioethers, isolated from *Dorycnium rectum* PA fractions according to Sivakumaran et al. (2004) as reported by Gu et al. (2002). Thiolysis 10- μ l subsamples were analyzed by the method of Meagher et al. (2004).

Mass Spectrometry

Electrospray ionization mass spectrometry data were acquired on a Shimadzu LC-MS QP8000 α in scan mode (m/z 250–1400) and detection in the negative ion mode using the conditions described by Meagher et al. (2004).

Matrix-assisted laser desorption/ionization time-of-flight mass spectra were acquired on a Micromass M@LDI LR time of flight mass spectrometer, equipped with delayed extraction and a N₂ laser, set at 337 nm. For positive reflectron mode spectra, an accelerating voltage of 15 kV and a reflectron voltage of 2 kV were used. The PA fractions were reconstituted in acetone/water (8:2, v/v; 0.5 mg/ml) and mixed with a matrix solution of 2,5-dihydroxybenzoic acid in acetone/water (8:2, v/v; 10 mg/ml) at a volumetric ratio of 1:1. The PA-matrix solutions were deionized on a cation exchange cartridge (Strata SCX, 100 mg, 1 ml) preconditioned with HCl (1 ml, 0.1 M), Milli-Q water (5 ml), and finally acetone/water (8:2, v/v; 2 ml). The deionized PA-matrix solutions were spiked with a NaCl solution (0.1 M, 0.5 μ l) to promote the formation of single ion adducts ($[M + Na]^+$), and the mixture (1 μ l) was applied to a stainless-steel target plate and crystallized at room temperature prior to analysis.

¹³C NMR. NMR spectra were recorded in methanol (CD₃OD) at 90 MHz using a Bruker 400 MHz instrument.

Results and Discussion

Estimation of Proanthocyanidin Concentration

Herbage samples of 15 *Lotus* species in an initial study were harvested in winter 2000, and regrowth was again sampled in spring 2000. The extractable PA content was estimated by the vanillin-HCl assay (Table 1) and ranged from 0.2 to 7.4% of DM in winter and from 0.9 to 10.9% of DM in spring. The four species with the highest PA content were selected for further investigation, together with the established forage species *L. corniculatus*, *L. pedunculatus*, and *L. tenuis*.

Extractable PA concentrations were estimated for individual plants in 2001, and extractable, protein-bound, and fiber-bound PA concentrations were estimated in bulk material

harvested during 2002 and 2003 using the BuOH–HCl assay. The estimates of PA concentration by the two methods were in reasonable agreement. Extractable PA concentrations ranged from 0.2 to 10.9% of DM (Table 1). There were variations in PA estimates between sampling dates, but on both occasions in 2000, PA concentrations were consistently lower for *L. creticus*, *L. ornithopodioides*, *L. arenarius*, *L. crassifolius*, *L. japonicus*, *L. decumbens*, *L. edulis*, *L. schoelleri*, and *L. tenuis* than for the other species. The remaining “high PA” *Lotus* spp. were retained for further examination. The PAs of these species were predominantly extractable with bound PAs comprising between 5 and 13% of DM of the total PAs in 2002–2003. At each sampling, the PA concentration was highest for *L. americanus* (9.8% DM total PA in 2002–2003), and at three of four samplings, the PA concentration was lowest for *L. corniculatus* (3.0% DM total PA in 2002–2003). PA concentrations in *L. pedunculatus*, *L. angustissimus*, *L. corniculatus* “creeping” selection, and *L. parviflorus* were intermediate (4.2–7.2% of DM total PA in 2002–2003). The PA content of the “creeping” selection of *L. corniculatus* was higher than in the standard cultivar, consistent with previous screening and selection (Rumball, unpublished observations). Only a trace amount of PA was determined in *L. tenuis* in agreement with reported values (Kelman and Tanner, 1990; Strittmatter et al., 1992; Terrill et al., 1992).

Of the *Lotus* species evaluated, the highest PA concentration (>6% of DM) was found for *L. americanus*, a bushy branched annual about 30 cm high, present in dry prairies and rangeland, used as forage (Table 1). Moderate PA concentrations (<6% of DM) were found in *L. angustissimus*, *L. parviflorus*, and *L. suaveolens*. These three species grow in habitats such as dry grassland that are accessible to grazing (Kirkbride, 1999a,b). The latter two also carry “hairy” foliage, which is generally regarded as a deterrent to predation. However, both low and high PA species are associated with Mediterranean grasslands, and there is no clear association between annual or perennial types and PA accumulation. The four species with the lowest PA concentrations (Table 1) are *L. tenuis*, *L. decumbens*, *L. japonicus*, and *L. edulis*. They are, respectively, (1) vigorous annual, (2) small and weak prostrate annual, (3) prostrate and moderately vigorous perennial, and (4) moderately vigorous short-lived species (ILDIS).

It is difficult to observe any clear ecological pattern to the occurrence of PAs in the *Lotus* spp. evaluated in this study. Although the ecological role of plant PAs has been extensively examined, a robust theoretical basis for their ecological role is not yet available. The interactions and trade-offs between plant growth and defense are complex (Stamp, 2003), and investigations of a single secondary metabolite class such as PAs provide a limited view of defensive chemistry. Thus, (Berger et al. 2003) found a complementary pattern of distribution of PAs and proteinase inhibitors in *Vicia* species. The *Lotus* spp. we have found to have low PA content may have alternative defensive chemistry or, in the case of the more vigorous species, have greater tolerance of herbivory. Considerations of plant defense would suggest that high-PA-containing plants might be found in environments with low resource availability (Coley et al., 1985). Considerations of nutrient cycling suggest that acidic and infertile soils might be favored (Kraus et al., 2003), and considerations of photoprotection suggest that they might be found at low latitudes and high altitudes (Close and McArthur, 2002). To directly address these environmental factors would require an extensive investigation of *Lotus* spp. in their natural environment that was beyond the scope of the present study.

Fractionation of Proanthocyanidins

Frozen herbage of each *Lotus* spp. was extracted with aqueous acetone. A single extraction provided sufficient material for fractionation. The composition of PA from a single

extraction had previously been found in the cases of *L. pedunculatus* and *L. corniculatus* (Meagher et al., 2004) and was similar to that reported following exhaustive extraction of plant material (Foo et al., 1997). The extracts were defatted and fractionated on a Sephadex LH-20 column. Low molecular weight proanthocyanidin (LMWPA) polymer fractions were recovered by elution with aqueous acetone and characterized by the presence of a broad unresolved hump at 280 nm by HPLC-PDA. The first aqueous acetone fraction containing flavanol monomers and dimer PAs was kept separate from the second polymeric PA fraction. The chemical nature of these polymer fractions was determined by ^{13}C NMR, the thiolysis degradation reaction, ESI-MS, and MALDI-TOF-MS.

In the case of *L. americanus*, a portion of the PA was not retained on the Sephadex LH-20 column and was separated into MMWPA and HMWPA fractions that were characterized separately (below). Similar observations have been reported for *L. pedunculatus* (Meagher et al., 2004) and the PA-containing plant *D. rectum* (Sivakumaran et al., 2004). The PA extracted from *L. tenuis* was not characterized as it was obtained in trace amounts.

Characterization of Proanthocyanidin Chemical Composition

The chemical composition of fractions was characterized by thiolysis and NMR. Fractions were acid hydrolyzed in the presence of benzyl mercaptan, which yielded the extension units as flavan-3-ol-4-benzylthioether adducts and terminal units as flavan-3-ols (Fig. 1). The compositional data and mDP were determined for each *Lotus* spp. PA fraction (Table 2). Catechin was the dominant terminal unit in the PA fractions from most *Lotus* species, with the exceptions of *L. parviflorus* where epicatechin was dominant and *L. suaveolens* where equal proportions of catechin and epicatechin were found. In contrast, there was more variation in the extension units: epigallocatechin was the dominant extension unit of *L. americanus*, *L. corniculatus* “creeping”, and *L. pedunculatus*, whereas epicatechin was the dominant extension unit of *L. corniculatus* and *L. angustissimus* (53 and 66% mol/mol, respectively). Epicatechin and epigallocatechin were found in equal proportions for *L. parviflorus* and *L. suaveolens* extension units. In contrast, *L. angustissimus* is the one species dominated by epicatechin in both the extender and terminal units.

Thiolysis gave a direct insight into the relative stereochemistry at C2 and C3 in the PA units. The *cis/trans* ratio of PA fractions was determined for the terminal and extension units for each species (Table 2). The terminal units were predominantly of *trans* configuration, whereas the extensions units were predominantly *cis*.

For each of the *Lotus* spp., a low molecular weight PA fraction (LMWPA) was isolated. The mDP determined by thiolysis for these fractions (Table 2) varied from 8.1 to 16. Variation in mDP of these fractions may be affected by the presence of flavan-3-ol monomers that were detected by ESI-MS (not shown in Table 3) in the LMWPA fractions of *L. angustissimus*, *L. corniculatus*, *L. parviflorus*, and *L. suaveolens*. For *L. americanus*, the mDP of the HMWPA and MMWPA fractions was estimated to be 97 and 40, respectively. These fractions were of higher mDP than the comparable fractions previously reported for *L. pedunculatus* (Meagher et al., 2004). The composition of the terminal units of the polymer fractions (LMWPA, MMWPA, and HMWPA) of *L. pedunculatus* (Meagher et al., 2004) and *L. americanus* was not significantly different between fractions of differing mDP. The epigallocatechin content of the extension units increased with the increasing mDP (Table 2) for *L. pedunculatus*, but such a trend was not as apparent for *L. americanus*.

The ^{13}C NMR spectrum of PA polymers from the *Lotus* spp. gave broad peaks, indicating the polymeric nature of the PA. Estimates of the *cis/trans* ratio and PC/PD ratio

^a From Meagher et al. (2004).

from the NMR data based on the calculation described by Porter et al. (1982) were generally in good agreement with the estimates from thiolysis (data not shown).

The molecular weight estimation from the carbon signal intensity gave approximate values of 7–10 mDP for the *Lotus* spp. LMWPA fractions and 15–18 mDP for MMWPA fraction of *L. americanus*, somewhat lower than the estimates from thiolysis. Because of the limited dynamic range of the NMR method, calculation of a credible mDP value from the NMR data was not feasible for the HMWPA fraction, but the NMR observations were consistent with a large mean molecular weight as found by thiolysis. Similar higher molecular weight PAs with mDP ranging from 33.8 to 189 have been reported for apple (Guyot et al., 2001), grape skin (Monagas et al., 2003), and *D. rectum* (Sivakumaran et al., 2004).

Determination of Polydispersity of Proanthocyanidins.

The polydispersity of the PA fractions was analyzed by ESI-MS in negative ion mode and MALDI-TOF-MS in positive mode. Although the MS ion intensities are not a quantitative measure of oligomer species, the patterns reflect polymer heterogeneity and polydispersity. The observed singly charged $[M - H]^-$ and doubly charged $[M - 2H]^{2-}$ ions, corresponding to the molecular ion masses of PA oligomers ranging from dimer (DP2) through to heptamer (DP7) observed in negative ESI-MS, are shown in Table 3. Multiple-charged species are observed for DP > 4, as with longer chain lengths, the charge can be better

Table 3 Observed m/z values of proanthocyanidin ions in negative ESI-MS analysis of *lotus* spp. polymer fractions

Numbers in bold represent the most intense ion observed.

^a Trimer $[M - H]^-$ at m/z 895, tetramer $[M - 2H]^{2-}$ or dimer $[M - H]^-$ at m/z 607, pentamer $[M - 2H]^{2-}$, and hexamer $[M - 2H]^{2-}$ at m/z 903 were observed, supporting the presence of A-type linkages in the ESI mass spectrum (see Table 4 for explanation of the calculated molecular ion masses).

distributed, minimizing repulsive forces in the polymer chain (Foo et al., 2000b). Positive-ion MALDI-TOF-MS of the PA fractions from the seven *Lotus* spp. were acquired, and trimer (DP3) to heptamer (DP7) homo- and heteropolymers of LMWPA fractions were detected as singly charged $(M + Na)^+$ adducts (Fig. 2). Monomers (DP1) and dimers (DP2) were not detected by MALDI-TOF because of noise and matrix interference. By comparison with the estimated mDP for these LMWPA fractions (Table 2), the ion intensities are biased toward the lower oligomers, as the MALDI-TOF in reflectron mode gives lower sensitivity for the larger ions because of greater breakdown as the result of longer flight paths and the postacceleration process (Yang and Chien, 2000). The calculated molecular ion masses for ESI and MALDI-TOF ranging from trimer (DP3) to hexamer (DP6) are shown in Table 4. The MALDI-TOF-MS were enhanced by desalting by cation exchange and subsequent addition of NaCl to increase the $[M + Na]^+$ ion signal and reduce the $[M + K]^+$ ions naturally present (Ohnoshi-Kameyama et al., 1997; Krueger et al., 2003). With $[M + Na]^+$ adduct ions dominant in the spectrum, the number of hydroxyl functions present in a PA polymer unit can be identified (Table 4).

The most intense ions observed by MALDI-TOF-MS for the trimer (DP3) to heptamer (DP7) series of *Lotus* spp. LMWPA fractions (Fig. 2) are generally in agreement with the most intense ions observed by ESI-MS as singly charged trimer (DP3) species or doubly charged tetramer (DP4) to pentamer (DP5) species (Table 3). Heteropolymer ions (containing both PC and PD units) dominate, except in the case of *L. angustissimus* (PC-only units dominant). Similar heteropolymer molecular forms and ionization patterns in a variety of plants have been reported in the literature (Behrens et al., 2003; Krueger et al., 2003; Taylor et al., 2003). The data for *L. corniculatus* is consistent with those from a study of several *L. corniculatus* cultivars reported by Hedqvist et al. (2000). Ions from the polymeric HMWPA and MMWPA fractions with mDP > 17 of *L. americanus* and *L. pedunculatus* were not detected by ESI-MS or MALDI-TOF-MS.

Proanthocyanidin oligomer ions observed in the ESI mass spectrum of the *L. americanus* LMWPA fraction suggest the presence of A-type interflavan linkages (Tables 3 and 4) in that doubly charged ions were observed that were one m/z unit less than that reported by Foo et al. (1996, 1997) for B-type linkages for *Lotus* PAs. Correspondingly, in the MALDI-TOF-MS from *L. americanus* PA, a series of (singly charged) ions was observed that was two m/z units lower than the species with B-type interflavan linkages (Fig. 2f, insert), indicative of A-type linkages (Table 4). Partial thiolysis results (not shown) suggested the presence of A-type linkages in the terminal units. The A-type interflavan linkage is known in PAs from cranberry, which are terminated by A-type linkages (46%; Foo et al., 2000a; Gu et al., 2002), and cinnamon (Anderson et al., 2004), but has not been reported for forage legume PAs.

Proanthocyanidin Structure, Geography, and Ecology

These results demonstrate that PAs from *Lotus* spp. differ widely in both concentration and structure. The extractable PA fractions are structurally heterogeneous differing in terms of constituent flavan-3-ol units, mDP, and dispersion of oligomers. Whereas the relationship between PA concentrations and ecology and geography is weak (above), the PC/PD ratio in the PA fractions (Table 2) shows a relationship with the geographical distribution of species (Table 1). *Lotus* spp. dominated by PC-type units *L. angustissimus* (70%), *L. corniculatus* (60%), and *L. parviflorus* (54%) have broad distribution and are adapted to a variety of habitats and have moderate PA concentrations (<6% of DM). *Lotus* varieties adapted to warm environments tend to be more widely distributed than those adapted to colder envi-

Mass calculations were based on the equation $2 + 288a + 304b + 23$, where 2 is the molecular weight of two additional hydrogen atoms of terminal flavan 3-ol units, a is the number of PC units, b is the number of the PD units, and 23 is the atomic weight of sodium. Formation of the one A-type linkage results in the loss of two hydrogen atoms.

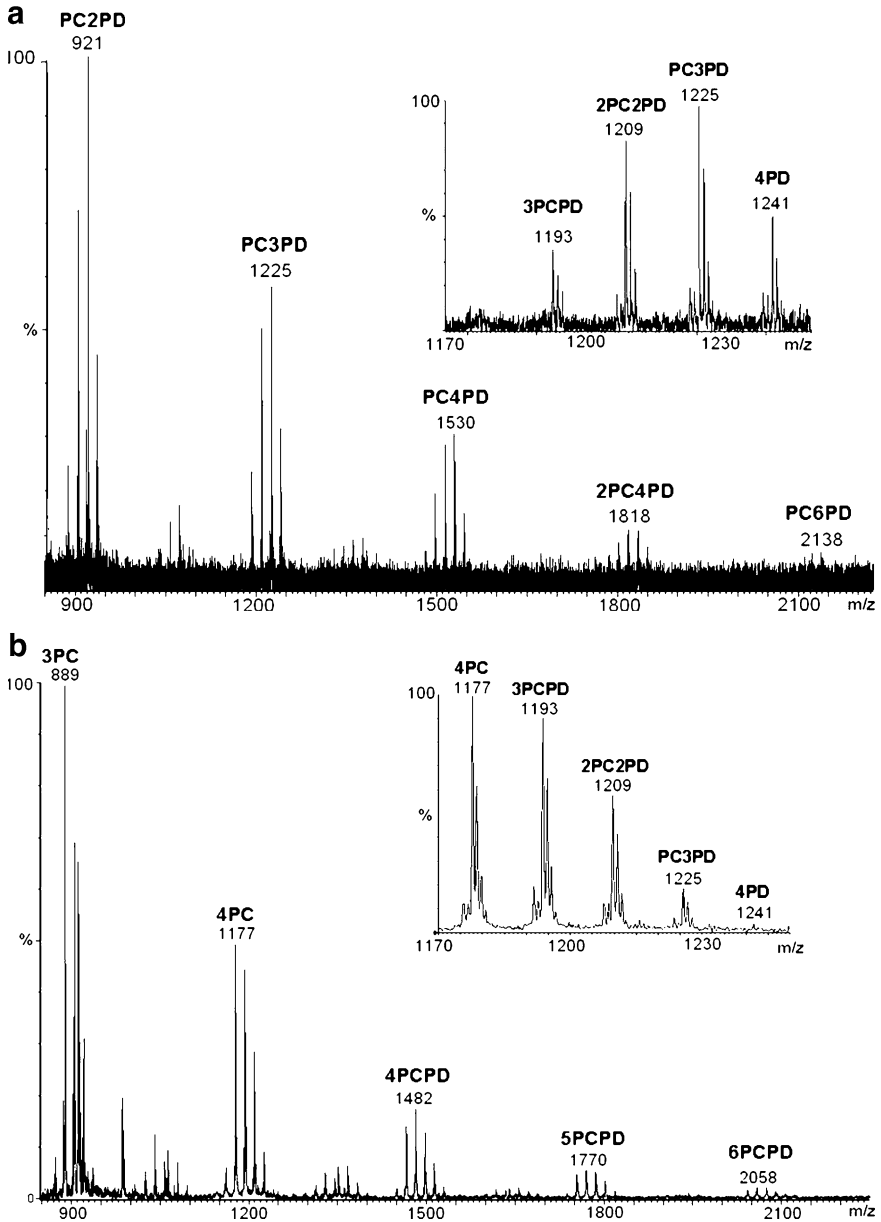

Fig. 2 MALDI-TOF-MS (positive reflectron mode) of a series of polymeric proanthocyanidin fractions from (a) *L. pedunculatus*, (b) *L. corniculatus*, (c) *L. corniculatus* “creeping”, (d) *L. suaveolens*, (e) *L. parviflorus*, (f) *L. americanus*, and (g) *L. angustissimus*. The most intense ions are shown. The inset is an enlarged spectrum of the tetramer series showing different chemical constitutions. See Table 4 for explanation of the calculated molecular ion masses

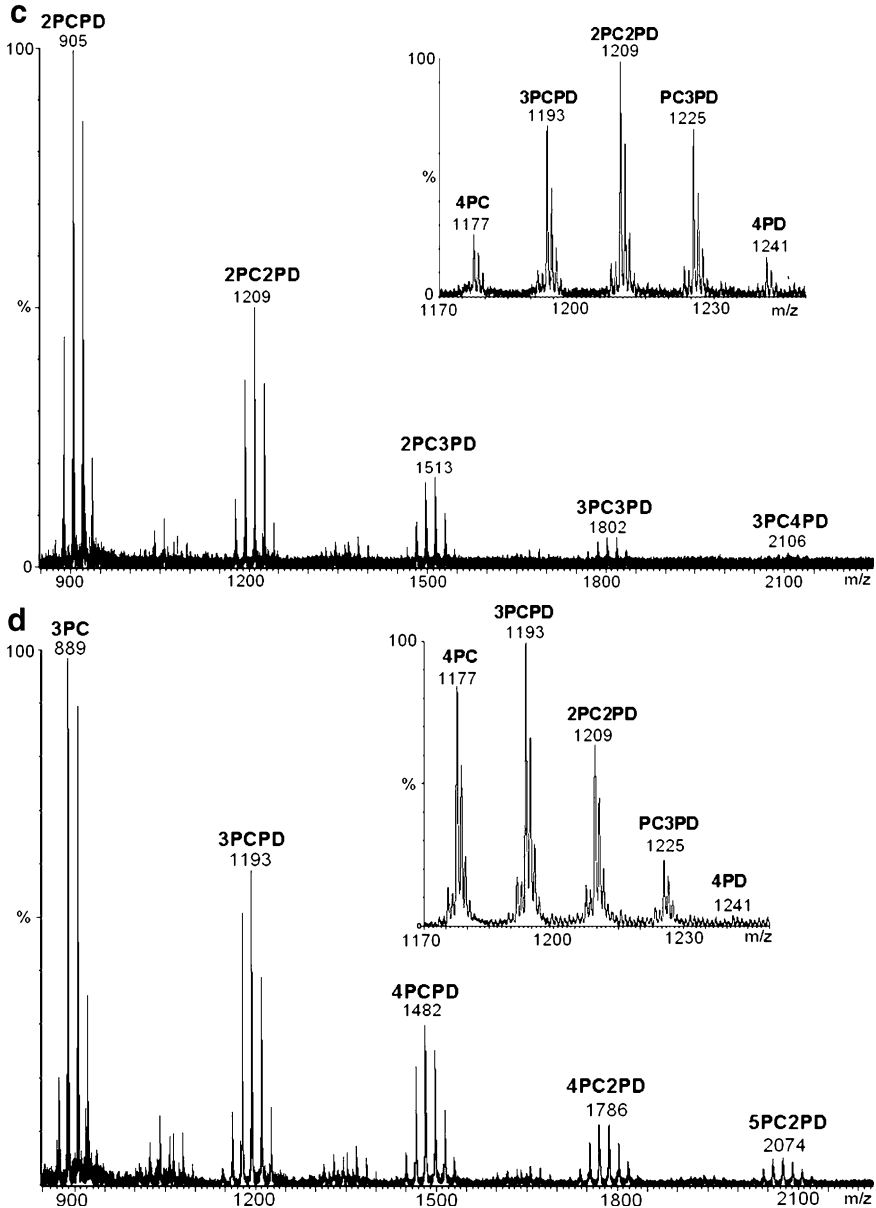

Fig. 2 (continued)

ronments (Steiner, 1999). *L. pedunculatus* and *L. americanus* PAs differ from other *Lotu* spp. examined here not only in having the highest PA concentrations, but also in polymer dispersion, containing higher mDP (>30) HMWPA polymer fractions, and in polymer composition, being dominated by PD-type extender units. An intermediate composition was observed for the “creeping” selection of *L. corniculatus* with a PD content of extender groups in the LMWPA fraction much higher than that for the standard *L. corniculatus*

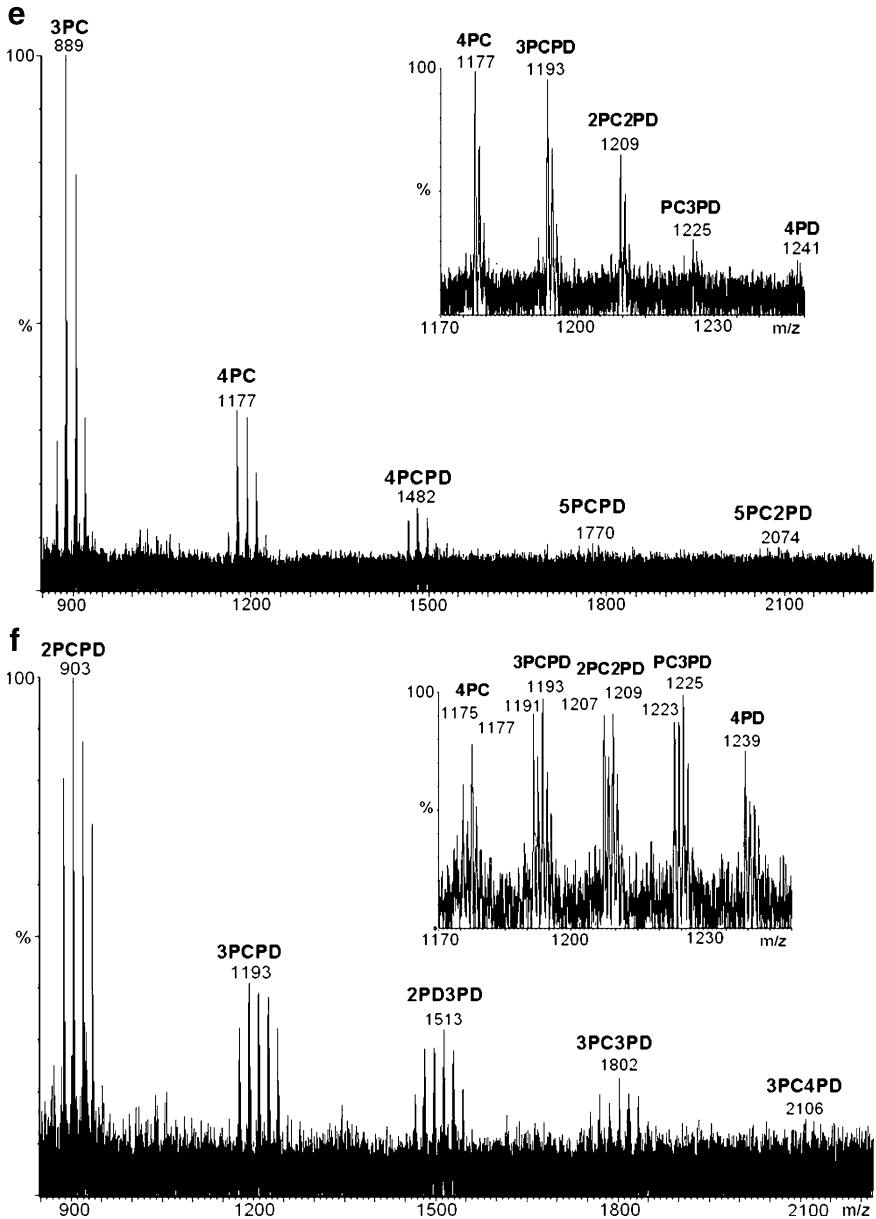

Fig. 2 (continued)

cultivar and comparable to that for *L. americanus*. However, no HMWPA fraction was separated in this case. The “creeping” selection is derived from material collected in Morocco, subsequently crossed and introgressed with standard agricultural cultivars of *L. corniculatus* (Rumball, unpublished observations). The observed structural differences in PAs suggest that there may be considerable variation between *L. corniculatus* populations in the wild. The sole “New World” species studied, *L. americanus*, contains PAs with doubly linked (A-type) units, and this is unique among reported PAs of not only these seven

Fig. 2 (continued)

Lotus spp. but also legumes in general (Koupai-Abyazani et al., 1993; Foo et al., 1982, 1996, 1997, 2000b; Sivakumaran et al., 2004).

Functional relationships between the differences observed and between the structures and estimated concentrations of PAs in these *Lotus* spp. and the ecological niche the plants occupy remain to be elucidated. This would require study of the variations in chemical composition of *Lotus* PAs in terms of growth period, season, and other environmental factors, as well as a detailed examination of their interactions with the environment. However, these findings draw attention to the need to consider the complexities of PA structure as well as the concentration of PAs in considering the ecological role of *Lotus* PAs and their effects on herbivores both in nature and in agricultural systems.

Acknowledgments We thank the New Zealand Foundation for Research Science and Technology Sustainable Development portfolio for funding. We acknowledge Reg Keogh and Willy Martin for their assistance with analyses of PA content of *Lotus* species.

Introduction

Soil solution concentrations of phenolic acids are a product of the inputs of phenolic acids (e.g., leaching of plant materials, microbial activity, root secretions and exudations, and root cell autolysis), losses of phenolic acids (e.g., sorption by soil particles, microbial utilization, uptake by roots), and soil water content. Unfortunately, we know little about “real-time” inputs and losses of phenolic acids into and from soil solutions under field conditions. For a discussion of the potential processes by which phenolic acids may be added and lost from soil solutions, see reviews by Siqueira et al. (1991) and Blum et al. (1999). Soil water content, which is highly variable, is determined by precipitation and/or irrigation, soil water holding capacity, and evapotranspiration. As soil water content decreases, concentrations of phenolic acids in the soil solution should increase, and soil water potentials (i.e., solute and matric) should become more negative. The opposite should happen when soil water content increases. Changes in soil solution concentrations of phenolic acids, however, may not be linearly related to changes in soil water content because changes in soil water content may also modify microbial utilization, soil sorption, leaching, and root uptake of phenolic acids.

Although it has been demonstrated that the inhibitory effects of phenolic acids on transpiration and leaf area expansion are concentration-dependent and that mild moisture stress and pretreatment with phenolic acid or water stress can enhance and reduce, respectively, the inhibitory activity of phenolic acids (Einhellig, 1995; Lehman and Blum, 1999; Blum and Gerig, 2005), no attempt has been made to determine how soil water content may be influenced by phenolic acid inhibition of transpiration or how soil water content may influence the level and duration of the inhibition of phenolic acids. Based on previous studies (Blum and Gerig, 2005; unpublished data), we have chosen to use *p*-coumaric acid, a *p*-hydroxycinnamic acid, and a (cucumber seedling)–[Cecil A_p soil–sand mixture (or soil)] system to address the following questions:

1. How do *p*-coumaric acid treatments affect evaporation, evapotranspiration, soil water content, leaf area, and leaf area expansion of cucumber seedlings?
2. How does soil water content influence the effects of *p*-coumaric acid?
3. What are the response and recovery times of evapotranspiration, lowest daily soil water, leaf area, and absolute and relative rates of leaf expansion for cucumber seedlings growing in soil treated one to four times with a range of *p*-coumaric acid concentrations?

Methods and Materials

Experimental Designs

Experiment 1a (effects of *p*-coumaric acid on soil evaporation): no cucumber seedlings, soil only—three *p*-coumaric acid concentrations (0, 0.5, and 1 $\mu\text{mol/g}$ soil), four replicates, four treatment times (d 6, 8, 10, and 12), and termination of experiment on d 14. Experiment 1b (effects of *p*-coumaric acid on cucumber seedlings and soil processes): plus cucumber seedlings—six *p*-coumaric acid concentrations (0, 0.125, 0.25, 0.5, 0.75, and 1 $\mu\text{mol/g}$ soil), four replicates, four treatment times (d 6, 8, 10, and 12), and termination of experiment on d 14. Experiment 2 (influence of soil water on the effects of *p*-coumaric acid): *p*-coumaric acid treatment (0.5 $\mu\text{mol/g}$ soil on d 6 and 8 and 1 $\mu\text{mol/g}$ soil on d 10 and 12),

two water levels (20 and 25 g water/150 g soil), four or eight replicates, and termination of experiment on d 13. Exp. 3 (response and recovery times after *p*-coumaric acid treatment): four *p*-coumaric acid concentrations (0, 0.25, 0.5, 0.75 $\mu\text{mol/g}$ soil), four different *p*-coumaric acid treatment combinations (d 6; d 6 and 8; d 6, 8, and 10; d 6, 8, 10, and 12), four replicates, and termination of experiment on d 16.

Daily water levels in seedling–soil systems were brought to 20 g water/150 g soil for Exp. 1 (determined values 19.31 ± 0.15 g water/150 g soil for Exp. 1a and 18.84 ± 0.21 g water/150 g soil for Exp. 1b), 20 (determined value 18.96 ± 0.08 g water/150 g soil) or 25 g water/150 g soil (determined value 23.65 ± 0.04 g water/150 g soil) for Exp. 2, and 25 g water/150 g soil (determined value 23.77 ± 0.03 g water/150 g soil) for Exp. 3. Field capacity for the Cecil A_p soil–sand mixture was approximately 0.095 g water/g soil (Lehman and Blum, 1997), which is below the 0.13 g water/g soil (20 g water) and 0.16 g water/g soil (25 g water) treatments used.

General Procedures

Cucumber seeds (*Cucumis sativus* cv. Early Green Clusters; Wyatt Quarles Seed Company, Raleigh, NC, USA) were germinated in trays of vermiculite in the dark at 30°C for 2 d. The resulting seedlings were placed under cool white fluorescent light banks (12-hr photoperiod, 140 $\mu\text{E}/\text{m}^2/\text{sec}$ PAR) located on laboratory benches for 2 d before being transplanted into cups containing 150 g of a Cecil A_p -horizon soil–sand mixture (1 part soil to 2 parts distilled water rinsed sand; w/w). Cecil A_p -horizon soil materials [Typic Kanhapludults, clayey, kaolinitic, thermic; pH = 5.7 ± 0.03 (mean \pm standard error); total carbon $2.2 \pm 0.20\%$] were collected in the summer of 1999 from experimental field plots at the Lake Wheeler Field Research Site, approximately 5 km south of North Carolina State University, Raleigh, NC, air-dried, sieved (2.5-mm mesh), and stored at room temperature ranging from 21 to 30°C in the laboratory. For additional soil characteristics, see Dalton et al. (1987). Cecil A_p soil was chosen because it is a dominate top soil in the southeastern United States and because it has been utilized by a number of researchers to study allelopathic–phenolic acid interactions (see Blum et al., 1999). Cups containing the soil–sand mixture and/or cucumber seedlings were placed in a randomized-blocked design under light banks (see above) in wooden racks so that substrate in the cups, except for the soil surface, was protected from light. Soil and seedling–soil systems under the light banks were kept at room temperature ranging from 21 to 30°C. The systems were supplied with nutrient solution (7 ml double strength Hoagland’s solution, pH 5.0; Hoagland and Arnon, 1950) every other day starting with d 5 and alternated with *p*-coumaric acid solution (pH 5.0) treatments starting with d 6. Water was added each day so that final volume was constant across treatments. Soil water levels and the number and concentrations of *p*-coumaric acid treatments varied with experiment (see “Experimental Designs”). *p*-Coumaric acid was chosen as the model compound to represent simple phenolic acids, such as ferulic, vanillic, and *p*-hydroxybenzoic acids, because their action on cucumber seedlings was so similar (Blum and Gerig, 2005). Because *p*-coumaric acid was rapidly depleted from soil solutions by sorption, microbial utilization, and root uptake (Blum et al., 1999), *p*-coumaric acid was added every other day to maintain a consistent range of soil solution concentrations over the experimental intervals of each experiment. A broad range of *p*-coumaric acid concentrations (0–1 $\mu\text{mol/g}$ soil) was added to systems in this modeling effort to maximize the likelihood of observing clear-cut responses by the soil and seedling–soil systems to *p*-coumaric acid.

Leaf Area, Absolute and Relative Rates of Leaf Expansion, and Seedling Weights

Cucumber seedling leaf areas were determined from leaf length and width measurements and the following equation: leaf area in $\text{cm}^2 = -1.457 + 0.008(L \times W)$, $P < 0.001$, $r^2 = 0.98$, where L and W are in mm (Blum and Dalton, 1985). Surface areas for cotyledons were determined by measuring cotyledon length and width and the following equation: area of cotyledon in $\text{cm}^2 = 1.293 + 0.006(L \times W)$, $P < 0.001$, $r^2 = 0.76$, where L and W are in mm. The mean absolute rates of leaf expansion ($\text{cm}^2/\text{seedling}/\text{unit time}$) for the cotyledons and/or true leaves were determined as follows: leaf area at time_{x+1} – leaf area at time_x . The mean relative rates of leaf expansion ($\text{cm}^2/\text{cm}^2/\text{unit time}$) were determined as follows: $\ln(\text{leaf area at } \text{time}_{x+1}) - \ln(\text{leaf area at } \text{time}_x)$. For a discussion on calculating growth rates, see Radford (1967). Fresh and dry (100°C for 24 hr) weights of shoots and dry weights of roots were determined at termination of each experiment. However, because shoot weights were only impacted by *p*-coumaric acid treatments, root dry weights were not modified by any treatment, and weights were determined at only one point in time, the end of each experiment, the data are not presented.

Evaporation, Evapotranspiration, and Soil Water

Evaporation and evapotranspiration were based on soil water depletion over various time intervals for soil and seedling–soil systems. Soil water content of systems was determined gravimetrically (i.e., differences in weight of systems between two time intervals).

Depletion of Phenolic Acid from Soil Solutions

Twenty to 30 g of soil subsamples from the seedling–soil systems were added to 30 ml autoclaved-distilled water in Erlenmeyer flasks. The flask containing the water and soil sample was shaken for 10 min on a platform shaker. Subsamples of the resulting soil slurry were placed into centrifuge tubes and centrifuged at $10,000 \times g$ for 10 min. Resulting supernatants were filter sterilized with 0.2- μm filters (Supor-200, Gelman Sciences, Ann Arbor, MI, USA) before high-performance liquid chromatographic (HPLC) analysis (Blum et al., 1994). *p*-Coumaric acid was quantified with a Waters (Milford, MA, USA) fully automated HPLC equipped with a model 484 absorbance detector set at 254 nm. A 4- μm particle size Nova-pak C_{18} Radial Pak cartridge in an RCM-100 cartridge holder was eluted for 20 min with 22% methanol, 0.5% ethyl acetate, 0.9% acetic acid, and 76.6% water to isolate and quantify the *p*-coumaric acid in the subsamples. Identification and quantification were confirmed by comparing retention times and areas with those of standard amounts of *p*-coumaric acid obtained from Sigma (St. Louis, MO, USA). *p*-Coumaric acid recovered (i.e., total available based on HPLC analysis) was then used to calculate available $\mu\text{mol } p\text{-coumaric acid/g oven dried soil}$ and $\text{mM of } p\text{-coumaric acid in the soil solution of the seedling–soil systems at various time intervals}$. Soil dry weight (100°C at 24 hr) and water content of the soil (i.e., soil solution; weight of moist soil – weight of oven dry soil) were determined gravimetrically. Available *p*-coumaric acid in $\mu\text{mol/g soil}$ or mM represents only the free or active fraction of *p*-coumaric acid remaining in the soil and excluded *p*-coumaric acid sorbed to soil particles, utilized by microbes, or taken up by roots.

Soil Bacterial Population

Bacterial populations that could utilize *p*-coumaric acid as a sole carbon source were determined by the plate dilution frequency technique (Harris and Sommers, 1968) utilizing a basal medium containing 0.5 mM *p*-coumaric acid as the only carbon source (Blum and Shafer, 1988; Shafer and Blum, 1991; Blum et al., 2000).

Data Analysis

Data were analyzed using SAS[®] system (SAS Institute Inc., 1999) employing SAS/GLM and SAS/MIXED procedures. For each data set, models were developed with the joint goals of providing a parsimonious explanation of the data while maintaining maximum predictive power. Initial model screening and computation of the r^2 statistic were handled using SAS/GLM. However, for many of the analyses, the data contained observations on the same unit measured repeatedly over time. This created a violation of the assumptions for standard analysis of variance and the need to use methodology for handling linear models with repeated measures. The tool used in this case was the SAS/MIXED procedure (Littell et al., 1996).

Results

How Do *p*-Coumaric Acid Treatments Affect Soil Evaporation (Exp. 1a)?

Multiple *p*-coumaric acid treatments up to 1 $\mu\text{mol/g}$ soil did not modify evaporation from Cecil A_p soil–sand mixture (or soil). However, evaporation varied significantly for time of day (daytime vs. nighttime) and from day-to-day (24 hr, d 6–13). The mean evaporation of 5.15 ± 0.091 g water/12 hr (mean \pm standard error) for the daytime was 1.58 times higher than the 3.27 ± 0.073 g water/12 hr for the nighttime (Fig. 1). Daily evaporation from the

Fig. 1 Evaporation (g water/unit time) from Cecil A_p soil–sand mixture treated with 0–1 $\mu\text{mol/g}$ soil *p*-coumaric acid on d 6, 8, 10, and 12. Because effects of *p*-coumaric acid were not significant, only overall means \pm SE are presented. Absence of error bars indicates that error bars are smaller than the symbol representing the mean

soil systems ranged from 7.20 ± 0.30 g water/24 hr on d 10 to 9.44 ± 0.30 g water/24 hr on d 12. The mean daily evaporation was 8.42 ± 0.14 g water/24 hr.

How Do *p*-Coumaric Acid Treatments Affect Evapotranspiration, Soil Water Content, Leaf Area, and Leaf Area Expansion of Cucumber Seedlings (Exp. 1b)?

Increasing concentrations of multiple treatments of *p*-coumaric acid reduced evapotranspiration, leaf area, and absolute and relative rates of leaf expansion, slowed the decline of soil water in the (cucumber seedling)–soil system, and elevated the daily lowest soil water content (see Figs. 2 and 3; Tables 1, 2, and 3 in [Supplementary Material](#)). Based on the models in Table 1, reductions for mean daytime (6.64 ± 0.35 g water/12 hr for controls), nighttime (3.82 ± 0.30 g water/12 hr for controls), and 24 hr (10.47 ± 0.40 g water/24 hr for controls) evapotranspiration ranged from 3% for the $0.125 \mu\text{mol/g}$ soil treatment to 22% for the $1 \mu\text{mol/g}$ soil treatment. Because evapotranspiration was reduced by *p*-coumaric acid, soil water content declined at a slower rate (see Figs. 2 and 3; Table 2 in [Supplementary Material](#)). Based on the models in Table 2, a 25% loss of water from the systems required approximately 7.8, 8.8, 9.1, 9.8, 11.4, and 13.5 hr for the 0, 0.125, 0.25, 0.5, 0.75, and $1 \mu\text{mol}/150$ g soil treatments, respectively. The largest difference in soil water content occurred just before solutions were added each day (Fig. 2). Based on the models in Table 2, mean lowest daily soil water ranged from 8.31 ± 1.08 g water/150 g soil for the control to 11.03 ± 1.08 g water/150 g soil for the $1 \mu\text{mol/g}$ soil *p*-coumaric acid treatment.

Leaf area (cm^2 , areas of cotyledons not determined) and relative rates of leaf expansion ($\text{cm}^2/\text{cm}^2/\text{d}$) of control cucumber seedlings increased approximately in a linear manner from d 10 to 14, whereas absolute rates of leaf expansion (cm^2/d) of control seedlings varied significantly from day-to-day (see Table 3 in [Supplementary Material](#)). Based on the models in Table 3, reductions in mean leaf areas ($13.95 \pm 3.71 \text{ cm}^2$ for control) and mean absolute rates of leaf expansion ($5.20 \pm 0.43 \text{ cm}^2/\text{day}$ for controls) ranged from 4% for

Fig. 2 Soil water content (g water/150 g soil) of (cucumber seedling)–(Cecil A_p soil–sand mixture) systems treated with 0–1 $\mu\text{mol/g}$ soil *p*-coumaric acid on d 6, 8, 10, and 12. Absence of error bars indicates that error bars are smaller than the symbol representing the mean

Fig. 3 Soil water content (g water/ 150 g soil) averaged over 24-hr periods for (cucumber seedling)–(Cecil A_p soil–sand mixture) systems treated with 0–1 $\mu\text{mol/g}$ soil *p*-coumaric acid on d 6, 8, 10, and 12. Data derived from models in Table 2 (see [Supplementary Material](#))

0.125 $\mu\text{mol/g}$ soil to 35% for 1 $\mu\text{mol/g}$ soil. Reductions of mean relative rates of leaf expansion ($1.14 \pm 0.90 \text{ cm}^2/\text{cm}^2/\text{d}$ for controls) ranged from 2% for 0.125 $\mu\text{mol/g}$ soil to 12% for 1 $\mu\text{mol/g}$ soil.

How Does Soil Water Content Influence the Effects of *p*-Coumaric Acid (Exp. 2)?

Effects of *p*-coumaric acid were not significantly different for the 20- and 25-g soil water treatments; that is, there were no significant interactions between *p*-coumaric acid and water treatments. (Cucumber seedling)–soil systems were treated with 0.5 $\mu\text{mol/g}$ soil on d 6 and 8 and 1 $\mu\text{mol/g}$ soil on d 10 and 12. Based on the models in Tables 4 and 5 (see tables in [Supplementary Material](#)), evapotranspiration (Fig. 4) and total leaf area (includes cotyledons) were inhibited by 10–19%, and lowest daily soil water was elevated by 8–21% by the 1 $\mu\text{mol/g}$ soil *p*-coumaric acid treatments given on d 10 and 12. Absolute rates of leaf expansion (Fig. 5) were inhibited 17–40% by 0.5 $\mu\text{mol/g}$ soil on d 6 and by 1 $\mu\text{mol/g}$ soil on d 10, 11, and 12. Relative rates of leaf expansion were inhibited 10–28% by both 0.5 and 1 $\mu\text{mol/g}$ soil *p*-coumaric acid (d 6–12).

The water treatments, however, did modify responses for the seedling–soil systems over the entire experimental period. Based on the models in Tables 4 and 5 (see tables in [Supplementary Material](#)), evapotranspiration was 8–15% (Fig. 4), lowest daily soil water was 26–42%, and absolute (Fig. 5) and relative rates of leaf expansion were 2–21% greater for the 25-g water treatments than the 20-g water treatments. Total leaf area, however, was 2–9% greater for the 20-g water treatments than the 25-g water treatments.

Starting with d 12, extra seedling–soil systems were destructively sampled at 0, 16, and 24 hr to determine soil moisture, water extractable $\mu\text{mol/g}$ soil *p*-coumaric acid, and mM of *p*-coumaric acid in soil solution (Fig. 6; see Table 6 in [Supplementary Material](#)). Based on models in Table 6, the 1 $\mu\text{mol/g}$ soil of *p*-coumaric acid added to the seedling–soil systems dropped immediately to 0.92 $\mu\text{mol/g}$ soil (time = 0) and then declined more gradually to 0.19 $\mu\text{mol/g}$ soil by 24 hr, a reduction of 79%. Over the same time period, soil water declined from 18 to 8 g/150 g soil for the 20-g water treatment and from 23 to 10 g/150 g

Fig. 4 Evapotranspiration (g water/24 hr) from (cucumber seedling)–(Cecil A_p soil–sand mixture) systems treated with two water levels (20 and 25 g water/150 g soil daily) and *p*-coumaric acid (0.5 $\mu\text{mol/g}$ soil was added on d 6 and 8, and 1 $\mu\text{mol/g}$ soil was added on d 10 and 12). Absence of error bars indicates that error bars are smaller than the symbol representing the mean

Fig. 5 Absolute rates of leaf expansion ($\text{cm}^2/24 \text{ hr}$) of cucumber seedling growing in (Cecil A_p soil–sand mixture) systems treated with two water levels (20 and 25 g water/150 g soil daily) and *p*-coumaric acid (0.5 $\mu\text{mol/g}$ soil was added on d 6 and 8, and 1 $\mu\text{mol/g}$ soil was added on d 10 and 12). Absence of error bars indicates that error bars are smaller than the symbol representing the mean

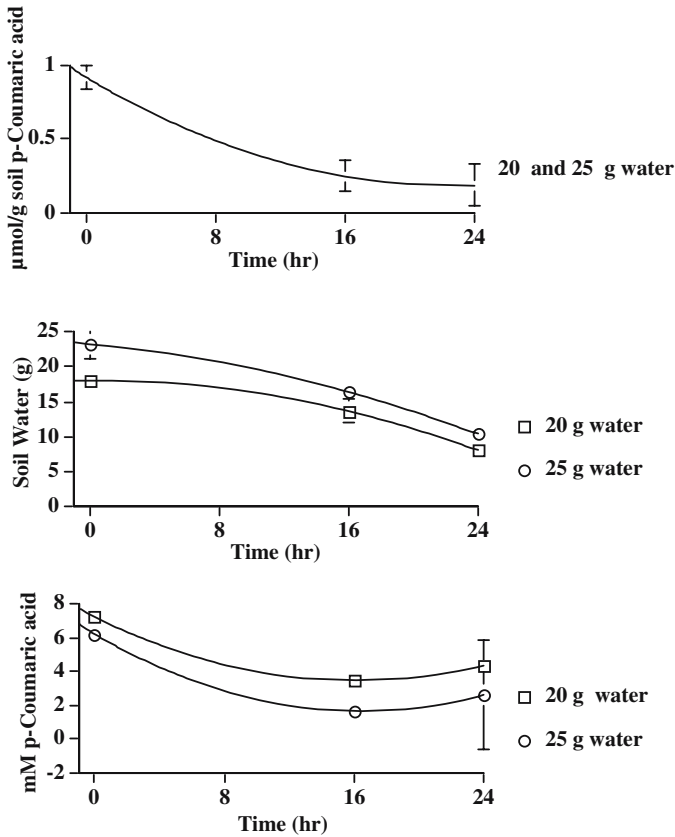

Fig. 6 $\mu\text{mol/g}$ soil *p*-coumaric acid, soil water (g/150 g soil), and mM of *p*-coumaric acid for 12- to 13-d-old (cucumber seedling)–(Cecil A_p soil–sand mixture) systems treated with 1 $\mu\text{mol/g}$ soil *p*-coumaric acid. Absence of error bars indicates that error bars are smaller than the symbol representing the mean

soil for the 25-g water treatment, approximately a 55% reduction for both water treatments. The concentration of *p*-coumaric acid in the soil solution based on the water-extractable *p*-coumaric acid and soil water content declined over the first 16 hr from 7.21 to 3.44 mM for the 20-g water treatment (a 52% reduction) and from 6.19 to 1.64 mM for the 25-g water treatment (a 74% reduction). Beyond 16 hr, the concentration increased for the next 8 hr from 3.44 to 4.34 mM for the 20-g water treatment (a 26% increase) and from 1.64 to 2.59 mM for the 25-g water treatment (a 58% increase). Finally, soil water and mM *p*-coumaric acid were higher and lower, respectively, for the 25-g water treatment than for the 20-g water treatment. Based on models in Table 6 (see [Supplementary Material](#)), soil water for the 25-g water treatment was 28, 20, and 29% greater than the 20-g water treatment at 0, 16, and 24 hr, respectively. The concentration of *p*-coumaric acid in the soil solution for the 25-g water treatment was 14, 52, and 40% lower than the 20-g water treatment at 0, 16, and 24 hr, respectively.

On d 13, additional sets of seedling–soil systems were also destructively sampled to determine the log colony forming units (CFU) of *p*-coumaric acid utilizing bacteria/g soil and soil pH. *p*-Coumaric acid utilizing bacteria were not modified by the 20- and 25-g water treatments, but were stimulated by the *p*-coumaric acid treatments. The control soil

contained 10.50 ± 0.31 log CFU/g soil (2.24×10^{11} CFU/g soil), and the *p*-coumaric-acid-treated soil contained 11.70 ± 0.17 log CFU/g soil (7.85×10^{11} CFU/g). Soil pH was not modified by the 20- and 25-g water treatments, but was increased by the *p*-coumaric acid treatments. The control soils had a pH value of 5.68 ± 0.03 , and the *p*-coumaric-acid-treated soil had a pH value of 6.10 ± 0.02 .

What Are the Response and Recovery Times of Evapotranspiration, Lowest Daily Soil Water, Leaf Area, and Absolute and Relative Rates of Leaf Expansion for Cucumber Seedlings Growing in Soil Treated One to Four Times with a Range of *p*-Coumaric Acid Concentrations (Exp. 3)?

Inhibition of evapotranspiration, total leaf area, absolute and relative rates of leaf expansion, and the elevation of daily lowest soil water were increased in a linear manner

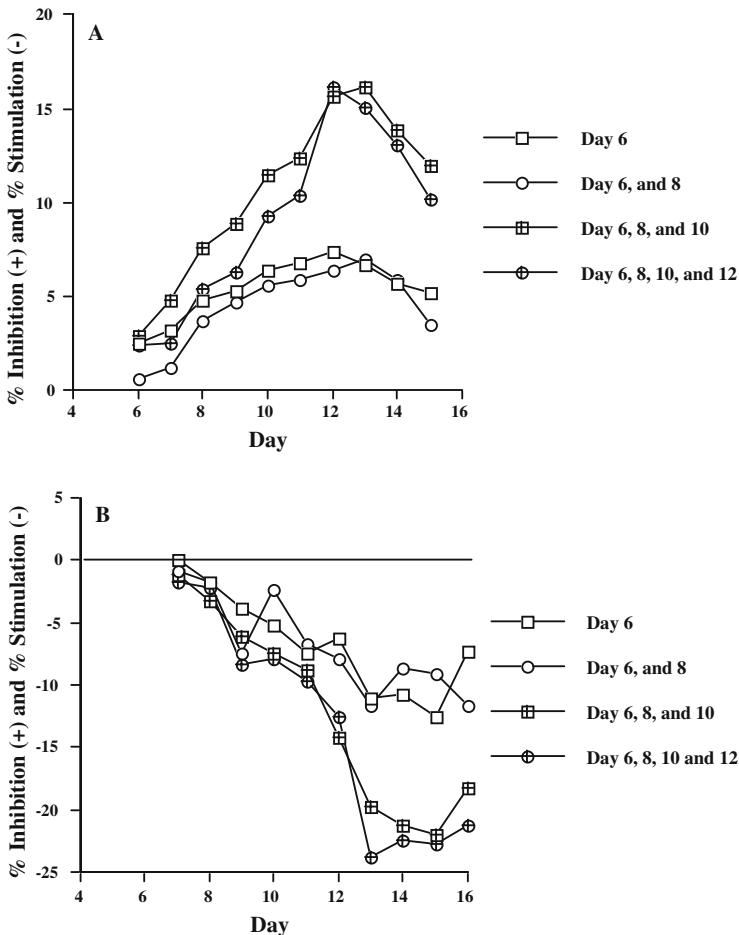

Fig. 7 Percent inhibition/stimulation of evapotranspiration (A) and daily lowest soil water (B) of (cucumber seedling)–(Cecil A_p soil–sand mixture) systems treated with $0.5 \mu\text{mol/g}$ soil *p*-coumaric acid one to four times. Percent inhibition presented as positive values and percent stimulation as negative values. Data derived from models in Table 7 (see [Supplementary Material](#))

with increasing concentrations of *p*-coumaric acid ranging from 0 to 0.75 $\mu\text{mol/g}$ soil (see Tables 7 and 8 in [Supplementary Material](#)). Significant effects of *p*-coumaric acid were first observed on the day of the first treatment (d 6) for absolute and relative rates of leaf expansion and on d 7–9 for evapotranspiration, lowest daily soil water, and total leaf area. Utilizing the models in Tables 7 and 8, maximum inhibition for all *p*-coumaric acid treatment combinations occurred for absolute and relative rates of leaf expansion on d 8 or 10 and for evapotranspiration and total leaf area on d 12 or 13, whereas maximum elevation of lowest daily soil water occurred on d 13 or 15.

Maximum inhibition for evapotranspiration and total leaf area and elevation of lowest daily soil water were not significantly different for the single (d 6) and double (d 6 and 8) *p*-coumaric acid treatments and averaged from 4 to 24% for the 0.25–0.75 μmol *p*-coumaric acid/g soil treatments (see Figs. 7 and 8, and Tables 7 and 8 in [Supplementary Material](#)).

Fig. 8 Leaf area of control seedlings (cm²/seedling) (A) and inhibition/stimulation of total leaf area (B) of seedlings growing in (Cecil A_p soil–sand mixture) systems treated with 0.5 $\mu\text{mol/g}$ soil *p*-coumaric acid one to four times. Percent inhibition presented as positive values and percent stimulation as negative values. Data for percent inhibition/stimulation were derived from models in Table 8 (see [Supplementary Material](#))

Also, maximum effects were not significantly different for the triple (d 6, 8, and 10) and quadruple (d 6, 8, 10, and 12) *p*-coumaric acid/g soil treatments and averaged from 8 to 34% for the 0.25–0.75 μmol *p*-coumaric acid/g soil combinations. Recovery for evapotranspiration and total leaf area was evident for all treatment exposures after d 12 or 13. Recovery for lowest daily soil water was evident on d 13 or 15. Complete recovery (not significantly different from control), which occurred from d 14 to 16, was observed only for the single and/or double *p*-coumaric acid treatments.

Total leaf area and evapotranspiration, and total leaf area and lowest daily soil water for Exp. 3 were positively and negatively related, respectively [(evapotranspiration, g water/day = $8.79 + [0.11 \times \text{total leaf area}] - [0.002 \times \{\text{total leaf area} - 27.24\}^2] + [0.00004 \times \{\text{total leaf area} - 27.24\}^3]$], where total leaf area is in cm^2 and 27.24 is a constant; $P < 0.001$ and $r^2 = 0.88$, observations = 620) and (lowest daily soil water, g water/150 g soil = $14.38 - [0.09 \times \text{total leaf area}] + [0.002 \times \{\text{total leaf area} - 27.24\}^2] - [0.00005 \times \{\text{total leaf area} -$

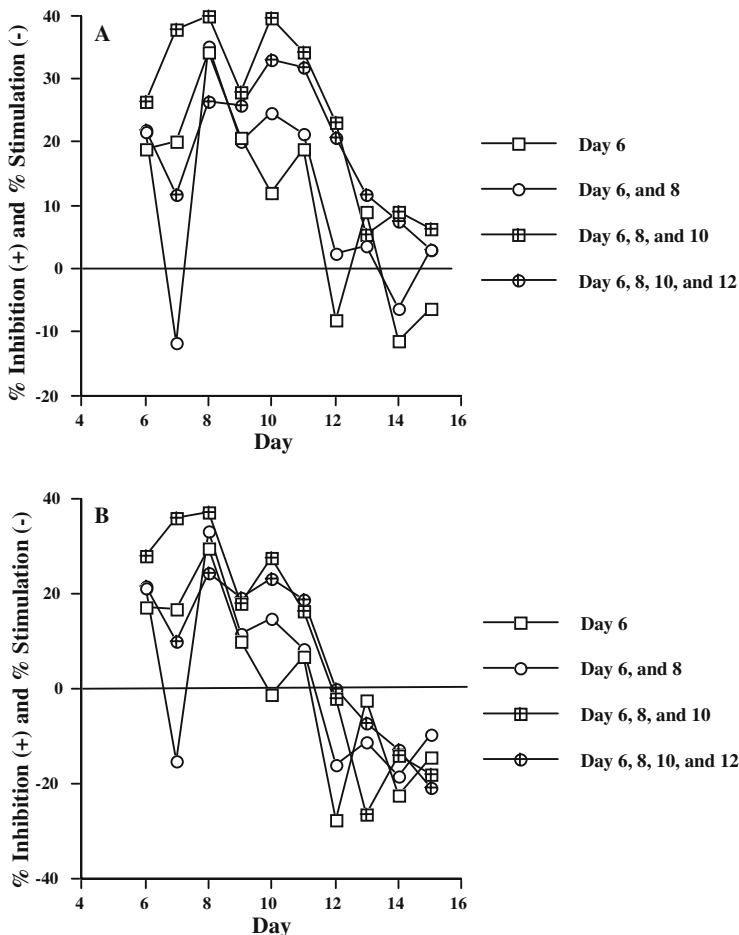

Fig. 9 Percent inhibition/stimulation of absolute (A) and relative rates (B) of leaf expansion of seedlings growing in (Cecil A_p soil–sand mixture) systems treated with 0.5 $\mu\text{mol/g}$ soil *p*-coumaric acid one to four times. Percent inhibition presented as positive values and percent stimulation as negative values. Data derived from models in Table 8 (see [Supplementary Material](#))

27.24 $\}^3]$, where total leaf area is in cm^2 and 27.24 is a constant; $P < 0.001$ and $r^2 = 0.69$, observations = 619)].

Maximum inhibition of absolute and relative rates of leaf expansion occurred on d 8 or 10, was not significantly different for all *p*-coumaric acid treatment combinations, and averaged from 16 to 53% for the 0.25–0.75 μmol *p*-coumaric acid/g soil treatments (see Fig. 9; Table 8 in [Supplementary Material](#)). Recovery was evident for all treatment combinations after d 8 or 10. Complete recovery (not significantly different from control), however, varied with treatment combination. Complete recovery for absolute rates of leaf expansion occurred on d 12 and 13 for the single and double treatments, and the triple and quadruple treatments, respectively. Complete recovery for relative rates of leaf expansion occurred on d 10, 11, and 12 for the single, double, and triple and quadruple treatments, respectively. Furthermore, relative rates of leaf expansion were subsequently stimulated. Maximum stimulations ranged from 12 to 35% for the 0.25–0.75 $\mu\text{mol/g}$ soil treatments for all treatment combinations.

Discussion

Phenolic acids, such as *p*-coumaric acid, inhibit transpiration and leaf area expansion and reduce leaf area of cucumber seedlings (Blum et al., 1985a,b; Blum and Gerig, 2005). What is new here is the demonstration that inhibition of phenolic acids, such as *p*-coumaric acid, on transpiration and leaf area expansion resulted in reduced rates of water depletion from soil and an elevation of mean lowest daily soil water (Exp. 1). Because the level of inhibition of transpiration and leaf area expansion is a function of concentrations of phenolic acids in soil solutions surrounding roots (Lehman and Blum, 1999; Blum and Gerig, 2005), one might anticipate that elevated soil water content associated with the presence of phenolic acids in soil solutions could decrease the level and duration of phenolic acid inhibition. In addition, such increases in water content and associated changes in soil solution concentrations could result in incorrectly identifying the actual dose in dose response studies. Furthermore, the increased soil moisture associated with phenolic acid treatments of sensitive species suggested a means by which the magnitude of some allelopathic interactions might be modified, and resource competition and allelopathy could interact in the presence of sensitive and insensitive species.

As a first step toward determining if such changes in soil water might influence the observed inhibition of phenolic acids, we attempted to maintain different water levels in the (cucumber seedling)–[Cecil A_p soil–sand mixture (or soil)] systems (Exp. 2). However, maintaining a specific narrow range of soil water for the seedling–soil systems was essentially impossible given the size of the cup system and the variations in seedling size and evapotranspiration. We therefore chose to supply different levels of water once a day, at the same time, to all systems, essentially a differential “dry-down” procedure. Bringing water levels to less than 20 g water/150 g soil each day required that water be added more than once during the day, particularly for control systems, to prevent wilting of cucumber seedlings. The first signs of wilting by cucumber leaves occurred whenever soil water in the seedling–soil system reached 7.24 ± 0.17 g water/150 g soil. Bringing water levels to more than 25 g water/150 g soil each day resulted in standing soil surface water for several hours during each 24-hr watering cycle, the time varying with seedling age and with *p*-coumaric acid treatment. Field capacity for the Cecil A_p soil–sand mixture was approximately 0.095 g water/g soil (Lehman and Blum, 1997), which is below the 0.13 g water/g soil (20 g water) and 0.16 g water/g soil (25 g water) water treatments used. Finally, the amount

of water actually added daily to the systems declined slightly over time as seedling weight increased. It also varied some with inhibition of seedlings by *p*-coumaric acid. Recall that water added at the beginning of each 24-hr water cycle was based on seedling–soil system weight. However, this error amounted to less than 1.5 g at the termination of all experiments and less than 0.5 g between controls and the *p*-coumaric acid treatments.

As expected, soil water was higher for the daily 25 g water/150 g soil treatment than the 20 g water/150 g soil treatment throughout each 24-hr watering cycle. However, leaf area expansion and evapotranspiration were also greater for the 25-g water treatment. Thus, watering the seedling–soil systems above field capacity apparently was not a problem for cucumber seedling development. Systems supplied with 25 g water/150 g soil (determined value 23.65 ± 0.045 g) had a range of 8–18% greater evapotranspiration, 26–42% higher lowest daily soil water, and 2–21% greater leaf area expansion than those supplied with 20 g water/150 g soil (determined value 18.96 ± 0.075 g). We suspect that this was primarily because of the more rapid decline (i.e., more negative) in soil solute and matric potentials each day for the 20-g water than for the 25-g water-treated (cucumber seedling)–soil systems. In other words, soil water became limiting earlier during each 24-hr watering cycle for the 20-g water than the 25-g water treatment. However, because the lowest daily soil water experienced by all seedlings was above the wilting point of cucumber seedlings and no visible wilting was observed, seedlings were not severely drought stressed at the end of each 24-hr water cycle.

Because the initial treatments of 0.5 $\mu\text{mol/g}$ soil of *p*-coumaric acid on d 6 and 8 in Exp. 2 did not result in a rapid and striking inhibition of evapotranspiration and leaf area expansion (only relative rates of leaf expansion were inhibited from d 6 to 10), the systems were treated with 1 $\mu\text{mol/g}$ soil on d 10 and 12. To determine the range and the differences in soil solution concentrations of *p*-coumaric acid for the two water treatments, we thus chose to extract soils toward the end of the experiment. Over a 24-hr period, seedling–soil systems containing 12-d-old cucumber seedlings treated with 1 $\mu\text{mol/g}$ soil *p*-coumaric acid had decreasing and then increasing soil solutions concentrations ranging from 7.12 to 3.44 mM for the 20-g water treatment and from 6.19 to 1.64 mM for the 25-g water treatment. The decreasing soil solution concentrations for the first 16 hr were a result of microbial utilization, soil sorption, and cucumber seedling root uptake (Blum and Shafer, 1988; Blum et al., 1994, 2000; Blum and Gerig, 2005). The increasing soil solution concentrations sometime after 16 hr were likely a result of a faster decline in the rates of microbial utilization, soil sorption, and/or root uptake of *p*-coumaric acid during the “dry down” than evapotranspiration; that is, water was declining proportionally faster than *p*-coumaric acid. The large error bars at 24 hr for mM of *p*-coumaric acid (Fig. 6) in soil solution (available *p*-coumaric acid) appeared to be caused by the variation in soil water content. Variation in soil water for the cup systems was small at time 0, when systems were watered, and became progressively larger during the “dry down” procedure, reaching a maximum at 24 hr, just before the next water addition. When the available *p*-coumaric acid was expressed in $\mu\text{mol/g}$ soil, soil being a constant, the increase in the error bars over the 24-hr water cycle was much smaller than when available *p*-coumaric acid was expressed in mM.

Given the significant differences in soil solution concentrations between the 20- and 25-g water treatments, it was surprising to find no significant differences in *p*-coumaric acid effects on cucumber seedlings for these two water treatments; that is, there were no significant interactions between *p*-coumaric acid and water treatment. In other words, the effects of water and *p*-coumaric acid treatments were independent of each other. The independence of *p*-coumaric acid and soil water treatments is counter to dose response studies and the observations in nutrient culture that effects of phenolic acids are primarily

determined by their active concentrations surrounding roots (Lehman and Blum, 1999; Blum and Gerig, 2005). Four possible reasons suggested themselves for this independence of response in soil systems: (1) that the mM of *p*-coumaric acid for both water treatments were too high; that is, range of concentrations experienced by seedling roots for both water treatments were at or close to maximum inhibition; (2) that the roots in both water treatments experienced identical doses despite different solution concentrations; (3) that the two water treatments lead to different cucumber seedlings responses to *p*-coumaric acid molecules, i.e., a difference in sensitivity; and/or (4) seedling responses in soil were too slow to determine these interactions within the time frame of this study.

Of the four, the first (1) appeared to be the least likely because inhibition of relative rates of leaf expansion (approximately 15%) by 0.5 $\mu\text{mol/g}$ soil *p*-coumaric acid treatments was also not significantly different for the two water treatments. In a subsequent experiment, *p*-coumaric acid soil solution concentrations ranging from 2.72 mM (1 hr after addition) to 0.92 mM (24 hr after addition) were observed for 12-d-old seedlings treated with 0.5 $\mu\text{mol/g}$ soil *p*-coumaric acid and 20 g water/150 g soil (unpublished data). Using a ratio method and data from the 1- $\mu\text{mol/g}$ soil treatment, we estimate that the range of soil solutions for a 25-g water treatment would have been approximately 2.36–0.44 mM.

The total amount of *p*-coumaric acid added to the seedling–soil systems every other day, the declining $\mu\text{mol/g}$ soil of available *p*-coumaric acid over a 24-hr watering cycle, soil pH, and the *p*-coumaric acid utilizing microbial populations were not significantly different between the two water treatments. The lack of difference in these variables indicated that the combined activities of root uptake and sorption by soil particles also were not different for the two water treatments. However, soil solution concentrations (mM) of *p*-coumaric acid were significantly lower and rates of evapotranspiration (primarily transpiration), lowest daily soil water, and absolute and relative rates of leaf expansion were significantly higher for the 25-g water treatment than for the 20-g water treatment. Thus, it is possible that either increased movement of *p*-coumaric acid molecules through the soil matrix to the roots, associated with higher transpiration rates, or a greater sensitivity of the faster-growing cucumber seedlings to *p*-coumaric acid molecules for the 25-g water treatment led to similar levels of *p*-coumaric acid inhibition for the two water treatments. Further research will be required to determine if either one or the other is true.

What about response times? To determine the time required for initial inhibition, maximum expression of inhibition, and recovery after *p*-coumaric acid treatment, (cucumber seedling)–soil systems were given single (d 6) to quadruple (d 6, 8, 10, and 12) *p*-coumaric acid treatment combinations (Exp. 3). The time required to initially detect inhibition of *p*-coumaric acid on evapotranspiration, lowest daily soil water, total leaf area, and absolute and relative rates of leaf expansion required 1–3 d after the first *p*-coumaric acid treatment. Maximum expression of inhibition of *p*-coumaric acid, however, required an additional 1 (leaf expansion) to 6 d (evapotranspiration and lowest daily soil water). Recovery occurred shortly after maximum expression, but full recovery for evapotranspiration, lowest daily soil water, and total leaf area only occurred for the single and/or double *p*-coumaric acid treatments. Full recovery of absolute and relative rates of leaf expansion for all treatment exposures occurred 2–5 d after maximum inhibition. Relative rates of leaf expansion not only recovered, but were also stimulated, maximum stimulation occurring 4–7 d after maximum inhibition.

The recovery after the single (d 6) *p*-coumaric acid treatment took longer than the recovery after the last *p*-coumaric acid treatment (d 12) of the quadruple treatment. This difference in recovery may have been related to the changing seedling leaf characteristics over the experimental period described below. Furthermore, given this range of times for

expression of inhibition, recovery, and/or stimulation, it was not surprising that the patterns and trends for the different *p*-coumaric acid treatment combinations were so similar and overlapping. However, the significant differences observed in *p*-coumaric acid effects between the single/double treatments and the triple/quadruple treatments were unexpected. The maximum effects of *p*-coumaric acid on evapotranspiration and lowest daily soil water for the triple/quadruple treatments were approximately twice that of the single/double treatments (Fig. 7). The difference for total leaf area was 1.4 (Fig. 8). One possible explanation for this outcome is as follows: On d 6, the start of *p*-coumaric acid treatments, cucumber seedling had no true leaves, only cotyledons, and these were almost fully developed (Fig. 8). The first and second true measurable leaves for the control seedlings did not occur until d 9 and 13, respectively. Thus, the single and double *p*-coumaric acid treatments primarily influenced the transpiration and growth of the cotyledons, whereas the triple and quadruple *p*-coumaric acid treatments influenced the transpiration and growth of both cotyledons and true leaves. The difference in leaf area of the developing seedlings (type and stage of leaf area expansion) and the ratio of succulent (cotyledons) and nonsucculent (true leaves) leaf tissue may help to explain the significant difference in the observed effects on evapotranspiration and lowest daily soil water for the single/double and triple/quadruple *p*-coumaric acid treatments.

Because *p*-coumaric acid treatments did not modify soil evaporation in the absence of cucumber seedlings (Exp. 1), the observed *p*-coumaric acid effects on evapotranspiration and lowest daily soil water were primarily related to effects on transpiration and/or leaf area. However, some effects on soil evaporation would be expected because of differences in soil surface shading by cucumber seedlings with different leaf areas. In a previous study, Blum and Gerig (2005) observed in nutrient culture that the effects of increasing concentrations of *p*-coumaric acid on water loss by cucumber seedlings were largely determined by leaf area. It was not surprising to find that total leaf area and evapotranspiration, and total leaf area and lowest daily soil water were positively and negatively related, respectively (see Exp. 3). Leaf areas of cucumber seedlings have been shown to be directly related to shoot and root dry weights, total and average root lengths of primary and secondary roots, and root numbers (Blum and Rebbeck, 1989). Thus, leaf area and the dynamics of leaf expansion (i.e., absolute and relative growth rates) provide an excellent means by which short- and longer-term responses of (cucumber seedling)–soil systems to phenolic acids, such a *p*-coumaric acid, may be monitored.

The rapid response times in nutrient culture led Blum and Gerig (2005) to suggest that negative feedback regulation of transpiration could be an important factor in determining the observed inhibitory activity of phenolic acids, such as *p*-coumaric acid. However, the slower initiation, maximum expression, and subsequent recovery after *p*-coumaric acid treatments in soil culture, particularly as related to transpiration, soil moisture, and leaf area, and the lack of significant responses to different water treatments suggested that negative feedback regulation by transpiration on seedling development (i.e., growth) is not a major concern to dose response studies in soil systems when time intervals are short. What role, if any, feedback inhibition may have over longer time intervals is still to be determined. We may also conclude that at least for this (cucumber seedling)–soil system and the time frame of this study that the initial input or treatment concentrations of *p*-coumaric acid represented a reasonable estimate of dose experienced by cucumber seedlings despite the dynamic nature of soil solution concentrations.

Allelopathic interactions can be altered by a variety of physical factors of the environment, among them, soil moisture (Einhellig, 1987; Lehman and Blum, 1997). Lehman and Blum (1997) observed that the inhibitory effects of soil-incorporated wheat

cover crop debris on pigweed seedling emergence were eliminated by increasing soil moisture. This suggested that increasing soil moisture associated with a reduction in water utilization by phenolic-acid-susceptible species could influence the magnitude of some allelopathic interactions. Furthermore, soil moisture will also influence a variety of other physical and chemical characteristics of soil, such as aeration, nutrient availability, and soil temperature, which also are known to influence the magnitude of allelopathic interactions (see Einhellig, 1987; Blum, 2006).

Finally, given two species with differing sensitivities to phenolic acids, such as *p*-coumaric acid, growing in proximity to each other in a water-limiting soil, water uptake would be inhibited more for the phenolic-acid-sensitive species than the less sensitive species, leaving more water for the less sensitive species. Similar observations can be made for mineral nutrition (Glass and Dunlop, 1974; Harper and Balke, 1981; Bergmark et al., 1991; Booker et al., 1992; Lehman and Blum, 1999). As the less sensitive species outgrows the sensitive species, its competitive effects on the sensitive species would intensify. Thus, resource competition by the less phenolic-acid-sensitive species could be intensified on the more phenolic acid sensitive species by the differential allelopathic effects of phenolic acids.

Acknowledgments The authors thank Jeff Weidenhamer and several anonymous reviewers for reviewing this manuscript and for their valuable and thoughtful suggestions.

Abstract Six perennial groundcovers including *Alchemilla mollis*, *Nepeta* × *faassenii*, *Phlox subulata*, *Sedum acre*, *Solidago cutleri*, and *Thymus praecox* were investigated for the allelopathic potential of their respective foliar tissues via evaluation of volatile constituents produced by foliage. These groundcovers were selected for further laboratory evaluation because of superior performance as weed-suppressive groundcovers in previous field experiments. Foliar volatile components of *N.* × *faassenii* exhibited the strongest inhibitory effects on seedling growth of curly cress (*Lepidium sativum*), but *S. cutleri* also showed allelopathic potential by reducing shoot growth of curly cress seedlings with extracted volatiles. Although *A. mollis* and *P. subulata* exhibited strong weed-suppressive traits in past field experiments, weed suppression is apparently associated with either competition for resources or other allelopathic mechanisms rather than an allelopathic effect caused by volatiles. Volatiles of *N.* × *faassenii* were further evaluated with gas chromatography coupled to mass spectrometry (GC-MS). A total of 21 chemical constituents were identified in the volatile cocktail; 17 components were identified from a direct crude leaf sample extraction, including sabinene, β -pinene, β -myrcene, 2-(2-ethoxyethoxy)-ethanol, 1,8-cineole, ocimene, neryl Acetate, 4 α ,7 α ,7 α -nepetalactone, α -copaene, *trans*-caryophyllene, alloaromadendrene, 4 α β ,7 α ,7 α β -nepetalactone, germacrene D, β -farnesene, χ -cadinene, germacrene B, and β -sesquiphellandrene. Five additional constituents were identified in a methanolic extract of dried of *N.* × *faassenii* foliage, but not the volatile cocktail collected from *N.* × *faassenii* foliage. These included methyl benzoate, 2,4-decadienal, neryl acetate, isodihydronepetalactone, and caryophyllene oxide. Three components, 2-(2-ethoxyethoxy)-ethanol, alloaromadendrene, and χ -cadinene, were not only

Introduction

Herbaceous perennial groundcovers have been popularly used in home gardens and landscapes because of their ability to rapidly cover the soil surface and prevent erosion, as well as for their aesthetic appeal. Certain herbaceous perennials evaluated in past field experiments have shown potential as weed-suppressive groundcovers for utilization in many urban landscapes including commercial properties, municipal settings, and even along roadsides (Eom et al., 2005).

Weed-suppressive groundcovers can be used in both private landscapes and roadside settings, and generally form dense foliar canopies, preventing light transmittance to the soil surface beneath the groundcover, thereby limiting weed seed germination and seedling establishment (Eom et al., 2005). The height and density of the groundcover canopy contribute to its ability to suppress weeds, and allelochemicals from vegetative plant parts may also contribute to weed suppression (Eom 2004). Establishment of groundcovers is limited by various environmental factors that influence plant growth, including physical soil condition, salinity, drought, previously established plant species, and temperature extremes (Usón and Poch 2000). Furthermore, relatively large-scale landscape settings are often affected by uncontrollable and undesirable environmental factors. Although we selected groundcovers that exhibited a strong ability to suppress weeds over time because of their competitive interference with weeds, the growth and establishment of groundcovers in difficult urban landscape settings is dependent upon many factors. Therefore, groundcovers that exhibit inherent allelopathic as well as competitive traits may be more successful in suppressing surrounding vegetation, especially on a long-term basis.

Allelochemicals are released from plants into the environment in several ways, including volatilization from leaf tissues, leaching of nonvolatiles from foliage by rainfall, exudation from living roots, or decomposition of residues by soil microorganisms (Shiraishi et al., 2002; Rai et al., 2003; Kobayashi, 2004). Persistence and activity of allelochemicals released under natural conditions or field settings are influenced by the environment, specifically meteorological and rhizospheric conditions, as well as physical distance from the source of production (Jose and Gillespie, 1998; Romero-Romero et al., 2002). Unlike other mechanisms of allelopathy, studies on volatile effects in plant–plant interactions have been less often investigated, although some significant effects have been associated with volatiles produced by mugwort (*Artemisia vulgaris*) and other species as well (Bradow and Connick, 1990; Barney et al., 2005). The evaluation of certain herbaceous ornamentals for their ability to suppress weeds through allelopathic interference has been reported (Shiraishi et al., 2002). Several groundcovers, including *Oxalis brasiliensis*, *Phlox subulata*, and *Lycoris radiata* were observed to

be strongly weed-suppressive when foliar tissues were bioassayed in the laboratory under controlled conditions.

As little information is available regarding the allelopathic potential of such groundcovers, we selected six of our top-performing weed-suppressive species for further evaluation in the laboratory. In our field evaluation, certain groundcovers, including *Alchemilla mollis*, *Nepeta* × *faassenii*, *P. subulata*, and *Thymus praecox*, were superior performers in terms of establishment and/or weed suppression (Eom et al., 2005). In addition, *Solidago cutleri* and *Sedum acre* were included for further investigation of allelopathic traits because these two groundcovers and related species are relatively stress-tolerant and establish well in field settings (Eom et al., 2005). We specifically sought to determine if these groundcovers exhibited allelopathic potential in *in vitro* bioassays by examining the activity of the foliar volatiles they produced. Certain herbaceous perennials, such as mints and common potherbs, emit large quantities of volatiles, likely associated with plant defense against pests or insect attraction. Because *N. × faassenii* exhibited strong potential allelopathic activity in these assays, we focused on isolation and evaluation of its volatile constituents.

Methods and Materials

Groundcover Growth

Six groundcovers and a commercial tomato plant (*Solanum lycopersicum* L.) were propagated for use in our volatile assays. The tomato plant was used as a positive control for production of foliar volatiles. *S. acre* L. (*Sedum* “Acre”) was propagated from 5-cm stem cuttings. Seeds of other perennial groundcovers—*A. mollis* L. (lady’s mantle), *N. × faassenii* L. (catmint “Walker’s Low”), *P. subulata* L. (creeping phlox “Emerald blue”), *S. cutleri* L. (ornamental goldenrod), and *T. praecox* L. (creeping thyme) were purchased from Jelitto Staudensamen GmbH (Schwarmstedt, Germany). Selected groundcovers had previously exhibited strong weed suppression (*A. mollis*, *N. × faassenii*, and *P. subulata*) in field and roadside experiments (Eom et al., 2005) or excellent establishment (*S. cutleri*, *T. praecox*, and *S. acre*) in landscape settings. Stratification of seed was required for uniform germination; therefore, seed was initially placed in moist, filter-paper-lined Petri dishes (4 ml of distilled H₂O/Petri dish) for 6 d at a 4°C dark condition, and then moved to a lighted growth chamber [150 μmol m⁻² s⁻¹ photosynthetic photon flux (PPF) overhead light intensity] at 25°C for 7 d according to instructions available in the Jelitto catalogue, 2000. Groundcovers were sown into Metro-mix[®] 510 growth media (Scotts Co., Marysville, OH, USA) and later transplanted into a soil mixture comprised of 50% local soil (Hudson silt clay loam), 25% sand, and 25% Metro-mix[®] 510 growth media based on volume. All groundcovers in 25 pots of each species for this experiment were grown in a propagation house for 12 mo. Plants were maintained under a 14-hr photoperiod with a light intensity of 200 μmol m⁻² s⁻¹ PPF from supplemental overhead lighting. Daytime temperatures in the greenhouse were maintained within 24–28°C, whereas nighttime temperatures were maintained at 18–22°C. Plants were fertilized biweekly with full-strength Hoagland’s solution (200–300 ml/pot).

Volatile Bioassay

In an assay similar to that developed in our laboratory to assess volatile activity in mugwort tissue (Barney et al., 2005), mature leaves of each groundcover species were excised and directly placed in a plastic ziplock bag submerged in ice water. In the laboratory shortly after collection, leaf samples were folded and wrapped in cheesecloth at amounts of 0, 5, 10, and 20 g of tissue (fresh weight). Each wrapped sample was suspended in a capped 500-ml glass flask in which curly cress (*Lepidium sativum* L.) seeds (20/bottle) were placed on moistened filter paper (Whatman #4) wetted with 5 ml distilled water (Figure 1). Selection of seedling indicators for use in the bioassay requires that the selected species exhibit a high level of germination and uniform growth over time (Bertin et al., 2003). Curly cress meets these requirements (Bertin et al., 2003) and does not require seed pretreatment or stratification; seeds rapidly germinated after storage in a dark, cold room (5°C) upon transfer to a moistened filter paper (4 ml of distilled H₂O/Petri dish) in parafilm-sealed Petri dishes and a light regime of 150 $\mu\text{mol m}^{-2} \text{s}^{-1}$ PPF overhead light intensity. As a control treatment, foliar tissues of tomato (*S. lycopersicum* L.), commonly known to produce volatile constituents from its foliage (Smith et al., 1996; Farag and Paré, 2002; Feng et al., 2004), were utilized for comparative purposes. Fully expanded leaves of tomato grown for 30 d were selected, and treatments were arranged in a completely randomized design maintained in a growth chamber at 28°C daily temperature and 200 $\mu\text{mol m}^{-2} \text{s}^{-1}$ PPF overhead light intensity. After 72 hr of growth in enclosed environments, length of curly cress seedling roots and shoots were measured. All treatments were replicated four times.

Sample Preparations for Analyzing *Nepeta Foliar* Constituents

A direct crude leaf volatile extract was made to analyze the volatile constituents from fresh leaves of *N. × faassenii* grown in a greenhouse. A potted *N. × faassenii*

Fig. 1 Volatile bioassay showing suspended foliar tissue of *Nepeta × faassenii* above germinating seedling indicators. From left to right, control, and increasing levels of catmint tissue at 5, 10, and 20 g/cheesecloth.

plant was brought into the laboratory where volatile analysis was performed with a gas chromatograph coupled to a mass spectrometer at room temperature and ambient conditions. Detached fully expanded young leaves were immediately submitted for volatile analyses as described below. In addition, both aqueous and methanolic extracts were formulated by using dried leaves. Ground foliage (100 g) was extracted with 1500 ml distilled water or HPLC (high-performance liquid chromatography)-grade methanol with a rotating shaker maintained in the dark at 5°C for 48 hr. Both extracts were filtered through eight layers of cheesecloth to remove coarse particulates, and centrifuged at 25,000 rpm for 20 min (RC5C[®], Sorvall Instruments, Du Pont, Wilmington, MA, USA) to remove the fine particulates. Final filtration was performed with #4 and #42 filter papers (Whatman) placed in a Büchner funnel. The methanol solvent was vacuum-evaporated at 38°C, and the remaining constituents were analyzed by gas chromatography-mass spectrometry (GC-MS). The aqueous water extract was reduced to dryness with a vacuum rotary evaporator at 38°C, and the residue was resolved in 250 ml distilled deionized water. The aqueous extract was partitioned sequentially $\times 6$ with 250 ml HPLC-grade solvents that included *n*-hexane, diethyl ether, and ethyl acetate by using a separatory funnel. After evaporation of solvents, activity of those residues was assessed by measuring the growth of 72 hr cress seedlings in comparison to an aqueous control with a standard Petri dish germination assay. Each concentrated fraction dissolved in its initial solvent was applied to filter paper in Petri dish. The Petri dish was placed into a 40°C oven for 48 hr to allow solvent evaporation. Ten cress seeds were arranged in glass Petri dishes containing 1 ml distilled water and #1 Whatman filter paper. After parafilm sealing, dishes were maintained in the dark at high humidity at 25–26°C for 72 hr, and root and shoot elongation were measured. Upon evaluation of the seedling bioassay, ether and ethyl acetate fractions were combined and subjected to flash column chromatography. Silica gel flash column chromatography was performed by using a chloroform/methanol solvent gradient, starting with 100% chloroform and terminating with 100% methanol, to further separate the active extracts. Fraction number 4 out of 25 total fractions collected was analyzed by GC-MS, based on activity-guided fractionation with the same cress seedling bioassay.

Identification of Volatiles by SPME Headspace GC-MS

Clear vials (2 ml, Supelco) with PTFE rubber seals (11 mm, Supelco) were used to obtain equilibrium of sample solids (groundcover foliage) with their respective gaseous phase (volatile constituents). After weighing fresh foliar tissues (1 g) of *N. \times faassenii* for analysis, volatile adsorption to SPME fiber (polyacrylate, 85 μ m) was conducted at room temperature for 30 min. In the injection port of the GC, temperatures of 260°C resulted in desorption of volatiles, which were continuously injected into the GC for 5 min. GC-MS (Agilent 6890 + Agilent 5973) was used to analyze all volatile constituents present in each sample. A DB-5MS capillary column (30 m \times 0.25 mm, film thickness 0.25 μ m) was used for the separation of analytes. The column was temperature-programmed from 50°C (held for 3 min) to 200°C (held for 2 min) at a rate of 10°C/min, and then to 300°C (held for 5 min) at a rate of 15°C/min. Helium was used as a carrier gas with a constant flow rate of 1.0 ml/min. For the mass selective detector (MSD), the electron energy was 70 eV, ion source

temperature was 230°C, quadruple temperature was 150°C, and interface temperature was 280°C. MSD was used in SCAN mode over a mass scan range at m/z 30–400, with every analysis verified with air as a blank control for injection between samples to reduce contamination.

Retention indices for all compounds on the DB-5MS capillary column were determined according to the Van Den Dool approach, with *n*-alkanes (especially *n*-hexane) as standards (Kovats 1958). Identification of the components was based on

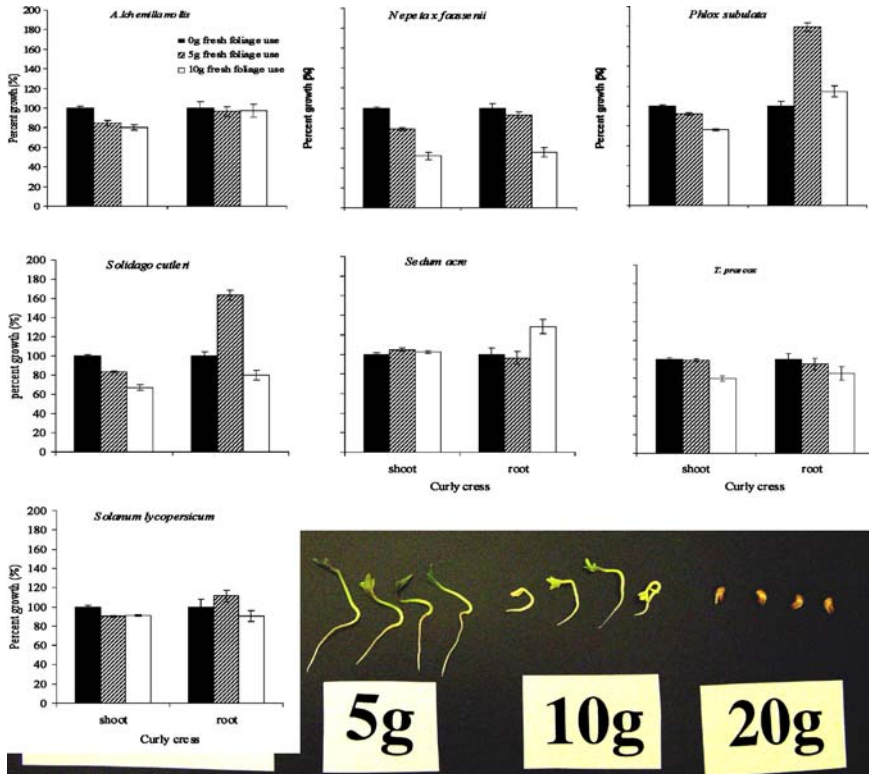

Fig. 2 Top: Inhibition of seedling growth of curly cress (*Lepidium sativum* L.) by volatiles produced by groundcover and tomato foliage (5 and 10 g fresh weight) as compared to an untreated control. Values presented are means of curly cress seedlings ($N = 80$) with standard errors. *Nepeta x faassenii* volatile effect: overall $Pr > F$ of curly cress shoot is <0.001 and $LSD = 1.336$, and overall $Pr > F$ of curly cress root is <0.001 and $LSD = 1.831$. *Solidago cutleri* volatile effect: overall $Pr > F$ of curly cress shoot is <0.001 and $LSD = 0.784$, and overall $Pr > F$ of curly cress root is 0.083 and $LSD = 2.0389$. *Phlox subulata* volatile effect: overall $Pr > F$ of curly cress shoot is >0.001 and $LSD = 1.042$, and overall $Pr > F$ of curly cress root is 0.001 and $LSD = 1.837$. *Alchemilla mollis* volatile effect: overall $Pr > F$ of curly cress shoot is >0.001 and $LSD = 1.183$, and overall $Pr > F$ of curly cress root is 0.795 and $LSD = 2.046$. *Thymus praecox* volatile effect: overall $Pr > F$ of curly cress shoot is >0.001 and $LSD = 1.078$, and overall $Pr > F$ of root is 0.023 and $LSD = 2.044$. *Sedum acre* volatile effect: overall $Pr > F$ of curly cress shoot is 0.009 and $LSD = 1.117$, and overall $Pr > F$ of curly cress root is 0.006 and $LSD = 2.476$. *Solanum lycopersicum* volatile effect: overall $Pr > F$ of curly cress shoot is >0.001 and $LSD = 1.012$, and overall $Pr > F$ of curly cress root is 0.423 , $LSD = 2.118$. Bottom: Seedling growth of curly cress after exposure to *Nepeta x faassenii* foliage. Activity of fresh foliage of *Nepeta x faassenii* was assessed at 0, 5, 10, and 20 g fresh weight in enclosed volatile bioassays.

comparison of their mass spectra with those of Wiley Libraries and those described by R. Adams, as well as by comparison of their retention indices with published values (Van Den Dool and Kratz, 1963).

Results

Effects of Groundcover Foliar Volatiles on the Growth of Curly Cress Seedlings

Of the groundcovers evaluated for volatile production, foliar tissue of most, with the exception of *S. acre*, inhibited the shoot growth of curly cress seedlings, with increasing inhibition observed with increasing rates of fresh foliage placed in the enclosed environment (Figure 1). In contrast, the volatiles of tomato leaves did not inhibit the growth of curly cress seedlings (Figure 2). Overall, *N. × faassenii* volatiles produced the greatest inhibitory effects by consistently reducing both shoot and root elongation. *N. × faassenii* volatiles inhibited shoot growth by 21% and 48% relative to the untreated controls at 5 and 10 g of foliage, respectively. Root elongation was inhibited by 7% and 44%, respectively

Fig. 3 Chemical structures of volatile components identified in leaf extracts of *Nepeta × faassenii*.

(Figure 2), in comparison to controls. Furthermore, radicle elongation and shoot growth were completely inhibited at the 20 g foliage treatment (Figure 2). Foliar volatiles of *A. mollis* also significantly inhibited shoot growth, but volatiles had little impact on root elongation. Interestingly, radical elongation of curly cress exposed to 5 g of *P. subulata* and *S. cutleri* foliage was increased by 179% and 164%, respectively, indicating some stimulatory activity of certain collected volatile constituents. In comparison, root elongation, when exposed to 5 g of *S. acre* foliage, was not significantly different from the control, but increased with exposure to 10 g of foliage, indicating that *S. acre* foliage also possessed stimulatory potential (Figure 2).

Identification of Volatiles in *N. × faassenii* by SPME-Headspace GC-MS

A total of 22 compounds were identified in *N. × faassenii* volatile headspace by GC-MS (Figure 3 and Table 1). Seventeen compounds were detected directly within the volatile cocktail collected from *N. × faassenii* leaf tissue (Table 1). The components included sabinene, β -pinene, β -myrcene, 2-(2-ethoxyethoxy)-ethanol, 1,8-cineole, ocimene, neryl acetate, 4 α ,7 α ,7 α -nepetalactone, α -copaene, trans-caryophyllene, alloaromadendrene, 4 α β ,7 α ,7 α β -nepetalactone, germacrene D, β -farnesene, χ -cadinene, germacrene B, and β -sesquiphellandrene. Many of the volatiles we observed were similar to those reported previously in the essential oils of *N. crassifolia*, *N. cataria* L., and *N. macrosiphon* Boiss. (Baranauskiene et al., 2003; Dabiri and Sefidkon, 2003; Javidnia et al., 2004).

As root elongation of curly cress seedlings were most affected by aqueous extracts of crude *N. × faassenii* foliar tissues, polyacrylate fibers (85 m) were also utilized to detect polar or semivolatile materials within one fraction (number 4) that was collected and further purified by column chromatography after aqueous extraction. Three components were detected, including 2-(2-ethoxyethoxy)-ethanol, alloaromadendrene, and γ -cadinene, at the detection limit ($\leq 0.04\%$ of GC peak

Fig. 4 Leaf and stem morphology of *Nepeta × faassenii*, showing trichomes and glands on leaf surfaces. (A, B) Leaf abaxial surface. (C, D) Leaf adaxial surface. (E, F) Stem. (G) Trichomes and glands.

area). These constituents were detected within the volatile cocktail collected from *N. × faassenii* foliage.

Methanolic extraction of *N. × faassenii* foliage produced similar results, with 10 similar constituents observed at similar detectable levels as above. Five of the 10 components, 5,5-dimethyl-2(5*H*)-furanone, methyl benzoate, 2,4-decadienal, isodihydronepetalactone, and caryophyllene oxide were only detected in the methanolic extract.

Leaf and Stem Structures of *N. × faassenii*

N. × faassenii, commonly known as catmint, is an attractive ornamental ground-cover used in the landscape for mass plantings. It forms a dense canopy of pubescent foliage, and produces attractive blue inflorescences for most of the summer season (Armitage 1997). Trichomes of *N. × faassenii* were observed in great density on the surface of both leaf and stem tissues (Figure 4). Trichomes were denser on the underside of the leaf in comparison to the upper surface, and were less numerous on the stem surface in comparison to leaf. Glandular exudates were also observed on both catmint leaf surfaces and stems.

Seedling Growth of Curly Cress on Either Aqueous or Methanolic Extracts

Seedling growth of curly cress was measured to compare the influence of extraction method, with water or methanol upon extract phytotoxicity (Figure 5). Inhibitory effects upon the seedling growth were more significant with water than with methanolic extracts, when similar dosages of extracts were evaluated (Figure 5). However, total yield of extracts was 26-fold higher in methanolic extracts (17.20 g/100 g DW foliar tissues) than in water extracts (0.77 g/100 g DW). Further fractionation with ether provided greater yield in comparison to other organic solvents (14.09 g).

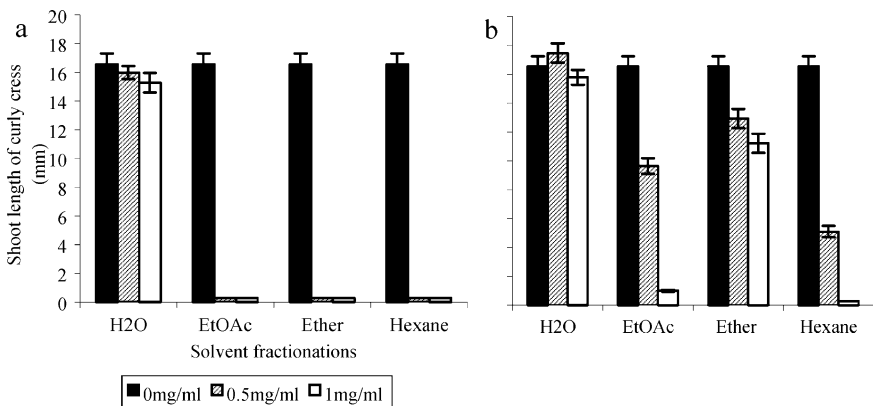

Fig. 5 A comparison of activity observed from aqueous (a) or methanolic (b) extraction of dried *N. × faassenii* shoot tissue using a curly cress seedling elongation bioassay. Each extract was fractionated with organic solvents using stepwise fractionation. Each fraction was dissolved in distilled water and bioassayed with solutions of 0, 5, and 10 mg/ml. Shoot length of curly cress was measured at 4 d after germination initiation. Values presented are means ($N = 80$) with standard errors.

^d Not detected or ≤ 0.04%.

0.5 mg/ml aqueous extracts or above. When methanolic extracts were further partitioned, the hexane fraction at 1.0 mg/ml dosage showed the strongest inhibitory activity among all fractions evaluated, indicating that less polar constituents were associated with inhibitory activity; curly cress seed germination was completely inhibited at 1.0 mg/ml concentrations.

Discussion

The same volatile bioassays we designed to assess *in vitro* inhibitory activity could be considered a potential means to assess the impact of leaf detachment upon volatile production from living plants. Leaf detachment may trigger the production of abscisic acid and ethylene that is caused by change in water status or availability in the leaf (Taiz and Zeiger, 2002). The presence of these hormones may further impact volatile production by inducing metabolic changes in higher plant systems (Taiz and Zeiger, 2002; Feng et al., 2004; LeNoble et al., 2004). We utilized foliar

tissues from tomato (*S. lycopersicum* L.) for comparison with groundcover tissues in this volatile bioassay as a positive control. It is well known that excised tomato leaves can produce significant levels of ethylene over time, besides other scented volatiles (Smith et al., 1996; Farag and Paré, 2002; Feng et al., 2004). In these studies, foliar volatiles of tomato did not greatly inhibit seedling growth of curly cress when compared to groundcover foliage (Figure 2), and neither groundcovers nor tomato produced significant levels of detectable ethylene in this closed assay system.

Given the large numbers of surface glands or trichomes observed on the abaxial surface of *N. × faassenii* leaves, it is likely that significant quantities of volatiles may be emitted by foliage under laboratory or field conditions. In past studies, we have shown that volatiles produced by foliage of mugwort (*A. vulgaris*) successfully bind to soil particles, and render soil in an enclosed environment inhibitory to subsequent seedling germination and growth (Barney 2004). Although we did not perform groundcover volatile assays in the presence of field soil in the laboratory or conduct field-based collections of volatiles under actual field conditions, few—if any—weed seedlings emerged directly around or beneath established *N. × faassenii* plants over a 3-yr period in two separate locations across New York state (Eom et al., 2005). Our findings indicate that foliarly produced allelochemicals may play a role in reduction of weed seedling growth, besides that of resource competition in plant interference. The volatiles of *N. × faassenii* could act as allelochemicals in field settings, if significant concentrations occur under field conditions. Our laboratory assays indicate that in an enclosed environment with detached tissues, foliar volatiles emitted from small quantities of *N. × faassenii* foliage are quite active as seedling growth inhibitors.

Plants of the genus *Nepeta*, commonly called catmints, synthesize and emit various volatiles through foliar trichomes and glands (Plepys et al., 2002). Trichomes were highly abundant in catmint foliage, especially along the abaxial surface of *N. × faassenii* leaves (Figure 4). Circular glands containing volatiles produced by *N. × faassenii* were also observed to be numerous and were located on the leaf surface itself. Of the volatiles detected, isomers of 7S-nepetalactone, which are monoterpenoids, were the principal constituents of the essential oil accumulated by the genus *Nepeta* (Hallahan et al., 1998). In our experiment, three forms of nepetalactone were detected in *N. × faassenii* foliar volatiles. Of the three forms, 4 α ,7,7 α -nepetalactone was the most abundant component, representing 73% of all detected components in a direct crude sample analysis using GC-MS (Table 1). Nepetalactones are believed to attract insects for insect plant pollination (Plepys et al., 2002). However, they have not yet been associated with inhibition of plant growth. Because of their complex structure and our inability to purchase or synthesize these compounds, we have yet to assess their biological activity. Many of the other volatile components detected are also reported allelochemicals, influencing either plant–plant or plant–microbial interactions, including β -myrcene (Ward et al., 1997), ocimene, β -farnesene (McAuslane and Alborn, 1998), and caryophyllene (Stipanovic et al., 1990). Subjected to volatile emission, curly cress was completely inhibited when 20 g or more of fresh foliar tissues of *N. × faassenii* were suspended in closed bioassay system in 500 ml glass bottles (Figure 2).

To investigate another possibility for the release of allelopathic constituents, we evaluated both the aqueous and methanolic extracts from foliar tissues of ground-

covers for inhibitory potential in order to assess possibilities for production of non-volatile inhibitors. By using a standard seed germination/radical elongation bioassay, both aqueous and methanolic extracts of dried foliar tissues of *N. × faassenii* (Figure 5) and *S. cutleri* inhibited seedling growth (data not shown). Although the use of solvent extraction for increasing yield of allelochemicals from extracts of plant tissues is common in the literature, certain extracted chemicals may not be typically released into a natural environment under average field conditions (Lovett and Jessor, 1982). Instead of the relatively harsh solvent extraction technique with methanol, we also decided to use an aqueous method to extract volatile and non-volatile constituents from the foliar tissues of *N. × faassenii*. In an activity comparison between aqueous and methanol extracts, the aqueous extracts of foliage exhibited greater specific activity in terms of seedling growth reduction on a per-weight basis (Figure 5). Not surprisingly, the actual amount of dried residue obtained after aqueous extraction was 26-fold less than that obtained by methanolic extraction. Volatile components were evaluated in both aqueous and methanolic extracts, even though nonvolatile allelopathic components may also be present in considerable quantities in catmint foliage.

From the GC-MS results, fractionation of the aqueous extracts by column chromatography resulted in only three chemicals being detected in purified active fraction number 4 including 2-(2-ethoxyethoxy)-ethanol, alloaromadendrene, and γ -cadinene, at the detected level ($\leq 0.04\%$ of GC peak area). Methanolic extraction yielded 10 chemical constituents including the key components also present in aqueous extracts (Table 1). Volatile analysis yielded 17 chemical constituents present in the crude sample of *N. × faassenii* foliage. As we were not able to evaluate all of these components individually or in mixtures in separate plant growth bioassays, it is unknown which constituents are associated with plant growth inhibition. Further analysis and separation of aqueous *N. × faassenii* extracts by HPLC would likely result in isolation of other active non-volatile constituents.

In summary, previous field experiments showed that *A. mollis* and *N. × faassenii* were highly suppressive of weed growth, as were several other groundcovers that were moderately suppressive. Laboratory experiments indicate that only one of these, *N. × faassenii*, may show strong potential to suppress curly cress growth by volatile allelopathic interference. It evidently produces allelochemicals that are active both as volatile and non-volatile forms from its foliar tissues. Although we examined the effects of allelopathic traits in an *in vitro* volatile assay, our fieldwork mainly focused on examination of weed suppression and competition for resources. Although we have no proof of allelopathy under field conditions, we have evidence to support the concept that catmint tissues could potentially interfere with weed seedling growth due to allelochemical production.

Acknowledgements We like thank Paul A. Weston for review of this manuscript and photos of *Nepeta* foliage, and Roselee Harmon for assistance in laboratory experimentation.

tosterone) male temporal gland secretions (TGS) is a multifaceted pheromone (Greenwood et al., 2005). Both enantiomers of frontalin are present in TGS, and behavioral responses by conspecifics depend on precise enantiomeric ratios. Bioassays strongly support the presence of a preovulatory pheromone in female African elephant urine (*Loxodonta africana*; Bagley et al., 2006). This communication describes our search for this African elephant pheromone using solid-phase dynamic extraction (SPDE) and gas chromatography–mass spectrometry (GC-MS), which has resulted in the discovery of several compounds (among hundreds) that are known insect pheromones and their precursors (Fig. 1).

Methods and Materials

Volatile organic components of African elephant urine, thawed after having been frozen (-70°C) since collection, were sampled by the powerful technique of automated SPDE/GC-MS (Lipinski, 2001), as well as by solid-phase microextraction (SPME) coupled with chiral column GC-FID and GC-MS (Goodwin et al., 2005; Greenwood et al., 2005). For automated SPDE analysis, the necessary accessories (Chromsys) were mounted on a CTC Analytics CombiPAL multipurpose sampler (Gerstel, MPS2). Urine samples (10 ml) in 20-ml screw-top vials (Viton septa) with a stir bar were analyzed under three conditions: unaltered, with addition of NaCl (3 g), or a protease (1 mg, Invitrogen proteinase K, fungal; #25530-015). Elephant albumin binds urinary and TGS pheromones in the Asian elephant; therefore, protease and NaCl may denature putative protein carriers in African elephant urine and force possible pheromones into the headspace (Lazar et al., 2004). After incubation at 37°C (15 min) and extraction (200 up-and-down syringe strokes over 13 min) by SPDE, desorption was at 250°C in the GC inlet. GC-MS analyses were conducted as published (Goodwin et al., 2005). For GC-MS references, racemic frontalin (**2**), *exo*- (**3**) and *endo*-brevicomins (**4**), enriched samples of (+) and (–) *exo*- and *endo*-brevicomins, ketones **7** (*E* and *Z*) and **9**, and (*E,E*)- α -farnesene (**6**) were obtained

from Pherotech. (*E*)- β -Farnesene (**5**) was purchased from Bedoukian. For enantiomerically enriched frontalin, ratios were established as published (Greenwood et al., 2005).

Results and Discussion

Representative data are shown in Table 1, for which aliquots of ovulatory urine samples from three African elephants were either untreated or treated with NaCl or protease. SPME/GC-MS was run daily for 7 d (stored at 24°C). Data such as those in the table lead to tentative conclusions for urine headspace analysis: (1) addition of NaCl increases the release of frontalin, maximizing around day 3; (2) frontalin precursor **9** is higher in untreated urine; (3) *exo*-brevicommin exceeds the *endo*- isomer, and both increase daily through day 7 in NaCl-treated urine; (4) brevicomin precursor **7** appears on day 3 after protease treatment and increases through day 7; (5) the farnesenes are present almost equally and generally require no treatment for detection after 2 or 3 days. Compounds **2**, **3**, and **4** are bark beetle aggregation pheromones (Francke and Schröder, 1999), whereas farnesenes **5** and **6** are aphid alarm pheromones and components of the mouse puberty accelerating pheromone mixture (Wyatt, 2003).

The importance of frontalin enantiomeric ratios in Asian elephant TGS chemical signaling (Greenwood et al., 2005) led us to investigate these ratios for frontalin and *endo*- and *exo*-brevicommins in female African elephant urine via SPME/chiral column GC-MS. Frontalin, difficult to detect by SPME/chiral column in urine samples, was consistently (-). For unaltered samples on the day of thawing (day 1), no brevicommins were detected. Day 3 revealed (-)-*exo* only, and on day 5, the ratio of (-)-*exo*/(+)-*exo*/(+)-*endo*/(+)-*endo* was 16.7/1/3.3/0. For NaCl-treated samples up to day 5, we saw (-)-*exo* only, but larger amounts. For protease-treated samples, we observed the following: day 1 (14.3/1/2.1/0), day 3 (12.1/1/1.8/0), and day 5 (10/1/0.8/0). Thus, (-)-*exo*-brevicommin was generally the dominant stereoisomer.

The discovery of elephant-derived beetle pheromones and their precursors is particularly intriguing. Various bark beetles can convert (*E*)- and (*Z*)-6-nonen-2-one to *endo*- and *exo*-brevicommin, respectively. (*Z*)-6-Nonen-2-one (**7**) was identified in the volatiles from western balsam bark beetles and male mountain pine beetles, suggesting it as a natural biosynthetic precursor. Furthermore, the latter have been shown to convert (*Z*)-6-nonen-2-one to (+)-*exo*-brevicommin through a keto epoxide intermediate (**8**), followed by an intramolecular carbonyl epoxide rearrangement (Vanderwel and Oehlschlager, 1992). Several beetle species synthesize frontalin when exposed to exogenous 6-methyl-6-hepten-2-one (**9**), although the ketone could not be detected naturally in the beetles (Francke and Schröder, 1999). Ketone **9** has been detected in hindgut extracts of frontalin-producing eastern larch beetles (Francke and Schröder, 1999) and Asian elephant TGS. Evidence exists that some *Dendroctonus* beetles synthesize frontalin via mevalonate in the isoprenoid pathway (Seybold and Tittiger, 2003). Our findings suggest that biosynthesis of brevicommins and frontalin via precursors **7** and **9** proceeds similarly in African elephants and beetles.¹

¹ The presence of both *exo*- and *endo*-brevicommin in the urine suggests the presence of both (*E*)- and (*Z*)-6-nonen-2-one precursors. Nonetheless, these are not yet separable via GC, and their mass spectra are similar; thus, the presence of both cannot be verified.

Questions yet to be answered include the following. (1) Are any of the insect pheromones functioning as pheromones in African elephants? (2) If so, is the chemical signal a single compound, or a blend? (3) Are these putative chemical signals from females to males, from females to females, or both? (4) Do enantiomeric ratios play a role in the proposed chemical signaling? (5) In nature, are these putative pheromones released slowly over time from carrier proteins, and if so, does the chemical signal change? (6) How do concentrations and ratios of the insect pheromones and precursors vary throughout the African elephant estrous cycle? In our laboratories, these questions and others are under active investigation involving both chemical and behavioral studies with a large number of samples.

Acknowledgments We are grateful to Scott and Heidi Riddle (Riddle's Elephant and Wildlife Sanctuary) for advice and assistance. Elephant urine samples and/or bioassay opportunities were provided by: Addo Elephant National Park (AENP; South Africa), Baltimore Zoo, Bowmanville Zoo, Cameron Park Zoo, Indianapolis Zoo, Knoxville Zoo, Lion Country Safari, Louisville Zoo, Memphis Zoo, Miami Metro Zoo, Nashville Zoo (R. and C. Pankow), North Carolina Zoo, Riddle's Elephant and Wildlife Sanctuary, Sedgwick County Zoo, Seneca Park Zoo, Six Flags Marine World, Toledo Zoo, West Palm Beach Zoo, and Wildlife Safari Park. Assistance was provided by Dr. G. Kerley and Dr. A. Whitehouse (Univ. Port Elizabeth), Mr. L. Moolman and Mr. J. Adendorf (AENP), and Mr. P. Jones (Tanzania). We thank Dr. J. Brown and her staff at the Elephant Endocrine Laboratory at the Conservation and Research Center, Smithsonian National Zoological Park, for providing estrous data that aided in timing urine collections and bioassays. Ingo Christ (Chromsys) provided SPDE assistance. We thank J. P. Lafontaine of Pherotech for samples. T.E.G., B.A.S., and L.E.L.R. are grateful to the National Science Foundation (NSF-DBI-02-17068, -17062, and -16862, respectively) for financial support.

et al., 2005; Theis and Raguso, 2005), and circadian rhythms (e.g., Dötterl et al., 2005; Negre et al., 2003).

Of particular interest is the variation in scent emission before and after pollination. Postpollination changes in scent production reduce metabolic costs and decrease the attractiveness of the flower, thus directing the pollinator to other flowers of the plant and increasing overall reproductive success (Schiestl and Ayasse, 2001). In *Silene latifolia* Poir (Caryophyllaceae), a perennial native to Europe, postpollination changes may have the additional function of reducing the attraction of seed predators (Dötterl et al., 2005). *S. latifolia* has a close relationship with *Hadena bicruris* Hufnagel (Lepidoptera, Noctuidae), with *H. bicruris* designated as a parasitic pollinator. The female moths pollinate the female flowers. After nectar ingestion, they lay their eggs in the flower. The larvae subsequently feed on the developing seeds (Bopp and Gottsberger, 2004). Usually, there is one larva hatching per vessel. Once the larva has eaten the whole seed set, it moves to another intact vessel (personal observation). Adult female moths are attracted to flowers mainly by scent, and lilac aldehydes A–D and veratrole were found to be key compounds in their attraction (Dötterl et al., 2006). These compounds make up about 80% of the total blend (Table 1).

If postpollination changes are adaptive in terms of reducing the attraction of seed predators, a specific downregulation of the behaviorally active compounds should be observed. The present study aimed at analyzing compositional and quantitative changes in the floral scent emission of *S. latifolia* after pollination. Furthermore, we analyzed whether pollinator-attracting and nonattracting compounds changed differently in the pollinated flowers.

Methods and Materials

Plant Material and Sample Size

Sixteen potted female plants were grown from seeds collected in 2003 from a *S. latifolia* population located in Leuk (Switzerland). The inflorescence of each potted plant was separated into two equal parts of 3–10 flowers. One part of each inflorescence was hand-pollinated, whereas the other remained unpollinated. Pollination was achieved at 7 p.m. by dabbing a female flower with a male flower. We used only female flowers that underwent anthesis 24 hr before treatment. Older flowers and buds were removed.

Scent Collection

Floral scent was collected during the first and second night after pollination, from 8 p.m. to 7 a.m. Each treated inflorescence was separately packed in an oven-baking bag (PET, Toppits®). A filter was placed inside the bag and connected to a vacuum pump (Personal Air Sampler, SKC Inc.) drawing the air at a rate of about 140 ml/min. Air in the bag was drawn over the filter consisting of 5 mg of Porapak Q as an adsorbent material, sealed in a small glass tube. Nine filters were connected by silicone tubes to one vacuum pump, one of them sampling surrounding air to identify background contamination. Before scent collection, filters were cleaned with 100 µl dichloromethane and 100 µl hexane. After sampling, desorption was achieved by slowly running 50 µl of a hexane/acetone mixture (9/1) through the filter. Desorption was carried out immediately after sampling. Eluates were stored at –20°C in sealed glass vials for later analysis.

Quantitative Gas Chromatographic Analysis and Compound Identification

Before analysis, 100 ng of n-octadecane (Fluka, Buchs) were added to each sample as an internal standard. One microliter of the eluate was injected splitless at a start temperature of 50°C into a gas chromatograph (Agilent 6890N) equipped with an HP5 column (30 m × 0.32 mm × 0.25 μm) and a flame ionization detector. Hydrogen was used as the carrier gas and nitrogen as make-up gas. The injector temperature was kept at 300°C. The oven was kept at 50°C for 1 min, then heated to 150°C at a rate of 5°C/min, and subsequently to 300°C at a rate of 10°C/min, and kept at 300°C for 10 min. Chromatograms were analyzed with the program ChemStation (Agilent Technologies). Absolute amounts of compounds were quantified by using the internal standard (IS) method, i.e., by integrating the peak of every substance and dividing every peak area with the integrated IS peak area and multiplying with the IS amount. None of the samples of surrounding air contained considerable amounts of one of the compounds used in our analyses. Thus, we did not subtract these samples. For a few samples, gas chromatographic analyses with mass selective detection (Hewlett Packard G1800 A) were conducted by using identical column and oven parameters. Compounds were identified by comparison of retention times and gas chromatography–mass spectrometry (GC-MS) spectra with those of known standard compounds.

Data were first checked for normality (Shapiro-Wilk test) and homogeneity of variances (Levene test) and then analyzed with *t* test and ANOVA.

Results and Discussion

We found 28 odor compounds in our samples, 2 of which belong to the class of fatty acid derivatives (nonanal and octanal), 8 to the class of benzoids (benzyl acetate, benzaldehyde, benzyl benzoate, methyl benzoate, 2-methoxyphenol, methyl salicylate, phenylacetaldehyde, phenylethyl alcohol, and veratrole), and 12 to the class of terpenoids (camphene, eucalyptol, lilac aldehyde A, lilac aldehyde B, lilac aldehyde C, limonene, linalool, 6-methyl-5-hepten-2-one, trans-β-ocimene, α-pinene, β-pinene, and β-farnesene) (see also Dötterl et al., 2005). Five of the reported compounds remained unidentified (Table 1).

Pollinated plants emitted significantly lower total scent amounts over the two nights than unpollinated plants (unpollinated: mean ± SE, 408.90 ± 105.33 ng·h⁻¹·l⁻¹·flower⁻¹; pollinated: mean ± SE, 95.68 ± 29.55 ng·h⁻¹·l⁻¹·flower⁻¹; *t* test: *t* = 2.86, *df* = 60, *P* < 0.01). Earlier studies on postpollination changes have also found a decrease in total scent emission. Tollsten and Bergström (1989) and Tollsten (1993), for example, detected a decrease in scent production of *Platanthera bifolia*. In *Ophrys sphegodes*, the scent emission also decreased after pollination (Schiestl et al., 1997). In two thistle species, scent decreased strongly after pollination leading to reduced attractiveness of the flowers to honey bees (Theis and Raguso, 2005). Dötterl et al. (2005) showed that *S. latifolia* almost completely stopped emitting scent only 24 hr after pollination. In our study, there was an approximately fourfold decrease in total scent emission (see above). Lilac aldehydes A and B as well as veratrole, which made up about 80% of total scent emission before pollination, contributed most to this decrease (Fig. 1). Most of the other compounds remained unchanged after pollination (Fig. 1). In terms of relative amounts, pollinated plants sampled on the first and second night emitted significantly lower proportions of lilac aldehydes A and B than unpollinated plants sampled in the first night [lilac aldehyde A: ANOVA, *F*(3,58) = 6.21,

Different letters indicate significant differences between groups as calculated by one-way ANOVA with LSD post hoc test, $P < 0.05$.

^aCompounds elicit electrophysiological signals (Dötterl et al., 2006).

^bAs lilac aldehyde C and benzyl acetate coelute and the amounts of benzyl acetate are much lower than the amounts of lilac aldehyde C, they are listed together in the class of terpenoids.

$P = 0.001$; Lilac aldehyde B: ANOVA, $F(3,58) = 5.84$, $P = 0.001$]. Unpollinated plants sampled on the second night, however, emitted the same relative amounts of lilac aldehydes A and B as pollinated plants sampled on the first and second night [lilac aldehyde A: ANOVA, $F(3,58) = 6.21$, $P = 0.001$; lilac aldehyde B: ANOVA, $F(3,58) = 5.84$, $P = 0.001$]. This could be due to senescence in flowers. For most of the other compounds, pollinated plants emitted the same or greater relative amounts than unpollinated ones (Table 1).

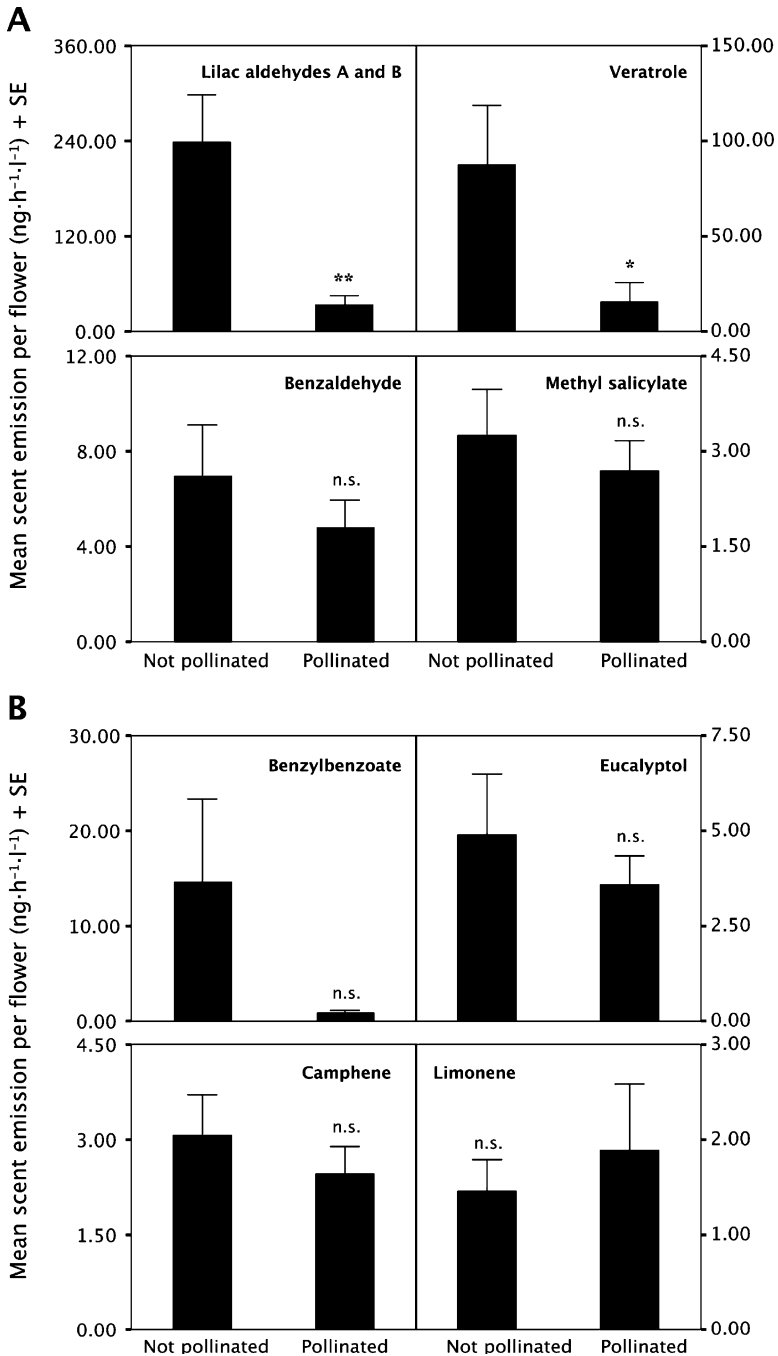

Fig. 1 Mean (+ SE) absolute amounts of (a) the four most abundant electrophysiologically active scent compounds and (b) the four most abundant electrophysiologically nonactive compounds (Dötterl et al., 2006) sampled over the 2 days. Lilac aldehydes A and B and veratrole significantly decreased after pollination (**t* test: $t = 2.20$, $df = 60$, $P < 0.05$; ***t* test: $t = 3.33$, $df = 60$, $P < 0.01$), whereas the other six analyzed compounds did not change significantly after pollination (*t* test, $df = 60$, $P > 0.05$, n.s.)

There are contradictory results on compositional changes in scent emission reported in the literature. In *P. bifolia*, the relative amounts of scent compounds remained almost constant after pollination (Tollsten and Bergström, 1989; Tollsten, 1993). By contrast, pollination changed the bouquet composition of *Cirsium repandum* (Theis and Raguso, 2005) and *O. sphegodes* (Schiestl et al., 1997). Interestingly, in the latter species, the emission of farnesyl hexanoate, which functions as a repellent compound for the pollinator (Schiestl and Ayasse, 2001), increases after pollination. This mechanism is thought to direct pollinators to other, as yet unpollinated flowers, thereby maximizing the overall reproductive success of the plant. The strong compositional changes in the floral odor of *S. latifolia* are mostly due to a decrease in lilac aldehydes A and B as well as in veratrole. Since these compounds have been demonstrated to be of key importance for host finding in *S. latifolia* (Dötterl et al., 2006), we interpret their drastic reduction after pollination as a mechanism for avoiding or reducing further parasitism by the nursery pollinator *H. bicruris*.

Taken together, our results show how adaptations in the chemical communication between plants and their pollinators can be fine-tuned to the regulation of specific compounds in the odor bouquet. Furthermore, our findings underline the key functions of the lilac aldehydes and veratrole for plants' reproductive success, which is largely determined by the attraction of pollinators and avoidance of seed predators.

(Thompson and Pellmyr, 1991). Plant compounds often serve as cues for phytophagous herbivores to identify suitable hosts for feeding and oviposition.

Many plant defenses are based on active compounds that are enzymatically released from glycosylated precursors accumulated in vacuoles. The general question arises whether the deterrent function is exclusively provided by the aglycones or whether the precursors also have a protective effect in themselves, as has been reported for bitter-tasting cyanogenic glycosides (Nahrstedt, 1985).

Cyanogenesis is a two-step mechanism in which cyanide-containing precursors are cleaved by specific β -glucosidases. The resulting α -hydroxynitriles are unstable and decompose spontaneously, or enzymatically, in the presence of α -hydroxynitrile lyase to yield hydrogen cyanide (HCN) and an aldehyde or a ketone. It is, thus, necessary to consider the effect on oviposition choices of both the release of hydrogen cyanide and the content of cyanogenic precursors to understand the role of host plant cyanogenic features in this ecologically important interaction. In lima bean, both factors underlie high quantitative variability (Baudoin et al., 1991; Ballhorn et al., 2005).

We used Mexican bean beetle, which represents an herbivore specialized on members of the Fabaceae. However, the insects show strong preference for cyanogenic lima bean [*Phaseolus lunatus* (Dover et al., 1988)], and cyanogenic glycosides act as a feeding stimulant for the beetles (Lapidus et al., 1963) indicating some specialization to this host plant. In choice experiments with intact lima bean plants characterized by cyanogenic properties, we addressed effects of cyanide release and cyanogenic precursor concentration on oviposition preference of female beetles.

Methods and Materials

Plants

Lima beans and snap beans were cultivated under greenhouse conditions adjusted to 25:20°C in a 16-hr light/8-hr dark period and a relative humidity of 60–70%. Lima beans were grown from seeds obtained from one mother plant.

Cyanogenic Features of Plants

Cyanogenic capacity (HCN_c) was measured in an airflow apparatus according to Ballhorn et al. (2005) using chloroform as an inductive agent for release of gaseous hydrogen cyanide from leaves. By this treatment, the plant's general capacity for cyanogenesis can be quantified. Cyanogenic potential (HCN_p) was measured by complete enzymatic degradation of cyanogenic precursors and quantitative measurement of released HCN (Ballhorn et al., 2005).

Beetles

Beetles were reared on noncyanogenic snap bean (*Phaseolus vulgaris* var. Saxa) under the same ambient conditions as plants. Snap bean represents another important host plant species of the beetle (Dover et al., 1988). Any possible adaptations to particular lima bean accessions were excluded by rearing beetles on snap beans. Beetles that emerged within 3 d were separated from the maintenance culture. Four days after they had started mating, females were removed. In parallel experimental settings, eight female beetles were placed

in cages (fabric tubes, 70 cm diam) containing four 30-d-old HC, LC⁽⁺⁾, or LC plants of different accessions (replications per combination of plants, $N = 4$). Order of placement of the four plants in each cage was random to eliminate any possible positional effects for oviposition. Plants were exchanged every 3 d, and the egg clutches on the leaves of the removed plants were counted. Oviposition of beetles was observed over a total period of 30 d.

Statistics

Effects of cyanogenic capacity on beetle oviposition choice and assignment of lima beans to homogeneous groups based on different cyanogenic capacity were carried out by application of a *post hoc* test [Tukey's honestly significant difference (HSD) test] after one-way analysis of variance (ANOVA) to the data set (Statistica 7.0).

Results

We found significant differences in HCNc and HCNp among the plants. Based on the differences in HCNc, plants were assigned to a high HCN-releasing group (HC) with also high HCNp and to a low HCN-releasing group (LC) with low HCNp. Accessions 2116 showed low HCNc under high HCNp (LC⁽⁺⁾). *P. vulgaris* cv. Saxa showed no cyanogenic precursors, and thus no ability to release gaseous HCN (Table 1). Screening of *P. lunatus* leaf material for nutritive factors, such as protein content and total phenolics, revealed, in contrast to cyanogenic variability, no significant differences among the accessions (unpublished data).

Each female beetle usually produced three egg clutches. Clutches were positioned on the undersurface of leaves in intervals of 8–9 d. The oviposition behavior of beetles was

Table 1 Cyanogenic features of lima beans (*Phaseolus lunatus*)

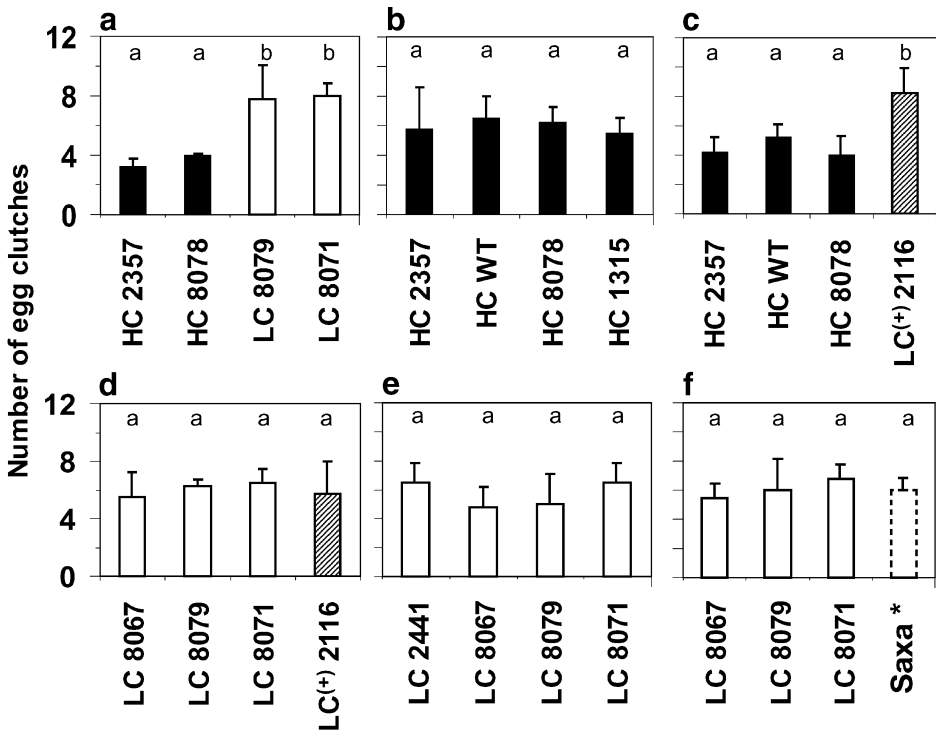

Accessions of <i>P. lunatus</i>	Cyanogenic status: high (HC) or low (LC)	Cyanogenic capacity (HCNc; $\mu\text{mol HCN g fw}^{-1} \text{ min}^{-1}$)	Cyanogenic potential (HCNp; $\mu\text{mol HCN g fw}^{-1}$)

Saxa ³	Noncyanogenic	0.00 ± 0.00^d	0.00 ± 0.00^d

Young leaves of the lima bean accessions were screened for their cyanogenic characteristics. Values shown for HCNc and HCNp are means \pm SD ($N = 12$ individual plants per accession). Significant differences were calculated by a *post hoc* test (Tukey's HSD; $P < 0.001$) after one-way ANOVA and are indicated by different letters.

¹ Accession 2233 represents lima bean, *P. lunatus*, wild type (WT) with small seeds, and small, relatively hard textured leaves.

² Accession 2116 showed low release of gaseous HCN under high concentrations of cyanogenic precursors.

³ Saxa represents *P. vulgaris* cv. Saxa.

Lima bean accessions with different cyanogenic capacity

Fig. 1 Oviposition choice of beetles. Shown is the number of egg clutches (mean \pm SD, $N = 4$ per choice experiment) deposited by eight females on leaves of lima beans from accessions with different cyanogenic features (HC \blacksquare : high HCN-releasing plants; LC \square : low HCN-releasing plants; LC⁽⁺⁾ \square : low HCN-releasing plants caused by low activity of endogenous β -glucosidase under high concentration of cyanogenic precursors). Plants were assigned to groups based on significant differences in cyanogenic capacity (HCN; see Table 1). Oviposition preference of beetles was analyzed in parallel experimental settings comprising different combinations of plants (a–f). Saxa* represents noncyanogenic *Phaseolus vulgaris* cv. Saxa. Different small-typed letters on top of the figure represent significant differences at $P < 0.001$ (*post hoc* test after one-way ANOVA; Tukey's HSD)

affected by the cyanogenic capacity of the lima beans. Beetles showed significant preference for LC plants compared to HC plants (Fig. 1a). In addition, LC⁽⁺⁾ plants were preferred for oviposition over HC plants (Fig. 1c), but they were not significantly refused compared to the LC plants (Fig. 1d). Female beetles that were kept exclusively on HC or LC plants showed no preference for single accessions (Fig. 1b, e). Choice experiments including noncyanogenic *P. vulgaris* plants revealed similar preference of beetles for LC plants compared to *P. vulgaris* (Fig. 1f).

Discussion

The results show that the Mexican bean beetle, although preferring to feed on lima bean (Dover et al., 1988), avoids high HCN-releasing varieties of its host plant. It was the

cyanogenic capacity that affected female oviposition choice. Beetles were repelled by high cyanogenic capacity, whereas high concentrations of cyanogenic precursors did not result in reduced oviposition.

Release of HCN is the result of cell damage. Thus, insect feeding on leaves is required as a precondition for repellent activity. In contrast to other defenses, which can be triggered by oviposition (Hilker et al., 2002), deposition of eggs on plant surfaces *per se* has no ability to initiate cyanogenesis.

Considering quantitative aspects, beetles did not differentiate between lima beans showing low capacity for release of HCN and snap beans, which did not contain any cyanogenic precursors at all. This finding indicates that cyanogenic capacity at lower concentrations provides no repellent activity against oviposition by female beetles. Both a role of cyanogenic capacity in female choice behavior as well as a homogeneous food quality of lima bean are supported by the finding that female beetles that were kept exclusively on HC or LC plants showed no oviposition preference for single accessions.

In general, nutritive traits have a strong impact on host plant quality and affect female oviposition preference (Raubenheimer and Simpson, 1994). However, substantial differences in host plant quality can be excluded here because we found contents of protein and total phenolics in leaves among the accessions to be homogenous (data not shown).

Taken together, the results demonstrate that oviposition choice of Mexican bean beetles depends on the cyanogenic capacity of host plants at high thresholds.

Acknowledgments Seeds and beetles were kindly provided by the “Institute of Plant Genetics and Crop Plant Research (IPK)” in Gatersleben and C. P. W. Zebitz (Hohenheim). We thank Andrea Pietrowski (Bayreuth) and Martin Heil (Essen) for many valuable discussions.

Introduction

Volatile organic compounds (VOCs) are commonly found to function as infochemicals in terrestrial ecosystems (e.g., Metcalf, 1987; Kessler and Baldwin, 2001). However, in aquatic ecosystems, they have only received attention in the limited context of water quality issues: VOCs produced by algae and cyanobacteria frequently cause unpleasant odors in source water and are a nuisance in water treatment, especially for drinking water. Important for most consumer complaints are the earthy–musty odor compounds geosmin and 2-methylisoborneol (Watson and Ridal, 2004). Planktonic (Watson, 2003) and benthic cyanobacteria (Izaguirre and Taylor, 1995) are the major sources of both compounds. Numerous other VOCs belonging to lipoxygenase, carotene oxygenase, and fermentation products have been detected in lake and river water (Jüttner, 1995). The large number of compounds described for fresh water contrasts with the sparse studies on their ecological functions.

Some possible biological functions of VOCs in aquatic ecosystems are becoming clear (Watson, 2003). Volatile aldehydes might play a role in an activated defense mechanism of marine diatoms (Miralto, et al., 1999). Wound-activated diatom cells release α -, β -, γ -, δ -unsaturated aldehydes (Pohnert, 2000; Pohnert et al., 2002) that drastically lower the hatching rate of copepod eggs and might serve as a defense at the population level (Ianora et al., 2004). An alternative role of polyunsaturated aldehydes is serving as repellents for crustacean grazers (Jüttner, 2005).

Aquatic systems are ideally suited for communication via chemical cues because infochemicals can be easily distributed in concentrations sufficient for a response (Wisenden 2000). In highly structured benthic ecosystems, VOCs remain more localized than in planktonic ecosystems and may form robust microzones (Blackburn et al., 1998). Infochemicals related to predation (von Elert and Loose, 1996), reproduction (Müller et al., 1971), and foraging (Thomas et al., 1980) are perceived by many groups of aquatic organisms, which use this information to optimize their fitness. Indeed, VOCs function as habitat-finding cues for both aquatic insects (Evans, 1982) and nematodes (Höckelmann et al., 2004).

In littoral marine and freshwater ecosystems, herbivorous gastropods are of major importance because they structure the algal community by strong top–down predation pressure; they also form an important link to higher trophic levels because they are preyed upon by both vertebrate (fish, birds) and invertebrate predators, e.g., crayfish (Turner et al., 2000). Gastropods generally lack good vision, and cannot easily locate food patches visually (Gal et al., 2004). Their locomotion is energetically demanding, primarily owing to the production of pedal mucus (Denny, 1980). Therefore, it should be adaptive for snails to rely on chemical cues to minimize these costs by directed chemotaxis toward potential food sources.

Chemical stimuli affect the behavior of gastropods, and aquatic snails use their sensitivity to chemical cues as a principal modality to detect distant objects in the environment (Croll, 1983). The osphradium, located in the mantle cavity, is considered to be the major chemosensory organ of freshwater gastropods, although it might also be involved in other sensory processes such as the detection of ambient CO₂ pressure (Wedemeyer and Schild, 1995). However, to date, it has not been investigated whether long-range chemical cues are involved in observed food preferences, which have been quantified only either as residence time on a particular food patch or as the amount of food consumed (e.g., Madsen, 1992; Brendelberger, 1995; Wakefield and Murray, 1998). Snail chemotaxis toward dissolved sugars, amino acids, and carboxylic acids has been determined only in the context of control mechanisms for snails that are intermediate hosts

for parasites (Thomas et al., 1980; Thomas, 1986). Therefore, it remains unclear how these dissolved chemical cues are related to the process of finding food.

Volatile organic compounds released from benthic algae are suitable for dispersion over distance, and are good predictors of the presence of algal food. We hypothesize that freshwater gastropods utilize algal VOCs as foraging kairomones (sensu Ruther et al., 2002) for finding food. To investigate this hypothesis, we first identified the VOCs released upon cell disintegration from the filamentous benthic green alga *Ulothrix fimbriata* (Bold). *Ulothrix* is a cosmopolitan genus commonly occurring in periphyton communities of marine and fresh waters (John, 2002). In a newly developed standardized assay, we then investigated the behavioral response of the common pulmonate snail *Radix ovata* (Draparnaud) to these VOCs to see if they could be utilized as food-finding infochemicals by the snails. We deliberately used snails naïve to *Ulothrix* odors to distinguish between genetically fixed food-locating abilities and preferences acquired by olfactory learning.

Methods and Materials

Cultures

An axenic culture of the filamentous benthic green alga *U. fimbriata* (Bold) SAG 36.86 (Chlorophyceae) was obtained from the Göttingen Algal Culture Collection, Germany. The alga was cultivated semicontinuously as a suspension at a dilution rate of 0.25 d^{-1} in WC medium (Guillard and Lorenzen, 1972) at a constant temperature of 20°C and a light intensity of 1×10^{16} quanta $\text{s}^{-1}\text{ cm}^{-2}$. The culture was aerated by heavy bubbling with sterile, compressed air to prevent sinking and attachment of the benthic algae to the bottom of the culture flasks. Algae were harvested, concentrated by centrifugation at $4000 \times g$, and resuspended in filtered ($0.45\text{ }\mu\text{m}$) Lake Constance water. In the resulting food suspensions, carbon concentrations were adjusted to 0.5 mg particulate organic carbon per milliliter by using photometric light extinction at 800 nm and carbon extinction regressions previously determined (P. Fink, unpublished data). Juvenile *R. ovata* (Draparnaud) snails with shell lengths of $5\text{--}10\text{ mm}$ were collected during the summer in the littoral zone of Lake Constance, and acclimatized in the laboratory (at 20°C under constant dim light) before use in the food choice experiments. During the acclimation period, snails were fed Tetra PlecoMin[®] fish food pellets (Tetra, Melle, Germany). Before the experiments, animals were moderately starved for 24 hr by placing them in filtered ($0.45\text{ }\mu\text{m}$) Lake Constance water without food to increase their food-searching activity.

VOC Analyses

To standardize VOC extraction, algal biomass equivalent to 10 mg particulate organic carbon was disintegrated by a freeze–thaw cycle in 40 ml ultrapure water. After addition of 25% NaCl, VOCs were extracted by closed-loop stripping for 45 min and sorbed onto Tenax TA (Supelco) as described by Jüttner (1988b). VOCs were then thermally desorbed from Tenax TA and directly transferred onto a capillary column (DB 1301, 30-m length, 0.32 mm i.d., J&W Scientific, Folsom, CA, USA) of a combined gas chromatograph–mass spectrometer (Thermo/Finnigan GCQ). Helium was used as the transfer and carrier gas. VOCs produced by *U. fimbriata* were separated with the temperature program 4 min at 0°C , $5^{\circ}\text{C min}^{-1}$ to 250°C , and 10 min at 250°C , and identified by comparing the retention times and mass spectra (EI at 70 eV) with those of reference compounds (Aldrich). The

major VOCs identified were quantified as described by Jüttner (1988b) by using the peak areas of characteristic mass fragments and a calibration curve for each compound. 3-Hexanone was chosen as the internal standard because it did not occur in *U. fimbriata* and exhibited intermediate volatility with respect to the VOCs of *U. fimbriata*.

Extraction of VOCs for Food Choice Assays

Volatile organic compounds adsorbed onto Tenax TA (see previous section) were eluted with 5 ml diethyl ether. The ether was gently evaporated to dryness with nitrogen gas, and the residue was immediately dissolved in 100 μ l of ethanol. Samples were stored in gas-tight vials at -20°C for <48 hr to avoid loss. Before the food choice assay, 7 ml filtered (0.45 μ m) Lake Constance water was added to each sample, and this solution was added to the containers placed in the aquarium (see below).

As a control, 40 ml of ultrapure water were stripped with 25% NaCl onto Tenax TA, eluted with diethyl ether, dried, and dissolved in ethanol. In another control, WC medium aerated for several days instead of ultrapure water was analyzed to exclude possible effects of contaminants introduced during cultivation.

Synthetic VOC Mixtures

Reference compounds (Aldrich) identified as the major VOCs of *U. fimbriata* were mixed to approximately match the concentrations in the algal VOC extract (Table 1). However, the (*Z*)-isomer of 2-pentenal and the (*E,Z*)-isomer of 2,4-heptadienal were not available. Thus, only the (*E*)- and (*E,E*)-isomers were used in the complete VOC mixture (Table 1). To resolve whether the attractant activity of *U. fimbriata* VOCs was dependent on specific substances or rather on multiple compounds, 2(*E*),4(*E*)-heptadienal and a mixture of the three C_5 compounds 1-penten-3-one, 1-penten-3-ol, and 2(*E*)-pentenal (C_5 mixture; Table 1) were also tested in the assay.

Food Choice Assays

The food choice assay was specifically designed to separate chemotaxis, mediated through foraging kairomones, from food preference resulting from taste-receptor-mediated effects on patch residence time. Therefore, it was important to offer the food source in a way that allowed for the release and detection of foraging kairomones, but prevented the experimental animals from accessing the food itself. The food choice assays were performed in an aquarium (320 \times 170 mm, 180 mm deep, total volume 10 l) in a climate-controlled room at 20°C . The aquarium was filled with 1 l of filtered (0.45 μ m)

Table 1 Composition of the synthetic VOC mixtures offered to *R. ovata* in the food choice assays

VOC	Supplier and product no.	Complete mixture ^a (μ g per container)	C_5 mixture (μ g per container)	C_7 compound (μ g per container)

^a The complete VOC mixture was designed to mimic the VOCs of *U. fimbriata*.

Lake Constance water. Special containers were designed to allow the introduction of algae and samples of extracted VOCs in water without disturbing the water body (Fig. 1a,b). The containers were modifications of the olfactometers described by Thomas et al. (1980) and consisted of two cylindrical Plexiglas® rings with radial bores (5 mm diam.) near the bottom side of the ring. The inner ring (40 mm diam) was closed at the bottom by gluing a circular Plexiglas® plate to the opening. The inner ring fitted exactly into the outer ring (Fig. 1a,b). Hence, the container could be opened by rotating the outer ring, thereby matching up the bores of the outer and inner rings (Fig. 1a). Likewise, the container could be closed by rotating the outer ring so that the bores did not match up; closing the container stopped the exchange of substances between the inside and the outside of the container (Fig. 1b). One container for the test extract was placed into the aquarium 10.5 cm from the center, and another container for the control extract was placed at the opposite end of the aquarium 10.5 cm from the center. Each container received 7 ml of sample in filtered lake water at the same temperature as the surroundings; the inner and outer water levels were the same. The water level was higher than the radial bores of the containers and lower than the opening at the top of the containers. The top of each container was covered with a circular glass plate. The assay was initiated by rotating the outer rings to open the containers, and introducing five juvenile *R. ovata* at the center of the aquarium. The relative distance (± 1 cm) of each individual snail to both containers was recorded every minute for a total time period of 40 min. The initial scoring value for each snail at the beginning of the experiment (equal distance to both containers) was set at 0; scoring values ranged from -21 (closest to the control) to $+21$ (closest to the test sample). After opening the containers containing samples, the dissolved substances could leave the containers through the bores. This was verified by analyzing the aquarium water 30 min after opening a container containing 1-penten-3-one: 16.6% of the compound ($1.7 \mu\text{g l}^{-1}$) were released into the surrounding water body of the aquarium within half an hour.

Fig. 1 Schematic drawing of the containers used in the food choice assays. (a) Open position. (b) Closed position

Statistical Analyses

Because the five individual snails in each experiment were not independent from each other, the mean of their distribution was calculated for every reading at intervals of 1 min. These mean values were plotted against the reading time and treated as one replicate experiment. All experiments were repeated at least five times, resulting in experimental series with $N = 5$ –10 for each treatment. Between replicate experiments, the sides of the test and control containers were exchanged to exclude directional effects introduced by the experimental setup. In a series of control experiments ($N = 14$), both containers were filled with filtered lake water. The distribution of the snails in this control series was tested against the distribution of the snails in the test series, in which one container contained the test sample and the other contained a control sample. Data were tested to meet assumptions for analysis of variance (ANOVA; normal distribution, homogeneity of variance, Levene's test) and, subsequently, results were compared by using repeated-measurement ANOVA and the GLM module of Statistica[®] v.6 software package (StatSoft, Inc., 2004) and a significance level of $\alpha = 0.05$.

Results

Analysis of VOCs Released by *U. fimbriata*

Although intact *U. fimbriata* cells did not release any detectable VOCs into the surrounding water, freeze-thawed *U. fimbriata* cells released a variety of VOCs (Table 2). The most dominant group detected was lipoxygenase products released upon cleavage of polyunsaturated fatty acids, e.g., 1-penten-3-one, 1-penten-3-ol, (*Z*)-2-pentenal, (*E*)-2-pentenal, (*E,Z*)-2,4-heptadienal, and (*E,E*)-2,4-heptadienal. Minor compounds were the nor-carotenoids 6-methyl-5-hepten-2-one, α -ionone, β -ionone, and β -cyclocitral (Table 2). These minor compounds resulted in peak areas of <10% of the peak area of the major compounds and were not quantified in detail. We determined the concentrations of the major VOCs released by *U. fimbriata* upon cell disintegration (Table 3). The C_5 compounds 1-penten-3-one, 1-penten-3-

	β -Ionone	192	35.08

^a Compounds are given with their molecular mass (M), grouped by their biosynthetic pathways, and sorted by retention time (Rt).

ol, and (*Z*)-2-pentenal were the dominant compounds, e.g., at concentrations of up to 0.9 µg per mg algal carbon (1-penten-3-ol). (*E*)-2-pentenal, (*E,Z*)-2,4-heptadienal, and (*E,E*)-2,4-heptadienal were released at concentrations 10.4–18.7% of that of 1-penten-3-ol (Table 3).

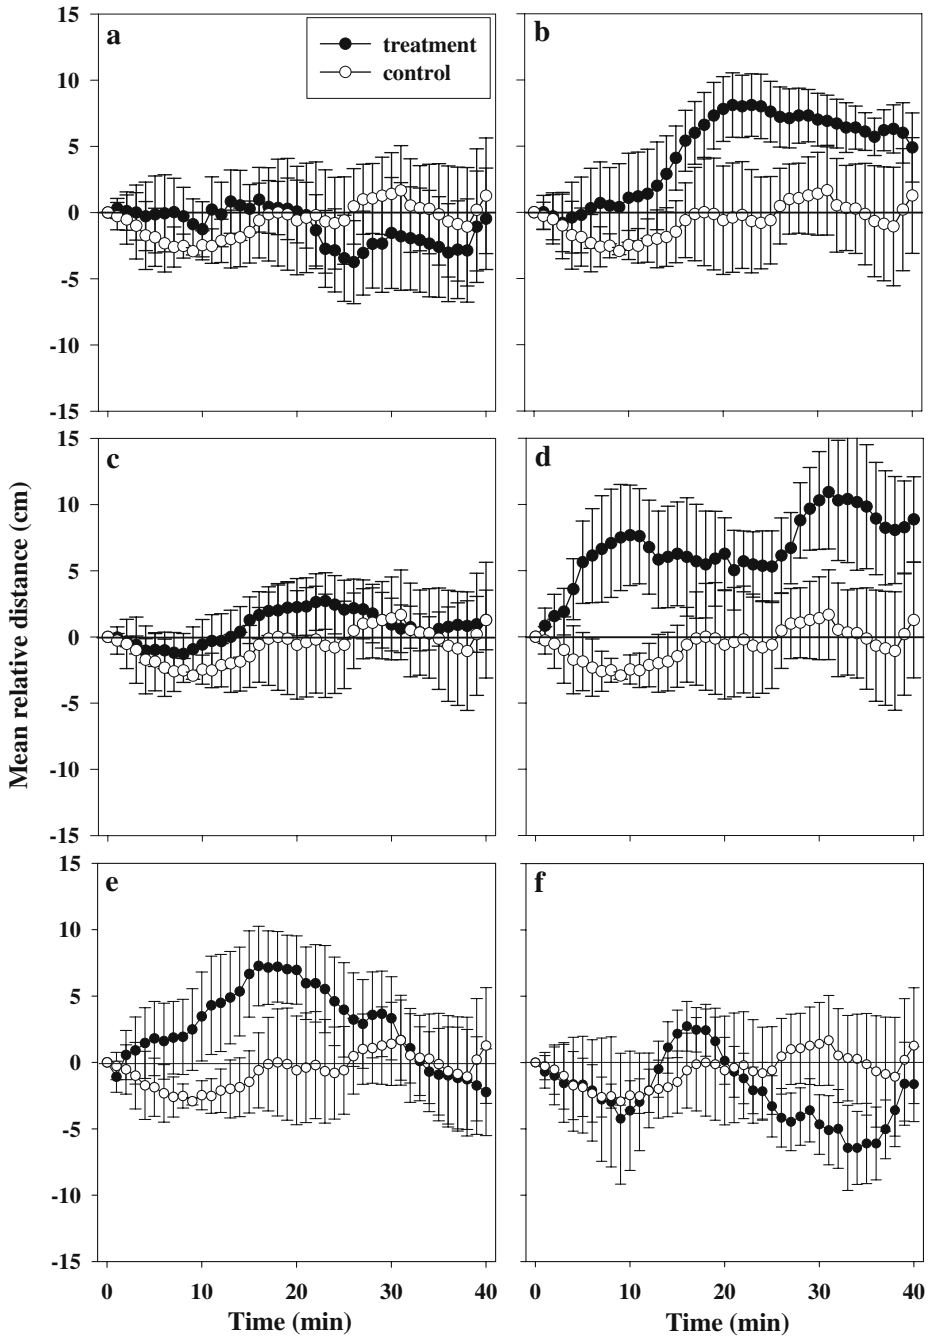

Food Choice Experiments with *R. ovata*

The results obtained in food choice experiments with intact and damaged *U. fimbriata* cells offered to *R. ovata* corroborated the hypothesized VOC release mechanism and the results of the VOC analysis: When a suspension of intact *U. fimbriata* cells was added to the test container and filtered lake water was added to the other container, juvenile *R. ovata* did not show any positive or negative chemotactic response to the algae (Fig. 2a; Table 4). Because intact algal cells did not release VOCs, the results indicate that the snails did not respond chemotactically to any other potential chemical gradient formed by the algae. Similarly, no response occurred when the supernatant of an exponentially growing culture of *U. fimbriata* was placed in the test container (Table 4), which indicated that exudates of actively growing cells do not evoke a chemotactic response. However, a positive chemotactic response was observed when VOCs released from the same amount of biomass of disintegrated *U. fimbriata* cells (trapped and eluted from Tenax TA), were placed in the test container; that is, the snails preferred the VOCs over the control (Fig. 2b; Table 4). This attraction was not caused by possible contaminants introduced during cultivation of the algae or by the VOC extraction process, because an equivalent VOC extract of aerated, sterile culture medium without algae was not preferred over the control (Fig. 2c; Table 4). Hence, the attraction of the snails clearly depended on the VOCs released from *U. fimbriata*. As expected from the results of VOC analysis, *R. ovata* preferred a synthetic mixture of pure C₅ and C₇ compounds designed to mimic the bouquet of released algal VOCs (Table 1) over the solvent control (Fig. 2d; Table 4). To determine whether *R. ovata* was attracted to the C₅ compounds or the C₇ compound or all, either a mixture of the three C₅ compounds or the C₇ compound 2(*E*),4(*E*)-heptadienal was offered (Table 1). Neither the mixture of C₅ compounds nor 2(*E*),4(*E*)-heptadienal alone significantly attracted *R. ovata* (Fig. 2e,f; Table 4). The results of the assays indicated that a mixture of C₅ and C₇ VOCs was needed to attract *R. ovata*, rather than a mixture of the C₅ compounds or 2(*E*),4(*E*)-heptadienal alone.

Table 3 Quantities of the six major compounds in the VOCS bouquet of *U. fimbriata*

VOC	Rt (min)	Release (ng mg POC ⁻¹)	Food choice assay (µg per container)
1-Penten-3-one	10.03	536	5.4
1-Penten-3-ol	10.71	924	9.2
2(<i>Z</i>)-Pentenal	12.44	488	4.9
2(<i>E</i>)-Pentenal	12.83	173	1.7
2(<i>E</i>),4(<i>Z</i>)-Heptadienal	21.62	170	1.7
2(<i>E</i>),4(<i>E</i>)-Heptadienal	22.06	97	1.0

^a Compounds are sorted by retention time (Rt). The amount released is given as mean of *N* = 3 replicate measurements as nanograms of compound per milligram of algal particulate organic carbon (POC). In the food choice assays, the indicated amount of VOCs extracted from 10 mg algal carbon was added to the container. As the (*Z*)-isomer of 2-pentenal and the (*E,Z*)-isomer of 2,4-heptadienal were not available, the calibration for these compounds was done using the signal strengths of the respective (*E*)- and (*E,E*)-isomers.

Discussion

Although diatoms (e.g., Pohnert and Boland, 1996; Wendel and Jüttner, 1996; Jüttner and Dürst, 1997) and especially cyanobacteria (Jüttner et al., 1983; Jüttner 1987; Watson and Ridal, 2004) have been the subjects of numerous studies of VOC production, the ecologically important group of green algae has been widely neglected in such studies. Green algae are phylogenetically related to higher plants, and therefore might be expected to produce similar VOCs. The so-called green leaf volatiles (GLVs) of terrestrial plants consist mainly of C₆ compounds (Croft et al., 1993) and play an important role in herbivory-activated defense mechanisms (e.g., Kessler and Baldwin, 2001; Halitschke et al., 2004). The VOCs released from the benthic green alga *U. fimbriata* upon cell disintegration differed from the GLVs released by terrestrial plants (Table 2). As in higher plants, lipoxygenase products were the major reaction products. Such products arise from the degradation of polyunsaturated fatty acids (Pohnert, 2002), but C₆ compounds, such as (*E*)-2-hexenal and (*Z*)-3-hexenal, which are primarily found in GLV mixtures from leaves, could not be unambiguously identified and, therefore, are not included in Table 2. The peaks assigned to the C₆ compounds in our study were small compared with the peaks of the C₅ and C₇ compounds; therefore, these C₆ compounds are not major VOCs in *U. fimbriata*. The position specificity of lipoxygenase/hydroperoxide lyases in *U. fimbriata* differed markedly from that of higher plants. In addition to VOCs resulting from fatty acid degradation, a variety of volatile nor-carotenoids were detected that are degradation products of carotenoids (Jüttner, 1988a; Simkin et al., 2004). Among others, β -ionone was found, which is an important component of flower odors (e.g., *Viola* sp.) and was shown to be a repellent for the freshwater nematode *Bursilla monohystera* (Höckelmann et al., 2004).

Using our newly developed assay system, we showed that *R. ovata* significantly preferred VOCs liberated from damaged *U. fimbriata* cells over control extracts. Cell damage was necessary for the liberation of the infochemicals perceived by the snails because neither undamaged algae nor a culture supernatant of exponentially growing *U. fimbriata* led to a chemotactic response. These results are in keeping with current ideas on the liberation of VOCs from algal phospholipids via rapid enzymatic degradation (Jüttner, 2001). The enzyme cascade is thought to start with a wound-activated lipase that cleaves algal lipids and releases polyunsaturated free fatty acids. These free fatty acids, which can be potent toxins for benthic herbivores (Jüttner, 2001), are in part rapidly oxygenated by a lipoxygenase that introduces dioxygen into the fatty acid molecule (Gardner, 1991). The hydroperoxides obtained are cleaved by specific lyases into a volatile compound and a nonvolatile short-chain oxo-fatty acid (Pohnert, 2002). Thus, cell damage seems to be a prerequisite for the formation of volatile oxylipins in filamentous green algae.

We unequivocally demonstrated that VOCs and not other compounds released upon cell lysis were responsible for the observed attractant activity, as the eluate of the Tenax adsorbent loaded with *U. fimbriata* volatiles was clearly preferred over a control eluate.

◀**Fig. 2** Mean relative distance (\pm S.E.) of the snails from the two containers in the food choice assays. One container with the test extract was placed into the aquarium 10.5 cm from the center (scoring value +21) and another container with a control extract was placed at the opposite end of the aquarium 10.5 cm from the center (scoring value -21). Test extracts (●): (A) undamaged *U. fimbriata* cells ($N = 7$). (B) VOC extract from disintegrated *U. fimbriata* cells ($N = 5$). (C) VOCs extracted from aerated algal medium ($N = 10$). (D) Synthetic complete VOC mixture containing three C₅ compounds and 2(*E*),4(*E*)-heptadienal ($N = 6$). (E) Synthetic VOC mixture containing the three C₅ compounds ($N = 10$). (F) Synthetic 2(*E*),4(*E*)-heptadienal ($N = 6$). Results from a series of control experiments (both containers with filtered lake water) are plotted for comparison (○).

^a Choice between control and intact cells of *U. fimbriata* ($N = 7$).

^b Choice between control and VOC extract of *U. fimbriata* ($N = 5$).

^c Choice between control and VOC extract of aerated WC medium ($N = 11$).

^d Choice between control and the complete VOC mixture ($N = 6$).

^e Choice between control and the synthetic C₅ mixture ($N = 10$).

^f Choice between control and the synthetic C₇ compound ($N = 6$).

^g Choice between control and the supernatant of an *U. fimbriata* culture ($N = 5$).

^h All analyses compared the treatment (choice between a given test treatment and a control) with a series of control experiments ($N = 14$) in which snails had to choose between two containers with filtered lake water. Asterisks indicate significant differences at $P < 0.05$ (*), $P < 0.01$ (**), and $P < 0.001$ (***); n.s.: not significant.

Only volatile organic compounds adsorb to Tenax TA, so these compounds must have been responsible for the attractant activity of the eluate. This was further supported by the finding that a synthetic mixture of pure reference compounds designed to mimic the VOC bouquet of *U. fimbriata* was also highly attractive to *R. ovata*. Because a mixture of the three major C₅ VOCs and the major C₇ compound alone did not attract *R. ovata*, a multicomponent odor is required for the response of the snails. This type of response is remarkably similar to that of the benthic freshwater nematode *B. monohystera* (Höckelmann et al., 2004), which responds to a bouquet of cyanobacterial VOCs, but not to single compounds. In terrestrial systems, multi-component odors are also frequently more effective in eliciting responses in insects than single compounds (Metcalf, 1987). The sesquiterpene β -ionone was a minor constituent of the VOC bouquet released by *U. fimbriata*. It was not tested whether it has an effect on the behavior of *R. ovata* as has been observed for nematodes (Höckelmann et al., 2004). However, as the complete VOC bouquet extracted from *U. fimbriata* and the synthetic mixture of the four most abundant compounds tested showed similar attractant activity, we believe that β -ionone and other minor compounds contributed neither significant attractant nor repellent activity to the observed effect.

In some of the repeated measurement analyses, there was a significant effect of the factor time and/or significant time \times treatment interactions (Table 4). This is due to the fact that the response of the snails is neither immediate nor persistent. When the animals are introduced into the aquarium, they need a while to detect and respond to odor cues in their environment. Then, the behavioral response develops gradually, causing the effect of and the interaction with the factor time. In the assays without an attractant odor source, the snails start a so-called “random search” behavior (Streit, 1981), which leads to high fluctuations in the distribution of the animals, and causes the significant interaction terms with the factor time.

For the behavioral assays, we deliberately used the filamentous green alga *U. fimbriata*, as members of the genus *Ulothrix* are commonly found in lake periphyton assemblages (John, 2002), but do not occur in the summer periphyton of the lake where the snails were sampled (M. Kahlert, pers. comm.). Therefore, snails had probably not encountered the odor bouquet of *U. fimbriata* before. These bouquets seem to be species specific (Wendel and Jüttner, 1996; Höckelmann and Jüttner, 2004). This choice allowed us to focus exclusively on genetically fixed abilities for food location, as snails are known to be capable of learning to respond to stimuli they have previously encountered (Croll, 1983). For the terrestrial gastropod *Helix pomatia*, preconditioning to odors even seems to be essential for attraction responses (Teyke, 1995). Thus, snail food preferences are influenced by both innate factors and olfactory learning (Croll and Chase, 1980). Additionally, freshwater gastropods are able to adapt their digestive enzymes to optimally suit the digestion of the most abundant food source (Calow and Calow, 1975; Brendelberger, 1997). Hence, the response in natural systems could be much higher if olfactory learning and conditioning of the array of digestive enzymes play a role. The response observed might be a rather conservative estimate of the potential of VOCs to induce food-finding behavior.

Diatoms are known to produce polyunsaturated straight chain and cyclic hydrocarbons, aldehydes, and alcohols (Pohnert and Boland, 1996; Wendel and Jüttner, 1996), some of which function as pheromones in brown algae (Müller et al., 1971). This interaction can possibly be explained by the phylogenetic relationship between brown algae and diatoms (Pohnert and Boland, 1996). Recently, polyunsaturated aldehydes from diatoms have been shown to act as repellents for crustacean grazers (Jüttner, 2005). To our knowledge, no results have been published either on the possible role of eukaryotic VOCs in interspecific communication or on the VOCs released by (benthic) green algae. Especially green algae

have been largely neglected in the context of biogenic VOCs despite their considerable importance in the field (Stevenson et al., 1996).

The results of our study provide the first indications that VOCs from damaged green algae serve as a food-finding cue for freshwater benthic herbivores. Certainly, VOCs are not the only group of potential infochemicals liberated upon cell damage. Various other organic compounds, e.g., sugars, amino acids, and other short-chain carboxylic acids (e.g., propionic acid and butyric acid), have been described as attractants (Thomas et al., 1980; Thomas, 1986) and feeding stimulants (Thomas et al., 1986, 1989) for (tropical) freshwater snails. Some of these might also play a role in the chemical orientation of gastropod species in temperate latitudes. However, *R. ovata* was not attracted to butyric acid and (chironomid) carrion (P. Fink, unpublished results), probably because *R. ovata* feeds almost exclusively on periphyton and to a lesser degree on detritus (Calow, 1970; Lodge, 1986), and usually not on dead animal tissue that could release significant amounts of carboxylic acids and amino acids. Furthermore, in the heterogeneous benthic environment, many organisms and processes probably release such substances that do not necessarily indicate a food source to *R. ovata*. Algal VOCs are distinguishable from such diverse sources, and might, therefore, be the more appropriate food-finding signal for *R. ovata*. The effectiveness of VOCs as foraging kairomones is further supported by our observation that the concentrations sufficient for a chemotactic response of the snails are about an order of magnitude lower than the effective minimal concentrations of dissolved amino acids (Thomas et al., 1983). This difference is not surprising because, from terrestrial systems, it is known that the detection limit of invertebrates for volatile infochemicals is remarkably low (Harborne, 1995).

In terrestrial plant–herbivore interactions, it has repeatedly been shown that the liberation of volatile lipoxygenase products requires the damage of cells to trigger the enzyme cascade responsible for the release of VOCs. Apart from herbivory (Kessler and Baldwin, 2001), pathogens and senescence (Batten et al., 1995) are known to lead to the liberation of volatile lipoxygenase products. The release of volatile infochemicals from benthic algae under natural conditions can be caused by a variety of mechanisms. In laboratory experiments, intact algal cells do not release any lipoxygenase products (Pohnert, 2000; Jüttner, 2001; this study). However, this is a rather artificial situation, as natural periphyton communities are subject to a constant and high turnover of energy, nutrient, and biomass (Lamberti et al., 1995; Steinman et al., 1995), which contributes to their high productivity and ecological importance for littoral food webs (Klumpp et al., 1992; Pinckney and Zingmark, 1993). This turnover unavoidably involves damage and lysis of benthic algal cells. Thus, senescence and mechanical damage by hydrodynamic forces (Cattaneo, 1990; Watson and Ridal, 2004) and resultant release of VOCs into the water (Watson and Ridal, 2004) are likely to occur in natural environments. Furthermore, algal cells can become infected with parasitic fungi (Van Donk, 1989) or viruses (Reisser, 1993), resulting in increased cell lysis. Thus, a constant release of algal degradation products is expected in any natural biofilm community.

Another potentially important release factor is the grazing of herbivores. Similar to findings from terrestrial plant–herbivore interactions, Durrer et al. (1999) have shown that grazing by herbivorous cladocera on planktonic cyanobacteria leads to the release of significant amounts of VOCs in both the field and the laboratory. Likewise, when snails or other herbivorous invertebrates graze on an algal biofilm in the benthos, algal cells will rupture and release VOCs. Other snails would then be able to detect this food patch. A similar mechanism has been proposed for the mangrove snail *Terebralia palustris*, where active feeding of individual snails on leaf litter leads to the release of odor compounds and,

subsequently, to the attraction of conspecifics (Fratini et al., 2001). In this study, we found such an attraction using a widely distributed (ITIS, 2004) and often highly abundant snail species and a benthic green alga commonly found in lake littoral zones as model organisms. Probably, such a VOC-mediated attraction is not restricted to these species but rather represents a new, so far not investigated means of chemical communication that generally applies to gastropod–algae interactions. Such behavioral response of gastropods to volatile lipoxigenase products (or oxylipins; Pohnert et al., 2002) might also explain the frequently observed patchy occurrence of snails in littoral zones (Lodge, 1986; Klumpp et al., 1992; P. Fink, pers. obs.). The results reported here suggest that VOCs are not only important information-transmitting cues in terrestrial ecosystems (Metcalf, 1987), but also in (benthic) freshwater habitats.

Acknowledgments We thank P. Merkel and E. Loher for technical assistance with the VOC analyses and S. Boekhoff, B. Kumpfmüller, and T. Basen for assistance with the food choice assays. W. Nagl gave advice on the statistical analyses, and L. Peters helped with the figure of the experimental containers. We are indebted to M. Wolf for manufacturing the experimental containers and to K. Brune for language correction. This study was supported by the Deutsche Forschungsgemeinschaft within the Collaborative Research Centre SFB 454—“Littoral of Lake Constance.”

Introduction

Marine algae are defended from herbivory by a variety of secondary metabolites (Paul et al., 2001), including polyphenolics, acetogenins, terpenes, amino-acid-based and halogenated compounds, which can influence palatability. These metabolites deter feeding by marine herbivores in the field and in laboratory assays (Hay et al., 1987a, b; Van Alstyne et al., 2001; Van Alstyne and Houser, 2003). Because algal chemical defenses influence herbivore preference, and herbivores, such as sea urchins, can structure marine algal communities (Carpenter, 1986; Wright et al., 2005), chemical defenses indirectly structure algal populations and communities in coral reefs and other nearshore habitats.

Numerous green algae (Chlorophyta) are especially deterrent to coral reef herbivores. Rhizophytic algae in the order Bryopsidales, including *Caulerpa*, *Halimeda*, *Udotea*, *Penicillus*, and *Rhypocephalus* spp., are less palatable than other species commonly found in reef habitats (Paul and Hay, 1986; Wylie and Paul, 1988; Meyer et al., 1994). Their extracts deter feeding in artificial assays (Paul and Van Alstyne, 1992). Algae also produce higher concentrations or additional defensive compounds in areas subject to high herbivore pressure (Paul and Fenical, 1986). In addition, algae in the order Ulvales and Cladophorales, such as *Ulva*, *Enteromorpha*, and *Cladophora* spp., are less palatable than other algae in the field and in live algal and artificial feeding trials toward some temperate herbivores (Paul and Hay, 1986; Van Alstyne et al., 2001; Van Alstyne and Houser, 2003), although less is known about their secondary chemistry.

Some green algae use an activated defense system whereby damage, which could result from feeding, results in the conversion of a stored secondary metabolite, which may have biological activity, into a product with greater bioactivity (Paul and Van Alstyne, 1992). Two notable examples of activated defenses occur in the Bryopsidales, which commonly produce bioactive terpenoids (mainly sesquiterpenes and diterpenes). These are caulerpenyne from *Caulerpa* spp. and halimeda-tetraacetate from *Halimeda* spp., which, upon wounding, are transformed into the more toxic and deterrent oxytoxins and halimeda-trial, respectively (Paul and Van Alstyne, 1992; Cimino et al., 1990; Gavagnin et al., 1994; Jung and Pohnert, 2001). Another activated system used by some macroalgae involves the conversion of dimethylsulfoniopropionate (DMSP) into acrylic acid and dimethyl sulfide (DMS). Many genera of green macroalgae have high DMSP concentrations that deter feeding by marine herbivores (Van Alstyne et al., 2001; Van Alstyne and Houser, 2003). For instance, both conversion products deter feeding by temperate sea urchins at relatively low concentrations (Van Alstyne et al., 2001; Van Alstyne and Houser, 2003; Lyons et al., unpublished data).

This study tested the relative effectiveness of different types of defenses that are commonly found in green algae on feeding by a common tropical and subtropical reef herbivore, the rock-boring sea urchin *Echinometra lucunter*. Live algal feeding assays were conducted to assess palatability of green algae relative to co-occurring red and brown macroalgae, found in the Indian River Lagoon, and at offshore sites near Fort Pierce, Florida. In addition, relative palatability was tested among unpalatable green algae that may use different defense systems (caulerpenyne-related terpenoids vs. products from the activation of DMSP). Finally, artificial feeding assays were conducted, where algal extracts or isolated metabolites were incorporated into agar-based foods, to assess if trends in palatability were related to algal chemistry. This study is the first to examine how DMSP-related defenses influence feeding by a subtidal, subtropical herbivore, and to assess the relative susceptibility of this herbivore to components of these different systems.

Methods and Materials

Collection of Organisms

Algae used in live algal feeding assays were collected from Fort Pierce, Florida, USA, in the Indian River Lagoon (27°27.769'N, 80°19.291'W), offshore at Pepper Park (27°29.566'N, 80°17.796'W), and from the Smithsonian Marine Ecosystems Exhibit from August to October, 2003. Green algae included *Caulerpa prolifera*, *Caulerpa racemosa* var. *laetevirins*, *Caulerpa sertularioides*, *Cladophora* sp., *Codium taylorii*, *Halimeda discoidea*, and *Ulva lactuca*. Red algae included *Amphiroa fragilissima*, *Gracilaria caudata*, *Gracilaria cervicornis*, and *Gracilaria tikvahiae*. Brown algae included *Dictyopteris deliculata* and *Lobophora variegata*. The cyanobacterium *Lyngbya confervoides* was obtained from a bloom off Fort Lauderdale, Florida, in the fall of 2003 (26°16.408'N, 80°03.833'W). *G. tikvahiae* for artificial feeding assays was obtained from cultures maintained at Harbor Branch Oceanographic Institution by D. Hanisak. Sea urchins (*E. lucunter*) were obtained from a rocky sea wall in the Indian River Lagoon (27°27.769'N, 80°19.291'W). This species is found in reef communities and rocky shores throughout the Caribbean, from North Carolina south to Brazil, and on the Atlantic coast of Africa (Hendler et al., 1995).

Live Algal Feeding Assays

Multiple-choice feeding assays were conducted with live algae commonly found in reef and rocky habitats to gain perspective on how algae rank in palatability. Individual sea urchins ($N = 15\text{--}20$) were offered pieces of similar volumes of four to six algal species (see figures for species used in each experiment). *G. tikvahiae*, an abundant red drift alga readily consumed in preliminary live algal feeding assays, served as a positive control. Algae were weighed before and after feeding, and assays were stopped once an alga was completely consumed or after 70 hr. Paired sea urchin exclusion controls were run at the same time in each aquarium to account for changes in algal mass unrelated to feeding (Peterson and Renaud, 1989). Consumption of each species by each sea urchin was determined by using the formula $[T_i \times (C_f / C_i)] - T_f$, where T_i is the initial algal mass, T_f is the final algal mass, C_i is the initial control algal mass, and C_f is the final control algal mass. The amount of each algal species consumed was expressed as the percentage of the total algae consumed by an individual sea urchin (Lockwood, 1998). Sea urchins that consumed <10% or >90% of the total algal mass per aquarium⁻¹ were excluded from statistical analysis. Friedman's repeated-measures ANOVA and Student–Newman–Keuls multiple comparison test were used to identify significant differences in the percentage of total consumption among algae (Lockwood, 1998). Based on the results from the live algal feeding assays, additional assays were performed, comparing palatability among the green algae *U. lactuca*, *Cladophora* sp., and *C. prolifera* as described above.

Preparation of Algal Extracts

Freshly collected *U. lactuca* and *C. prolifera* were individually homogenized in solvent and extracted $\times 3$ in 1:1 ethyl acetate/methanol to yield a nonpolar extract and then $\times 2$ in 1:1 ethanol/distilled H₂O to yield a polar extract. It is possible that nonpolar extracts might contain some polar compounds that are partially soluble in methanol, and that some polar compounds were excluded from the polar extract due to the presence of 50% ethanol.

Extracts were filtered, dried by rotary evaporator, and stored at 4°C until used in feeding assays. There was not enough *Cladophora* sp. to perform extractions and use in feeding assays.

Artificial Feeding Assays with Algal Extracts

Methods were similar to those used by Hay et al. (1998). To make the artificial diet, 1 g agar was dissolved in 30 ml distilled H₂O and heated in a microwave. Two grams of dried, ground *G. tikvahiae* were added. Algal extracts were dissolved in 2 ml ethanol and incorporated into the food at natural concentrations on a dry weight basis. Ethanol (2 ml) also was added to the control foods. Artificial food with and without extracts was spread into a mold with parallel, rectangular wells over window screen, cooled, and cut into replicate strips containing one piece of each food type. Sea urchins were fed extract-free artificial food before feeding trials. For artificial assays, sea urchins ($N = 15\text{--}20$) were offered a strip of screen containing three pieces of food of equal size, one with nonpolar extract, one with polar extract, and a control piece without extract (placement of extract-containing and control food was randomized on strips among assays). Sea urchins were allowed to feed until half of the artificial food of one food type was consumed or until 48 hr passed. Preference was quantified as the number of window screen squares revealed after food was consumed. Sea urchins that did not eat or consumed all food were excluded from statistical analysis. Friedman's repeated-measures ANOVA and Student–Newman–Keuls multiple comparison test were used to identify significant differences in the number of squares consumed.

Measurement of DMSP in Green Algae

Tissue concentrations of DMSP in *U. lactuca*, *C. prolifera*, and *Cladophora* sp. were measured with methods similar to those described in Van Alstyne et al. (2001). Dried algae ($N = 10$) were weighed and placed in 4 N NaOH in 30 ml gas-tight vials that were stored at 4°C in darkness overnight. The next day, DMSP was measured as DMS from the headspaces of the vials by direct injection into an SRI gas chromatograph (Chromosil 330 column, flame photometric detector; detection limit: 5 µg DMS). Known concentrations of commercially obtained DMSP were used as standards. A Kruskal–Wallis ANOVA and Tukey's multiple comparison test were used to compare concentrations among species.

Artificial Feeding Assays with Algal Compounds

Dimethyl sulfide (Acros Organics) and acrylic acid (Sigma-Aldrich) were incorporated at natural concentrations, and multiples thereof, into artificial foods composed of 2:1 dried *G. tikvahiae*/agar. Because DMS is volatile, it was mixed into artificial food after food cooled to a temperature below 40°C. Equal amounts of distilled H₂O were added to control foods. Evaporative losses of DMS during food preparation were determined through gas chromatography. These numbers were used to adjust the concentration of DMS added to the foods to achieve the desired concentration for the start of the assay. The diet was presented on strips of window screen, as above, for acrylic acid assays. For DMS assays, artificial food was created by spreading food evenly into a thin layer over clean sand (to weight food down), allowing it to cool, and cutting replicate pieces by using different shapes of known size for DMS and controls. This was performed to reduce the time from

incorporation of volatile DMS into food and the start of the assay. Sea urchins were not starved before feeding assays, because starvation reduced feeding rates (A. Erickson, personal observations). Feeding assays ($N = 15\text{--}20$) consisted of pairs of food, with and without a compound, that were offered simultaneously. Sea urchins were allowed to feed until half of one food type was consumed or until 2 hr passed. This time period was based on established diffusion rates of DMS, where 50% was lost from experimental diets after 1 hr and 75% after 4 hr (Van Alstyne and Houser, 2003). Consumption was quantified for acrylic acid as the number of window screen squares revealed when food was consumed and for DMS assays as the number of squares eaten when food pieces were held against window screen. Sea urchins that did not eat or consumed all food were excluded from statistical analysis. Paired t -tests were used to identify significant differences in the number of squares consumed.

Caulerpenyne was semipurified from *C. sertularioides* crude extract with flash column chromatography (Paul and Fenical, 1986). It was found in the 95:5 hexane/ethyl acetate fraction of a florisil column, and nuclear magnetic resonance indicated ~90% purity. The caulerpenyne fraction was dissolved in ethanol and incorporated into artificial food (2:1 dried *G. tikvahiae*/agar) at concentrations that approximate the natural concentration in *Caulerpa* spp. Foods were presented on strips of window screen, as above, along with a control containing ethanol without caulerpenyne. Sea urchins were allowed to feed until half of one food type was consumed or until 48 hr passed. Consumption was quantified as

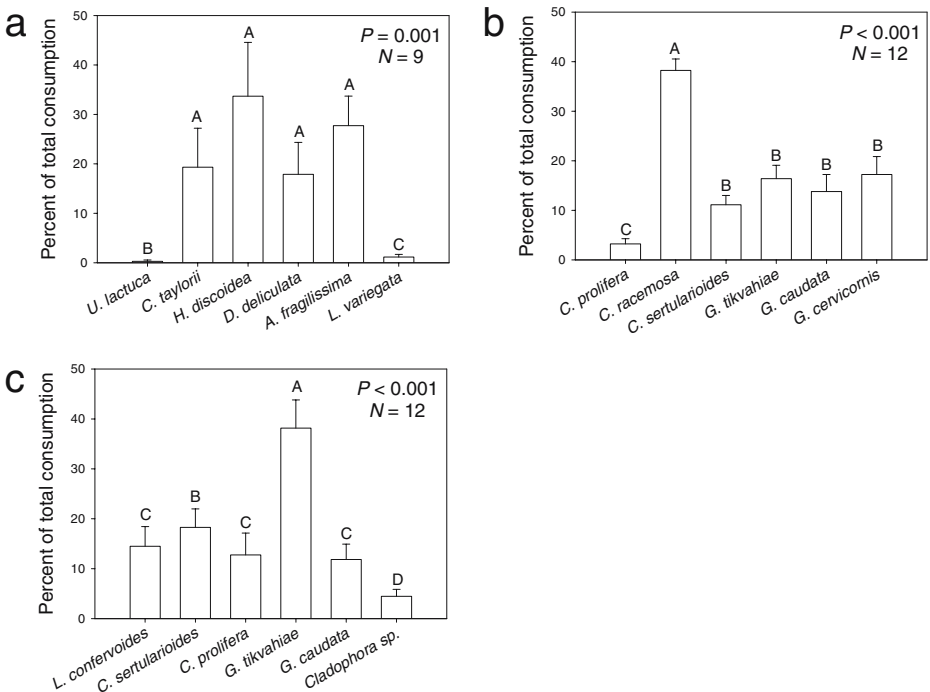

Fig. 1 Percentage of total consumption for a variety of algae offered to *E. lucunter* in live algal multiple-choice feeding assays. Treatments were compared by Friedman’s repeated-measures ANOVA followed by the Student–Newman–Keuls *post hoc* test. Error bars represent standard error and letters above bars denote significant differences

Fig. 2 Percentage of total consumption for select algae offered to *E. lucunter* in a live algal multiple-choice feeding assay. Algae include those deemed highly palatable (*G. tikvahiae*) and unpalatable (*U. lactuca*, *C. prolifera*, and *Cladophora* sp.) from assays in Fig. 1. Treatments were compared by Friedman's repeated-measures ANOVA followed by the Student–Newman–Keuls *post hoc* test. Error bars represent standard error and letters above bars denote significant differences

the number of window screen squares revealed when food was eaten. Sea urchins that did not eat or consumed all food were excluded from statistical analysis. Friedman's repeated-measures ANOVA and Student–Newman–Keuls multiple comparison test were used to identify significant differences in the number of squares consumed.

Results

Live algal multiple-choice feeding assays revealed that certain species of algae were of low preference to *E. lucunter*. *U. lactuca* and *L. variegata* were preferred less compared with other green, brown, and red algae (Friedman's $\chi_r^2 = 19.835$, $P = 0.001$; Fig. 1a). *C. prolifera* was the least preferred species of *Caulerpa* and was eaten less than *Gracilaria* spp. (Friedman's $\chi_r^2 = 32.446$, $P < 0.001$; Fig. 1b). *Cladophora* sp. was fed upon less than *Caulerpa* spp., *Gracilaria* spp., and the cyanobacterium *L. confervoides* (Friedman's $\chi_r^2 = 24.326$, $P < 0.001$; Fig. 1c). Three of the four least preferred algal species were green, suggesting that *E. lucunter* may be more sensitive to secondary metabolites of green algae than those found in other types. Hence, this report concentrates on the influence of

Fig. 3 The number of squares consumed by *E. lucunter* in an artificial feeding assay. Nonpolar (NP) and polar (P) extracts of *U. lactuca* (UI) were incorporated into artificial food and offered, in conjunction with extract-free controls, simultaneously to sea urchins. Treatments were compared by the Friedman's repeated-measures ANOVA followed by the Student–Newman–Keuls *post hoc* test. Error bars represent standard error and letters above bars denote significant differences

Fig. 4 The number of squares consumed by *E. lucunter* in an artificial feeding assay. Nonpolar (NP) and polar (P) extracts of *C. prolifera* (Cp) were incorporated into artificial food and offered, in conjunction with extract-free controls, simultaneously to sea urchins. Treatments were compared by the Friedman's repeated-measures ANOVA followed by the Student–Newman–Keuls *post hoc* test. Error bars represent standard error and letters above bars denote significant differences

green algal chemistry on feeding by *E. lucunter*. In each case, the low-preference algae composed <5% of the average total consumption. When the three green algae that were the least preferred in previous experiments were offered to sea urchins simultaneously, there was no significant difference in consumption among them. However, they were all consumed less than *G. tikvahiae* (Friedman's $\chi_r^2 = 21.663$, $P < 0.001$; Fig. 2). *U. lactuca* and *C. prolifera* each composed <10% of the average total consumption, whereas *Cladophora* sp. was just below 20% of the average total consumption.

Consumption of artificial food with polar *U. lactuca* extracts was about $\times 3$ greater than for food with nonpolar extract or the control (Friedman's $\chi_r^2 = 9.000$, $P = 0.011$; Fig. 3). Food with nonpolar *U. lactuca* extract also was consumed significantly less than the control. Similarly, artificial food with polar *C. prolifera* extract was consumed two to three times more than food with nonpolar extract or the control (Friedman's $\chi_r^2 = 8.423$, $P = 0.015$; Fig. 4); however, there was no difference in consumption between food with nonpolar extract and the control.

Dimethylsulfoniopropionate concentrations were $\sim 2.76 \pm 0.15\%$ of the dry mass (DM) or $0.44 \pm 0.01\%$ of the fresh mass (FM) in *U. lactuca*. Trace levels of DMSP (0.14 ± 0.00 DM, $0.02 \pm 0.00\%$ FM) were found in *Cladophora* sp., and DMSP was not detected in *C. prolifera*. DMSP concentrations (%DM) were greater in *U. lactuca* than in both *Cladophora* sp. and *C. prolifera* (Kruskal–Wallis ANOVA $H = 26.852$, $P \leq 0.001$).

Fig. 5 The number of squares consumed by *E. lucunter* in paired artificial feeding assays. Acrylic acid was incorporated into artificial food at natural concentration (1.38% DM) and twice the natural concentration (2.76% DM). Then, it was offered, in conjunction with acrylic-acid-free controls, to sea urchins. Treatments were compared by paired *t*-tests. Error bars represent standard error and letters above bars denote significant differences

Fig. 6 The number of squares consumed by *E. lucunter* in paired artificial feeding assays. DMS was incorporated into artificial food at natural concentration (1.38% DM), and twice (2.76% DM) and four times (5.52% DM) the natural concentration. Then, it was offered, in conjunction with DMS-free controls, to sea urchins. Treatments were compared by paired *t*-tests. Error bars represent standard error and letters above bars denote significant differences

There was no difference in consumption between controls and artificial food containing either DMS or acrylic acid, the cleavage products of DMSP. Acrylic acid at natural (1.38% DM) and twice the natural concentrations failed to reduce consumption by *E. lucunter* (paired *t*-test $t = 0.092$, $P = 0.929$; paired *t*-test $t = -0.159$, $P = 0.876$; respectively; Fig. 5). DMS at natural (1.38% DM), twice, and four times natural concentrations also failed to reduce consumption (paired *t*-test $t = -0.023$, $P = 0.982$; paired *t*-test $t = -1.432$, $P = 0.180$; paired *t*-test $t = -0.542$, $P = 0.595$; respectively; Fig. 6). There was no significant difference in consumption of artificial food containing caulerpenyne at 2% DM with controls, whereas artificial food containing caulerpenyne at 4% DM was fed upon approximately one third as much as controls (Friedman's $\chi^2_r = 7.115$, $P = 0.029$; Fig. 7).

Discussion

This study examined feeding preferences of the sea urchin *E. lucunter* and whether preferences were chemically mediated. The green algae *U. lactuca*, *C. prolifera*, and

Fig. 7 The number of squares consumed by *E. lucunter* in an artificial feeding assay. Extract from the caulerpenyne-containing fraction was incorporated into artificial food at concentrations of 2% and 4% DM, which approximates what is naturally found in *Caulerpa* spp. Then, it was offered, in conjunction with caulerpenyne-free controls, to sea urchins. Treatments were compared by paired *t*-tests. Error bars represent standard error and letters above bars denote significant differences

Cladophora sp., and the brown alga *L. variegata* were unpalatable to *E. lucunter* relative to other algal species. Given that three of four species avoided were green algae, *E. lucunter* may be more sensitive to chlorophyte defenses than those of other types of algae. Feeding responses to these algae, and related species, in past studies have been herbivore specific. For instance, *Caulerpa* spp. were avoided by the surgeonfish *Zebrasoma flavescens* (*C. prolifera*, *C. racemosa*, *Caulerpa serrulata*, *C. sertularioides*; Wylie and Paul, 1988) and the sea urchins *Paracentrotus lividus* (*Caulerpa taxifolia*; Lemee et al., 1996), and *Lytechinus variegatus* (*C. prolifera*, Lowe, 1974; Vadas et al., 1982). In contrast, many reef fish, including parrotfish, surgeonfish, and rabbitfish, consumed *Caulerpa* spp. (*Caulerpa cupressoides*, *C. prolifera*, *C. racemosa*, and *C. sertularioides*; Paul and Hay, 1986; Paul et al., 1990). The percentage of *C. prolifera* individuals eaten by reef fish has ranged between 8% and 70% in preference experiments (Paul and Hay, 1986). *E. lucunter* also preferred *C. racemosa* var. *laetevirins* (Fig. 1b). Alternatively, *Cladophora* spp. were avoided by parrotfish and some surgeonfish (Paul and Hay, 1986), yet were consumed by *Z. flavescens* (Wylie and Paul, 1988) and the amphipod *Amphithoe longimana* (Hay et al., 1987a). *Ulva* spp. were avoided by the sea urchins *Strongylocentrotus droebachiensis* (Van Alstyne and Houser, 2003), *P. lividus* (Lemee et al., 1996), and *L. variegatus* (Lowe, 1974), the spottail pinfish *Diplodus holbrooki* (Hay et al., 1987a), and *A. longimana* (Duffy and Hay, 1994). However, *Ulva* spp. were fed upon by reef fish (Littler et al., 1983), the sea hare *Aplysia californica* and the shore crab *Pachygrapsus crassipes* (Sousa, 1979), the gastropods *Littorina striata*, *Osilinus atratus* (Granado and Caballero, 2001), *Turbo undulatas* (Davis et al., 2005), and the amphipod *Gammarus mucronatus* (Duffy and Hay, 1994).

It is likely that algal chemistry influenced feeding by *E. lucunter*. In this study, nonpolar *U. lactuca* extract reduced, and polar extract stimulated, feeding by *E. lucunter*. The average DMSP concentration in *U. lactuca* was $0.44 \pm 0.01\%$ FM, which was lower than for deterrent *Ulva* spp. from the Pacific northwest ($0.49 \pm 0.22\%$ FM to $1.58 \pm 0.31\%$ FM; Van Alstyne et al., 2001). Previous studies demonstrated that DMS strongly deterred feeding by *S. droebachiensis* at concentrations between 0.04% and 2% FM (Van Alstyne and Houser, 2003), and acrylic acid deterred feeding by *Strongylocentrotus purpuratus* and *S. droebachiensis* at concentrations between 0.1% and 2% FM (Van Alstyne et al., 2001). Although the DMSP concentrations in *U. lactuca* were high enough to generate sufficient DMS and acrylic acid to deter feeding by sea urchins in past studies (Van Alstyne et al., 2001; Van Alstyne and Houser, 2003), no differences in feeding by *E. lucunter* resulted between controls and artificial food containing either acrylic acid or DMS at natural and elevated concentrations. Similarly, no effect of high DMS concentrations was found on feeding by the fish *Thalassoma bifasciatum* (Pawlik et al., 2002), whereas *Ulva* spp. extracts deterred feeding by the amphipod *Gammarus palustris* (Borowsky and Borowsky, 1990), and acrylic acid stimulated feeding by the isopod *Idotea wosnesenskii* at 0.1% to 1% FM (Van Alstyne et al., 2001). DMS may have diffused out of artificial food during this experiment, preventing differences in feeding on experimental food versus controls. However, established DMS diffusion rates (Van Alstyne and Houser, 2003) suggest that DMS should have been present at the end of the assay. *E. lucunter* may be less sensitive to acrylic acid and DMS than temperate sea urchins, as the effects of metabolites can be herbivore specific (Hay et al., 1987b; Paul et al., 2001).

The secondary metabolite caulerpenyne can be converted through activation, degradation, and oxidation to a variety of additional compounds that may have greater toxicity than the precursor, including oxytoxins (1 and 2), epoxycaulerpenynes (6, 7, and 10, 11), 7,7-C-

didehydro-6-hydroxy-6,7-dihydrocaulerpenyne, taxifolials (A–D), and taxifolione (Guerriero et al., 1993; Guerriero and D'Ambrosio, 1999; Jung and Pohnert, 2001). During activation, the 1,4-diacetoxybuta-1,3-diene(bis-enol acetate) moiety is hydrolyzed by esterases in seconds and is replaced with 1,4 dialdehydes, which are suggested to be responsible for significant bioactivity. In this study, the chemistry of *C. prolifera* influenced feeding by *E. lucunter*. Artificial food with polar *C. prolifera* extract stimulated feeding by *E. lucunter*; however, there was no effect of food with nonpolar extract on feeding. Despite the inactivity of the nonpolar extract, caulerpenyne deterred feeding by *E. lucunter* at natural concentrations (>2% and 4% DM). Although sea urchins (McConnell et al., 1982) and a few reef fish (Targett et al., 1986; Paul et al., 1987) have been deterred by caulerpenyne, most reef fish were not deterred by *Caulerpa* spp. extracts or caulerpenyne (Paul et al., 1987; Wylie and Paul, 1988; Paul et al., 1990, 1992).

Variation in herbivory may relate to caulerpenyne concentration, which varies within and among species (Paul and Hay, 1986; Amade and Lemee, 1998; Dumay et al., 2002). For instance, in *C. prolifera*, it varies from 20% to 40% of the nonpolar extract (Paul and Hay, 1986), and *C. taxifolia* and *C. prolifera* have twice the caulerpenyne concentration of *C. racemosa* (Jung et al., 2002). The discrepancy between the deterrent live algae and nondeterrent, nonpolar *C. prolifera* extract may have resulted from activation of caulerpenyne in the live algae. Conversion to oxytoxins or other metabolites requires active algal esterases no longer present in artificial food. While partial activation may have occurred with extraction (Jung et al., 2002), the effect may not have been as great as that of natural activation through feeding. Finally, the discrepancy between the deterrent caulerpenyne and nondeterrent, nonpolar *C. prolifera* extract may have resulted if the extract contained less caulerpenyne than 4% DM, which was tested. Although feeding assays have not been conducted with isolated algal oxytoxins, due to their unstable and reactive nature, some studies have tested the effect of oxytoxins, mucus, and additional compounds derived from caulerpenyne-sequestering sacoglossans. Compounds and mucus inhibit microbial and protistan growth and feeding by freshwater and carnivorous marine fishes (Cimino et al., 1990; Guerriero et al., 1993; Gavagnin et al., 1994).

Chemical defenses against herbivory have not been explored as well in *Cladophora* spp. Some studies have found numerous sterols, free fatty acids and esters, terpenes, aldehydes, betaines, halogenated, and nitrogen-containing compounds in *Cladophora* spp. (Elenkov et al., 1995; Kamenarska et al., 2004). In addition, some studies have demonstrated antibacterial, anti-inflammatory, and cytotoxic activity of individual compounds or extracts (Kamenarska et al., 2004).

The unpalatable green algae used in this study, and related species, have been implicated in macroalgal blooms and invasions globally (Valiela et al., 1997; Jousson et al., 2000; Meinesz et al., 2001). The presence of such species has led to phase-shifts, where dominant structural species of an ecosystem, such as seagrass and corals, have been replaced by algae (Meinesz et al., 1993; Valiela et al., 1997; Thomas and Bell, unpublished data), leading to concomitant alterations in community and ecosystem parameters. Consequences of phase shifts include habitat loss, reduced biodiversity, and altered environmental parameters, species dominance, and trophic dynamics (Valiela et al., 1997; Thomas and Bell, unpublished data).

Algal chemical defenses have been proposed as a mechanism that promotes phase shifts and invasions due to deterrent, toxic, and allelopathic effects (Guerriero et al., 1993; Paul et al., 2001; Jung and Pohnert, 2001). Toxic effects have influenced a wide range of taxonomic organisms. *Ulva* spp. extracts and caulerpenyne are toxic to larval and adult stages of many marine invertebrates and vertebrates (Paul and Fenical, 1986; Lemee et al.,

1993; Pedrotti et al., 1996; Nelson et al., 2003). Ulvoid extracts have reduced the growth and germination of seagrass epiphytes and macroalgal zygotes (Nelson et al., 2003). Caulerpenyne is also toxic to bacterial and fungal pathogens (Paul and Fenical, 1986). Although studies often test for toxicity by bathing organisms in algal extracts, which may not accurately assess potential for deterring settlement or feeding, these studies demonstrate that bloom-forming and invasive species have the potential to impair or kill organisms if they release metabolites into the water column. Given the toxic and deterrent effects of these algae, it appears that their chemistry has the potential to promote bloom persistence and invasion success.

In summary, algal chemistry is partially responsible for feeding patterns observed in this study. Nonpolar extracts of *U. lactuca* and caulerpenyne reduced feeding by *E. lucunter*, whereas polar extracts stimulated feeding. Further analysis is needed to determine (1) which nonpolar *U. lactuca* compounds deter herbivory; (2) whether nonpolar compounds of *C. prolifera*, in addition to caulerpenyne, deter herbivory; and (3) other chemical defenses in *Cladophora* spp. Finally, it is important to understand how algal chemistry influences herbivory, thus indirectly influencing algal communities, given the current rise in algal blooms and invasions.

Acknowledgments We thank S. Reed and P. Monahan for their assistance with collection of sea urchins and algae. We are also grateful to D. Hanisak for providing *G. tikvahiae* for artificial feeding assays. In addition, W. Lee, J. Piraino, M. Puglisi, and R. Ritson-Williams provided significant assistance in the laboratory. Finally, commentary from anonymous reviewers and G. Cronin was appreciated. Grants funding this project were awarded to V.J.P. from the Smithsonian Marine Science Network (SMS contribution no. 645) and the Florida Center of Excellence for Biomedical and Marine Biotechnology (COE contribution no. P200608), and to K.L.V. from the National Science Foundation (IBN-0090825).

Introduction

Plants have evolved a broad spectrum of inducible defense mechanisms to resist damaging insects and pathogens (Karban and Baldwin, 1997). Induced plant defenses may act directly against herbivores or microorganisms, and comprise mechanisms as diverse as the strengthening of plant cell walls, hypersensitive cell death, or the production of toxic and deterrent substances. In addition, plants may employ indirect defenses for instance by emitting volatile compounds in response to feeding or oviposition by arthropods (Dicke and Sabelis, 1988; Hilker and Meiners, 2002). These volatiles can serve as long-range signals for parasitoids and predators, by indicating the presence and location of their often inconspicuous prey.

A central question in the study of indirect plant defenses is how specific the plant-provided volatile cues are (Vet and Dicke, 1992; Dicke, 1999; Turlings et al., 2002). It has been argued that ideally volatile cues should not only be easy to detect but, should also be specific enough to provide information on the identity of the herbivore and its suitability as a host or prey (Vet and Dicke, 1992). Plants can vary considerably in the volatile blends they emit, both in terms of the chemical composition (quality) and in the quantity of volatile compounds. Depending on what factors cause it, this variability may either interfere with or enhance the specific information that the signals contain. Evidence has been found for both, existence and absence of specificity, depending on the studied system (reviewed by Dicke, 1999). At least in some plant–herbivore systems it has been shown that different insect species and instars may elicit different odor blends, resulting in preferential attraction of natural enemies to plants on which their specific (De Moraes et al., 1998; Guerrieri et al., 1999) or preferred host stages (Takabayashi et al., 1995) were feeding. It remains to be resolved, however, how this specificity in plant signals can exist in the face of considerable variability in induced volatile blends caused by other factors. Major differences in the chemical composition can be found among different plant species (Turlings et al., 2002), but within a species genotypic effects have also been found to be important (Loughrin et al., 1995; Peacock et al., 2001; Gouinguéné et al., 2001; Hoballah et al., 2002). Moreover, abiotic factors such as humidity, temperature, light intensity, light cycle, and nutrient availability all can have an effect on the quantity and the quality of herbivore-induced plant odors (Gouinguéné and Turlings, 2002).

An additional complicating aspect is that plants live in environments in which they face the possibility of multiple, synchronous attacks by insects and pathogens. Host finding with the aid of plant-provided volatiles may prove difficult for parasitoids if plant pathogens significantly alter the chemical composition of herbivore-induced odor blends. Pathogen-derived or pathogen-induced odors could mask the host-induced blend or reduce the emission of important compounds. On the other hand, odor blends resulting from simultaneous herbivore and pathogen attack may provide useful information for natural enemies if their hosts are less or better suitable due to poorer or better development on a diseased plant. So far, cross effects between plant-feeding insects and microorganisms have been investigated almost exclusively in the context of induced direct defenses (Hatcher, 1995; Agrawal et al., 1999; Rostás et al., 2003). Whether induced indirect defense against herbivores is compromised by pathogen attacks remains almost unexplored, with the exception of the studies conducted by Cardoza et al. (2002, 2003a,b), who found a significant effect of fungus infection on direct and indirect defenses in peanut plants (see Discussion).

At the biochemical level, pathogen infection commonly induces the salicylic acid (SA) defense pathway, whereas insect attack triggers a defense based on jasmonic acid (JA).

Cross talk between these pathways, however, may occur (Felton and Korth, 2000; Thaler et al., 2002; Devoto and Turner, 2003). It is conceivable that the induction of the SA pathway may also interact with the JA-dependent induction of volatiles in response to herbivory. If so, a change in the emission of many compounds should be the result, and members of the third trophic level may adapt their responses to optimize the exploitation of the signals.

The induced indirect defense mechanism has been extensively investigated in the tritrophic system maize, *Spodoptera* spp., and several larval endoparasitoids (Turlings et al., 1995; Alborn et al., 1997; Hoballah et al., 2002). Feeding by *Spodoptera* larvae leads to the release of green leaf volatiles and induces the accumulation of JA and ethylene. These phytohormones are responsible for the emission of indole, terpenoids, and other compounds (Schmelz et al., 2003a,b; Ruther and Kleier, 2005). Parasitic wasps are highly attracted to these odors (Turlings et al., 1990), and this attraction may benefit the attacked plant (Hoballah and Turlings, 2001). In contrast to some plants, the induction of the SA pathway does not lead to any detectable release of volatiles in maize (Turlings et al., 2002; Van Poecke and Dicke, 2004). Because of the available information on caterpillar-induced emissions of maize and its attractiveness to parasitoids, this tritrophic system lends itself well to studies on the effects of pathogen infection on indirect defense.

In this study, we assessed the effect of the necrotrophic fungus *Setosphaeria turcica* (Leonard et Suggs) on the emission of maize volatiles induced by *Spodoptera littoralis* (Boid.), and the consequences for the third trophic level. The ascomycete *S. turcica* causes the foliar disease known as northern corn leaf blight and is a serious problem for maize growers worldwide (Borchardt et al., 1998). The fungus cooccurs with *S. littoralis* and its parasitoid *Microplitis rufiventris* (Kok.) in Egypt and the countries of the Middle East (Gerling, 1969; Hegazi, 1977; CAB International, 1988). It also cooccurs with *Cotesia marginiventris* in the United States and Latin America (CAB International, 1988; Molina-Ochoa et al., 2003). This parasitoid species uses *S. exigua* and *S. frugiperda* larvae as hosts. These two hosts trigger the release of the same inducible compounds in maize when compared to *S. littoralis* (Turlings et al., 1995; Hoballah, 2001). In a six-arm olfactometer, we tested the responses of the parasitoids *M. rufiventris* and *C. marginiventris* (Cresson) to odors of maize seedlings attacked either by the fungus, the herbivore, or by both. Simultaneously, all odor blends were sampled and subsequently analyzed for comparison. Furthermore, the performance of *S. littoralis* feeding on fungus-infected maize plants and the performance of its natural enemy, *M. rufiventris*, developing in larvae that fed on diseased maize was evaluated.

Methods and Materials

General Methods

Maize (*Zea mays* var. Delprim) plants were grown in polypropylene pots (11 cm high, 4 cm diam) containing commercial soil mix (Coop, Basel) in a climate chamber (23°C, 60% r.h., and 16:8 hr L/D, 550 $\mu\text{mol m}^{-3} \text{sec}^{-1}$). This maize variety was chosen because it is partially resistant to *S. turcica*. Stronger and/or faster induced responses to fungal attack as well as less necrotic tissue that does not produce volatiles can be expected from partially resistant compared to susceptible varieties. In addition, “Delprim” is a variety that emits exceptionally high amounts of herbivore-induced volatiles.

Eggs of *S. littoralis* (Lep., Noctuidae) were supplied by Syngenta (Stein, Switzerland). Newly hatched larvae were reared in transparent plastic boxes on a wheat germ-based artificial diet until used. Colonies of the solitary endoparasitoids *M. rufiventris* and *C. marginiventris* (both Hym., Braconidae) were maintained in the laboratory. For the rearing, 25 *S. littoralis* caterpillars (3–4 d) were offered to a single mated female (4–7 d) for 3 hr in a plastic box (5 cm high, 9.5 cm diam). The parasitized caterpillars were kept in an incubator (25°C, L:D 16:8 hr) until the parasitoids formed cocoons. The cocoons were kept in Petri dishes until adult emergence. Emerging adults were sexed and kept in plastic cages (30 × 30 × 30 cm; Bugdorm I, MegaView Ltd, Taichung, Taiwan) in the same incubator (*C. marginiventris*) or under ambient laboratory conditions (*M. rufiventris*). Cages were supplied with moist cotton wool and droplets of honey.

The necrotrophic fungus *S. turcica* (anamorph: *Exserohilum turcicum*, Dothideaceae) was obtained from Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH (Braunschweig, Germany) and cultivated on V8 agar in darkness under laboratory conditions.

Plant Inoculation and Volatile Induction

Spores of *S. turcica* were harvested prior to plant inoculations. A Petri dish culture was flooded with 5 ml 0.05% aq. Tween 20, and then brushed gently with a small paintbrush to detach the spores from the mycelium. The density of the spore suspension was determined with an improved Neubauer chamber and adjusted to 6×10^4 spores ml⁻¹. Maize seedlings (7 d) were inoculated by applying 100 µl spore suspension to the second and third leaves, respectively. Spores were spread homogeneously with a paintbrush. Control plants were mock-inoculated in the same manner with 0.05% aq. Tween 20. All seedlings were placed into two cool boxes with wet tissue papers laid out on the bottom. Plants were kept in darkness for 16 hr (17:00–09:00) at >90% r.h. and ambient temperatures. The following morning, all plants were transferred to a climate chamber (23°C, 60% r.h., and L/D 16:8 hr, 550 µmol m⁻² sec⁻¹). Disease symptoms were allowed to develop for 72 hr after which the plants were used in the experiments. Strength of infection was calculated by scanning the diseased leaves ($N = 9$) and measuring the necrotized areas with Photoshop 7.0 (Adobe) and Surface (© C. Thiemann, Berlin, Germany). On average, 11% of the leaf surface was visibly affected by *S. turcica*. This was the highest achievable disease rate for the partially resistant variety Delprim in the seedling stage.

Volatile Collections

Volatiles from maize seedlings were collected with a six-arm olfactometer, a device allowing for simultaneous odor collection and testing of parasitoid host location behavior (described by Turlings et al., 2004). A single maize plant was placed into one of the six odor source vessels of the olfactometer. Trapping filters were attached to each vessel consisting of glass tubes (7 cm) containing 25 mg of 80–100 mesh Super Q adsorbent (Alltech, Deerfield, IL, USA) that was kept in place by two fine mesh metal screens (described by Heath and Manukian, 1992). Filtered and humidified air was pushed into the odor source vessels at a rate of 1.2 l min⁻¹ vessel⁻¹ originating from a central in-house compressor. Half of the air flow (0.6 l min⁻¹) was pulled through the trapping filter with a vacuum pump (ME2, Vacuubrand, Wertheim, Germany), whereas the other half was allocated to the olfactometer choice chamber. Before each experiment, traps were rinsed with 1 ml methylene chloride. Collections lasted 3 hr after which traps were removed, extracted, and analyzed.

Chemical Analysis

Volatile traps were eluted with 150 μl methylene chloride after each collection, and two internal standards (*n*-octane for green leaf volatiles and nonyl acetate for terpenoids and others, each 200 ng in 10 μl methylene chloride; all chemicals were purchased from Sigma-Aldrich, Germany) were added to these samples. Aliquots (3 μl) of the samples were analyzed by gas chromatography/mass spectrometry (GC: HP 6890 N, MSD: Agilent 5973) equipped with a split/splitless injector and an HP-1 ms column (30 m \times 0.25 mm ID, 0.25 μm film thickness). Samples were injected in pulsed splitless mode. The oven was held at 40°C for 3 min and then programmed at 8°C/min to 230°C, where it was maintained for 9.5 min. Helium (24 cm sec⁻¹) was used as carrier gas. Compound identities were confirmed by comparison with mass spectra of the National Institute of Standards and Technology (NIST) library and mass spectra of commercially available standards. Quantification of compounds was based on comparison with the internal standards. Only those compounds that were reliably found in each sampled plant of the same treatment were quantified. The evaluated compounds comprised >90% of the total amount of the analyzed volatile blends.

Host Location Behavior of Parasitoids

Attraction of *M. rufiventris* and *C. marginiventris* was assessed in the six-arm olfactometer, and simultaneously a part of the volatiles released from the plants was collected for subsequent analyses. Mated 2- to 4-d-old female wasps were used in all experiments. Insects were naïve in a sense that they had no contact to host insects or plants during the adult stage. Six wasps were removed from the cage with an aspirator and released into the central choice chamber of the olfactometer. Previous experiments had shown that female wasps do not interfere with each other in their choices (Turlings et al., 2004). Wasps initially walked up to the top, attracted by the light above the choice chamber. Most would walk into an arm with an attractive odor until the path was blocked by a stainless steel screen. Eventually, they walked up into a glass trapping bulb where they could easily be counted and removed. Each group of insects was given 30 min to make a choice, after which they all were removed, and a new group was released. Five groups of six wasps were tested on a given day. Each olfactometer experiment was replicated on 8 d with a new set of plants ($N = 8$). The position of the plants was changed clockwise after each day of testing. Different sets of plants were used for each parasitoid species. *M. rufiventris* and *C. marginiventris* were tested to simultaneously presented odors of: (1) three undamaged maize plants, (2) one herbivore-damaged maize plant, or (3) one fungus-infected maize plant, or (4) one herbivore-damaged/fungus-infected maize plant. The three undamaged plants were alternated with attacked plants and arranged in a circle. Herbivory treatment was achieved by transferring the plants into the odor source vessels and then placing ten 2nd instars of *S. littoralis* into the whorl of a healthy or infected maize plant (10 d old) the evening (17:00) before an experiment was performed. All other plants were placed in the olfactometer at the same time. The subsequent olfactometer assays were carried out between 09:00 and 13:00 hours.

Development of *S. littoralis* on Fungus-Infected Maize

The performance and mortality of *S. littoralis* caterpillars on *S. turcica*-infected maize plants was tested in two separate experiments. In the first assay, fifteen 4-d-old caterpillars

were selected for equal weight (2.6 ± 0.15 mg) and then placed singly into the whorl of a potted maize seedling. The host plants had previously been inoculated with the fungus or mock-inoculated with Tween 20. Symptoms of the fungus were present on the first three leaves, but not on the youngest fourth leaf. This reflects the heterogenic distribution of fungal infection in nature allowing the herbivore to choose between locally and systemically induced leaves. A cellophane bag (Celloclair, Liestal, Switzerland) over each plant prevented caterpillars from escaping while permitting gas exchange. After 5 and 10 d of feeding, larvae were weighed and placed on a new host plant. Finally, the pupal weight was calculated 2 d after pupation. In another experiment, we measured leaf consumption and survival of *S. littoralis* on infected and healthy leaves. A group of 10 neonate caterpillars was placed into each of 15 Petri dishes (9 cm diam) with moist filter paper. As a food source, each group of caterpillars received either a piece of (1) *S. turcica*-infected leaf bearing symptoms (third leaf), (2) healthy leaf (third leaf), (3) symptom-free leaf (fourth leaf), or (4) healthy leaf (fourth leaf). All Petri dishes were kept in an incubator (25°C, 16:8 hr L/D). The leaf area removed by *S. littoralis* was evaluated as described above for lesion area measurement after 2 d, and the number of surviving caterpillars was recorded.

Development of *M. rufiventris* inside Caterpillars Feeding on Fungus-Infected Maize

We assessed whether *S. turcica* infection had an indirect effect on the parasitoid *M. rufiventris*. Two groups of either five fungus-infected or five healthy maize plants were placed into four insect rearing tents (Bugdorm 2, Megaview, Taiwan). Ten neonate *S. littoralis* caterpillars were transferred onto each plant with a small paintbrush and allowed to feed for 3 d. All caterpillars were collected from the plants and placed into a transparent plastic box. From this pool, 20 caterpillars were randomly chosen and placed in a Petri dish into which a female parasitoid was introduced. The wasp was allowed to oviposit into six caterpillars. Wasp and parasitized caterpillars were then removed and the procedure was repeated five times with new wasps and herbivores. This yielded 36 parasitized caterpillars from fungus-infected and healthy maize plants, respectively. The *S. littoralis* larvae were allowed to continue to feed on the same type of plant they had originated from, either infected or healthy maize plants, for 6 d, i.e., 2 d before the first parasitoid hatched from its host. Caterpillars were then individually placed in Petri dishes (5.5 cm diam) containing a piece of filter paper and artificial diet. After emergence, the hatching rate, survivorship, pupal weight, developmental time, and longevity of *M. rufiventris* were measured. Parasitoid longevity was assessed by measuring the time from egg deposition until the adult died. Adults were supplied with water but were not fed.

Statistics

Data obtained from the six-arm olfactometer were analyzed by modified G-statistics for comparison of log linear models based on a quasi-Poisson distribution and thus fitted to overdispersed data. The software package R (<http://stat.ethz.ch/CRAN/>) was used. For detailed explanations, see Turlings et al. (2004). Two-way ANOVA with treatment and compound as main effects was performed for comparison of volatiles. Herbivore and parasitoid performances were also compared by using Student's *t*-test for independent samples. However, numbers of surviving *S. littoralis* on healthy and diseased plants were analyzed by Mann–Whitney *U* test, and hatching rate and survivorship of parasitoids were assessed via chi square tests.

Results

Effect of *S. turcica* on Volatile Emission

Fungal infection had a quantitative but no detectable qualitative effect on the odor bouquet of maize seedlings, i.e., no new compounds were detected (Fig. 1). Healthy and fungus-infected maize seedlings, both exclusively released linalool at the same rate (Newman–Keuls test after ANOVA, Treatment effect: $P = 0.794$). In contrast, caterpillar feeding triggered the release of large amounts of green leaf volatiles, monoterpenes, indole, and sesquiterpenes. Plants double-treated with *S. turcica* and *S. littoralis* emitted the same blend as plants damaged by *S. littoralis* alone, but most of the induced volatiles were found in significantly lower amounts. Fungus- and herbivore-damaged plants released 48% less of the total amount of volatiles than herbivore-only damaged plants (Newman–Keuls test after ANOVA, Treatment effect: $P < 0.001$). Compounds not reduced in their amounts due to pathogenic infection were (Z)-3-hexenal, (Z)-3-hexen-1-yl-acetate, and β -caryophyllene (Newman–Keuls test after ANOVA, Compound \times Treatment, P values > 0.05). The ratios between a given volatile compound and the total emission did not differ significantly between double-treated and herbivore-only treated plants with one exception: fungal infection lowered the indole/total amount ratio from 14% to 5% ($t = 3.467$; $P = 0.002$).

Host Location Behavior of Parasitoids

Parasitic wasps *M. rufiventris* and *C. marginiventris* preferred the odor of plants that were damaged by *Spodoptera* larvae when compared with healthy (*M. rufiventris*: estimate \pm SE: -2.72 ± 0.31 , $P < 0.001$; *C. marginiventris*: estimate \pm SE: -2.33 ± 0.23 , $P < 0.001$) and fungus-infected maize (*M. rufiventris*: estimate \pm SE: -2.45 ± 0.45 , $P < 0.001$; *C. marginiventris*: estimate \pm SE: -3.10 ± 0.54 , $P < 0.001$) (Fig. 2). However, they did not

Fig. 1 Plant volatiles emitted from seedlings of *Zea mays* (var. Delprim) after single or combined herbivore feeding and fungal infection. Means \pm SE are shown. $N = 10$ –13. Asterisks denote significant differences between treatments: * $P < 0.05$, ** $P < 0.01$, n.s. = not significant. Newman–Keuls test after two-way ANOVA. 1 = (Z)-3-Hexenal; 2 = (Z)-3-hexen-1-yl acetate; 3 = linalool; 4 = (3E)-4,8-dimethyl-1,3,7-nonatriene; 5 = indole; 6 = geranyl acetate; 7 = β -caryophyllene; 8 = (E)- α -bergamotene; 9 = (E)- β -farnesene

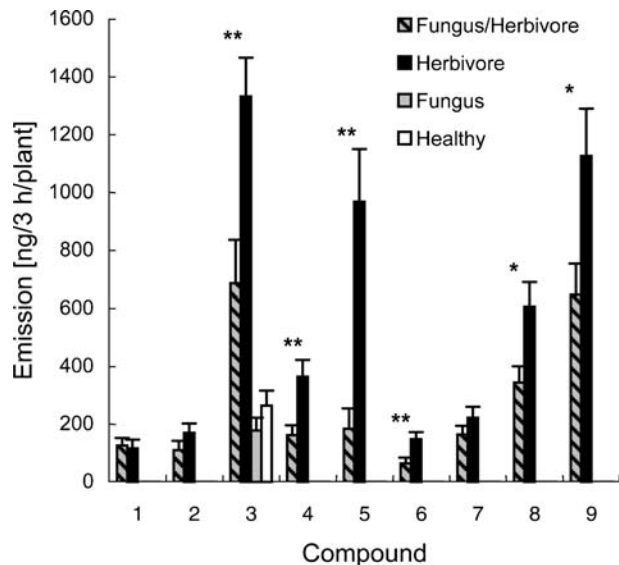

Fig. 2 Responses of naïve female parasitoids to odors emanating from: H = herbivore-infested, F = fungus-infected, H/F = herbivore- and fungus-attacked, or C = healthy maize seedlings in a six-arm olfactometer. The experiments were replicated on 8 d with different sets of plants for each parasitoid species. Per day 30 wasps were released in groups of six. Responding wasps: 80% of *Cotesia marginiventris*, 81% of *Microplitis rufiventris*. Bars represent mean number of parasitoids (\pm SE) per experimental day responding to an odor source. Significant differences between treatments are indicated by different letters above bars ($P < 0.05$)

respond differently to the odors of plants that had been damaged by *S. littoralis* alone and those that had been inoculated with *S. turcica* in addition (*M. rufiventris*: estimate \pm SE: -0.12 ± 0.18 , $P = 0.522$; *C. marginiventris*: estimate \pm SE: -0.14 ± 0.16 , $P = 0.377$). No significant differences in preference were found between fungus-infected and healthy maize seedlings (*M. rufiventris*: estimate \pm SE: 0.27 ± 0.51 , $P = 0.597$; *C. marginiventris*: estimate \pm SE: -0.77 ± 0.56 , $P = 0.172$).

Fig. 3 Performance of *Spodoptera littoralis* on healthy or *Setosphaeria turcica*-infected maize plants. One caterpillar fed on a single plant. All plants were exchanged after 5, 10, and 15 d of feeding. Means \pm standard errors are given. No significant differences were found between treatments. Student's *t*-test for independent samples

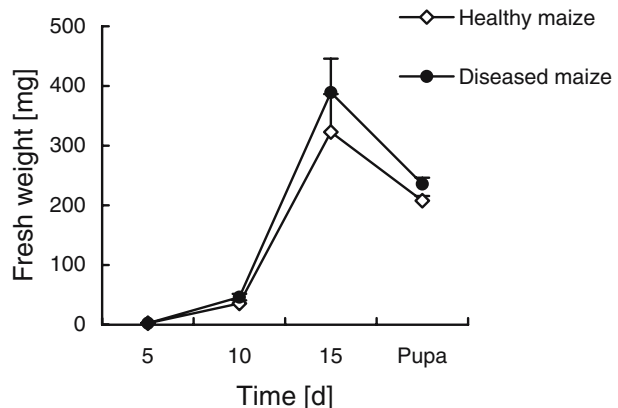

Table 1 Performance of *Spodoptera littoralis* (L₁) on *Setosphaeria turcica*-infected or healthy maize

	Fungus ^a		Healthy ^a		<i>P</i> ^c
	Local	Systemic	Local	Systemic	
Area fed [mm ²] ^b	102 ± 7.0	139 ± 11.0	103 ± 9.3	125 ± 15.4	n.s.
Surviving larvae/leaf	9.6 ± 0.17	9.2 ± 0.27	9.4 ± 0.20	9.6 ± 0.15	n.s.

^aTen caterpillars were kept on detached leaves (local = second leaf, systemic = fourth leaf) for 2 d.

^bMeans and standard errors are given for fed leaf areas ($N = 14-15$).

^cn.s. = Not significant, $P > 0.05$. Student's *t*-test for independent samples and Mann–Whitney *U* test.

Development of *S. littoralis* on Fungus-Infected Maize

Feeding on fungus-infected whole maize plants had no negative impact on the development of *S. littoralis* when compared with caterpillars feeding on healthy plants. No significant differences in larval fresh weights (after 5 d: $t = -1.666$, $P = 0.116$; 10 d: $t = -1.209$; $P = 0.245$, 15 d: $t = -1.21$; $P = 0.245$) or pupal fresh weights ($t = -2.071$, $P = 0.056$) were found at any time point of measurement (Fig. 3). Also, the duration of development was not affected by pathogen infection ($t = 0.355$, $P = 0.728$). Neonate larvae survived equally well on locally or systemically induced leaves of infected maize as on the corresponding leaves from healthy plants (local: $U = 166$, $Z = -0.137$, $P = 0.891$; systemic: $U = 109.5$, $Z = 0.954$, $P = 0.340$) (Table 1). Caterpillars on healthy leaves did not consume significantly different amounts of leaf material than those on diseased leaves (local: $t = 0.219$, $P = 0.828$; systemic: $t = -0.900$, $P = 0.376$).

Development of *M. rufiventris* inside Caterpillars Feeding on Fungus-Infected Maize

No indirect effect of *S. turcica* on the development of *M. rufiventris* was found (Table 2). Larvae of the parasitoid developed equally well in *S. littoralis* caterpillars feeding on infected maize as in caterpillars feeding on control plants. Hatching rate ($\chi^2 = 1.19$, $P = 0.276$), developmental speed (egg–pupa: $t = -0.398$, $P = 0.693$), pupal weight ($t = -1.692$, $P = 0.097$), and survivorship ($\chi^2 = 0.89$, $P = 0.345$) did not differ between treatments.

Table 2 Performance of *Microplitis rufiventris* in caterpillars of *Spodoptera littoralis* that had been reared on either fungus-infected or healthy maize plants

	Fungus	Healthy	<i>P</i> ^d
Hatched pupae ^a [%]	69	80	n.s.
Hatched adults ^b [%]	47	58	n.s.
Developmental time (egg to pupa) [d]	8.7 ± 0.14	8.7 ± 0.12	n.s.
Pupal weight ^c [mg]	3.2 ± 0.04	3.2 ± 0.04	n.s.
Longevity ^c (egg to adult) [d]	25.9 ± 1.10	26.3 ± 0.57	n.s.

^aParasitoid larvae that left the host and pupated outside.

^bAdult parasitoids emerging from cocoon.

^cMeans and standard errors are given.

^dChi square test and Student's *t*-test for independent samples. $N = 36$. n.s. = not significant.

Discussion

The results demonstrate that fungal infection had an impact on the emission of caterpillar-induced plant volatiles. Herbivore-damaged maize seedlings emitted lower amounts of the most abundant volatiles if they were previously infected by *S. turcica*. Pathogen infection alone did not result in the emission of detectable amounts of any compound other than linalool, which is also emitted by healthy plants. Typical fungus volatiles, such as 3-octanone, were not found. We also found no methyl salicylate that could have resulted from the induction of the SA pathway by *S. turcica* (Rostás et al., unpublished), despite using more sensitive methods (MS in single ion mode) to detect this compound. Although it was not possible to achieve a higher infection rate in this maize variety, it is doubtful that a heavier disease rate would have led to the emission of additional volatiles: treatment with a high dose (5 mM) of the SA mimic BTH did not lead to any differences in volatile emission (Rostás et al., unpublished data). Attenuated volatile emission due to double infestation has also been reported by Rodriguez-Saona et al. (2003), but in their case both plant antagonists were insects. It was found that cotton plants damaged by caterpillars of *S. exigua* emitted 60% less volatile compounds if simultaneously infested by the phloem-feeding insect *Bemisia argentifolii*. This is noteworthy because herbivores with a sucking–piercing–feeding mode can induce the SA pathway and, consequently, plant responses that are comparable with defenses against pathogens (Walling, 2000). Concerning the underlying mechanism, we hypothesize that fungal infection could reduce plant volatile emission as a result of the negative cross talk between the pathogen-induced SA pathway and herbivore-induced JA signaling. This antagonistic interaction has been shown for direct defenses in several plants (Fidantsef et al., 1999; Preston et al., 1999; Thaler et al., 2002).

Our observations contrast with reports on the only other plant–fungus–herbivore system investigated so far: in peanut plants, the emission of volatiles induced by *Spodoptera exigua* was not attenuated by the fungus *Sclerotium rolfsii*. However, methyl salicylate (MeSA), an attractive compound for a number of natural enemies (James, 2003a,b; de Boer and Dicke, 2004), was emitted by fungus-infected and double-attacked plants (Cardoza et al., 2002, 2003a,b). This difference in odor emission between maize and peanut is also reflected in the interactions with the second and third trophic level. On peanut plants, *S. exigua* eat more leaf tissue and perform better when the plant is diseased, thus leading to increased volatile emission (Cardoza et al., 2002). More individuals of *C. marginiventris* were found to land on fungus- and herbivore-attacked peanut plants than on plants infested by *S. exigua* alone (Cardoza et al., 2002, 2003a,b). These observations suggest that the wasp's response may be adaptive. However, it needs to be verified whether *C. marginiventris* performs better in *S. exigua* feeding on diseased compared to healthy plants.

In our study, neither *C. marginiventris* nor *M. rufiventris* preferred herbivore-damaged plants to double-treated maize seedlings, although the latter emitted less volatiles. We expected both parasitoid species to be more attracted by plants that were damaged by the herbivore alone, as they emitted about 50% more in total than maize seedlings attacked by both antagonists. Both *C. marginiventris* (Turlings et al., 2004) and *M. rufiventris* (C. Tamó, personal communication) respond in a dose-dependent manner in the six-arm olfactometer. As a general rule, the stronger the volatile emission, the stronger the attraction of the wasps. However, the odor blends in our experiments were not directly comparable to blends offered in dose–response assays where all compounds in the odor blends were equally reduced or increased. In contrast, in double-damaged maize not every compound was significantly reduced: the green leaf volatiles (*Z*)-3-hexenal and (*Z*)-3-hexen-1-yl acetate, as well as the sesquiterpene β -caryophyllene, were not affected by *S. turcica*

infection. The unaltered emission of green leaf volatiles in double-treated plants and their significance for both parasitoid species could be a sufficient explanation as to why the wasps did not change their preference. Hoballah (2001) and D'Alessandro and Turlings (2005) found that green leaf volatiles from maize are important attractants for naïve *M. rufiventris* and, in particular, for *C. marginiventris*. For the latter species, green leaf volatiles and/or related compounds were more attractive than induced terpenoids, as long as wasps had had no oviposition experience in the presence of induced maize odors. Further experiments will have to reveal whether *C. marginiventris* will respond differently to herbivore-infested maize plants with or without fungal infection after associative learning.

Alternatively, the unaltered responsiveness of wasps to caterpillar-damaged plants with fungus infection may be adaptive in the sense that there appears to be no selection pressure on female *M. rufiventris* to avoid *S. turcica*-infected maize. The offspring of *M. rufiventris* developed equally well in caterpillars feeding on healthy or *S. turcica*-infected maize leaves. It is conceivable that for this reason the wasps mainly use those volatiles for host location that are not affected by the fungus. To our knowledge, this is the first study to relate the potential impact of a phytopathogen to parasitoid performance.

Our research shows (1) that fungal infection is another factor that leads to variability in herbivore-induced odor emissions, and (2) that certain variability in the odor bouquet does not necessarily disrupt the mutualistic relationship between parasitoid wasps and plants.

Acknowledgments We wish to thank Cristina Faria, Cristina Tamò, Marco d'Alessandro, and Matthias Held for discussions and technical assistance. We also thank Syngenta for supplying us with eggs of *S. littoralis*. This work was supported by the Deutsche Forschungsgemeinschaft (grant to Michael Rostás, Ro2409/1-1) and the Swiss National Centre of Competence in Research "Plant Survival." All experiments complied with current laws in Switzerland.

Introduction

Plants commonly respond to herbivore damage through the synthesis of volatile compounds, a process generally assumed to be detrimental to the herbivore through indirect defense mechanisms (Paré and Tumlinson, 1997, 1999). Induced plant volatiles attract natural enemies of herbivores (Dicke and Sabelis, 1988; Turlings et al., 1990, 1995), indicate the presence of potential competitors, and coincide with the mobilization of direct plant defenses (Karban and Baldwin, 1997). As semiochemicals, induced volatiles may alter the recruitment of herbivores to the damaged host plant, not only by providing chemical cues for host plant location, but also information on the damage status of the host plant (Bernasconi et al., 1998). Behavioral responses of foraging lepidopterans to these cues have been examined primarily in adults because selection of an appropriate host plant for offspring is largely a consequence of female oviposition preferences rather than the consumer (caterpillar) itself (Thompson, 1988). Several species of noctuid moths preferentially oviposit on undamaged rather than damaged plants in response to volatile cues, presumably thus limiting exposure of their offspring to risks of higher predation, parasitism, and competition from older larvae, and performance costs incurred with induced plant defenses (Landolt, 1993; Anderson and Alborn, 1999; De Moraes et al., 2001). Alternatively, some adult coleopterans exploit the relatively greater volatile output of induced plants to locate hosts and conspecifics (Harari et al., 1994; Lougrin et al., 1995; Bolter et al., 1997; Landolt et al., 1999). In both cases, the greater mobility of adults allows for expanded search capabilities for suitable host plants with reduced search time, minimal search costs, and limited exposure to mortality factors (Stamps and Krishnan, 2005; Stamps et al., 2005).

Although adults are the primary life stage for dispersal of most lepidopterans, caterpillars of some species disperse from the original oviposition site and search for new host plants by ballooning (as neonates; Zalucki et al., 2002) or crawling. These larvae forage when suitable food sources are exhausted (Singer and Stireman, 2001), thus avoiding natural enemies (Bernays, 1997; Singer and Stireman, 2003), reducing competitive interactions (Kakimoto et al., 2003), limiting exposure to toxins or balancing nutrients (Singer and Stireman, 2001; Singer et al., 2002), or compensating for suboptimal oviposition choices by females (Beredegué et al., 1992; Roitberg and Mangel, 1993; Doak, 2000). These herbivores rely, to varying degrees, on visual and olfactory cues to orient to new host plants. Despite the fact that volatiles are induced in response to caterpillar attack, their reciprocal effects on the host location behaviors of the same foraging herbivores are poorly understood. The high volatile emissions associated with induced plants may serve as better olfactory cues for host plant location by slow-moving larvae in part through greater chemical apparency (Landolt et al., 2000). Conversely, larvae that select a damaged host plant usually suffer more direct and severe exposure to the deleterious effects of induced defenses and a more restricted ability to move to an alternative host plant than adults (Van Dam et al., 2001). Given the limited choices and greater consequences faced by foraging caterpillars, we investigated larval orientation responses to odors from herbivore-damaged and undamaged host plants in a highly mobile lepidopteran that disperses frequently as a caterpillar.

The fall armyworm (FAW) *Spodoptera frugiperda* (Smith) is a polyphagous noctuid that feeds on over 60 species of plants and is a periodic, but serious, pest of maize, rice,

sorghum, turf grasses, cotton, and peanuts (Luginbill, 1928; Sparks, 1979). Larvae often disperse from the original host plant, in part because of frequent and negative effects of overcrowding. Females lay up to 200 eggs in an egg mass on a single host, often exceeding the resources available to offspring (Sparks, 1979; Pitre et al., 1983; Chapman et al., 1999b). Individuals that remain on the original host plant face competition for resources and the threat of cannibalism from conspecifics (Chapman et al., 1999b). At high densities, FAW can completely defoliate their host plants and migrate in search of new hosts *en masse*, hence the name armyworm (Martin et al., 1980). To compensate, larvae disperse from the oviposition site both within and between host plants. Both neonates and older larvae will move off their host plant if food resources are exhausted or severely degraded by the presence of conspecifics. Despite the polyphagous nature of the species as a whole, selection of an appropriate new host plant can impact larval growth and development. Larval performance of individual FAWs from different host strains varies considerably among host plant species (Pashley, 1988; Meagher et al., 2004) and also can be impacted by previous damage from other herbivores (Bultman and Conard, 1998; Tindall and Stout, 2001). Given that volatiles from herbivore-damaged and undamaged plants differ quantitatively at a minimum, foraging FAW are presented with differences in olfactory cues when making a choice.

We examined FAW responses to herbivore-damaged plants in maize, *Zea mays* L., a crop plant frequently attacked by this pest. FAW caterpillars preferentially feed on leaf whorls and young seedlings (Davis et al., 1999; Meagher and Nagoshi, 2004), and stimulate the release of copious amounts of induced volatiles in response to caterpillar attack (Gouinguéné et al., 2003; Hoballah et al., 2004). The volatile profile of caterpillar-damaged maize changes quantitatively over time as individual volatile components are induced at different rates (Turlings et al., 1998). Roughly speaking, “fresh” damage odors rapidly released by mechanical damage (i.e., green leaf volatiles) can be distinguished from “old” damage odors consisting of terpenoids and other compounds slowly synthesized by the attacked plant (Turlings et al., 1998; Hoballah and Turlings, 2005). We intentionally examined old damage odors because these emissions include induced volatiles that are specifically triggered by insect attack rather than mechanical damage. We also asked whether variation in a single volatile component of old damage odors could alter responses to FAW-damaged plants. The monoterpene linalool is a common constituent of floral and foliar odors that is induced in maize seedlings some hours after initial feeding damage (Turlings et al., 1998). Linalool is attractive to *Spodoptera* spp. (Carlsson et al., 1999; Jonsson and Anderson, 1999; Deng et al., 2004) and responded to by receptor neurons of noctuid adults (Jonsson and Anderson, 1999; Malo et al., 2004; Røstelién et al., 2005). Given the similarities in adult and larval odorant binding proteins essential to olfaction reception (Laue, 2000) and the profile of FAW-induced volatiles from maize, we evaluated sixth instar FAW responses to linalool both as an individual volatile and a component of whole plant odors.

Methods and Materials

Plants

We used *Z. mays* var. Golden Queen, a commercially grown sweet corn variety that, like other sweet corn varieties, is frequently attacked by FAW in Florida (Foster, 1989; Nagoshi and Meagher, 2004). Maize seeds were planted in professional growers mix potting soil (Piedmont Pacific, GA, USA) in 4-in. square pots and maintained under ambient greenhouse light supplemented with high-pressure sodium lamps on a 12 hr light/12 hr

dark photoperiod. Supplemental lighting was used from 7:00 AM to 7:00 PM. Eleven to 14-d-old seedlings with 3–4 leaves were used in all experiments.

Insects

Fall armyworms were obtained from a predominantly corn strain colony at Center for Medical, Agricultural, and Veterinary Entomology, U.S. Department of Agriculture-Agricultural Research Service (Gainesville, FL, USA), maintained on a pinto-bean-based artificial diet (King and Leppla, 1984). One of our main concerns was that the larvae obtain sufficient feeding experience on damaged maize before the behavioral bioassays. Previous studies have indicated that prior feeding experience strongly influences both larval orientation and feeding preferences in polyphagous noctuids (Anderson et al., 1995; Carlsson et al., 1999). In preliminary experiments, we noted that naive (pinto-bean-diet-fed) sixth instars had different olfactory preferences toward damaged plants from experienced (maize-fed) sixth instars; however, one night of feeding on maize was sufficient to switch olfactory preferences. To provide larvae with adequate experience, larvae reared on pinto bean diet were transferred at the end of the fifth instar to Golden Queen maize and allowed to feed overnight. Larvae were intentionally placed on maize in sufficient numbers to ensure near total defoliation of host plant material, thereby gaining exposure to heavily damaged plants as might occur at outbreak densities. All larvae were reared at 25°C under a 16 hr light/8 hr dark photoperiod.

Treatment of Herbivore-Damaged Maize Seedlings

To obtain maize seedlings emitting “old” damage odors during the early peak feeding hours of the FAW, each plant was fed upon by 10 sixth instar FAW at 2:00 PM, 6 hr before their use in bioassays or volatile collections later in the evening (8:00 PM). Damage was inflicted under normal light conditions (previously described) to obtain maximal induction of photosynthate-dependent volatiles. Larvae were removed after 60 min to limit both the extent and the time frame of feeding damage.

Plant Volatile Collections

Because FAW is primarily nocturnal in its feeding activity (Miranda-Anaya et al., 2002), all plant volatile collections were conducted at night several hours after initial damage. Collections of volatiles emitted by maize seedlings were conducted in large glass chambers by using an automated volatile collection system (Analytical Research Systems, Gainesville, FL, USA) modified after Heath and Manukian (1994). Sampling was restricted to above-ground plant structures through the use of a guillotine base. An excess of filtered air (1 l/min) relative to the vacuum pull was added to the chamber to ensure that outside air did not contaminate volatile sampling. Volatiles were sampled for 1 hr by pulling air at 300 ml/min over the plants and through a Super Q absorbent filter (80–100 mesh, Alltech Associates, Inc., Deerfield, IL, USA). Volatiles were eluted from the Super Q absorbent with 200 μ l dichloromethane and 400 ng nonyl acetate as an internal standard.

Identification and Quantification of Plant Volatiles

Volatile analysis by positive ion electron impact gas chromatography–mass spectrometry was performed on an HP 6890 gas chromatograph coupled to an HP 5973 MS detector. One μ l of the sample was injected (240°C) onto an Agilent HP-5MS dimethylpolysiloxane

column [30 m × 250 μm (i.d.) × 0.25 μm, Agilent Technologies, Inc., Palo Alto, CA, USA] and separated by temperatures programmed from 35°C (1.0 min hold) to 230°C at 10°C/min. Helium was used as a carrier gas at 1.2 ml/min. Volatiles were identified by comparison of mass spectra with NIST and Department of Chemical Ecology, Gothenburg University (Sweden) mass spectra libraries and retention times with authentic standards.

Quantities of plant volatiles were estimated by using an Agilent 6890 GC coupled to a flame ionization detector (250°C). One microliter of the sample was injected (splitless, 220°C) onto an Agilent DB-1 dimethylpolysiloxane column [15 m × 250 μm (i.d.) × 0.25 μm, Agilent Technologies Inc., Palo Alto, CA, USA] and separated with temperatures programmed from 40°C (0.50 min hold) to 180°C at 12°C/min followed by a 220°C post run (2 min). Helium was used as a carrier gas at 1.2 ml/min.

Y-tube Olfactometer

The olfactory orientation responses of sixth instar FAW to plant and individual volatile odors were evaluated with a y-tube olfactometer. The experimental choice arena consisted of a horizontal glass y-tube (7.5 cm for each arm and base, 15 cm total length, 10 mm i.d., 12.7 mm o.d.; Chemglass, Inc., Vineland, NJ, USA) with different odor sources introduced separately at the distal end of each arm and pulled through the y-tube past the larva by a vacuum line attached at the base. Volatiles were obtained in the airstream by passing prehumidified, carbon-filtered air over the source of the odor. Volatiles were relayed from the distal odor sources to the y-tube arms by 1/4-in. OD corrugated Teflon tubing. Total airflow was maintained and monitored at 150 ml/min through each arm (0.08 km/hr) and 300 ml/min (0.16 km/hr) out of the base of the y-tube by a flowmeter (Aalborg Instruments, Orangeburg, NY, USA)-regulated Tygon vacuum line. To securely connect the glass y-tube to odor source and vacuum lines of differing diameters, rigid Teflon tubing sections of an intermediate diameter were employed as tight-fitting unions. Larvae were prevented from crawling into the odor source lines by a nylon mesh barrier secured between the Teflon union and the glass y-tube. To minimize ambient vibrations that could disturb the larva, each y-tube was secured to a heavy laminate base consisting of white foam board overlaying a brick.

Whole plant odors were sampled by the methods previously described for volatile collection. (–)Linalool (97% pure, Fluka Chemie AG, Buchs, Switzerland) was introduced into the odor source airstream by capillary release, a method that allows for predictable and stable release of a volatile from a capillary tube based on physiochemical characteristics (Weatherston et al., 1985). Appropriate volatile concentrations were obtained by diverting off and diluting (with filtered air) part of a concentrated odor before it entered the y-tube. The odors were filtered through multiple nylon mesh baffles to thoroughly mix the various volatile components before introduction to the y-tube.

Bioassays

Because FAW is primarily nocturnal in its peak-feeding activity (Miranda-Anaya et al., 2002), all bioassays and volatile collections were conducted at night. Early sixth instars that had molted within the previous 24 hr were used in the bioassays. These caterpillars were starved for 2 hr before the bioassay to obtain hungry, but mobile, larvae with feeding experience on damaged maize. We initially encountered problems with larvae that did not respond due to handling or ambient vibrations. To minimize direct handling, larvae were transferred to the olfactometer by using a detached piece of the apparatus. A single larva

was allowed to crawl into the Teflon tube union between the y-tube base and vacuum line, which was reattached in-line. The larva was then given an hour to make a choice between the odors emanating from each arm. Most larvae began moving into the airflow within a few minutes of introduction to the olfactometer. A choice preference for an odor was scored when a larva touched the mesh barrier separating the distal end of the y-tube arm from the odor source line. Larvae that remained completely motionless for 30 min were assumed to be disturbed by handling and were replaced by a new larva in a fresh Teflon tube union. Larvae that moved but did not make a choice within 1 hr were scored as neutral nonresponders and were excluded from the statistical analysis. Few larvae that moved failed to make a choice (<5%)—This low rate probably occurred because the method used to introduce each larva (crawling into a tube) favored actively mobile caterpillars. Up to 10 larvae were run in parallel in separate y-tube olfactometers.

All parts of the y-tube apparatus between the odor source and vacuum line were cleaned or replaced between bioassay trials to remove contaminants. Both the glassware and Teflon parts were thoroughly rinsed with successive washes of acetone, ethanol, ethanol-water, and Milli-Q-filtered water (Millipore, Inc., Billerica, MA, USA) to remove volatiles. Glassware was dried for 1 hr in a 160°C oven while Teflon parts were dried for at least 1 hr in a strong laminar air flow (90 l/min).

Statistics

The preference ratios obtained in the bioassays were compared for departure from a random distribution by a two-tailed binomial exact test. Neutral responses were excluded from the

Fig. 1 Orientation responses of sixth instar *S. frugiperda* to FAW-damaged and undamaged maize seedling odors and clean air controls presented in a y-tube olfactometer. NR—number of neutral or nonresponding larvae that moved but did not score a preference for one of the odor within 1 hr. *, probability of ratio departure from a random distribution, two-tailed binomial exact test (neutral responses excluded)

analyses. Volatile component release rates were compared by a Student's *t*-test (JMP 4.0.4, SAS Institute Inc., Cary, NC, USA).

Results

Sixth instars were strongly attracted to plant odors in the olfactometer bioassays, regardless of damage status (Fig. 1). In a direct comparison, FAW preferred odors from damaged plants over those of undamaged plants (Fig. 1).

In a comparison of volatiles collected from attacked and undamaged plants 6 hr after damage, the major induced compounds were linalool and (3*E*)-4,8-dimethyl-1,3,7-nonatriene (Fig. 2). Among the 13 volatiles quantified, (*E*)-2-hexenal, myrcene, (*Z*)-3-hexenyl acetate, (*E*)- β -ocimene, linalool, (3*E*)-4,8-dimethyl-1,3,7-nonatriene, bergamotene, α -humulene, and (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene were significantly induced (Fig. 2). Other volatiles may be induced at different times after damage. Lipoxygenase products, collectively known as the green leaf volatiles, were not prominently induced at this late time point because their peak induction in maize occurs immediately after damage, then rapidly declines (Turlings et al., 1998; Hoballah and Turlings, 2005).

Damaged plants were fed on for 1 hr by 10 sixth instar FAWs, 5 hr before the onset of scotophase. * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$, NS (not significant) $P > 0.05$ by Student's *t*-test. (1) (*E*)-2-hexenal; (2) (*Z*)-3-hexenyl-ol; (3) β -myrcene; (4) (*Z*)-3-hexenyl acetate; (5) (*E*)- β -ocimene; (6) linalool; (7) (3*E*)-4,8-dimethyl-1,3,7-nonatriene; (8) indole; (9) (*E*)- α -bergamotene; (10) α -humulene; (11) (*E*)- β -farnesene; (12) (*E*)-nerolidol; (13) (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene

Linalool was an olfactory attractant to sixth instars in the olfactometer bioassays. They were attracted to linalool rather than clean air over a broad range of volatile emissions (Fig. 3). When two release rates were presented in the olfactometer, FAW preferred the higher amount (Fig. 3). These results indicate that FAW is capable of discerning between and responding to different aerial concentrations of linalool, such as would be encountered between induced and uninduced plants.

Direct manipulation of an odor source airstream with capillary-released linalool was sufficient to alter, and in some cases, supplant orientation preferences toward whole plant odors. We first evaluated the effect of linalool supplementation on FAW responses to two split-flow airstreams originating from an undamaged plant. FAW did not demonstrate a significant preference for either airstream without supplementation, both sides representing equivalent proportions of emissions from the common source (Fig. 4). By contrast, FAW preferred a linalool-supplemented plant odor rather than an unsupplemented one (Fig. 4). In a direct comparison of odors from an undamaged maize seedling against linalool introduced at release rates equivalent to an undamaged plant, FAW significantly preferred linalool (Fig. 4).

Fig. 3 Orientation responses of sixth instar *S. frugiperda* to linalool and clean air controls presented in a y-tube olfactometer. Linalool release rates (ng/hr) measured for each odor source immediately before the bioassay are given in parentheses. Discussion

The olfactory orientation preferences of sixth instars for linalool over whole undamaged plant odors indicate that a single volatile component can alter preferences toward damaged-plant odors. These preferences could be attributed to attraction to higher amounts of linalool in damaged plants (against undamaged plants) and in the supplemented airstream (against undamaged plants). Our bioassays demonstrated that sixth instars responded favorably to a 10-fold difference in capillary-released linalool concentration (2 ng/hr against 20 ng/hr), of relevance to the average amounts released by undamaged (12 ng/hr) and induced (239 ng/hr) maize seedlings. Our split flow bioassays demonstrate that a preference developed as a result of the addition of an attractant to otherwise equivalent, if already attractive, odor streams. If strong orientation biases for individual volatile components over the plant odor exist, such olfactory preferences could be exploited in trap crop strategies designed to move insects away from valuable crop tissues to expendable plants (Shelton and Badenes-Perez, 2006).

However, linalool is unlikely to be the only volatile from maize seedlings that could evoke behavioral responses in sixth instar FAW, due in part to the role of feeding experience in orientation behaviors of generalist noctuid larvae. Olfactory preferences of polyphagous noctuids, such as FAW, are strongly influenced by exposure to odors during feeding (Anderson et al., 1995; Carlsson et al., 1999; Glendinning, 2002). Experience-based preferences are thought to confer a certain degree of behavioral plasticity on the development of host location

and feeding cues in individual generalist larvae that feed preferentially on specific hosts. Carlsson et al. (1999) demonstrated that either linalool or geraniol could serve as olfactory attractants to third instar *Spodoptera littoralis*, provided that the larvae had previous feeding experience in the presence of the volatile. We contend that while linalool is an olfactory attractant to experienced sixth instars, other induced volatiles may serve a similar role in preferences for damaged maize seedlings and should be evaluated as such in future studies.

Perhaps the most striking aspect of our results is that sixth instars are strongly attracted to herbivore-damaged rather than undamaged host plant odors, despite the disadvantages of association with a damaged host plant (Bolter et al., 1997) and the intensity of density-dependent mortality factors in this species. Like many caterpillars, FAW experiences significantly higher predation rates in association with severely damaged plants (Chapman et al., 2000). Several major parasitoids of FAW have been shown to be specifically attracted to volatiles from caterpillar-damaged maize (Turlings et al., 1995; Gouinguéné et al., 2005; Hoballah and Turlings, 2005). Furthermore, intraspecific competition and conflict are intense in later FAW instars. FAW frequently engages in cannibalism even when food resources are adequate, resulting in an estimated 40% to 60% mortality rate among larvae (Chapman et al., 1999a). Consequently, later instars rarely cohabit in the same leaf whorl and readily attack conspecifics, particularly younger instars. Chapman et al. (1999b) noted that the mere presence of conspecifics reduced larval performance, even when cannibalism was prevented. One consolatory benefit of sixth instar preferences for damaged plants is that asymmetrical encounters between foraging sixth instars and any earlier instar occupying the damage site is likely to favor the older instar (Chapman et al., 1999b; Kakimoto et al., 2003). Otherwise, the advantages of being attracted to a damaged plant when there is an undamaged alternative remain unclear.

One mechanistic constraint that favors attraction to damaged plant odors is the extent of prior feeding experience on attacked plants. Caterpillars feed primarily on attacked plant tissues previously damaged by themselves. Induction of monoterpenes in maize is highly localized to the wounded leaf rather than the whole plant (Turlings and Tumlinson, 1992), so a sixth instar feeding on different leaves experiences repeated inductions of monoterpenes, including linalool, as part of its olfactory experience. Future studies should examine whether plant-reared larvae that are prevented from experiencing induced volatiles (i.e., by frequent movement or use of a mutant host plant deficient in induced volatile responses) prefer herbivore-damaged plants over undamaged plants. Due to their reliance on experience as a mechanism for preference, polyphagous caterpillars such as FAW may fail to realize an optimal choice (orient to a undamaged seedling) because of preferences for more familiar host odors.

Because volatiles of attacked and unattacked Golden Queen maize seedlings vary quantitatively, but not qualitatively, it is not clear whether the observed responses indicate a true orientation preference for damaged plants or simply attraction to a greater source of host volatiles. Orientation to higher amounts of volatile attractants may serve as a mechanism for assessing how close two volatile sources are to the foraging caterpillar, with damaged plants appearing “closer” by virtue of higher volatile output. Other foraging caterpillars use appearance for relative assessment, rather than direct measurement, of distance to select between two competing stimuli. Diurnally foraging caterpillars that orient visually to host plant shapes cannot distinguish between nearby small objects and distant large objects that appear to be of the same size (share the same visual angle; Saxena and Khattar, 1977; Marchand and McNeil, 2004).

Paradoxically, a preference for odors from suboptimal, but detectable, damaged hosts might be a behavioral strategy to cope with the uncertainties of host plant location. Foragers that experience high mortality and costs while searching for ephemeral hosts can be expected to have host-seeking behaviors that emphasize detectability over quality (Ward,

1987; Stamps and Krishnan, 2005; Stamps et al., 2005). In contrast to highly mobile flying adults, the set of potential hosts available to a foraging caterpillar is greatly reduced and widely dispersed due to the “small-scale” search capabilities imposed by the slow speed of crawling (Singer and Stireman, 2001; Stamps et al., 2005). To a foraging caterpillar with limited mobility and search capabilities, the costs encountered with not locating an appropriate host plant may outweigh the risks associated with an induced host plant. Caterpillars searching for a new host plant face mortality from predation, exposure, and starvation as well as sublethal opportunity costs incurred by slow search capabilities and uncertain quality of the new host plant (Sih, 1993; Zalucki et al., 2002; Kaitaniemi et al., 2004). Foraging neonate codling moth *Cydia pomonella* prefer odors from apples damaged by conspecifics over undamaged fruits, in part because damaged fruit release greater amounts of the olfactory attractants, such as α -farnescene, that increase detectability (Landolt et al., 2000). Induced volatiles from an attacked maize seedling may be more apparent, and, therefore, more reliable, olfactory cues for a foraging FAW caterpillar. An emphasis on reliability and detectability at the expense of quality may also explain olfactory preferences for widely produced but relatively nonspecific volatile cues such as linalool by FAW (Stamps and Krishnan, 2005; Stamps et al., 2005). Attraction to induced volatiles may be particularly advantageous to foraging FAWs in the location of host plants that occur in patchy distributions, including agroecosystem and pasture monocultures. Enhanced foraging success may occur directly through perception of the greater aggregate volatile output produced by several neighboring damaged plants, or indirectly through the association of undamaged plants with induced volatile cues from highly detectable herbivore-damaged conspecifics (associational susceptibility; Rodriguez-Saona and Thaler, 2005).

Attraction to a damaged host plant may also be advantageous if the caterpillar can evade some of the consequences associated with induced tissues by feeding away from the damage site. Although our results indicate that sixth instar FAW preferentially orient to the odors of herbivore-damaged plants over undamaged plants, it remains unknown if these preferences hold once the caterpillar locates and comes into contact with the plant. The olfactory preferences reported here may represent a mechanism for host plant location, but not necessarily host acceptance and feeding. Orientation to a distant host plant by definition is restricted to sensory modalities that do not require contact. By contrast, acceptance of a host plant and establishment of a feeding site on a plant involves feeding stimuli received from olfactory, gustatory, and tactile assessment of the tissue (Schoonhoven and van Loon, 2002). Host plant location and acceptance behaviors toward damaged plants are partially decoupled in other lepidopterans. Studies on related noctuid caterpillars in other plants indicate that larvae tend to move away from herbivore-damaged or induced plant tissues, if they move at all on the plant (McAuslane and Alborn, 2000; Anderson et al., 2001). Female *Trichoplusia ni* moths orient toward herbivore-damaged rather than undamaged plants, but preferentially oviposit on undamaged plants when given a choice (Landolt, 1993, 2001). Our preliminary observations indicate that sixth instar FAWs do not display strong preferences for damaged leaves over undamaged leaves when they select an initial feeding site. Such a switch in behavioral responses to damage would be consistent with changes in risk assessment expected for dispersers (Stamps and Krishnan, 2005; Stamps et al., 2005)—Once a host plant is contacted by a foraging caterpillar, the risks associated with host plant location and foraging diminish, leaving only the disadvantages inherent in an herbivore-damaged plant.

Acknowledgments We thank Hans Alborn, Sean Collins, Art Zangerl, and two anonymous reviewers for helpful comments that improved the manuscript. We also thank Julia Meredith, Nancy Lowman, and Valerie McManus for assistance in the maintenance of plants and insects used in this experiment.

Introduction

Iridoids, cyclopentanoid terpenes, are an important group of secondary defensive plant compounds known to deter feeding or decrease growth rates in many generalist insect herbivores (Bowers and Puttick, 1988; Harvey et al., 2005); they are also bitter tasting and have emetic effects on vertebrates (Seigler, 1998). However, iridoids are often feeding stimulants for the larvae of specialist butterfly species. The sequestration of iridoids by these larvae and their subsequent retention during the adult phase (e.g., Bowers, 1991; Dyer, 1995) have been shown to provide larvae with chemical defense mechanisms for deterring generalist predators, such as birds, ants, wasps, and spiders (e.g., Camara, 1997; Theodoratus and Bowers, 1999).

In addition, iridoids have also often been considered as oviposition cues for specialist butterfly species, which can benefit from the negative effects these compounds have on predators and parasitoids (Pereyra and Bowers, 1988). Recently, it was shown that *Plantago lanceolata* plants chosen for oviposition by the specialist butterfly *Melitaea cinxia* have higher concentrations of iridoids than plants not chosen (Nieminen et al., 2003). Although these results may indicate that ovipositing females select plants with the highest iridoid concentrations, it is also possible that it is the act of oviposition that induces iridoid glycoside production (Nieminen et al., 2003). The induction in plants of other chemical defenses—for example, volatile emissions—has been described elsewhere (Hilker et al., 2002, 2005; Colazza et al., 2004). There is also some indication that the production of iridoid glycosides in *Plantago lanceolata* leaves may be induced by herbivory, although the variation in concentrations with leaf age appears to be much greater (Darrow and Bowers, 1997; Stamp and Bowers, 2000).

Our objective was to test the hypothesis that the specialist butterfly *Euphydryas aurinia* (Lepidoptera: Nymphalidae) lays eggs on leaves of *Lonicera implexa* plants with higher iridoid concentrations. We conducted the study in a Mediterranean site under field conditions with naturally occurring egg clusters. We compared iridoid concentrations in leaves with and without eggs from *L. implexa* plants that had been chosen for oviposition with those in leaves of plants with no *E. aurinia* egg clusters.

Methods and Materials

Studied System: Butterflies, Plants, and Experimental Design

Euphydryas aurinia (Lepidoptera: Nymphalinae, Melitaeini) is a univoltine butterfly occurring throughout Europe, temperate Asia, and North Africa (Tolman and Lewington, 1997). In most of northern and central Europe, it is monophagous on *Succisa pratensis* (Dipsacaceae), whereas in the southern part of its range it uses a diversity of hosts, mainly from the families Dipsacaceae (e.g., *S. pratensis*, *Knautia arvensis*, *Scabiosa columbaria*, and *Cephalaria leucantha*) and Caprifoliaceae (*L. implexa* and *Lonicera etrusca*; Mazel, 1986; Kankare et al., 2005). Despite this diversity of hosts, most populations are monophagous on a local scale (Singer et al., 2002). For instance, in Catalonia, most populations from typical Mediterranean habitats (such as the one studied in this article) are monophagous on *L. implexa*.

During the flight period from mid April to early June, females lay large egg batches of about 200–300 eggs on the underside of leaves of *L. implexa*. Larvae hatch in synchronization within 3 wk and spin a large silken web around the leaves, within which

they feed for about 3 wk. Immediately after their third molt, larvae enter diapause within a winter web (usually at the base of the plant) and do not resume feeding until early next spring. Pupation takes place at the end of the sixth instar, normally by the end of March or early April. This life cycle resembles most other Melitaeini butterflies (see Kuussaari et al., 2004 for a comprehensive review).

During the growing season in June 2004, *L. implexa* plants bearing *E. aurinia* egg clusters were searched for in Olesa de Bonesvalls in the Garraf Natural Park (Barcelona province). It was known from previous research that a good population of *E. aurinia* occurs in this area, which is dominated by evergreen oak (*Quercus ilex*) forest and holly oak (*Quercus coccifera*) shrubland. There is also a high density of *L. implexa*, an evergreen climber usually with several shoots that grows either in dense scrub and forests or as an isolated plant in hedgerows and on slopes.

In 2004, the flight period of *E. aurinia* occurred between the second week of May and the second week of June (as assessed by weekly counts following the standard methodology of the Catalan Butterfly Monitoring Scheme; see Stefanescu, 2000). In early June, right at the end of the flight period, we searched for plants of *L. implexa* bearing egg clusters laid by *E. aurinia*. For this purpose, all plants along a 1-km transect were monitored. Previous observations had indicated that females rarely oviposit on plants growing in dense clumps of scrub, and so searching was restricted to plants growing more or less in isolation (e.g., on the edge of paths). In all, 18 plants were investigated, half of which bore egg clusters. The egg masses were between 1 and 2 wk old.

Once an egg cluster was found, half of the leaf bearing the eggs (the half without eggs to avoid damaging the egg batches) was taken. Then, half of the leaf immediately opposite the leaf with the egg cluster was also sampled. In addition, four to five half leaves from the same plant, all with similar morphological traits (age, size, and color) as the leaves with egg clusters but with no signs of oviposition, were also sampled. Likewise, adjacent plants without any oviposition were also sampled.

In the field, we placed the leaf samples in paper bags and then left them in open plastic boxes between sheets of tissue to dry. In the laboratory, we measured the iridoid content of the four groups: leaves from *L. implexa* plants with no oviposition (9 groups), leaves without oviposition from plants with oviposition present (9 groups), leaves with egg clusters from these same plants (9), and the leaves immediately opposite those leaves with egg clusters (9).

Iridoid Analyses

Air-dried leaf samples were ground with a mill, and stored at -27°C until extraction. We used the hot water extraction method described by Suomi et al. (2000) and Nieminen et al. (2003). Five ml of hot water (90°C) were added to 50 mg of ground sample and then placed for 30 min in an ultrasonic bath with temperature control (TRANSSONIC 570H, Elma group, Pforaheim, Germany). Extract solutions were filtered (Millipore, in $0.22\ \mu\text{m}$ nitrocellulose), and the filtered liquid was evaporated with a rotavapor model LABO ROTA B300 (Resona Technics, Gossau, Switzerland). The residue was diluted to 2 ml with water.

Iridoid compounds were detected by combined high-performance liquid chromatography (HPLC)/mass spectrometry (MS) analysis and fully characterized by high-resolution multidimensional nuclear magnetic resonance (NMR) spectroscopy. We used two different HPLC elution modules to establish the experimental elution method and to validate it. We used a WATERS 2695 separation module with temperature furnace with PDA detector WATERS 2996, and an AGILENT 1100 separation module with PDA AGILENT 1100. The

column utilized was a XTERRA MS C185 (4.6 × 100 mm) of WATERS in the two HPLC equipments. On-line filters (of 0.5 μm) were used as precolumns. Twenty-eight different HPLC elution conditions were tested with a reverse phase column. The method that provided the best separation of the eight highest peaks that were present in all analyzed samples had the following elution conditions: The carriers were A (0.1 KH₂PO₄ in water) and B (acetonitrile), the elution process was 0–9 min gradient of 96% A–4% B until 91% A–9% B at 0.8 ml min⁻¹, 9–27 min isocratic 91% A–9% B at 1.2 ml min⁻¹, 27–29 min gradient 91% A–9% B until 25% A–75% B at 1.2 ml min⁻¹, 29–33 min isocratic 96% A–4% B isocratic at 0.8 ml min⁻¹.

All NMR measurements were carried out at 500.13 MHz on a DRX500 BRUKER spectrometer (Bruker Biospin, Rheinstetten Germany) equipped with a 5-mm triple-resonance inverse TXI probe. All data were acquired and processed using the TOPSPIN v1.3 software package (Bruker Biospin). NMR analysis and assignments of complex mixture samples were also performed at 298 K by concerted use of the following modern 2D NMR measurements: 2D ¹H-¹H COSY, 2D ¹H-¹H TOCSY, 2D ¹H-¹H NOESY, 2D ¹H-¹³C HSQC with multiplicity editing, and 2D ¹H-¹³C HMBC. When undesired overlapping effects occurred, chemical shift assignments and coupling constant determinations were individually confirmed by performing the analogous and better-resolved selective 1D NMR measurements. Solvent presaturation techniques were used in all measurements when required to minimize the residual solvent signal.

The iridoid quantification was conducted by using a calibration curve of loganin standard. The loganin standard was injected at 0, 50, 100, 150, 200, 500, and 1000 ppm. We used the mean of four chromatograms for each concentration.

The acetonitrile (Panreac, Barcelona, Spain) was of HPLC grade, while the water was purified on a Milli-Q system from Millipore (Bedford, MA, USA). The KH₂PO₄ was purchased from Fluka (Buchs, Switzerland). All solvents were previously filtered through a 0.45 μm filter (Millipore, Bedford, MA, USA). Loganin standards were purchased at Extrasynthesis (Genay, France). Secologanin was purchased at Phytoconsult (Gorlaens Lab., Leiden, The Netherlands).

Statistical Analyses

We used independent and paired *t*-tests, one way ANOVAs, and Bonferroni *post hoc* tests (Statistica, StatSoft Inc., Tulsa, OK, USA) to compare the leaf iridoids of the different groups of leaves (9 leaves with egg clusters, 9 leaves directly opposite the previous ones, 9 groups of leaves with no egg clusters from plants with oviposition, and 9 groups of leaves from plants without oviposition).

Results and Discussion

We detected eight different iridoids in the sampled plants (Fig. 1), of which secoxyloganic, loganic, and, above all, secologanic acids were the most abundant (Figs. 1 and 2).

Iridoid concentrations in the leaves of plants with no oviposition (1.00% dry weight ± 0.11 S.E.) and in leaves without oviposition from plants with oviposition (2.2% dry weight ± 1.52 S.E.) were in the range previously described from Finland and the United States in other studies of related plant species [aucubin concentration 1.6–2.7% in Bowers (1991), 0.5–5% in Darrow and Bowers (1997), or 0.6–2.2% in Nieminen et al. (2003); catalpol concentrations 0.4–3.6% in Bowers (1991), 0.2–2.2% in Darrow and Bowers (1997), 0.7–2.0% in Nieminen et al. (2003), or 0.01–1.41% in Willinger and Dobler (2001)].

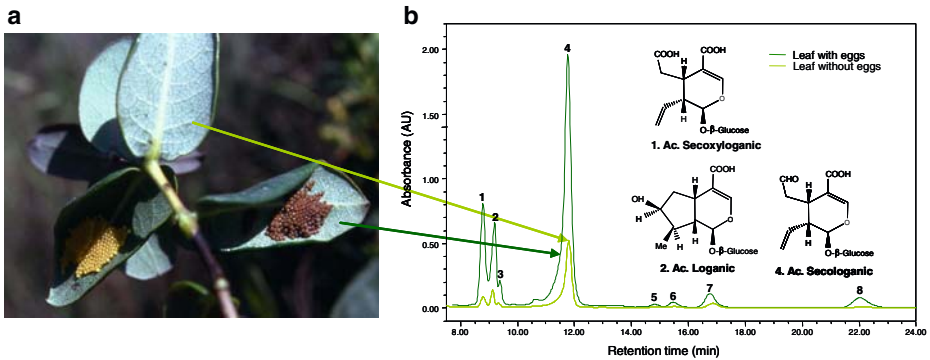

Fig. 1 Increased iridoid concentrations in *L. implexa* leaves used for oviposition by the butterfly *E. aurinia*. The picture (a) shows 1-wk-old (light) and 2-wk-old (dark) egg clusters. The HPLC chromatograms (b) were obtained from foliar hot water extracts

The leaves with oviposition, however, had mean concentrations of all eight detected iridoids that were on average 15 times higher than those found in the leaves without oviposition from the same plant (including the leaves directly opposite those with oviposition and leaves from neighboring plants with no oviposition; $P < 0.05$, Student's *t*-test; Figs. 2 and 3).

The lack of any significant differences in iridoid glycoside concentrations between leaves from plants that did not receive any eggs and the unused leaves from plants receiving eggs (Figs. 2 and 3) would seem to indicate that *E. aurinia* butterflies do not choose plants for oviposition according to their iridoid content.

Nevertheless, *E. aurinia* butterflies might choose the leaves of a plant with the highest iridoid concentrations, although it is highly unlikely that this huge 15-fold difference in iridoid concentrations between leaves with oviposition and leaves directly opposite without oviposition on the same stem—which are clearly out of the common range (Bowers, 1991; Darrow and Bowers, 1997; Willinger and Dobler, 2001; Nieminen et al., 2003)—can be explained by any other process than that of the stimulation of iridoid production by oviposition. Previous studies have also reported plant responses to egg deposition, which include volatile emissions (Colazza et al., 2004; Hilker et al., 2005) and changes in photosynthesis rates (Schroeder et al., 2005).

Further studies are needed to discern how eggs or oviposition signal a leaf to increase its iridoid production; in other words, we need to identify the elicitors responsible for the apparently oviposition-induced change or at least to find out what the kinetics are that are operating behind the changes in iridoid content that occur after oviposition.

Whatever the mechanism, leaves with oviposition were full of defenses (15% leaf dry weight) that might be used by hatching larvae, because iridoids have been shown to be sequestered by caterpillars in other *Euphydryas* species and to act as a chemical defense against natural enemies (e.g., Bowers, 1980, 1981; Bowers and Puttick, 1986; Stermitz et al., 1986, 1994; Franke et al., 1987; Gardner and Stermitz, 1988; Belofsky et al., 1989; L'Empereur and Stermitz, 1990). First instars are the most prone to be attacked by the summer generations of specialist parasitoids such as *Cotesia melitaeorum* and *C. bignellii* (M. R. Shaw, S. van Nouhuys and C. Stefanescu, pers. obs.), which may cause important mortality rates in butterfly populations (Porter, 1983). These parasitoids, however, seem to avoid or perform poorly in host larvae in other Melitaeini species with high iridoid contents

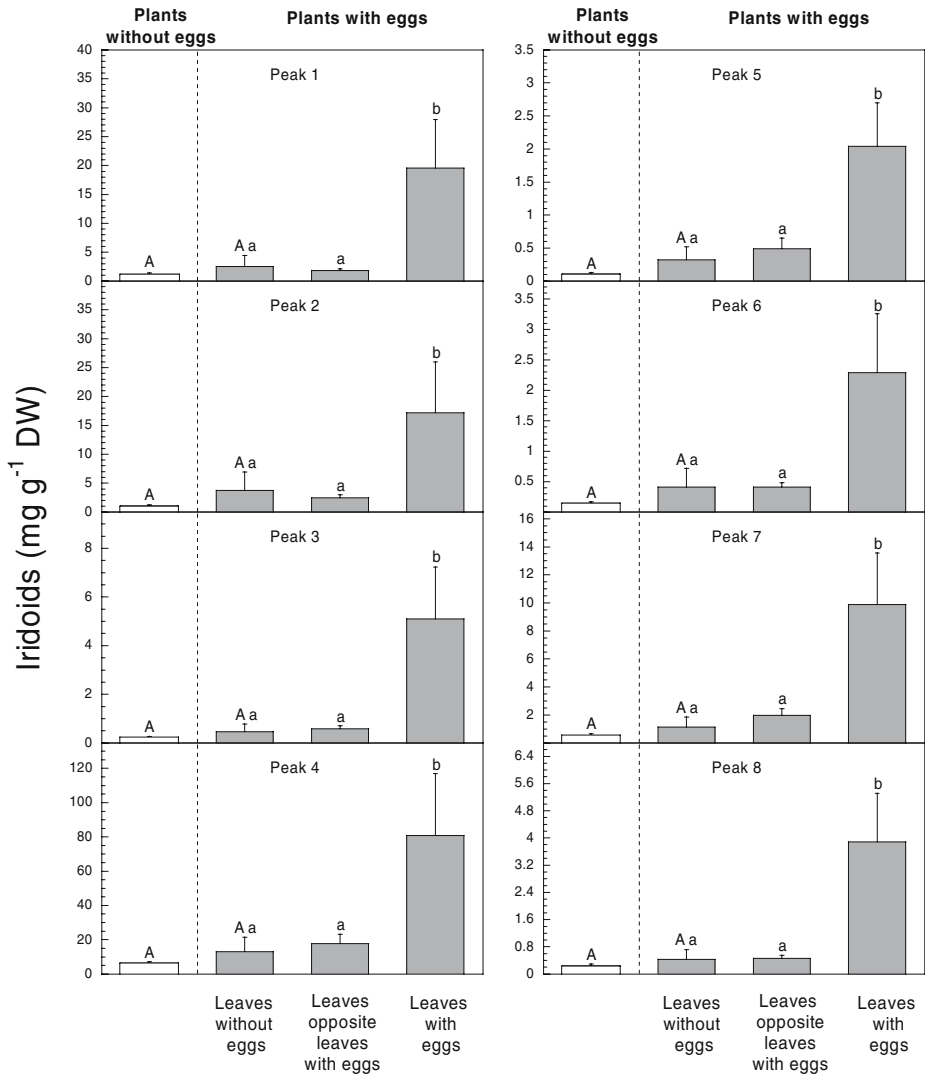

Fig. 2 Concentrations of the different iridoids [the most abundant were fully characterized by high-resolution multidimensional NMR spectroscopy, secoxyloganic (peak 1), loganic (peak 2), and secologanic (peak 4) acids; mean + S.E., $N = 9$] found in *L. implexa* plants with no egg clusters and in leaves with and without egg clusters from plants with oviposition by *E. aurinia*. The letters a and b above the bars indicate statistically significant differences ($P < 0.05$, paired *t*-test) between leaves from the same plants with and without eggs. The capital letter A indicates statistically nonsignificant differences ($P > 0.05$, *t*-test) between plants with and without egg clusters

(Nieminen et al., 2003). Because specialist herbivores seem to be able to sequester secondary compounds from their host plants and incorporate them in their own defense systems, the results presented here may mean that herbivores are able to change their hosts' physiology to make them more suitable for their own defensive purposes. Further studies are needed to assess whether any of the iridoids found in *L. implexa* are actually sequestered by *E. aurinia* larvae, especially in light of Bowers and Williams' (1995)

Fig. 3 Total iridoid concentrations (mean + S.E., $N = 9$) in *L. implexa* plants with no oviposition and in leaves with and without egg clusters from plants with egg clusters. The letters a and b above the bars indicate statistically significant differences ($P < 0.05$, paired *t*-test) between leaves with and without eggs from the same plants. The capital letter A indicates statistically nonsignificant differences ($P > 0.05$, *t*-test) between plants with oviposition and plants without

findings that larvae of *E. gillettii* feeding on another *Lonicera* species were unable to sequester its secoiridoids.

In any case, there are other possible positive effects of the huge amounts of iridoids in leaves with egg clusters. Even if they do not sequester the toxin, larvae could benefit from the host's defense mechanisms by using a leaf that will not be used by generalist herbivores; that is, they would avoid competition for food by using a toxic host.

There are also, however, possible negative effects for the specialist butterfly *E. aurinia*. It is possible that this leaf response—an extremely high and localized production of iridoids—is specifically in response to *E. aurinia*, although it is a specialist on the plant. Iridoid levels must be reached at some point that are too much even for specialist herbivores and will overcome their sequestration capacity and their toxin tolerance capacity. If defenses against generalists are used against a specialist, it will not be cost-effective for the plant to have systemic response mechanisms, and so responses may be only local. This was what we found. Although, the iridoid contents of leaves without oviposition from plants with oviposition tended to be greater than those of leaves from plants with no oviposition, thereby providing a slight indication of systemic reaction (Figs. 2 and 3), as reported, for example, in the induction of plant synomones after oviposition by a phytophagous insect (Meiners and Hilker, 2000), the differences were small and statistically not significant.

Like all plant secondary compounds (e.g., Bowers et al., 1992; Herms and Mattson, 1992; Adler et al., 1995; Peñuelas and Estiarte, 1998), iridoid presence and concentrations often vary considerably in space and time between leaves, plants, and populations in accordance with genetic, developmental, and environmental drivers such as time of day, weather, and soil nutrient conditions (e.g., Teramura, 1983; Bowers et al., 1992; Adler et al., 1995; Darrow and Bowers, 1997; Seigler, 1998; Marak et al., 2000). These results show that oviposition may also be a strong driver of increased foliar iridoid concentrations.

In summary, these results show that *L. implexa* leaves bearing egg clusters had dramatically greater (over 15-fold) concentrations of iridoid glycosides than directly opposite leaves on the same plant and leaves on plants that bore no eggs. These huge and localized foliar iridoid concentrations were likely the result of a plant response to egg deposition. Further studies are needed to definitively prove the induction, to elucidate the elicitor mechanism of the increased production, to check the possible sequestration of iridoids by the larvae, to study the responses of the herbivore predators to this possible

sequestration, and to figure out whether such huge amounts of iridoids are beneficial or not to herbivores.

Acknowledgments This research was partly supported by grants REN2003-04871 and CGL2004-01402/BOS from the Spanish Government, ISONET (Marie Curie network contract MC-RTN-CT-2003-504720) from the European Union, SGR2005-00312 from the Catalan government, and Fundación BBVA-2004. We would like to thank Sergi Herrando and David Requena for their help with the field work.

take the seeds to sites with improved conditions for germination and survival (Andersen, 1988; Bond et al., 1991; Espadaler and Gomez, 1996, 1997). Within the ant nest, seeds may be protected from fire and predators (Handel and Beattie, 1990; Bond et al., 1991; Christian and Stanton, 2004).

However, not all ants that carry seeds are plant mutualists. Granivorous ants take a wide range of seeds and consume the majority, although they may have a minor dispersal role by dropping some seeds (Hulme, 2002; Retana et al., 2004). Granivores tend to have a specialized seed diet (Hölldobler and Wilson, 1990), while mutualistic ants are generally scavengers with a predominantly invertebrate diet (e.g., *Myrmica*, *Formica*, *Lasius*) and collect only seeds with an elaiosome, which they remove and leave the seed unharmed (Hölldobler and Wilson, 1990; Gomez and Espadaler, 1998).

Thus, elaiosomes are a specific adaptation that facilitates non-predatory seed dispersal. A wide variety of tropical and temperate plants are myrmecochores (i.e., have an elaiosome)—currently 2100–3000 species in 60–80 families (Brew et al., 1989; Hughes and Westoby, 1992; Gomez and Espadaler, 1998)—and four of the seven ant families distribute seeds (Beattie, 1991). Elaiosomes are usually white or yellow appendages on the seed coat (Marshall et al., 1979) and are nutrient-rich, containing lipids, proteins, starch, sugars, vitamins (Kusmenoglu et al., 1989; Beattie, 1991; Lanza et al., 1992; Ohkawara et al., 1997), and essential nutrients that cannot be synthesized by ants, such as linoleic acid and sterols (Gammans et al., 2005).

Many studies have concluded that the elaiosome alone attracts mutualistic ants and induces them to carry the seed. Seeds with the elaiosome removed are often ignored in comparison with intact seeds or separated elaiosomes (Kjellsson, 1985; Skidmore and Heithaus, 1988; Brew et al., 1989). However, the mechanism by which the elaiosome affects ant behavior is not well understood. One hypothesis is that ants are responding simply to a food stimulus (Brew et al., 1989), but the chemical behavior-releaser hypothesis proposes that one or more chemical compounds from the elaiosome induces seed-carrying behavior (Sheridan et al., 1996). Several studies have suggested that this chemical inducer may be the fatty acid oleic acid or the diglyceride 1,2-diolein (Wilson et al., 1958; Marshall et al., 1979; Gordon, 1983; Skidmore and Heithaus, 1988; Brew et al., 1989; Kusmenoglu et al., 1989; Lanza et al., 1992; Table 1). For example, Marshall et al. (1979) investigated the interaction between the ant *Aphaenogaster rudis* and the plant *Viola odorata*. Ants were found to react most strongly to lipid fractions in bioassays, and further fractionation of lipids into fatty acids, sterols, and diglycerides showed that the last induced the greatest reaction from *Aphaenogaster*. An alternative hypothesis to chemical cues is that the brightly colored elaiosome acts as a visual attractant (Davidson and Morton, 1981), but this has not been tested.

In general, studies of elaiosome attraction of ants have not differentiated between granivorous and mutualistic ants. In fact, certain ant species tested, such as *Pogonomyrmex*, *Pheidole*, *Rhytidoponera*, and *Messor* (see Rice and Westoby, 1986; Gomez and Espadaler, 1998), are usually seed eaters. If elaiosomes attract all ants equally, there is clearly a trade-off between the benefit of attracting mutualists and the disadvantage of attracting predators. There should be a selective advantage in being able to attract only mutualists. However, there has been no comparison of the attractiveness of elaiosome chemicals to mutualistic vs. granivorous ants.

Myrmica ruginodis is a mutualistic disperser of a wide range of myrmecochores (Kjellsson, 1985; Mark and Olesen, 1996; Heinken, 2004), including *Ulex* species on European lowland heaths (Stokes et al., 2003; Gammans et al., 2005). *Tetramorium*

caespitum is a granivore that eats seeds of many plants including *Ulex* spp. (Brian, 1977; Skinner, 1987). In this article, we used laboratory colonies of *M. ruginodis* and *T. caespitum* to test the following hypotheses. (1) Chemicals on the surface of the elaiosome attract the mutualist *M. ruginodis* to the seed, but the granivore *T. caespitum* does not respond to these chemical cues. (2) *M. ruginodis* responds most strongly to the diglyceride fraction. (3) The yellow elaiosome on *Ulex* seeds is a visual cue for *M. ruginodis*. Our expectation was that patterns of response of either *M. ruginodis* or *T. caespitum* to elaiosome chemical extracts should be similar for both *Ulex* species.

Methods and Materials

Study Species

In southern England, *Ulex minor* produces seeds from the end of May for approximately 2 wk and *U. europaeus* from the middle of June until the end of July. The seeds are ejected explosively from pods that contain one to two (*U. minor*) or three to six (*U. europaeus*) seeds. Ants collect the seeds where they fall. *U. minor* seed length without the elaiosome is 2.0 ± 0.1 mm (mean \pm S.E.). The elaiosome length is 1.2 ± 0.1 mm. *U. europaeus* seeds are slightly longer, 2.2 ± 0.1 mm, and the elaiosome is 1.2 ± 0.1 mm.

Myrmica ruginodis is a red ant 3–6 mm in length that forms polygynous (multiple queen) colonies with between 18 and 6560 workers (Wardlaw and Elmes, 1996). *Myrmica* species are generally scavengers with ~80–90% of their diet made up of homopterans, hemipterans, dipterans, and arachnids, but they are also known to collect plant matter (Brian, 1977). In heathland habitats, nests of *M. ruginodis* are found under small heather (*Calluna*, *Erica*) or gorse (*Ulex*) bushes, and they forage in close proximity to *Ulex* species

(Gammans et al., 2005). In contrast, *T. caespitum* eats seeds of grasses, *Calluna vulgaris*, *Erica cinerea*, and *Ulex* spp. on English heaths, although it will occasionally eat insect prey (Brian, 1977). It is a small black ant, typically 2–3 mm in length, which forms colonies of up to a few thousand workers (Skinner, 1987) in open habitats on southern English heaths (Brian, 1964).

Collection of Study Species

In 2004, ripe seed pods of *U. minor* and *U. europaeus* were collected from three heathland sites in the county of Dorset, southern England. Seed pods were stored in paper bags at 4°C. Seeds were extracted when needed. During March 2004, seven *M. ruginodis* colonies were collected from four Dorset heathlands. These colonies were split to form 40 laboratory nests comprising 50 workers and ~20 larvae. Larvae were added to all nests to encourage the workers to forage for food. Each nest was placed into a nest box of 22 × 22 × 10 cm, which was attached to another smaller “foraging box” of 7 × 7 × 4 cm by a 20-cm-long plastic tube. Six *T. caespitum* colonies were collected from four heathlands in Dorset. Thirty laboratory nests (50 workers with 20 larvae) were set up in the same way, except that the boxes were slightly smaller at 12 × 8 × 2 cm and 7 × 4 × 2 cm, due to the smaller size of this species.

All colonies were fed each week with a standard diet of white sugar and *Drosophila melanogaster* larvae placed into the foraging box, and were watered regularly (Brian and Abbott, 1977; Elmes et al., 2004; Gammans et al., 2005). All colonies survived the experiment and there was a low mortality of ants, similar to other studies (Wardlaw et al., 1998; Gammans et al., 2005).

Standard Procedure for Laboratory Bioassays

All colonies were allowed to habituate to the laboratory nests for 1 wk before the first bioassays. Nests were selected at random, and each nest was used only once in each set of bioassays. When no bioassays were conducted, ants were allowed to roam freely between the nest and foraging boxes. Before each bioassay, any remaining food was removed from the foraging box, which was then cleaned with water to remove any food residue and any possible pheromone trails. Any ants within the foraging box were removed except for a randomly chosen “focus” ant, which was allowed to settle, and the foraging tube was then closed. If the focus ant left the foraging box during the bioassay, the foraging tube was opened and remained so until a new ant entered under its own volition. If no ant was present in the foraging box at the start of the experiment, the tube was left open until an ant entered. This procedure minimized disturbance and ensured that the workers observed were active foragers.

During bioassays, seeds, elaiosomes, or filter paper with chemical extracts were always handled with sterile forceps to prevent contamination. The lid of the foraging box was kept open during the bioassay to prevent build up of any volatile compounds.

Bioassays were conducted during times of day when both ant species normally forage; for *M. ruginodis* 06:00–12:00 and for *T. caespitum* 12:00–18:00 hr. Experiments were conducted with *U. minor* from May 26 to July 9, 2004, and with *U. europaeus* from July 12 to August 2, 2004. Although this approach meant that bioassays were conducted on the two *Ulex* species at different times of the year, it was preferred to ensure that seeds were as fresh as possible for the bioassays. Data analysis reflected this lack of randomization by analyzing results for the two *Ulex* species separately.

Ant Responses to Seeds, Elaiosomes and Diaspores

Bioassays were carried out to assess ant responses to diaspores, separate elaiosomes, and seeds from which the elaiosome had been removed. Three of each “treatment” (diaspore, elaiosome, or seed) were placed into a foraging box, and the number removed to the nest box was counted after 24 hr. Each treatment was replicated in 20 nests for each ant species.

Ant Behavior Toward Diaspore Surface Compounds

Further bioassays were done using extracts of elaiosome chemicals on filter papers. The surface chemicals of 90 *U. minor* or *U. europaeus* diaspores (seed plus elaiosome) were extracted by immersion in diethyl ether for 8 hr. When required, the extract was added to filter paper squares of 2–3 mm, which were then left overnight at room temperature to allow the ether to evaporate. Filter paper was used as the substrate to test reaction to chemical extracts on an object that did not resemble a diaspore. The amount of extract added was equivalent to one diaspore. Control paper squares were immersed in diethyl ether, and then left overnight to allow evaporation. Three control or extract filter paper squares were placed into the foraging boxes of randomly selected nests with only one treatment used per nest. Fifteen colonies were given the extract and 15 the control. Ant behavior was recorded for a period of 20 min. Four distinct ant behaviors were recorded as follows: (1) ignore: the ant paid no attention to the filter paper; (2) antennate: the ant touched the filter paper with its antennae; (3) bite: the ant bit the filter paper with its mandibles; (4) carry: the ant carried the filter paper in its mandibles. We also noted the time between the start of the bioassay and the first antennation of the filter paper. In preliminary experiments, it was noticed that the focus ant would repeat behaviors, especially when showing interest in the filter paper, but might then ignore it for some time, before returning and showing renewed interest. Repetition of behaviors also occurred when a focus ant was replaced by another. Therefore, the total time spent (to the nearest second) and the number of repetitions of all four behaviors was recorded.

Lipid Fractions from Elaiosome Extracts

For each *Ulex* species, 70 elaiosomes were removed from the diaspore and slightly macerated and submerged for 24 hr in 3 ml of chloroform to separate the different lipid fractions of the elaiosomes. The lipid fractions of these extracts were separated with solid phase extraction (1 ml SPE NH₂; Qmx) using the standard methodology described by Kalunzy et al. (1985). Solvents were used in the following sequence: 15% ethyl acetate in hexane to separate diglycerides; hexane for cholesterol esters; 2:1 chloroform/methanol for monoglycerides; 1% diethyl ether in 10% methanol in hexane for triglycerides; 5% ethyl acetate in hexane for cholesterol; a second elution with 5% ethyl acetate in hexane for residual cholesterol; 2% acetic acid in diethyl ether fatty acids; and methanol for phospholipids. The eluent from each wash was stored at –20°C until use in bioassays. The diglyceride fraction (to which *M. ruginodis* reacted) for *U. minor* was sent to the MRS Lipid Analysis Unit in Dundee for quantitative analysis.

For all bioassays, a volume of the lipid fraction equivalent to one elaiosome was added to a filter paper square, and the respective solvent used in the fractionation was added to filter paper as a control. Both sets of papers were left overnight at room temperature to allow the solvent to evaporate. As before, three filter papers of either treatment or control (only one treatment used per nest) were then placed into the foraging box of a randomly selected nest. Thirty nests were used for each ant species; half were given the extract and half the control. All replicates and controls for

each particular fraction were run consecutively. The different fractions were used in random order. The behavior of the focus ant was recorded for 20 min using the protocol described above.

Visual Cues

An experiment was designed to investigate whether visual cues are used by *M. ruginodis* when finding *Ulex* diaspores. *U. minor* diaspores ($N = 270$) were submerged in diethyl ether for 8 hr to remove any surface chemicals. In sets of 30 diaspores, the elaiosomes were painted different colors with nontoxic acrylic paint: brown, yellow, green, red, and blue; one set was left unpainted. A further 30 diaspores were also used without the surface chemicals removed. Three diaspores per color were placed into 10 randomly chosen nests (some nests were repeated), and ant behavior was recorded for 20 min using the protocol described above. Diaspores were left in the foraging arena, and their final location was recorded after 24 hr.

Analysis

All results were analyzed with the Minitab statistical package by using analysis of variance ANOVA where the data were normally distributed. Some data sets had many zero values and remained nonnormally distributed after transformation. These data sets were analyzed by Kruskal–Wallis tests. Treatments and, where relevant, ant species were included as factors in the analyses, with a fully randomized design. Because the *Ulex* species were subjected to bioassays on different dates, they were analyzed separately.

Results

Ant Responses to Diaspores, Seeds and Elaiosomes

The ant *M. ruginodis* moved more elaiosomes (58%; i.e., proportion of the three elaiosomes removed across 20 replicates) than diaspores (18%), and moved seeds without diaspores the

Table 2 Behavioral responses (mean \pm S.E.) of *M. ruginodis* and *T. caespitum* ants to elaiosome surface chemical extracts of two *Ulex* species

Ant species	Plant species	Treatment	Time till antennation (sec)	Duration of antennation (sec)	Number of antennations
<i>M. ruginodis</i>	<i>U. minor</i>	Control	184 \pm 194	1.3 \pm 3.5	1.0 \pm 0.4
		Extract	36 \pm 40 $F_{1,12} = 0.97$ nsd	9.3 \pm 0.6 $F_{1,12} = 30.25^{***}$	7.0 \pm 4.3 $F_{1,12} = 12.81^{**}$
<i>T. caespitum</i>	<i>U. minor</i>	Control	91 \pm 26	24 \pm 20	2.6 \pm 0.6
		Extract	211 \pm 53 $F_{1,24} = 3.35$ nsd	4.0 \pm 1.4 $F_{1,28} = 0.99$ nsd	2.9 \pm 0.6 $F_{1,28} = 0.15$ nsd
<i>M. ruginodis</i>	<i>U. europaeus</i>	Control	188 \pm 62	2.7 \pm 0.8	2.1 \pm 1.2
		Extract	44 \pm 19 $F_{1,15} = 6.67^*$	7.1 \pm 1.7 $F_{1,15} = 4.21$ nsd	4.9 \pm 1.1 $F_{1,15} = 4.90^*$

nsd $P > 0.05$, $***P < 0.001$, $**P < 0.01$, $*P < 0.05$. The difference in degrees of freedom reflects the number of times a focal ant was present during the experiment.

least (6%), while the respective percentages for *T. caespitum* were 30%, 8%, and 5%. Therefore, while the strong preference of both species for elaiosomes led to a treatment effect ($F_{2,108} = 29, P < 0.001$), the preference of *M. ruginodis* for diaspores over seeds compared with the relative lack of distinction between the diaspore and seed-only treatments by *T. caespitum* led to an ant species \times treatment interaction ($F_{2,108} = 3.2, P < 0.05$).

Surface Compounds

The major response of ants to filter papers involved antennation. The biting and movement of papers was rare, so the data were not analyzed. ANOVA indicated that *M. ruginodis* antennated the filter papers containing the surface extract for longer and for a greater number of times than the control for both *Ulex* species, although time till first antennation was significantly different between treatments only for *U. europaeus* (Table 2). *T. caespitum* showed no difference in any behavior in response to the extracts of either *Ulex* species (Table 2).

Table 3 *M. ruginodis* and *T. caespitum* behaviors toward the lipid fractions of *U. minor* elaiosomes

Ant species	Solvent vs. lipid fraction	Number of antennations	Duration of antennation	Time until first antennation
<i>M. ruginodis</i>	15% Ethyl acetate in hexane vs. <u>diglyceride</u>	$F_{1,15} = 32.3^{***}$	$F_{1,15} = 13.5^{**}$	$F_{1,13} = 8.4^*$

<i>T. caespitum</i>	Methanol vs. phospholipid	$F_{1,17} = 4.2$ nsd	$F_{1,18} = 4.2$ nsd	$F_{1,9} = 3.7$ nsd

nsd $P > 0.05$, $***P < 0.001$, $**P < 0.01$, $*P < 0.05$. Where behaviors toward the control and lipid fraction were significantly different (in bold), the underlined chemical is that to which the ants responded most strongly. The differences in degrees of freedom reflect the number of times a focal ant was present during the experiment.

Lipid Fractions from Elaiosome Extracts

Sixteen analyses (i.e., eight fractions \times two *Ulex* species) were performed on the data from the lipid fraction experiments for each behavior of each ant species. A 5% significance threshold means $16/20 = 0.8$ tests on average would be significant by chance. However, if the behavioral responses toward a particular fraction are consistent, and biologically meaningful, one would expect an ant species to show responses to a fraction that is similar for the two *Ulex* species. Tests on the two *Ulex* species were independent, and the probability of significant response in terms of a particular behavior to the same fraction of both *Ulex* species is $8/20$ (probability of one test in eight being significant at 5%) \times $1/20$ (probability of the same fraction in the second *Ulex* species having a significant effect at 5%) = 2%.

The comparison of *M. ruginodis* behaviors toward each lipid fraction and its solvent revealed that the only fraction that caused significantly greater reactions than its solvent was

Table 4 *M. ruginodis* and *T. caespitum* behaviors toward the lipid fractions of *U. europaeus* elaiosomes

Ant species	Solvent vs. lipid fraction	Number of antennations	Duration of antennation	Time until first antennation
<i>M. ruginodis</i>	15% Ethyl acetate in hexane vs. <u>diglyceride</u>	$F_{1,9} = 7.6^*$	$F_{1,9} = 13.0^{**}$	$F_{1,9} = 0.9$ nsd
<i>M. ruginodis</i>	<u>Hexane</u> vs. cholesterol ester	$F_{1,14} = 4.2$ nsd	$F_{1,14} = 4.8^*$	$F_{1,14} = 1.4$ nsd
<i>M. ruginodis</i>	2:1 Chloroform:methanol vs. monoglyceride	$F_{1,22} = 2.8$ nsd	$F_{1,22} = 3.5$ nsd	$F_{1,22} = 0.9$ nsd
<i>M. ruginodis</i>	1% Diethyl ether in 10% methanol in hexane vs. triglyceride	$F_{1,8} = 2.2$ nsd	$F_{1,8} = 2.0$ nsd	$F_{1,8} = 0.2$ nsd
<i>M. ruginodis</i>	5% Ethyl acetate in hexane vs. cholesterol residual	$F_{1,12} = 2.5$ nsd	$F_{1,12} = 0.1$ nsd	$F_{1,12} = 0.3$ nsd
<i>M. ruginodis</i>	5% Ethyl acetate in hexane vs. cholesterol	$F_{1,8} = 1.7$ nsd	$F_{1,8} = 2.0$ nsd	$F_{1,8} = 2.2$ nsd
<i>M. ruginodis</i>	2% Acetic acid in diethyl ether vs. fatty acid	$F_{1,14} < 0.01$ nsd	$F_{1,14} = 0.01$ nsd	$F_{1,14} = 0.9$ nsd
<i>M. ruginodis</i>	Methanol vs. phospholipid	$F_{1,13} = 0.05$ nsd	$F_{1,13} = 0.08$ nsd	$F_{1,13} = 0.6$ nsd
<i>T. caespitum</i>	15% Ethyl acetate in hexane vs. diglyceride	$F_{1,18} = 1.0$ nsd	$F_{1,18} = 2.2$ nsd	$F_{1,18} = 1.1$ nsd
<i>T. caespitum</i>	Hexane vs. cholesterol ester	$F_{1,28} = 1.8$ nsd	$F_{1,28} = 3.0$ nsd	$F_{1,28} = 1.7$ nsd
<i>T. caespitum</i>	2:1 Chloroform/methanol vs. monoglyceride	$F_{1,22} = 2.8$ nsd	$F_{1,22} = 3.5$ nsd	$F_{1,22} = 0.9$ nsd
<i>T. caespitum</i>	1% Diethyl ether 10% methanol in hexane vs. triglyceride	$F_{1,28} = 2.3$ nsd	$F_{1,28} = 1.1$ nsd	$F_{1,28} = 2.2$ nsd
<i>T. caespitum</i>	5% Ethyl acetate in hexane vs. cholesterol residuals	$F_{1,24} = 0.6$ nsd	$F_{1,24} = 0.05$ nsd	$F_{1,24} = 1.6$ nsd
<i>T. caespitum</i>	5% Ethyl acetate in hexane vs. cholesterol	$F_{1,23} = 0.2$ nsd	$F_{1,23} = 0.3$ nsd	$F_{1,23} = 1.9$ nsd
<i>T. caespitum</i>	2% Acetic acid in diethyl ether vs. fatty acid	$F_{1,21} = 2.5$ nsd	$F_{1,21} = 2.0$ nsd	$F_{1,21} = 4.2$ nsd
<i>T. caespitum</i>	Methanol vs. phospholipid	$F_{1,22} = 0.3$ nsd	$F_{1,22} = 0.7$ nsd	$F_{1,22} = 0.3$ nsd

nsd $P > 0.05$, $***P < 0.001$, $**P < 0.01$, $*P < 0.05$. Where behaviors toward the control and lipid fraction were significantly different (in bold), the underlined chemical is that which the ants responded to most strongly. The differences in degrees of freedom reflect the number of times a focal ant was present during the experiment.

Table 5 The fatty acid composition of the diglyceride fraction of *U. minor* elaiosomes

Fatty acid	Proportion of total fatty acids (%)
Hexadecadienoic acid (C 16:2)	24.87
Stearic acid (C 18:0)	22.59
Arachidic acid (C 20:0)	21.89
Palmitic acid (C 16:0)	13.49
Oleic acid (n-9; C 18:1)	5.77
Linoleic acid (C 18:2)	3.85
Palmitoleic acid (C 16:2)	2.98
Myristic acid (C 14:0)	1.93
Margaric acid (C 17:0)	1.58
Oleic acid (n-7; C 18:1)	1.05

the diglyceride fraction for both *Ulex* species. The number (*U. minor* extract mean = 4.5, control mean = 0.9; *U. europaeus* extract = 8.0, control = 2.0) and duration (*U. minor* extract = 7 sec, control = 0.9 sec; *U. europaeus* extract = 16.2 sec, control = 3.7 sec) of antennations were greater for both *Ulex* species, and the time till first antennation was faster for *U. minor* (extract = 127 sec, control = 446 sec; Tables 3 and 4). For *U. europaeus*, the hexane solvent was also antennated for significantly longer than the cholesterol ester fraction (Table 4).

Unlike *M. ruginodis*, *T. caespitum* did not show a changed behavior toward the diglyceride fraction (Tables 3 and 4) and there were no significant difference among any fractions and their solvents for *U. europaeus* (Table 4). Comparing the *U. minor* fractions with controls, the time until first antennation was significantly faster for the triglyceride fraction (extract mean = 205 sec, control mean = 734 sec), the cholesterol residual was antennated for a greater duration (extract = 5 sec, control = 0.4 sec) and frequency (extract = 2.7, control = 0.4), and the cholesterol fraction was antennated more times than its solvent (extract = 3, control = 0.4; Table 3).

According to the argument above, the responses of *M. ruginodis* to the diglyceride were greater than expected by chance. However, the *T. caespitum* responses were unconvincing, being inconsistent across the two *Ulex* species and, on average, only slightly more frequent than expected by chance.

The main constituents of the diglyceride fraction were hexadecadienoic acid, stearic acid, and arachidic acid. Oleic acid was present but in small amounts (Table 5).

Visual Cues

ANOVA and Kruskal–Wallis tests showed significant differences in all behaviors of *M. ruginodis* among the five artificial elaiosome colors, the diaspore with surface chemicals removed, and the unaltered diaspore (Table 6). Comparison of means suggested that the unaltered diaspore was more attractive than all the other treatments. When the unaltered diaspore treatment was removed from the analyses, there were no differences among the remaining treatments. The mean values for behaviors to all these other treatments were low, suggesting they were generally unattractive.

Discussion

The data suggest that elaiosomes attract mutualistic ant species through chemical cues. *M. ruginodis* responded both to the general diaspore surface chemicals extracted with diethyl ether, and more particularly to the diglyceride fraction of elaiosome chemicals. Both

Table 6 Behavioral reactions (Mean ± S.E.) of *M. ruginodis* to *U. minor* diaspores with natural and artificial coloration

Behavior	Unaltered diaspore	Diaspore without surface chemicals	Artificial colors				Test with unaltered diaspore		Test without unaltered diaspore	
			Blue	Red	Brown	Green	Yellow	$F_{5,43}$	H_5	$F_{5,43}$
Duration of antennation	81.4 ± 26.2	9.1 ± 3.8	4.8 ± 2.2	7.0 ± 3.5	3.6 ± 1.6	2.4 ± 0.8	3.0 ± 2.0	$F_{5,43} = 6.6^{***}$	$F_{5,43} = 1.0$ nsd

Data were analyzed by ANOVA (F) or Kruskal–Wallis (H).

mutualistic and granivorous species carried the diaspore, and both carried elaiosomes more frequently than the diaspore, probably because the elaiosome was easier to carry. The seed with the elaiosome removed produced less of a response, especially from *M. ruginodis*, which suggests the importance of the elaiosome in attracting this ant compared with *T. caespitum*. The lack of reaction of *T. caespitum* to the diethyl ether extracts suggests that the granivore did not respond to chemical cues.

The testing of *T. caespitum* responses to the chemical fractions showed four significant effects. These may be chance events because they were inconsistent across the two *Ulex* species, only slightly more frequent than expected by chance, and they conflict with the lack of response to the complete extract. In contrast, the *M. ruginodis* responses toward the diglyceride fraction were consistent for both *U. minor* and *U. europaeus* and, therefore, probably biologically meaningful.

Our results agree with those of Marshall et al. (1979), Brew et al. (1989), and Kusmenoglu et al. (1989) who found that ants responded to the diglyceride fraction of elaiosomes. However, this response seems to be more specific than has been assumed previously, and our results support the hypothesis that selection has acted on the evolution of cues that attract mutualists but not predators. The granivore detects seeds, possibly by simple mechanical cues, whereas the mutualist has more sensitive and accurate chemically-based recognition. *M. ruginodis* dependence on this chemical cue for finding *Ulex* diaspores was further demonstrated by the experiment on visual cues. It seems that visual cues are not used, as no color produced a greater reaction than another. In contrast, the removal of surface chemicals in this experiment decreased the responses of ants to the diaspore.

It is unclear whether the recognition of chemicals is gustatory, by antennation on or near the elaiosome, or by olfaction of volatiles. Slingsby and Bond (1981) suggested that ants can detect elaiosome chemicals over some distance, but Sheridan et al. (1996) produced evidence that elaiosome chemicals are detected by gustation. We often observed *M. ruginodis* antennating the air within 1–2 cm of elaiosome extracts or diaspores, suggesting olfaction. Diglycerides are not volatile, however, (Sheridan et al., 1996), and an olfactorial response is likely to involve a more volatile and as yet undetected compound(s). However, if it exists, there should be a trade-off between the volatility and the longevity of such a cue. Such trade-offs have been encountered with the parasitoid *Ichneumon eumerus* that attacks caterpillars of the butterfly *Maculinea rebeli* inside host ant colonies. A mimic of the ants alarm pheromone is used. However, mimic compounds have a greater molecular weight and are less volatile than the template, providing the intruders with more time to attack the caterpillar (Thomas et al., 2002).

M. ruginodis rarely bit or picked up filter papers, in contrast to behavior toward the diaspore. This result contrasts with Brew et al. (1989), who found that piths treated only with oleic acid, 1,2-diolein, and triolein were removed by ants at the same rate as elaiosomes. This suggests that in the *Ulex*–*M. ruginodis* system diglycerides act only in the initial stages of attraction, and that the stimulus to remove the diaspore comes subsequently. This may be a simple food cue released when the elaiosome is damaged by biting.

In this myrmecochorous system of *Ulex* seeds and *M. ruginodis* ants, there appears to be a highly evolved relationship between the species. *Ulex* elaiosomes release chemicals that attract *M. ruginodis* and contain essential nutrients, linoleic acid, and sterols, which increase nest productivity (Gammons et al., 2005). It may be that the specific chemical attractant arose because *M. ruginodis* evolved a refined ability to detect such chemicals, or *Ulex* elaiosome chemicals have evolved and become specifically attractive to a mutualistic ant, or both processes have occurred through coevolution.

It is well established that many plant species use chemicals to manipulate insect behavior for their benefit, e.g., through repelling herbivores (De Moraes et al., 2001) or attracting

ants that defend the plant (Raine et al., 2004). The study of chemical attractants is important for understanding biotic interactions that affect populations and communities, and is an area in which further research is needed (Weissburg et al., 2002; Muller and Riederer, 2005).

Acknowledgments We thank Sophie Everett, Andrew Worgan, and Emma Napper for help and advice with the chemical protocols; Michael Fenner and Judith Wardlaw for criticisms; and Francis Haynes for her help. Two anonymous referees gave useful criticisms. This study was funded by the UK Natural Environment Research Council research studentship to Nicola Gammans, NER/S/A/2002/11078.

Introduction

Avocado (*Persea americana*: Lauraceae) originated in the neotropics where it is naturally pollinated by a wide range of insects, mainly stingless bees and social wasps (Ish-Am et al., 1999; Can-Alonzo et al., 2005). It is an important crop in many tropical and subtropical regions around the world (Knight, 2002). Its open and rather small (1 cm diam) flowers can also be visited by honey bees, which are its main pollinators in agricultural landscapes (Gazit and Degani, 2002). However, even when colonies of honey bees are placed inside the orchards, avocado flowers often suffer from insufficient pollination activity, resulting in low fruit yields (Vithanage, 1990; Ish-Am, 1998; Ish-Am and Eisikowitch, 1998; Gazit and Degani, 2002).

The attractiveness of nectar to pollinators is probably most affected by its taste (Adler, 2000), but may also be affected by odor (Raguso, 2004) and color (Thorp et al., 1975). The taste of nectar is dominated by a high sugar concentration. Several studies have attempted to define whether honey bees prefer nectars that are rich in sucrose or hexose. Wykes (1952) showed that honey bees prefer a sugar ratio of 1:1:1 (sucrose/fructose/glucose) over a pure sucrose solution. Avocado nectar contains almost exclusively sucrose and a low concentration of the unique seven-carbon sugar alcohol, perseitol (Ish-Am, 1994; Liu et al., 1995; Dvash et al., 2002; Dag et al., 2003). Indeed, the high ratio of sucrose in avocado nectar has been suggested as the cause for the low attractiveness of avocado flowers to honey bees (Ish-Am, 1994). A preference for hexoses over sucrose is also suggested by physiological considerations, because sucrose has to be broken down before it can be utilized (Harborne, 1993). Other studies, however, have found that honey bees are indifferent to the ratio of sugars (Southwick et al., 1981), or even prefer a high sucrose concentration (Bachman and Waller, 1977; Hagler et al., 1990). The sensitivity of honey bees to perseitol has never been evaluated.

Other components of nectar, including minerals, phenolic compounds, and amino acids, may make a cardinal contribution to its attractiveness to honey bees. Minerals such as potassium (Waller et al., 1972) and sodium chloride (von Frisch, 1950) deter honey bees. Phenolic compounds affect the taste of nectar even at very low concentrations (Baker, 1977), and in some cases they have been suspected of repelling honey bees (Hagler and Buchmann, 1993; Adler, 2000). Several nectar amino acids have also been shown to affect preference (Kim and Smith, 2000; Gardener and Gillman, 2002; Carter et al., 2006). Ish-Am (1994) found that glycine and histidine are the dominant amino acids in some avocado cultivars; at their naturally occurring concentrations, however, these amino acids do not repel honey bees (Inouye and Waller, 1984) and may even attract them (Kim and Smith, 2000). Avocado nectar is poor in proline, which is attractive to honey bees (Carter et al., 2006), but so is citrus (cv. "Valencia") nectar, and yet it is highly attractive to bees (Ish-Am, 1994). Hence, it does not appear that amino acid composition can explain the low attractiveness of avocado nectar.

Odors guide bees toward flowers and may affect their attractiveness (von Frisch, 1967). The volatile components of nectar, including phenolic compounds, form particular odor bouquets (Anklam, 1998). Some of these compounds are more attractive to honey bees than others (Jay, 1986; Henning et al., 1992; Winston and Slessor, 1993).

Colors also affect the attractiveness of flowers (von Frisch, 1967; Giurfa et al., 1995), and nectar may contribute to their visual display (Thorp et al., 1975). Color differences are especially salient when comparing honeys, which are derived from nectar, and can be used in choice experiments for testing the influence of nectar components on bees' preferences

(Afik et al., 2006). Nectar and honey colors are produced by dissolved light-absorbing compounds. Whereas sugar solution is transparent, dark honeys such as avocado honey have relatively high concentrations of minerals (Petrov, 1970; Terrab and Heredia, 2004; Dag et al., 2006). Other compounds, including flavonoids (Anklam, 1998) and organic acids (Mato et al., 2003), may also affect honey color, in either the visible or ultraviolet spectra, which are visible to bees (Hagler and Buchmann, 1993).

Previous work has revealed that avocado honey is relatively unattractive to honey bees when compared with honey from competing flowers (Afik et al., 2006). These results suggest that some attributes of avocado nectar are responsible for the relatively low attractiveness of avocado flowers. Here, we studied the influence of odor, color, sugar composition, phenolic compounds, and minerals on the selection of sugar source by honey bees.

Methods and Materials

Mineral Composition

We measured mineral composition in avocado honey, nonavocado honey, avocado (cv. “Ettinger”) nectar, and citrus (cv. “Shamouti”) nectar. The honey was extracted from colonies placed in avocado orchards during the blooming season. Its avocado origin was confirmed by sugar analysis, perseitol constituting 2.5% of the total sugars (Dvash et al., 2002). The nonavocado honey was extracted from colonies placed in citrus orchards during the citrus blooming season; it contained no perseitol. Nectar samples were collected from flowers by hand using microcapillary tubes. Flowers were covered with paper bags on the evening before collection to prevent nectar consumption by insects.

Nitric acid (5 ml of 65%, w/w) was added to the two honey and two nectar samples. Samples were prepared for analysis by microwave-assisted digestion, using an MLS 1200 mega microwave digestion unit [Milestone Sorisole (BG) Italy] at 500 W for 10 min. Liquid residues were taken up in deionized water to a final volume of 25 ml. Concentrations of the different elements were determined simultaneously by inductively coupled plasma–atomic emission spectrometry (ICP-AES), according to EPA 6010B (1996), using two ICP-AES systems, models “Spectroflame” and “Spectroflame Modula E” from Spectro (Kleve, Germany).

Behavioral Bioassay—Proboscis Extension Response

Odor

We employed the proboscis extension response (PER) bioassay to test the responses of harnessed bees to the odors of avocado and citrus flowers and honey. In this bioassay, subjects extend their proboscis in response to an odor associated with an appetitive reinforcement (Bitterman et al., 1983). The experiment was conducted in April 2003, in Rehovot, Israel. We tested bees from two colonies. One hive was located in the field, between citrus and avocado orchards, during their simultaneous blooming period. Thus, the foragers from this colony may have visited citrus and avocado flowers before being tested. A second hive was introduced into a 12 × 6 × 3 m enclosure (15 mesh) before the blooming period to avoid preconditioning. This colony was fed sugar solution and pollen patties during the experimental period.

Each morning, 30 bees from one colony were caught in glass vials as they flew out of the hive. The vials were placed on ice for 1 or 2 min until the bees were motionless, and then the bees were strapped into a sectioned hollow plastic tube (6 mm diam), with a 3-mm-wide strip of duct tape that wrapped around the tube and (dorsal) thorax of the bee (Shafir et al., 1999). When they awoke, bees were fed 5 μ l of a 30% (w/w) sucrose solution. Typically, only a few bees did not feed, and they were removed from the experiment. Each day, 24 bees were chosen and allowed to adapt to the harness for 1 hr. We tested a total of 142 bees from the colony in the orchard and 215 bees from the colony in the enclosure.

During the experiment, odor was delivered to each bee for 3 sec. An air pump delivered air through valves controlled by a computer, and a Tygon tubing connected to a 50-ml plastic syringe filled with fresh flowers or a 130-ml glass vial filled with 30 ml honey solution, diluted to a total sugar concentration of 60% (w/w). The vial was placed in a warm water bath (40°C; Abramson and Boyd, 2001). Tubing from the odor source delivered odors to within 2 cm of the bee.

Each bee experienced five different odors with an intertrial interval of 10 min. The first two presented were of avocado flowers (“Ettinger” or “Fuerte” cultivars) and citrus flowers (“Shamouti”). The order of odor presentation was alternated every day. Because these were unrewarded trials, after the first two trials the bees were fed 2 μ l of 30% sucrose solution to avoid starvation. The subsequent three trials included odors of avocado honey, nonavocado honey, and an air control. The order of the two honey sources was alternated every day, but the air control was always last. An extension of the proboscis in response to a particular odor was considered a positive response and the proportion of bees responding to each odor was calculated.

Sugars

The sensitivity of honey bees to increasing concentrations of various sugar solutions was tested in February and July of 2002, respectively, in two sets of PER experiments (Page et al., 1998). The first experiment tested the sensitivity of bees to different sugars ($N = 150$ bees, 37–38 bees for each sugar). The second tested the bees’ sensitivity to different sugar mixtures ($N = 275$ bees, 68–69 bees for each mixture). The bees were caught and harnessed as described for the odor experiment. Each trial with a sugar concentration was preceded by a trial with distilled water, which served as a baseline to which the effect of the sugar component of the solution was compared. The intertrial interval was 4 min.

The experiment was begun by touching the right antenna of each bee with a cotton ball soaked in distilled water. The PER to the touch was recorded, and in the next trial the same antenna was touched again, this time with a cotton ball soaked in a sugar solution. We rotated between antennae so that the next two trials (water and increasing sugar solution) were to the left antenna, and so forth. The total sugar concentrations of the examined solutions were as follows: 0.1%, 0.3%, 1%, 3%, 10%, and 30% w/w (g solute/g solution).

On each day of the experiment, the tested bees were separated randomly into four different groups, which were tested for their response to four different sugar solutions. In the first experiment, each solution contained only a single sugar: sucrose, glucose, fructose, or perseitol, with an added concentration of 4.5% (w/w), the highest concentration that could be reached using perseitol. In the second experiment, four sugar mixtures were used: (1) “avocado nectar”: 95% sucrose and 5% perseitol, to simulate the sugar composition of avocado nectar (Ish-Am, 1994); (2) “perseitol-enriched”: 90% sucrose and 10% perseitol; (3) “citrus nectar”: 50% fructose, 30% glucose, and 20% sucrose, to simulate the sugar composition of citrus nectar (Ish-Am, 1994); (4) sucrose solution, used as a reference.

Behavioral Bioassay—Free-Flying Bees

General Procedure

The effects of honey color, and phenolics and mineral composition, were studied with a cafeteria-style choice paradigm, in which free-flying honey bees could choose from three available feeders. Five-frame nucleus hives were kept in screened enclosures. For the honey color and phenolics experiments, colonies were kept in a $12 \times 6 \times 3$ m (15 mesh) enclosure. Only one colony was tested at a time, and the entrances to the other colonies were closed the evening before each test. The mineral composition experiment was conducted in $5 \times 2.5 \times 2$ m (20 mesh) enclosures, each housing one colony. The bees had *ad libitum* access to a water source and were provided with a pollen patty once a week.

Three different honey solutions were prepared each day by diluting honey or sucrose with distilled water to reach 60% (w/w) total dissolved solids. The concentration was measured by a hand refractometer (REF 114, brix units, 28–62 ATC). Although the tested honeys contain mainly glucose and fructose (Dag et al., 2006), their refractive index is similar to that of sucrose (Kearns and Inouye, 1993). The three different solutions used in the experiments were avocado honey, nonavocado honey, and sucrose.

The solutions were presented to the bees in 200-ml bird feeders. The three feeders were placed in a circle, 15 cm apart, on a carousel that rotated at a velocity of 2 rpm, to prevent a potential location bias. The volume consumed from each feeder was measured every 20 min. The experiment ended when 130 ml were consumed from one of the feeders, or after 4 hr had elapsed. The volume of solution consumed from each feeder was measured at the end of the experiment. The solution from which bees consumed the highest volume was set to represent 100% consumption, and the consumed volumes from the rest of the feeders were compared with this highest volume. The results are presented as relative percentage consumption from the different solutions.

Color

Avocado honey is characterized by its dark brown color (Terrab and Heredia, 2004; Dag et al., 2006). To test whether the bees' preference for nonavocado over avocado honey is influenced by color (Afik et al., 2006), we tested 10 colonies in a preference experiment in which the feeders were covered with an opaque green plastic cover. A narrow opening (marked in yellow) was left at the bottom of the cover, allowing bees to reach the feeder inside. The choice was between avocado honey, nonavocado honey, and sucrose solution.

Phenolic Compounds in Honey

To test the effect of phenolic compounds in avocado honey on preference, an experiment was conducted in which bees had a choice between dilute avocado honey, sucrose solution with a phenolic concentrate produced from avocado honey, and sucrose solution with ethanol (the solvent). The phenolic concentrate was made by dissolving 600 g of avocado honey in 1.2 l distilled water; 200 ml of ethyl acetate was mixed with the honey solution and then separated from the solution using a funnel separator. This process was repeated five times. All ethyl acetate fractions were pooled, and the solvent was evaporated under reduced pressure on ice (Singleton et al., 1999). The residue was dissolved in 2 ml ethanol, because such a low concentration of ethanol is known to have only a minor effect on honey bees (Abramson et al., 2000).

Each feeder of avocado honey solution contained 200 g of honey (200 ml of 60% diluted honey solution; Weast, 1988). Therefore, the 2 ml phenolic concentrate that was extracted from 600 g of honey was divided into three portions of 0.67 ml, which sufficed for three replicates of the preference test, with three different colonies. Similarly, 0.67 ml of ethanol was added to each feeder of sucrose solution.

Potassium

To test the effect of potassium concentration in honey on preference, an experiment was conducted in which bees had a choice between avocado honey, nonavocado honey, and nonavocado honey enriched with potassium. Potassium concentrations were 3768 and 325 mg/kg in the avocado and nonavocado honeys, respectively (Table 1). We, therefore, dissolved 3443 mg potassium in 1 kg nonavocado honey solution to reach a concentration equivalent to that of the avocado honey solution. Four different potassium salts were used: potassium chloride (KCl), potassium hydrogen phosphate (K_2HPO_4), potassium D-gluconate ($C_6H_{11}KO_7$), and tri-potassium citrate ($C_6H_5K_3O_7$). The amounts of potassium salts added were calculated from their molecular weights to reach the desired concentration of potassium. Eight colonies were tested for each of the four salts. Each day, all the colonies were tested for the same potassium salt, with 1 or 2 d between tests. Because the addition of potassium salts did not noticeably change the color or odor of the honey, the feeders were placed on colored cardboards (yellow, blue, or purple) to allow the bees to visually discriminate between the solutions. The colors were rotated between colonies and between days of the experiment to avoid potential color bias.

Statistical Analyses

Differences in the responses of harnessed bees to odors were tested by χ^2 test. The sugar sensitivity experiment was analyzed by two-way ANOVA, including the honey source as a nominal factor, the log of the sugar concentration as a continuous factor, and the proportion of discriminating bees at each sugar concentration as the dependent variable. A discriminating bee was defined as a bee that extended its proboscis in the trial with sugar solution but not in the preceding trial with water. This provided a conservative measure of the sensitivity to the sugar itself. Differences in the preferences of free-flying bees between

Table 1 Concentrations (mg/kg) of detected minerals in avocado and nonavocado honey and nectar

Mineral	Avocado honey	Nonavocado honey	Avocado nectar	Citrus nectar
K	3768.3	324.8	3946.2	184.7
P	651.5	47.0	511.2	18.5
Mg	204.6	18.5	188.3	<5
S	188.3	27.7	170.4	<5
Ca	82.7	75.8	<150	<150
Na	58.9	79.1	53.8	18.5
Si	18.0	7.0	43.9	29.5
Zn	10.9	1.5	<30	<30
B	9.9	7.2	10.8	4.2
Fe	9.3	2.7	13.5	<5
Cu	3.2	0.1	3.1	<0.5
Pb	1.2	2.9	<1	<1

honey sources were tested by one-way ANOVA. Differences between pairs of treatments within the same experiment were tested by Tukey–Kramer test. The arcsin square root transformation was employed on the percentage honey consumption data before analysis (Sokal and Rohlf, 1995). Statistical analyses were performed using JMP 5.0.1 software (SAS Institute, Inc.).

Results

Odor

Approximately half of the bees from the enclosure responded spontaneously to floral odors, and there was no difference between the response rates to avocado and citrus flowers ($\chi^2_{1,428} = 3.03, P > 0.05$; Fig. 1a). The response of the orchard bees to the odor of avocado flowers was similar to that of the bees from the enclosure ($\chi^2_{1,355} = 0.27, P > 0.05$), but a significantly higher proportion responded to citrus flowers than to avocado flowers ($\chi^2_{1,282} = 16.8, P < 0.001$).

Fig. 1 The percentage of bees that responded spontaneously, by proboscis extension, to different odors: (a) floral odors and (b) honey odors. Bees from two colonies were tested. One hive was placed in an orchard ($N = 142$ bees) and the second in an enclosure ($N = 215$ bees). * indicates significant differences between treatments with $P < 0.001$ (χ^2 test)

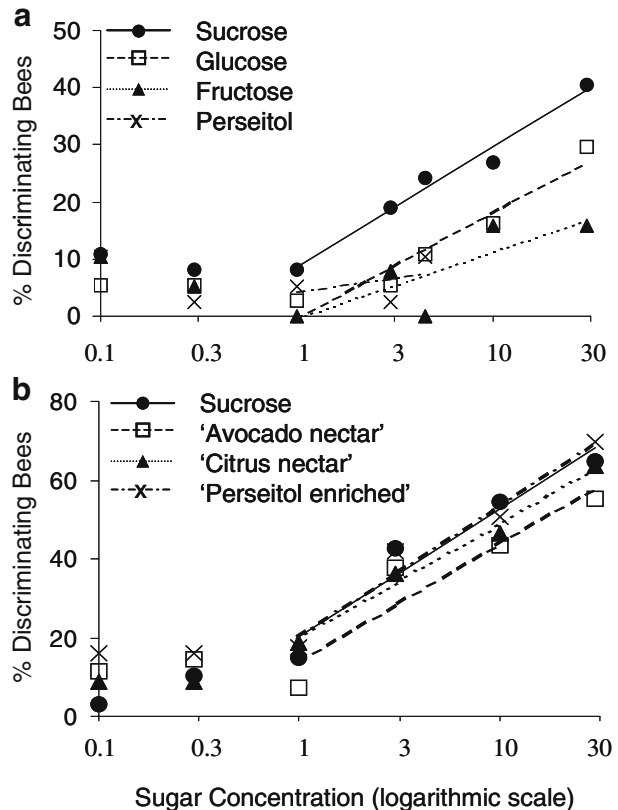

The spontaneous response rate of bees to honey odors was 65%, and it was not affected by honey source ($\chi^2_{1,712} = 0.40$, $P > 0.05$; Fig. 1b) or location ($\chi^2_{1,712} = 0.74$, $P > 0.05$). The spontaneous response to the air flow was lower than the responses to either honey odor ($\chi^2_{2,1067} = 176.7$, $P < 0.001$).

Sugars

Visual inspection shows that bees started detecting sugars only at concentrations $>1\%$ (Fig. 2). Therefore, we analyzed the effect of sugar type and concentration for concentrations of $\geq 1\%$. In the first experiment, which measured the sensitivity of bees to different sugars, bees were most sensitive to the sucrose solution (Fig. 2a). Both sugar type ($F_{3,10} = 14.7$, $P = 0.001$) and concentration ($F_{1,10} = 31.2$, $P < 0.001$) affected discrimination, but the interaction between them was not significant ($F_{3,10} = 1.99$, $P > 0.05$). Nevertheless, separate linear regressions for each sugar showed that the percentage of discriminating bees increased with increased sucrose ($F_{1,3} = 139.5$, $P = 0.001$) and glucose ($F_{1,3} = 41.5$, $P = 0.008$) concentration, while no concentration effect was evident for fructose ($F_{1,3} = 6.21$, $P > 0.05$) or perseitol ($F_{1,1} = 0.23$, $P > 0.05$).

In the second experiment, which measured the bees' sensitivity to four sugar mixtures, bees responded similarly to all sugar mixtures ($F_{3,8} = 1.77$, $P > 0.05$; Fig. 2b). Sensitivity

Fig. 2 The percentage of bees that discriminated between having their antennae touched with cotton balls soaked with distilled water and sugar solution according to their proboscis extension response. (a) The discrimination percent in response to different sugars at increasing concentrations ($N = 150$ bees). (b) The discrimination percent in response to different sugar mixtures at increasing concentrations ($N = 275$ bees). Lines are linear best fits

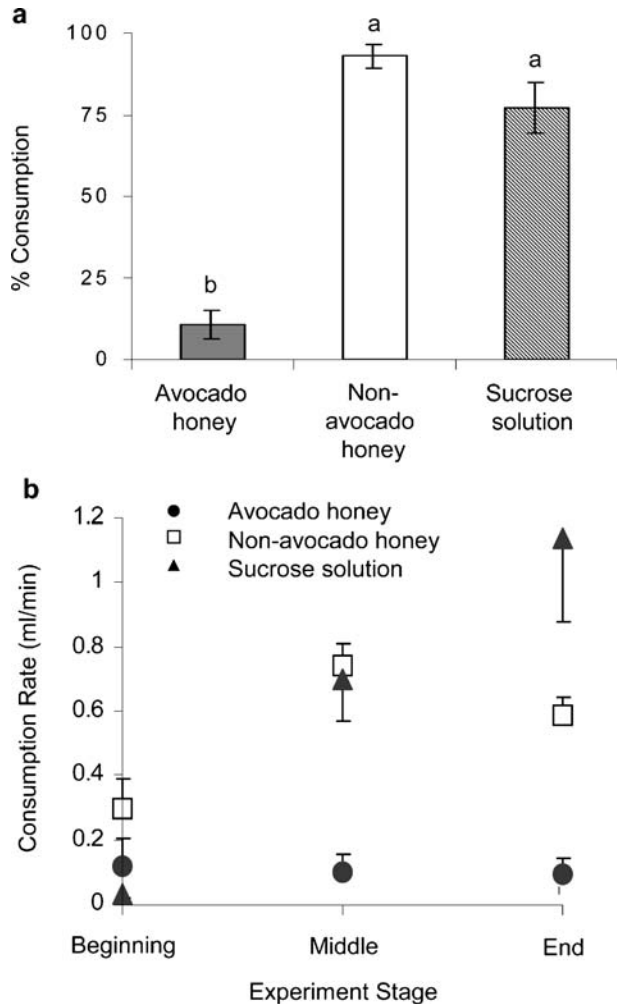

increased with concentration ($F_{1,8} = 127.0, P < 0.001$) in a similar fashion for all sugar mixtures (sugar mixture \times concentration: $F_{3,8} = 0.12, P > 0.05$).

Color

Repellence by avocado honey was observed even when opaque feeders were used, and bees could not discriminate between the solutions by their color ($F_{2,27} = 44.9, P < 0.001$; Fig. 3a). Consumption of avocado honey was lower than that of nonavocado honey and sucrose solution (Tukey’s test, $P < 0.05$). No significant differences were found in final consumption between nonavocado honey and sucrose solution (Tukey’s test, $P > 0.05$).

The consumption rate of the solutions was measured every 20 min. Figure 3b shows the average rate of the first, middle, and last 20-min increments of the experiment for every colony. Consumption rate was affected by the solution source ($F_{2,81} = 18.8, P < 0.001$), by the time point in the experiment ($F_{2,81} = 13.8, P < 0.001$), and by the interaction between

Fig. 3 (a) Bees’ mean (\pm S.E.) relative consumption of different sugar solutions presented in covered feeders ($N = 10$ colonies). Relative consumption represents the ratio between the amount consumed from each solution and the amount consumed from the solution with the highest consumption, for each colony tested. Different letters indicate significant differences between treatments with $P < 0.05$ (Tukey’s test). (b) Consumption rate (ml/min \pm S.E.) as the experiment progressed. Beginning—The rate during the first 20 min of the experiment. Middle—The rate during 20 min in the middle of the experiment. End—The rate during the last 20 min of the experiment

them ($F_{4,81} = 7.46$, $P < 0.001$). Consumption rate of the nonavocado honey was highest after the first 20 min and increased until the middle of the experiment. Consumption rate of the sucrose solution showed a different pattern. Sucrose was consumed the most slowly at the beginning, but the rate increased consistently, and it was consumed at the highest rate toward the end of the experiment.

Phenolic Compounds

Consumption of the sucrose solution enriched with phenolics from avocado honey was higher than that of the sucrose solution or of the avocado honey ($F_{2,6} = 30.6$, $P = 0.001$; Fig. 4), with no significant difference between the latter two (Tukey's test, $P > 0.05$), probably due to the strong attraction to the enriched sucrose solution.

Mineral Composition

Twelve different minerals were found in avocado honey at concentrations higher than 1 mg/kg (Table 1). The concentrations of 10 minerals out of the 12 were higher in the avocado honey than in the nonavocado honey, in some cases by an order of magnitude. Among the minerals that were detected in the honey samples, nine were also detected in avocado nectar, and only five in citrus nectar, all of them with higher concentrations in avocado than in the citrus nectar. Potassium was the most dominant mineral in all samples, with a concentration in avocado honey and nectar that was >10-fold that in nonavocado honey and citrus nectar.

Potassium

The consumption of nonavocado honey enriched with potassium salts was intermediate between those of nonavocado honey and avocado honey (Fig. 5). Three salts significantly reduced consumption relative to nonavocado honey, but were still preferred to avocado honey (KCl: $F_{2,21} = 42.4$, $P < 0.001$; K-gluconate: $F_{2,21} = 101.3$, $P < 0.001$; K_3 -citrate: $F_{2,21} = 234.5$, $P < 0.001$). Only K_2 -phosphate reduced consumption to the level of avocado honey ($F_{2,21} = 85.5$, $P < 0.001$).

Fig. 4 Bees' mean (\pm S.E.) relative consumption of solutions containing avocado honey, sucrose solution, and sucrose solution enriched with phenolics extracted from avocado honey. Different letters indicate significant differences between treatments with $P < 0.05$ ($N = 3$ colonies; Tukey's test)

Fig. 5 Bees' mean (\pm S.E.) relative consumption of solutions containing avocado honey, nonavocado honey, and nonavocado honey enriched with different potassium salts: (a) KCl, (b) K-gluconate, (c) K₃-citrate, and (d) K₂-phosphate. Different letters indicate significant differences between treatments with $P < 0.05$ ($N = 8$ colonies for each potassium salt; Tukey's test)

Discussion

The dissolved solids in nectar consist mainly of carbohydrates (Luttge, 1977), but a wide variety of minor components may define its nature (Adler, 2000). This complicates the identification of individual taste and odor compounds that may affect its attractiveness to pollinators. Here, we separated various constituents of nectar and tested their effects on the preferences of honey bees. The response of honey bees to floral and honey odors evaluated the importance of volatile compounds. The odor of citrus flowers was more attractive to experienced bees than that of avocado flowers. These foragers were collected from a colony located among blooming citrus and avocado trees. Because honey bees tend to prefer citrus

over avocado (Vithanage, 1990; Ish-Am and Eisikowitch, 1998; Gazit and Degani, 2002), it is likely that we collected more bees that were foraging on citrus than on avocado. The higher response to the odor of citrus flowers probably reflected the bees' foraging experience in the field. The indifference of naïve bees to the floral odors supports the notion that odors act mainly as signals that bees learn to associate with their respective floral rewards, and do not themselves affect choice behavior greatly. This view was also supported by the indifference of bees to honey odors, while they clearly preferred nonavocado honey in taste assays. Taste, rather than odor, probably affected the choice of honey, because honey bees find it difficult to discriminate between honey odors (Bonod et al., 2003).

The response of bees to different sugar solutions indicated that the sugar composition of avocado nectar cannot explain its low attractiveness. Their sensitivity to sucrose was found to be higher than their sensitivity to glucose or fructose, separately, thus supporting the findings of Wykes (1952), Waller (1972), and Bachman and Waller (1977). Sugar mixtures, however, are perceived differently relative to pure sucrose (Wykes, 1952; Waller, 1972; Bachman and Waller, 1977). The response to a hexose-rich mixture, "citrus nectar" in the present experiments, was similar to that of sucrose. Therefore, it appears that high sucrose content in avocado nectar does not diminish its attractiveness, in contrast to previous assumptions (Ish-Am, 1994). Bees did not respond to perseitol solution, and their response to sucrose solution containing perseitol was similar to their response to pure sucrose solution. Perseitol, which was suspected to deter honey bees from avocado (Ish-Am, 1994; Can-Alonzo et al., 2005), seems to have no effect on preference. Thus, differences in sugar composition between avocado and citrus nectar cannot account for the bees' stronger preference for citrus flowers. Moreover, during the process of honey ripening, sucrose is inverted into glucose and fructose. As a result, the sugar compositions of avocado and nonavocado honeys are similar (Dag et al., 2006). Nevertheless, higher consumption of nonavocado honey in the color and potassium experiments indicated that preference is determined by a component other than the dominant sugars.

Honey color also could not explain the bees' preferences. Bees were repelled by the avocado honey even when feeders were covered. Comparison of the consumption rate as the experiment progressed revealed a potential role of odor in establishing preference. The honey solutions would be easy to locate due to their aromas, whereas sucrose solution is odorless. Bees visiting the nonavocado honey feeder would further mark it with Nasonov pheromone (Winston, 1987), and bees visiting the avocado honey feeder would abandon it. Thus, a rapid preference for the nonavocado honey feeder would develop (Fig. 3b). Eventually, bees finding the sucrose solution would start marking it with pheromone, and by the end of the experiment, it did indeed attract the greatest number of bees, revealing that it is even more attractive than nonavocado honey.

Phenolic compounds have been suspected of being repellent to bees (Baker, 1977; Rhoades and Bergdahl, 1981; Adler, 2000), but actual repellence has seldom been found. Hagler and Buchmann (1993) tested two phenolic compounds and found that they were repellent at high concentrations, but at low concentrations they did not deter bees and even increased attractiveness. They also found repellence to phenolic-rich nectars and honeys from three different botanical sources. One of them was almond honey, which was later found to be repellent due to amygdalin (London-Shafir et al., 2003). Another source was salt cedar, which contains high potassium concentrations (Waller et al., 1972). Our results indicated that phenolics increase the attractiveness of sucrose solution to honey bees, probably by adding odor to the solution, making it easier to locate. A similar increase in

visitation rate to phenolic-rich nectar was found for *Apis cerana* (Liu et al., 2004). Hence, no support was found for a repellent effect of phenolics on honey bees.

Little is known about the effect of nectar minerals on honey bee foraging behavior (Nicolson and W.-Worswick, 1990). A repellent effect of sodium chloride in sucrose solution was demonstrated by von Frisch (1950), who showed that a 0.015 M salt solution deterred honey bees, although a 0.0075 M solution no longer deterred them. The sodium component in the latter solution was 173 ppm. We found lower sodium concentrations than that in all honeys and nectars tested, and they were within a similar range in all samples. Hence, sodium does not seem to be responsible for deterring bees from avocado. Waller et al. (1972) found a repellent effect of potassium in onion nectar, at potassium concentrations similar to those found in the current study for avocado nectar. Our results indicate that, for three out of four potassium salts tested, dissolving 3500 ppm potassium in nonavocado honey to equalize its concentration with that of avocado honey decreases consumption by half. This indicates that potassium is a major cause for the low attractiveness of avocado honey, but not the only one. Cations such as potassium are usually accompanied by anions, although selective secretion to nectar is also possible (Luttge, 1977). In avocado nectar, potassium may be coupled with perseitol (Ishizu et al., 2001). This is supported by the strong correlation between perseitol and potassium in avocado honey (Dag et al., 2006). The most dominant anion found in avocado honey was phosphate, but its concentration was too low to equalize the potassium concentration. Adding K_2 -phosphate to nonavocado honey reduced consumption to a level similar to that of avocado honey. Thus, high mineral concentrations, mainly of potassium and phosphate, seem to be the main cause for the low attractiveness of avocado flowers. The effect of other minerals, such as magnesium, sulfur, and copper, whose concentrations differ between avocado and nonavocado honeys, still remains to be tested. Potassium concentration in avocado nectar may often be higher than that measured in this study and, therefore, high enough to repel honey bees from avocado flowers. Potassium concentration in avocado nectar is high, but not unique (Hiebert and Calder, 1983; Waller et al., 1972). The effect of nectar minerals, potassium in particular, on the foraging behavior of pollinators may be widespread.

The reason for the presence of repellent components in nectar is not clear, but several possible roles have been suggested (Rhoades and Bergdahl, 1981; Adler, 2000). To answer this question for avocado, we have to compare the honey bees' response with avocado nectar, these insects not being its natural pollinators, with the response of avocado's natural pollinators. These natural pollinators may not be as strongly repelled by the nectar. For example, various hummingbird species have been found to differ in their response to mineral-rich nectar (Bouchard et al., 2000). Another approach would be to test whether potassium concentration in the nectar correlates with its abundance in the soil. It is possible that in avocado's natural habitat, the infertile soils of the neotropical rainforest (Wolstenholme, 2002), potassium concentration in the nectar is lower than in cultivated plots, and does not repel pollinators. It would also be interesting to study the influence of the agricultural practice of intensive fertilization of avocado (Lahav and Whaley, 2002) on the pollination effectiveness of bees.

Acknowledgments We thank Lia Yehonatan, Tahel Shejtman, and Pnina Weinberg for helping with the experiments. (Wink and Witte, 1991). Early in the twentieth century, German plant breeders started producing “sweet” lupins with seed alkaloid contents lower than 0.01%, making them suitable as a high-protein animal feed (Wink, 1994). Narrow-leafed lupin, *Lupinus angustifolius*, and white lupin, *L. albus*, comprise, to date, most of the grain lupin produced worldwide (Gladstones, 1998; Berlandier, 2001; Littlewood and Garlinge, 2001). A consequence of reducing alkaloid content in cultivated lupins has been an increased susceptibility to generalist herbivore species such as the aphid *Myzus persicae* (Wink, 1994).

M. persicae is a highly polyphagous species, feeding on plants from more than 50 families (Weber, 1985). However, despite the well-documented polyphagia of *M. persicae* as a species, there is considerable variation among populations in performance on different hosts (Weber, 1985; Hales et al., 1997). Thus, rather than being characterized by a general-purpose genotype (Vorburger et al., 2003a,b), *M. persicae* populations are more often locally adapted to a regional complement of host plants often varying in time and space (Weber, 1985; Nikolakakis et al., 2003). For example, the tobacco aphid described previously as a separate species *M. nicotianae* (Blackman, 1987), is now generally accepted to be a host-adapted subspecies of *M. persicae* (Clements et al., 2000; Zitoudi et al., 2001; Margaritopoulos et al., 2003). In the “wheatbelt” of Western Australia (WA), *M. persicae* populations show little variation in host use. In a previous study, all of 30 WA-collected clones of *M. persicae* tested were capable of successfully feeding on cultivated narrow-leafed lupins (Edwards, 2001). Unlike other generalist legume aphids in WA (i.e., *Acyrtosiphum kondoi*, *Aphis craccivora*), *M. persicae* feeds successfully on the narrow-leafed lupin varieties “Kalya” and “Tanjil” (Edwards et al., 2003), which have been bred for aphid resistance (Littlewood and Garlinge, 2001).

We examined the hypothesis that successful lupin feeding by *M. persicae* in WA is not a species characteristic, but instead indicates local adaptation of WA clones to a novel host plant. This hypothesis predicts that *M. persicae* clones from eastern Australia, where cultivated narrow-leafed lupins are not commonly grown, could not utilize this host as well as clones from Western Australia. To test this, we measured the growth rate and colonization ability on narrow-leafed lupins of nine aphid clones collected off a wide range of host plants from various locations around eastern Australia to a lupin-feeding clone from Western Australia. The plant varieties used have well-characterized levels of resistance to aphids with “Tallerack” being the most susceptible, “Tanjil” showing moderate levels of resistance, and “Kalya” being the most resistant of the three varieties (Cowling, 1999; Littlewood and Garlinge, 2001; Zehnder et al., 2001; Edwards et al., 2003). We tested our hypothesis by comparing the performance of selected clones on artificial diet containing the most abundant phloem alkaloids in these varieties.

Methods and Materials

Experimental Species

Radish plants, *Raphanus sativus* “Long Scarlet”, used to maintain the aphid cultures, were planted in commercially available UC Riverside potting soil mix and were used for aphid rearing at 3–4 wk after emergence. Narrow-leafed lupin seeds for varieties Tallerack, Kalya, and Tanjil were donated by Kadambot Siddique (Center for Legumes in Mediterranean Agriculture, University of Western Australia, WA). Seeds of all varieties were sown in pairs in commercially available topsoil (Soils ain’t Soils, Balcatta, WA) in seedling trays and transplanted, 1 wk after emergence, to 1-l plastic pots containing the same soil. Each pot

received 50 ml tap water three times per week. Plants were used for experiments 15–20 d after transplanting. At this time, they had 5–7 fully expanded leaves. All plants were kept in a temperature-controlled glasshouse maintained at $20 \pm 5^\circ\text{C}$ under natural light (approx. 14:10 hr L:D) until needed.

The clones of *M. persicae* used were provided by Christoph Vorburger and Paul Sunnucks (Department of Genetics, La Trobe University, VIC, Australia) or Dinah Hales (Department of Biological Sciences, Macquarie University, NSW, Australia) except for the lupin-feeding clone (“Lupin” clone), which was collected in September 2002 from *L. angustifolius* in the wheatbelt region of Western Australia (Table 1). Because a previous extensive survey of WA clones showed little variation in feeding ability on narrow-leaved lupins in the wheatbelt area (Edwards, 2001), the lupin-feeding clone was considered representative of the common lupin-feeding phenotype in WA. Because all the colonies could not be successfully maintained on narrow-leaved lupin, experimental consistency was maintained by rearing them for at least three generations on radish before they were used in the experiments. The rearing methods and procedures were as described by Edwards (2001). Additionally, a bulk-rearing of the clones was maintained on whole 3- to 4-wk-old radish plants kept in an incubator at 20°C and 14:10 hr L:D photoperiod. New radish plants were infested with 10 apterae every 7–10 d to maintain a constant supply of suitable insects for the experiments.

Immature Performance

Each aphid clone was tested for performance on each of the 3 lupin varieties. Performance was assayed on eight individual replicate plants of each variety. Individual plants were infested with ten 2nd-instar nymphs (<48 hr old) randomly selected from the pool available, weighed collectively on a microbalance, and placed on the cotyledons or on the lowermost axillary leaf on the plant. Each plant was covered with a mesh sleeve made from Voile material to fit snugly around the pots. Sleeves were held upright over the plant canopy by loops made from electrical wire (25 mm diam) with their ends buried in the soil within the pot. The experiment was terminated after 5 d to ensure that the aphids did not begin to produce nymphs (Edwards, 2001), then the surviving aphids were removed from the plants and again weighed as a group. The mean relative growth rate (MRGR) was calculated as the difference between the logarithms of the weight of aphids put on the plant and the weight of aphids removed from the plants, divided by the number of days the aphids had been on the plant (Edwards, 2001). The experiment was set up in single replicates including

all aphid clones and repeated over time to obtain eight replicates for each plant variety/aphid clone combination. Analysis of variance (ANOVA) was used to test for differences in MRGR among clones within lupin varieties (PROC GLM, SAS Institute, 1996). All data were $\log(x)$ transformed as required to conform to the assumptions of normality before analyses. Significant results obtained by ANOVA were subjected to Tukey's mean separation test (PROC GLM; SAS Institute, 1996).

Colonization Ability of Apterous Females

Based on the MRGR data from the three lupin varieties, we selected five clones of aphids for further testing: C61, BP2, C70, X13, and the lupin-feeding clone. This experiment was designed to determine the ability of newly molted (<24 hr) females to establish a colony on each of the lupin varieties. This assay was selected for more detailed clonal comparisons because, compared to the MRGR assay in the previous section, it provided a greater capacity to distinguish among the clones by measuring reproductive capacity in addition to growth. A single apterous female was placed on the growing tip (shoot) of a plant and confined by using "sock-cages" made out of Voile material as described. Apterous were chosen for this experiment because of their higher fecundity, and because previous studies have shown no difference in host acceptance between apterous and alate *M. persicae* on lupins (Edwards, 2001; Cardoza et al., 2005). Insects were allowed to feed and reproduce for 12 d. The experiment was set up in single replicates consisting of 5 clones \times 3 varieties, and was repeated over time as needed to obtain a total of five replicates for each clone/variety combination. At the end of the experiments, all insects were removed from the plants, and their cumulative weights were determined and recorded. Differences in colonization ability among the clones on the three lupin varieties (PROC GLM, SAS Institute, 1996) were tested by ANOVA. Significant results obtained by ANOVA were further analyzed by Tukey's mean separation test (PROC GLM, SAS Institute, 1996).

Gas Chromatography-Mass Spectrometry Analysis of Lupin Phloem Alkaloids

Plants were grown as described above, and phloem samples were obtained by submerging the stems of two excised lupin plants (approx. 2 g FW) in 3 ml 20 mM EDTA-2 Na for 5 hr. The concentration of ethylenediaminetetraacetic acid (EDTA) was chosen as optimal based on preliminary experiments testing a range of concentrations. A total of 6 samples per plant variety were obtained in this manner. Samples were immediately stored at -80°C and freeze-dried within 24 hr of collection. The dry phloem sample was dissolved in 2 ml double-distilled water. An aliquot of 1 ml of this solution was used for alkaloid analysis. Phloem samples (1 ml) were made basic with 200 μl of $\text{NH}_3\text{H}_2\text{O}$ to pH 10.0, and extracted with dichloromethane twice. The pH was further increased with 200 μl of 10 M NaOH to pH 14.0 and extracted with dichloromethane twice. Dichloromethane extracts were combined, concentrated under nitrogen gas to yield total alkaloid extracts, and dissolved with ethyl acetate before GC-MS analysis.

The presence of lupin alkaloids in phloem was determined by gas chromatography-mass spectrometry (GC-MS) with an HP5986 GC-MS instrument equipped with an HP-5MS column (0.24 μm film thickness, 10 m \times 0.35 mm i.d.) and helium as the carrier gas. Injector temperatures were maintained at 250°C , and oven temperature was programmed from 40°C (isothermal for 2 min) to 290°C at a rate of $10^{\circ}\text{C}/\text{min}$. Injections of 1 μl were performed on-column. Auxiliary temperature was 250°C . The electron impact mass spectra were recorded at 70 eV ionization energy, and at a scan mode covering a mass range (m/z) of 50–500 amu.

Identifications were made by comparison of the mass spectral data and retention times to those of authentic samples (lupanine and 13-OH-lupanine) provided by David Harris (Harris and Spadek, 1986; Brooke et al., 1996). Phloem samples were coinjected with authentic samples. The amounts of individual alkaloids were determined by using standard curves for the appropriate compounds at five concentrations, using eicosane as internal standard. Differences in the amounts of the detected alkaloids among the three lupin varieties were evaluated using ANOVA (PROC GLM; SAS Institute, 1996). Significant results obtained by ANOVA were then subjected to Tukey's mean separation tests.

Artificial Diet Feeding Assays

Alkaloids were isolated from the high-alkaloid (1.8%) *L. angustifolius* cv. Fest by David Harris at the Western Australia Chemistry Centre. Mixed alkaloids were extracted with trichloroacetic acid and then made basic with 10 M caustic. Individual alkaloids were extracted with dichloromethane, then converted to perchlorate salts, and allowed to precipitate from methanol. Salts were purified by recrystallization, and the final products were >99% pure (Harris and Spadek, 1986; Brooke et al., 1996).

Artificial diet sachets were used to evaluate the effect of the individual alkaloids detected in the GC-MS profiles of the lupin varieties. The diet used was that described in Dadd and Mittler (1966). Diet sachets were prepared by dispensing 135 μ l of the diet in between two layers of Parafilm[®] stretched over a Plexiglass ring (20 mm diam; 5 mm high), and insects were confined to the feeding arena within the ring with a round glass coverslip secured with a metal bulldog clip (Ridsdill-Smith et al., 2004). The lupin-feeding clone, along with clones BP2 and X13, was used to test the effect of different alkaloid concentrations on aphid performance, based on MRGR. Two alkaloids (13-OH-lupanine and lupanine) were tested, based on their detection in our phloem sample analyses. Treatments consisted of artificial diet containing 0% (control), 0.001%, or 0.01% for the lupanine alkaloid. In preliminary experiments, amending the diet with similar amounts of 13-OH-lupanine did not cause any significant effect on aphid survival and weight gain; therefore, this compound was tested at 0% (control), 0.01%, and 0.1% concentrations instead. Amended diet solutions were prepared fresh on the day of the experiment. Insects used for this assay were 1st instar nymphs (\leq 48 hr) of BP2, X13, and the lupin-feeding clone. Nymphs were procured by transferring approximately 20 apterous females from the bulk rearing cages to Petri plates containing a single radish leaf. The petiole of the leaf was embedded in an agar slab to prevent desiccation.

Females were allowed to feed and nympho-posit for a period of 48 hr, after which nymphs were randomly collected and weighed in groups of 5 with a Sartorius 3MP microbalance (Göttingen, Germany). Nymphs were then transferred to the different treatment sachets and allowed to feed for 5 d. After this feeding period, surviving nymphs were counted, collected, and collectively weighed. These data were used to determine the MRGR of the different clones on the diet treatments. The experiment was set up in triplicates with each replicate containing three concentrations of the compounds for each of the three aphid clones. The experiment was repeated over time to obtain a total of nine replicates for each compound concentrations/aphid clone combination. All insects and experimental sachets were kept in a 20°C incubator maintained at a 14:10 hr L:D photoperiod for the duration of the experiment. The effect of each alkaloid on *M. persicae* clonal MRGR was statistically analyzed by ANOVA with "clone" as a treatment and alkaloid concentration as a covariate (PROC GLM; SAS Institute, 1996). To test for discriminating dosages, clonal MRGR comparisons were conducted by using single-factor analyses of variance, with Bonferroni correction for multiple comparisons (PROC GLM, SAS Institute, 1996).

Results

Immature Performance

Immature performance (MRGR) of the clones was significantly affected by the plant variety ($F = 19.23$; $df = 2,231$; $P < 0.001$). The greatest variation in performance was obtained in the most susceptible narrow-leaved lupin variety Tallerack, on which 70% of the clones tested achieved a positive MRGR (Fig. 1). The MRGR of the lupin-feeding clone was higher than that of all other clones ($F = 4.28$; $df = 9,71$; $P < 0.001$), except clone C61 (Fig. 1). The lupin-feeding clone had the highest MRGR on the resistant varieties Tanjil ($F = 2.31$; $df = 9,71$; $P < 0.001$) and Kalya ($F = 4.85$; $df = 9,71$; $P < 0.001$) (Fig. 1).

Colonization Ability of Apterous Females

We found a significant effect of variety ($F = 91.3$; $df = 2,70$; $P < 0.001$) and clone ($F = 10.3$; $df = 4,70$; $P < 0.001$), but not their interaction on the insect weight accumulated by *M. persicae*. The highest insect mass was attained by the lupin-feeding clone on all three lupin varieties (Fig. 2). The greatest variability in colonization performance was observed on the susceptible variety Tallerack with the lupin-feeding clone showing a greater increase in overall weight gain ($F = 3.38$; $df = 4,21$; $P = 0.029$), followed by clones C61, X13, C70, and finally BP2 (Fig. 2). In contrast, the total weight gain obtained by clone BP2 on this lupin variety was lower compared to those of all other clones ($F = 3.38$; $df = 4,21$; $P = 0.029$) (Fig. 2). The lupin-feeding clone also outperformed all other clones on the resistant varieties Tanjil ($F = 3.41$; $df = 4,21$; $P = 0.027$) and Kalya ($F = 4.23$; $df = 4,21$; $P = 0.012$) (Fig. 2). Interestingly however, the accumulated weight of the lupin-feeding clone was greater on Kalya than on Tanjil ($F = 5.82$; $df = 2,12$; $P = 0.017$) (Fig. 2).

Fig. 1 Mean relative growth rate (MRGR) of 10 Australian *M. persicae* clones on three *L. angustifolius* varieties, “Tallerack” (susceptible), “Tanjil”, and “Kalya” (resistant). “Lupin” refers to the lupin-feeding *M. persicae* clone. Different letters represent significant differences in MRGR for individual clones across the three lupin varieties tested (Tukey’s mean separation test, $P \leq 0.05$). Error bars denote 1 SE

Fig. 2 Accumulated colony weight gain of 5 Australian *M. persicae* clones on *L. angustifolius* varieties, Tallerack (susceptible), Tanjil, and Kalya (resistant). Lupin refers to the lupin-feeding *M. persicae* clone. Different letters represent significant differences between insect clones within plant varieties whereas numbers represent significant differences within clones across the three plant varieties (Tukey’s mean separation test, $P \leq 0.05$). Error bars denote 1 SE

Gas Chromatography-Mass Spectrometry Analysis of Lupin Phloem Alkaloids

Analyses of phloem collected via EDTA chelation showed no qualitative differences between the susceptible variety Tallerack and its resistant counterparts. Furthermore, amounts of the 13-OH-lupanine alkaloid did not differ among lupin cultivars. However, the amounts of the

Fig. 3 Level of alkaloids 13-OH-lupanine and lupanine in phloem collected from *L. angustifolius* varieties, Tallerack (susceptible), Tanjil, and Kalya (resistant), based on GC-MS analyses. Significant differences were found in the levels of alkaloids between the most resistant Kalya and the other two varieties tested (Tukey’s mean separation test, $P \leq 0.05$). Error bars denote 1 SE

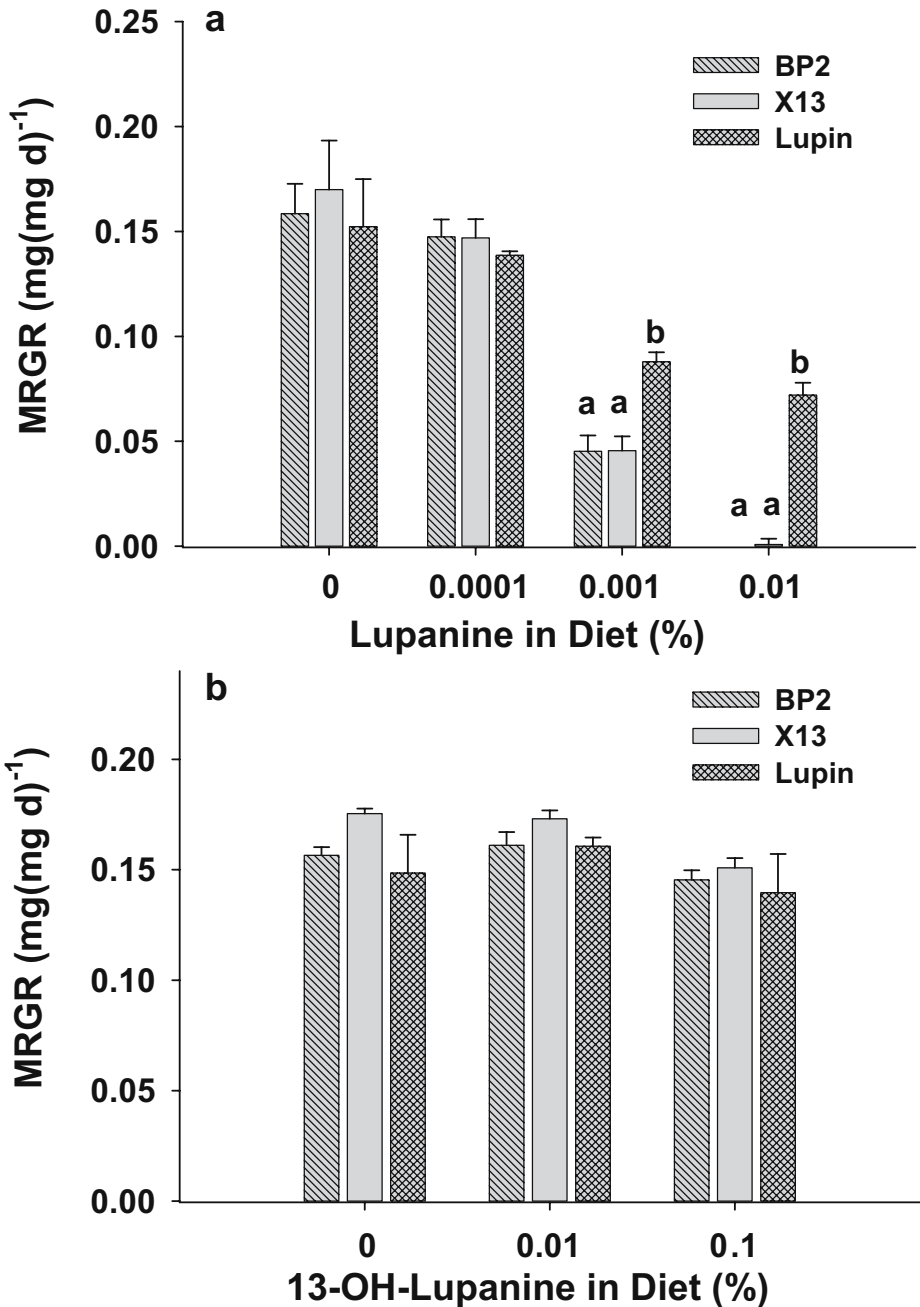

Fig. 4 Performance, based on MRGR, of selected *M. persicae* clones on artificial diet amended with different levels of *L. angustifolius* alkaloids. Lupin refers to the lupin-feeding *M. persicae* clone. (a) Diet amended with 0 (control), 0.0001%, 0.001%, and 0.01% lupanine, and (b) Diet amended with 0 (control), 0.01%, and 0.1% 13-OH-lupanine. Different letters indicate significant differences between insect clones within alkaloid concentrations (Tukey's mean separation test, $P \leq 0.05$). Error bars denote 1 SE

lupanine alkaloid differed among the three lupin cultivars ($F = 4.18$; $df = 2,14$; $P = 0.038$) (Fig. 3). Not surprisingly, Tallerack (the most susceptible variety) yielded the lowest amount of this alkaloid and Kalya (the most resistant variety) had the highest amount. However, differences in phloem lupanine content were only significantly higher for Kalya, compared to the levels of the other two cultivars (Fig. 3).

Artificial Diet Feeding Assays

Aphid MRGR was affected by lupanine concentration ($F = 152.8$; $df = 1,105$; $P < 0.001$), but did not differ among the clones across all concentrations ($F = 0.344$; $df = 2,105$; $P = 0.71$) (Fig. 4a). Aphid MRGR decreased with increasing lupanine concentration in all the tested clones (Fig. 4a). The lupin-feeding clone showed a higher MRGR than the other two clones at a lupanine concentration of 0.01% ($F = 21.046$; $df = 2,24$; $P < 0.001$), but not at 0.001% ($F = 3.840$; $df = 2,26$; $P = 0.036$) (Fig. 4a). Aphid MRGR also differed among the tested 13-OH lupanine concentrations ($F = 7.44$; $df = 1,89$; $P = 0.008$), but did not suppress aphid growth to the same degree as lupanine—even at a higher concentration of 0.1% (Fig. 4b). The tested clones did not respond differentially to 13-OH lupanine.

Discussion

In this study, a lupin-feeding *M. persicae* clone from the Western Australia wheatbelt was shown to significantly outperform nine clones from eastern Australia on both susceptible and resistant narrow-leaved lupin varieties. This suggests that the ability to feed on narrow-leaved lupins in *M. persicae* is not characteristic of the species. Previous work has shown that the ability to feed on lupins by Western Australian *M. persicae* clones is not related to the host plant upon which they were collected, nor does it vary with collection location in the wheatbelt (Edwards, 2001). Aphids, in general, and *M. persicae*, in particular, show phenotypic plasticity that allows them to exploit new host species, overcome novel resistance mechanisms in newly developed plant varieties, and become resistant to the most common insecticidal compounds used for their control. Host plant adaptation frequently occurs in many aphid species. The pea aphid (*Acyrtosiphon pisum*) has been demonstrated to form host races specialized to particular host plant genera (Via, 1991; Sandstroem, 1994). In some generalist aphid species including *M. persicae*, genetic structuring among host plants has been reported (Zitoudi et al., 2001; Ruiz-Montoya et al., 2003). Local selection pressures acting on asexually reproducing aphid populations often result in the predominance of specialized clones (Haack et al., 2000; Vorburger et al., 2003a,b). The abundance of narrow-leaved lupins during the WA growing season may provide sufficient selection pressure for a lupin-adapted clone to predominate.

Lupin alkaloids have been previously implicated in providing defense against insect herbivores, including aphids (Waller and Nowacki, 1977; Berlandier, 1996; Sweetingham et al., 1998). These alkaloids are known to be present in the phloem (Wink and Roemer, 1986), and we have shown, with EDTA chelation, that levels of the bioactive alkaloid lupanine appear to correlate with the levels of aphid resistance in the lupin varieties Tallerack and Kalya. Despite being moderately resistant, the lupin variety Tanjil did not exhibit significantly higher phloem lupanine levels than Tallerack. There is some evidence that resistance in Tanjil involves an induced component (Edwards et al., 2003; Cardoza et al., 2005), so it is possible that phloem lupanine levels could be elevated by aphid feeding. Differences in *in planta* performance among aphid clones were reproduced by using artificial diet supplemented with lupanine,

further implicating this alkaloid in aphid resistance. Thus, it appears that the improved lupin-feeding performance of the lupin-feeding clone from Western Australia is related to its ability to overcome the toxic effects of the phloem alkaloid lupanine.

Insect herbivores can overcome host plant chemical defenses in a number of ways including olfactory discrimination, reduced rates of gut resorption, improved metabolic detoxification, and/or toxin sequestration (Bernays and Chapman, 1994). Polyphagous generalists often select plants, or tissues within plants, in which toxin levels are lower (Schoonhoven, 1972), but aphids appear not to discriminate among narrow-leaved lupin varieties with varying levels of resistance (Edwards et al., 2003). Successful aphid feeding may also involve avoiding the induction of plant defenses (Zhu-Salzman et al., 2004), but there appears to be at most a minor induced component to aphid resistance in resistant narrow-leaved lupin varieties (Cardoza et al., 2005). As such, behavioral avoidance of alkaloid ingestion does not appear to be the mechanism by which *M. persicae* successfully feeds on lupin. Rather, as suggested by the diet bioassays in this study, lupin-feeding *M. persicae* must have a higher tolerance of lupanine in their diet.

The mechanism by which the lupin-feeding clone accomplishes this has yet to be determined. Little is known of the mechanisms underlying host use in aphids (but see Hawthorne and Via, 2001; Via and Hawthorne, 2002; Del Campo et al., 2003). There is no evidence that *M. persicae* has the capacity to sequester alkaloids as is accomplished by the specialist lupin aphid, *M. albifrons* (Wink and Roemer, 1986). It is possible that, like *M. albifrons*, the lupin-feeding clone of *M. persicae* has reduced gut resorption of lupanine, and the majority is excreted in its honeydew (Wink and Roemer, 1986). Pyrrolizidine alkaloids are excreted in the honeydew of *M. persicae* feeding on *Senecio* spp., but the honeydew also contains hydrolyzed by-products including retronecine (Molyneux et al., 1990). The reduced toxicity of 13-OH lupanine compared to lupanine suggests one mechanism by which *M. persicae* could successfully detoxify lupanine. Salivary oxidative enzymes are widely present in aphids (Urbanska et al., 1998; Miles, 1999; Cherqui and Tjallingii, 2000), as are a myriad of enzyme systems (e.g., esterases, glutathione-*S*-transferases) known to function in the breakdown of toxic phytochemicals (Loayza-Muro et al., 2000; Francis et al., 2001). Evidently, further research is necessary to determine the fate of lupanine in the lupin-feeding clone. A comparative study of the lupin feeding physiology between the lupin-feeding clone and clone BP2, which achieved the poorest performance on all narrow-leaved lupin varieties, may shed light on this.

We present evidence of intraspecific variation in Australian *M. persicae* in its ability to feed on lupins with varying degrees of aphid resistance. Our data show high variability in aphid response to resistance factors in narrow-leaved lupins. We believe that the information provided on aphid clonal performance provides the basis for future work on the biochemical and/or genetic factors underlying host-adaptive plasticity in *M. persicae* and other generalist aphid species.

Acknowledgments The authors thank Rick Horbury, Vince Campisi, and Louisa Bell for technical contribution. Aphid clones from Eastern Australia were shared by Dinah Hales (Macquarie University), Christoph Vorburger, and Paul Sunnucks (LaTrobe University). The authors are also grateful to Christoph Vorburger and James Ridsdill-Smith for comments on a previous version of this manuscript. This project was funded by the Grains Research and Development Corporation.

Introduction

Variation in the concentration of plant phenolics and increased activities of oxidative enzymes in response to insect attack are common phenomena in plants (Felton et al., 1994; Bi et al., 1997; Constabel and Ryan, 1998; Stout et al., 1998; Constabel et al., 2000). The relationship between reduced growth of Lepidopteran larvae and phenolic compounds in attacked plants has been described in several reports (Hartley and Firm, 1989; Stamp 1990; Felton et al., 1992b; Horwath and Stamp, 1993; Stamp and Yang, 1996). However, studies of plant metabolic pathways that are activated in response to insect attack are relatively recent, and the results are far from conclusive.

Phenolic oxidation catalyzed by polyphenol oxidase (PPO) and peroxidase (POD) is potentially a plant defense mechanism against herbivorous insects. Covalent bonds formed between oxidized phenols (quinones) and leaf proteins can alter the availability of amino acids (Felton et al., 1989). Alkylation of amino acids, especially essential amino acids, can result in reduced nutritional value of plant proteins for insects (Felton et al., 1992a; Stout et al., 1998). Also, quinones can be directly toxic to herbivores (Duffey and Stout, 1996), and the cyclic reduction of oxidized phenols can form reactive oxygen species ($\cdot\text{OH}$, H_2O_2 , and $\text{O}_2^{\cdot-}$), that damage essential nutrients and/or complex molecules, such as lipids, proteins, and nucleic acids (Bi and Felton, 1995).

The leaf miner, *Leucoptera coffeella* (Guérin-Méneville, 1842) (Lepidoptera: Lyonetiidae), the main insect pest of coffee plants in Brazil, is also an important primary pest in other coffee-producing countries. It is a microlepidopteran, in which butterflies only lays eggs in the adaxial leaf surface during the night. After a period of approx. 5 d, larvae arise directly from eggs to the leaf mesophyll, without contact with the external environment (Parra 1985). Larvae feed exclusively on palisade parenchyma cells, which in coffee leaves are formed by a single layer of cells (Deddeca 1957). On average, after 10 d the larva leave the leaf mesophyll to pupate, which lasts approx. 5 d. Adults survive on average 10 d under laboratory conditions (Parra 1985). Leaves attacked by this leaf miner usually fall and, depending on the defoliation intensity, yield loss, may account for 50% losses in coffee production (Paulini et al., 1976; Thomaziello et al., 1979).

The genus *Coffea* includes two commercially important species, both susceptible to *L. coffeella*: *C. arabica* L. and *C. canephora* Pierre. Seventy percent of commercial coffee plantations use Arabic-type plants, because of the superior quality of their beans (Pereira 2000).

A strategy for the development of cultivars resistant to leaf miners has been the transfer of resistance genes from the wild species *C. racemosa*, via successive back crosses to *C. arabica*. Although resistance to this pest is conferred by two complementary and dominant genes, little is known about the biochemical nature of the resistance (Guerreiro-Filho et al., 1999). There have been few studies on the biochemical nature of resistance of coffee plants to the leaf miner. Recently, Guerreiro-Filho and Mazzafera (2000) studied plants from 13 *Coffea* Species and *C. arabica*/*C. racemosa* hybrids, and concluded that resistance is not related to leaf concentrations of caffeine. The differences observed in the leaf structures of *C. arabica*, *C. racemosa*, and susceptible and resistant hybrids are not related to their resistance to leaf miners (Ramiro et al., 2004). However, Ramiro et al. (2004) observed reduced insect growth on leaves of resistant plants. This suggests that chemical substances in the palisade parenchyma might interfere with feeding and the consequent development of leaf miners.

Chlorogenic acid is a general term used to identify a series of esters formed by quinic acid with cinnamic acids (Clifford 1985). Among several isomers found in coffee,

5-caffeoylquinic acid is the most abundant in *C. arabica* seeds (Clifford 1985) and leaves (Mazzafera and Robinson, 2000). This phenol is susceptible to the action of PPO and POD and can be rapidly converted by PPO into chlorogenoquinone, a highly reactive molecule capable of bonding covalently to other molecules, principally proteins, making them less available for assimilation by the digestive tract of insects (Felton et al., 1989). The quantity of constitutive PPO in coffee leaves is relatively high compared to that found in other species. However, induction of this enzyme by mechanical wounding and by treatment with methyl jasmonate is limited (Mazzafera and Robinson, 2000).

Our objective was to analyze the physiological importance of phenolic oxidation and its role in resistance of coffee plants to attack by *L. coffeella*, in *C. arabica*, *C. racemosa*, and in some of their hybrids presenting different levels of resistance.

Methods and Materials

Plant Material

Analyses were carried out on healthy leaves of mature coffee plants maintained under field conditions at the Experimental Center of Instituto Agronômico (IAC), Campinas (SP), Brazil. Plants received the same agricultural practices, such as fertilization and weed control. Plants were not subjected to drought or cold stress, and did not receive any form of chemical treatment to control pests in order to prevent any detrimental effect on the experiments. Plants were divided into four groups: (1) *C. arabica* (susceptible); (2) *C. racemosa* (resistant); (3) susceptible hybrids; and (4) resistant hybrids. The hybrids belong to two progenies of advanced generations of crosses between *C. arabica* and *C. racemosa*, obtained through genetic breeding to produce coffee plants resistant to the leaf miner *L. coffeella*.

Five individuals from each group were chosen by using plant vigor and resistance or susceptibility as selection criteria. They were as follows: *C. arabica* cultivar Obatã IAC-1669-20, lot 100 (C 400, C 215, C 393, C 576, C 569); *C. racemosa* (H6608-1, H6611-1, H6593-1, H6593-3, IAC 5057); *C. arabica* × *C. racemosa*—resistant (H14954-7, H14954-29, H14954-37, H14954-45, H14954-46); *C. arabica* × *C. racemosa*—susceptible (H13685-1-10, H13685-1-2, H14949-14, H13376-8, H13685-1-26). The alphanumeric designators in parenthesis refer to the identification of each individual plant.

Resistance Evaluation

Insects were produced in rearing cages, using the method described by Katiyar and Ferrer (1968) and adapted by Parra (1985). Cages made with voile tissue and containing infested plants were maintained in a room with high humidity, and a 10% aqueous sucrose solution was offered to insects by wetting a filter paper placed inside of the cage. Coffee plant resistance was evaluated according to Guerreiro-Filho (1994), who validated the method by comparing laboratory evaluations with nursery and field evaluations. Here, healthy mature leaves were collected from the field, with their peduncles immersed in distilled water in assay tubes. Leaves were exposed overnight to insect oviposition in the cages. The next day, using a stereo microscope, a place on the adaxial leaf surface containing three eggs was chosen, and a leaf disk (1 cm diam) was removed with a cork borer. Nine disks were obtained for each plant, and they were transferred into a plastic box containing foam in the bottom. The box was closed with transparent glass and placed under dim laboratory light at room temperature ($25 \pm 2^\circ\text{C}$). Humidity inside the boxes was maintained by adding

distilled water to the foam. Evaluation of the degree of resistance was made after 10 d of infestation using a scale from 1 to 4 (Guerreiro-Filho et al., 1999): 1 = point lesions (resistant); 2 = small filiform lesions (moderately resistant); 3 = large irregular lesions (moderately susceptible); 4 = large rounded lesions (susceptible). The experimental model adopted for data analysis was a fully randomized allocation, with nine replications (disks), and with the factors “group” and “plants” being analyzed by nested analysis of variance (ANOVA).

Biochemical Analyses

Biochemical analyses consisted of comparative analyses between infested and uninfested leaves in different stages of insect development. For extraction of total soluble phenols, 20 healthy mature leaves were collected from each plant in the field. Ten leaves were infested in the insect rearing cages as previously described, whereas 10 others remained uninfested. Except for exposure to insects, all leaves were maintained under the same conditions. In the case of leaves exposed to leaf miners, eggs deposited on one side of the central leaf vein were eliminated with a scalpel, leaving only those deposited on the other side. Eggs were eliminated under a stereo microscope (Guerreiro-Filho et al., 1999). Infested leaves were maintained in humid boxes until 2 d after eclosion of the caterpillars. The uninfested leaves were maintained in separate boxes under the same conditions and for the same period of time. After eclosion, a 25 mm² leaf disk was removed from each side of the central vein of the leaves (sides with and without lesions). On the infested sides, leaf disks were taken from undamaged areas, near the lesions. Soon after they were removed, the disks were individually identified, weighed, and maintained on ice for further extraction. For phenol extractions, each leaf disk was placed into 3 ml ethanol, in screw-top vials, and maintained in a water bath at 50°C until the leaf tissue was completely discolored. Total soluble phenols (Swain and Hillis, 1959) and chlorogenic acid (5-caffeoylquinic acid) (Mazzafera 1999) were determined in this extract. Chlorogenic acid was used as a standard to build a calibration curve ($y = 0.01028x + 0.043$, $R = 0.9936$) to measure total soluble phenols.

A chromatographic profile of the phenolic compounds was obtained with a Shimadzu high-performance liquid chromatography (HPLC), equipped with a diode array detector. Detection of compounds was monitored between 190 and 400 nm. The detector signal was acquired with a workstation, using the Shimadzu Class VP system. An LC18 reverse phase column (Supelco) was used for separation. The separation gradient was 0–70% methanol in 0.5% sodium acetate for 25 min, progressing from 70% to 100% in 25–26 min, and maintained at 100% methanol until 35 min. The solvent flow was 1 ml/min. Quantification of chlorogenic acid for each treatment was made by calculating the areas of the graphs at 326 nm and compared to those obtained with pure chlorogenic acid (Sigma, St. Louis, MO, USA). The elution time of chlorogenic acid was 10 min. Data were analyzed by using a factorial model (infestation group) in a completely randomized experimental design, with five replications (plants). Chlorogenic acid concentration indices were transformed using the equation $y = \log(x + 1)$.

To determine POD and PPO activities, leaves were removed from each plant, placed into leaf-miner-infested cages, and transferred into humid chambers. They were analyzed 1 d (1 DAE) or 4 d (4 DAE) after eclosion of the larva. Controls were uninfested leaves maintained in the humid chambers during the same periods as the infested leaves. Freshly sampled leaves were also collected for analysis. The leaves of five plants were used for each group.

As eclosion of coffee leaf miner eggs occurs approximately 5 d after egg laying (Parra 1985), leaf segments 1 and 4 DAE were evaluated 7 and 10 d, respectively, after the leaves were collected from the field.

Enzymes were extracted with 100 mM sodium phosphate buffer, pH 7, containing 5 mM dithiothreitol (DTT) and polyvinylpyrrolidone (1:10 w/v) in a Polytron homogenizer (Kinematica AG, USA). Leaves were cut into small pieces and submitted to a 10-sec pulse at speed 3, followed by an additional 20 sec at speed 5. Part of the extracts was transferred into Eppendorf tubes, and centrifuged in an Eppendorf bench-top centrifuge at 14,000 rpm for 15 min. The supernatant was collected for protein concentration determination (Bradford 1976). Extracts were stored at -80°C for later analysis. POD and PPO measurements followed the methods used by Mazzafera et al. (1989). POD activity was measured with 5 μM guaiacol and 0.05% H_2O_2 in 100 mM K-phosphate buffer, pH 7, following the absorbance variation at 420 nm (25°C , 30 min, in the absence of light). PPO activity was measured with 7 μM chlorogenic acid and 45 mM glycine at 100 mM K-phosphate buffer, pH 7, following the absorbance variation at 420 nm (30°C , 30 min, in the absence of light). Data were analyzed by using the factorial model (days after eclosion populations) in a fully random experimental design, with five replications (plants). Rates were transformed using the equation $y = \log(x + 1)$.

ANOVA was determined with the statistical program SANEST (Zonta and Machado, 1992), and the means compared with the Tukey test, at 5% probability.

Results

Damage to Leaf Disks

The expression of resistance by plants is shown in Table 1. ANOVA confirmed the existence of significant differences in the expression of resistance to leaf miners among the coffee groups. However, there were no significant differences among plants belonging to the same group. Comparison of means by the Tukey test did not show significant differences between *C. arabica* and the susceptible hybrids, or between *C. racemosa* and the resistant hybrids.

Table 1 Level of resistance (scale of 1 to 4, with 1 being very resistant) to coffee leaf miner in plants sampled from four groups evaluated for the type of lesion in leaves

Groups	Individuals evaluated ^a					Mean
	1	2	3	4	5	
<i>Coffea arabica</i>	4.0	4.0	4.0	4.0	4.0	4.0a
<i>Coffea racemosa</i>	1.7	2.4	1.2	2.1	2.4	2.0b
Susceptible hybrids	2.7	4.0	2.9	3.2	2.7	3.0a
Resistant hybrids	1.6	1.0	1.1	1.0	1.0	1.1b

$F_{\text{groups}} = 49.41^{**}$
 $F_{\text{Plant (groups)}} = 0.37^{\text{ns}}$

^a Mean of nine leaf disks evaluated in the laboratory.

**Significant at the 1% probability level; n.s., not significant at the 5% probability level.

Total Soluble Phenols

Feeding by the coffee leaf miner did not significantly alter the phenol levels in leaves, either on the damaged side of the leaves, or on the side from which the eggs were removed, in each group of plants (Table 2). However, infested leaves showed a trend toward a decrease in phenolic compounds in all populations, although the decrease was not significant. Infested leaves of *C. arabica*, *C. racemosa*, and susceptible hybrids had 19.8%, 15.2%, and 17.0% decreases in phenol concentrations, respectively, compared to uninfested leaves. Resistant hybrids showed little change (3.0%) when infested (Table 2). This decrease in phenolic content was significant only in the means of the treatments (Table 2), demonstrating that these plants, in general, responded to feeding damage by the leaf miners with a reduction in the total soluble phenols in the leaves.

On average, phenolic compounds represented 5.3% of the fresh weight of the leaves of *C. arabica*, 4.8% in the susceptible hybrids, 5.1% in the resistant hybrids, and 2.3% in *C. racemosa*. The high phenolic content of *C. arabica* leaves seems to be a characteristic of the species, as *C. racemosa*, the resistant parent, showed significantly lower content compared with plants from the other groups (Table 2).

Qualitative Comparison of Phenolic Compounds

HPLC analysis did not reveal qualitative differences in the phenolic compounds in infested leaves compared to uninfested leaves (data not shown). On the other hand, *C. racemosa* had a considerably different elution pattern compared to the other genetic groups (Fig. 1). In this species, a large peak was detected at 20 min, but its identity could not be established. It showed two peaks of maximum absorbance at 270 and 326 nm (data not shown).

The leaf contents of chlorogenic acid were significantly different in all treatments. Uninfested leaves of *C. racemosa* had approximately six times less chlorogenic acid than *C. arabica* and the hybrid populations, which did not differ significantly from each other (Table 3).

Chlorogenic acid concentration showed a similar tendency to that observed for total phenols in the hybrids and in *C. arabica*, i.e., a reduced content in infested tissues. There was a 54.9% reduction in the quantity of chlorogenic acid on the infested side of *C. arabica* leaves compared to uninfested leaves. In the susceptible hybrids, reduction in phenol concentration was less pronounced (27.7%), but it was significant. In the resistant hybrid, there was a 19.4% reduction in chlorogenic acid in infested leaves; however, this trend was not significant. On the other hand, opposite to what was observed for total phenols, *C. racemosa* responded to leaf miner attack with a 66.6% increase in chlorogenic acid concentration.

Table 2 Mean concentrations of phenolic compounds [mass equivalents (mg) of chlorogenic acid per G fresh leaf] in leaves of *C. arabica* and *C. racemosa* and of two hybrids derived from a cross between these species

Groups	UL	USL	IL	Mean*

Evaluation of Oxidative Enzyme Activity

POD activities, measured soon after leaves were collected, were higher in *C. arabica* and the resistant progeny than in the susceptible hybrid. Lowest activities were observed in *C. racemosa*, which had up to 15 times less activity.

Under insect infestation, the groups responded differently to treatments 1 and 4 DAE. There was no induction of POD activity due to insect attack in any of the populations at 1 DAE (Table 4). At 4 DAE, leaf miners provoked a 72.4% increase in POD activity in *C. arabica* and 89.6% in the susceptible hybrids. POD activity induced by *L. coffeella* was positively correlated with the type of lesion provoked by feeding activity (Table 1, $R = 0.46$, $T = 2.17$, $P < 0.05$). In these plants, the damage caused by insect feeding was characterized by a massive and localized destruction of a large number of palisade cells (Ramiro et al., 2004).

PPO activity in recently collected leaves varied significantly among populations (Table 5). *C. racemosa* leaves had twice the activity of *C. arabica* leaves, and was fivefold higher than leaves from hybrid plants. The constitutive PPO concentrations in resistant and susceptible hybrids were lower than in the parental species. At 1 DAE, leaf miner attack did not induce PPO activity in any of the populations. At 4 DAE, PPO was significantly induced by insect feeding only in *C. racemosa*. Activity was lower in leaves of resistant and susceptible hybrids, in all the treatments, when compared to the parents.

Discussion

Resistance of *C. racemosa* to the leaf miner *L. coffeella* was attributable to expression of two dominant and complementary genes that were transferred to *C. arabica* by successive backcrosses of the interspecific hybrids to the later parent (Guerreiro-Filho et al., 1999). Among the hybrids obtained from these backcrosses, we selected one resistant and one susceptible to the leaf miner to study the role played by phenols and oxidative enzymes in resistance. Although the defensive role of phenolic compounds and oxidative enzymes appear to be more evident in other plant–insect interactions (Felton et al., 1989; Duffey and Stout, 1996), our results suggest that phenol content apparently does not play a central role in the resistance of coffee to the coffee leaf miner. We found differences between parental species in total soluble phenol concentration, chlorogenic acid content, and oxidative PPO activity; however, the hybrids, did not differ for any of these characteristics.

Data obtained here show that feeding by *L. coffeella* is correlated with quantitative alterations in phenol metabolism and in the activity of oxidative enzymes in coffee leaves. In general, plants responded to feeding damage by reducing the total soluble phenols in the leaves (Table 2). High phenol concentration seems to be characteristic of *C. arabica*, whereas *C. racemosa*, the donor of resistance genes, showed significantly lower concentration. However, the values of hybrids were similar to *C. arabica*. Additionally, the chromatographic profiles of the hybrids were similar to *C. arabica*.

C. racemosa showed a large peak on HPLC, not detected in other plants used in this study. Although speculative, this peak might be an isomer of chlorogenic acid because it showed a maximum absorption peak at 326 nm, a characteristic wavelength for this group of compounds (Clifford 1985). Identification of chlorogenic acid isomers has been carried out mostly in *C. canephora* and *C. arabica* (Clifford 1985; Clifford et al., 2003). The only report on *C. racemosa* indicated the presence of 5-caffeoylquinic acid as the main isomer in seeds (Clifford et al., 1989).

The peak was absent in the hybrids and *C. arabica*, suggesting that it might not be related to leaf miner resistance. However, insect attack in *C. racemosa* was correlated with a significant induction of chlorogenic acid and PPO. Consequently, this compound is being isolated for identification and to determine its participation in the resistance of *C. racemosa* to *L. coffeella*.

The significant increase in chlorogenic acid and PPO activity observed only in insect-infested *C. racemosa* suggests a strategy to increase the availability of substrate for the production of quinones via enzyme activity. However, this does not seem to be the key factor in the defense of resistant hybrids against the leaf miner, because neither chlorogenic acid induction nor increased PPO activity was observed in these plants.

In a recent report, Melo et al. (2006) showed that constitutive PPO activity was higher in leaves of *C. racemosa* than *C. arabica*, and that it was induced by methyljasmonate in the former species, but not by mechanical damage. Also, two other hybrids from these species showed PPO activity close to the *C. arabica* values. Additionally, the phenol content was higher in *C. arabica*. In support of our results, infestation of the two hybrids and *C. arabica* plants with *L. coffeella* did not cause an increase in PPO activity, although a discrete drop of the constitutive activity was also observed in *C. arabica* leaves after insect exposure. Melo et al. (2006) also studied several other coffee species, but did not find a relationship between PPO activity and phenolic contents with resistance to coffee leaf miner or coffee leaf rust disease. These authors concluded that coffee resistance may be related to the oxidative potential of the tissue regarding the phenolic composition rather than simply to a higher PPO activity.

Unexpectedly, recently collected leaves of *C. arabica* showed higher constitutive levels of POD than either infested or uninfested leaves. We do not have a reasonable explanation for this decrease in activity after insect exposure except to speculate that it might be related to leaf detachment. This was not observed for other coffee populations. However, it is interesting to note that the resistant hybrid also showed high constitutive POD activity, but did not decrease after detachment. Leaf detachment does not affect resistance level as shown by Guerreiro-Filho (1994), who compared data obtained from infested coffee plants in the field and nursery with data from the leaf test used here.

Induction of POD due to attack by the leaf miner occurred in *C. arabica* and in the susceptible hybrids. Stout et al. (1994) suggested that the plant response to damage could be related to the type of tissue attacked and to the duration (persistence) and/or magnitude of the lesion. The ratio between damage intensity and response magnitude was almost always positive, indicating that the number of damaged cells influenced the response.

Our results showed a significant correlation between the amount of damage caused by caterpillars (level of resistance) and POD activity. Nevertheless, this differential induction of peroxidase may not be a reaction to insect attack, but rather an effort to replace damaged tissue, because this enzyme is responsible for lignification and suberization in vegetal tissues (Goldberg et al., 1985). Additionally, POD activity might also be related to oxidative stress developed during the larvae feeding (Bi and Felton, 1995).

According to Stout et al. (1994), the induction of PPO and POD in response to insect feeding is not definitive evidence that oxidative enzymes are directly involved in plant defenses to restrict insect attack, because of the complex relationship between these enzymes and several chemical compounds in the cell, and their multiple biological activities.

The action of phenols in biological systems seems to be influenced by several different factors, such as cell concentration, environmental conditions, structural variations, and the degree of specificity between the organisms involved (Appel 1993). *L. coffeella* has high specificity for coffee. It feeds exclusively on cells of the palisade parenchyma in susceptible *C. arabica* (Ramiro et al., 2004). Studies to evaluate phenols, carbohydrates, proteins, and other compounds in the palisade tissue of *C. arabica* and *C. racemosa* might bring important information for understanding of the resistance mechanism to this pest.

Assuming that resistant hybrids inherited the two resistance genes from *C. racemosa* (Guerreiro-Filho 1994), these results for phenolic content and POD/PPO activity are not strong evidence to suggest their participation in a direct defense mechanism of coffee

against *L. coffeella*. However, coinduction of chlorogenic acid and oxidative enzymes was observed in *C. racemosa*, indicating that the two resistance genes transferred to *C. arabica* (Guerreiro-Filho 1994) may not be related to such a mechanism.

Acknowledgments This study was partially financed by the Consórcio Brasileiro de Pesquisa e Desenvolvimento do Café. D.A.R. and P.M. thank CAPES and CNPq-Brasil for research fellowships. The authors thank Geraldo A. Melo for technical assistance with enzymes and HPLC analyses.

Introduction

Intraguild interactions between carnivores that share the same trophic resources include intraguild predation, which has been well documented (Rosenheim et al., 1993; Colfer and Rosenheim, 1995; Rosenheim 1998; Ferguson and Stiling, 1996; Raymond et al., 2000; Snyder and Ives, 2001), but also may involve interactions that serve to avoid intraguild predation (Doubtina et al., 1998; Taylor et al., 1998; Nakashima and Senoo, 2003). Immature stages of parasitoids often become intraguild prey in interactions between predators and parasitoids operating in the same guild, and so adult parasitoids would benefit by developing avoidance responses to cues from intraguild predator species living in the same habitats to reduce predation risks to their offspring. Aphids are associated with a large assemblage of insect natural enemies (Mackauer and Finlayson, 1967; Takada, 1968; Wheeler, 1977; Wratten and Powell, 1991; Ekbom, 1994), and so adult aphid parasitoids would encounter different types and species of intraguild predator during host searching. The more generalist aphid parasitoids, which can forage in a range of habitats, might be expected to develop a generalized response to predator cues.

Semiochemicals mediating intraguild interactions are poorly defined. Hydrocarbons have been reported previously as components of chemical trails left on substrates by seven-spot ladybirds, *Coccinella septempunctata* (Kosaki and Yamaoka, 1996). The same study suggested that large amounts of these chemicals were secreted from the tarsi. Recently, two aliphatic hydrocarbons, *n*-tricosane (C₂₃H₄₈) and *n*-pentacosane (C₂₅H₅₂), were shown to induce avoidance responses by the aphid parasitoid, *Aphidius ervi*, toward *C. septempunctata* (Nakashima et al., 2004). These hydrocarbons were present in the chemical trails left by the ladybirds on plant surfaces. Adult *A. ervi* females spent a significantly shorter time foraging on plants treated with these chemicals, resulting in lower parasitism rates of the pea aphid, *Acyrtosiphon pisum*, than on untreated plants (Nakashima et al., 2004).

In this study, we compare the responses to ladybird trails of three parasitoid species that attack *A. pisum* but which differ greatly in their host and habitat ranges. *A. eadyi* is a specialist on *A. pisum* (Pennacchio, 1989), and forages predominantly in habitats containing legume plants, whereas eight aphid species belonging to seven genera, including *A. pisum*, have been recorded as host species of *A. ervi* (Pennacchio, 1989), allowing it to forage in a wider range of habitats. *Praon volucre* is an even more polyphagous parasitoid, attacking at least 30 species belonging to 13 genera (Stary, 1976), which occur in a greater variety of habitats including forests. Therefore, each parasitoid species may be at risk from different species and numbers of intraguild predators due to these differences in the range of habitats in which they forage. For example, *C. septempunctata* occurs predominantly on herbaceous plants, while the two-spot ladybird, *A. bipunctata*, is found on both herbaceous plants and trees (Honék, 1985), suggesting that *P. volucre* would regularly encounter both *C. septempunctata* and *A. bipunctata*, but the two *Aphidius* species would probably encounter *A. bipunctata* much less frequently than *C. septempunctata*. It is hypothesized that *P. volucre* would detect and avoid a broader range of chemicals in ladybird trails than would the two *Aphidius* species, and that the *Aphidius* species should be more sensitive to the particular chemicals in trails of ladybirds that are dominant species in their preferred habitat. The aims of our study were to compare the avoidance responses of these three parasitoid species to the chemical trails of the two ladybird species, and to measure their sensitivity to the different hydrocarbons present in the trails.

Materials and Methods

Insects

The three aphid parasitoids, *Aphidius eadyi*, *Aphidius ervi*, and *Praon volucre*, were obtained from laboratory colonies that had been initiated with mummies of pea aphids, *Acyrtosiphon pisum*. The first two species were initially collected from pea fields in Harpenden, Hertfordshire, and Sharnbrook, Bedfordshire, UK, during spring 2001, while *P. volucre* was collected in Harpenden during spring 2002. Overwintered, adult, seven-spot ladybirds, *Coccinella septempunctata*, were collected from evergreen shrubs at Rothamsted Research during March and April, 2002. Overwintering, adult, two-spot ladybirds, *Adalia bipunctata*, were collected from window frames at Horticultural Research International in East Malling, Kent, UK, in November 2001. Parasitoids and ladybirds were both kept at 20°C and a light–dark 16:8 hr photoperiod, and provided with *Acyrtosiphon pisum*, reared on broad bean plants, *Vicia faba* L. (Fabaceae; var. Sutton), as food. Parasitoids were removed from colony cages at the mummy stage, and were kept in petri dishes (9 cm diam, 1.5 cm height) containing honey solution on cotton wool as adult food until emergence. Two days after the first adult emergence was observed, females were individually confined in small petri dishes (5.0 × 1.5 cm) with ~50 *A. pisum* and honey solution on cotton wool. All females used in bioassays were 4–5 d old.

Ladybird Chemicals

Extracts of ladybird chemical trails were prepared by confining a single *C. septempunctata* or *A. bipunctata* adult in a glass petri dish (9 × 1.5 cm) for 18 hr at 20°C, then removing the ladybirds and washing the dishes with distilled hexane (10 ml per dish). Glass surfaces provide an ideal substrate for the isolation and collection of insect chemical trails. The extracts were evaporated to 100 µl under a gentle stream of high-purity nitrogen and stored in microvials at –20°C until further use. These procedures were repeated six times for adults of each ladybird species.

Gas Chromatography

The ladybird footprint hexane extracts were analyzed on a Hewlett-Packard 6890A gas chromatograph (GC) equipped with a cool on-column injector, a flame-ionization detector, and a 50 m × 0.32 mm (0.52 µm film thickness) i.d. HP-1 bonded-phase fused-silica capillary column (J & W Scientific). The oven temperature was maintained at 30°C for 0.5 min, then programmed at 5°C/min to 150°C, held at this temperature for 0.1 min, then programmed at 10°C/min to 280°C. The carrier gas was hydrogen. Quantities of *n*-tricosane, *n*-pentacosane, and *n*-heptacosane in the extracts were determined by comparison of GC peak areas with those obtained from authentic samples (100 ng).

Coupled GC–Mass Spectrometry

A capillary GC column (50 m × 0.32 mm i.d. HP-1) fitted with a cool on-column injector was directly coupled to a mass spectrometer (Thermo-Finnigan MAT95XP, Bremen, Germany). Ionization was by electron impact at 70 eV, 200°C. The oven temperature was maintained at 30°C for 5 min, then programmed at 5°C/min to 280°C. The carrier gas was helium. Tentative identifications were made by comparison of mass spectrometry (MS) data

with published spectra (NIST, 2002). Confirmation of tentative identifications was accomplished by peak enhancement on GC with authentic samples obtained from commercial sources (Pickett, 1990).

Chemicals

n-Tricosane (C₂₃H₄₈), *n*-pentacosane (C₂₅H₅₂), and *n*-heptacosane (C₂₇H₅₆; all 99% purity) were purchased from the Aldrich Chemical Company (Gillingham, UK). For behavioral studies, individual solutions of these chemicals were prepared in distilled ethanol at the following concentrations: 10, 1, 0.1, and 0.01 µg/ml. All solvents were distilled before use.

Application of Chemicals to Plants

Pure authentic compounds in ethanol were applied to broad bean plants, *V. faba*, for use in behavioral bioassays, as previously described (Nakashima et al., 2004). These solutions were applied to the plants (six- to eight-leaf stage, one plant per pot) by using a rotary atomizer mounted on a multispeed track. The atomizer operated at 4500 rpm and produced a drop size of approximately 110 µm VMD. Applications were made at a velocity of 0.4 msec⁻¹ at a height of 25 cm above the plants, providing an application rate of 1.04 ml m². Control leaves were prepared in a similar manner with distilled ethanol. By using the ethanolic solutions of compounds prepared at the concentrations described above, and based on the application rate and the dimensions of the leaf squares (see below), the leaf squares generated (1.5 × 1.5 cm) were coated with 4, 0.4, 0.04, and 0.004 ng test compound, respectively.

Behavioral Bioassays

The effects of *C. septempunctata* and *A. bipunctata* trails and trail extracts on aphid parasitoid responses were investigated by using a dual-choice bioassay. Treatment leaves with ladybird trails were prepared by inserting a leaf from a bean plant (six- to eight-leaf stage) into a plastic container via a slit, releasing a ladybird adult into the container, allowing it to walk upon the leaf for 24 hr, and then removing it from the plant. Control leaves were left untouched for a similar length of time. Leaves were used for experiments immediately after exposure ended. Treated and control leaf squares (1.5 × 1.5 cm) were taken from the plants and placed 0.5 cm apart in a petri dish (5 cm diam), into which a single parasitoid female was then released. After allowing the parasitoid to settle (1 min), the time spent foraging on each leaf square was measured for a period of 10 min. Each experiment was repeated 20 times. To account for potential temporal effects, equal numbers of each of the three parasitoid species were tested each day, randomizing the order of testing between days.

Statistical Analysis

The durations of visits by parasitoids were analyzed by using Wilcoxon's signed rank tests and Mann–Whitney *U* test. The degree of avoidance was expressed as time allocated on leaf squares with treatments divided by total residence time on control and treatment leaf squares. The index of avoidance responses were analyzed by an ANOVA with chemical compounds, their concentrations and parasitoid species as main effects; the proportional data were arcsine transformed to stabilize the variance before this analysis. The amounts of

Fig. 1 Effect of seven-spot ladybird, *C. septempunctata*, and two-spot ladybird, *A. bipunctata*, chemical trails on time spent foraging by female aphid parasitoids, *A. ervi*, *A. eadyi*, and *P. volucre*, on broad bean, *V. faba*, leaf squares. Data are expressed as time spent on leaf squares treated with ladybird trails divided by total residence time on control and treated leaf squares in choice bioassays. Vertical lines indicate \pm S.E

trail chemical compounds were compared by Mann–Whitney *U* test. For the latter, the data were transformed to logarithms to stabilize the variance before analysis.

Results

In dual-choice leaf square bioassays conducted immediately after leaf exposure to *C. septempunctata* and *A. bipunctata* adults, parasitoids avoided the leaf squares treated with ladybird trails in all combinations of parasitoid and ladybird species (Wilcoxon’s signed rank test, $P < 0.05$; Fig. 1). The degree of avoidance of *C. septempunctata* trails was stronger than that of *A. bipunctata* trails for *A. eadyi* and *A. ervi* (Mann–Whitney *U* test, $P <$

Fig. 2 Typical gas chromatograms of adult (a) seven-spot ladybird, *C. septempunctata*; (b) two-spot ladybird, *A. bipunctata*, footprint extracts. Peak numbers correlate to compounds listed in Table 1 identified by coupled GC–MS. Extracts were collected from individual *C. septempunctata* and *A. bipunctata* adults over 18 hr in a glass petri dish. Flame ionization detector responses are provided on the same scale for comparison

^c Identification confirmed by peak enhancement on GC using authentic samples.

^d Compound identified in adult seven-spot ladybird, *C. septempunctata*.

0.05), but it was statistically similar for the trails of both ladybirds in the case of *P. volucre* (Fig. 1).

To identify the chemicals responsible for parasitoid avoidance, hexane extracts of footprint trails from adult *C. septempunctata* and *A. bipunctata* were analyzed by high-resolution GC and coupled GC–MS. Samples from both species were comprised almost entirely of aliphatic hydrocarbons (Fig. 2; Table 1). Components identified in both species were *n*-tricosane, *n*-pentacosane, and *n*-heptacosane. By comparison with authentic samples using GC, the levels of *n*-tricosane, *n*-pentacosane, and *n*-heptacosane in the footprint trails of *C. septempunctata* and *A. bipunctata* adults were determined. Larger amounts of *n*-pentacosane and *n*-heptacosane were found in the trails of *C. septempunctata* than in those of *A. bipunctata* (Mann–Whitney *U* test, $P < 0.05$), but no significant difference was found in the levels of *n*-tricosane (Table 2). Other major aliphatic hydrocarbons were identified tentatively as branched hydrocarbons by comparison with MS data from similar studies elsewhere (Table 1; Hemptinne et al., 2001; Nakashima et al., 2004). Compounds identified specifically for *C. septempunctata* included 13-, 9-, and 7-methylheptacosane; 9,13-, 7,11-

Table 2 Mean levels (Nanograms \pm S.E.) of three hydrocarbons found in chemical trail extracts of the Ladybirds *C. septempunctata* and *A. bipunctata* ($N = 6$)

Compound	Log amount \pm S.E.	
	<i>C. septempunctata</i>	<i>A. bipunctata</i>
<i>n</i> -Tricosane	2.77 \pm 0.06 a	2.73 \pm 0.14 a
<i>n</i> -Pentacosane	2.52 \pm 0.11 a	2.13 \pm 0.04 b
<i>n</i> -Heptacosane	2.69 \pm 0.10 a	2.40 \pm 0.06 b

Values followed by different letters in the same row are significantly different (Mann–Whitney *U* test, $P < 0.05$). Mean levels were determined per GC injection (4 μ l).

Table 3 Anova for effects of different hydrocarbons from Ladybird trails, hydrocarbon concentration, and parasitoid species on proportion of time spent foraging by female parasitoids on treated leaf squares

Factor	df	F	P
Hydrocarbon	2	8.1	<0.01
Concentration	3	5.9	<0.01
Parasitoid species	2	0.9	0.40
Hydrocarbon × concentration	6	0.7	0.67
Hydrocarbon × parasitoid species	4	2.6	0.036
Concentration × parasitoid species	6	0.4	0.87
Hydrocarbon × concentration × parasitoid species	12	0.8	0.66

dimethylheptacosane, and 7,11,15-trimethyl-heptacosane. Compounds identified specifically for *A. bipunctata* were *n*-heneicosane, and 9- and 7-methyltricosane.

An ANOVA of proportions of time spent by parasitoids on leaf squares treated with individual hydrocarbons from ladybird trails indicated significant effects of both hydrocarbon type and concentration (Table 3). The interaction between hydrocarbon type and parasitoid species was also significant (Table 3), indicating that parasitoids differed in their responses to different hydrocarbons.

The total residence times of *A. eadyi* on leaf squares treated with *n*-tricosane were shorter than those on control leaves for all treatment concentrations (Wilcoxon’s signed rank test, $P < 0.05$), but significant effects were only found at higher doses (0.4 and 4 ng) for *A. ervi* and only at the highest dose (4 ng) for *P. volucre* (Wilcoxon’s signed rank test, $P < 0.05$; Fig. 3). In the case of *n*-pentacosane, the residence times for all three parasitoid species were reduced by the hydrocarbon only at the two highest doses (0.4 and 4 ng; Wilcoxon’s signed rank test, $P < 0.05$; Fig. 3). There were no significant differences between residence times on control leaf squares and those treated with *n*-heptacosane, at any concentrations used, in the cases of the two *Aphidius* species, but *P. volucre* spent less time on treated leaf squares at the two highest doses (0.4 and 4 ng; Wilcoxon’s signed rank test, $P < 0.05$; Fig. 3).

Fig. 3 Response of female aphid parasitoids, *A. ervi*, *A. eadyi*, and *P. volucre* to leaf squares treated with either *n*-tricosane ($C_{23}H_{48}$), *n*-pentacosane ($C_{25}H_{52}$), or *n*-heptacosane ($C_{27}H_{56}$). For each compound, concentrations of 10, 1, 0.1, and 0.01 $\mu\text{g/ml}$ were applied, equivalent to doses of 4, 0.4, 0.04, and 0.004 ng per leaf square. Data are expressed as time spent on leaf squares treated with ladybird trail hydrocarbons divided by total residence time on control and treated leaf squares. Vertical lines indicate \pm S.E. Asterisks indicate significant difference from control (Wilcoxon’s signed rank test, $P < 0.05$)

Discussion

To our knowledge, this is the first report that adult parasitoids vary in their avoidance of different species of intraguild predators, and that this variability potentially relates to differences in the amounts of specific chemical compounds in the predator trails. The two *Aphidius* species tested responded more strongly to trails of *C. septempunctata* than to trails of *A. bipunctata*, but there were no statistically significant differences in the responses of *P. volucre* to the trails of either of the two ladybird species. Components identified in both species were *n*-tricosane, *n*-pentacosane, and *n*-heptacosane, the presence of which in *C. septempunctata* had been previously demonstrated (Nakashima et al., 2004). All three parasitoid species showed avoidance responses to *n*-tricosane and *n*-pentacosane, as shown in a previous study (Nakashima et al., 2004), but only *P. volucre* responded to *n*-heptacosane. Other chemicals found specifically in *C. septempunctata* and *A. bipunctata* trails were not investigated for avoidance activity in this study, as previous work (Nakashima et al., 2004) showed that *n*-tricosane, *n*-pentacosane, and *n*-heptacosane accounted for parasitoid avoidance responses.

The differences in the levels of avoidance behavior shown toward the two different ladybird trails by both *Aphidius* species could be due to differences in the amounts of specific hydrocarbons present in the two trails (Table 2). *n*-Tricosane and *n*-pentacosane are known to be the main ladybird avoidance stimuli for *A. ervi*, and these two chemicals additively increase avoidance responses (Nakashima et al., 2004). This finding, together with the present results, suggests that larger amounts of *n*-pentacosane in the trails of *C. septempunctata* may induce the stronger avoidance responses recorded for *A. ervi* and *A. eadyi* to trails of this ladybird than to those of *A. bipunctata* (Fig. 1), the same chemical compounds stimulating the avoidance behavior in these closely related species. *P. volucre* showed no difference in the level of response to trails of the two ladybird species, but this parasitoid responded to all three hydrocarbons and so may have a more general sensitivity to hydrocarbons in ladybird chemical trails.

The presence of aliphatic hydrocarbons specific to *C. septempunctata* and *A. bipunctata* adults implies that these compounds have a function in the behavioral ecology of the ladybirds. Studies elsewhere have implied that such compounds may play a role in mediating intraspecific ladybird interactions (Hemptinne et al., 2001), specifically the oviposition deterrent response of adult *A. bipunctata* following detection of intraspecific larval footprints. Previous work on avoidance of *C. septempunctata* footprints by *A. ervi* (Nakashima et al., 2004) revealed virtually identical hydrocarbon profiles for adults and larvae. Thus, it can be expected that these compounds play a role in *C. septempunctata* oviposition deterrent behavior, and that a similar outcome can be expected for *A. bipunctata*. Further studies are required to confirm the role of these compounds.

As a specialist parasitoid of pea aphid, *A. eadyi* is likely to restrict its foraging to habitats containing legume plants (Pennacchio, 1989). Thus, *A. eadyi* would encounter a limited number of ladybird species, and principally *C. septempunctata*, which is a dominant species in legume crops (Ekbohm, 1994; Nakashima and Akashi, 2005). *A. ervi* forages commonly on legume plants, but also forages on other arable crops, including cereals, where *C. septempunctata* is the dominant aphidophagous ladybird (Wratten and Powell, 1991). Therefore, it may be adaptive for females of these two *Aphidius* species to optimize their sensitivity to the chemical trails of the ladybirds that they are most likely to encounter as intraguild predators, thereby maximizing the avoidance behavior that reduces the predation risk to their offspring. However, little is known about encounter rates in natural habitats, and such studies are needed to help elucidate the evolutionary development of intraguild interactions.

A. eadyi was the most sensitive of the three parasitoids to *n*-tricosane, responding to very low concentrations. Detection of early instar predators, which deposit much smaller amounts of trail chemicals than adults and mature larvae, could be important because ladybird larvae are likely to stay and complete development within an aphid patch (Dixon, 2000). Additionally, ladybird trails appear to have relatively short active periods, possibly due to absorption of the hydrocarbons into the plant cuticular lipid layer, or even evaporation/sublimation from the leaf surface over time (Nakashima et al., 2004). Increased sensitivity to one of the chemical components of ladybird trails may help *A. eadyi* to perceive trails that *A. ervi* and *P. volucre* cannot detect, giving this extreme specialist species a competitive advantage in the restricted range of habitats in which it forages. In contrast, *P. volucre* is a more generalist parasitoid at both the host species and host plant levels (Pennacchio, 1989). In this case, a more generalized sensitivity to trail chemicals may be advantageous, as parasitoids with broader host/habitat ranges would face a predation risk from a larger number of predator species.

The overall results showed that hydrocarbon types and their concentrations affected parasitoid avoidance responses, and the level of avoidance responses shown to the three chemical compounds differed among the parasitoid species (Fig. 3). *P. volucre* avoided all three hydrocarbons in contrast to the *Aphidius* species, which avoided only *n*-tricosane and *n*-pentacosane. Thus, the range of trail chemicals detected by the generalist *P. volucre* was wider than that detected by the two *Aphidius* species, which both have narrower host ranges. The specialist *A. eadyi*, which is only known to attack the pea aphid, *A. pisum*, was the most sensitive to *n*-tricosane, responding to this chemical at the lowest concentration tested.

The results of the present study suggest that oviposition preferences by aphid parasitoids in response to intraguild predators are common in *Aphidius* and *Praon* species. Nakashima and Senoo (2003) and Nakashima et al. (2004) suggested that both intraguild predation and its avoidance play important roles in determining top–down forces by predator guilds, and consequently affect herbivore populations in local areas. Although several reports have revealed that aphidophagous predators, such as coccinellids and chrysopids, are deterred from ovipositing when exposed to areas where heterospecific competitors are present (Ruzicka, 1998, 2001; Agarwala et al., 2003), there was little evidence for this behavior in parasitoids. We predict that intraguild predator avoidance by adult parasitoids should be widespread in other systems because immature parasitoids in/on hosts are always at risk from predators. Additionally, host/prey density is known to affect the degree of predator avoidance by parasitoids (Nakashima and Senoo, 2003) as well as intraguild predation (Lucas et al., 1998). Further research should determine how extrinsic (e.g., prey density) and intrinsic (e.g., experience and physiological state) factors affect the magnitude of intraguild predation and its avoidance to understand the role of these interactions in the dynamics of predator–parasitoid–herbivore systems.

Introduction

The family Papilionidae includes over 500 species and is traditionally divided into three subfamilies: the Baroniinae (a single tribe, Baroniini), the Parnassiinae (tribes Zerynthiini and Parnassiini), and the Papilioninae (tribes Troidini, Graphiini, and Papilionini) (Munroe and Ehrlich, 1960; Scriber, 1995). The morphology, color, and patterning of papilionid larvae differ among species and instars. Some larvae appear to mimic bird droppings, whereas others are snake-like in appearance with false eyespots. Colorations, presumably cryptic, are typically green or brown, often with mottled or striped patterns. These visual traits are likely to be effective in reducing detection by predators (Takagi et al., 1995) though they may also serve as aposematic signals in unpalatable larvae (Järvi et al., 1981). Whatever their visual appearance, swallowtail larvae possess a characteristic two-pronged eversible gland (osmeterium) on the middorsal intersegmental surface between the head and the prothorax. When disturbed, they extrude this gland, from which an odoriferous liquid is secreted. Behavioral studies have shown that the osmeterial secretions are especially effective at deterring arthropod predators, including ants, spiders, mantids, wasps, and soldier bugs (Eisner and Meinwald, 1965; Honda, 1983a; Chow and Tsai, 1989; Takagi et al., 1995). In the field, Damman (1986) showed that mortality of *Eurytides marcellus* larvae due to ants and small spiders was substantially increased among larvae that had been experimentally prevented from extruding their osmeterial gland. Many insect predators, however, are able to ignore or circumvent the osmeterial defenses of swallowtails (Damman, 1986; Berenbaum et al., 1992; Takagi et al., 1995).

The chemical nature of the osmeterial secretion has been examined for very few species but in representatives of all swallowtail tribes. *Baronia brevicornis*, the only species in the tribe Baroniini, secretes two aliphatic acids as the osmeterial components in fifth instars (Eisner et al., 1970). Of approximately 14 species in the Zerynthiini (Hancock, 1983; Miller, 1987), two *Luehdorfia* and one *Sericinus* species produce monoterpene secretions in both the fourth and fifth instars (Honda, 1980a; Honda and Hayashi, 1995). The osmeteria of *S. montela* also contain aristolochic acids (Nishida, 1995). In the Parnassiini, with approximately 35 species, *Parnassius glacialis* produces aliphatic acids and esters in the osmeterial secretions from third and fourth (ultimate) instars (Honda and Hayashi, 1995). Although the Troidini includes about 130 species, only three have been examined for volatiles in osmeterial secretions. *Battus polydamas* secretes two sesquiterpenoids in abundance in fourth instars (Eisner et al., 1971), whereas *Atrophaneura alcinous* and *Pachliopta aristolochiae* produce sesquiterpenoids as dominant components in both fourth and fifth instars (Honda 1980a; Honda and Hayashi, 1995). In addition, osmeterial exudates from the caterpillars of several troidine species contain aristolochic acids (Nishida and Fukami, 1989; Nishida et al., 1993; Nishida, 1995; Sime et al., 2000). In the Graphiini, a tribe containing about 150 species, *E. marcellus* secretes two aliphatic acids as major osmeterial components in fifth instars (Eisner et al., 1970), whereas *Graphium sarpedon* and *G. doson* contain aliphatic acids and their esters as major components in both fourth and fifth instars (Honda, 1980a). The Papilionini is dominated by the large genus *Papilio*, consisting of about 200 species. About 20 of these have been investigated for the chemical nature of their larval osmeterial secretions. While most earlier studies were restricted to either the fourth or the fifth instars (e.g., Eisner et al., 1970; Lopez and Quesnel, 1970; Seligman and Doy, 1972), subsequent studies compared the secretions of both fourth and

fifth instars in a total of nine *Papilio* species. These confirmed that the fourth instars secrete terpenoids as the major constituents, while the fifth instars secrete aliphatic acids and their esters (Honda, 1980b, 1981; Burger et al., 1985; Young et al., 1986).

On the basis of whether or not the final larval ecdysis is accompanied by a shift in the dominant osmeterial chemistry, papilionid species can be divided into two groups. Whether their secretions are dominated by terpenoids or by aliphatic acids and esters, the species so far studied from most papilionid tribes belong to the “homogeneous” group (Honda, 1980a), in which there is no major change in chemistry. By contrast, those *Papilio* species for which sufficient information is available can be assigned to the “heterogeneous” group (Honda, 1980a). Whether or not the heterogeneous trait is characteristic of the tribe Papilionini, however, remains uncertain as such a small fraction of its species has been examined. Moreover, the larval host plants of those *Papilio* species for which we already know the osmeterial chemistry of both fourth and fifth instars belong either to the Rutaceae or the Apiaceae—families that share many features of their secondary chemistry (Hegnauer, 1971). To investigate the possibility that variation in the composition of osmeterial secretions might be related to host-plant chemistry, it is desirable to examine *Papilio* species with larval host plants in more distantly related families such as the Lauraceae and Magnoliaceae.

In this study, we describe the chemical composition of volatile substances in the osmeterial secretions from both fourth and fifth instars of eight species belonging to the tribe Papilionini. Six belong unambiguously to the genus *Papilio* (*P. demoleus*, *P. polytes*, *P. paris*, *P. macilentus*, *P. troilus*, and *P. glaucus*). *P. demoleus* and *P. paris* feed as larvae on rutaceous plants and are widely distributed from India to Southeast Asia and from West Asia to Southeast Asia and Australia, respectively. *P. polytes* and *P. macilentus*, Rutaceae feeders, occur from India to Southeast Asia and in China, the Korean Peninsula, and Japan, respectively. *P. troilus* inhabits the eastern regions of the United States and Canada, and feeds on lauraceous plants. *P. glaucus* is widely distributed in North America and is notable for its relatively wide spectrum of host plants, which includes the families Magnoliaceae and Lauraceae. Previous work revealed the dominance of two aliphatic acids in the osmeterial secretions of fifth instars of both *P. troilus* and *P. glaucus* (Eisner et al., 1970), but no data were presented for fourth instars.

We also included *Chilasa epycides* and *C. agestor*, Lauraceae-feeding swallowtails inhabiting Formosa, West China, and Burma. The dozen or so species in the genus *Chilasa* are unusual in their mimicry, as adults, of danaid butterflies that are known or suspected to sequester defensive compounds from their host plants. While the genus *Chilasa* is supported by Hancock (1983) and Igarashi (1984), other scholars include the group within the genus *Papilio* (Miller, 1987; Zakharov et al., 2004).

Methods and Materials

Insects

Larvae of *P. polytes* and *P. macilentus* originated from Yaeyama and Kanagawa populations, respectively, in Japan. They were reared on *Citrus* spp. and *Orixa japonica* (Rutaceae), respectively. Larvae of *P. troilus* and *P. glaucus* were derived from female adults collected in Ithaca, NY, USA, and reared on *Sassafras albidum* (Lauraceae) and *Liriodendron tulipifera* (Magnoliaceae), respectively. *P. demoleus*, *P. paris*, *C. epycides*, and *C. agestor* were all obtained from Taiwan. Larvae of *P. demoleus* and *P. paris* were raised on *Citrus* spp. and *Fagara ailanthoides* (Rutaceae), respectively, whereas

Cinnamomum camphora (Lauraceae) was used for rearing *Chilasa epycides* and *C. agestor* larvae. All larvae were reared at 25°C under a photoperiod of 16L:8D.

Collection of Secretions

Using the methods of Honda (1980b), we collected osmeterial secretions separately from fourth and fifth instars of each species on the third day after larval ecdysis by absorption into pieces of filter paper (5 × 5 mm, No. 2, Advantec, Tokyo, Japan). From these, they were each extracted by approximately 2 ml of purified (twice distilled) dichloromethane, and the resulting extracts were stored at -10°C until analysis. For each species except *C. agestor* and *P. glaucus*, 15–36 larvae were sampled, which permitted both qualitative and quantitative analysis. Chemical analyses were duplicated for these species, using different batches of larvae. Since only five or six larvae of *C. agestor* and *P. glaucus* were sampled, their secretions were subjected to qualitative analysis only.

In a study on the osmeterial chemistry of *P. demodocus*, Burger et al. (1985) found that individual fourth instars produced mixtures of terpenoids that were qualitatively similar to one another but varied greatly in quantitative content. The authors attributed this variation to different levels of irritation of the larvae during sampling: minor irritation resulted only in partial eversion of the forks, which were fully everted only on more persistent irritation. Such variability of osmeterial chemistry among individual larvae may have influenced the results of our study but was not explicitly measured. For those species with large enough numbers of larvae for quantitative analyses, we found no appreciable interbatch differences in the overall profiles of the secretions.

Chemical Analyses of Volatile Components

The secretion extracts were examined by gas chromatography (GC) and GC-mass spectrometry (GC-MS). GC analyses were conducted with a Shimadzu GC-14A gas chromatograph equipped with a flame ionization detector at a temperature of 250°C, whereas GC-MS analyses were performed at 70 eV using a Shimadzu QP5000 mass spectrometer coupled with a Shimadzu GC-17A gas chromatograph. Most of the analyses were carried out with a Varian CP-Wax 58CB fused-silica capillary column (0.25 mm ID × 25 m for GC or 50 m for GC-MS, 0.20 μm film thickness), with a temperature program of 40°C (held initially for 2 min) to 220°C (held for 20 min) at 5°C/min. Some analyses, however, were conducted with a GL-Sciences OV-101 fused-silica capillary column (0.25 mm ID × 25 m, 0.20 μm film thickness), under the same analytical conditions described above (Honda, 1980b). Samples were injected splitless at 250°C using N₂ and He as the carrier gas (1 ml/min) for GC and GC-MS, respectively. Identification of the components was based on comparison of GC retention data and mass spectra with those of authentic compounds purchased commercially (Tokyo Chemical Industry) or with those of osmeterial components previously identified in other *Papilio* species (Honda, 1980b, 1981), unless otherwise noted. The percentage composition of each component was calculated by estimating its peak area as a percentage of the total peak area on gas chromatograms.

Results

Secretion Components from Fourth Instars

In the osmeterial extracts from fourth instars, 19, 7, 10, 24, 15, and 16 components with an area percentage of more than 0.1% were detected in *C. epycides*, *P. demoleus*, *P. polytes*, *P.*

^a Components less than 0.1% of the total are not listed. Major components exceeding 10% in each species are represented by bold figures.

paris, *P. macilentus*, and *P. troilus*, respectively (Table 1). In all species, the osmeterial secretions had a faint odor and most of the compounds detected were terpenoids.

Peaks 1–5, detected from five species, gave a molecular ion (M^+) at m/z 136 with fragmentation patterns typical of monoterpene hydrocarbons. Based on these mass spectra and GC retention data, peaks 1, 2, 3, 4, and 5 were identified as α -pinene, sabinene, β -myrcene, limonene, and β -phellandrene, respectively. Peaks 6 and 7 also had M^+ at m/z 136 and were determined to be (*Z*)- β -ocimene and (*E*)- β -ocimene, respectively. Peak 8 exhibited M^+ at m/z 136 [relative intensity (%): 59] and typical terpenoid fragment ions at m/z 121 (70), 107 (15), 93 (100), 91 (57), 79 (47), 65 (17), 53 (27), and 41 (61). This compound was readily identified as *p*-mentha-1,4(8)-diene.

Peak 10 gave several fragment ions, at m/z 117 (0.3), 103 (11), 87 (9), 74 (32), 59 (9), and 43 (100), but its M^+ never appeared. The fragmentation pattern and the GC retention datum of this compound conformed well to those of authentic methyl 3-hydroxy-*n*-butyrate.

Peaks 12 and 25, each present in five of the species tested, shared M^+ at m/z 204, the base peak at m/z 41, and fragmentation patterns characteristic of sesquiterpene hydrocarbons. The mass spectra and GC retention data of peaks 12 and 25 were in agreement with those of β -elemene and germacrene-A, respectively, which also occur in the osmeterial secretion of *Papilio protenor* (Honda, 1980b).

Peaks 13, 15, and 29, exhibiting M^+ at m/z 204, also appeared to be sesquiterpene hydrocarbons and readily corresponded to β -caryophyllene, (*E*)- β -farnesene, and germacrene-B, respectively.

Peak 22 was found only in *P. macilentus*. This component had M^+ at m/z 204 and fragment ions at m/z 189 (1), 161 (2), 147 (1), 133 (2), 119 (39), 107 (19), 93 (53), 79 (26), 69 (37), 55 (47), and 41 (100). The fragmentation pattern and GC retention datum were identical to those of an unidentified sesquiterpene hydrocarbon found in the osmeterial secretions from fourth instars of *P. protenor* (peak 10 in Honda, 1980b). In comparison with an authentic mixture sample of farnesenes, this component was recognized as (3*Z*,6*E*)- α -farnesene.

Peak 23 showed M^+ at m/z 204 (16) and characteristic fragment ions at m/z 189 (4), 175 (1), 161 (7), 147 (7), 133 (13), 119 (20), 109 (20), 93 (100), 79 (27), 67 (28), 55 (25), and 41(72). This component was identified as (*Z*)- α -bisabolene. Peak 28 was the (*E*)-isomer with a similar fragmentation pattern but a GC retention datum differing from that of peak 23.

Although structural elucidation of peaks 9, 11, 14, 16–21, 24, 26, and 27 was not achieved, all of them had M^+ at m/z 204 and fragmentation patterns characteristic of terpenoids, strongly suggesting that they were sesquiterpene hydrocarbons with the molecular formula of $C_{15}H_{24}$.

Table 2 Volatile components of fifth instar osmeterial secretions of six papilionid butterflies

Code	Component	Composition (%) ^a					
		<i>C. epycides</i>	<i>P. demoleus</i>	<i>P. polytes</i>	<i>P. paris</i>	<i>P. macilentus</i>	<i>P. troilus</i>
a	Methyl isobutyrate	37.3	28.9	4.6	12.5	72.0	49.5
b	Ethyl isobutyrate	1.2	0.1		0.6		0.1
c	Methyl 2-methylbutyrate	16.9	8.0	1.5	6.0	8.2	24.3
d	Ethyl 2-methylbutyrate	0.9	0.1		0.9		0.2
e	Acetic acid					0.2	
f	Isobutyric acid	13.9	33.0	51.0	49.3	12.7	1.4
g	2-Methylbutyric acid	24.7 ^b	30.0 ^b	42.9	23.3 ^b	6.9 ^b	15.5

^a Components below 0.1% of the total are not listed.

^b Combined percentage with other substance suggested as isovaleric acid.

Peaks **30–32**, **34**, **35**, **37**, **39**, and **40**, sharing M^+ at m/z 220, were all considered to be oxygenated sesquiterpenoids, for which the molecular formula of $C_{15}H_{24}O$ seems appropriate. Peak **33** gave a fragment ion at m/z 204 and the base peak at m/z 161, suggesting a sesquiterpene hydrocarbon. However, since the GC retention datum of this compound corresponded to those of oxygenated sesquiterpenoids rather than those of sesquiterpene hydrocarbons, it is likely an oxygenated sesquiterpenoid, the original M^+ of which did not appear in the mass spectrum. Peaks **36**, **38**, and **41** exhibited M^+ at m/z 222, 222, and 218, respectively, and were tentatively recognized as oxygenated sesquiterpenoids with molecular formulae of $C_{15}H_{26}O$, $C_{15}H_{26}O$, and $C_{15}H_{22}O$, respectively.

Secretion Components from Fifth Instars

In contrast to those of the fourth instars, the osmeterial secretions of fifth instars of all six species gave off intense and offensive odors. Seven compounds, all aliphatic acids or their esters, were identified in the extracts (Table 2).

Peak a showed M^+ at m/z 102 and was identified as methyl isobutyrate. From their mass spectra, peaks b–d were all assumed to be homologous esters. As the M^+ and base peaks were at m/z 116 and 43, 116 and 57, and 130 and 57, respectively, peaks b, c, and d were concluded to be ethyl isobutyrate, methyl 2-methylbutyrate, and ethyl 2-methylbutyrate, respectively.

Peak e was detected only in *P. macilentus*. This compound had M^+ at m/z 60, and the base peak at m/z 43, and was identified as acetic acid. Peak f, indicating M^+ at m/z 88, was recognized as isobutyric acid. Peak g, distributed in all species tested, was identified as 2-methylbutyric acid on the basis of its fragmentation pattern, with M^+ at m/z 102, and its GC retention datum. However, in *C. epycides*, *P. demoleus*, *P. paris*, and *P. macilentus*, the mass spectrum of this peak contained an ion at m/z 60, significantly higher in proportion than the value expected for 2-methylbutyric acid alone. As in previous studies (Honda, 1981), this result suggested that isovaleric acid, the base peak of which was at m/z 60, was present in small amounts.

Chemical Nature of Larval Secretion in *C. agestor* and *P. glaucus*

Although detailed chemical analyses were not carried out, the osmeterial secretions of fourth instars of *C. agestor* contained large amounts of methyl 3-hydroxy-*n*-butyrate and sesquiterpenoids, such as (*Z*)- α -bisabolene, β -caryophyllene, and β -elemene, as well as small amounts of monoterpenoids. The secretions of fourth instars of *P. glaucus* contained a relatively high proportion of monoterpenoids, such as α -pinene, *p*-mentha-1,4(8)-diene, and limonene, and also included (*Z*)- α -bisabolene and germacrene-A as dominant components. The secretions from fifth instars of both species contained isobutyric and 2-methylbutyric acids and their methyl esters as major constituents.

Discussion

Our findings that the osmeterial secretions from fourth instars of all eight species consist mainly of terpenoids, whereas those from the corresponding fifth instars comprise aliphatic acids and their esters, show that all these species alter the chemical profile of their osmeterial secretions at the final larval ecdysis. Although we investigated only two *Chilasa*

species, it is likely that the genus *Chilasa*, as well as the genus *Papilio*, can also be assigned to the heterogeneous group in terms of the larval osmeterial secretion. Moreover, we found the same pattern in larvae of *P. glaucus*, which include the Magnoliaceae among their hosts, and in the larvae of *P. troilus* that, like those of the two *Chilasa* species, feed on plants in the family Lauraceae. Because larvae of previously studied *Papilio* species, all of which share the same pattern of shifting osmeterial chemistry, feed on the families Rutaceae or Apiaceae, it appears that the pattern is not related to host-plant affiliation. Combined with the earlier work on other *Papilio* species (Table 3), our results strongly suggest that the heterogeneous trait is characteristic of the tribe Papilionini as a whole. This distinguishes the Papilionini from other major swallowtail tribes, in which earlier work points to a lack of chemical change in osmeterial secretions between the penultimate and ultimate larval instar (Table 3).

As is common in the genus *Papilio*, larvae of four of the *Papilio* species (*P. macilentus*, *P. demoleus*, *P. paris*, and *P. polytes*) undergo a dramatic change in body coloration and pattern at the final larval ecdysis, coincident with the change in osmeterial chemistry. While the fourth instars are apparent mimics of brown and white bird droppings, the fifth instars resemble small green snakes (Igarashi, 1979). In *P. troilus* and *P. glaucus* (Igarashi, 1979), however, the change in appearance occurs at the fourth instar, thus preceding the shift in chemistry. This pattern is known also in *P. machaon*, where the shift from bird dropping to green and black stripes (Igarashi, 1979) likewise precedes the change in chemistry (Honda, 1981). Young et al. (1986) reported a shift in osmeterial chemistry from terpenoids to aliphatic acids in last-instars of *P. anchisiades* despite only minor changes in the mottled brown coloring of the larvae. A comparable pattern is seen in the two *Chilasa* species (Fig. 1). Therefore, it seems clear that there is no necessary ontogenetic linkage in papilionid larvae between the changes in osmeterial chemistry and those in larval appearance.

Fig. 1 Fourth (left) and fifth (right; protruding its osmeterium) instars of *Chilasa agestor*

The compositions of the fifth instar secretions revealed no surprises. All species were characterized by aliphatic acids and their esters. In particular, they shared methyl isobutyrate, methyl 2-methylbutyrate, isobutyric acid, and 2-methylbutyric acid as major components, in spite of considerable quantitative differences. These findings are consistent with those previously reported for other *Papilio* species (Honda, 1980b, 1981). The chemical profiles of secretions from fourth instars, by contrast, were characteristic of each species, especially in their content of sesquiterpenoids. Although most of the individual compounds have been reported earlier, (3*Z*,6*E*)- α -farnesene (**22**), (Z)- α -bisabolene (**23**), and (E)- α -bisabolene (**28**) have not been found previously in the osmeterial secretions of papilionid larvae. The osmeterial secretion from fourth instars of *P. macilentus* contained a large amount of (3*Z*,6*E*)- α -farnesene (**22**), earlier shown to be a host finding kairomone for fruit flies (Nigg et al., 1994) and the codling moth (Bengtsson et al., 2001). Because this sesquiterpene hydrocarbon turned out to be identical to an unidentified component from the secretion of *P. protenor* (Honda, 1980b), we confirm here that fourth instars of this species also secrete compound **22**. (Z)- α -Bisabolene (**23**), reported as the aggregation pheromone for green stinkbugs such as *Acrosternum hilare* and *Nezara viridula* (Aldrich et al., 1987, 1989), was a major constituent of the osmeterial secretions from *C. epycides* and *P. troilus*, alongside minor amounts of its (E)-isomer (**28**).

The larvae of at least some *Papilio* species are able to biosynthesize aliphatic acids from amino acids (Seligman and Doy, 1973) and terpenoids *de novo* from acetate precursors (Honda, 1983b, 1990). Also, the overall chemical profiles of the larval osmeterial secretions of at least some *Papilio* species remain unaffected even if the larvae are reared on different plants (Honda, 1983b). It seems likely, therefore, that the chemical composition of papilionine osmeterial secretions is largely heritable. Consistent with this hypothesis are the findings of K. Honda (unpublished data) that larvae of *P. protenor* from several different sites across the main Japanese island of Honshu share similar profiles of osmeterial chemistry. No data are yet available to permit comparison of more distantly related populations of papilionine swallowtails. However, larvae of the troidine species *Atrophaneura (Parides) alcinous* from Honshu show slight differences in sesquiterpenoid profiles from larvae in the Yaeyama islands (Okinawa Prefecture) (Honda, unpublished data). Thus far, the evidence suggests that the chemical profiles of osmeterial secretions are species-specific while subject to some degree of variation.

Preliminary phylogenetic comparisons of osmeterial chemistry within the Papilionini reveal few obvious trends. In some cases, closely related species (Zakharov et al., 2004) share similar osmeterial chemistry. Secretions from *P. demodocus* (Burger et al., 1985) and *P. demoleus* (this study), for example, both contain germacrene-A (**25**), β -elemene (**12**), and methyl 3-hydroxy-*n*-butyrate (**10**) as major components. On the other hand, secretions from *P. bianor* and *P. maackii* differ greatly from those of *P. paris*, their sister taxon (this study and Honda, 1981). Despite substantial interspecific variation in the terpenoid content of fourth-instar osmeterial secretions, these could be separated into a group rich in monoterpene hydrocarbons (nearly 50% of total peak area) and a group dominated by sesquiterpenoids (more than 70% of total peak area). In the monoterpene group were *P. macilentus* and *P. troilus*, whereas the sesquiterpene group consisted of *C. epycides*, *P. demoleus*, *P. polytes*, and *P. paris* (cf. Table 1). In previous studies, the secretions of most *Papilio* species were rich in sesquiterpenoids, whereas only *P. bianor* and *P. maackii* belonged to the monoterpene group (Honda, 1980b, 1981; Burger et al., 1985). Although *P. bianor* and *P. maackii* are sister species, they are more distantly related to *P. macilentus* and (especially) *P. troilus* (Zakharov et al., 2004). We discern no obvious relationship between overall terpenoid grouping and *Papilio* phylogeny.

Although the switch from terpenoids to aliphatic acids and esters at the final larval ecdysis in papilionine swallowtails is typically sharp and complete, exceptions are known. Young et al. (1986) found several terpenoids along with the dominant aliphatic acids and esters in the osmeterial secretions of fifth-instar *P. anchisiades*, whereas aliphatic acids and esters accompanied the typical terpenoids in secretions from fourth-instars of *P. xuthus* (Honda, 1981). Such examples suggest that there is no fundamental biochemical incompatibility between the two types of osmeterial secretion and that their typically sharp separation could be the result of selection rather than of developmental constraint.

The changes in osmeterial chemistry in papilionine larvae, like those in color and pattern, are likely to reflect shifting patterns of predation on larvae as they increase in size (Brower, 1984; Leslie and Berenbaum, 1990; Reavey, 1993). Young larvae are likely to be primarily attacked by small invertebrate predators, which are typically most successful when attacking prey similar in size or smaller than themselves (Stamp, 1986). Older larvae are likely to be more apparent to larger invertebrate predators and small vertebrates, for which they also represent greater food rewards (Reavey, 1993). Field studies on *P. polyxenes* (Feeny et al., 1985) and *P. xuthus* (Watanabe, 1981) have confirmed that young larvae suffer proportionately greater mortality due to small, invertebrate predators, whereas larger larvae are more vulnerable to larger predators such as wasps and birds. One might expect to find, therefore, that osmeterial secretions containing terpenoids are most effective as deterrents of smaller, invertebrate enemies, whereas those containing aliphatic acids and esters are most effective against larger invertebrates and perhaps small vertebrates.

Most experiments that demonstrate the effectiveness of osmeterial secretions in papilionine swallowtails have been conducted with last-instars, in which the secretions are primarily composed of aliphatic acids and esters (Table 3). These are capable of warding off attacks by a variety of invertebrate predators such as ants (Eisner and Meinwald, 1965; Honda, 1983a), mantids (Chow and Tsai, 1989), small spiders (Damman, 1986), and wasps (Takagi et al., 1995). The acid/ester profiles typically contain only a few compounds, often dominated by isobutyric acid and 2-methylbutyric acid (Table 2). These two acids, along with acetic acid, were among the five most potent of 17 individual compounds from osmeterial secretions tested by Honda (1983a) for their ability to deter ants from sucrose baits. Acetic and 2-methylbutyric acids, moreover, both evoked alarm behavior in the ant *Lasius niger* (Honda, 1983a). These secretions appear to act as powerful irritants, and their relatively uniform composition across the family seems to suggest selection for compounds of particular efficacy.

Although papilionine swallowtails are sometimes subject to severe bird predation (Hirose et al., 1980; Takagi et al., 1995), several studies have failed to show that their osmeteria have any significant deterrent effect against birds in a captive setting or suburban environment (Järvi et al., 1981; Honda, 1983a; Leslie and Berenbaum, 1990; Takagi et al., 1995). In natural habitats, though, papilionine females typically disperse their eggs over wide areas, and larvae are thinly distributed and less likely to trigger search image formation by foraging birds (cf. Brower, 1958; Takagi et al., 1995). Under these conditions, deployment of the osmeterium as part of a “threat display” might be more likely to deter the occasional and tentative initial attack by a foraging bird. Experiments by Järvi et al. (1981) and Leslie and Berenbaum (1990) have shown that the larvae of *P. cresphontes*, *P. machaon*, and *P. polyxenes* are distasteful to birds, with or without their osmeteria, when feeding on typical food plants. This unpalatability may result from sequestration of toxins from host plants in the Rutaceae and Apiaceae, and could be frequent among oligophagous swallowtails in the Papilionini (Leslie and Berenbaum, 1990). In such situations, foraging birds may learn by association to avoid the odor or taste of osmeterial secretions. Exploitation of these secretions

as aposematic cues by birds and perhaps other predators could provide strong selection for convergence in osmeterial chemistry. Larvae of palatable swallowtail species, such as *P. glaucus*, might gain protection through Batesian mimicry (Leslie and Berenbaum, 1990), whereas caterpillars of two or more protected species in the local community might benefit from Müllerian mimicry. If widespread, such chemical aposematism might provide a compelling explanation for why last-instar papilionine larvae, those most likely to be attractive targets for birds, share such similar osmeterial profiles of acids and esters.

The effectiveness of terpenoids, present in the secretions of earlier instars, has received little explicit study. Of several individual terpenoids included in Honda's (1983a) bioassays, most were weakly or moderately deterrent to ants. D-Limonene, however, was a strong deterrent to *Crematogaster matsumurai*, though not to *L. niger*, whereas caryophyllene oxide strongly deterred ants of both species. A convincing overall comparison of the efficacy of terpenoids and aliphatic acids/esters in osmeterial defense will require further research. However, a comparison of the two secretory profiles raises the possibility that the two types of secretion might function in different, although perhaps overlapping, ways. As shown in this report (Table 1), terpenoid profiles are typically diverse. These compounds are widely used by insects as attractants and deterrents in host recognition (Gershenson and Croteau, 1991; Harrewijn et al., 1995), and their function in osmeterial secretions may be as much to disrupt recognition as to provide a toxic defense. Blum (1981) has suggested that the chemical diversity typical of many arthropod defensive secretions may act as a chemical smokescreen, effectively concealing the emitter by producing undecipherable sensory input from the receptors of potential predators. Such a strategy could be especially effective against smaller invertebrate predators for which the chemical senses predominate in prey finding and capture. The lack of any apparent phylogenetic pattern among terpenoid osmeterial secretions, noted earlier, could result from evolutionary lability in terpenoid profiles. Chemical novelty is typically deterrent to phytophagous insects (Bernays and Chapman, 1987). If the same can be said of predatory insects, one might expect selection to favor the idiosyncratic production of novel metabolites in response to shifting suites of invertebrate enemies. It may be no coincidence that the plant families containing the majority of swallowtail host plants are unusually rich in essential oils that contain a wide variety of terpenoids (Hegnauer, 1983). Whether the osmeterial terpenoids are acquired from the plants or synthesized *de novo*, as seems more likely (Honda, 1983b, 1990), their deployment in defense would be consistent with an overall emphasis on crypsis in earlier instars.

The presence of aliphatic acids and esters in the osmeterial secretions of *Baronia*, *Parnassius*, and various species in the tribes Graphiini and Papilionini suggests that they represent a plesiomorphic trait in the family Papilionidae (Sime et al., 2000). It is striking that two tribes (Troidini and Zerynthiini) apparently lacking these compounds are rich in species that are known or suspected to sequester aristolochic acids and perhaps other toxins from their food plants in the Aristolochiaceae (Nishida, 1995; Sime et al., 2000). These compounds are present on the surfaces of eggs as well as in the cuticle and osmeteria of larvae, in pupae, and in the adults. Because they are strongly deterrent to birds and some invertebrates (Sime et al., 2000; Sime, 2002), it is tempting to speculate that they have replaced acids and esters in the osmeterial secretions of larvae in these tribes. Young (1973) has suggested that bodily unpalatability due to sequestered aristolochic acids is the primary defense of troidine larvae against birds and other vertebrates, while the osmeteria, containing both aristolochic acids and terpenoids, provide defense against invertebrates. The characteristic heterogeneity in osmeterial defense of larvae in the tribe Papilionini may represent an evolutionary compromise. Terpenoids, shared with the sister tribe Troidini (Miller, 1987), may be the primary defense against invertebrate enemies of the younger larvae while acids and esters

are deployed in the final instar as the more effective defense against larger invertebrates and perhaps vertebrates.

Acknowledgments We thank Y. Zhang for collecting samples from *C. epycides*, *C. agestor*, *P. demoleus*, and *P. paris*. We also thank A. Agrawal, A. Kessler, and F. Sperling for helpful discussion.

Buchmann, 1981; Simpson and Neff, 1981; Buchmann, 1987; Simpson et al., 1990). One role suggested for the floral oil has been in the construction of nest cells that consist of several different materials depending on the species, including soil, sand, wood chips, or plant material (Vinson et al., 1996; Pereira et al., 1999; Jesus and Garófalo, 2000). Floral oil may be used to aid in the collection of these construction materials (see Vinson et al., 1996; Pereira et al., 1999), but it is not clear if the hardened cell wall also contains floral oil (see Vinson et al., 1996).

Furthermore, floral oil is used as a nest provision in many species, and Neff and Simpson (1981) suggested that the use of oil as a larval provision may be related to the high moisture content of the ground where these bees nest, oil being less likely to be leached from the nests by groundwater during the rainy season. In fact, we observed *C. aethiocesta* nesting in sand at the edge of estuaries that often flood (Vinson and Frankie, 1988). Neff and Simpson (1981) also suggested that their view of the importance of using oil in wet regions was supported by the fact that the oil-collecting habit has been lost in some species that nest in xeric environments.

However, some *Centris* species nest in twigs or above ground cavities (Frankie et al., 1988). Simpson et al. (1977) reported that the nest cells of *C. trigonoides*, a species that nests in cavities in twigs, contained pollen and lipid with no appreciable amounts of nectar (carbohydrate). Later, Neff and Simpson (1981) reported that nests of *C. maculifrons* from Peru contained oils as well as “appreciable” amounts of glucose and fructose, the later presumably from floral nectar sources. This led Simpson et al. (1990) to question the absence of nectar in the nest provisions in their studies of *Centris* nest resources. A similar report of provisioning with oil and nectar was reported for *C. vittata* (Pereira and Garófalo, 1996) and this mixture was suggested to make up the liquid provisions of *C. tarsata* (Aguar and Garófalo, 2004). Whereas both Vinson et al. (1996) and Jesus and Garófalo (2000) suggest that *C. analis* and *C. bicornuta* use nectar, there is no evidence that nectar is used, and it is not clear whether some floral oil is used to provision nests as well.

In the lowland dry forest of Costa Rica, we have been studying 14 species of *Centris*, all of which have been observed collecting floral oil from *Byrsonima crassifolia* (Malpighiaceae) (Vinson et al., 1993, 1997). Five of these species, in addition to *C. aethiocesta* (op. cit.), are ground nesters in the lowland dry forest, and their nests are subjected to wet season conditions (Vinson and Frankie, 1977; Coville et al., 1983, 1986; Vinson et al., 1987; Vinson and Frankie, 1988).

An analysis of the oil collected from *B. crassifolia* flowers yielded thin layer chromatography (TLC) spots consistent with glyceride-fatty acid standards (Vinson et al., 1997). Using gas chromatography (GC), we found that floral oil consist primarily of monoglycerides (60–70%) and diglycerides (15–20%), with less than 10% consisting of triglycerides, and less than 5% consisting of free fatty acids. Upon hydrolysis and methylation, the floral oil yielded six fatty acids ranging from C₁₆ to C₂₀ with the shortest chain fatty acid, myristic acid, accounting for 6%, and oleic acid making up the largest percentage at 30% of the total (Vinson et al., 1997).

When the liquid nest provisions of four of the available ground-nesting species (*C. adani*, *C. flavifrons*, *C. flavofasciata*, and *C. aethyctera*) were examined by TLC and GC, the results (Vinson et al., 1997) revealed an identical pattern of glycerides and fatty acids to the *B. crassifolia* floral oil. Only a trace of carbohydrate was detected. These results confirmed the earlier suggestion by Neff and Simpson (1981) that the nest liquid provisions of at least some of the ground nesters consisted of floral oil only.

However, we have also been working with several cavity or twig-nesting *Centris* that occur in the same dry forest. We observed that both the consistency and odor of the nest

provisions of four of these *Centris* spp. differed from those of the ground-nesting species, from the floral oils, and from the floral nectars we had collected. In particular, the nest liquid had a slight acrid or goat-like odor. This led us to examine the liquid contents of nests of four species (*C. analis*, *C. bicornuta*, *C. nitida*, and *C. vittata*). Here, we report the results of those examinations.

Methods and Materials

Study Site and General Study Preparation

We set out artificial wooden-nesting cavities (trap nests) in 1997 to 2000, and then sporadic trap nest placements since 2000, at the Hacienda Monteverde site, 8 km NNW of the town of Bagaces in the Tempisque region of Guanacaste Province (Frankie et al., 1993, 1998). Trap nests were first placed in January and then collected and replaced on a biweekly basis through June.

Between 1999 and 2002, trap nest sticks in the trap nest blocks (see Frankie et al., 1993 for a description of the trap nest blocks) that had just been completed, as evidenced by a fresh nest plug, were removed from the block. These sticks were maintained in a horizontal position (nests are constructed in a horizontal position) and returned to our field station. They were opened as described earlier for the ground-nesting species with some modification (Vinson et al., 1997). Thus, the sticks were split lengthwise, revealing a row of cells (Fig. 1). In most cases, the provisioned bee cells were also split lengthwise, revealing the contents. If this did not occur, we used a pair of forceps to cut a groove along the edge of

Fig. 1 Nest of *Centris bicornuta* in a pine stick split lengthwise showing four cells composed of the cell wall, pollen packed at the back end of the cell, overlaid with a liquid on which an egg is floated. The cell usually is three-fourths full of pollen and the liquid (nectar consisting of water and carbohydrate)

the exposed cell and then thrust the forceps through the wall and pried the side off. The opened cell was examined under a dissecting microscope. If a bee egg was still present and there was no evidence of parasites, the liquid contents were removed for analysis. The egg was removed and the liquid contents were collected in 10 μl calibrated 50 μl capillary tubes. Usually, more than one tube was needed to remove all the contents. The numbers of tubes, or fractions thereof, were recorded in microliters, and the tube contents were placed in 2 ml Wheaton vials (Alltech Associates, Deerfield, IL, USA), transported to Texas A&M University, and placed in the freezer until analysis. These samples were not refrigerated during the 3 d involved in transport.

Analysis

Nest contents had a slight acid, goat-like fragrance in the field and caused a slight burning sensation when sniffed, indicating the possible presence of short-chain acids. In preliminary studies, the liquid provisions were spotted on silica gel TLC plates (Merck Si60, F254), developed in hexane/ether (1:1), and the compounds were visualized with iodine vapor. The results of the TLC study, along with an indication that the contents were not oils because they were not greasy and drops on tweezers were sticky and could be cleaned with water, led us to partition the samples between distilled water and hexane. This was done to determine if any hexane-soluble compounds were present. Nest contents were soluble in water with the exception of a few pollen grains in some samples and a lot of pollen in the case of the nest contents of *C. vittata*. After partitioning between water and hexane, the hexane fractions were dried by passing through a short column of anhydrous sodium sulfate. The hexane extracts of the liquid provisions were analyzed for volatiles by GC on a 25 m \times 0.25 mm I.D. BP1 column (Scientific Glass Engineering, Austin, TX, USA), using 20 psig He carrier gas, with an initial temperature of 50°C for 1 min, to 250°C at 10°C/min. The extracts were found to contain almost no volatile materials separated from the solvent (see short-chain acid analysis below).

These results suggested that the liquid contents may consist of nectar. To determine if the liquid provisions consist of sugar, a carbohydrate analysis was undertaken. Thus, 5 μl of a standard glucose, fructose, and sucrose sample (50% wt/vol) were treated with 75 μl of Supersil (Alltech) silylating reagent and held at 70°C for 20 min. Gas chromatography conditions were the same as described above, except that the initial temperature was 110°C for 1 min, to 300°C at 15°C/min. Peaks at 8.71, 9.28, and 13.95 were used to quantify fructose, glucose, and sucrose, respectively. Bee nest liquid (5 μl) from the various nests was subjected to the same methods and conditions. For the purpose of this study, the sugars were quantified using glucose as the standard set at 1.

Because the presence of nectar was indicated, we applied 10 μl of the nest liquid from four *C. bicornuta* and two *C. analis* nests to preweighed microscope cover slips, desiccated for 3 d in a CaCl_2 desiccation chamber, and reweighed on a Mettler-Toledo GmbH[®] microbalance (Greifensee, Switzerland). The amount of sugar was expressed as percent of the original sample weight.

Tests with standard short-chain acids indicated that under the GC conditions for volatiles (above), they could not be seen. To test for their presence, butyl esters were prepared by reaction of 5 μl of the water-soluble nest provisions with 50 μl of 14% boron trifluoride in butanol at 65°C for 5 min. The reaction mixture was poured into 1 ml of water and extracted with 1 ml hexane, which was dried with anhydrous sodium sulfate. A standard was prepared by adding 5 μl each of C-2 through C-10 straight chain fatty acids to 500 μl of distilled water and treating 5 μl of the solution in the same manner as the water-soluble

nest contents. Two small butyl ester peaks from the bee nest samples were matched by their retention times with the butyl ester standards derived from butanoic and octanoic acids. However, a much larger peak, approaching 100% of the butyl ester sample, eluted between nonanoyl and decanoyl butyl esters and, therefore, could not be a simple straight chain butyl ester of a short-chain fatty acid. Mass spectrometry (MS) analysis showed the characteristic m/z 116 ion of *n*-butyl esters, but no parent ion was observed.

To identify the unknown butyl ester, we pooled a number of samples of *C. bicornuta* nest liquid. A sample of approximately 500 μg was purified for nuclear magnetic resonance (NMR) analysis by preparative GC, using a 3.66 m \times 4 mm I.D. 5% OV-101 on Chromosorb G column operated isothermally at 160°C, and a Brownlee–Silverstein liquid nitrogen cooled collection system (Brownlee and Silverstein, 1968). The purified sample was dissolved in 100 μl of CDCl_3 , and the analysis was performed using 3 mm Broad Band\Hydrogen or Hydrogen\Broad Band probes on a Bruker ARX 500 NMR instrument.

Possible Source of the Fatty Acids

To determine the possible source of the fatty acids, we concentrated on the nests of *C. bicornuta* because they were more common. First, we repeatedly collected the nest cell liquid as it was being provisioned by using a 50 μl capillary tube. By collecting the cell liquid as soon as the female bee left, she would continue to return with liquid, presumably until a certain cell liquid level was reached. As a result, the foraging bee foraged for and provided more nectar than is normally provisioned. This collection was continued until 1 ml or so was collected by repeatedly emptying the capillary tube into 2 ml Wheaton vials. Five hundred μl of hexane were added to the vial, which was sealed (to reduce the chance of oxidation, contamination, or enzyme action), and returned to Texas for analysis for fatty acids or their esters as described above. We repeated this collection from three different nests.

In addition to being collected with or being associated with the nectar, there are a number of other possible sources of the fatty acids; however, we only had the equipment and time to determine whether the female bee was adding these compounds directly to the provision. For this study, we collected females that had just completed provisioning a nest with the liquid, but prior to oviposition, which was indicated by two situations. First, inserting a thin wire into the nest, removing it, and then measuring the length of the contamination on the wire determined the depth of the provision. Second, conformation that oviposition had not occurred but was about to occur was evidenced by the presence of a slight ring at the point where the cell cap will be placed on the cell. This ring, inside the cell, is placed just prior to the female leaving and returning to oviposit and to begin to close the cell (Vinson and Frankie, unpublished data). The returning female was captured, placed in a vial on ice, then dissected a few hours later. Tissues removed were the crop and contents, head with associated glands, the hind gut, the poison and Dufours gland, the reproductive system and the abdomen devoid of digestive system, reproductive system, and accessory reproductive glands. These various tissues or parts were placed in hexane in 3 ml Wheaton vials until analysis for the presence of short-chain fatty acids (described above).

Results

For *C. bicornuta*, *C. analis*, and *C. nitida*, each cell is provisioned with pollen as a compact layer at the back of the cell followed by a provisioned layer of liquid. The liquid contents of

the cells of *C. bicornuta* averaged 88.6 μl ($N = 25$, range = 78–97 μl), and the cells of *C. analis* contained a similar amount of liquid (mean = 86.0 μl , $N = 12$, range = 76–95). We only had one cell of *C. nitida*, which contained 93 μl of liquid. This bee had become rare in our study area after 1996. In contrast, the contents of the cells of *C. vittata* consisted of a mixture of orange pollen with the liquid provisions. This mixture was very thick, which made the quantitative separation and measurement of the quantity of the liquid difficult. Thus, these data are not reported for this species.

The nest contents of the four wood- or twig cavity-nesting *Centris* species examined by TLC did not contain any mono-, di-, or triglycerides, or long-chain fatty acids detectable by TLC. Similar negative results were obtained with the hexane extract of the nest liquid, which left no detectable (weighable) residue upon evaporation. Evaporation of the water extract left a gum-like residue that was shown upon silylation to contain sugars. An evaluation of the carbohydrates in the liquid contents of the nests revealed that sucrose was present in small quantities (Table 1). Most of the liquid contents of the nest consisted of a solution of two monosaccharides, glucose and fructose, in a ratio of 1:2–3. No peaks other than glucose, fructose, or sucrose were revealed. The % total sugar in the liquid of five nests ranged from 41% to 57% (Ave. 47.2%).

Although no GC peaks above C-8 were found in the hexane extracts, peaks were found matching the retention times of butyl butanoate and butyl octanoate in approximately equal amounts in the derivatized samples. These were present as less than a tenth of 1% of the liquid sample. However, a larger peak, approximately 99.8% of the sample of butyl esters, had a retention time slightly shorter than that of butyl octanoate, indicating that it was not a butyl ester of a simple straight chain fatty acid. Because MS analysis revealed the characteristic m/z 116 ion of *n*-butyl esters but with no parent ion, visible, NMR analysis was used to identify this compound. The ^1H spectrum showed a methyl singlet at δ 2.21 and two sharp methylene triplets at δ 2.77 and δ 2.21, and a cross peak in the H, H COSY spectrum indicated that the methylene triplets were coupled to each other. The ^{13}C NMR spectrum had an additional carbonyl peak at about 201 ppm in addition to the expected ester peak at 173 ppm. From these data, the compound was identified as butyl levulinate (Fig. 2). Samples of levulinic acid and butyl levulinate were purchased (Aldrich) and found to be identical to the nest-derived materials.

An analysis of the liquid provisions collected just before oviposition failed to reveal any of the fatty acids or their esters. An analysis of the various possible sources of fatty acids or their esters from various tissues of the female bees also yielded negative results.

Table 1 Carbohydrates (Glucose Set at 1) found in the liquid contents of the nest cells of twig-nesting *Centris* spp. in guanacaste province, Costa Rica

Nesting species	Number of samples	Glucose (set at 1)	Fructose	Sucrose
<i>C. bicornuta</i>	4	1	2.70–2.81	T–0.0021
<i>C. analis</i>	3	1	2.43–3.97	T–0.0035
<i>C. nitida</i>	4	1	2.79–3.27	T–0.0028
<i>C. vittata</i> ^a	3	1	2.45–3.36	T–0.002

^a Only species where the pollen and liquid were thoroughly mixed.

Fig. 2 Butyl levulinate derived from the levulinic acid found in the nests of four twig-nesting *Centris* species in the dry forest of Costa Rica

Discussion

The liquid nest provisions of *C. bicornuta*, *C. analis*, *C. nitida*, and *C. vittata* did not contain any fatty acids above C_{14} characteristic of the triglycerides and fatty acids of the oil from *B. crassifolia* (Vinson et al., 1997). Although all four species appear to collect oil from *B. crassifolia*, the role of the oil remains unclear. The liquid nest provision did contain large quantities of carbohydrate, primarily glucose and fructose with a trace quantity of sucrose. The sugar concentration of 47.2% is slightly higher than a number of common nectar resources for these bees that are thought to be important for adult maintenance (Vinson et al., 1993). The average sugar concentration of the nectar of flowers of *Tabebuia rosea* (Bignoniaceae), *Caesalpinia eriostachys* (Caeciliaceae), *Dalbergia retusa*, *Gliricidia sepium*, *Lonchocarpus hondurensis*, and *Myrospermum frutescens* (Fabaceae) ranged from 20% to 42% (Frankie et al., 1983). The difference could be attributable to a number of factors, but the pollen is dry and may have soaked up some of the water, concentrating the sugars slightly.

In addition, trace amounts of several short-chain fatty acids were present, including levulinic acid. Although levulinic acid could be present as a monoglyceride, the monoglyceride would have shown up as a silylated product on GC analysis of the water/hexane extract. Furthermore, if it were a mono-, di-, or triglyceride product, it should have shown up as a GC peak when the hexane extract was examined before derivatization. Because BF_3 /butanol reagent can perform transesterification, it is possible that levulinic acid is present as a water-soluble polar ester. This seems unlikely and we believe that levulinic acid exists as the free acid. These acids probably serve as a preservative, because short-chain fatty acids, particularly levulinic acid, are known to be antimycotic (Radoev et al., 1961).

Both butanoic and octanoic acid have strong odors, whereas levulinic acid has little to no odor. Thus, the two short-chain saturated fatty acids may be responsible for the slight goat-like fragrance of the cell contents, but the unusual levulinic acid predominates and is more likely to play a role in retarding fungal growth.

Our results concerning the absence of floral oil in the provisions of *C. vittata* differ from the report of Pereira (1997), who reported that *C. vittata* provisioned the cell with pollen, nectar, and an oily substance that was deposited on the surface of the pollen and nectar “loaf” (a mixture of pollen and nectar that is a kneadable solid). We did not observe any nectar loaf, and no oil was found in the liquid when separated from the pollen. However, the provision of *C. vittata* differed from the provisions of all the other *Centris* species we have worked with in Costa Rica (Vinson et al., 1993, 1997) in that the pollen and liquid provisions were blended rather than being separate. The liquid in the other species was always placed on the pollen resource, resulting in two layers.

We were unable to find the source of the small amount of fatty acids in the provision collected before oviposition, suggesting that these compounds are not present in nectar

collected by the female bee. Also, the female bee does not appear to add these three fatty acids directly to the provision by regurgitation, or from gland secretions from the head, reproductive system, or abdomen. However, there are a number of other possibilities. Because we found these acids in the liquid provision several days after oviposition but from cells in which the egg had been removed, the possibilities include the production and release of these compounds by the female bee at or just following oviposition, the release of enzymes into the provision by the female, or something that leaches from the pollen. If an enzyme were involved, the 3 or 4 d exposure of the provisions to warm temperatures during transportation could have led to an increase in these compounds, increasing our ability to detect them.

Whereas the four *Centris* species reported here have been observed visiting and collecting oil from *B. crassifolia* (Frankie et al., 1989; Vinson et al., 1993), it is clear that any oil collected by the four *Centris* species is not being used as a nest provision. What the oil is being used for by these species is not clear. The results of this study support the suggestion (Neff and Simpson, 1981) that the habit of using oil provisions may be related to exposure of the nest cells to abundant water, because the cells of the small wooden cavity-nesting species would not be subjected to standing water, even in the wet season.

Acknowledgments We acknowledge the help of Peter Ronchi in placing the nest blocks and maintaining our research plots. We also thank the Friends of Lomas Barbudal in Bagaces, Guanacaste, Costa Rica, for logistic support, and the Stewart family for allowing us access to their property in and around Hacienda Monteverde. We also acknowledge the support of the Texas and California Agricultural Experiment Stations.

Introduction

The key characteristic of ant societies is a reproductive division of labor, with morphologically specialized queens producing most or all the offspring, and workers performing other tasks such as foraging or caring for the brood (Wilson, 1971). In ca. 150 ectatommine and ponerine species, however, the specialized queen caste is rare or absent, and mated workers or “gamergates” take over the role of the queen in some or all of the colonies (Peeters, 1991). Because all individuals in these species are totipotent, i.e., able to mate and reproduce, there is potential for reproductive conflict (Monnin and Ratnieks, 2001; Ratnieks et al., 2006). One expression of this conflict is dominance behavior, which in most species is critical in establishing and maintaining a reproductive division of labor (Ito, 1993; Liebig et al., 1999; Monnin and Peeters, 1999). Dominance behavior, however, is potentially costly, because individuals that engage in dominance interactions generally work at a lower rate than labor workers (Cole, 1986; Gobin et al., 2003; Ito and Higashi, 1991; Monnin and Peeters, 1999; Monnin and Ratnieks, 1999).

Dominance interactions are usually most prominent immediately after colonies are orphaned, when the reproductive dominance hierarchy is first established (Gobin et al., 2001; Monnin and Peeters, 1999). Aggression typically occurs only between individuals of similar dominance status and reduces to a low level as soon as one or a few dominant individuals start to reproduce (Monnin and Peeters, 1999; Gobin et al., 2001; Cuvillier-Hot et al., 2004). This reduction in aggression may coincide with the development of a specific cuticular hydrocarbon profile in egg-laying individuals. Indeed, consistent chemical differences in the cuticular profiles between fertile and infertile individuals have now been shown in *Diacamma ceylonense* (Cuvillier-Hot et al., 2001), *Dinoponera quadriceps* (Monnin et al., 1998), *Harpegnathos saltator* (Liebig et al., 2000), *Myrmecia gulosa* (Dietemann et al., 2003), *Pachycondyla* cf. *inversa* (Tentschert et al., 2001; Heinze et al., 2002), and *Streblognathus peetersi* (Cuvillier-Hot et al., 2004). By secreting specific pheromones, it is thought that active egg layers signal their high fertility (Cuvillier-Hot et al., 2001) so that low-ranking individuals concede reproduction to high-ranking fecund individuals. In this way, the reproductive division of labor would be reinforced.

It is currently unknown whether a reproductive division of labor in queenless colonies can be regulated purely through chemical signaling, without the use of aggression. In some species, dominance behavior appears to be lacking altogether, even after colonies have been orphaned (*Gnamptogenys striatula*, Blatrix and Jaisson, 2000; *Pachycondyla berthoudi*, Peeters and Crewe, 1985, 1984; Sledge et al., 2001; *P. krugeri*, Wildman and Crewe, 1988; *Platythyrea lamellosa*, Villet et al., 1990; *P. schultzei*, Villet, 1991; *Rhytidoponera aurata*, Komene et al., 1999; *R.* sp. 12, Tay and Crozier, 2000; *Streblognathus aethiopicus*, Ware et al., 1990). This suggests that in these species, reproductive regulation is entirely pheromone-based.

The aim of the present study was to provide the first detailed test of the hypothesis that reproductive regulation is purely pheromone-based in a species that lacks dominance behavior. We used the facultatively queenless ant *G. striatula* (Blatrix and Jaisson, 2000) to examine the cuticular chemistry of fertile and infertile individuals with respect to different stages of ovarian development and mating status. As predicted, we showed that active egg layers have a unique cuticular hydrocarbon profile that, thus, can provide nestmates with reliable signals of fertility. In the interest of colony productivity, this allows reproduction to be regulated without the use of aggression.

Methods and Materials

Study Species

The ant *G. striatula* is a New World species, typically found in open habitats (Giraud et al., 2001) and humid forests (Lattke, 1995). Colonies are headed by either one or several queens, or more commonly, by several gamergates (up to 31; Blatrix and Jaisson, 2001). In our study population, 15 out of 23 colonies (65%) were queenless and headed by gamergates. Removing queens or gamergates from nests results in sexual calling and egg laying by some of the virgin workers inside the nest. The labor workers then transport nearby males to the nest, where the males will mate with any worker that assumes the sexual-calling position (Blatrix and Jaisson, 2000). The ability of workers to mate after loss of the queen or gamergates renders the colonies potentially everlasting.

Collection and Housing of Colonies

Colonies of *G. striatula* were collected in Santa Rosa National Park, Costa Rica, in October 1999 (four colonies) and October 2003 (six colonies). Colonies were transferred to the laboratory in Belgium, where they were housed in plaster of Paris nests with foraging arenas of $20 \times 10 \times 6$ cm or $20 \times 20 \times 6$ cm, depending on colony size, and glass covered nest cavities of $50 \times 40 \times 3$ mm to $150 \times 85 \times 3$ mm.

Collection of Individuals of Differing Reproductive Status

Five individuals were selected for each of the following categories from gamergate-right supply colonies and orphaned groups.

From gamergate-right colonies: G1—gamergates: mated workers, typically with well-developed ovaries, i.e., with many developing and mature oocytes, yellow bodies (an indicator of previous egg-laying; Billen, 1985; Fénelon and Billen, 1996), and the main or sole reproducers in the colony. The spermathecae of these individuals were opaque, indicating the presence of semen. G2—nonreproductive workers: workers with nonactive ovaries, i.e., without or with very few developing oocytes and without yellow bodies.

From orphaned colonies: O1—reproductive workers with fully developed ovaries: virgin workers with well-developed ovaries, i.e., with many developing and mature oocytes, and yellow bodies, an indication of high fertility and previous egg laying. A transparent spermatheca shows they were unmated. O2—reproductive workers with partly developed ovaries: virgin workers with numerous developing and mature oocytes but no yellow bodies. These intermediates were likely on the verge of oviposition or they might be ovipositing already (it is unclear how many ovipositions are required for the development of yellow bodies). O3—former reproductive workers: virgin workers with yellow bodies but only few developing oocytes. Video observation revealed that these individuals did not lay eggs and behaved like foragers. We therefore considered them former egg layers. O4—nonreproductive workers: virgin workers with nonactive ovaries, i.e., without or with very few developing oocytes and without yellow bodies.

To obtain workers of categories O1–O4, we created five orphaned groups of 20 virgin workers by isolating them from their natal gamergate colonies. When five eggs were present in the experimental chamber, each worker's cuticle was sampled for chemical analysis. Dissection of these workers showed they all had empty spermathecae. We also counted the number of ovarioles and the number of yolky and nonyolky oocytes, as oocytes

progress from nonyolky to yolky during maturation (Peeters, 1993; Gobin et al., 1998) and noted whether yellow bodies were present. To obtain five individuals for each O1–O4 category, we chose for each category five workers out of the dissected ants that had ovary characteristics that best fit the description. For categories O1 and O2, we retained the individuals with the highest number of yolky oocytes, and for categories O3 and O4 the individuals with the least or preferably no oocytes (and never having yolky oocytes). Samples from these individuals were analyzed for their cuticular chemicals.

Chemical Analysis

Cuticular chemicals were extracted by placing ants in individual vials containing 10 μl of hexane for 30 min. The chemical extracts were analyzed by gas chromatography (GC) in splitless mode [Agilent 6850 Series, Agilent Technologies, USA, equipped with a capillary column (Agilent HP-1; coated with methyl siloxane; length: 30 m; I.D.: 0.32 mm; film thickness: 0.25 μm ; Agilent Technologies) and flame ionization detector]. The injector and detector temperatures were 290°C and 300°C, respectively, with an inlet pressure of 6.74 psi and a constant flow of 1.1 ml/min. The oven was programmed from 90°C to 180°C at 20°C/min, then to 290°C at 5°C/min, and held for 30 min. We used helium as the carrier gas. Data were analyzed using *Chemstation* (Rev A.09.01, Agilent Technologies).

Gas chromatography/mass spectrometry analysis (GC-MS) was carried out on an HP 6890 GC (equipped with an HP-5MS column; length: 30 m; ID: 0.25 mm; film thickness: 0.25 μm) connected to an HP5973 MSD (quadrupole mass spectrometer with 70 eV electron impact ionization). Samples were injected in the splitless mode, and the oven was programmed from 60°C to 250°C at 10°C/min and then from 250°C to 320°C at 5°C/min, and held for 7 min at 320°C. Helium was used as carrier gas, at a constant flow rate of 1.0 ml/min. Cuticular hydrocarbons (alkanes and mono-, di-, and trimethyl alkanes) were characterized by the use of standard MS databases and diagnostic ions and by determining Kovats indices by the method of Carlson et al. (1998). The position of the double bond in nonacosene and hentriacontene was not determined.

Statistical Analysis

Before doing multivariate analysis, data were standardized by calculating relative peak areas, i.e., peak areas of compounds divided by the total sum of all peak areas for one individual. This was performed to ensure that each individual was given the same weight in the analysis. The total sum of all peak areas for each individual was added as a control variable. We only considered compounds with relative peak areas >1% in at least two individuals. This reduced the number of compounds to 51. In two cases, MS revealed two different compounds with the same retention time in two individuals (peaks 18 and 25; Table 1). Because these compounds could not be distinguished with GC only, they were excluded in all statistical analyses.

Data were subjected to principal component analysis (PCA) to allow compounds that differed between groups to be graphically identified. To focus on the compounds with the greatest difference between groups, we only considered compounds that had factor loadings with an absolute value >0.75 on the first axis.

To assess the significance of the differences in cuticular profiles between the different groups, we used MANOVA on the first four factors of the PCA, which together explained 73% of the observed variation. All statistical calculations were performed using *Statistica* 6.0 (Statsoft, Inc.).

Table 1 Chemical compounds identified by GC/MS and their relative concentration for each group (group mean \pm standard deviation)

Peak	Compound name	Group					
		G1	G2	O1	O2	O3	O4

Table 1 (continued)

Peak	Compound name	Group					
		G1	G2	O1	O2	O3	O4
27	4,x-Dimethyl tetraatriacontane	1.2 ± 0.3	0.9 ± 0.3	2.1 ± 0.5	1.9 ± 0.3	0.8 ± 0.3	0.9 ± 0.3
28	3,13- and 3,15-Dimethyl pentatriacontane	1.9 ± 0.8	0.18 ± 0.15	3.0 ± 0.4	3.2 ± 0.8	0.11 ± 0.13	0.09 ± 0.04
29	3,11,15-Trimethyl pentatriacontane	1.3 ± 0.8	0.4 ± 0.3	2.6 ± 0.4	2.6 ± 1.2	0.4 ± 0.2	0.40 ± 0.13
30	3,13- and 3,15-Dimethyl heptatriacontane	1.1 ± 0.7	0.03 ± 0.02	2.1 ± 0.5	2.0 ± 0.6	0.05 ± 0.07	0.05 ± 0.03
31	3,11,15-Trimethyl heptatriacontane	1.0 ± 0.8	0.05 ± 0.04	2.3 ± 0.4	2.0 ± 1.2	0.06 ± 0.07	0.005 ± 0.04

The peak numbers correspond with the numbers on the total ion chromatograms shown in Fig. 1. Peak 20', shoulder peak of peak 20. Group codes: from gamergate-right colonies: G1, gamergates; G2, nonreproductive workers; from orphaned colonies: O1 and O2, reproductive workers with fully and partly developed ovaries; O3, former reproductive workers; O4, nonreproductive workers. For peaks 18 and 25, the superscripts 1 and 2 indicate that it is the first resp. second of the two possible sets of compounds that occur.

Results

General Characteristics of Cuticular Chemical Profiles

The cuticular profiles contained a mixture of alkanes; alkenes; and mono-, di-, and trimethyl alkanes with chain lengths ranging from C₂₈ to C₃₇ (Fig. 1; Table 1). Several compounds occurred in high proportions in all individuals (nonacosane, 12- and 18-methyl triacontane, and 3-methyl hentriacontane, peaks 3, 8, and 16). Other compounds were specific to gamergates or nonreproductive workers (see below).

Statistical Analysis

Principal component analysis shows that differences in fertility explain most of the variation in cuticular hydrocarbon profiles, with the first axis of the PCA clearly differentiating active egg layers from nonreproductive workers (percentage of the variance explained: 44%; Fig. 2). Reproductive workers with fully and partly developed ovaries (O1 and O2) cluster together with gamergates (G1; Fig. 2). This shows that mating as such did not influence cuticular hydrocarbon profiles. Former reproductive workers (O3) cluster together with nonreproductive workers (O4 and G2; Fig. 2), and reproductive workers with fully developed ovaries (O1 and G1) cluster with reproductive workers with partly developed ovaries (O2). This demonstrates that chemical profiles accurately reflect current fertility independent of previous egg laying. A MANOVA on the first four factors of the PCA confirms that there were significant differences in the chemical profile of ants with high and low fertility (groups O1, O2, and G1 vs. groups O3, O4, and G2; $F_{4,23} = 57.3$; $P < 10^{-6}$) but that there were no significant differences detectable between mated (G1) and unmated egg layers (O1 and O2; $F_{4,23} = 1.42$; $P = 0.26$) nor between workers with (O1, O3, and G1) and without yellow bodies (O2, O4, and G2; $F_{4,23} = 0.78$; $P = 0.55$).

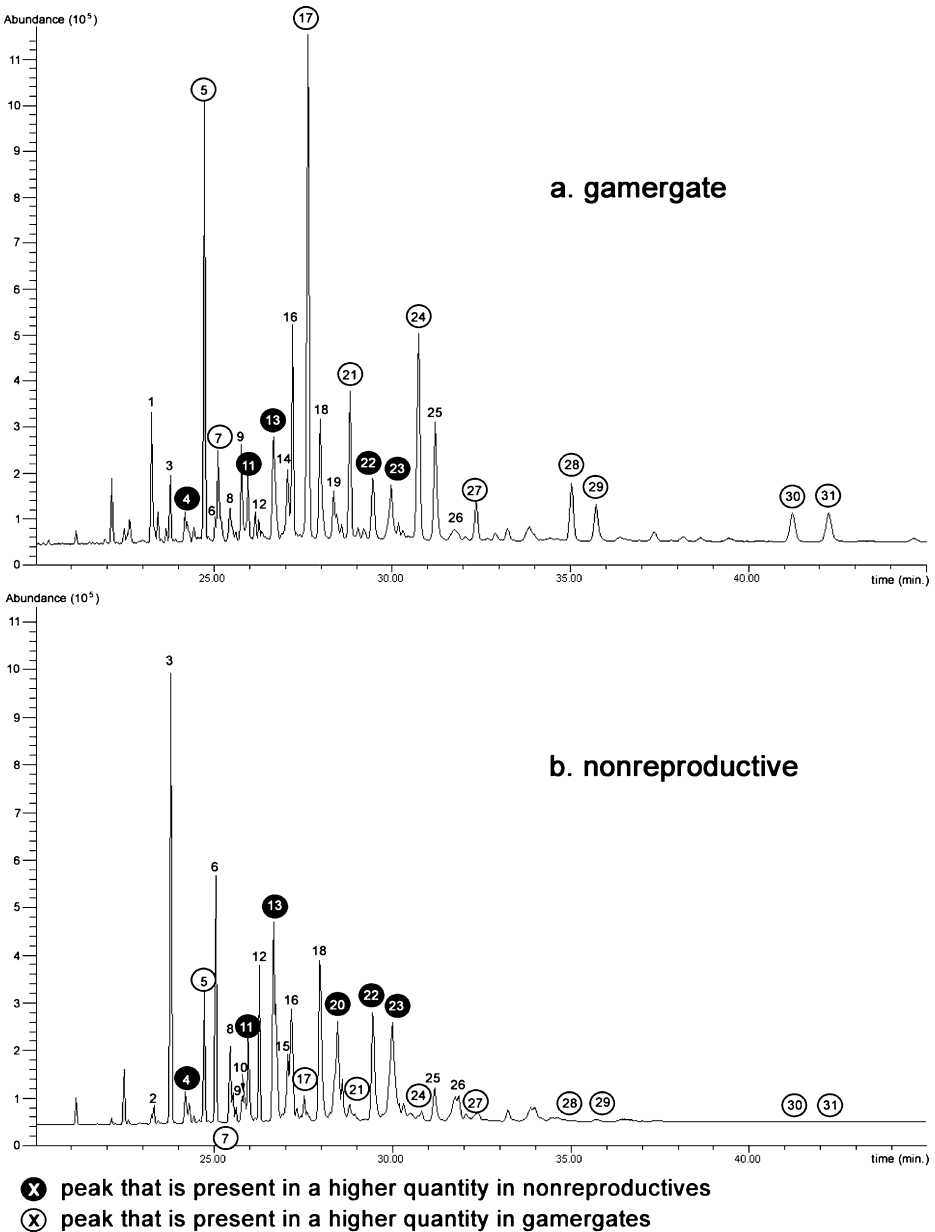

Fig. 1 Representative cuticular chemical profiles of a gamergate (a) and a worker with undeveloped ovaries (b). The peak numbers correspond to the identified compounds listed in Table 1.

Chemical Differences between Fertile and Infertile Individuals

To determine which compounds correlate most with differences in fertility, we can look at those compounds that show the strongest correlation with the first factor of the PCA (compounds with factor loadings with an absolute value >0.75; Fig. 2). In this way, it can

Fig. 2 Biplot showing the first two factors of a PCA. The symbols represent the factor scores of individuals belonging to different groups. The lines radiating from the origin indicate the factor loadings of the different compounds. The overlap between both plots shows the correlation between the two. Factor scores were reduced 10-fold to facilitate comparison with the factor loadings. Compound numbers correspond to those listed in Fig. 1 and Table 1. “Sum” is the total quantity of chemicals on the cuticle, i.e., the sum of all compounds. Symbols refer to the following groups: from gamergate-right colonies: (○) gamergates (G1) and (▲) nonreproductive workers (G2); from orphaned colonies: (Δ and ●) reproductive workers with fully and partly developed ovaries (O1 and O2), (■) former reproductive workers (O3), and (□) nonreproductive workers (O4).

be seen that there are 18 compounds that are strongly negatively correlated with factor 1, and occur in higher concentration on the cuticle of fertile individuals, i.e., gamergates and unmated egg-laying workers. These compounds comprise one monomethyl alkane: 3-methyl nonacosane (peak 5; Table 1); 15 dimethyl alkanes: 3,15-dimethyl nonacosane (peak 7), 3,11-, 3,13-, and 3,15-dimethyl hentriacontane (peak 17), 4,10-, 4,12-, and 4,14-dimethyl dotriacontane (peak 21), 3,11-, 3,13-, and 3,15-dimethyl tritriacontane (peak 24), 4,*x*-dimethyl tetratriacontane (peak 27), 3,13- and 3,15-dimethyl pentatriacontane (peak 28), and 3,13- and 3,15-dimethyl heptatriacontane (peak 30); and two trimethyl alkanes: 3,11,15-trimethyl pentatriacontane (peak 29) and 3,11,15-trimethylheptatriacontane (peak 31). In this group, peaks 17, 24, and 28 show the strongest negative correlation with factor 1 (factor loading <-0.95). The compounds 3,13- and 3,15-dimethyl pentatriacontane (peak 28), 3,13- and 3,15-dimethyl heptatriacontane (peak 30), and 3,11,15-trimethyl heptatriacontane (peak 31) are unique for active egg layers (Table 1).

Similarly, 14 compounds are strongly positively correlated with factor 1 (factor loadings >0.75), and occur in higher concentration on the cuticle of nonreproductive workers. These compounds comprise one alkene: hentriacontene (peak 11); eight monomethyl alkanes: 11- and 13-methyl nonacosane (peak 4), 9-, 11-, and 13-methyl hentriacontane (peak 13), 9-, 11-, and 13-methyl tritriacontane (peak 22); and five dimethyl alkanes: 10,14- and 8,12-dimethyl dotriacontane (peak 20) and 9,21-, 9,23-, and 11,23-dimethyl tritriacontane (peak 23). Peak 13 shows the strongest correlation with factor 1 (factor loading 0.89). None of the compounds included in the PCA were unique to nonreproductive workers. The total of all compounds (“sum”) was independent of the first principal component, and hence was independent of fertility (Fig. 2).

In summary, there were at least 32 compounds strongly correlated with reproductive status, 18 of which were more abundant on the cuticle of gamergates and reproductive workers, and 14 of which were more abundant in nonreproductive workers. In addition to these compounds, MS indicated that 10-, 12-, 14-, and 20-methyl dotriacontane (peak 18), and 12-, 14-, and 20-methyltettriacontane (peak 25) were unique to gamergates, and that 12,*x*-dimethyl dotriacontane (peak 18) and 3,11,15-trimethyl tritriacontane (peak 25) were unique for nonreproductive workers. Unfortunately, because the retention times of monomethyl dotriacontane and dimethyl dotriacontane (peak 18), and of monomethyl tettriacontane and trimethyl tritriacontane (peak 25), were identical, these differences could not be statistically confirmed in a larger sample by using GC.

Discussion

Our results show that there are pronounced differences in the cuticular chemistry of fertile and infertile individuals in queenless colonies of the ant *G. striatula*. Both qualitative and quantitative differences in over 32 hydrocarbons contributed to this result. Previously, cuticular hydrocarbons linked to fertility have also been found in ant species that form aggressive dominance hierarchies, for example, *D. ceylonense* (Cuvillier-Hot et al., 2001, 2002), *D. quadriceps* (Monnin et al., 1998), and *S. peetersi* (Cuvillier-Hot et al., 2004). These fertility signals are supposed to help in resolving intracolony conflicts by stimulating low-rankers to concede reproduction to more fecund high-ranking ones (Cuvillier-Hot et al., 2001). Our species, however, is unique in that it lacks any observable dominance behavior. Hence, our study is the first to show that chemical fertility cues may alone regulate reproduction. It remains to be elucidated which of the identified compounds act as the main signal. As several compounds are either up- or down-regulated depending on status, it is likely that more than one compound is involved in fertility regulation in *G. striatula*. In *P. inversa*, however, D'Ettore et al. (2004) showed that the ants are able to detect a single compound that is specifically associated with ovarian activity.

Overall, the chemicals characterizing fertile workers are hydrocarbons with longer chain lengths compared with the compounds found on the cuticle of infertile workers. A shift toward heavier hydrocarbons in ants with well-developed ovaries has also been found in other ponerine species, e.g., *P. inversa* (Heinze et al., 2002) and *H. saltator* (Liebig et al., 2000). The elongation reactions, following a switch to reproductive maturation, have been well studied in other insect taxa (Tillman-Wall et al., 1992; Blomquist et al., 1995, 1998; Tillman et al., 1999), and it is likely that a similar mechanism is acting in the species studied here, *G. striatula*. In two species, the dolichoderine ant *Linepithema humile* and the myrmecine ant *M. gulosa*, the shift has been shown to proceed in the opposite direction (de Biseau et al., 2004; Dietemann et al., 2003), with queens being characterized by shorter-chain hydrocarbons than workers. Mechanistically, the chemical differences between fertile and infertile individuals might be caused by the differential activity of oenocytes, which are involved in yolk production (Jensen and Borgesen, 2000) and are also the producers of cuticular hydrocarbons (Diehl, 1975; Fan et al., 2003).

A major conclusion of our results is that the chemical profiles accurately reflect the current fertility of an individual. This was shown by the fact that workers with yellow bodies in their ovaries, which are thought to be workers that have recently stopped laying eggs, had the same cuticular profiles as nonlaying workers. By contrast, it is clear that mating did not produce any detectable changes in cuticular chemistry, as gamergates and unmated workers with active ovaries had essentially the same chemical profiles. This also

appears to be true for other queenless ants (*D. ceylonense*, Cuvillier-Hot et al., 2002; *H. saltator*, Liebig et al., 2000) and it suggests that signaling fertility is generally more important than signaling mating status.

In summary, our results demonstrate that in the ant *G. striatula*, cuticular hydrocarbon profiles can provide nestmates with reliable information about each individual's fertility. We suggest that in this way, reproduction can be regulated without the use of aggression. The ability to regulate reproduction without the use of aggression has a large colony-level benefit, as costs associated with fighting, such as reduced colony efficiency and mortality, can be avoided. Nevertheless, most species go through an aggressive phase before chemical signals take over regulation of the reproductive conflict (among others Monnin and Peeters, 1999; Cuvillier-Hot et al., 2001, 2002, 2004; Gobin et al., 2001). *G. striatula* apparently lacks this aggressive phase, for a reason that remains unclear. Further studies are required to answer this.

Acknowledgments We are grateful to T. Lauwers for ant care and K. Collart for technical assistance. The Ministry of Environment and Energy granted permission to collect the ants in Costa Rica (resolution no. 131-2002-OFAU and 282-2003-OFAU). We also thank the Research Council of the University of Leuven (research project 01.24), the Fund for Scientific Research-Flanders (Belgium, research project G.0247.02), and the European Community's Improving Human Potential Programme (contract HPRN-CT-2000-00052 "INSECTS") for financial support. This study complies with Belgian and Costa Rican law.

contents after disturbance. However, most of the volatiles released by bugs after disturbance came from Brindley's glands. The locomotor activity of fourth instars increased significantly after stimulation with the odors emitted by disturbed adults, as compared with larvae stimulated by the odor of undisturbed adults or by clean air. We also studied the directional behavioral response of fifth instars to the disturbance scent in a locomotion compensator. Larvae exposed to volatiles released by disturbed adults walked away from the direction of the odor. The results suggest that this blend or part of it functions as an alarm pheromone for *T. infestans*. We suggest that the metasternal glands of this species are involved both in the sexual and the alarm contexts, and that the Brindley's glands probably have both alarm and defensive roles.

Keywords Triatominae · Metasternal gland · Brindley's gland · Male aggregation pheromone · Alarm pheromone · Chemical communication · SPME · Chagas disease

Introduction

Triatomine bugs (Heteroptera: Reduviidae) are the natural vectors of the protozoan flagellate, *Trypanosoma cruzi*, the etiological agent of Chagas disease. This disease occurs from the southern United States to central Argentina, and it affects 16–18 million people (WHO, 1999; Dias et al., 2002). *Triatoma infestans* Klug 1834 is the main vector of Chagas disease in the southern countries of South America.

Most Reduviidae have several exocrine glands in the thorax and abdomen, i.e., the metasternal glands, Brindley's glands, dermal glands, ventral glands, and abdominal glands (Carayon et al., 1958; Staddon, 1983). Ventral and abdominal glands are apparently absent in the subfamily Triatominae, and only adult insects possess both metasternal and Brindley's glands (Schofield and Upton, 1978).

Brindley's glands produce chemicals that may have defense and alarm functions (Schofield, 1979; Ward, 1981). The saclike Brindley's glands are dorsally located; they extend into the lateral portion of the second abdominal segment and open onto the metathoracic epimeron (Kálin and Barrett, 1975; Staddon, 1983). When disturbed, adult triatomines emit a secretion from these glands (Games et al., 1974; Cruz López et al., 2001). Several reports show that in *Rhodnius prolixus* Stål 1859, and other species of Triatominae, this secretion or the blend emitted after disturbance is composed of isobutyric acid (Pattenden and Staddon, 1972; Games et al., 1974; Schofield, 1979) or a mixture of isobutyric acid and other minor compounds, including diverse fatty acids and unidentified esters (Rojas et al., 2002; Guerenstein and Guerin, 2004). Based on the behavioral response of triatomines to synthetic isobutyric acid, Ward (1981) suggested that the compounds emitted by Brindley's glands act as an alarm pheromone. It is unclear whether isobutyric acid and other compounds emitted by Brindley's glands constitute an imaginal alarm signal, or whether they also play a role affecting the behavior of immature instars. Moreover, the behavioral responses evoked when isobutyric acid is released by conspecific insects have not been characterized.

The metasternal glands are located in the ventral metathorax and consist of a small reservoir and an unbranched or branched secretory tubule. The opening of each gland is located laterally to the sternal apophyseal pit. 3-Methyl-2-hexanone is produced by the metasternal glands of *Dipetalogaster maxima* (Uhler, 1894) (Rossiter and Staddon, 1983), and detected when bugs of this species are disturbed (Guerenstein and Guerin, 2004). The compositions of the secretions of these glands in other triatomines are unknown (Cruz López et al., 1995).

Behavioral data indicate that copulating pairs of *R. prolixus* (Baldwin et al., 1971) and *T. infestans* (Manrique and Lazzari, 1995) emit a volatile signal that promotes the aggregation of males around the couple and apparently mediates polyandry. The chemical identity of this signal is unknown. Fontán et al., (2002) described a series of compounds, including aldehydes, from copulating *T. infestans*, and they indicated that these compounds could represent the sexual pheromone of that species. Rojas et al., (2002) partially identified the contents of Brindley's glands in *R. prolixus* and suggested that those compounds would affect sexual behavior. However, the behavioral data did not clearly support this hypothesis.

In this report, we demonstrate that the metasternal glands of *T. infestans* are sources of volatile compounds, and we identify several of the substances emitted. We suggest that the contents of the metasternal glands of *T. infestans* are emitted during copulation, and we examine whether or not the metasternal gland contents are concurrently emitted with the products of Brindley's glands during the mechanical disturbance of adults. Moreover, we attempt to clarify the identity of volatiles released by disturbed adult *T. infestans* and volatiles emanating from a preparation of excised Brindley's glands. Along with results on the chemical identities, we present behavioral experiments that suggest their biological roles.

Methods and Materials

Insects

T. infestans was reared in the laboratory at $28 \pm 1^\circ\text{C}$ and fed on live chickens. Insects used for identification of gland and disturbance odors came from a colony collected from Northern Minas Gerais state, Brazil. This colony has been maintained for 20 yr at the Laboratory of Triatomines and Epidemiology of Chagas disease. Insects were sorted by sex as fifth instars (Espínola, 1966) and maintained apart until the experiments were performed. Emerged adults were fed weekly and kept in plastic containers, which had a piece of folded filter paper as substrate. Insects used for chemical sampling were virgin and prone to copulate (Manrique and Lazzari, 1994). For behavioral assays, we used fourth and fifth instars that had been starved for 1–2 wk postecdysis.

Volatile Sampling: Solid Phase Microextraction

Solid phase microextraction (SPME) (Arthur and Pawliszyn, 1990) was used to sample odors in the headspaces of vials containing adult bugs or preparations of excised metasternal or Brindley's glands. Among several fiber coatings tested, the CAR/PDMS stationary phase (75 μm film thickness) (Supelco, Bellefonte, PA, USA) was used throughout this study, because it proved especially effective for collecting most of the compounds present in the headspace.

Gas Chromatography Coupled to Mass Spectrometry

Volatiles were analyzed on a Shimadzu 17A gas chromatograph (GC), linked to a mass selective detector (Shimadzu 5050 A). The interface temperature was 250°C , and the ionization energy was 70 eV. The mass spectrometer was programmed to scan for masses of 40 up to 300 m/z . The capillary column used was a SupelcoWax-10; 30 m length, 0.25 mm i.d., 0.25 μm film thickness. The SPME fibers were inserted in the heated split/splitless injector (240°C) for 1 min to desorb the compounds. The split ratio was set to 1:4. Helium

(30 cm/sec linear velocity) was used as the carrier gas. The temperature program for the column oven was 50°C for 1 min, heating to 75°C at 10°C/min, and finally to 240°C at 15°C/min.

Preliminary identification of the volatiles studied here were based on the analysis of their mass spectra, and comparisons of the experimental data with a standard mass spectrum library (NIST). In most cases, the structures proposed were confirmed through injections of synthetic standards.

Sampling Procedure

Analyses of Volatiles Released by Metasternal and Brindley's Glands

Adult *T. infestans* were dissected several days after feeding to avoid contamination with feces (another potential source of volatiles). Before dissection, insects were kept at -18°C for 10 min to avoid disturbances during subsequent manipulations. They were then fastened with plasticine (Massa de modelar base amido, Faber-Castell, Sao Carlos, Sao Paulo, Brazil), leaving their thorax and abdomen exposed. These preparations were placed into an ice-cold phosphate buffer solution to minimize the evaporation of substances. Immediately after mounting the insects, we used a microsurgical knife to remove a pair of either metasternal or Brindley's glands together with an attached piece of cuticle surrounding the gland opening (ca. 0.25 mm²). Preparations were placed into a glass vial (2 ml), after which the vial was closed with a Teflon®/silicone-lined cap and kept in an ice bath until the end of the dissections that followed. For the analysis of the metasternal gland volatiles, each sample was prepared by using eight glands from at least four insects of the same sex. Three samples were analyzed for each sex. For the analysis of the Brindley's gland volatiles, each sample was prepared from 10 glands from at least five insects of the same sex. Three samples of these glands were analyzed for each sex. Control samples of cuticular pieces with internal tissues from other segments of the insects were prepared and similarly analyzed. Before adsorbing the volatiles by SPME, the preparation was sonicated (Thorton Inpec Eletrônica, Vinhedo, Sao Paulo, Brazil, 40 kHz, 100 W) for 3 min and then heated at 50°C for 10 min. The fiber was inserted through the Teflon®/silicone septum into the closed gland-containing vial, and sampling proceeded at 50°C for 30 min. Volatiles were desorbed from the SPME fiber in the injection port of the GC under the chromatographic conditions described above.

Odors Emitted by Copulating Couples

A *T. infestans* female and a male were gently introduced into a 10-ml vial, by using a piece of filter paper to avoid pressing the insects with forceps (see below). The vial was closed with a Teflon®/silicone-lined cap. After copulation had begun, volatiles present in the headspace were sampled for 10 min with the SPME fiber. Volatiles were desorbed inside the GC injection port immediately after sampling the headspace. Five assays were performed at 25 ± 1°C and 53–60% RH. Each pair of insects was used twice to sample the odors emitted: (1) before copulation and (2) during copulation. The pair was then discarded.

Because no volatiles were detected by gas chromatography-mass spectrometry (GC-MS) analysis before and during copulation using the full mass scan mode, we decided to search for key compounds from metasternal and Brindley's glands of adult *T. infestans*, by using the more sensitive single ion monitoring GC-MS analysis mode (SIM). 3-Pentanone (with characteristic ion fragments at *m/z* 29, 57, and 86) was chosen as the diagnostic compound for the metasternal gland, as it was the most abundant compound found in these glands

(see Results). Isobutyric acid (with characteristic ion fragments at m/z 27, 41, 43, 55, and 88) was used as the diagnostic compound for the Brindley's glands, as it was the most abundant compound found in these glands (see Results). For the single ion monitoring experiment, each pair of insects was used only once (during copulation) and then discarded.

*Analyses of Volatiles Released by Disturbed *T. infestans**

To study the volatiles released by disturbed insects, two individuals per assay were placed in a 10-ml vial containing a piece of filter paper (3×1.5 cm) as substrate. The insects were each disturbed by pressing one of their legs with forceps, placing them into the vials, and subsequently agitating them for 15 sec. After the insects had been introduced, the vials were closed with caps equipped with Teflon[®]/silicone-lined septa. Volatiles were collected for 10 min ($25 \pm 1^\circ\text{C}$, 53–60% RH) with the SPME fiber. Two control series were performed: vials with filter paper only ($N = 5$ assays), and vials with undisturbed insects ($N = 5$ assays, 2 bugs per assay). In the latter case, insects were allowed to climb onto a piece of filter paper, which was subsequently introduced into the vial to avoid disturbing the insects. In all cases (control and treatment), volatiles were desorbed by immediately inserting the fiber in the GC injection port after sampling the headspaces of the vials.

A total of 17 treatment assays were conducted for females ($N = 3$ assays, two bugs per assay), males ($N = 3$ assays, two bugs per assay), and heterosexual pairs ($N = 11$ assays, two bugs per assay). As no qualitative differences were detected between males and females, the identification of compounds from disturbed insects was made by pooling the results from all samples.

Quantifying the Odors Detected in Triatomine Samples

To quantify some of the substances detected from metasternal glands or from copulating pairs, we performed a series of quantification trials with synthetic substances. Known quantities of the latter compounds were added to equivalent vials and exposed to the same environmental and handling conditions as were used in gland or copulation assays. Afterwards, SPME samplings were performed for constructing calibration curves.

*Behavioral Responses of *T. infestans* Larvae to Scent Emitted by Disturbed Adults*

Assays of Locomotor Activity

We studied whether volatile substances emitted by disturbed adults evoked changes in the level of locomotor activity of ca. 45-d-old, fourth instars of *T. infestans*. In each assay, one insect was placed in an experimental arena (Fig. 1), either in the presence or in the absence of volatiles emitted by disturbed adults. The arena was an acrylic box ($13.5 \times 9.5 \times 4$ cm height) divided into two horizontal compartments (each 2 cm high), the upper one with a removable cover with a series of lines painted on the outside. This compartment had Teflon[®] tape wrapped around its inner perimeter to eliminate corners and thereby diminish the thigmotactic responses of bugs, i.e., the spontaneous tendency to maximize contact of the body with the substrate. The lower compartment had a stimulus delivery tube connected by an open screw cap (with a 1.5-cm hole in its center) and fixed in the center of the inferior face to allow the volatiles to diffuse from the delivery tube into the lower compartment. Uniformly spaced holes (1.5 mm diam) in the base of the upper compartment and in the substrate (a piece of filter paper) allowed the diffusion of the volatile stimulus

Fig. 1 Experimental arena used for measuring the walking behavior (locomotor activity) of *Triatoma infestans* larvae stimulated with volatiles released by disturbed *T. infestans* adults

from the lower to the upper compartment. Insect behavioral responses (i.e., locomotor activity) were quantified by counting activity bouts, which occurred every time a bug crossed one of the lines in the upper face of the box. The number of activity bouts was counted for a period of 5 min.

There were three treatments in this experiment: (1) larvae stimulated by volatiles coming from disturbed adults (disturbed); (2) larvae stimulated by volatiles coming from undisturbed adults (undisturbed); and (3) larvae without stimulation (control) ($N = 20$ for each treatment). In the first treatment, two adult bugs were placed into the delivery tube and disturbed by pressing their legs with forceps, and then tapping the tube for 20 sec. Volatiles were allowed to diffuse for 5 min to permit their passage from the tube to the lower and upper compartments. Subsequently, one larva was placed in the center of the upper compartment of the arena and after 2 min of acclimatization, its behavior was filmed with an infrared-sensitive camera and recorded on videotape. In the second series, adults were allowed to climb onto a piece of filter paper before being placed into the delivery tube (to avoid disturbance); the experiment then proceeded as in the first series. In the third series, a clean stimulus delivery chamber was exposed in order to determine the baseline activity level. In all cases, the room temperature was maintained at $25 \pm 2^\circ\text{C}$, and the experiments were performed in complete darkness. Differences between treatments were analyzed by one-way analysis of variance (ANOVA), followed by Tukey–Kramer multiple comparison tests (Zar, 1984).

Assays of Orientation Response

For the analysis of the orientation responses of fifth instars of *T. infestans* towards odors from disturbed adults, behavioral assays were performed by using a locomotion compensator (Barrozo et al., 2003). It consisted of a hollow Styrofoam sphere (97 mm diam, 2.85 g weight) that floated on a vertical air stream generated by an air pump. The bugs were starved (1 wk) and tethered by attaching the thorax and abdomen with two-sided sticky tape to a freely rotating stiff steel wire, centered at the apex of the sphere. Once

tethered in the apparatus in a normal walking posture, the animals started spontaneous locomotion when brought into contact with the sphere, by displacing it with their legs. Insects could rotate freely without modifying their distances to the source. Larvae tested were placed and kept on the apex of the sphere for 2 min to acclimatize before the beginning of each test. Movements of the insects were recorded for 3 min with an infrared-sensitive camera. Two glass containers (20 ml), sealed with plastic caps and located at opposite sides of the sphere, were used for the delivery of stimuli. Each cap was attached by a Teflon[®]/silicone tubing (20 cm) to a glass tube (0.65 cm diam, 8.5 cm length). The outlet of each tube was positioned 5 cm away from the insect. The behavior of each insect was recorded for 3 min in the absence or presence of the stimulus. To test for response asymmetry, a control series was performed in which both stimulus containers were empty ($N = 20$). Afterwards, stimulated insects were tested, i.e., one container was empty, whereas the other contained odors coming from disturbed adults ($N = 22$). In this series, one adult insect was disturbed as described above.

To quantify the behavioral responses of the larvae, we established a line that divided the top view of the sphere into two equal areas: the stimulus (i.e., odor from disturbed adults) was presented perpendicularly to that line. We determined the time that bugs spent walking towards these two areas. Three different categories of behavior were considered: walking towards the source; walking away from the source; and no walking (i.e., stationary behavior). We computed an orientation index as the difference between the time that the bugs spent walking towards one vial (i.e., either the vial containing the volatiles from disturbed animals or the clean vial in the test or control series, respectively) and the time that the bugs spent walking to the opposite side, divided by the total experimental time (3 min). The position of the stimulus was randomly alternated between assays. The resulting differences between treatments were analyzed with the Mann–Whitney test (Zar, 1984). The behaviors of control animals were also compared by means of a one-sample nonparametric test (Wilcoxon signed rank test) to determine whether those behaviors differed from those expected by chance (i.e., 50% of the time walking towards each of the sides).

Results

Secretion from Metasternal Glands

The secretion from the metasternal glands contained several compounds, some of which were highly volatile aliphatic ketones and alcohols (Fig. 2, Table 1). No compounds from metasternal glands were detected in the analyses of control samples, i.e., cuticular pieces and other internal tissues. The six substances identified from the glands were consistently found in all samples of both sexes obtained from metasternal glands. 3-Pentanone was the main component in all samples. The quantities of 3-pentanone present in the samples apparently varied between 10 and 100 μg per adult. Similarly, the quantities of 2-methyl-1-butanol and 3-pentanol varied between 1 and 10 μg per insect, and 3-hexanol apparently varied between 0.1 and 1 μg per insect.

We were not able to establish the identity of the second largest peak. The molecular ion is apparently 143, indicating a nitrogen-containing compound (Fig. 3). The even fragments m/z 128, 114, and 86 might result from nitrogen-containing fragments formed by cleavages of methyl-, ethyl-, and butyl groups, respectively. Fragment m/z 101 could have been formed by a molecular rearrangement losing a common m/z 42 mass unit (i.e., propene), whereas the m/z 57 and 41 fragments could be butyl- and propenyl cations, respectively. The short elution time

^aThe mass spectrum of each gland compound was identical with that of the corresponding synthetic reference compound.

from the GC column makes it unlikely that the unknown compound has a molecular weight greater than 143. The hypothetical molecular formulas $C_9H_{21}N$ and $C_8H_{17}NO$ were considered and a few analogs of saturated amines and amides were synthesized. These compounds had very different mass spectra and eluted much later than the unknown compound.

Odors Emitted by Copulating Pairs of *T. infestans*

Volatile compounds were not detected before or during copulation by GC-MS analysis under full mass scan conditions. Nevertheless, SIM analysis mode revealed that 3-

Fig. 4 Total ion chromatogram of the volatile compounds present in the headspace of Brindley's glands (pool of 10 glands) of *T. infestans* adults (see Table 2 for an explanation of the peak numbers)

pentanone was never found in control assays, but was in the headspace over one-third of the samples from copulating couples. A single small peak of isobutyric acid in one of these experiments was also detected, and it was much smaller than the corresponding 3-pentanone peak. Under our experimental conditions, the minimum detectable amount of isobutyric acid was 100 pg.

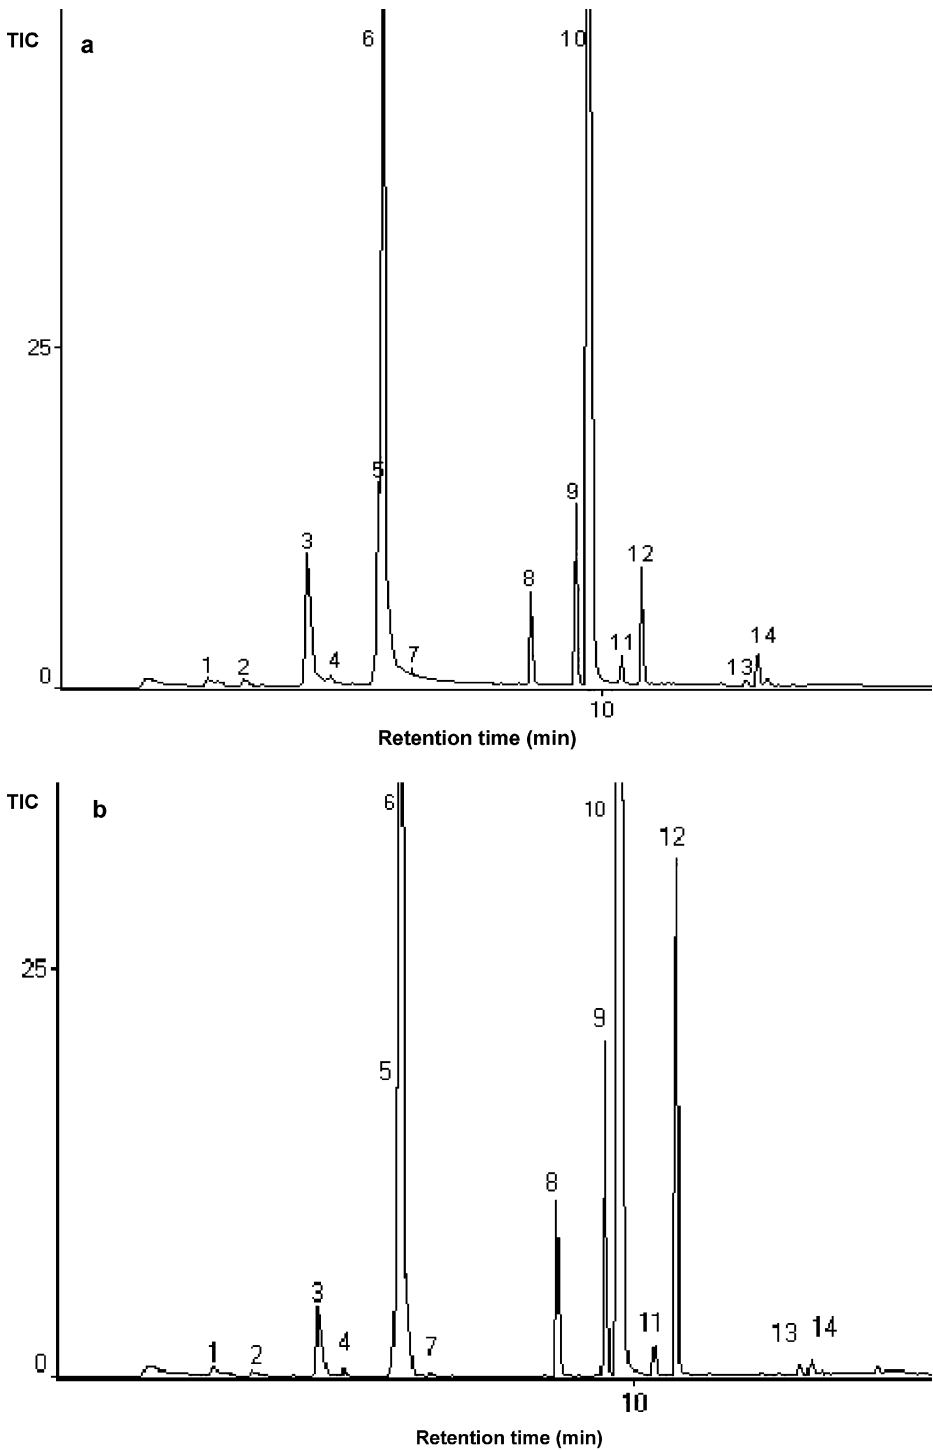

Fig. 5 Total ion chromatograms of the volatile compounds present in the headspace of mechanically disturbed *T. infestans* adult females (a) and males (b) (see Table 3 for an explanation of the peak numbers)

Secretion from Brindley's Glands

Compounds found in the headspace of vials containing excised Brindley's glands were primarily short chain acids, alcohols, esters, and a ketone (Fig. 4, Table 2). Isobutyric acid was the main component of this blend; 2-butanone and 2-methylbutyric acid are newly described from these glands. Two aromatic compounds (phenylethyl alcohol and phenylethyl isobutyrate) were also present at low levels. We did not find any qualitative differences between the sexes in the composition of the volatile blend (Table 2). Volatiles collected from pieces of cuticle and internal tissues (not shown) did not contain any of the compounds found in the headspace of glands, except for a peak related to traces of acetic acid (peak 8, Fig. 4).

Volatiles Released by Disturbed *T. infestans*

Compounds found in the headspace of disturbed *T. infestans* adults included short chain acids, alcohols, esters, and ketones (Fig. 5, Table 3). We did not find any qualitative differences between the sexes in the composition of the volatile blend. No compounds were detected in the control series with undisturbed insects or in the control vials with filter paper. Isobutyric acid (peak 10) was the main component of the mixture, comprising approx. 50% of the total peak area of all compounds in either sex (Table 3). 2-Butanone (peak 1), 3-pentanone (peak 2), 2-methylbutyl alcohol (peak 6), 3-methyl-3-buten-1-ol (peak 7), and 2-methylbutyric acid (peak 12) are reported here for the first time as volatiles emitted by *T. infestans*. Some of the compounds, possibly esters, released by disturbed bugs could not be identified.

Behavioral Responses of *T. infestans* Larvae to the Scent Emitted by Disturbed Adults

Assays of Locomotor Activity

When we analyzed the larval responses of *T. infestans* to volatiles from disturbed adults, we found that the locomotor activity of the bugs was affected by the treatment (ANOVA: $F = 19.12$, $df = 2,57$, $P < 0.001$). The activity level of bugs stimulated by the odor of disturbed adults was higher than the activity level of bugs exposed to the odor of undisturbed adults (Tukey–Kramer, $q = 4.06$, $df = 2,57$, $P = 0.016$) or of a clean vial (Tukey–Kramer, $q = 8.74$, $df = 2,57$, $P < 0.001$) (Fig. 6). Even though we did not detect volatile substances in the headspaces of undisturbed adults, the larvae also appeared to show significantly higher activity levels when adults were present than in clean-vial assays (Tukey–Kramer, $q = 4.68$, $df = 2,57$, $P = 0.047$).

Assays of Orientation Response

The behaviors of nonstimulated *T. infestans* larvae in the locomotion compensator did not show differences from the response expected by chance (Wilcoxon signed rank test: $W = 14$, $P = 0.8124$). This indicated that control animals spent an equivalent amount of time walking in both halves of the sphere. When larvae were exposed to volatiles released by

Fig. 6 Locomotor activity of *T. infestans* larvae stimulated with clean air, air from undisturbed *T. infestans* adults (ANOVA, $F = 19.12$, $df = 2,57$, $P < 0.001$). Pairwise comparisons were significant for all three pairs [(a, b) $P = 0.047$, no insects vs. undisturbed insects; (a, c) $P < 0.001$, no insects vs. disturbed insects; (b, c) $P = 0.016$, undisturbed insects vs. disturbed insects, $N = 20$]

Fig. 7 Orientation response of *T. infestans* larvae exposed to volatiles from disturbed *T. infestans* adults on a locomotor compensator. Control series ($N = 20$): clean air vs. clean air. Test series ($N = 22$): odors from disturbed adults vs. clean air

disturbed adults, they walked away from the stimulus (Mann–Whitney, $U = 94$, $P = 0.0016$) (Fig. 7).

Discussion

We evaluated the origins and functions of chemicals produced by exocrine glands of *T. infestans*, and observed that these insects produce blends of odors that promote both nondirectional and directional responses, probably for avoidance of predators. We propose that the metasternal glands are the sources of a number of volatile substances, of which at least the main component of the secretion is apparently emitted during copulation.

Our data show that the metasternal gland of *T. infestans* is the source of a scent, whose main constituent is 3-pentanone. This compound has been reported as a male-emitted aggregation pheromone of at least two species of Coleoptera (Giblin-Davis et al., 1996; Rochat et al., 2000). Other detected compounds include the corresponding alcohol, 3-pentanol, and other aliphatic alcohols. No differences between males and females were found in the composition of the scent produced by these glands.

T. infestans males aggregate around mating pairs and this behavior supports the existence of a male aggregation pheromone in this species (Manrique and Lazzari, 1995). We detected 3-pentanone in one-third of the copulating pairs of *T. infestans*, and suggest that this emission may have a role in the communication of *T. infestans* in the context of sexual behavior. Fontán et al. (2002) reported the release of isobutyric acid in quantities of

about 250 ng by one pair of *T. infestans* during copulation, but we found this compound only in one of 15 copulation assays. In that case, the peak of isobutyric acid was small and only just above our detection threshold of approximately 100 pg of this substance. The results thus showed a more prominent emission of metasternal gland substances during the copulation of *T. infestans*. Aliphatic acids, alcohols, and aldehydes had also been reported as being released during copulation by *T. infestans* (Fontán et al., 2002), but we did not detect any aldehydes in the secretion from metasternal glands or Brindley's glands.

In some insect species, the same volatile substances are involved in different behavioral contexts (e.g., for defensive purposes and for sexual attraction; Blum, 1996). It has been suggested that the glands producing those compounds have evolved from nonsexual to sexual functions. Several vertebrates also emit isobutyric acid and related compounds produced in the Triatominae, so such compounds may also function as host-related kairomones (Guerenstein and Guerin, 2001). Therefore, increased activity after stimulation with a single synthetic compound, e.g., a short aliphatic acid or another vertebrate-related compound, may not necessarily be related to a sexual context.

The profile of compounds present in excised Brindley's glands matched that emitted by mechanically disturbed adult insects, suggesting that most (but not all) of the volatiles released by bugs during the disturbance came from these glands. No differences were found between males and females in the composition of the scent produced by these glands.

We found that the blend produced by Brindley's glands included most of the compounds described in previous reports. This might indicate that the previously conflicting results regarding the compositions of those secretions might have arisen as a result of differences in methodology. Therefore, we propose that the blend produced by Brindley's glands is complex, based primarily on isobutyric acid but includes other fatty acids, a ketone, several aliphatic alcohols, esters, and an aromatic alcohol and ester.

During disturbance, adult *T. infestans* of both sexes released a complex mixture of at least 14 different compounds (Table 3). 3-Pentanone, one of the compounds released after mechanical disturbance, was the main component of the metasternal glands of this species (Table 1), but it was not detected among the volatiles collected from excised Brindley's glands (Table 2). It remains unclear whether 3-pentanone and/or other compounds secreted by the metasternal glands of *T. infestans* are relevant in the alarm or defensive contexts.

In *T. infestans*, Cruz López et al., (1995) reported an unidentified chromatographic peak likely containing an unresolved mixture of amyl and isoamyl alcohols in samples from disturbed insects and from Brindley's glands. This might be related to our resolved peak 6, corresponding to 2-methylbutyl and 3-methylbutyl (isoamyl) alcohols. According to our results, amyl alcohol (*n*-pentan-1-ol) was not part of that peak, because its retention time in our chromatographic conditions differed from those of the other two alcohols (data not shown). In addition, the spectrum observed for that peak appeared to be determined by the binary mixture reported here. Moreover, isobutyric acid (peak 10) was not the only acidic component of the mixture (Cruz López et al., 1995; Guerenstein, 1999). In agreement with Hack et al., (1980) and Juárez and Brenner (1981), we found acetic (peak 8), propionic (peak 9) and butyric (peak 11) acids among volatile compounds emitted by disturbed insects. We also detected alcohols and esters in the mixture, as reported by Cruz López et al., (1995) and Guerenstein (1999). In this sense, the experimental protocol used here, allowing the detection of a wider spectrum of emitted substances, appeared to be more sensitive than those previously used for studies on triatomine secretions.

Differences in reports of the composition of volatiles emitted by disturbed insects and/or by excised Brindley's glands might be attributable to different methodologies used, e.g., volatile sampling techniques or chromatographic conditions. The use of different colonies

could also account for these discrepancies, suggesting that insects from diverse populations emit different blends of compounds. However, the fact that the profile of volatiles described here includes most of the compounds previously reported weakens the latter hypothesis.

Ward (1981) suggested that *T. infestans* releases isobutyric acid at high concentrations for defense and also for communication as an alarm pheromone. However, this suggestion was solely based on the quantification of avoidance responses from adult bugs to different concentrations of synthetic isobutyric acid. Kälén and Barrett (1975) found that stimulation with pure isobutyric acid dissolved aggregations of adult *R. prolixus*, but this was not observed when the animals were stimulated by volatiles released by disturbed adults. The same authors observed no response when fifth instars were stimulated with pure isobutyric acid, thus arguing that only adults might be alerted by this signal. In the present work, we quantified the effect of the naturally occurring blend of volatiles released by mechanically disturbed *T. infestans* adults on the behavior of larvae. Our experiments showed that odors coming from disturbed adults evoked a significant increase in the locomotor activity of larvae. Although we could not detect any compound from undisturbed adults using SPME (using full scan mode or SIM), the increase in locomotor activity of larvae to undisturbed adults was evident and significant. This suggests that undisturbed adult bugs also emit volatile substances that promote increased larval activity. The identity and function of these odors in the biology of *T. infestans* remains unclear.

The responses observed in the experiments that tested odors from disturbed bugs using the locomotor compensator revealed a directional escape behavior that would lead the insects away from the source (i.e., a tactic mechanism; Kennedy, 1977). The dual effect of the blend to (1) increase the activity of neighboring conspecifics, and (2) evoke repellency to lead the insects away from the source, provides additional evidence for the role of the blend of odors as an alarm pheromone for *T. infestans*. It is likely that these substances also have a defensive function, particularly the short chain fatty acids, because of their corrosive and probably toxic nature (Kälén and Barrett, 1975; Kanehisa and Kawazu, 1982; Hilker and Schulz, 1994). Isobutyric acid topically applied to *R. prolixus* larvae can cause what previous authors described as “paralysis” (Kälén and Barrett, 1975). It has also been shown that isobutyric and 2-methylbutyric acids function to deter predators in the caterpillar of *Papilio troilus* (Eisner, 2004).

It is worth emphasizing that, during disturbance, two pairs of exocrine glands (Brindley’s and metasternal glands) discharge their contents. It is likely that substances from different glands have different roles in the biology of these insects. Behavioral experiments to evaluate the responses of larvae stimulated by the scents emanating from disturbed adults with occluded metasternal or Brindley’s glands should improve our understanding of the exact functions of these glands. Future studies should also analyze the functions of the compounds produced by metasternal and Brindley’s glands and determine which odors, if any, are responsible for evoking the aggregation response of males around copulating pairs. Alternative potential sources of chemical signals in glandular areas described by Barth (1980) and Weirauch (2003, 2004) should also be considered in those studies.

Acknowledgments The authors are indebted to Prof. K.-E. Kaissling (Max Planck Institut für Verhaltensphysiologie, Seewiesen, Germany) for suggestions and improvements in the manuscript, and to C. Reisenman (University of Arizona) for critically reading the manuscript. We thank G. Aulin-Erdtman, Stockholm, Sweden, G. Flores, New York, USA, and M. Melcón, Buenos Aires, Argentina, for corrections of the English. We wish to thank S. Minoli and R. Barrozo for advice on behavioral experiments, and the staff members of our laboratories for many fruitful discussions. We thank T. C. Insausti (Universidad de Buenos Aires, Argentina) for guidance to A. Vitta in the dissection of glands. We are also indebted to P. Guerenstein

(University of Arizona) for his advice and criticism, and to M.C. Rodriguez and G. Vélez (both from Universidad de Buenos Aires, Argentina) for the provision of some chemical standards. This investigation received financial support from the UNDP/World Bank/WHO Special Programme for Research and Training in Tropical Diseases (TDR), CAPES-SETCIP, PRONEX, PAPES, FIOCRUZ, Swedish International Development Cooperation Agency (SIDA), CONICET and Universidad de Buenos Aires.

Introduction

Usnic acid is synthesized by a mycobiont (Bjerke and Dahl, 2002; Cocchietto et al., 2002) of several epiphytic lichens (Shibamoto and Wei, 1984), and has been found in species from a wide range of phylogenetically distant genera (Ingólfssdóttir, 2002). Lichens undergoing stressful climatic conditions [temperature, humidity, ultraviolet and photosynthetically active radiation (PAR), oxidative stress] synthesize large amounts of secondary metabolites, including usnic acid (BeGora and Fahselt, 2001; Caviglia et al., 2001; Bjerke et al., 2002; Toledo Marante et al., 2003). It may accumulate in the thallus, reaching up to 6% of dry mass (Proksa et al., 1996). The rhizines of lichens can penetrate tissues, and usnic acid may enter into vascular plants (Ascaso et al., 1980). Moreover, it can be lixiviated from the lichen thallus by rainwater on the plant surface or into the soil and taken up by leaves and roots, respectively (Dawson et al., 1984). Usnic acid is able to pass through the plasmalemma (Vavasseur et al., 1991). The physiological effects differ considerably, depending on the type of plant treatment (leaf, xylem, root, or intracellular feeding) (Vavasseur et al., 1991). Usnic acid has a pH-dependent toxic effect; its interaction with individual metabolic processes may be modified by the pH in the cell compartments (Bačkor et al., 1998; Gardner and Müller, 1981). Several studies support the allelopathic activity of usnic acid against different organisms (Gardner and Müller, 1981; Carbonnier, 1986; Lauterwein et al., 1995; Proksa et al., 1996; Ingólfssdóttir, 2002). Two natural enantiomers of usnic acid (“+” and “-”) differ in their biological activity and probably their mechanisms of action. In natural conditions, in some thalli more (+)- than (-)-enantiomer is produced (Huneck and Yoshimura, 1996; Kinoshita et al., 1997). A number of reports have documented the biological effects of both enantiomers. Romagni et al. (2000) tested both for phytotoxicity; (-)-usnic acid proved significantly more potent. The (+)-enantiomer has proved more effective as an antimicrobial agent (Ghione et al., 1988; Lauterwein et al., 1995), although no specific mode of action has been determined. The antimitotic effects of (+)-usnic acid on cultured plant cells and its ability to inhibit seed germination is known (Cardarelli et al., 1997). Long-term feeding of a micromolar concentration of (+)-usnic acid to roots retarded plant growth, altered morphological features, and reduced the accumulation of biomass and some elements (Lechowski et al., 2006). A (+)-usnic acid concentration greater than 40 μM led to death; the duration of survival depended on concentration in the medium. Maize and sunflower plantlets treated by root feeding with (+)-usnic acid for only 24 hr decreased photosynthesis and transpiration rates (Lascève and Gaugain, 1990).

Limiting studies on the long-term action of usnic acid have demonstrated phytotoxic effects on vascular plants similar to effects observed in nature. The literature provides some results on global long-term effect of allelochemicals synthesized by lichens on the physiology of some trees (Orús et al., 1981), but few systematic studies under controlled conditions have been reported. To date, all experiments on the effect of this allelochemical on plant metabolism have dealt with crops (lettuce, maize, spinach, tobacco, tomato) (Inoué et al., 1987; Lascève and Gaugain, 1990; Cardarelli et al., 1997; Romagni et al., 2000) or other plant species (*Commelina communis*, *Funaria hygrometrica*) (Gardner and Müller, 1981; Vavasseur et al., 1991) that will never be encountered in nature. Nonetheless, the results obtained by this route may be applicable to communities rich in lichens.

This article provides data on the effects of long-term treatment with (+)-usnic acid on a range of metabolic processes observable in plants. We used tomato plants because they are a genetically uniform material, their physiological processes are well known, and they are easy to cultivate under controlled conditions. Ecologically relevant physiological studies are needed on plants growing in lichen-rich vs. lichen-poor communities.

Methods and Materials

Plant Material

The experiments used tomato plants (*Lycopersicon esculentum* Mill. cv. Perkoz F₁). Within 10 d of seed germination (DAG), plants were transplanted to a chemostatic system for hydroponic cultivation previously described in detail (flow rate, aeration, and temperature of medium) by Bialczyk et al., 1994). Plants were cultivated in Hoagland media (pH 6.9 ± 0.5) containing 0–30 μM of (+)-usnic acid (Aldrich). The solubility of usnic acid depends on pH (Dawson et al., 1984), so the medium pH was monitored, kept constant, and corrected when necessary during cultivation. To maintain a constant concentration, the medium in the growth chamber (20 l, 25 plants) was changed every second day. During plant growth, usnic acid concentration of the media was assayed by HPLC analysis as described by Caviglia et al. (2001). Plants were cultivated for 21 d (from 10 to 31 DAG) in a glasshouse under a natural photoperiod, with maximum PAR at about 1000 μmol/m² sec and 70–75% relative humidity. Plant growth conditions and the method of preparing the media with (+)-usnic acid were previously described (Lechowski et al., 2006).

Chlorophylls and Carotenoids

Chlorophylls (chl) and carotenoids (car) were extracted from leaves with 80% aqueous solution of acetone (v/v). Quantitative determinations were carried out as described by Wellburn (1994). Results were expressed as pigment content per dry mass (DM) unit.

Photodegradation of Chlorophyll

High irradiation was applied to a detached leaf that was placed on damp filter paper and screened by black light-resistant foil, with the remaining 1 cm² exposed fragment subjected to irradiation. Radiation was provided by two 1000-W projector lamps (Tungsram) and concentrated by two independent optical systems adjusted so that the light spots (1 cm²) formed at the plane of the leaf surface were superimposed. Leaves were irradiated for 1–6 hr at constant PAR of 5000 μmol/m² sec, measured with a spectroradiometer (Li-1800; Li-Cor, USA). Infrared radiation emitted by the lamps was eliminated by passing through heat-eliminating cutoff filters (5 cm well of 3% aqueous solution of CuSO₄, and 1.5 mm BG-38 glass filter; Schott, Jena, Germany). The leaf surface temperature during irradiation was 25 ± 1°C as measured with a constantan–copper thermocouple. After irradiation, chlorophyll was extracted, and its concentration was determined as described above.

Gas Exchange

Gas exchange (photosynthesis, respiration, and transpiration) of fully expanded second leaves was monitored in situ with an open gas exchange system [model LCA 2 (ADC Ltd., Hoddesdon, UK) supplied with a PLC-B Parkinson Leaf Chamber] at 25°C, air flow of 300 ml/min, and CO₂ concentration in the air flow at 350 ± 8.2 μmol/mol with or without PAR of 1000 μmol/m² sec. Respiration was measured in the dark and transpiration in both the light and dark.

Water Use Efficiency

The water use efficiency (WUE) coefficient was calculated as the ratio of the net CO₂ assimilation rate and transpiration rate (Rawson et al., 1977).

Hill Reaction

The PS II activity of chloroplasts isolated from the leaf was expressed as the electron transport rate determined using 2,6-dichlorophenol indophenol (DCPIP) as the electron acceptor. Chloroplasts from leaves of the control plants were isolated in the cold as described by (Synková et al., 1997). The concentration of chlorophyll in the supernatant was determined as described above. The Hill reaction was followed in the assay medium having a final volume of 2 ml, with 50 μmol DCPIP, 40 μg chlorophyll, and 6 μl (+)-usnic acid in acetone, and 6 μl acetone without (+)-usnic acid for the control. The final concentration of usnic acid in the tested mixture ranged from 0 to 40 μM. Samples were irradiated with 1000 μmol/m² sec PAR for 3 min at 25°C. DCPIP photoreduction was assayed spectrophotometrically (Cary UV–Vis Varian Bio 50 spectrophotometer) at 590 nm.

Stomata Resistances and Density

The diffusive resistance of stomata (r_s) was measured for water vapor on both surfaces of the leaves with an automatic porometer (Delta-T, A4, UK). The density of stomata on both surfaces (number of stomata per unit area) of the second leaves was estimated by microscopic examination of cellulose acetate imprints. Leaf disks 0.5 cm diam were pressed onto acetone-soaked cellulose acetate sheets supported on a glass slide. The epidermal imprint was made halfway between the base and tip of the leaves, and halfway between the midrib and edge of the leaflets. After several minutes, leaf disks were gently removed after the cellulose acetate sheet had dried. Stomata density per unit area of leaf was counted under a microscope with a micrometric scale.

Root Hydraulic Conductance

These experiments used roots of plants cultivated for 21 d in media with different concentrations of (+)-usnic acid (A), or roots of control plants transplanted for 5 hr to media with different concentrations of (+)-usnic acid (B). Root hydraulic conductance (RHC) [L_p , ml H₂O/MPa hr g root fresh mass (FM)] was calculated with Fiscus's formula (Fiscus, 1975): $L_p = J_v / [\alpha(P_x - P_e)]$, where J_v is the water flux (ml/hr), α is the reflection coefficient, and P_x and P_e are the pressure (MPa) of the xylem exudate and external solution, respectively. For calculation of L_p , α was set to 1. The J_v rate was calculated from the quotient of the collected volume of xylem exudate and the collecting time. For measurements of J_v , plant shoots were removed 3 cm above the root. The phloem was removed from 2 cm of the stem length. Next, the stem was wiped off with a damp paper towel to avoid contamination with phloem exudate and wounded cells. After 20 min the xylem exudate was collected with a Pasteur pipette for 30 min (storage on ice) and subsequently stored at -20°C. J_v and P_x were determined in the light phase of the diurnal cycle. At the end of the experiments, roots were completely drained on filter paper and FM was determined.

Osmotic and Water Potential

The osmotic potentials (ψ_o) of the xylem exudate, the nutrient solutions, and the cell sap of the leaf or roots were determined with a dew-point microvoltmeter. Cell sap of the leaf or roots was squeezed onto filter paper for ψ_o measurements. Water potential (ψ_w) was measured in leaf disks (7 mm diam) or root pieces (30 mg FM). Plant materials for determining ψ_o or ψ_w were placed in the sample chambers of a Wescor C-52 thermocouple psychrometer for 1 hr and then equilibrated with a dew-point microvoltmeter (model HR-

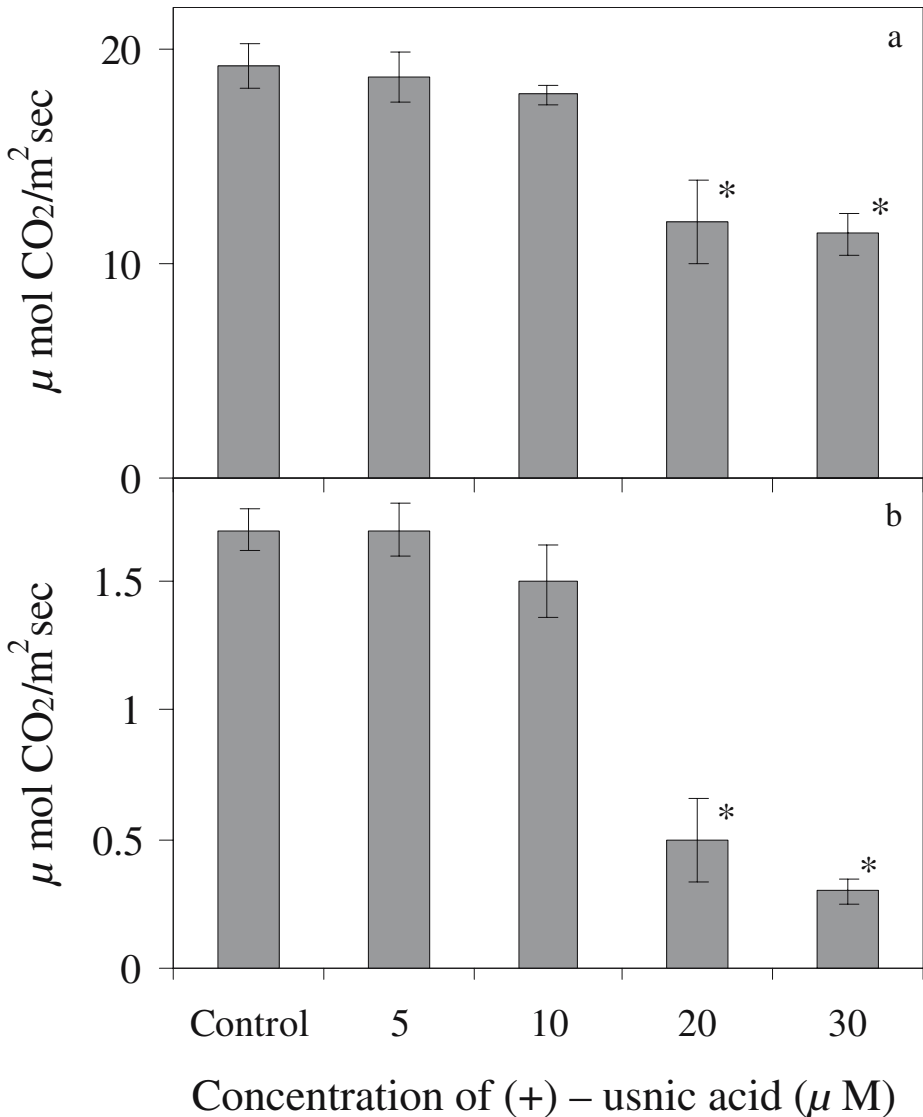

Fig. 1 Photosynthesis (a) and respiration (b) rates of leaves of tomato plants cultivated 21 d (10–31 DAG) in media with different concentrations of (+)-usnic acid. Values are means of five replicates. Bars represent \pm SE. *Significant difference from the control at $P < 0.05$

33T, Wescor, USA) operated in the dew-point hygrometric mode, and recorded when the instrument readings were stable. A solution of 55 mM NaCl of known water potential (-2.5 MPa at 25°C) was routinely used to verify the calibration of the individual chamber.

Statistical Analyses

The reported data are averages of five replicates. The standard errors (SE) of the means were determined. All obtained results were subjected to one-way ANOVA, and the means were tested for significant differences ($P < 0.05$) with Tukey's test.

Results

Gas Exchange

Tomato plants cultivated long-term in media containing (+)-usnic acid had lower photosynthetic activity (Fig. 1a). The degree of that decrease depended on the (+)-usnic acid concentration in the growth media. At ≤ 10 μM concentration, the reduction was within the margin of statistical error ($<7\%$). The rate photosynthesis in media containing 20 or 30 μM (+)-usnic acid declined 38% or 41% vs. control, respectively. Respiration was inhibited by usnic acid more than photosynthesis was. The respiration rate was reduced by 70% and 80% vs. control in plants cultivated in media with 20 and 30 μM usnic acid, respectively (Fig. 1b).

*Significant difference from the control at *P* < 0.05.

Hill Reaction

The Hill reaction activity of isolated chloroplasts depended on the concentration of (+)-usnic acid in the reaction mixture (Fig. 2). With 1 μM (+)-usnic acid it fell by 25% vs. control. Increases in concentration gradually reduced it further until complete inhibition of the Hill reaction occurred in the 40 μM treatment.

Fig. 3 Kinetics of chlorophyll photodegradation in tomato leaves irradiated with high-intensity PAR (5000 μmol/m² sec). Chlorophyll and Carotenoid Content

Results of the chlorophyll and carotenoid assays in tomato leaves are presented in Table 1. Generally, long-term cultivation of plants in media containing (+)-usnic acid led to reduction of photosynthetic pigment content. In leaves of plants cultivated in media with 30 μM (+)-usnic acid, chl_{tot} , chl_a , chl_b , and car content decreased vs. control by 30%, 33%, 18%, and 35%, respectively. The depressive effect of 30 μM (+)-usnic acid concentration on chl_a accumulation was 1.67 times stronger than its effect on chl_b accumulation; the $\text{chl}_a/\text{chl}_b$ ratio fell from 3.5 (control) to 2.87. Under these cultivation conditions, the $\text{chl}_{\text{tot}}/\text{car}$ ratio increased from 4.33 (control) to 4.66. This result indicates that usnic acid had a greater depressive effect on carotenoid than on chlorophyll accumulation.

Photodegradation of Chlorophyll

As presented in Fig. 3, photodegradation of chlorophyll was dependent on irradiation time. The lag phase and chlorophyll degradation phase were reduced in leaves of plants cultivated in media with 30 μM (+)-usnic acid; the lag phase was only 1 hr, and chlorophyll content declined more or less linearly to the sixth hour (chlorophyll content declined to less than 5% of the initial value). Leaves of the control plants were more resistant to high-intensity PAR. The lag phase in the control leaves was 5 hr; after that time the chlorophyll photodegradation phase began, and after 6 hr irradiation, the chlorophyll content decreased by 10% of the initial value. Chlorophyll content of detached leaves left under growth irradiance did not change significantly over the duration of the experiment (data not shown).

10	3.51 ± 0.20
20	$3.86 \pm 0.14^*$
30	$3.98 \pm 0.22^*$

^a Values are means of five replicates \pm SE.

*Significant difference from the control at $P < 0.05$.

Transpiration and Water Use Efficiency

The rate of leaf blade transpiration gradually dropped as (+)-usnic acid concentration in the growth media increased (Fig. 4). Compared with the control, the transpiration rate of plants cultivated in media containing $30 \mu\text{M}$ (+)-usnic acid was 2.1-fold lower in the light and 3.7-fold lower in the dark. The calculated WUE coefficients (Table 2) correlated positively with the (+)-usnic acid concentration in the medium during plant cultivation. Plants cultivated in media with $30 \mu\text{M}$ (+)-usnic acid had a WUE coefficient 1.5 times higher than in the control.

Stomatal Characteristics

Plants cultivated for 21 d in media containing $\leq 10 \mu\text{M}$ (+)-usnic acid did not differ significantly from the control in the diffusive resistance of their stomata (Fig. 5). Increasing

Fig. 5 Stomatal diffusive resistance (r_s) for the water vapor on upper (white column) and lower (gray column) surfaces of the leaves of tomato plants cultivated for 21 d (10–31 DAG) in media with different concentrations of (+)-usnic acid. Values are means of five replicates. Bars represent \pm SE. *Significant difference from the control at $P < 0.05$

Fig. 6 Stomata densities on upper (white column) and lower (gray column) surface of leaves of tomato plants cultivated for 21 days (10–31 DAG) in media with different concentrations of (+)-usnic acid. Values are means of five replicates. Bars represent \pm SE. *Significant difference from the control at $P < 0.05$

its concentration in the growth media caused a rise in r_s and in the r_s ratio of the upper/lower surfaces of leaves. In plants cultivated in media with 30 μM (+)-usnic acid, the r_s of the upper surface of leaves increased by 3.1-fold, and 1.5-fold for the lower surface, and the r_s ratio of the upper/lower surfaces of leaves increased from 3.1 in the control to 6.6. The increase in r_s in leaves of plants cultivated in media with (+)-usnic acid might be a result of the decline in the density of stomata per surface unit as its concentration in the growth media increased (Fig. 6). The stomatal densities of plants cultivated in media containing 30 μM (+)-usnic acid were 60% and 40% lower than the control on the upper and lower surfaces, respectively, and the ratio of stomata frequency on the upper/lower surfaces decreased from 0.34 (control) to 0.21. As the concentration of (+)-usnic acid in the growth media rose, root hydraulic conductance decreased (Table 3); by limiting water transport to the leaf, this could affect r_s and consequently lower the transpiration rate.

Table 3 Effect of (+)-usnic acid concentration on hydraulic conductance of tomato roots^a

Concentration of usnic acid (μM)	A	B
0 (control)	25.67 \pm 1.2	25.67 \pm 1.2

^a ml $\text{H}_2\text{O}/\text{MPa hr g}$ fresh mass.

Fig. 7 Osmotic potential ψ_o (a) and water potential ψ_w (b) of tomato plants cultivated for 21 d (10–31 DAG) in media with different concentrations of (+)-usnic acid; leaves (white column), roots (gray column), and xylem exudate (black column). Values are means of five replicates. Bars represent \pm SE. *Significant difference from the control at $P < 0.05$

Osmotic and Water Potential

In roots, xylem exudate, and leaves, ψ_o did not decline significantly as the (+)-usnic acid concentration in the growth media increased (Fig. 7a). The maximum difference between ψ_o determined for the organs of control plants and of plants cultivated in media with 30 μ M (+)-usnic acid was 13%. In contrast to ψ_o , ψ_w decreased from control levels by 52% in roots and 9% in leaves of plants cultivated in media with 30 μ M (+)-usnic acid (Fig. 7b).

Root Hydraulic Conductance

RHC decreased in both the long-term (21 d) and short-term (5 hr) treatments with (+)-usnic acid. In both cases, the fall in RHC was drastic, and the results were proportional to the concentration of (+)-usnic acid in the media (Table 3). In the treatment with 30 μM (+)-usnic acid, the RHC value fell from control levels by 12.3-fold for long-term and 3-fold for short-term exposure.

Discussion

Usnic acid exerts a multidirectional toxic effect on metabolic processes in plants (Cardarelli et al., 1997; Romagni et al., 2000; Cocchietto et al., 2002; Lechowski et al., 2006), which is likely associated with its action on key enzymes (Vavasseur et al., 1991). The lower content of photosynthetic pigments in the leaves treated with usnic acid (Table 1) may be the result of depressed synthesis and/or increased susceptibility to degradative processes. Romagni et al. (2000) found that (–)-usnic acid irreversibly inhibited protoporphyrinogen oxidase IX activity, which catalyzes the oxidation of protoporphyrinogen IX to protoporphyrin IX in the chlorophyll biosynthesis pathway. It is also a strong inhibitor of enzymes of the carotenoid biosynthesis pathway: phytoene desaturase, which converts phytoene to carotenoids (Romagni et al., 2004), and/or 4-hydroxyphenylpyruvate dioxygenase-catalyzed synthesis of plastoquinone, which activates phytoene desaturase (Endo et al., 1994). Photodegradation of chlorophyll by irradiation with our very-high-intensity PAR was significantly accelerated in plants cultivated in media with (+)-usnic acid, via shortening of both the lag and the photooxidation phases (Fig. 3). The duration of the lag phase of chlorophyll photodegradation reflects the action of all the protective mechanisms responsible for photostabilization of the photosynthetic apparatus, which ensure the undisturbed functioning of the electron transport chain (Lechowski and Bialczyk, 1990; Osmond, 1994). The effects of the interaction of these two stresses, (+)-usnic acid and high irradiance, suggest that usnic acid can predispose chlorophyll to photoinhibitory damage by: (1) inhibiting electron flow in thylacoid membranes by chelating Mn^{2+} ions and disturbing the electron flow from the splitting of water to PS II (Inoué et al., 1987; Cardarelli et al., 1997); (2) binding to the electron transport component at the oxidation side of PS II (Inoué et al., 1987); (3) reducing the content of carotenoids, which quench excess excitation energy from chlorophyll in its triplet state and release it in a nonradiative way (Müller et al., 2001); and (4) causing the formation of a highly reactive singlet oxygen, resulting in destabilization of thylacoid membranes (Romagni et al., 2004).

The leaves of plants fed (+)-usnic acid had reduced water content and more dry matter in the leaf blade, largely the result of an increase in the share of cell wall structural elements (Lechowski et al., 2006). The decrease in CO_2 diffusion to carboxylation centers (Fig. 5) and the water loss (Fig. 4) in plants treated with (+)-usnic acid may be attributable to increased r_s resulting from narrowing of the stomatal aperture and also to the lower density of stomata on the leaf (Fig. 6). Stomata closure induced by (+)-usnic acid may take the form of a direct disturbance of guard cell physiology when (+)-usnic acid is applied to the leaf surface (Lascève and Gaugain, 1990), or a secondary effect on water transport when plants are fed via roots. In both cases, the guard cells lose turgor and the stomatal aperture narrows. The direct effect of usnic acid on the guard cells that induce stomatal closure may be attributable to one or more of the following: (1) chelation of K^+ ions or ionophoresis towards K^+ ions (Carbonnier, 1986), which are basic components of the osmotic potential;

(2) increased membrane permeability (Bačkor et al., 1997) and leakage of electrolytes from cells under light (Romagni et al., 2004); and (3) reduction of the ATP pool when photosynthetic electron transport is disrupted (Orús et al., 1981; Inoué et al., 1987; Cardarelli et al., 1997), respiration is diminished (Fig. 1b) and oxidative phosphorylation is decoupled (Abo-Khatwa et al., 1996; Vavasseur et al., 1991).

Both long- and short-term feeding with (+)-usnic acid via roots dramatically reduced RHC (Table 3), the water transpiration rate (Fig. 4), and turgor (Lechowski et al., 2006). The mechanism of this interaction is not yet fully explained. One reason might be strong reduction of root growth (Lechowski et al., 2006) and the consequent decrease in water absorption surface. As illustrated in the present experiments, the decline in RHC (Table 3) does not result from the lack of a water potential gradient on the water transport route (Fig. 7), but more likely from changes in cell membrane permeability (Bačkor et al., 1997; Romagni et al., 2004). As illustrated by the calculated WUE coefficients (Table 2), restriction of the effective supply of water by usnic acid, and reduction of transpiration, led to more efficient use of water. This result agrees with earlier data from (Lascève and Gaugain, 1990). The mode of action of usnic acid remains unknown, and the explanations put forward remain speculative.

Anthraquinones and anthrones also have antimicrobial and antiviral activity (Teuscher and Lindequist, 1994, and references therein).

A galerucine species intensively investigated with respect to the presence of anthraquinones is the tansy leaf beetle, *Galeruca tanacetii* L. (Coleoptera: Chrysomelidae), which deposits eggs in clutches of about 65 eggs in autumn on dry plant material. These clutches overwinter on the plants until larvae hatch in spring (April–May) (Obermaier et al., 2006, and references therein). Despite the presence of anthraquinones and anthrones, freshly laid eggs of *G. tanacetii* are frequently parasitized by *Oomyzus galerucivorus* (Hymenoptera: Eulophidae).

The host plants of *G. tanacetii* (mainly yarrow and tansy) do not contain anthraquinones and anthrones (Hilker and Schulz, 1991). Thus, these polyketides must be produced in the beetles. When studying the biosynthesis of these defensive components in *G. tanacetii*, we hypothesized that: (1) *G. tanacetii* is able to produce anthraquinones and its precursors by its own specific enzymes, and/or (2) endosymbionts associated with the beetle produce these components.

This study addressed the question whether anthraquinones and anthrones are actively produced within the eggs. Two motifs drove our study: (1) On one hand, knowledge of the site of anthraquinone biosynthesis in *G. tanacetii* may help elucidate whether the producer is *G. tanacetii* itself or a symbiotic microorganism. If anthraquinones are actively produced inside the eggs, mRNA coding for polyketide synthases involved in the biosynthesis of 1,8-dihydroxylated anthraquinones, for example, may specifically be searched for at this site. (2) On the other hand, we are not aware of any previous investigation that has analyzed whether the defensive products change during egg development. Knowledge of changes in quantities of such products during egg development will provide clues to the activity of the embryo and its potential to contribute to egg defense. Thus, we determined the quantities of anthraquinones and anthrones shortly after egg deposition and shortly prior to larval hatching. An increase in anthraquinone content would indicate an active anthraquinone biosynthesis within the eggs. Metabolization of the substances by the embryo would be indicated by a decrease in total anthraquinone and anthrone contents.

Insect eggs are known to respond to microbial attack via induction of several enzymes (Gorman et al., 2004). To elucidate whether parasitization of *G. tanacetii* eggs by the wasp *O. galerucivorus* affects the anthraquinone content and induces/suppresses anthraquinone production, parasitized eggs were also included in our measurements.

Methods and Materials

Insects

Egg clutches of *G. tanacetii* were collected at the end of October (autumn) and the end of March (spring) in the nature conservation area “Hohe Wann”, Lower Franconia, Germany. Each clutch was divided into two parts: one was directly frozen and stored at -80°C , and the other was kept in glass vials at 25°C , 18:6 hr (L:D) cycles. When parasitoids emerged from the latter, the clutch was labeled “parasitized”. When only beetle larvae emerged, the clutch was denoted “unparasitized”. Thirty unparasitized and 17 parasitized egg clutches were analyzed.

Sample Preparation

The anthraquinone-free extrachorion (Meiners et al., 1997) was removed from the eggs, and 20 eggs of a clutch were used per sample. While anthraquinones found in microorganisms

and marine animals are present as free substances, plants contain anthraquinones mainly bound to glycosides (Teuscher and Lindequist, 1994). Because we cannot exclude bindings of anthraquinones in *G. tanacetii*, the egg extract was subjected to acidic hydrolysis in order to measure the total anthraquinone and anthrone quantities. Twenty eggs of an egg clutch were homogenized in 100 μ l 1 N HCL in acetone, and this mixture was incubated at room temperature for 24 hr. This method had been shown to completely hydrolyze glycosidically bound anthraquinones (Derksen et al., 2003). To measure the nonconjugated, free anthraquinones, 20 eggs of an egg clutch were homogenized in 100 μ l acetone with 1% acetic acid and also incubated at room temperature for 24 hr.

All samples were centrifuged at 13,000 rpm for 1 min. The supernatant was applied onto an SI column (Isolute[®]Spe columns: 100 mg, 3 ml; IST, Mid Glamorgan, UK), equilibrated with 100 μ l acetone prior to application. A first elution was made with 250 μ l acetone. Before the second elution step with 250 μ l acetone, 25 μ l of the internal standard (2-hydroxy-methyl-anthraquinone; 0.1 mg/ml; Aldrich, Steinheim, Germany) were applied to the column. Two final elution steps were made with 250 μ l methanol each. Twenty μ l of the eluate were evaporated with N₂. The dried sample was resolved in 20 μ l BSTFA (BSTFA + TMCS, 99:1; Supelco, Bellefonte, PA, USA) and incubated for 1 hr at 80°C.

GC-MS Analysis

One μ l per sample was analyzed by coupled gas chromatography-mass spectroscopy (GC-MS) (Fisons model 8060 GC coupled to an MD 800 quadrupole mass spectrometer) (Thermo Finnigan, Egelsbach, Germany) under the following conditions: injector temperature, 240°C; column, DB-1 fused silica, 30 m \times 0.32 mm i.d.; film thickness, 0.25 μ m (J & W Scientific, Folsom, CA, USA); carrier gas, helium with inlet pressure 10 kPa; temperature program, 100°C for 4 min, increase in temperature with a rate of 10°C/min to 280°C; solvent delay, 10 min. Measurements were conducted in the single ion mode (SIM) with the following *m/z* values of silanized anthraquinones (chrysazin: *m/z* 369, chrysophanol: *m/z* 383), anthrones [dithranol: *m/z* 442 (all from Aldrich, Steinheim, Germany), chrysarobin: *m/z* 456 (gift from Alfred Köpf, Zürich, Switzerland)], and the internal standard (2-hydroxy-methyl-anthraquinone: *m/z* 279; Aldrich, Steinheim, Germany). For quantification of the anthraquinones and anthrones, relative peak areas were calculated as a quotient of the peak area of the substance and of the internal standard. Calibration curves were obtained by injection of standard substances under the conditions described above.

Data Calculation and Statistics

All data were calculated on the basis of the quantity of anthraquinone and anthrone per single egg. Anthraquinone and anthrone quantities were statistically compared by using the Mann-Whitney *U* test (Statistica 4.5 scientific software, StatSoft, Hamburg, Germany).

Results and Discussion

Eggs of *G. tanacetii* contained chrysarobin and chrysophanol as major components, whereas dithranol and chrysazin were detected only in small amounts or traces. The mean weight of a single egg (without extrachorion) was 425 µg (SD ± 101 µg, $N = 19$). The % weight of total anthrones and anthraquinones per freshly laid unparasitized egg was highest for chrysarobin (approx. 0.21%), followed by chrysophanol (approx. 0.1%), dithranol (approx. 0.009%), and chrysazin (approx. 0.003%). The total amounts of these components were much higher than the amounts of free substances, indicating that they tended to bind, likely to cryoprotective components (Wang and Kang, 2005) (Table 1a, b).

Significant seasonal differences were detected when comparing anthrone and anthraquinone quantities of freshly laid eggs and eggs close to larval hatching:

- In unparasitized eggs (Table 1a), the amounts of free chrysarobin decreased during the winter diapause. Total amounts (free and bound) of the anthrone dithranol (−65%) and

Table 1c Statistical comparison (*P* levels)^a of anthraquinone and anthrone contents between unparasitized and parasitized eggs

	Compound	Free AQ	AQ total
Before winter	Chrysarobin	0.032	0.026
	Dithranol	0.698	0.418
	Chrysophanol	0.972	0.972
	Chrysazin	0.503	0.805
After winter	Chrysarobin	0.003	0.134
	Dithranol	0.096	0.267
	Chrysophanol	0.013	0.956
	Chrysazin	0.912	0.267

^aMann-Whitney *U* test; significant differences are in bold; amounts are given in Table 1a, b.

the anthraquinone chrysophanol (−30%) decreased significantly. The total chrysazin content tended to be much lower (−50%) after winter ($P = 0.054$).

- In parasitized eggs (Table 1b), the quantities of the free anthrones (chrysarobin and dithranol) decreased significantly during the winter period. In contrast, total anthrone and anthraquinone contents of parasitized clutches did not significantly change during winter.

If these components bind to carbohydrates or other components, they would be detected after the acidic hydrolysis (Derksen et al. 2003). In contrast to plants, no insoluble cell material with anthraquinone binding affinity is known. If the anthrones were transformed to dianthrones by oxidative coupling (Teuscher and Lindequist, 1994), the dimers or their fragments should have been detectable. However, no such components were found. If anthrones and anthraquinones were transformed and precipitated (as discussed for carminic acid in *Dactylopius coccus*; Hernández-Hernández et al., 2003), we also should have been able to find the dark precipitates in the *G. tanacetii* eggs; however, nothing similar to this was detected. Thus, the results indicate that the embryo or endosymbionts within the eggs degrade the anthrones and anthraquinones.

When comparing unparasitized and parasitized eggs, the anthraquinone and anthrone contents of the samples collected before winter (i.e., shortly after parasitization) differed from those collected after winter (Table 1c). The total amounts of chrysarobin were lower in parasitized eggs than in unparasitized ones only before winter. The amounts of free chrysophanol were significantly lower only after winter in parasitized eggs. However, the amounts of free chrysarobin were lower in parasitized eggs than in unparasitized ones both shortly before and after winter.

On one hand, the lower amounts of anthrones and anthraquinones in parasitized eggs might point to the involvement of these components in immediate immune responses against invaders. On the other hand, the difference between parasitized and unparasitized eggs might be attributable to the metabolization of these components by the developing parasitoid living in the host egg. However, the fact that the parasitoid is excreting polyketides with its feces within the host egg indicates that these components may pass the parasitoid gut at least in part unchanged (Meiners et al., 1997).

In summary, our study provided no evidence for the production of anthraquinones within eggs, thereby excluding anthraquinone-producing activity of the embryo. If endosymbionts are involved in anthraquinone biosynthesis and if they are vertically transferred by eggs, they are inactive during the host egg stage. Parasitization of the eggs also does not induce the production of anthraquinones and anthrones. Instead, a decrease in these components during embryogenesis was detected both in parasitized and unparasitized eggs, indicating metabolic transformation of the components by the *G. tanacetii* embryo and the parasitoid larva, respectively. Therefore, our data suggest that anthraquinones and anthrones are transferred into the eggs by the mother, and that the site of biogenesis of these polyketides is not within the eggs.

Acknowledgments We are grateful to Frank Müller for support with the GC-MS analyses. We also thank Barbara Randlkofer, Freie Universität Berlin, Germany, and Ina Heindinger, University Wuerzburg, Germany, for help with egg mass collections. This study was supported by a grant of the Deutsche Forschungsgemeinschaft Hi 416/16-1,2.

Intact lima bean plants attract the predatory mite, *P. persimilis* when they have been exposed to volatiles emitted from conspecific plants infested by its prey, *T. urticae* (Dicke et al., 1990). Furthermore, in this tritrophic system, the exposed intact lima bean plants increase: (1) their direct defenses against spider mites (Arimura et al., 2000), and (2) the production of herbivore-induced volatiles that attract *P. persimilis* (indirect defense) (Choh et al., 2004). These enhanced defenses are called “priming,” which has intensively been studied in plant–pathogen interactions (Conrath et al., 2002). In addition, we recently reported that intact lima bean plants increased the secretion of extrafloral nectar (EFN) when they were exposed to VIP, and that this consequently increased the residence time of *P. persimilis* on the exposed plants (Choh et al., 2006; Kost and Heil, 2006). We also found that unexposed lima bean plants increase EFN production when they are infested by the herbivorous mite, *T. urticae* (herbivore-induced EFN; Choh et al., 2006). We hypothesize that such an herbivore-induced EFN production was also primed by previous exposure to VIP. We tested the hypothesis by changing the duration of the infestation.

Methods and Materials

Plants and Mites

Lima bean plants were grown in soil in a greenhouse at $25 \pm 2^\circ\text{C}$, 60–70% r.h. under a photoperiod of 16:8 hr (L:D). We used plants grown for 4–6 d after germination.

T. urticae were obtained from the Laboratory of Ecological Information, Graduate School of Agriculture, Kyoto University, and were reared on lima bean plants in a climate-controlled room ($25 \pm 2^\circ\text{C}$, 60–70% r.h., 16:8 hr L:D).

Exposure of Plants to Volatiles

For exposure of plants to VIP, we used six acrylic $60 \times 60 \times 60$ cm cages with two 30×30 cm windows on opposite sides of the cage. Three cages were used for the experiment, and another three for control. The windows were covered with $225 \mu\text{m}$ nylon gauze, and airflow within the cage was below detection level. The cage had a 30×30 cm sliding door at the front. As odor sources, we used 8 plants that had been infested with 60 adult *T. urticae* females per plant for 1 d. The number of the odor source plants was determined on the basis of our preliminary experiments to ensure plant exposure to sufficient amounts of volatiles. Eight uninfested plants were used as control odor sources. Two uninfested plants were placed into a cage with the odor source plants (see Choh et al., 2006 for details of the setup) and exposed to either VIP or uninfested plant volatiles (UPV) for 10 d in a climate-controlled room ($25 \pm 2^\circ\text{C}$, 60–70% r.h., 16:8 hr L:D). All plants were placed in plastic containers (12 cm diam, 9 cm high) filled with water to prevent the migration of *T. urticae* from infested plants to uninfested plants. The distance between the exposed plants and the odor source plants was 25 cm. Both infested and uninfested plants had 2–3 unfolded trifoliolate leaves 10 d after exposure. We used newly cleaned cages for each experimental replicate. Under these experimental conditions, we visually inspected the exposed plants for signs of infestation and found that no spider mites invaded the exposed plants.

Measurement of EFN

After exposure of plants to VIP and UPV for 10 d, most of the EFN that had already been secreted was removed from VIP- and UPV-exposed plants with $5 \mu\text{l}$ capillaries (Ringcaps[®],

Hirschmann Laborgeräte GmbH, Germany). Measuring the length of nectar in the capillary enables the direct and precise quantification of the collected nectar volume. One of two exposed plants in a cage was used for the *T. urticae* infestation experiment, and the other was used as an intact (uninfested) control. We placed 30 *T. urticae* on the two primary leaves (total 60 *T. urticae* per plant) of the VIP- or UPV-exposed plants. As a control, no *T. urticae* were placed on VIP- and UPV-exposed plants. Thus, EFN quantities were measured in four sets of plants: (1) plants exposed to VIP and infested later, (2) plants exposed to VIP and kept uninfested later, (3) plants exposed to UPV and infested later, (4) plants exposed to UPV and kept uninfested later.

The amounts of newly secreted EFN were measured 2 d after infestation with *T. urticae* (herbivore-induced EFN). After removal of most of the induced EFN, we kept the plants for another 2 d under the same conditions, and then the secreted EFN was measured on the fourth day of infestation. Similarly, EFN secretion on intact plants (constitutively produced EFN) was measured 2 and 4 d after exposure to plant volatiles. We used 20 plants per treatment. The collection was always carried out between 10 and 12 A.M. in case the secretion of nectar showed a diel pattern (Raine et al., 2002). The experiments were conducted in a climate-controlled room (25 ± 2°C, 60–70% r.h., 16:8 hr L:D.). The amounts of secreted EFN per plant were analyzed by using a *t*-test and a Tukey-Kramer’s test.

Fig. 1 Quantities of extrafloral nectar (EFN) (mean ± SE) secreted by lima bean plants obtained from following treatments: intact UPV-exposed plants, intact VIP-exposed plants, infested UPV-exposed plants, and infested VIP-exposed plants. UPV = uninfested plant volatiles; VIP = volatiles from infested plants. The duration of plant volatile exposure was 10 d. Immediately after exposure, test plants were infested with *T. urticae*, and controls were kept uninfested (intact). Quantities of EFN were measured (a) 2 d and (b) 4 d after cessation of plant volatile exposure. Different letters above bars indicate significant differences among treatments within each time period by Tukey-Kramer’s test ($P < 0.05$).

Results and Discussion

EFN secretion of intact lima bean plants was increased when measured directly after a 10-d exposure to volatiles from infested plants (intact UPV-exposed plants: $0.928 \pm 0.053 \mu\text{l}$; intact VIP-exposed plants: $1.38 \pm 0.113 \mu\text{l}$; $P < 0.001$, *t*-test). These findings corroborated those of our previous study (Choh et al., 2006). When measuring EFN quantities 2 and 4 d after cessation of a 10 d exposure to plant volatiles, no differences were observed between intact VIP- and UPV-exposed plants ($P > 0.05$, Tukey-Kramer's test; Fig. 1a and b). Results indicate that increased EFN secretion of intact plants in response to exposure to VIP (Choh et al., 2006) did not continue once exposure was terminated. Compared with intact UPV-exposed plants, UPV-exposed plants infested by *T. urticae* did not significantly increase EFN secretion 2 d after infestation ($P > 0.05$, Tukey-Kramer's test; Fig. 1a). However, UPV-exposed plants infested with *T. urticae* secreted significantly more EFN during days 3 and 4 of infestation when compared with intact UPV-exposed plants ($P < 0.05$, Tukey-Kramer's test; Fig. 1b).

VIP-exposed plants infested for 2 d by *T. urticae* secreted significantly more EFN than the other three treatments ($P < 0.05$, Tukey-Kramer's test; Fig. 1a). Although VIP-exposed plants infested by *T. urticae* for the following 2 d (third and fourth days of damage) secreted more EFN than VIP- and UPV-exposed uninfested plants, these differences were not statistically significant ($P > 0.05$, Tukey-Kramer's test; Fig. 1b). Similarly, EFN secretion did not differ significantly between VIP- and UPV-exposed plants that were infested by *T. urticae* for the following 2 d (i.e., 4 d after damage) ($P > 0.05$, Tukey-Kramer's test; Fig. 1b).

The enhanced EFN secretion observed in the first 2 d may be adaptive to the plants, as previous studies have already demonstrated that increased EFN secretion by lima bean plants can be used for indirect defense (Kost and Heil, 2005; Choh et al., 2006). Together with our previous study (Choh et al., 2004), we showed priming effects of plant–plant interaction in lima bean plants: VIP exposure not only resulted in increased VIP emission (Choh et al., 2004), but also in increased herbivore-induced EFN secretion ($P < 0.05$, Tukey-Kramer's test; Fig. 1a). This protects against attack by herbivores, thus benefiting lima bean plants in nature (Heil, 2004).

revealed important ecological roles of ascidian crude extracts and isolated metabolites (reviewed in Pawlik, 1993; Paul et al., 2006). Although the ecological and applied importance of tunicate secondary metabolites is well recognized, little is known about the dynamics of their production. The few existing studies have focused on the intraspecimen location, at both the cellular and organism levels (Pawlik, 1993; Paul et al., 2006).

Temperate seas present strong seasonal fluctuations in environmental parameters that are often reflected in the life-cycle patterns of marine invertebrates (reviewed in Coma et al., 2000). Therefore, temporal changes in the production of secondary metabolites can be expected as a result of trade-offs with other biological functions or as a response to biotic interactions, both of which vary seasonally. So far, however, no study has attempted to determine the temporal variation of co-occurring secondary metabolites in an ascidian.

Colonies of the ascidian *Cystodytes* spp. generally lack epibionts and present scarce signs of predation (López-Legentil et al., 2006). In the Mediterranean, (López-Legentil et al., 2005a) described two chemotypes in the nominal species *C. dellechiajei*, one of which presented the sulfur-containing pyridoacridines shermilamine B (**1**), kuanoniamine D (**2**), and their deacetylated forms, deacetylshermilamine B (**3**) and deacetylkuanoniamine D (**4**). All of them were isolated from a purple morph (Fig. 1). Some of these substances are cytotoxic (Bowden, 2000). In addition, the crude extract of this morph showed anti-predatory properties against both puffer and damselfish, but not against sea urchins (López-Legentil et al., 2006). The main goal of this study was to establish whether there was a temporal variation in the production of these four pyridoacridine alkaloids.

Methods and Materials

Sampling

We monitored a population of the purple morph of *Cystodytes* in L'Escala (NE Spain; 42° 06'52"N, 3°10'07"E). From July 2004 to February 2006, five different colonies per month were randomly collected by scuba diving. They were frozen alive, freeze-dried within a week, and kept at -30°C until analysis.

1: R=COCH₃ shermilamine B

2: R=COCH₃ kuanoniamine D

3: R=H deacetylshermilamine B

4: R=H deacetylkuanoniamine D

Fig. 1 Structures of the four main alkaloids isolated from the purple morph of *Cystodytes*. (**1**) Shermilamine B; (**2**) kuanoniamine D; (**3**) deacetylshermilamine B; (**4**) deacetylkuanoniamine D

Chemical Extraction

Approximately 250 mg of each freeze-dried colony were weighed and extracted $\times 3$ in a 1:1 (v:v) mixture of dichloromethane and methanol and passed through a 20- μm polytetrafluoroethylene (PTFE) filter. The resulting solution was dried by vacuum rotary evaporation. Each crude extract was redissolved in methanol, and the final volume was adjusted to 10 ml. An aliquot of 1 ml was passed through a 13-mm, 0.20- μm PTFE syringe filter before high-performance liquid chromatography (HPLC) injection. The injection volume was fixed at 20 μl .

HPLC Analysis and Quantification

The HPLC elution conditions consisted of eluants A (water/methanol/acetic acid, 9:1:0.1 v:v:v) and B (methanol), an elution profile based on a linear gradient from 0% B to 100% B in 10 min, and a flow rate of 0.8 ml min⁻¹, with a fixed temperature of 30°C. We used an Agilent Eclipse XDB-C8 (4.6 mm ID \times 15 cm) analytical column. Analyses were performed with a Waters Alliance 2695 Separations Module with a Waters 996 photodiode array detector. The sulfur-pyridoacridine purifications and identifications were performed as described by (López-Legentil et al., 2005a). Shermilamine B, kuanoniamine D, and their deacetylated forms were detected at 308 nm. The peak area obtained for each compound was integrated and compared to a calibration curve obtained by using each of the isolated pyridoacridines as an external standard. The final amount of each compound was calculated by averaging three replicate injections. All analyses were processed with Empower software.

Quantification of Total Organic Matter

After chemical extraction, the remaining colony pieces were oven-dried to a constant weight (60°C for at least 24 hr), placed in aluminum cups, weighed, and burned in a furnace oven at 500°C for 12 hr. Total organic matter content for each colony was obtained by subtracting the ash from the total dry mass weight. We standardized the metabolite concentration in relation to organic mass, as variations in inorganic material (e.g., spicules) could confound the results.

Data Analysis

For the analysis of the production of shermilamine B, kuanoniamine D, and their deacetylated forms over time, we used one-way analysis of variance (ANOVA) with time (month) as factor after checking for normality and homoscedasticity of the data. Nonparametric equivalents (Kruskal–Wallis test) were applied when necessary (detailed in the next section).

Results and Discussion

All samples showed a low chemical diversity, with four peaks, identified as deacetylkuanoniamine D (retention time, 4.5 min), deacetylshermilamine B (retention time, 5.4 min), kuanoniamine D (retention time, 7.2 min), and shermilamine B (retention time, 8.1 min). Changes in the concentrations of kuanoniamine D, shermilamine B, and their deacetylated forms (mean \pm SE) are shown in Fig. 2 as the percentage of each compound relative to

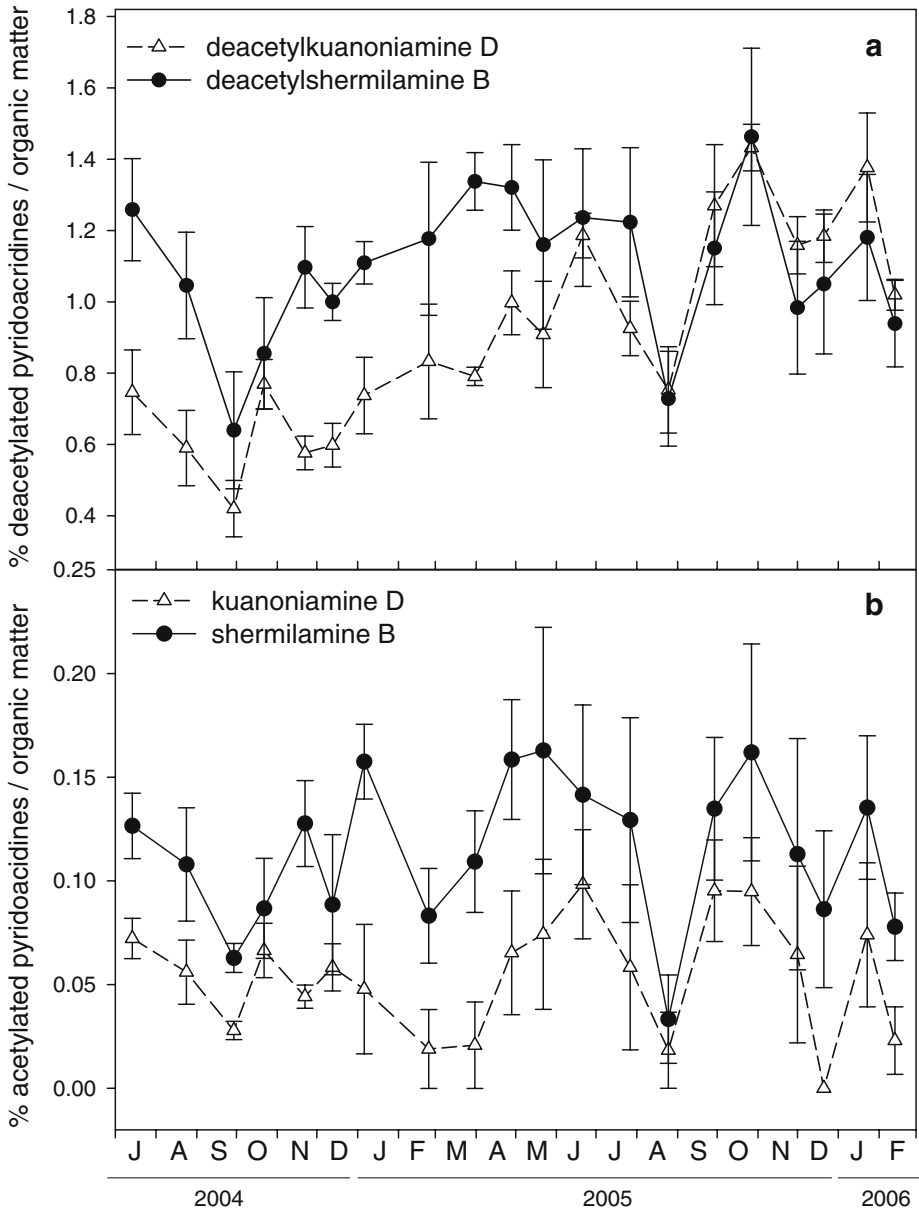

Fig. 2 Time course of the percentage of the four sulfur-containing pyridoacridines studied relative to total organic matter of each colony from July 2004 to February 2006. (a) Deacetylkuanoniamine D (dotted line) and deacetylshermilamine B (solid line); (b) kuanoniamine D (dotted line) and shermilamine B (solid line). Bars indicate standard errors (SE)

total organic matter. Deacetylshermilamine B was the most abundant compound, whereas kuanoniamine D was the least abundant. The percentages of deacetylkuanoniamine D and deacetylshermilamine B showed similar trends, with minima in September 2004 and August 2005 (Fig. 2a). However, only the production of deacetylkuanoniamine D significantly varied over time (Kruskal–Wallis, $P < 0.001$). Pairwise multiple comparison

procedures (Dunn's method) revealed that values in September 2004 were significantly lower, and values in October 2005 significantly higher. No significant difference was detected for the production of deacetylshermilamine B over time (ANOVA, $P = 0.073$). The concentration of shermilamine B showed no significant variation with time (Kruskal–Wallis, $P = 0.197$), although a minimum was observed in August 2005 and a less marked one in September 2004 (Fig. 2b). There was also no clear temporal pattern in the percentage of kuanoniamine D (Kruskal–Wallis, $P = 0.158$), but minima were found in September 2004, February and August 2005, and December 2006 (Fig. 2b). The large standard errors found in the production of these compounds showed that there was noticeable interindividual variability, which is commonplace among sessile invertebrates. All in all, there was no clear seasonal pattern in the production of any of the four compounds studied, except for the presence of minimum values in late summer 2004 and 2005. There was no evidence either of a biotransformation between acetylated and deacetylated compounds (or *vice versa*) that would have been reflected by an inverse time course of their abundances.

López-Legentil et al. (2005b) observed that the purple morph of *Cystodytes* had marked seasonal cycles for reproduction and growth, with larval release in summer (July–August) followed by a period of asexual growth. Investment in reproduction in this species is high, as the weight of larvae produced by a single zooid is almost equal to the weight of the zooid itself (Tarjuelo and Turon, 2004). Therefore, larval release (assuming they take secondary metabolites with them) could contribute to the low values in the production of deacetylshermilamine B and deacetylshermilamine D observed after sexual reproduction. However, these deacetylated compounds are present in both tunic and zooids (López-Legentil et al., 2005a), and the total mass of larvae is only 4% of the colony weight (Tarjuelo and Turon, 2004). A combination of larval release and “sexual exhaustion” after reproduction (Berrill, 1935) may account for the decrease in secondary metabolite concentration recorded in late summer 2004 and 2005.

Interacting organisms may also influence the production of secondary metabolites in *Cystodytes*. Predation and competition for space and food, if seasonally variable, may modulate the production of defensive secondary metabolites. Finally, abiotic factors should also be taken into account. Summer is an unfavorable season for many sessile filter feeders in the Mediterranean due to the existence of a food shortage period (Coma et al., 2000). This unfavorable season may be reflected by a decrease in investment in secondary metabolite production. A mixture of biotic interactions, and physiological and physical factors may all have shaped the trends observed in the production of the main pyridoacridine alkaloids.

Acknowledgments J. Pawlik kindly made useful comments to improve this manuscript. Diving assistance was provided by C. Menniti and C. Palacin. This study was funded by a Ministry of Education and Science/Fulbright grant to S.L.-L., the project CTM2004-05265 of the Spanish Government, and by the Interreg IIIA n. I3A-1-72-E program of the EU.

ultimately be regarded as interesting subjects for scientific investigations, with little real value. (Ridgway et al., 1990).

In fairness, for a number of insect species, mating disruption and other methods of insect control based on pheromones are simply not practical or economical, as opposed to being not efficacious. For example, a number of pheromone structures are too complex to synthesize economically, or too unstable to survive long periods in the field without degradation. However, for other species, pheromones are or could be readily accessible for large-scale use, but repeated efforts to make mating disruption work have been at best only partially successful. One likely cause for some of these failures was voiced by Sanders (1996) in the introduction to his chapter on mechanisms of mating disruption in the book *Insect Pheromone Research: New Directions*. Sanders stated:

Unfortunately, the mechanisms of how mating disruption works are still largely unknown. Because the technique involves complex behavioral interactions between insects in a communication mode (olfaction) to which humans have little inherent affinity, understanding disruption is not easy. (Sanders, 1996).

Remarkably, these comments were made some 30 years after the first mating disruption trial, and now, some 10 years later, our understanding of how and why mating disruption does or does not work with a particular species remains rudimentary. Possible mechanisms by which mating disruption might work (as discussed in the next two articles) were proposed more than 30 years ago (Bartell, 1982). The subject continues to be contentious because it has proven difficult to design experiments which unequivocally show that one mechanism or another, or a combination of mechanisms, are operative. Furthermore, it is unlikely that all insects will be affected in the same way by pheromones. For example, some species are much more sensitive to high rates of pheromone release than others, suggesting that they might be most susceptible to sensory fatigue or habituation. In contrast, species that tolerate relatively high pheromone release rates may be more susceptible to false trail following.

In the two papers that follow, Miller and his coworkers have developed a theoretical framework and mathematical models that, to our knowledge, represent the first attempt to deconstruct the results of mating disruption trials with the goal of determining which possible mechanisms of mating disruption were operative. The editors recognize that these articles may be controversial, and the models and their underlying assumptions may ultimately require extensive revision or modification. Nevertheless, we feel that these manuscripts represent an important first step in reenergizing the debate about the mechanisms of mating disruption. Researchers have indulged in speculation and hand-waving arguments about these mechanisms for several decades, with little actual research being done to prove that one or more mechanisms are indeed operative. Thus, the editors hope that the following papers will revitalize this area of research, and stimulate the design of experiments to specifically test the predictions and postulates deriving from the mathematical models of Miller and his colleagues.

attractiveness of traps, females, and dispensers is known. The absolute value of the slope of the Miller-de Lame plot is a measure of each dispenser's activity (D_a) for suppressing catch of male moths in traps. An application activity ($D_{\bar{A}a}$) for a given dispenser can be calculated by multiplying D_a by the number of such dispensers applied per hectare of crop.

Keywords Mating disruption mechanisms · Disruption kinetics · Mathematical modeling · Percent disruption · Dispenser activity

Introduction

Mating disruption as currently applied to insects is the practice of continuously dispensing synthetic sex attractants into a crop for extended periods so as to suppress pest reproduction by interfering with mate finding. This pest management tactic holds considerable promise for management of moths and other pests that rely on long-distance chemical communication. In the United States, the demands for pest control by behavioral modification are rising as availability of conventional insecticides dwindles in the face of increasingly stringent regulatory policies. However, protocols for pheromone disruption of many important moth pests have not been optimized. In some cases, this tactic works robustly (e.g., redbanded leafroller, Novak and Roelofs, 1985; also in oriental fruit moth, Rice and Kirsch, 1990; Trimble et al., 2004, and other examples in Cardé and Minks, 1995), whereas in other cases results are mixed (e.g., obliquebanded leafroller, Agnello et al., 1996; Lawson et al., 1996; spruce budworm, Seabrook and Kipp, 1986).

General agreement has not been reached as to whether it is better to broadcast pheromone uniformly throughout a crop (e.g., microencapsulated formulations, Balkan, 1980; Vickers and Rothschild, 1991; Waldstein and Gut, 2003), or whether pheromone dispensers should be discrete sources spaced regularly throughout. In orchards, a spacing of 1–2 dispensers per tree is recommended for long-lasting, hand-applied pheromone dispensers like polyethylene tubes (ropes) (Rothschild, 1975; Nagata, 1989; Knight et al., 1998). The disruptive products used in some other crops favor an intermediate density of small and highly distributed point sources (e.g., hollow fibers, Doane and Brooks, 1981; Swenson and Weatherston, 1989; or laminated flakes, Tcheslavskaja et al., 2005). Likewise, there is divergence of opinion regarding the quantity of pheromone necessary for high-performance disruption and whether it is better to use the complete natural blend or just one or two of the major pheromone components (Knight et al., 1998; Minks and Cardé, 1988; Evenden et al., 1999). Different release devices, spacings, and chemistries may be called for (Gut et al., 2004) depending on the mechanism(s) of disruption to which a particular pest species is thought to be vulnerable.

It has often been pointed out that optimizing mating disruption will be aided by understanding the actual behaviors evoked or suppressed when insects are exposed to particular formulations of synthetic pheromones (e.g., Valeur and Löfstedt, 1996; Cardé et al., 1998; Evenden et al., 2000; Gut et al., 2004). The major mechanisms postulated to explain communicational disruption (Rothschild, 1981; Bartell, 1982; Cardé, 1990) include (formal definitions below): (1) false-plume-following; (2) camouflage; (3) desensitization—including adaptation and habituation; (4) sensory imbalance; and (5) combinations thereof. However, the evidence for which mechanism is mainly responsible for communicational disruption for particular pests under particular regimes of disruption remains largely circumstantial. We are aware of no example where a particular mechanism has been definitively proven to be the leading cause of mating disruption for any insect under actual field conditions.

Some might argue that biological phenomena like mating disruption are too complex to be usefully represented by simplistic explanatory models. Complications in interpretation are easy to envision if several disruption mechanisms operate simultaneously. However, we see value in attempting to break this seemingly complicated phenomenon into defined component causes, and assessing how each could shape overall outcomes. Recognizing and understanding patterns in disruption outcomes associated with individual explanatory models should facilitate recognizing and understanding outcomes from mixed models.

This analysis emphasizes competitive attraction as a primary contributor to mating disruption of moths by pheromone point sources. Competitive attraction has been variously referred to as: confusion (Knipling, 1979 *et ante*; Bartell, 1982), false-trail-following (Maini and Schwaller, 1992), and false-plume-following (Cardé, 1990; Stelinski et al., 2004a). Our attention was drawn to this mechanism when direct behavioral observations (Stelinski et al., 2004a, 2005a,b) revealed that oriental fruit moth (*Grapholita molesta*), obliquebanded leafroller (*Choristoneura rosaceana*), redbanded leafroller (*Argyrotaenia velutinana*), and codling moth (*Cydia pomonella*) all approached their respective polyethylene tube dispensers of pheromones at frequencies rivaling catches of moths occurring simultaneously in monitoring traps. Combined with earlier reports of attractiveness of dispensers used in mating disruption (e.g., Bartell, 1982; Barrett, 1995; Cardé et al., 1998; Witzgall et al., 1999; Maini and Accinelli, 2000), there is mounting evidence that competitive attraction is involved in communicational disruption of various moth species. In this paper, we: (1) explicitly define and formalize the competitive attraction explanatory model; (2) detail its predictions; and (3) determine where these predictions do or do not overlap with non-competitive explanatory models. This work sets the stage for a companion paper (Miller et al., 2006) that analyzes case studies from the literature for fit to competitive vs. noncompetitive disruption.

Definition, Assumptions, and Predictions of the Competitive-Attraction Explanatory Model for Communicational Disruption

Definition

We take *competitive attraction* to mean that the frequency with which male moths find calling females or monitoring traps (proxy for calling females) in a crop under disruption is reduced because males are diverted from orienting to females or traps due to preoccupation with nearby attractive or arrestive plumes from dispensers of synthetic pheromone. Accordingly, communicational disruption by sex attractant pheromones utilizes the same behavioral mechanisms normally enabling the responder to *find* (*sensu* Miller and Strickler, 1984) a calling female. These mate-finding mechanisms are mainly positive, plume-following anemotaxis combined with arrestment. Female moths under pheromone disruption by competitive attraction are envisioned to compete with sources of synthetic pheromone for responses from males.

Mating System in Which Pheromone Disruption by Competitive Attraction Operates

The mating system of moths using sex attractants for long-distance mate finding has been labeled *scramble polygyny* (Thornhill and Alcock, 1983) to describe the situation in which males compete heavily during limited windows of time for a share of calling females whose individual availability is fleeting. The sex ratio in a moth population is usually approximately one, but this does not mean that every male succeeds in mating. Individual males are rewarded for proficiency in detecting pheromone plumes and arriving at their sources.

Provided he is not physically or behaviorally defective, the first-arriving male usually mates with the calling female. Moreover, some males may mate numerous times, whereas others may never mate. When females mate infrequently, intrasexual competition among male moths is high, whereas that among females is comparatively low. This is because mated females cease calling (at least for a time), whereas all able-bodied males continue competing sexually throughout their lives. Under a regime of pheromone disruption by competitive attraction, scramble competition would be intensified for males by the addition of “false females” that make it more difficult for males to find authentic females. In addition, intrasexual competition would be intensified for females by deployment of many false females into the system. The effect is analogous to diminishing male density, or lowering the ratio of males to females. In the natural situation and with appreciable moth populations, any calling female is expected to be quickly found and mated. However, the signals of females could go unheeded under mating disruption operating by competitive attraction because males would be preoccupied by visits to the more abundant false females.

In the several cases where it has been quantified, fecundity of both male and female moths diminishes substantially with age (Knight, 1997; Jones and Aihara-Sasaki, 2001; Torres-Vila et al., 2002). Thus, delaying mating can contribute to pest control. However, when each mated female produces 100 or more viable eggs and mortality of larvae is low, efficacy in mating disruption must exceed ca. 98% for the pest population to decline (Knipling, 1979).

Assumptions of a Probability Model for Competitive Attraction

Figure 1 provides the spatial and numerical context in which we envision moth mating disruption to occur in one small portion of an orchard crop. This figure depicts a 0.3-ha plot of fruit trees infested with a tortricid moth pest. Active spaces of pheromone plumes generated by hand-applied pheromone dispensers in such an orchard vary from ca. 5–30 m in length, as estimated by portable electroantennogram devices (EAGs) (Suckling et al., 2006). For ease in viewing and interpreting Fig. 1, the density of dispensers (D) (Table 1 provides a key to abbreviations) is reduced from the usual 1–2 dispensers per tree. Instead, 24 dispensers of pheromone are spaced regularly throughout the 72-tree plot, which also contains 20 male (M) and 20 female (F) moths. One monitoring trap (T) baited with an optimized pheromone lure is deployed centrally in this plot, as is usual for assessing the effectiveness of communicational disruption, measured as inhibition of catch of males in traps relative to catch in an equivalent control plot not treated with pheromone. Wind, currently from the top left of the orchard, generates a pheromone plume from each dispenser and the trap. Active spaces are approximated by the light-gray ellipsoids snaking across tree rows. Shifts in wind direction over time would shift the direction and shape of plumes such that pheromone from individual sources would waft over varying sets of trees and moths through time. As females begin calling, their plumes mingle and compete with those from pheromone dispensers and the trap. Over a moth's lifetime, the encounters of males with pheromone sources (T , F , and D) are envisioned to occur in proportions approximating the relative densities and strengths of pheromone sources of each type in this orchard. The densities of male and female moths in this orchard would shift across time in accordance with their respective curves for entrance into and exit from the local reproductive pool. Variation in nightly reproductive activity would be influenced by abiotic factors like weather. However, orientational outcomes averaged across a full moth generation are envisioned to stabilize sufficiently to permit meaningful contrasts among different disruptive treatments sharing common conditions.

Fig. 1 Diagram of a 0.3-ha orchard plot of 72 trees containing 24 evenly distributed pheromone dispensers (D), 20 randomly distributed male moths (M), 20 randomly distributed female moths (F), and one centrally located monitoring trap (T). Wind originates from the top left.

Predictions of time-averaged outcomes from orientational events of male moths under disruption by competitive attraction are easiest to understand for the simplified, hypothetical situation where: (1) attractiveness is equal for *F*, *D*, and *T*; (2) each male engages in one attraction event per night; (3) the number of males removed by the one sticky trap has negligible impact on the male population; and (4) all females call and remain attractive through most of a several-hour reproductive period. Complexity will be systematically added once predicted outcomes of the simpler case are described.

Mathematically, this problem corresponds to that of loading a bag with 20 white spheres [= density of moth females (F_D) in Fig. 1], 24 green spheres [= density of dispensers (D_D)], and one red sphere [= density of traps (T_D)] and thoroughly mixing these spheres of equal size and mass. One male orientational event corresponds to reaching into the bag, randomly withdrawing one sphere, and then replacing it. The probability one draw will yield a white sphere is: $20/45 = 0.44$. Likewise, the probability one draw will yield a green or red sphere is: $24/45 = 0.53$, or $1/45 = 0.022$, respectively. With sufficient replication, the number of spheres of a given color drawn per set of draws equals the probability of drawing the given color at each draw multiplied by the number of draws per set, which equals the number of males in the plot when each male is allotted only one attraction event per night.

Translating the probability principles of the scenario described above to Fig. 1, the theoretically predicted male visitation rate per night to the trap is taken as synonymous with catch (*C*) to yield:

$$C = T_D M_D / (T_D + F_D + D_D) \tag{1}$$

Catch in this case = $1 * 20 / (1 + 20 + 24) = 0.44$ males/trap/night. Similarly, the predicted male visitation rate per night to the 20 females and 24 dispensers of Fig. 1 = 8.9 and 10.7, respectively.

There is ample precedent for applying standard probability theory to predict time-averaged male catches when females call in competition with attractive traps. Knippling (1979) and coworkers did so when exploring the possibilities of annihilating insect populations using a trap-out tactic. Other researchers (e.g., Mertins et al., 1967; Hardee et al., 1969; Roelofs et al., 1970; Nakasuji and Fujita, 1980) built on this approach to modeling competitive attraction and found its predictions realistic in field tests.

Predictions of Competitive Attraction Models

1. General predictions from the mass trapping literature.

Key predictions already validated in literature (above references) taking this probabilistic approach to competitive attraction are as follows: (1) efficacy is strongly and positively correlated with the density of traps baited with artificial pheromone; (2) efficacy of competitive attraction is strongly and negatively correlated with pest density; and (3) the density of traps required to control a substantial population of pest moths is prohibitively high due to material costs.

Table 1 Key to abbreviations

Term	Definition
A	Total area of crop (ha)
A_c	Area of crop covered by camouflaging pheromone plumes
A_{uc}	Area of crop not camouflaged by pheromone plumes
$C = V_{Tt}$	Catch (males/trap/time)
C_{max}	Male catch in traps placed into crop not receiving pheromone dispensers
D	Dispenser of synthetic pheromone deployed for disrupting sexual communication
D_a	Dispenser activity = suppressive effect of a dispenser on ability of males to find females or monitoring traps; the units are area (ha) over which one dispenser can theoretically reduce C_{max} by 50%
$D_{\bar{a}a}$	Dispenser application activity = $D_a * D_D$ = potency of a given pheromone formulation as applied to one ha
D_D	Dispenser density (dispensers/ha)
D_{sa}	Dispenser specific activity = $D_a/\mu\text{g}$ pheromone released by 1 dispenser/hr; the units are $\text{ha} * \text{hr}/\mu\text{g}$
F	Female moth
F_D	Female moth density (females/ha)
k_D	Attractiveness of a pheromone dispenser relative to that of a trap or female moth
k_F	Attractiveness of a female moth relative to that of a trap or dispenser
k_T	Attractiveness of a trap relative to that of a female or dispenser
M	Male moth
M_D	Male moth density (males/ha)
T	Trap baited with a pheromone lure; attracts and captures male moths
T_D	Trap density (traps/ha)
$V_{/D}$	Visitation rate of male moths to a dispenser (male visits/dispenser/time)
$V_{/F}$	Visitation rate of male moths to a female moth (male visits/female/time)
$V_{/T} = C$	Visitation rate of male moths to a trap (males/trap/time)

2. Predictions of mating disruption outcomes from our competitive-attraction model as applied to Fig. 1.

According to Equation (1), the nightly probability that a male will visit a given trap or a given female under the competitive-attraction assumptions of Fig. 1 is 0.44. If each visit to a female resulted in mating, 8.9 out of the 20 total females would mate on night 1. The comparable number of male visits to a given female in a control plot equivalent to that of Fig. 1, but without pheromone dispensers can also be calculated using Equation (1) as: $1T * 20M / (1T + 20F) = 20/21 = 0.95$. Mating disruption outcomes are typically scored by % inhibition of male catch in traps, calculated as: $[1 - (\text{mean catch per trap in the pheromone-treated plot} / \text{mean catch per trap in the check plot})] \times 100\%$ (Roelofs and Novak, 1981). That value for the current example is: $[1 - (0.44/0.95)] 100\% = 54\%$.

From the perspective of pest control, a 54% mating disruption efficacy per night for the 24 pheromone dispensers per 72 fruit trees is inadequate. Moreover, having nine of the 20 females mate on the first night lowers the total density of attractant sources for the second night: 11F, 24D, and 1T = 36 total. The calculated male catch on the second night for one trap or male visitation rate to a given female is: $1 * 20/36 = 0.56$, a value slightly higher than 0.44 male visits per female for night 1. It follows that 6.1 females of the 11 remaining virgins would mate on night 2, leaving only 4.9 of the original 20 virgin females after two nights. After night 3, the preponderance of females would have mated. The number of pheromone dispensers in Fig. 1 is clearly too low to control the pest under competitive attraction operating within the above assumptions.

A key prediction of competitive attraction is that moth catch per trap will be negatively correlated with density of competing attractant sources. This relationship is specified in Fig. 2a for the conditions of Fig. 1. However, densities of dispensers, moths, and traps are now scaled per hectare. An identical profile would result if male visitation rate per 3.3 virgin females per night were plotted on the *y*-axis of Fig. 2a. The effect of increasing dispenser density is nonlinear for competitive attraction. Initially, the impact of small increases in dispenser density is great; however, the return for a given increment in dispenser density progressively diminishes. Unfortunately for pest management, complete cessation of male visits per female or trap under a regime of competitive attraction is approached only asymptotically and never reached. The shape of this response profile is an inherent property of inverse functions, where a swelling D_D in the denominator of Equation (1) initially overwhelms but never completely negates T_D and M_D in the numerator.

Inverse functions lend themselves well to graphical analyses after an inverse transformation. Indeed, the simulated competitive attraction data from Fig. 2a when plotted as the inverse of male catch/trap/night ($1/C$) on the *y*-axis vs. D_D on the *x*-axis (designated hereafter as a Miller-Gut plot) yield a straight line. Equation (1) rearranged into the $y = mx + b$ format yields:

$$1/C = 1/T_D M_D * D_D + (T_D + F_D) / T_D M_D \quad (2)$$

For a given moth and trap density, the greater the slope of a Miller-Gut plot, the greater is the disruption per dispenser. Moreover, when attractiveness of $T = F = D$, the inverse of this slope equals $T_D M_D$ and hence reveals M_D , when T_D is known. Furthermore, the absolute value of the *x*-intercept of a Miller-Gut plot of competitive-attraction data equals $T_D + F_D$, when attractiveness of $T = F = D$. Even more importantly, this value also equals the number of dispensers D per hectare (D/ha) required to reduce male catch by $1/2C_{\text{max}}$, under these specified conditions. Larger absolute values for *x*-intercepts equate to lower disruptive

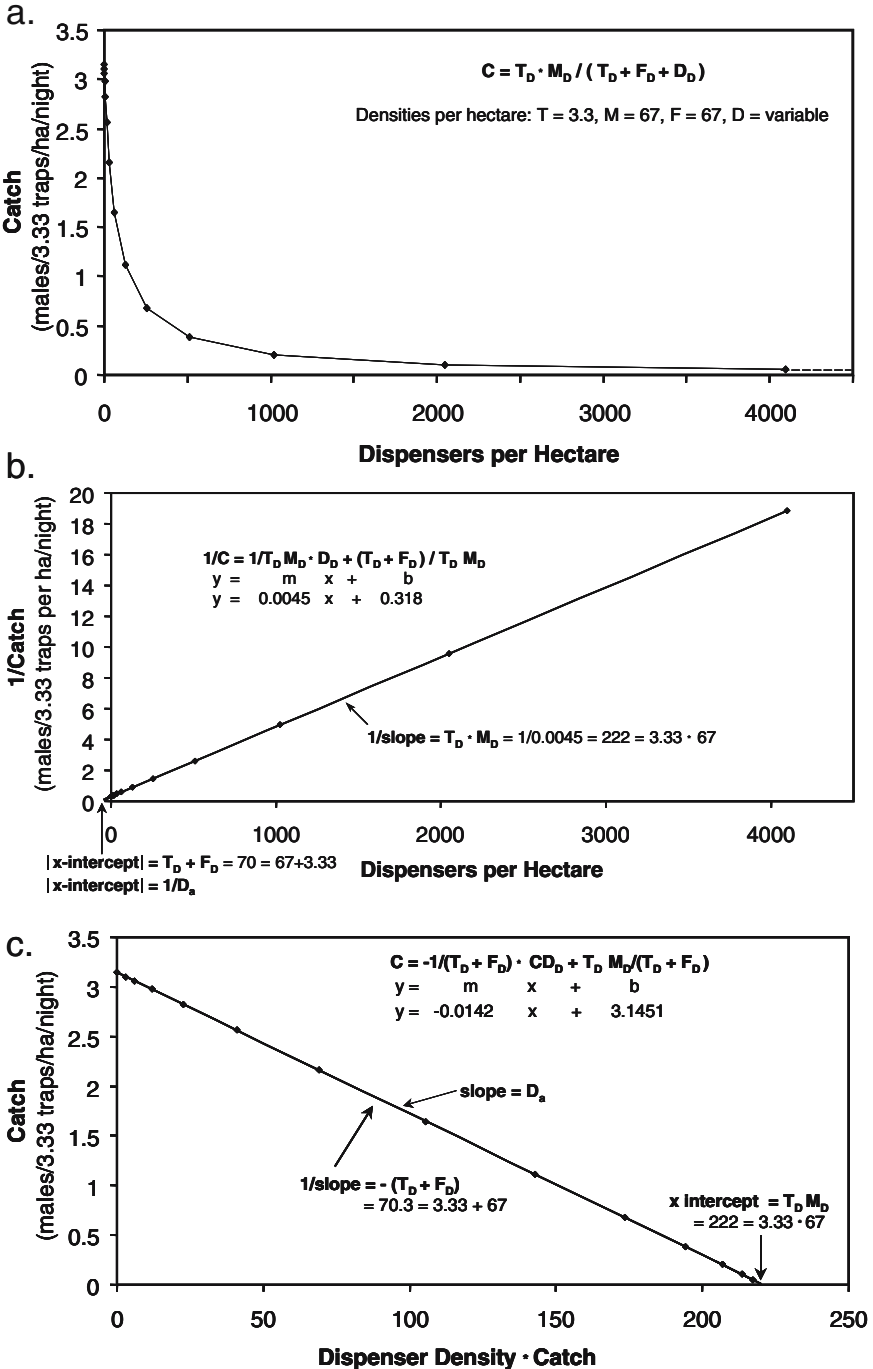

Fig. 2 Plots of a simulated communicational disruption profile for competitive attraction operating under the conditions of Fig. 1 and the assumptions given in text. (a) Untransformed plot; (b) Miller–Gut plot; (c) Miller–de Lame plot. See Table 1 for definition of abbreviations. Mathematical simulations were performed in Microsoft Excel.

potency per dispenser. The reciprocal of the absolute value of the x -intercept offers the most useful measure of disruptive activity per dispenser (D_a) expressed as the fraction of one ha over which a given dispenser would be capable of reducing catch by $1/2C_{\max}$. In Fig. 2b, $D_a = 1/70 = 0.0142$. Theoretically, each dispenser would be capable of suppressing catch in 0.042 ha (420 m²) by 50%. An increase in D_a for a given T_D and F_D reflects an increase in a dispenser's competitive attractiveness relative to the traps and females against which it was competing. D_a can be calculated variously:

$$\text{absolute value of the Miller – Gut } x\text{-intercept} = D_D \text{ yielding } 1/2 C_{\max} = 1/D_a \quad (3)$$

The x -intercept is calculated from the $y = mx + b$ equation by setting $y = 0$ and solving for x , which yields $x = y\text{-intercept}/\text{slope} = 1/D_a$. Rearrangement yields

$$D_a = \text{Miller – Gut slope} / \text{Miller – Gut } y\text{-intercept} \quad (4)$$

Substituting terms from Equation (2) yields, for the special case when attractiveness of $T = F = D$:

$$D_a = (1/T_D M_D) * T_D M_D / (T_D + F_D) = 1 / (T_D + F_D) \quad (5)$$

Under competitive attraction, we suggest that $D_{\bar{A}a}$ (dispenser application activity) become the designation for the disruptive activity of a given number of dispensers per designated area of treated crop and with each dispenser sharing a common D_a ; thus:

$$D_{\bar{A}a} = D_a * D_D \quad (6)$$

$D_{\bar{A}a}$ is unitless, since it results from multiplying ha/dispenser by dispensers/ha. Use of standard units of measure (i.e., hectare) will facilitate comparisons of disruption potencies across experiments and pest species. Substitution of $1/T_D + F_D$ from Equation (5) for D_a in Equation (6) yields:

$$D_{\bar{A}a} = D_D / (T_D + F_D) \quad (7)$$

In what we designate as a Miller-de Lame plot, male catch (C) is plotted on the y -axis against dispenser density * male catch ($D_D C$) on the x -axis. The resultant graph (Fig. 2c) yields a straight line; C_{\max} is the y -intercept, $T_D * M_D$ is the x -intercept, and the absolute value of the slope directly reveals D_a . Equation (1) can be rearranged into the $y = mx + b$ format as:

$$C = -1 / (T_D + F_D) * C D_D + T_D M_D / (T_D + F_D) \quad (8)$$

We suggest that the Miller-de Lame plot will be the more stringent test of whether actual experimental results from the field fit the theoretical predictions of competitive attraction. However, before that fit can be judged, assurance will be needed that deviation from the linear profile indicative of competitive attraction is not primarily attributable to sampling error inherent in low male catches. In field experiments, sampling error will rise as catch of males drops to tiny values because many dispensers are present. Moreover, this error will be compounded as increasingly imprecise values of C are multiplied by a swelling D_D . Thus, adherence of actual field data to a Miller-de Lame function like that of Fig. 2c is expected to deteriorate when moving from left to right on such a graph.

The principle that competitive attraction outcomes vary strongly with density of the target pest is demonstrated in Fig. 3a, as calculated under the conditions of Fig. 1 and its stated assumptions. Application of attractive pheromone sources at 50 dispensers per 72 trees of Fig. 1 predicts ca. 95% trap catch suppression for a moth population of 5 males and

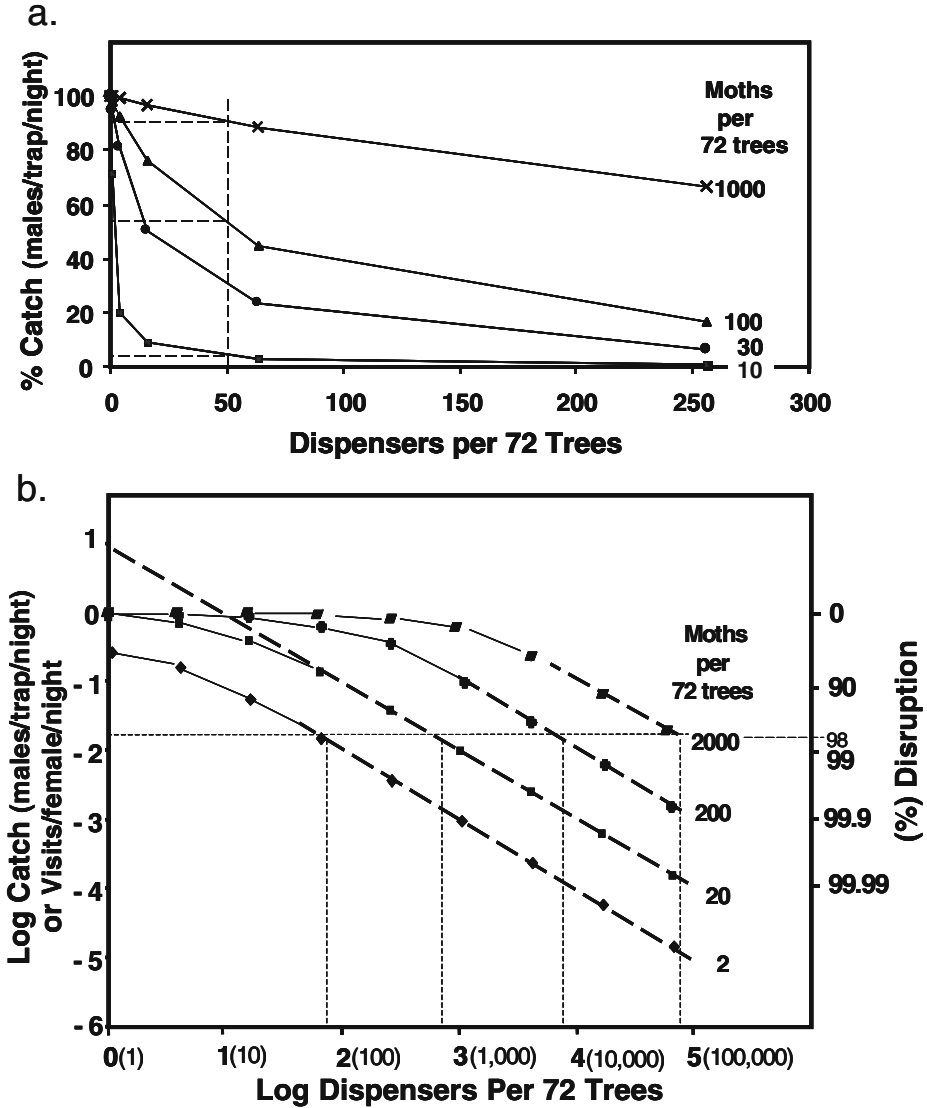

Fig. 3 Efficacy of simulated communicational disruption by competitive attraction as influenced by moth density under the conditions of Fig. 1 and its assumptions and a 1:1 sex ratio. Percent catch is expressed relative to catch in an equivalent plot not receiving pheromone dispensers. (a) Plot on untransformed axes; (b) plot on $\log_{10} \times \log_{10}$ axes; numbers within parentheses along the x -axis are the untransformed densities of pheromone dispensers.

5 females per 72 trees (Fig. 3a). However, the predicted disruption efficacy for 100 and 1000 moths per 72 trees is only ca. 45% and 10%, respectively.

A $\log_{10} \times \log_{10}$ plot of communicational disruption as a function of pheromone dispenser density displays this relationship across a wide range of pest and dispenser densities (Fig. 3b). Under competitive attraction, $\log \times \log$ plots for all pest densities become linear with a slope of negative 1 when the numbers of female moths become

inconsequential relative to the total number of attractant sources. Furthermore, the elevation (projected y -intercept) of each linear portion (bold) of the various profiles graphed in Fig. 3b reveals the density of males in the system. Conveniently, Fig. 3b also prescribes the number of dispensers required for a desired percent reduction in male visits (mating) across the various pest densities. This is accomplished by projecting a horizontal line across the graph at the desired value of percent disruption and reading out values of x at the intersections. For example, the horizontal dashed line in Fig. 3b indicates a 98% suppression of nightly male catch of males or visits per female. Values of x at the intersections along the dashed horizontal line prescribe that ca. 90, 900, and 9000 dispensers per 72 trees would be required to achieve 98% communicational disruption for moth densities of 2, 20, and 200 per 72 trees. This equates to 1.3, 12.5, and 125 dispensers per tree. These numbers are strikingly high but they are similar to the densities of traps Knipling (1979) and Roelofs et al. (1970) concluded from experimental data would be required for competitive trapping to control moth populations actually encountered in the field. Effective densities of traps proved cost-prohibitive. Fortunately, technologies are available (e.g., Miller et al., 2006) for deploying attractive pheromone dispensers at costs of materials and labor much less than required for a sticky trap.

A subset of data from Fig. 3b is displayed as a Miller-Gut plot in Fig. 4a. This plot is not as immediately useful as the $\log \times \log$ plot (Fig. 3b) in prescribing dispenser densities needed for desired levels of disruption for particular pest densities. However, a distinct advantage of Miller-Gut and Miller-de Lame plots is that all data contribute to shaping a straight line, including the zero-pheromone treatment, where numbers of males caught are maximal (C_{\max}). Considering all data simultaneously maximizes precision when deriving secondary measures from each data set, such as D_a .

Inspection of Equation (5) and Fig. 4a reveals that D_a will rise as the density of calling females declines during a given moth generation. However, D_a is independent of male density. We suggest that sufficiently stable measures of D_a to permit efficacy comparisons of different disruption formulations can be obtained from tests averaging results across a full moth generation. Initial low D_a values obtained when the density of calling females is maximal will be averaged with more abundant higher D_a values from later in that generation. However, the best direct comparisons of disruption efficacy under competitive attraction will be those made with comparable moth populations, confirmed by reliable direct measurements of both male and female densities.

Simulations varying T_D , F_D , and D_D and theoretical calculations established that the x -coordinate of the point of convergence for Miller-Gut plots of varying moth densities (Fig. 4a) equals T_D (Fig. 4b), whereas the y -coordinate of the point of convergence equals $(F_D/T_D M_D)$ when $M_D = F_D$. Moreover, in simulations including no traps and where females and dispensers competed only with one another, Miller-Gut plots for male visitation rate to females under differing moth densities converged on the y -axis.

A final and the most obvious prediction of the competitive attraction model of pheromone disruption is that males approach pheromone dispensers in the field. It should be possible to document such attraction by direct visual observations, or indirectly, by trapping. The relative attractiveness of dispensers, lures, and females can be ascertained by deploying and observing them simultaneously under equivalent male populations and for equivalent times. For most experiments reported in the literature, traps collecting males operate continuously whereas females are thought to call for only part of the time that males are responsive. Such tests reveal time-averaged rather than instantaneous attraction of traps relative to females. Full understanding of attractiveness of traps vs. females will be necessary for a full interpretation of competitive-attraction data.

Fig. 4 Miller-Gut plots of simulated outcomes of communicational disruption by competitive attraction. (a) Influence of moth density; (b) expansion of the x - y intersection of (a); (c) influence of varying values of k_T , k_F , and k_D . See Table 1 for definition of abbreviations.

Variations from Initial Assumptions

Inequality of T , F , and D Attractiveness

Accommodating inequalities in attractiveness of pheromone point sources requires insertion of factors adjusting attraction strength into Equation (1). The expanded equation is:

$$C = k_T T_D M_D / (k_T T_D + k_F F_D + k_D D_D) \tag{9}$$

where k_T , k_F , and k_D are positive numbers representing the attractiveness of T , F , and D , respectively, relative to the most attractive of the trio, whose value is taken here as 1.0. When attractiveness of $T = F = D$, all k values equal one and drop out of the equation.

Changes in outcomes of competitive attraction due to shifts in relative attractiveness of D , F , and T can be calculated as follows. If attractiveness of D is 10-fold less than that for F and T , then $k_F = k_T = 1$, but $k_D = 0.1$. When all k values are expressed in terms of k_T , the equation becomes $C = k_T T_D M_D / (k_T T_D + k_T F_D + k_T D_D / 10) = k_T T_D M_D / k_T (T_D + F_D + 0.1 D_D) = T_D M_D / (T_D + F_D + 0.1 D_D)$. On the other hand, if attractiveness of D is 10 times greater than that of T or F , the k_T -substituted equation reduces to $C = T_D M_D / (T_D + F_D + 10 D_D)$. Effects of other changes in relative attractiveness of T , F , and D on male catch or visitation rate per female can likewise be calculated. In all cases, the graphical shape of the output remains unaltered, i.e., Miller-Gut (Fig. 4b) and Miller-de Lame plots yield straight lines (Fig. 4c). However, slopes and intercepts are shifted by alterations in k values (Fig. 4c). Values of k need to be considered when deriving values of $T_D M_D$ or $T_D + F_D$ from Miller-Gut or Miller-de Lame plots as per Fig. 2b and 2c. The following rules apply when $k_T = 1$:

$$1/\text{Miller-Gut slope} = \text{Miller-de Lame } x\text{-intercept} = T_D M_D / k_D \tag{10}$$

$$\text{Miller-Gut } x\text{-intercept} = 1/\text{Miller-de Lame slope} = -(T_D + k_F F_D) / k_D, \tag{11}$$

or when $k_T < 1$:

$$1/\text{Miller-Gut slope} = \text{Miller-de Lame } x\text{-intercept} = k_T T_D M_D k_D \tag{12}$$

$$\text{Miller-Gut } x\text{-intercept} = 1/\text{Miller-de Lame slope} = -(k_T T_D + k_F F_D) k_D \tag{13}$$

For example, the equation for graph (c) in Fig. 4c is: $y = 0.0003x + 0.0706$. It was generated from a relationship where $k_T = k_F = 1$, and $k_D = 0.1$; thus, attraction of $T = F = 10D$. Applying Equation (10), $1/\text{Miller-Gut slope} = 1/0.0003 = 3333 = T_D M_D / k_D$. This value matches (within rounding error) the expected value of 3300, where $T_D = 3.3$, $M_D = 100$, and $k_D = 0.1$, as per Fig. 4c. Applying Equation (11) to this same equation of Fig. 4c (c) yields: $\text{Miller-Gut } x\text{-intercept} = -0.0706/0.0003 = -235 = (T_D + k_F F_D) / k_D$. This value matches (within rounding error) the expected value of -233, where $T_D = 3.3$, $M_D = 100$, and $k_D = 0.1$, as per Fig. 4c. Thus, in addition to sensitivity to densities of moths and traps, slopes of transformed plots for competitive attraction data and x -intercepts are affected by the relative attractiveness of T , F , and D . When this experimentally accessible relationship is measured, densities of male and female moths can be computed with confidence from Miller-Gut or Miller-de Lame plots of experimental data.

The density of traps (T_D) in disruption protocols is usually low relative to F_D and D_D . Under this condition, altering attractiveness of T relative to F and D has negligible effect on mating disruption of female moths. However, varying the potency of the lure in a monitoring trap relative to that of F and D can markedly shift male catch. If nightly attractiveness of traps monitoring disruption efficacy exactly equaled nightly attractiveness of the average female, inhibition of male catch would be an exact proxy measure of mating disruption. When traps are more attractive than females, actual mating disruption will be under-estimated, but sampling will be more sensitive. Conversely, using monitoring traps that are less attractive than females could over-estimate the efficacy of mating disruption. Thus, knowledge of the relative attractiveness of T , F , and D is essential in order to accurately predict disruption efficacy via catch of males in traps under competitive attraction.

Raising the density of monitoring traps in a crop under disruption by competitive attraction will increase sample size and thus accuracy of the measured value for disruption.

However, mating disruption as measured by suppression of catches of males in traps deployed in disruption plots relative to control plots is not independent of trap density under competitive attraction. This is demonstrated in Fig. 5. Variation in relative inhibition of catch with varying trap density is greatest (albeit never extreme) for low moth densities and low densities of pheromone point sources. Percent disruption values shift with trap density because of inequalities in the total number of attractant sources in the control vs. treated crop. As was acknowledged above for D_a , the percent disruption measure will vary with T_D and F_D under competitive attraction. Thus, under disruption by competitive attraction, it is not surprising that discrepancies in disruption efficacy are reported for the same pest by different investigations by using a common disruption formulation but operating under different pest densities.

Multiple Attraction Events by Males per Diel Cycle

Assuming that most male moths engage in only one bout of orientation to a source of pheromone per day is an over-simplification leading to a liberal assessment of disruption efficacy in the above simulations. The effect of multiple orientations of males to pheromone sources per night can be accounted for by multiplying the above-calculated outcomes by the mean number of orientations/male/d. For example, if the average male successfully found four different pheromone sources per day, that disruption outcome is approximated by calculations as described above, but using four times the original density of males. In this example, the resultant diminution in disruption efficacy due to repeated male orientations could be offset by quadrupling the density of pheromone dispensers assuming that disruption occurs primarily by competitive attraction.

Fig. 5 Influence of trap and moth densities per hectare on simulated outcomes of communicational disruption by competitive attraction. Percent disruption in treated plots is expressed as male catch relative to that in equivalent control plots not receiving pheromone dispensers.

Variation in the Density of Females Calling

Increasing the density of calling females decreases simulated male visitation rates to a given female (Fig. 6). A similar pattern would emerge for catch of males per monitoring trap. This effect is pronounced only at low dispenser densities. During early emergence of adult moths of a given generation, the proportion of females in the population that call would be maximal and then drop as females exit the reproductive pool. A large number of females competing with traps could suppress male catch markedly in the beginning of the adult generation. The simulations in Fig. 3b suggest that, early in a moth generation, male catch could be slightly less than 1 male/trap/night for moth densities varying across 3 orders of magnitude at low pheromone dispenser densities. On a night when many females call, a catch of 1 male/trap/night indicates that every calling female would mate that night. However, as the majority of females became mated and few or none were left to call, male catch/trap/night could increase by orders of magnitude. This would result in the disruption profiles of Fig. 3b becoming increasingly linear and their actual y-intercepts would more nearly match their projected y-intercepts, i.e., the female depressive effect on male catch would be removed (Fig. 3b).

The idea that calling females can depress catch of male moths in pheromone-baited traps has been documented in the field. For example, Kehat et al. (1985) recorded a strong depressive effect of abundant virgin females on catch of *Spodoptera littoralis* males in pheromone-baited traps deployed in cotton. Catch of males was initially very low when males and virgin females began eclosing simultaneously in the crop and abundant mating pairs were directly observed. Catch in pheromone-baited traps began increasing and peaked

Fig. 6 Influence of dispenser and female moth densities on male visitation rates per female in simulated outcomes of disruption by competitive attraction.

5–6 after peak abundance of visible mating pairs. These authors cite similar findings for other moth species, where temporal patterns in appearance and abundance of virgin and mating moths were compared with highly resolved trapping data.

Shifting female competition for males over time may explain why catch of male moths in monitoring traps has proven to be poorly or indirectly correlated with crop damage (Knight, 1995; Gut et al., 2004). A catch of 1 male/trap/night can be obtained from the same moth population that later yields e.g., 30 males/trap/night, depending on how many females are unmated. However, the number of females mating on nights yielding catches of one or fewer males per night could have been many times higher than on nights yielding catches of 30 males/trap/night. Inconsistency between catches in pheromone monitoring traps and actual moth mating frequencies is an explicit prediction of competitive-attraction phenomena. A poor or offset relationship between male catch and crop damage can follow.

Variation in Moth Spatial Distribution

Barclay (1992) and Barclay and Judd (1995) pointed out that outcomes of competitive attraction vary depending on whether senders and receivers are regularly dispersed or clumped. Translated to the context of Fig. 1, it follows that mating would be more likely if multiple males and females were found on a given tree than when randomly distributed as in Fig. 1. Barclay (1992) explored the magnitude of this effect through simulation modeling and “found that control [by competitive attraction] would be about four times as difficult for a population that is highly clumped (k of the negative binomial distribution = 0.25) as for a regularly dispersed population.” Thus, where pests clump, the density of pheromone dispensers operating by competitive attraction will need to be increased at least several fold over the value suggested by our simulations that assumed a regular or random distribution.

Predictions of Alternative, Non-Competitive Models

The tradition of *strong inference* (Platt, 1964; Giere, 1984) recommends that researchers detail the predictions of all the alternative models potentially explaining a phenomenon and determine where the sets of predictions for explanatory models do or do not overlap. Strong tests aim at non-overlapping predictions. Although it is not feasible here to detail the predictions from all explanatory models and their combinations that might possibly contribute to pheromone disruption, we address those for which overlap in predictions is critical to valid interpretation of field data to be analyzed in the following paper (Miller et al., 2006).

Camouflage (Signal Jamming) and Its Predictions

Camouflage is proposed as the explanation for mating disruption where a calling female cannot be recognized and located by males encountering her pheromone plume because its guiding boundaries are obscured by ubiquitously present synthetic pheromone. Such a mechanism of communicational disruption seems better explained as *jamming* of the female’s signal—making it unintelligible by broadcasting signal of the same type—rather than blending it into a natural, heterogeneous background, as the term *camouflage* usually implies. Nevertheless, *camouflage* is entrenched in the literature and useful if defined. Under a pure camouflage model of pheromone disruption, males would not be attracted to pheromone dispensers. However, they would always retain the ability to orient to females

and traps that happen to emit pheromone into air not already containing a camouflaging background dosage.

It follows that each camouflaging plume released from a dispenser precludes males from finding females in that plume. If plumes from camouflaging dispensers were of average area (x) and not so dense as to overlap, then the total area of crop camouflaged (A_C) would be approximated by the linear function:

$$A_C = D_D * x. \quad (14)$$

If moths did not exit camouflaging plumes, efficacy of disruption by camouflage could be calculated as:

$$\% \text{ Disruption} = (1 - P_{\text{Auc}})100 = P_{\text{Ac}} * 100 \quad (15)$$

where P_{Auc} is defined as the proportion of total crop area that is uncamouflaged and P_{Ac} is defined as proportion of total crop area that is camouflaged. Assuming an even distribution of male and female moths, an average of 16 females and 16 males would not mate if 80% of the crop shown in Fig. 1 containing 20 male and 20 female moths were camouflaged. Assuming that the four uncamouflaged females mated with the four available males, this would yield a disruption of 80%. Female visitation rate would decrease linearly with dispenser density and disruption would be independent of moth density. Both of these predictions differ strikingly from those of competitive attraction.

Movement of female and male moths without regard to the distribution of pheromone from camouflaging dispensers is likely to diminish rather than enhance mating disruption over the situation where moths do not exit camouflaging plumes. If even brief periods in clean air resulted in successful calling, any receptive female spending a portion of her diel reproductive period outside a camouflaging plume could potentially mate. If so, the probability of remaining unmated would mirror the probability of never exiting a camouflaging plume upon successive flights. Under this scenario, efficacy of mating disruption would initially increase slowly as a function of dispenser density and then increase dramatically as plume coverage approached 100%. Such a disruption profile differs dramatically from that predicted for competitive attraction (Fig. 2a).

Temporarily invoking mixed explanatory models, disruption efficacy could be dramatically inferior to that predicted by Equation (15) if virgin females were repelled or deterred from calling by plumes from camouflaging dispensers. On the other hand, disruption efficacy would be enhanced if males were attracted into and remained within camouflaging plumes, while females aggregated outside camouflaging plumes. Here, competitive attraction would again be a major component of that overall phenomenon.

Quantitative Contrast of Predictions of Competitive Attraction vs. Camouflage

The above discussion suggests that mating disruption by camouflage generates a set of predictions different from that of competitive attraction. Explanations involving moth movement (but not attraction) diverge even further from the predictions of competitive attraction than does Equation (15). Thus, Equation (15) was selected for further contrast with competitive-attraction predictions of Equation (9), so as to differentiate among them quantitatively.

Adding traps into crops disrupted by camouflage so as to measure mating disruption injects a small element of competitive attraction. This causes a male-catch measure of disruption to vary somewhat with moth density. Males not camouflaged can respond either to females or to traps that are not camouflaged. Thus, for trapping data, the camouflage

equation needs to be modified to reduce male visitation rate to females by a proportion attributable to that absorbed on average by the trap used to measure the experimental outcome. This adjustment can be made as follows where $V_{/F}$ represents male visits/female/night and A the total crop area:

$$V_{/F} = M_D / (F_D + T_D) (A - A_c) \quad (16)$$

We simulated camouflage outcomes by two methods applied to Fig. 1. First, Equation (16) was employed after the proportion of Fig. 1 that was camouflaged was calculated by multiplying the measured area of one dispenser plume by the number of plumes to be overlaid and then subtracting the product from total crop area. Second, the proportion of area not covered in Fig. 1 by the various densities of plumes was measured experimentally, before invoking Equation (16). Using Microsoft PowerPoint™, varying densities of dispenser plumes were overlaid in a regular pattern onto the 72-tree orchard plot of Fig. 1, while minimizing plume overlaps. Areas covered by plumes from dispensers were blackened, whereas uncovered areas remained white. The percentage of total area that was white vs. black in each treatment picture so generated was quantified by using Scion Image™ software (National Institute of Standards and Technology, Gaithersburg, MD, USA; <http://www.nist.gov/lispix/imlab/>).

Outcomes of our first approach to camouflage simulations are compared in Fig. 7 with those for competitive attraction when both moth and dispenser density were variables. Camouflage profiles fell linearly with increasing dispenser density (Fig. 7a); the reduced slopes with reduced moth densities reflect the competitive effect of the monitoring trap. A similar outcome resulted from the overlay simulations (hence data not shown). However, beyond the highest dispenser densities of Fig. 7a, appreciable overlap of plumes was unavoidable. The effect was that additional crop coverage per added dispenser progressively declined. It was difficult to blot out the last vestiges of white from Fig. 1 even when 200 plumes were overlaid with the restriction that they must originate from a tree and not the aisles between rows of trees. Thus, both camouflage and competitive attraction simulations approached 100% disruption asymptotically.

We caution that experimental proof of an asymptotic profile for camouflage is required before much weight can be placed upon pictorial over-lay simulations. We have little confidence that pheromone dispersal can be approximated by such elementary modeling. It seems likely that turbulence and diffusion would homogenize pheromone distribution within the crop over time, particularly if fields were large and dispenser densities were high. Moreover, the simulations were conducted in two- rather than three-dimensional space. To disappear from the crop, pheromone would need to rise above the treated crop, exit from field edges, or be irreversibly absorbed or degraded. Alternatively, pheromone molecules could reversibly become adsorbed on solid surfaces (Karg et al., 1994; Gut et al., 2004), allowing buildup of pheromone to some above-threshold steady-state. Thus, camouflage should result in total communicational disruption. So, where moth densities were high and sample sizes robust, a linear or near-linear descent of a disruption profile to zero male visits per trap or female can be taken as strong evidence for one of the noncompetitive disruption mechanisms, like camouflage. Such a profile is inconsistent with competitive attraction. However, until the ambiguity is removed as to whether or not plumes from point-source dispensers of pheromone do or do not become spatially homogenized over time, an asymptotic approach of disruption profiles toward an efficacy of 100% cannot be used as a criterion to unequivocally differentiate between competitive vs. noncompetitive disruption mechanisms.

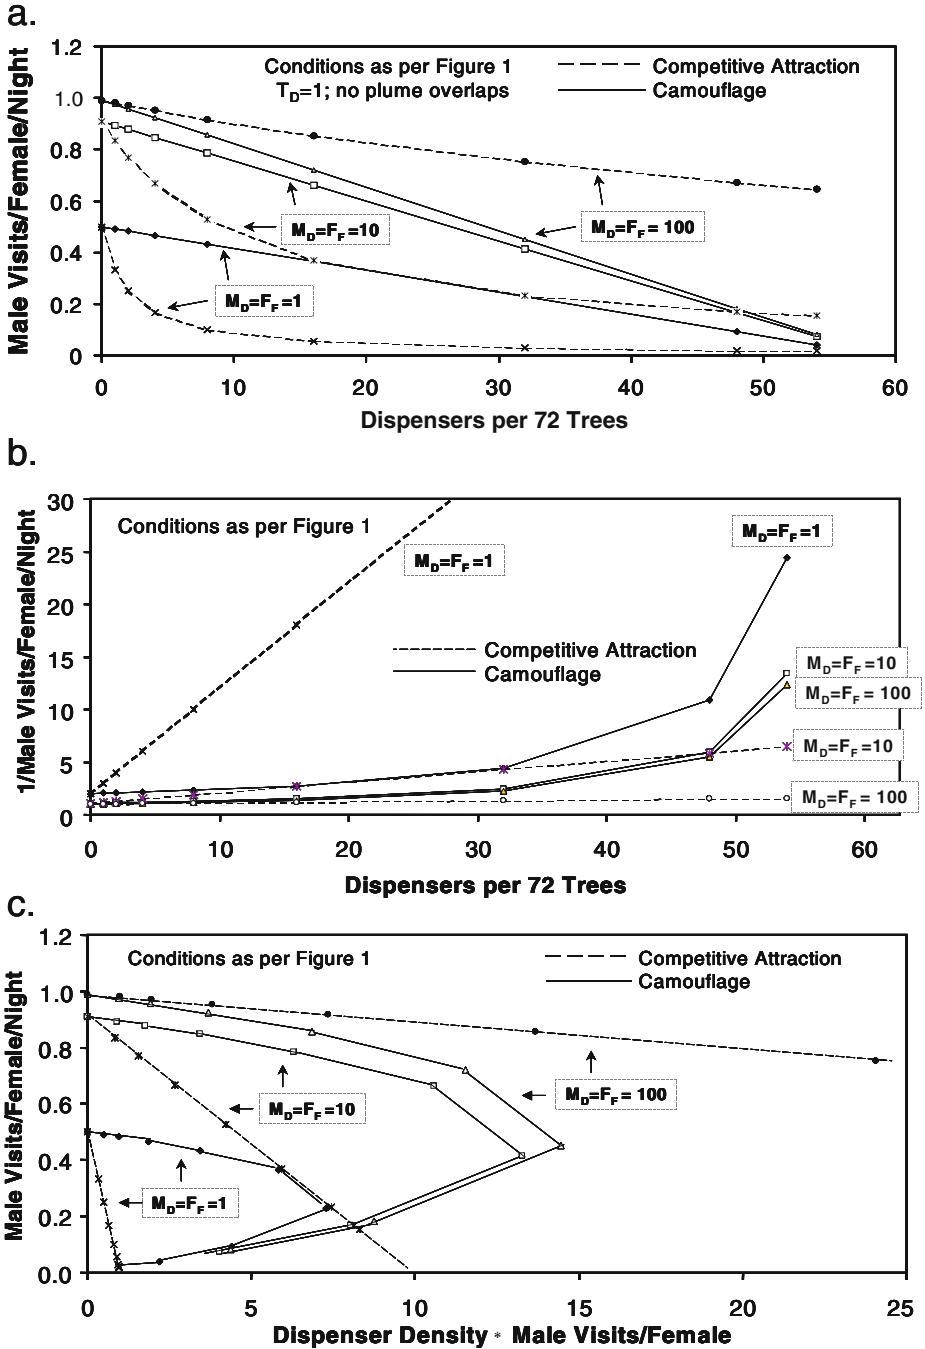

Fig. 7 Comparison of dosage–response profiles for simulated communicational disruption outcomes mediated by competitive attraction vs. camouflage. Plot types are (a) untransformed; (b) Miller–Gut; and (c) Miller–de Lame. In (b), outcomes for the lower two camouflage plots fall mostly on top of one another.

Nevertheless, Fig. 7 offers other distinctive predictions for such differentiation. The high sensitivity of competitive attraction outcomes to pest density has already been emphasized. With successive increases in moth density, disruption profiles become increasingly less concave on graphical plots (Figs. 3a and 7a). In contrast, the shape of camouflage profiles of catches of males in traps changes only slightly when moth densities are appreciable (Fig. 7a). The greatest influence of moth density on male visits/female/d in the Fig. 7a simulations occurred at the extreme of only one female competing with one trap. As the density of female moths increased, presence of a trap had progressively less influence on measured outcome. It is important to recognize that relative efficacy of communicational disruption operating by camouflage would not be influenced by pest density if pheromone dispensers were completely unattractive and no monitoring traps were inserted into the system. This is yet another case where applying an instrument (attractive trap) for measuring the performance of a system slightly alters the system.

Under extremely high pest densities, the predictions of competitive attraction and camouflage by large plumes become increasingly similar (Fig. 7a). Furthermore, simulations suggest camouflage would out-perform competitive attraction at high dispenser and pest densities. At very high pest densities, it is also possible that male and female moths may begin finding one another by non-chemical means (e.g., visual search; Levinson and Hoppe, 1983), further blurring interpretation of disruption mechanisms. If data analysis were limited only to untransformed plots like Fig. 7a, differentiation of camouflage vs. competitive attraction mechanisms would be best achieved at low pest and low dispenser densities.

Simulated camouflage and competitive-attraction outcomes were compared by using both Miller-Gut (Fig. 7b) and Miller-de Lame (Fig. 7c) plots in preparation for pattern recognition during comparisons of disruption data from the field (Miller et al., 2006) with data from simulations. A key distinction between mechanism classes is that competitive attraction yields straight lines on both types of secondary plots, whereas camouflage yields concave profiles on Miller-Gut plots (Fig. 7b) and distinctively recurved profiles on Miller-de Lame plots (Fig. 7c). Mathematical simulations confirmed a general rule that, when D_D causes a linear decrease in C , the maximum $D_D C$ for plots of C vs. $D_D C$ always equals $\frac{1}{2}C_{\max}$. This is because $D_D C$ values are being generated by the quadratic equation— $D_D C = -mD_D^2 + C_{\max}D_D$ —resulting from substituting $-mD_D + C_{\max}$ for C in the equation $y = CD_D$. Quadratic equations always yield symmetrical plots with their maximum midway between their intercepts, in this case 0 and C_{\max} .

Finally, the most direct way to differentiate whether camouflage or competitive-attraction mechanisms of disruption are operating under field conditions is to observe whether males orient to and closely approach pheromone sources. Such occurrences are inconsistent with pure camouflage, but are required by competitive attraction. However, experimenters would need to guard against false negatives. Under a high density of pheromone dispensers and a moderate pest density, the probability that males would be attracted to a dispenser under observation is low for competitive attraction. However, overall visitation rate to this type of source could be high when considering all such dispensers. Observational time required to acquire strong evidence either for or against competitive attraction or camouflage by directly observing occurrence or absence of orientations by male moths would be equally great.

Desensitization and Its Predictions

We take *desensitization* to mean that synthetic sex pheromone released from point sources in a crop causes male moths exposed to the pheromone to become less sensitive and/or less

responsive than they normally would be to female-produced pheromonal signals or their equivalents. Adaptation of olfactory receptor neurons of male moths can occur following continuous exposure of antennae to pheromone (Kuenen and Baker, 1981; Baker et al., 1988, 1989). This phenomenon is dosage-dependent, but reversible in pheromone-free air. A “long-lasting” adaptation has been described for several moth species (Kaisling, 1986; Stelinski et al., 2003a,b; Judd et al., 2005); it lasts for 10 to >60 min after the removal of moths from air containing high concentrations of pheromone. Pre-exposure to continuous or pulsed pheromone can decrease behavioral responsiveness to normal pheromone signals in many moth species (Bartell and Roelofs, 1973; Bartell and Lawrence, 1976; Sanders, 1985; Rumbo and Vickers, 1997; Daly and Figueredo, 2000). These behavioral modifications after exposure to volatilized pheromone last much longer than antennal adaptation, suggesting habituation (Bartell and Roelofs, 1973; Figueredo and Baker, 1992; Rumbo and Vickers, 1997; Stelinski et al., 2003a,b; Judd et al., 2005).

Despite the considerable attention desensitization has received as a candidate for explaining mating disruption, there is substantial evidence in the literature against it. The major inconsistency is that effective mating disruption occurs in crops at pheromone concentrations much lower than those required for desensitizing moths by adaptation or habituation (Schmitz et al., 1997; Rumbo and Vickers, 1997; Judd et al., 2005). Such data suggest that desensitization is not a leading contributor to mating disruption. For example, male grapevine moths (*Lobesia botrana*) were able to find pheromone-baited traps in the field following 8 hr of confinement in vineyards treated with mating disruption dispensers (1 dispenser/5 m²; each dispenser contained 500 mg of (E7,Z9)-dodecadienyl acetate; Schmitz et al., 1997). Reduction in the numbers of males captured in optimized pheromone traps in the field was obtained only when males were pre-exposed in the laboratory to pheromone at 4 µg/l air. This concentration vastly exceeds the average airborne concentration of pheromone (1–2 ng/m³) achieved in a crop treated with hand-applied mating disruption dispensers (Koch et al., 1997, 2002). In another example, reduction of male oriental fruit moth (*Grapholita molesta*) captures in optimized monitoring traps in the field occurred only after 1 hr of laboratory exposure to pheromone at 65 µg/m³ (3200 female equivalents/m³) (Rumbo and Vickers, 1997). Again, this high atmospheric concentration of pheromone required to desensitize *G. molesta* males far exceeded that achieved under typical mating disruption conditions in the field plots.

Long-lasting peripheral desensitization in obliquebanded leafroller (*C. rosaceana*) occurred only after minutes-long confinement in the laboratory in containers with pheromone concentrations of at least 1 ng/ml, or in the field after 1 d of confinement a few centimeters from polyethylene tube dispensers (Stelinski et al., 2003b). Given that feral *C. rosaceana*, *A. velutinana*, *G. molesta*, and *C. pomonella* approach and remain near such pheromone dispensers for only ca. 30 sec in apple trees (Stelinski et al., 2004a, 2005a), it is unlikely that this level of pheromone exposure is sufficient to induce long-lasting adaptation.

Nevertheless, key predictions of the desensitization model of mating disruption are: (1) efficacy should increase with dosage of pheromone released and thoroughness of coverage; (2) compared to that for competitive attraction, efficacy for desensitization would be relatively independent of pest density at low to moderate pest populations for reasons identical to those presented above for camouflage; and (3) the overall frequency with which male moths are observed orienting toward pheromone point sources in disruption plots would be greatly reduced relative to responses to similar sources in plots not treated with pheromone. Under increasing dispenser densities, male moths would have commensurately less chance to find pheromone-free spaces where they could recover normal sensory and behavioral capability. Thus, at high dispenser densities, disruption profiles for desensiti-

Table 2 Distinguishing traits of the two major categories of mating-disruption mechanisms

Trait	Competitive ^a	Non-competitive ^b
Shape of disruption profiles	Concave profile on untransformed plot; straight line with positive slope on M–G ^c plot; straight line with negative slope on M–de L ^d plot	Straight line on untransformed plot; concave profile on M–G plot; recurved profile on M–de L plot ^e
Convergence of efficacy profiles	Converge at coordinates $-T_D$, $+(F_D/T_D)/M_D$ on M–G plot when attractiveness of $T = F = D$	No regular pattern of convergence on M–G plots
Influence of pest population on disruption efficacy	Strong	Little to none except when pest density rises to where mate-finding is possible without long-range pheromone
Sensitivity to plume size	Efficacy not highly sensitive to plume size so long as plume size for $T = F = D$	Efficacy directly proportional to plume size

^a Competitive attraction.

^b Includes camouflage, desensitization (adaptation; habituation), and sensory imbalance.

^c Miller–Gut plot = 1/catch on y-axis vs. dispenser density on x-axis.

^d Miller–de Lame plot = male catch on y-axis vs. dispenser density * catch on x-axis.

^e Certain types of non-competitive disruption are possible that deviate from these given predictions in ways that make them more dissimilar to the predictions of competitive attraction.

zation could drop even faster than those for camouflage. Such profiles should reach 100% efficacy at high densities of pheromone point sources.

Sensory Imbalance and Its Predictions

Sensory imbalance (Bartell, 1982; Flint and Merkle, 1983) is defined here as *disrupting mate-finding not via adaptation or habituation but by interfering with the male's ability to perceive (as opposed to receive) the normal sensory inputs associated with their species' sex pheromone*. For example, dispensing only one of the major components of a pheromone blend from dispensers could adulterate the normal blend of a female's plume that commingles with the dispenser plume, rendering her plume unrecognizable to males. Sensory imbalance shares the above predictions for desensitization.

Combinations of Explanatory Models

Until now, this paper has emphasized non-overlapping explanatory models. However, we recognize that, for moths under field conditions, these mechanisms may come into play sequentially or in combinations. For example, competitive attraction may bring males close to dispensers where desensitization might occur for certain pests. Thus, in evaluating actual field data, care needs to be taken to recognize patterns in outcomes indicative of single mechanisms acting alone, as well as multiple mechanisms perhaps acting sequentially or concurrently.

Conclusions

This analysis revealed that mating disruption by competitive attraction operates predominantly by division; the attention of males is literally divided between a given

female and nearby dispensers. On the other hand, non-competitive disruption operates predominantly by subtraction; moths in effectively treated areas of crop are literally subtracted from the total pool. Key traits useful in differentiating between these mechanisms are summarized in Table 2. They will be used to judge which category of mechanism is supported by actual experimental disruption profiles from the pheromone literature (Miller et al., 2006).

Acknowledgments We thank Travis Reed for technical assistance during simulations of camouflage using pictorial overlays, checking many of the calculations in this manuscript, and for manuscript editing. disruption by pheromone point sources are listed. We believe that the congruence of diverse sets of mating disruption field data with explicit *a priori* predictions validates competitive-attraction theory. The analytical tools and principles governing competitive attraction that were uncovered during this study of mating disruption of moths should be generally applicable to competitive-attraction phenomena.

Introduction

Miller et al. (2006, this issue) reported analytical procedures and criteria whereby mechanisms of mating disruption by point sources of sex pheromone can be differentiated into two main categories: competitive (false-plume following) vs. non-competitive (camouflage, desensitization, and sensory imbalance). In this report, we apply those procedures to case studies mainly from the published literature on mating disruption of moths. The objectives were to: (1) determine to what extent experimental disruption profiles were congruent with the various theoretical predictions detailed by Miller et al. (2006); (2) determine whether one category of disruption is more common than the other; and (3) begin to interpret the practical consequences of the results of these analyses.

Methods

We searched the literature for experimental data sets allowing graphical analysis of suppression of catches of male moths in monitoring traps vs. density of point sources of synthetic sex pheromone. A target of at least three densities of pheromone dispensers in addition to zero pheromone narrowed the prospective cases. Ideally (Miller et al., 2006), such experiments would have recorded dispenser density (D_D), trap density (T_D), relative attractiveness of traps (T), females (F), and dispensers (D), catches of males (C) over most of a moth generation, and densities of female (F_D) and male moths (M_D) (see Table 1 of Miller et al., 2006 for a key to abbreviations). However, we found no study where all these parameters were recorded. In all cases analyzed in this work, data were sufficient for valid determinations of competitive vs. non-competitive disruption. However, moth densities computed from the competitive-attraction equations of Miller et al. (2006) could be compared with measured densities in only a few cases because relative attractiveness of T , F , and D usually was not measured.

Disruption profiles were examined with three types of graphical plots: untransformed (C vs. D_D), Miller-Gut ($1/C$ vs. D_D), and Miller-de Lame (C vs. $C^* D_D$) (Miller et al., 2006). Patterns in profiles consistent with competitive vs. non-competitive disruption are summarized in Table 2 of Miller et al. (2006). Where applicable, straight lines were fit to data by weighted regression. In most cases, statistical analyses were not possible because the raw data were not accessible. For our own field experiments, statistical procedures are explained in the respective figure captions.

When estimating or interpreting male and female densities from given dosage–response profiles, we elected to first show the calculations most simply by operating on a starting premise that attractiveness of $T = F = D$. Judgments about fit of actual field data to theory should be withheld until the justification for departure from attractiveness of $T = F = D$ is

revealed and the appropriate mathematical adjustments are made. Most cases ultimately supported a competitive-attraction equation more complex than Equation (1) of Miller et al. (2006) where attractiveness of $T = F = D$.

Results and Discussion

Cases Consistent with Competitive Attraction and Inconsistent with Camouflage or Other Non-competitive Disruption Mechanisms

Oriental Fruit Moth (Grapholita molesta)

Rothschild (1975) conducted one of the most complete disruption experiments useful to the current analyses when he documented communicational disruption of oriental fruit moth (OFM) in Australian peaches. The pheromone formulation was 98% (*Z*)-8-dodecenyl acetate (2% *E*-isomer) dispensed from 1 ml closed polyethylene tubes (precursor to pheromone ropes) each releasing ca. 15 µg/hr of pheromone. This pheromone blend did not fully match that of the female, now known to also include ca. 1% (*Z*)-8-dodecenyl alcohol (Cardé et al., 1979). In a test originally aimed at determining the number of dispensers required to prevent males from finding pheromone-baited monitoring traps, dispensers were deployed in duplicate 100 tree plots (0.4 ha) at 0, 0.5 (every other tree), 1, and 2 dispensers per tree. Twelve monitoring traps were deployed in a 3 × 4 grid in each plot. Trap catches were reported as the total for all 12 traps/plot over three sampling periods of 20–30 d spanning each of three moth generations (Rothschild, personal communication). Before this test began, the OFM population was quantified at 0.6–1 pupae per tree based on tree banding, and subsequently at 0.5–1 moths per tree by counting OFM adults recovered from cloths laid under trees fogged with pyrethrum. Assuming an equal sex ratio, this equates to an F_D and M_D of 0.4/tree, or about 150 moths/ha of each sex.

Rothschild's disruption outcome is scaled to 1 ha and plotted on untransformed axes in Fig. 1a, as a Miller-Gut plot in Fig. 1b, and as a Miller-de Lame plot in Fig. 1c. Although few, the data support an interpretation of competitive attraction. The untransformed plot (Fig. 1a) is more curvilinear than linear. It resembles the competitive-attraction profile in Fig. 3a of Miller et al. (2006) for a simulated moth population of about 30 moths per 72 trees (0.4/tree). The initially steep drop in catches of males with dispenser density leveled out by ca. 1 dispenser per tree. This data set is reasonably linear on a Miller-Gut plot (Fig. 1b), which then justifies derivation of secondary measures. The density of males in this experiment can be estimated (procedures of Miller et al., 2006) from Fig. 1b as: $1/\text{slope} = M_D T_D = 1/0.0004 = 2,500$. Since $T_D = 30/\text{ha}$, calculated $M_D = 83$ males/ha compared to the measured value of 150 males/ha. Allowing for some mortality and a trap efficiency of less than 100%, it is not surprising that this derived value of M_D was somewhat lower than the initial M_D directly measured by Rothschild at the start of the adult generation. Female density in this test can be derived from the absolute value of the *x*-intercept = $0.0213/0.0004 = 53 = T_D + F_D$. Because $T_D = 30/\text{ha}$, $F_D = 23$ females/ha. The derived F_D/M_D ratio is $23:83 = 1:3.6$. A time-averaged F/M ratio favoring males is expected in the kinetics of competitive attraction for OFM, whose females are not known to mate frequently, whereas males continue to seek females throughout their lives. Therefore M_D would be the more stable measure of OFM density during a given generation. However, the accuracy of such F/M ratio calculations,

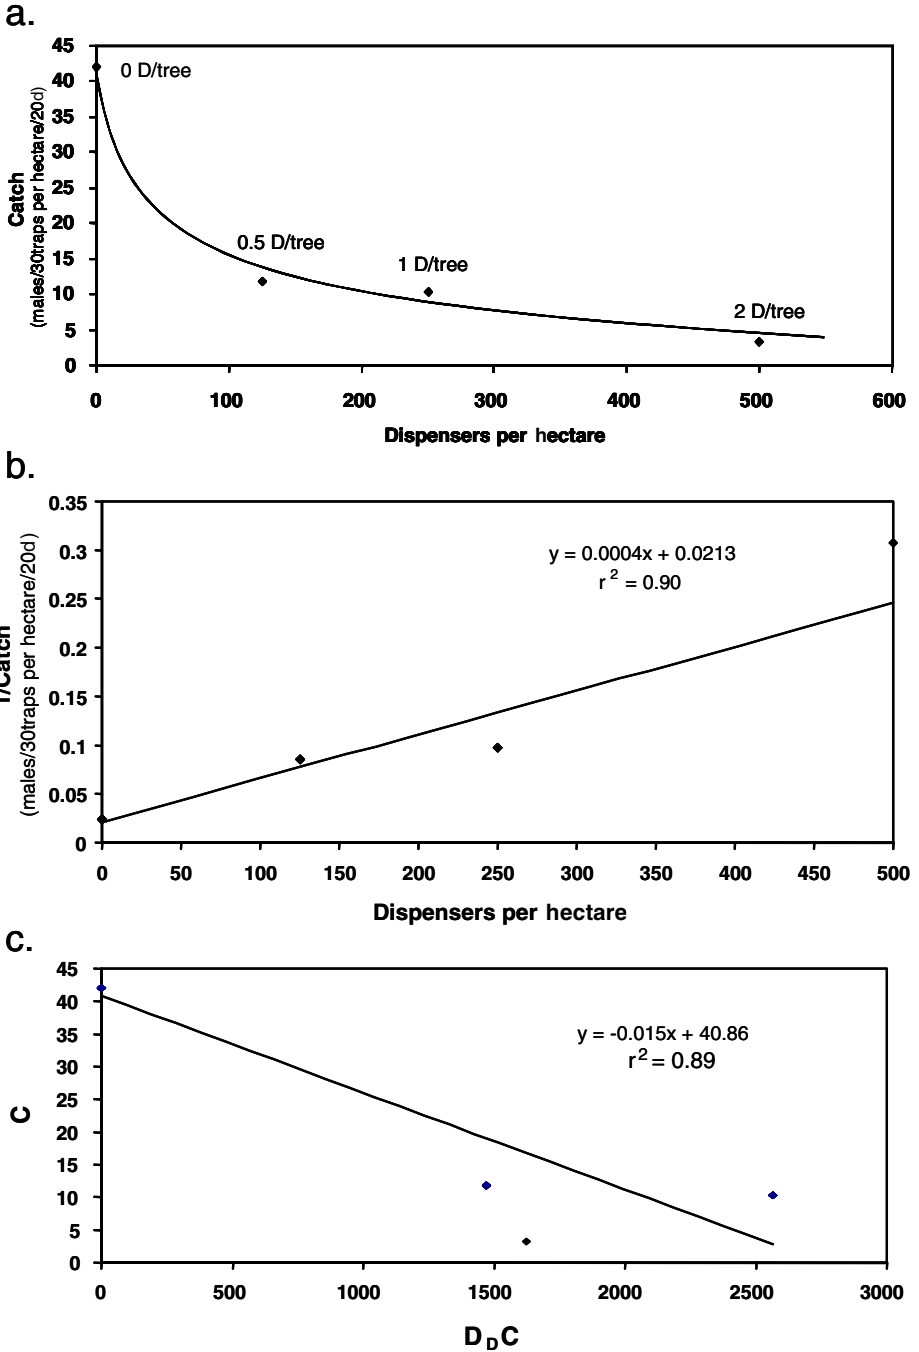

Fig. 1 Untransformed (a), Miller-Gut (b), and Miller-de Lamé (c) plots of the disruption profile from Rothschild’s (1975) test deploying polyethylene tube dispensers of pheromone targeting oriental fruit moth, *Grapholita molesta*, in peaches. The curve for panel (a) was hand-drawn and fit by eye. The straight lines in (b) and (c) (as well as those in subsequent figures) were fit by weighted regression

as well as moth density calculations, are based on the untested assumption that attractiveness of $T = F = D$ in Rothschild's test. The adequate agreement between calculated and measured M_D as well as a reasonable F/M ratio in this test supports approximate equivalency in attractiveness of T , F , and D in this particular case.

The Miller-de Lame plot of Rothschild's (1975) data (Fig. 1c) is also consistent with competitive attraction. The linear fit is reasonable given the few data and the susceptibility of the lowest catches of males to sampling error. There was no convincing evidence of a consistent recurve having its inflection near $1/2y_{\max}$ like that expected for non-competitive mechanisms such as, e.g., camouflage (Fig. 7c of Miller et al., 2006). However, the current analysis would have greatly benefited by including $D_D C$ values falling between 0 and 1400. The estimate of M_D as derived from the x -intercept of Fig. 1c = $T_D M_D$ is 91 males/ha compared to 83 for the Miller-Gut plot. This translates into an estimate of 0.23 males/tree, and falls near the measured range (0.25–0.5) for M_D . F_D can be derived from the inverse of the slope of this Miller-de Lame plot: absolute value of $1/\text{slope} = (T + F) = 67$. Since $T_D = 30$, $F_D = 37$. Thus, the F/M_D ratio derived from the Miller-de Lame plot is 37:91 or 1:2.5, which is similar to the Miller-Gut estimate as required by competitive attraction theory based on Equation (1) of Miller et al. (2006).

Collectively, Rothschild's OFM data are a reasonable fit to the full set of predictions generated from our competitive-attraction model of pheromone disruption. The probability of having the data fit all these predictions by chance alone appears small. No evidence was uncovered that refuted competitive attraction for this study. Conversely, this data set is inconsistent with camouflage or other non-competitive mechanisms of pheromone disruption.

Only after fit is found consistent with competitive attraction and inconsistent with other explanatory models is it appropriate to calculate a dispenser activity (D_a) value by using procedures unique to competitive attraction. Using Equation (4) of Miller et al. (2006), D_a for Rothschild's dispenser = slope (from Fig. 1b)/ y -intercept = $0.0004/0.0213 = 0.019$. D_a , as directly revealed by the slope of Fig. 1c, was 0.015. When using the latter value and invoking Equation (6) of Miller et al. (2006), D_{Aa} for Rothschild's dispenser densities of 125, 250, and 500 dispensers/ha = 1.9, 3.8, and 7.5, respectively.

As pointed out in Miller et al. (2006), D_a values are theoretically independent of the units used to record true catches. Nevertheless, all values accumulated in Table 1 were derived by using units of male catch/trap/d, for the sake of consistency. However, valid calculations of moth densities and sex ratios must be done with catch values for actual trap densities accumulated over the total elapsed time of the test, as per the Fig. 1 example.

We (Stelinski et al., 2005c) recently quantified OFM communicational disruption in response to an emulsified wax formulation (Atterholt, 1996, 1998; De Lame, 2003) of pheromone releasing a 93:6:1 blend of (*Z*)-8-dodecenyl-acetate: (*E*)-8-dodecenyl-acetate: (*Z*)-8-dodecenol, present in the wax at a total starting concentration of 5%. This experiment was conducted in 12-tree (0.05 ha) rectangular plots of apples in Western Michigan (USA). Drops of wax (0.1 ml) were applied by syringe to branches and twigs of the trees with the aim of achieving a uniform distribution from the bottom of basal limbs to treetop. There were five replicate plots with densities of wax drops per tree of: 0, 3, 10, 30, and 100. Two sticky traps deployed in the center two trees of each plot and baited with optimized OFM monitoring lures measured male catches. A new set of wax drops was applied after each OFM adult generation, when rising trap catches revealed waning efficacy due to pheromone depletion, confirmed also by gas chromatographic analysis. During the 40 d of effective disruption per application, release rate per 0.1 ml wax drop fell from ca. 0.4 to 0.1 $\mu\text{g/hr}$ /drop.

Table 1 Comparison of Moth Communicational Disruption Outcomes Mediated by Competitive Attraction

Insect	Reference	Pheromone composition	Type of dispenser	Release rate per dispenser ($\mu\text{g/hr}$)	Experimental plot size (ha)	Maximum dispensers/ha	Maximum % disruption ^a	C_{max} (males/trap/night)	D_a (M–G slope/ \pm -intercept) ^b	D_{sa} ($D_d/\mu\text{g}$ pheromone/hr)	Maximum D_{sa} (D_a^* D_b)

^a % Disruption = (1 – (male catch under pheromone treatment/male catch for control)) 100.

^b Number of dispensers/ha required to suppress catch by 50% is given by $1/D_a$.

Periodically during this experiment, observers positioned themselves to be able to observe and record behaviors of male moths in the vicinity of wax drops. Moth behaviors were directly observed within tree canopies on 26 total nights throughout three generations of OFM flight. In each control plot, a single wax drop was randomly deployed in one tree for observation; these plots were otherwise untreated. Two or three observers worked simultaneously, rotating among plots and conducting 20-min observational bouts per treatment, such that multiple treatments were under observation concurrently. Behavioral events were dictated into a hand-held audio recorder by the observer standing ca. 1 m from a pheromone dispenser. Observations after dusk were assisted by night-vision goggles as described by Stelinski et al. (2004a).

Male OFM were commonly observed visiting wax drops containing pheromone (Stelinski et al., 2005c). More than 75% of these males approached within 20–60 cm of the pheromone source, and over 70% moved away from wax drops within 20 sec by flying upwind. None remained near pheromone dispensers for more than 2 min (Stelinski et al., 2005c). Similar results were documented for three other tortricid pests of Michigan fruit, all of which closely (ca. 0–100 cm) and briefly (ca. 2–30 s) approached Isomate-type, polyethylene tube dispensers (Stelinski et al., 2004a, 2005a,b). We conclude that males of all these tortricids are attracted to and briefly arrested by commercially available (Pacific Biocontrol Corp., Portland, OR, USA) synthetic pheromone dispensers releasing high amounts of their respective pheromones relative to females, but in a suboptimal blend.

The OFM disruption profile for wax drops, averaged across the three moth generations per season, well fits the predictions of competitive attraction. On an untransformed plot, the disruption profile was concave rather than linear (Fig. 2a). Moreover, disruption never reached 100% despite deployment of 100 wax drops per tree. However, catches of males at 30 and 100 wax drops per tree averaged less than 1 male/trap/20 d per OFM generation. Thus, to obtain a more reliable measure of central tendency, the data for the two highest dispenser densities were combined into a mean of 65 dispensers/ha. This disruption profile was perfectly linearized by a Miller-Gut plot (Fig. 2b). Analysis of these OFM data by the Miller-de Lame (Fig. 2c) plot was compromised by not having any $D_D C$ values fall near $1/2C_{\max}$.

Female vs. male densities in these plots were not directly measured experimentally. However, M_D can be calculated from Fig. 2c via the x -intercept of 820,218. Because attractiveness of D was measured at 0.1 that of T (Stelinski et al., 2005c), the intercept of $820,218 = T_D M_D / k_D$ [Equation (10) of Miller et al., 2006]. Because $T_D = 40$ traps/ha, and $k_D = 0.1$, M_D was 2,051 males/ha, or about 9 males/tree. If $k_T = k_F$, female density can be calculated from the absolute value of the slope of Fig. 2c; $1/\text{slope} = 1/0.0087 = 115 = T_D + F_D$. Because $T_D = 40/\text{ha}$, $F_D = 75$ females/ha, yielding an F/M activity-density ratio favoring males by 1:27. We consider it likely that attractiveness of females was somewhat less than that of the optimized trap that is constantly releasing pheromone. If k_F is taken at 0.1 k_T , the calculated F/M ratio becomes 1:3 and more nearly matches the Rothschild (1975) outcome. Only after this k_F value is established experimentally can this type of calculation be made with confidence.

The D_a for wax drops, as derived from the slope of Fig. 2c, was 0.009. It was 0.007 when male catch was graphed as males/trap/d (slight difference due to rounding error judged smaller for males/trap/d). The D_{sa} for wax drops (0.028) exceeded that for Rothschild's (1975) larger dispensers (0.0014) (Table 1). Perhaps this is because our formulation was a more complete blend that included the (*Z*)-8-dodecenol. Even at a considerably greater OFM density as judged by C_{\max} (Table 1) and calculations of M_D from the above respective Miller-de Lame plots, 10 wax drops per tree disrupted as well as did

Fig. 2 Untransformed (a), Miller-Gut (b), and Miller-de Lame (c) plots of the disruption profile from Stelinski et al.'s (2005c) test deploying 0.1 ml wax drops targeting oriental fruit moth, *Grapholita molesta*, in apples. Within a panel, means not sharing a common letter are statistically different at $P < 0.05$ by an LSD test after ANOVA on data transformed to $(x+0.5)^{1/2}$ for (a) and (c), and $\ln(x+0.5)$ for (b)

Rothschild's two polyethylene tubes per tree while using 2.5 rather than 30 μg of total pheromone/hr/tree. However, each of Rothschild's dispensers was capable of containing up to 800 mg of pheromone compared to 4 mg per wax drop. Thus the larger dispensers had the advantage of lasting longer than one adult generation.

Pink Bollworm (Pectinophora gossypiella)

Flint and Merkle (1983) quantified the relationship between inhibition of pink bollworm (PBW) traps vs. density of rubber septa deployed on stakes in 0.03 ha plots of cotton in Arizona, USA. The pheromone was gossyplure, a 50:50 mixture of 16-carbon acetates listed in Table 1. Two monitoring traps were deployed per plot to yield a T_D of 6.7/ha. The study design was complex; the various pheromone dosages were tested sequentially through time, not simultaneously. Moreover, the population of PBW increased through time. Thus, to generate a continuous disruption profile, all catches needed to be scaled to the highest catch (78 males/trap/night) via the known ratio of catch in disrupted plots relative to its paired control, also set to 78.

On untransformed axes (Fig. 3a), the disruption profile for PBW was consistent with an inverse function. Catches of males initially fell steeply, leveled off, and then appeared to approach zero asymptotically. This profile was more linear in a Miller-Gut plot (Fig. 3b) than concave as a non-competitive profile would be (Fig. 7b of Miller et al., 2006). The Miller-de Lame plot would have benefited from more data particularly at low values for $D_D C$ (Fig. 3c), but even so, the few and scattered data are not inconsistent with competitive attraction. Moth densities were not calculated for this case because the units for trapping data were unclear and the relative attractiveness of T , F , and D was not determined. D_a for these gossyplure-loaded septa was 0.0038 (slope of Fig. 3c). A D_{sa} could not be calculated because there was no report of the pheromone release rate per septum. The D_{Aa} for a D_D of 1821/ha was 6.9 (Table 1), which corresponded to 88% inhibition of catches of males relative to traps in the control plots. Disruption of PBW in response to septa loaded with gossyplure was expected to be mediated by competitive attraction, because similar dispensers had strongly attracted males. The current analysis is consistent with that expectation.

Obliquebanded Leafroller (Choristoneura rosaceana)

Lawson et al. (1996) measured obliquebanded leafroller (OBLR) disruption efficacy in 0.04-ha plots of apples in Western New York (USA) in response to four densities of polyethylene tube dispensers releasing 25 $\mu\text{g/hr}$ of total pheromone blend [83% (*Z*)-11-tetradecenyl acetate, 8% (*E*)-11-tetradecenyl acetate, 9% (*Z*)-11-tetradecenol]. This formulation was not highly disruptive; it yielded a slightly concave profile for dispenser density vs. inhibition of catch in monitoring traps (Fig. 4a) akin to that for competitive attraction under a high moth population (Fig. 3a of Miller et al., 2006). This profile yielded a straight line in Miller-Gut and Miller-de Lame plots (Fig. 4b and c), providing the strongest profile evidence for competitive attraction out of all the case studies.

Male density was not directly measured in this study. $T_D M_D$ as calculated via the x -intercept of Fig. 4c was extremely high (2,193,214) under an assumption that attractiveness of $T = F = D$. Given the T_D of 50/ha, M_D computes to 43,864 males/ha, a value incongruent with a C_{\max} of only 6,100. We suspect that attractiveness of these rope dispensers was considerably less than that for the optimized traps. If k_D were taken as 0.2 of

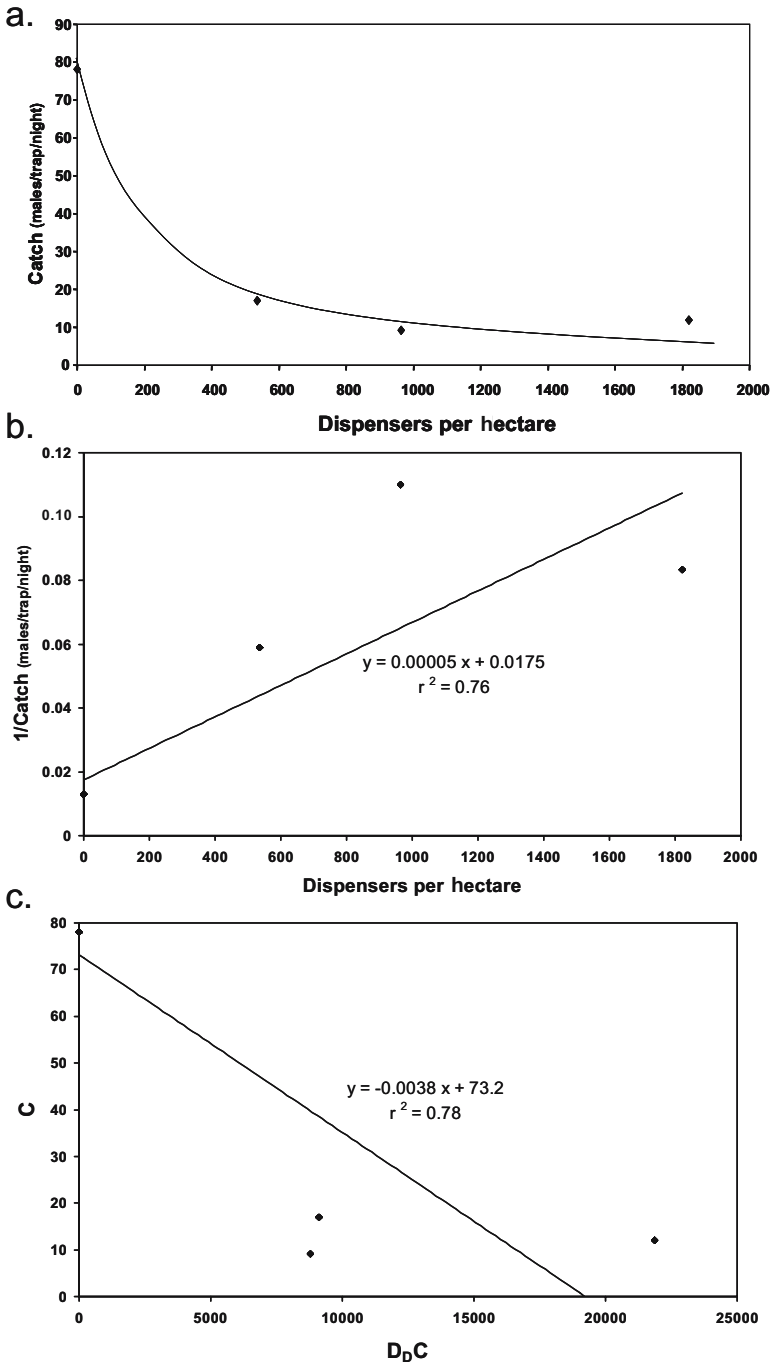

Fig. 3 Untransformed (a), Miller-Gut (b), and Miller-de Lame (c) plots of the disruption profile from Flint and Merkle's (1983) test deploying rubber septa dispensers targeting pink bollworm, *Pectinophora gossypiella*, in cotton

Fig. 4 Untransformed (a), Miller-Gut (b), and Miller-de Lame (c) plots of the disruption profile from Lawson et al.'s (1996) test deploying polyethylene tube dispensers targeting obliquebanded leafroller, *Choristoneura rosaceana*, in apples

k_T and k_F , the calculated M_D would be $43,864 * 0.2 = 8,800$ males/ha, which is more realistic. F_D as computed by the inverse of the Fig. 4c slope was 357 females/ha under an assumption that attractiveness of $T = F$.

D_a for OBLR responding to pheromone ropes was calculated as 0.0052 from a plot expressing catch as males/trap/d, and D_{sa} was a mere 0.0001. Thus, it is not surprising that D_{Aa}^- , even for 960 ropes/ha, was only 2.1 (Table 1) and efficacy as measured by % inhibition of male catch in these plots relative to that in untreated plots was only 70%.

Better disruption of OBLR has been reported in the Western United States and Canada. Deland et al. (1994) achieved ca. 90% disruption by using 1,000 and 2,000 Hamaki-con polyethylene tube dispensers per hectare. These data (plots not shown) were a better fit to competitive than non-competitive mechanisms, e.g., the Miller-de Lame plot did not recurve. D_a and D_{sa} were calculated at almost three times the corresponding values for Lawson et al.'s (1996) OBLR test (Table 1). However, whether this difference in disruption potency was attributable to the pheromone formulation or physiological/behavioral differences across OBLR races is unknown.

Deland et al. (1994) collected data for two other leafroller species along with OBLR. Disruption of both the European leafroller (*Archips rosana*) and fruittree leafroller (*A. argyrospila*) conformed to competitive attraction better than to non-competitive disruption mechanisms (plots not shown). Disruption outcomes were superior to that for OBLR (Table 1). The D_{Aa}^- for fruittree leafroller was a remarkable 196 at 2,000 dispensers/ha. Notably, the relative attractiveness of optimized pheromone lures in traps was found to be 3.3 times greater than male catch in traps baited with virgin females, i.e., $k_F = 0.3k_T$.

Gypsy Moth (Lymantria dispar)

Tchesslavskaja et al. (2005) recently reported dose–response data on gypsy moth (GM) disruption by using a 3 × 3 mm Hercon (Hercon Laboratories, Emigsville, PA, USA) Disrupt[®] II flake formulation of racemic disparlure, emitting at ca. 93 ng/flake/hr (Webb et al., 1988). This formulation was applied at five dosages by airplane to replicated 25 ha forest plots in Virginia. Communicational disruption was evaluated by suppression of catch in eight (+)-disparlure-baited traps per plot (0.32 traps/ha). When this test site was found to have few feral gypsy moths, ca. 150 laboratory-reared males were released in the center of each plot each week of the 6-wk test. Because gypsy moth males live ca. 2 wk (Capinera and Barbosa, 1975), the mean male population density interacting with attractant sources over this test should have stabilized around 300 males per plot (ca. 12 males/ha). Catches of ca. 270 males per plot averaged across this test suggest emigration was not substantial.

The untransformed dosage–response profile (Fig. 5a) fits competitive attraction. Male catch dropped precipitously in response to the lowest densities of flakes applied. Thereafter, efficacy increased modestly with order-of-magnitude increases in the density of flakes. Nevertheless, trap catch was suppressed to remarkably low levels (up to 99% trap inhibition). However, traps were never completely inhibited, despite the very high densities of applied flakes.

Although there was scatter in the data, the gypsy moth disruption profile was reasonably linear on Miller-Gut and Miller-de Lame plots (Fig. 5b and c). Evidence was lacking for a concavity in Fig. 5b or a recurve in Fig. 5c. D_a from a Miller-de Lame plot expressing catch as males/trap/night was 0.00052. D_{sa} was somewhat higher (0.006), because the release rate per flake was less than 1 µg/hr (Table 1). Even though the density of dispensers was 5-fold higher for GM than OFM disrupted with wax drops, D_{Aa}^- was lower for GM than that for the

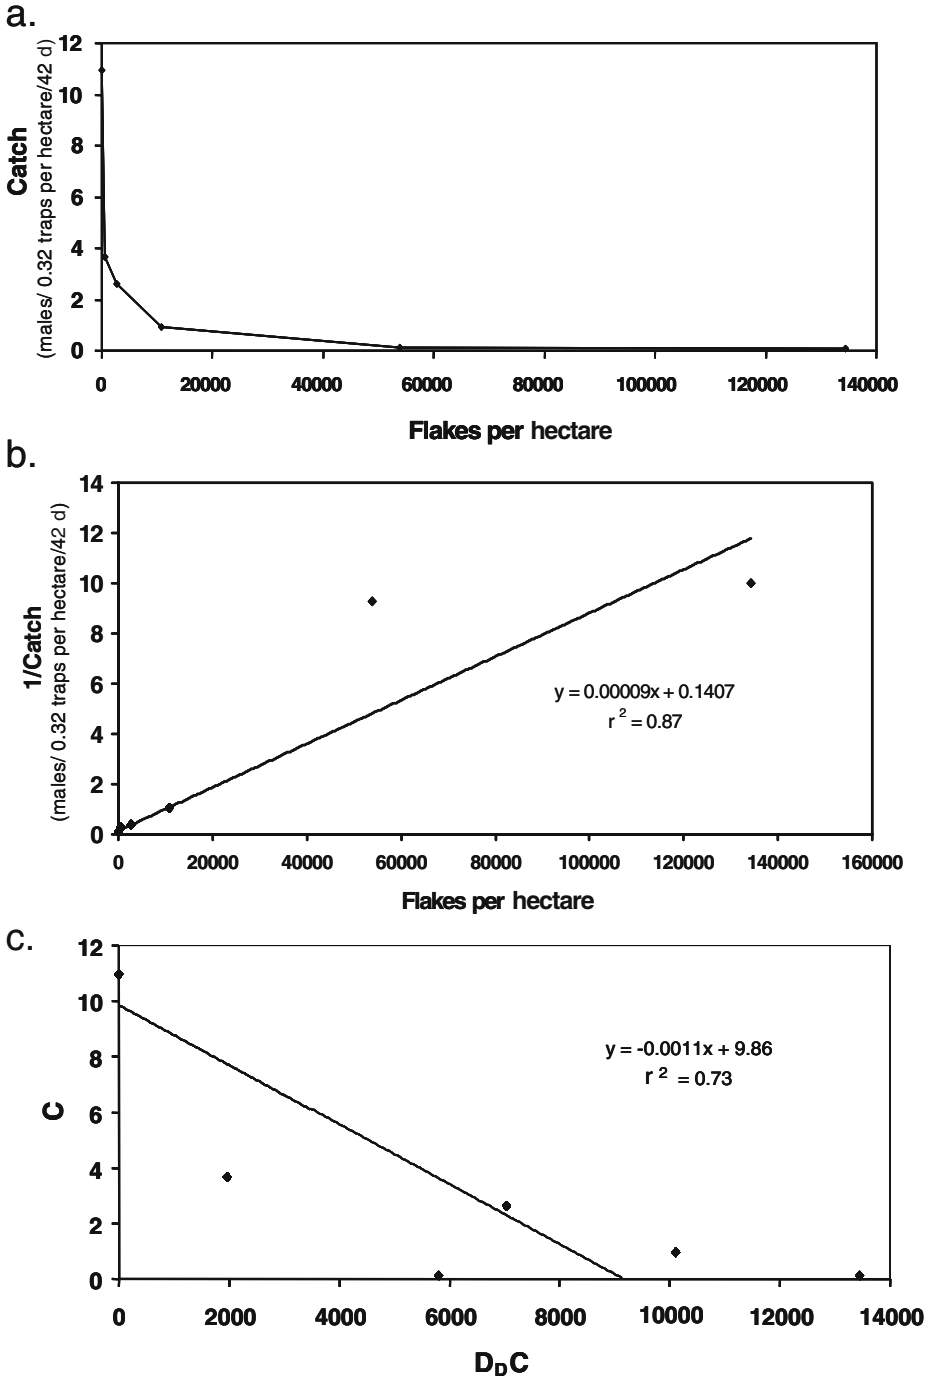

Fig. 5 Untransformed (a), Miller-Gut (b), and Miller-de Lame (c) plots of the disruption profile from Tcheslavskaja et al.'s (2005) test deploying laminated flake dispensers targeting gypsy moth, *Lymantria dispar*, in forest plots

Stelinski et al. (2005c) OFM test (Table 1) because the potency of each flake was 1/13 of that for each wax drop. It would be interesting to document how much greater D_{sa} for GM would be for flakes charged with the natural and more attractive (as well as costly) (+)-rather than (\pm)-disparlure (Miller et al., 1977).

The $T_D * M_D$ value calculated from the x -intercept of Fig. 5c was 8,964. Because $T_D = 0.32$ traps/ha in this case, M_D calculated on an assumption that attractiveness of $T = F = D$ is 28,000. This number is far higher than the 12 males/ha calculated to be in these plots based upon the male releases. The most likely explanation for this incongruence is that each flake was less attractive than a trap. We found no published data on the attractiveness of GM pheromone flakes relative to monitoring traps or females. However, by using Equation (10) of Miller et al. (2006), the k for flakes can be calculated at about 0.0004 relative to k for traps. With this adjustment, a calculated M_D becomes a reasonable 11 males/ha, or 280 males/plot. Putting this value for k_D into Equation (11) of Miller et al. (2006) yields $k_F F_D = 0.04$; so, if $k_F = 1$, $F_D =$ nearly zero, as was known to be true in this test. Thus, here is a case where attractiveness of D relative to T can be calculated with confidence from competitive attraction equations because both M_D and F_D were known, along with T_D and D_D . Although attractiveness of flakes seems trivial relative to traps, this test established that even weakly attractive (or perhaps arrestive) sources of pheromone can have important practical impact when dispensed at very high densities.

A note of caution needs to be sounded. This test was conducted in the absence of a normal density of female moths; this would inflate % inhibition of male catch and D_a . Both of these measures of disruption efficacy are sensitive to T_D and F_D , but not M_D (Miller et al., 2006). A somewhat less optimistic outcome than reported above would likely be obtained under a normal F/M ratio for GM.

Studies Varying Density of Release Sites along with Release Rate per Site

Suckling and Angerelli (1996) recorded a disruption profile for polyethylene tube dispensers targeting the lightbrown apple moth (LBAM), *Epiphyas postvittana*, in 0.5-ha plots of New Zealand apples. The pheromone formulation (Table 1) contained (*Z*)-11-tetradecenyl acetate as an “antagonist” in addition to the natural pheromone blend. This study held the overall density of sources to 200 dispensers/ha, while varying the number of release sites/ha: 0, 2, 18, and 200. This design now permits quantification of D_a and D_{Aa} when dispensers were deployed individually vs. clusters of 11 and 100 per release site.

Surprisingly, given inclusion of an “antagonist”, the disruption profile for LBAM (Fig. 6a) was consistent with competitive attraction rather than camouflage or some other non-competitive mechanism. Polyethylene tube dispensers thought to contain “antagonists” of OBLR (Stelinski et al., 2004a,b) and codling moth (CM) (Witzgall et al., 1999) have likewise been found to be attractive to males. In the LBAM study, one 100-dispenser cluster yielded 67% inhibition of male catch compared to 97% for 100 dispensers deployed individually. Thus, clustering the dispensers greatly reduced the overall treatment potency.

The Miller-Gut plot of the LBAM disruption profile was convex rather than straight (Fig. 6b). This pattern is consistent with competitive attraction where, as a group, each cluster of dispensers was more disruptive than an individual dispenser; however, the density of individual dispensers was higher than the density of clusters. We broke down the convex profile of Fig. 6b into three segments for calculations of D_a under the three different dispenser distributions. D_a for individual dispensers was 0.19 as calculated by dividing the slope of segment A–D (Fig. 6b) by its intercept [Equation (4) of Miller et al., 2006]; D_{Aa}

Fig. 6 Untransformed (a) and Miller-Gut (b) plots of the disruption profile from Suckling and Angerelli’s (1996) test deploying polyethylene tube dispensers targeting lightbrown apple moth, *Epiphyas postvittana*, in apples

was 38. As dispensers were clustered, D_a /source (Fig. 6b) increased by only 5.5-fold, but D_{Aa} diminished by 18-fold. This outcome confirms previous knowledge of a tradeoff between dispenser density vs. disruption strength per release site. However, the current analysis emphasizes that the loss in potency due to clumping dispensers may be greater than previously understood. Under competitive attraction, the first few dispensers deployed into a plot will dramatically decrease male catch (e.g., Fig. 2; Miller et al., 2006), except when moth density is extraordinarily high. This advantage of being the first (even though few) release sites into a plot may obscure the offsetting dramatic decline in D_a and D_{Aa} when dispensers are clumped and the density of release sites is kept low because the overall release rate of pheromone is already high.

The Miller-de Lame plot (not shown) for these LBAM was concave, as expected for competitive attraction under source clustering with a concomitant reduction in D_a per cluster. The potency of single LBAM dispensers deployed at 200 per ha was excellent ($D_a = 0.19$) and superior to that of any other dispenser in Table 1. D_{sa} of LBAM dispensers was surpassed only by that for wax drops deployed for OFM. This finding suggests that

mating disruption of LBAM would be highly effective under the approach of using thousands rather than hundreds of point sources of pheromone per hectare.

Other investigators have recorded disruption outcomes while varying pheromone release rates along with density of release sites. For example, Charlton and Cardé (1981) used 0, 668, and 1,336 release sites per ha (plot size was 0.03 ha) to measure OFM disruption in apple plots in response to Albany International Corp. (no longer available) hollow fibers releasing the three components of this moth's pheromone (see Table 1), but not in the precise natural blend. The densities of fibers per source were 0, 16, 96, and 880. These data (graphs not shown) were also consistent with competitive attraction. D_a per fiber (calculated as described above for LBAM) was 0.0019, in line with other OFM pheromone release devices (Table 1). D_a per fiber declined from 0.0019 for 16 fibers per source to 0.00034 for 880 fibers per source. This OFM research confirms that increasing pheromone release per site did not fully compensate for a reduction in the density of release sites. Reducing the density of release sites comes at a cost of reduced D_{sa} and $D_{\bar{a}}$. Both release rate per source and density of sources matter in communicational disruption mediated by competitive attraction. For LBAM and OFM within the parameter ranges tested, however, source density was more influential than overall release rate of pheromone per source.

Shorey et al. (1994) conducted an elegant study conducive to evaluation of the relationship between density of pheromone release sites and release rate per site. They arranged a test where (in our terminology) k_D and D_D were experimentally manipulated, whereas k_T and k_F , along with moth density, remained constant. This test was conducted on the beet armyworm (BAW), *Spodoptera exigua*, in plots of tomato and cotton. Only the major pheromone component, (Z9,E12)-tetradecadienyl acetate, was released from 2-cm-long Teflon™ capillary tubes varying in diameter from 0.30 to 1.32 mm. Release rate was purportedly directly proportional to capillary diameter. Single capillary tubes attached to wooden stakes were deployed into the crop, always in a 36×36 grid, but with variable separation between stakes: 4.6, 3.0, and 1.5 m. Therefore, plot size varied from 0.006 to 0.05 ha, and D_D varied from 0 to 6,429/ha. One monitoring trap was deployed at the center of each treatment and control plot (five replicates). Because T_D varied somewhat in these tests, we made no attempt to calculate or interpret moth densities.

With rises in k_D relative to k_T and k_F , the competitive-attraction simulations of Fig. 4c of Miller et al. (2006) predicted a series of diverging straight lines with increasing slopes on Miller-Gut plots. The Shorey et al. (1994) BAW disruption profiles fit this prediction well (Fig. 7), except for the profile for the 0.56-mm capillary, which was flatter than expected. D_a increased directly with pheromone release rate from the capillaries ($D_a = 0.018D_{sa}$; $r^2 = 0.99$), revealing that D_{sa} remained a constant 0.018, irrespective of capillary diameter. $D_{\bar{a}}$ was 129 for the largest diameter capillary (1.32 mm) releasing pheromone at $1 \mu\text{g/hr}$ and deployed at 6,429 capillaries per ha (Table 1).

Shorey et al. (1994) seem to have over-interpreted their BAW data when they concluded that release rate of pheromone point sources was much more important than density of release sites. By starting with a relatively high density of dispensers (679/ha) and progressing only upward, these investigators realized only a small gain in % disruption with additional increases in dispenser density. This probably was because their lowest treatment density occurred at a point on this disruption profile beyond the rapidly falling phase and in the asymptotic phase. On the other hand, the pheromone release rates per release site in this experiment began very low (83 ng/hr) and progressed only to $1 \mu\text{g/hr}$. D_a increased steadily across this narrow range of release rates. However, there is no guarantee that disruption potency would have increased indefinitely with increasing

Fig. 7 Miller-Gut plot of the disruption profile from Shorey et al.’s (1994) test deploying four differently sized capillary tube dispensers targeting beet armyworm, *Spodoptera exigua*, in tomato and cotton

release rate per release site. Not realizing that this test favored showing a strong release-rate effect and a weak dispenser-density effect, these authors suggested that, for BAW, “if a certain amount of pheromone component is to be evaporated per hectare per day, it may be more effective to do so from relatively few evaporators, each releasing large amounts of pheromone and spaced far apart, than for small evaporators releasing lesser amounts of chemical and positioned correspondingly closer together” (Shorey et al., 1994). From here, it was a short step to aerosol and similar dispensers (Mafra-Neto and Baker, 1996; Shorey and Gerber, 1996; Shorey et al., 1996; Isaacs et al., 1999) releasing very high rates of pheromone from few point sources per hectare.

A more complete picture can now be constructed from the classic data of Shorey et al. (1994) for the roles of dispenser density (D_D) and rate of pheromone release per site (k_D) in influencing disruption efficacy. Under this example of competitive attraction appearing to conform to Equation (9) of Miller et al. (2006), both factors are mutual partners interacting multiplicatively to reduce the probability of a male visit to a female from ca. 1 to $1/k_D D_D$. As such, any increase in k_D is multiplied by D_D , and *vice versa*. The mathematics indicate it is maximization of $k_D D_D$ that matters, and that this could be done variously, e.g., by using a high density of point sources, each with low attractiveness. Here, an additional benefit is that spatial coverage of the crop would be thorough. In reality, however, the pheromone release rate per dispenser cannot be permitted to fall below some minimal level required to generate an attractive plume. Conversely, few point sources releasing pheromone at high rates might theoretically generate a very high $k_D D_D$. However, deploying just a few large plumes may leave gaps in coverage, especially when fields are small. Moreover, there are usually limits to pheromone concentrations that can attract male moths. Releasing pheromone at rates too high to be attractive could nullify a competitive-attraction mechanism in favor of an alternative disruption mechanism. Maximizing $k_D D_D$ as well as D_{sa} for expensive pheromone compounds will be a worthy economic goal of applied pheromone research for the foreseeable future. It will require experiments like that of Shorey et al. (1994), but with a wider range of release rates per dispenser to reveal shifts and limits in k_D . Also, dispensers will need to be observed to determine to what degree they are attractive to males.

Summary of Case Studies Supporting Competitive Attraction

More than 10 disruption profiles were uncovered that fit the set of predictions for competitive attraction detailed by Miller et al. (2006). This set of cases can be further tested for internal consistency by correlating values for $D_{\bar{A}a}$ and % disruption (Table 1). If all cases were properly classified as competitive attraction, a consistent and interpretable

Fig. 8 Graphical comparison of measures for disruption potency arising from Table 1. (a) Relationship between % disruption vs. $1/D_{\bar{A}a}$ (b) Untransformed plot of % disruption vs. dispenser application activity ($D_{\bar{A}a}$)

relationship should be found when % disruption is plotted vs. $D_{\bar{A}a}$. This prediction is confirmed by Fig. 8a. Values of % disruption for both simulated and actual data rose dramatically with increases in $D_{\bar{A}a}$; then they rapidly tapered off and approached 100% disruption asymptotically. The fit between real and simulated data under conditions detailed in Fig. 8a was excellent.

Figure 8a demonstrates that % disruption and $D_{\bar{A}a}$ offer strikingly nonparallel measures of disruption potency. Tiny numerical differences in % disruption near 100% obscure very large differences in disruption potency as measured by $D_{\bar{A}a}$. Expansion at the bottom end and compression at the top end of the % disruption scale can distort judgments of the relative potency of disruptive formulations operating by competitive attraction. For example, an alteration in a formulation that increases disruption from 50% to 90% appears to be considerably more impressive than an increase from 98% to 99%. However, a rise from 50% to 90% inhibition of male catch in traps corresponds to an increase in $D_{\bar{A}a}$ of only 8, whereas the rise from 98% to 99% corresponds to a $D_{\bar{A}a}$ increase of 50. From the perspective of practical pest control, this suggests that % disruption values below 90% may all reflect trivial disruptive potency under competitive attraction, unless pest density is very high.

Percent disruption of male catch in traps has been a useful measure of practical outcomes of disruption experiments, but its proper interpretation requires reevaluation. We recommend that consideration be given to additional measures of disruption potency and efficacy beyond % disruption. As research fields mature, it is usual that multiple measures are devised for a given phenomenon, e.g., degrees Fahrenheit, centigrade, and Kelvin for temperature. D_a and $D_{\bar{A}a}$ can serve as alternative disruption measures for cases of disruption operating by competitive attraction. These variables seem better suited than % disruption to differentiate among the high-performance treatments (> 98% disruption) that will increasingly become the practically relevant zone of interest for pest managers and the pheromone industry.

Given that D_D occurs only in the denominator of Equation (1) of Miller et al. (2006), evidence should be found that D_D reduces catch by some consistent inverse function. Indeed, when % disruption values in Table 1 were plotted vs. the inverse of the corresponding $D_{\bar{A}a}$ values, a precise relationship was uncovered when % disruption exceeded 90% (Fig. 8b). The regression equation was: % disruption = $94(1/D_{\bar{A}a}) + 100$; the r^2 value was 0.99. This outcome was also virtually identical with that for the simulated data of Fig. 8b. Rearrangement and rounding up the slope yields (equation numbering continued from Miller et al., 2006):

$$\% \text{ Disruptions} \approx 100 - 100/D_{\bar{A}a} \quad (17)$$

Similarly, if catch in control plots is normalized to 1,

$$\text{Catch in crop receiving pheromone} \approx 1 - 1/D_{\bar{A}a} \quad (18)$$

These equations should prove useful in interconverting the mass of % disruption data already in the literature. However, Equations (17) and (18) are applicable only when disruption operates by competitive attraction and D_D values are very high so as to dominate the generative equations. Finding a consistent and precise relationship between $D_{\bar{A}a}$ and % disruption across cases classified as competitive attraction offers powerful evidence for internal consistency and hence validity of the current approach to classifying disruption mechanisms.

Cases Consistent with Non-competitive Disruption Mechanisms and Inconsistent with Competitive Attraction

Our literature search uncovered only one case supporting a non-competitive disruption mechanism. This test was conducted by McLaughlin et al. (1972) in Southern California (USA) on pink bollworm in cotton. This work pre-dated identification of the PBW's pheromone (Table 1) and used a related compound (*Z*-7-hexadecenyl acetate; hexalure) attractive to males but less so than extracts of female pheromone glands. Hexalure was released at 6 $\mu\text{g}/\text{dispenser}/\text{hr}$ from stainless steel planchets attached to wooden stakes deployed at crop height in a 10×10 array. Inter-stake distances varied (3, 10, and 30 m); thus, plot sizes varied from 0.09 to 9 ha. Disruption in each plot was evaluated from catch of males in one central sticky trap baited with several virgin females. The results were presented only as % reduction in catch relative to control plots; actual catches were not reported.

It was not apparent from the untransformed plot of McLaughlin et al.'s (1972) test (Fig. 9a) whether the data fit competitive or non-competitive disruption. Catch did not initially drop precipitously with initial increases in dispenser density, but this pattern also can be realized under competitive attraction when moth density is very high (Fig. 3a of Miller et al., 2006). However, the subsequent approach to the x -axis was quicker than expected for competitive attraction under high moth density (Fig. 9a vs. Fig. 3a of Miller et al., 2006).

Secondary plots of this disruption profile were consistent with a non-competitive disruption mechanism. The Miller–Gut plot was concave (Fig. 9b), as expected for non-competitive disruption (Fig. 7b; Miller et al., 2006). The Miller-de Lame plot was recurved and its inflection point occurred near $1/2y$ -maximum (Fig. 9c), as is diagnostic for non-competitive disruption (Fig. 7c of Miller et al., 2006). Because this PBW profile was a better fit to non-competitive than competitive disruption, the steps taken above to calculate D_a and D_{sa} could not be taken.

The release rate in this PBW study was 8.2 mg/ha/hr; it yielded 99% communicational disruption. For comparison, 6.8 mg of pheromone/ha/hr in Stelinski et al.'s (2005c) test with OFM yielded 99.4% disruption, whereas 12.5 mg of pheromone/ha/hr yielded 99% disruption in the GM test of Table 1. Thus, disruption efficiencies may not vary greatly between competitive and non-competitive disruption when rates of pheromone dispersed/ha are high as in Table 1. This finding is consistent with the simulations of Fig. 7a of Miller et al. (2006). However, these simulations suggested that efficiency of disruption by competitive attraction would be superior to that for non-competitive mechanisms, when moth and dispenser densities are moderate to low.

A previously unpublished data set of our own also fits non-competitive disruption. This test targeting OFM was conducted over the full 2003 growing season in 0.15-ha, plots (45 trees) distributed across a 3-ha, recently abandoned apple orchard in Southeastern Michigan. The pheromone blend and dispenser formulation were identical to those reported by Stelinski et al. (2005c; see Table 1). However, rather than 0.1 ml wax drops, 12-ml dollops of wax were applied to a tree branch ca. 2 m above ground level as described by De Lame (2003). Dispenser densities were 0, 50, 130, and 230/ha. The experimental design was randomized complete block with four replicates. Two monitoring traps (Stelinski et al., 2005c) spaced ca. 12 m apart and near the center of each plot assessed catch of male moths across the full 2003 growing season. Traps were checked weekly and lures were replaced at the beginning of each OFM flight (every 6–8 wk). These emulsified wax dollops were sufficiently large to remain disruptive throughout the season. Release rate per dollop slowly

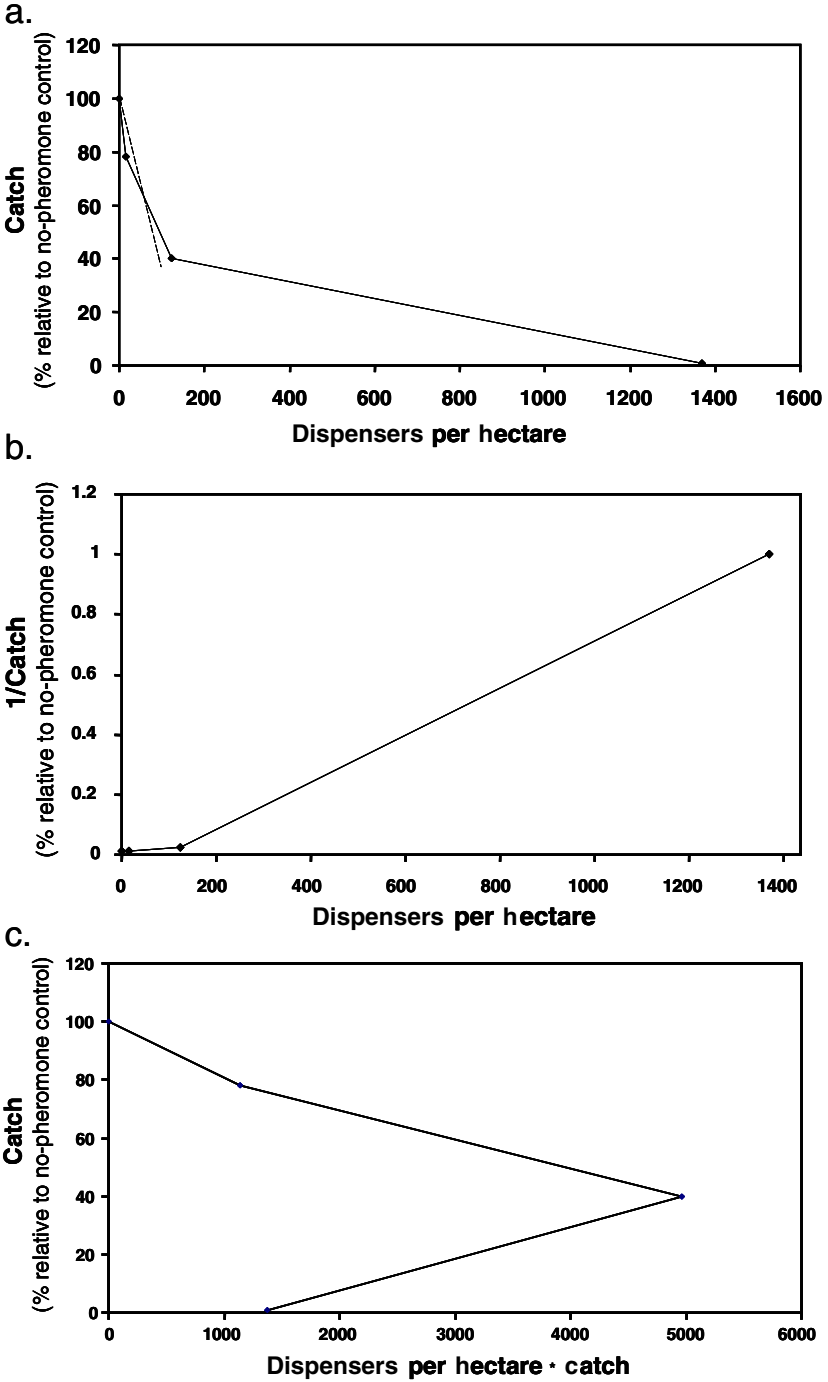

Fig. 9 Untransformed (a), Miller-Gut (b), and Miller-de Lamé (c) plots of the disruption profile from McLaughlin et al.'s (1972) test deploying planchette dispensers targeting pink bollworm, *Pectinophora gossypiella*, in cotton

declined from ca. 150 to 40 $\mu\text{g/hr}$ as determined by solvent extraction (De Lame, 2003) followed by gas chromatography (Stelinski et al., 2005c).

The season-long disruption profile for this test is plotted in Fig. 10a. With initial increases in dispenser density, catch dropped almost linearly until 130 dollops/ha. However, disruption did not increase significantly with the final increment in dispenser density. Having only one datum after the slope change was insufficient for assessing whether or not the approach to total inhibition of male catch was asymptotic (Fig. 10a).

Both secondary plots of the data supported a non-competitive disruption mechanism. The Miller-Gut plot (Fig. 10b) was concave, as expected for non-competitive disruption (Fig. 7b of Miller et al., 2006). Moreover, the Miller-de Lame plot (Fig. 10c) recurved significantly ($P < 0.05$) and according to the signature of non-competitive disruption (Fig. 7c of Miller et al., 2006). Finding some cases consistent with non-competitive disruption and inconsistent with competitive attraction, as well as *vice versa*, helps to authenticate the quantitative tools proposed by Miller et al. (2006) for differentiating between the two major classes of disruption mechanisms.

Release rate is the most obvious reason for the switch from competitive to non-competitive disruption mechanisms when using 0.1-ml wax drops vs. 10-ml wax dollops to disrupt OFM. As measured by male catch in traps, attraction of OFM is strongest when sources release between 0.07 and 0.72 $\mu\text{g/hr}$ (Baker et al., 1980). Release rate from our wax dollops ($> 40 \mu\text{g/hr}$) far exceeded OFM's upper limit for attraction of males very close to a source. Graphical analysis of the resulting disruption profile suggests that attraction was nullified, and plumes were generated that disrupted moth communication by some unspecified non-competitive mechanism, such as camouflage or desensitization. During this test, we unfortunately did not yet realize the importance of observing dispensers for evidence of male attraction. Thus, critical evidence that male OFM did not orient to these wax dollops is lacking.

This experiment documented a small efficiency improvement in OFM disruption when mediated by competitive attraction vs. a non-competitive mechanism. Dollops (230) releasing pheromone at 6.4 mg/ha/hr gave 96% disruption, a questionable level for practical control. Pheromone released at 6.8 mg/ha/hr from 27,300 wax drops effected an encouraging 99.4% disruption, also under high pest pressure. However, the large wax dispensers lasted all season, whereas a new set of drops had to be applied for each moth generation.

The slope derived from the first three points of Fig. 10a was 0.055; it reflects the decline in male catch per trap per wax dollop added per hectare, when starting catch was 8.2 males/trap/night for the control plot receiving no synthetic pheromone. Thus, each dispenser diminished catch by 0.67% ($0.055/8.2$) during the linear portion of Fig. 10a. Under a pure camouflage model of pheromone disruption, Equations (14) and (15) of Miller et al. (2006) proposed that each equivalent dispenser would camouflage an equal area (x) of crop, and that the total area camouflaged would be $D_D * x$. Combining this proposition with the measured Fig. 10a slope of 0.67% suggests that each wax dollop in this OFM test operated on 0.67% of 1 ha, which equates to only 67 m^2 /dollop. Under the spacing of 225 trees/ha, 67 m^2 equates to camouflaging plume coverage of only 1.5 trees/wax dollop. Accordingly, it would take a minimum of 150 dollops to completely cover the 1 ha under a scenario of perfect packing and no plume overlaps. However, even the highest dispenser density of 230 dollops/ha allowed a catch of 4% relative to the control catch. Thus, there must be a difference between plume sizes required to impact catch vs. inhibit it completely. The current OFM experimental data suggest there were small spaces within the treated crop that were difficult to disrupt by non-competitive mechanisms. Perhaps it is the zones immediately downwind of traps and females, where their pheromone plume concentrations are highest, that are not being covered by sufficient dosages of background pheromone to effect complete non-competitive disruption.

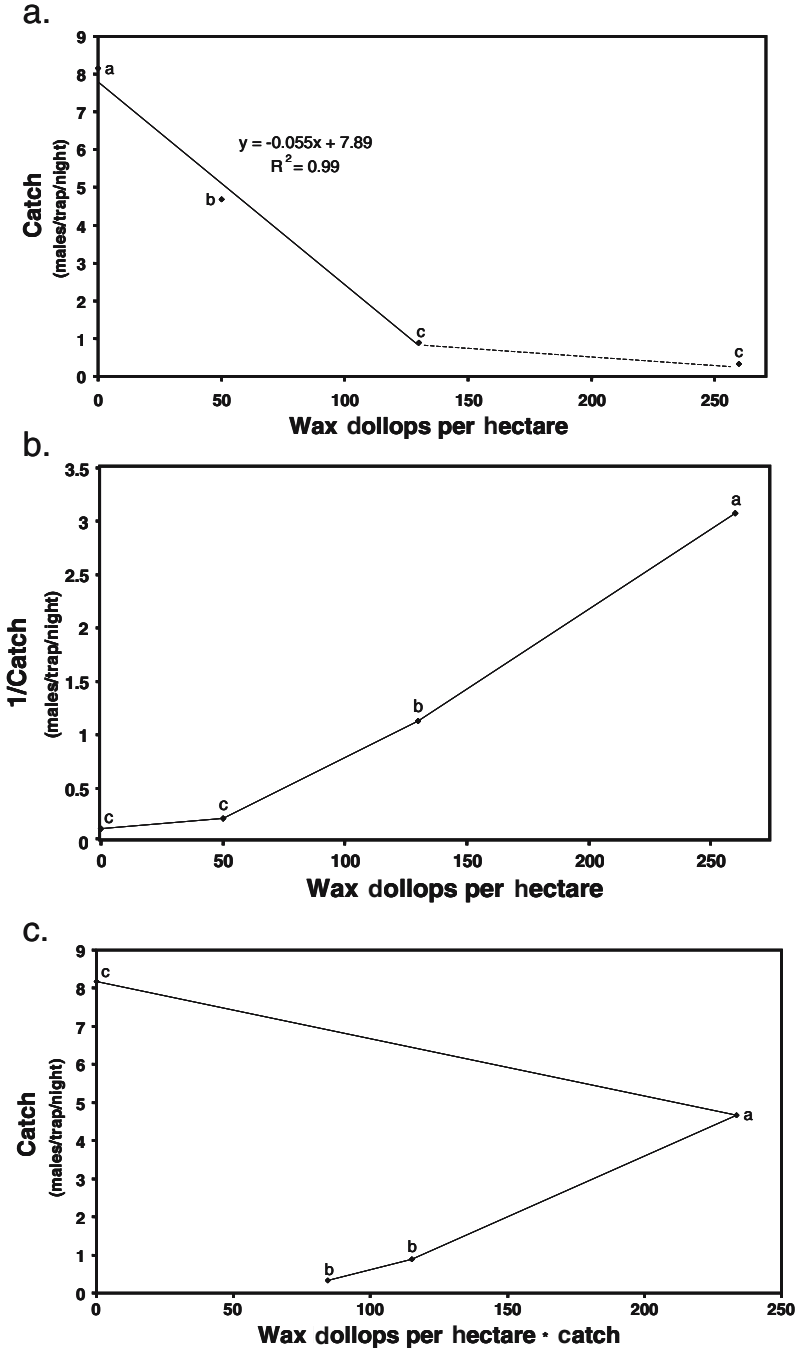

Fig. 10 Untransformed (a), Miller-Gut (b), and Miller-de Lame (c) plots of the disruption profile from our own test deploying 12 ml emulsified wax-dollop dispensers targeting oriental fruit moth, *Grapholita molesta*, in apples. Within a panel, means not sharing a common letter are statistically different at $P < 0.05$ by an LSD test after ANOVA on data transformed to $(x+0.5)^{1/2}$ for panels (a) and (c), and $\ln(x+0.5)$ for (b)

Alternatively, even our highest density of dispensers may have been insufficient to eliminate small gaps in coverage far from dispensers.

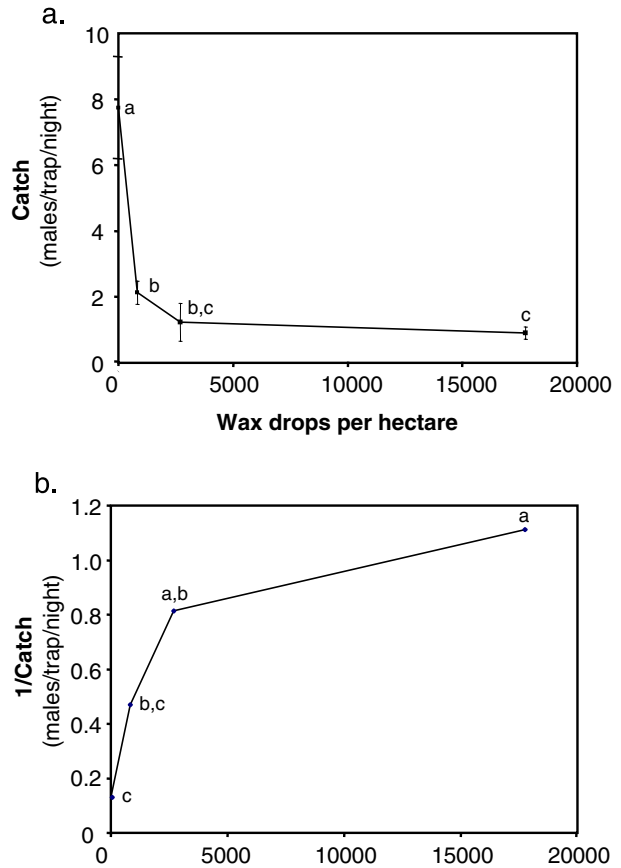

The capacity to shift from a competitive to a non-competitive disruption mechanism by using a common dispenser medium, but varying the deposit size, bodes well for emulsified wax as a flexible disruption formulation useful across a range of pest densities. By varying dispenser size and/or release rate, it might be possible to tailor the disruption mechanism for a given pest based upon its particular density, as suggested by Miller et al.'s (2006) Fig. 7a. At very high pest densities, it could be advantageous to disrupt pests by a non-competitive mechanism. On the other hand, competitive attraction appears to be the more efficient disruption mechanism for moderate to low pest populations (Fig. 7a of Miller et al., 2006). However, these decisions will also be influenced by the desired longevity of a given pheromone application. Small, but densely-distributed dispensers are likely to give the most efficient disruption for many pests, but reapplication will be required if small dispensers have limited longevity.

A Case Possibly Blending Competitive and Non-competitive Disruption Mechanisms

During the 2004 field season, we tested efficacies of varying densities of 0.1 ml emulsified wax drops in disrupting CM (*Cydia pomonella*) sexual communication. The methods were identical to those reported by Stelinski et al. (2005c) for OFM, with a few exceptions. Plots consisted of 16 rather than 12 trees, and only the major pheromone component for CM [(E8,E10)-dodecadienol] was incorporated into the wax at a starting concentration of 5%. Catch of male moths in each plot was monitored with two centrally located sticky traps baited with red rubber septa loaded with 0.1 mg of pure codlemone. This test ran for only 14 d during the first generation of moths, after which efficacy of wax drops noticeably diminished and the test was terminated. Release rate of codlemone over this period averaged 3 $\mu\text{g/hr/wax}$ drop as quantified by gas chromatography with the methods of De Lame (2003).

The resulting disruption profile for CM was a better fit to competitive attraction than to a non-competitive mechanism. The untransformed plot was sharply concave and not linear (Fig. 11a) and the Miller-de Lame plot did not recurve (data not shown). However, the Miller-Gut plot (Fig. 11b) was convex, much like that for LBAM (Fig. 6b). This is curious, because there was no clumping of wax drops as was true for ropes in Suckling and Angerelli's (1996) test. In contrast to the other competitive-attraction cases compiled in Table 1, disruption potency per dispenser declined for CM as density of wax drops rose. Emission rate of pheromone from wax drops was probably not influenced by their density, and so it is more likely that the response of CM males to monitoring traps was somehow shifted under the increasing density of pheromone plumes. One possibility is that CM males became partially desensitized to the emissions from high densities of wax drops, but not to the higher emissions from the monitoring traps, i.e., the threshold for response to pheromone point sources shifted upward (less sensitive) as the density of point sources increased. If so, visitation rate to the traps may have risen relative to weakly competing wax drops. Not having assessed the relative attractiveness of traps vs. females vs. wax drops, or deployed virgin females to assess mating, we cannot say whether disruption of females exactly reflected the disruption of traps. Disruption of females needs to be measured, as it was perhaps better or worse than disruption measured for traps. Although we are unable to fully interpret the disruption profile for this CM study, this case demonstrates the utility of these new analytical procedures in extracting potentially useful information hidden within a raw disruption profile (Fig. 11a). We expect other cases will be found

Fig. 11 Untransformed (a) and Miller-Gut (b) plots of the disruption profile from our own test deploying 0.1 ml emulsified wax-drop dispensers targeting codling moth, *Cydia pomonella*, in apples. Within a panel, means not sharing a common letter are statistically different at $P < 0.05$ by an LSD test after ANOVA on data transformed to $(x+0.5)^{1/2}$

that do not fit pure competitive or non-competitive disruption, and that more powerful analyses of these profiles will aid recognition and interpretation of mixed as well as pure disruption mechanisms.

Listing of Some Practical Ramifications When Competitive Attraction is the Leading Mechanism of Moth Mating Disruption

Pheromone Formulations for Disruption

If disruption primarily involves attraction, attractiveness of pheromone formulations should be optimized, e.g., match the natural blend of the female and optimize the release rate so as to generate plumes matching or exceeding those of females. In some cases, it may be cheaper to use an off-blend, i.e., if attractiveness of dispensers releasing abnormally high rates of a cheaper pheromone component can match attractiveness of females releasing a blend containing expensive minor components.

The density of point sources is strongly and positively correlated with the efficacy of a pheromone treatment. The higher the density of dispensers, the more effective is the treatment, provided that each dispenser remains highly attractive. However, it may be possible to apply dispensers at densities so high that they no longer attract. This could shift disruption from a competitive to non-competitive mechanism. To date, disruption efficacy per unit of pheromone used appears to be slightly higher for competitive vs. non-competitive disruption. Furthermore, it is advantageous for pheromone point sources to be thoroughly dispersed in the crop so as to avoid zones with no coverage. This is particularly important when field size is small. Very large fields may lend themselves to some reduction in dispenser density, provided pest density is low.

The release rate of individual pheromone point sources also matters; it interacts multiplicatively with dispenser density. Dispenser density and release rate should be manipulated so as to maximize $k_D * D_D$.

Formulations of pheromone to be used in disruption by competitive attraction should be flexible in the sense of offering opportunity to vary the density of dispensers and the timing of application. When pest densities are high, the number of dispensers will likely need to exceed the numbers affordable for manual application, i.e., future formulations will need to be amenable to application by machine. Desirable attributes for machine application are as follows: capability to be pumped or otherwise mechanically moved from storage reservoir to applicator; ability of the parent stock to be subdivided into particles or drops of desired sizes; transferability from applicator onto the crop; effective self-adhesion of the dispenser particles onto the crop; long-lasting release of the pheromone; avoidance of phytotoxicity or other undesired impacts of the formulation; ability to be biodegraded. An example of the type of formulation we foresee as viable for disruption that maximally exploits competitive attraction is the emulsified wax used in our OFM and CM studies. Exclusive of the active ingredients, the formulation is relatively inexpensive; it is formulable in large batches by using ordinary equipment; the product is storable in common containers; it is flowable and can be pumped to an applicator; techniques like extrusion through holes in a spinning hub can break the parent material into deposits ranging from droplets of microliter size through drops measured in hundreds of microliters, to dollops ranging up to several milliliters; this wax is self-adhering to diverse plant parts and adhesion can be increased by the addition of small amounts of benign glues; cleanup of equipment and clothing is easily accomplished using soap and water; the release rate of wax drops is surprisingly long and decreases slowly when the starting concentration of pheromone is kept below 5%; the wax carrier is not phytotoxic, as certain pheromones such as codlemone can be phytotoxic to leaves and fruits (Giroux and Miller, 2001); and these wax deposits eventually fall to the ground and biodegrade without known consequence. Other technologies with a similar set of desirable traits are the pheromone flakes (referred to above in the gypsy moth study) and pheromone fibers extensively explored several decades ago (Charlton and Cardé, 1981) and making a reappearance (Scentry Biologicals Inc., Billings, MT, USA; Knight, 2003).

Factors Influencing Performance of a Given Pheromonal Formulation

Disruption outcomes under competitive attraction are extremely sensitive to pest densities (Fig. 3; Miller et al., 2006). Generally, the density of pheromone dispensers should exceed the density of females by ca. 100-fold. Dispenser density can be somewhat lower, if attractiveness of each dispenser is commensurately greater than that of females or if a pest is

not highly fecund. We are aware of no case where an increase in the rate of pheromone released per dispenser fully compensated for reduction in dispenser density.

Measuring pest density in a crop is a required antecedent to optimizing a disruption protocol under competitive attraction.

Pheromone-baited monitoring traps might not always offer sufficient sensitivity and consistency for safely guiding real-time management decisions for mating disruption. Where attractiveness of traps equals that of females, obtaining a mean catch of one male per trap per several nights could indicate that disruption has failed, irrespective of an impressive value for % disruption. On the other hand, obtaining catches of zero in multiple traps known to be highly attractive to males constitutes the strongest evidence for success in mating disruption obtainable from traps.

Complexity, Reliability, and Sustainability of Mating Disruption

Under competitive attraction, it will probably not be possible to combine the pheromones of multiple species into one cocktail, as was explored for aerosol dispensers of pheromone (Isaacs et al., 1999). In crops like Michigan tree fruit where there are more than four key moth pests, this could translate into a substantial total number of pheromone applications over one season. Doing so will require convenient machine application of each pheromone and the capability to make applications in accordance with the appearance and abundance of each generation of each pest. This requirement adds complexity to pest management compared to application of long-lasting, broad-spectrum insecticides. Hopefully, this disadvantage for pheromones will be offset by absence of environmental hazards and sustainability of this pest management tactic.

One of the challenges to adoption of mating disruption has been reliability. In some situations, mating disruption has worked well for a given pest, whereas in other situations it has not. We suspect that widely varying pest densities explain much of this variability. With changes in formulation and application technologies, and attention paid to the principles of competitive attraction, substantial improvements in the reliability of mating disruption should be possible for many pests.

An advantage of competitive attraction is that it is already directed at forestalling the key behavior leading males to females—attraction. In contrast, when exploiting camouflage or desensitization, it will be the few males in the population capable of orienting to females despite the presence of the dispensed pheromone that will be resistant to the control measure and whose ethotype will dominate under this strong selection pressure. It may be better to sidestep this potential weakness of non-competitive mating disruption by engineering disruption to explicitly and immediately target attraction. Resistance is less of a threat under competitive attraction, if attractiveness of disruption formulations is adjusted to track the blend from authentic females over time. Nevertheless, rotating mating disruption with other management tactics is always advised.

Possible Outcomes

It is our hope that insights gained from this analysis will lead to developments that make mating disruption more practical and reliable at a time when the number of pest management tools is shrinking. Furthermore, the analytical procedures and principles arising from the study on moths may prove useful to competitive-attraction phenomena generally, be they,

e.g., use of attracticides (Eviden and McLaughlin, 2004), other kinds of insects (Polavarapu et al., 2002), competitive insect–plant interactions (Miller and Cowles, 1990), vertebrates responding to attractants (Li et al., 2002), sperm competition (Berkhead, 1998), or humans responding to competing products in the marketplace. This knowledge might also inform outcomes of the competitive interactions of inanimate homing devices involving attraction to or diversion from competing long-distance cues, e.g., <http://www.fas.org/spp/starwars/program/nmd/>).

Acknowledgments J.M. credits Professor Joseph Meier of Millersville University for teaching the benefits of analyzing data as a set so as to comprehend underlying relationships, rather than being satisfied with an ANOVA and assignments of statistical significance to pairs of means. Appreciation is expressed to Naomi Miller and to senior technician Piera Siegert for affording J.M. the many long periods with few interruptions necessary to produce this and the previous paper. Aspects of this work were financially supported by grants to J.M. and L.G. from the USDA Special Grants Program, Michigan State University Project GREEN, and The Michigan Apple Commission.

Introduction

A recurring need in practical entomology is to simulate attractive natural volatile sources with effective synthetic versions for use in insect management programs. Natural sources, often host-related, typically involve multiple chemical components, which greatly complicates simulation and behavioral analysis. A situation of this sort arose for an Australian fruit pest, *Carpophilus davidsoni* Dobson (Coleoptera: Nitidulidae). This article describes a research approach for developing a synthetic attractant based on a relevant natural model.

Nitidulid beetles are the most serious pests of ripening stone fruit in southern Australia, and *C. davidsoni* is the most significant of these (James et al., 1997; Hossain et al., 2006; and references therein). *Carpophilus* beetles cause damage by direct feeding (Hely et al., 1982) and by transmission of brown rot (*Monilinia* spp., Kable, 1969) and other harmful microorganisms. In recent years, growers have reported losses of up to 30% of the crop (Hossain et al., 2000).

Currently, no conventional insecticide is registered and practical for controlling *Carpophilus* spp. in stone fruit, but attractants have good potential in nitidulid management as alternatives to insecticides. It has been known for many years that *Carpophilus* beetles are attracted to odors from ripening fruit or fermenting foods (e.g., Wildman, 1933). In California, a mass-trapping program that used fermenting figs as bait led to a moderate damage reduction in fig orchards (Warner, 1961). In Australia, the native species are readily attracted to fermenting peach and apple juice, which have been used in traps for population monitoring (James et al., 1998; Hossain et al., 1999; Mansfield and Hossain, 2004). In general, attraction of *Carpophilus* spp. to food or fermentation odors is due to the emission of blends of small alcohols, aldehydes, and esters (Smilanick et al., 1978; Lin and Phelan, 1991; Phelan and Lin, 1991; Bartelt and Wicklow, 1999), although no specific information had been published regarding *C. davidsoni*.

In addition to host-related attractants, male-produced aggregation pheromones have been identified for the key Australian *Carpophilus* species, including *C. davidsoni* (Bartelt and James, 1994). The pheromones attract both males and females, and they function synergistically with food volatiles (reviewed by Bartelt, 1999). Baits containing both the pheromones and food-related attractants are more potent and have greater pest management potential than those containing food attractants alone.

Using attract-and-kill stations baited with *Carpophilus* pheromones, ripe and rotting peaches, and fermenting peach juice, Hossain et al. (2001, 2006) demonstrated protection of ripening stone fruit. The peaches contained within the stations were treated with insecticide, and the attracted beetles were killed when they landed and fed. The stations (three per hectare) were deployed well before fruit maturation in the orchard, and the concept was to remove as much of the local beetle population as possible before the fruit became susceptible to attack. From the standpoint of efficacy, the method has potential, but the large volumes of fruit and juice in the stations make them unwieldy and time-consuming to service. For the technique to become acceptable to growers, an easy-to-use alternative for the fruit and juice is required.

The specific objective of this research was to develop a synthetic food-related attractant that might replace the fruit and fruit juice in the attract-and-kill stations. Using fermented peach juice and intact fruit as natural models, volatile emissions were analyzed both qualitatively and quantitatively and characterized for attractiveness to *C. davidsoni* in a

laboratory wind tunnel. Synthetic blends were prepared that matched the natural sources, both in emission rates of key chemicals and in attractiveness. The activity of the final synthetic formulation was verified under field conditions.

Methods and Materials

Natural Volatile Samples

The laboratory experimentation was carried out in Peoria, Illinois, USA. Emissions from fermenting peach juice and whole peaches and nectarines were analyzed chemically and evaluated for attractiveness as the initial step of synthetic attractant development. The canned peach juice was the same type (Golden Circle™, Brisbane, Queensland) that had been used previously in field tests (Mansfield and Hossain, 2004). Fermentation was started by adding dried baker's yeast (0.25 g/50 ml of juice). Juice samples (10 ml) were placed in 50-ml Erlenmeyer flasks, which were equipped with glass inlet/outlet adapters (both the flasks and adapters had 24/40 ground glass fittings, so that connections would be air tight and chemically inert). All connections to flasks were made with 4-mm ID Teflon tubing. There was a constant flow of air (10 ml/min) through the headspace of each sample flask. Flasks were kept at room temperature. New juice samples were inoculated on consecutive days for 7 d and comparisons of all ages were performed on the eighth day, both with respect to chemical emissions and attractiveness to beetles. An unfermented juice sample was also included.

Peaches and nectarines of white-flesh and yellow-flesh varieties, from a local market in Peoria, were also studied. Fruit was unripe when purchased, and chemical and behavioral analyses were performed on consecutive days to document changes in chemistry and attractiveness over time. Individual pieces of fruit were placed in wide-mouthed canning jars of ca. 0.5- or 1-l volume, using the smaller size possible, and kept at room temperature. Fittings installed in the air-tight lids served as air inlets and outlets, and all external connections were with Teflon tubing of 4 mm ID. In addition, a piece of Teflon tubing extended inside the jar from the inlet fitting to the bottom, so that incoming air would circulate before exiting. There was a constant (24 hr/day) airflow of 10 ml/min through each jar so that emitted volatiles could not accumulate in the jar. With this configuration, the chemical emission rate at the outlet port fairly represented the emission rate from the piece of fruit, both qualitatively and quantitatively.

Synthetic Volatile Samples

Solutions of synthetic compounds were prepared to simulate natural samples in the emission rates of one or more components. Blends were formulated in 10 ml of water or oil and placed in 50-ml Erlenmeyer flasks with 10 ml/min airflow, as with fruit juice samples. A magnetic stirrer aided volatilization of compounds into the headspace. Compounds formulated in water were acetaldehyde, ethanol, ethyl acetate, 2-methyl-1-propanol, 3-methyl-1-butanol, and 2-methyl-1-butanol; compounds formulated in oil were methyl acetate, ethyl acetate, 2-methylpropyl acetate, 3-methylbutyl acetate, hexyl acetate, Z-3-hexenyl acetate, and ethyl octanoate. Synthetic chemicals were obtained from Aldrich Chemical Co. (Milwaukee, WI). Vacuum pump oil (Duoseal, Welch, Skokie, IL) served well because it had an extremely low volatile background. Based on solid-phase microextraction–gas chromatography (SPME-GC) analyses of volatiles from standard solutions, emission rate was nearly proportional to concentration in solution. Thus, the

concentration of a compound required to give a particular emission rate (i.e., to simulate a natural sample) could be readily calculated once baseline information was obtained. Dilute stock solutions of individual synthetic compounds (between 0.1 and 100 mg/ml, made up in advance) facilitated the preparation of target blends. Synthetic blends were generally prepared fresh each day.

Four individual samples of fermenting juice (1–3 d after inoculation) were chosen for simulation on 4 separate days. For each of these, an SPME-GC analysis was conducted on the natural sample early in the day, target composition of the synthetic blend was calculated, the synthetic blend was prepared and analyzed (and if necessary, adjusted), and the natural and synthetic materials were compared in the wind tunnel bioassay. A need was to complete sample preparation quickly, before the natural model had time to change significantly and to allow enough time for bioassays. The amount of time between the analysis of the natural sample and the beginning of wind tunnel bioassays was typically 2 hr.

In addition, a bioassay standard was prepared, adapted from earlier work with *C. humeralis* (Bartelt and Zilkowski, 1998). The standard consisted of an aqueous mixture of acetaldehyde (0.3 mg/ml), ethanol (90 mg/ml), and ethyl acetate (0.18 mg/ml). This mixture (10 ml in a 50-ml flask, magnetically stirred at 25°C, airflow through the headspace at 10 ml/min) delivered the three compounds at rates of 7000, 98,000, and 9500 ng/min, respectively.

Chemical Analysis

Gas chromatography and coupled GC/mass spectrometry were performed as previously described (Bartelt and Wicklow, 1999), using DB-5MS columns (30 m × 0.25 mm ID, with a 1 μm film thickness, J&W Scientific, Folsom, CA). The oven temperature program was 50°C for 1 min, increasing at 10°C/min to 250°C, with a final hold at 250°C for 3 min. Chemical identifications were made by reference to the Wiley mass spectral library and were confirmed by comparing GC retention times and mass spectra to authentic standards.

Quantitative sampling of emissions from the fruit, juice, and synthetic sources was performed by SPME. SPME is a simple, sensitive, and solventless analytical technique (Pawliszyn, 1997) where chemicals are absorbed (in this case, from the air) by a thin, polymer-coated, silica fiber, which is manipulated with a syringe-like holder (Supelco, Bellefonte, PA, USA). Absolute quantitation by SPME was based on previously established absorption-kinetics properties for fibers of the 100-μm poly(dimethylsiloxane) type (Bartelt and Zilkowski, 2000). Sampling was always performed at the air outlets of the containers with volatile sources. The coated portion of an exposed SPME fiber was situated 2 to 3 cm inside the open end of the Teflon outlet tube, along the central axis. Airflow rate in the outlet tube was always 10 ml/min, and room temperature during sampling was recorded. Sampling time was 30 min, and GC injection of the SPME sample followed immediately.

The absolute emission rates from the sources of volatiles (in ng/min) were calculated directly from the GC peak areas by using relationships developed previously (Bartelt, 1997; Bartelt and Zilkowski, 1999, 2000). The mathematical equations were programmed into the data system with the Hewlett Packard ChemStation macro language. Thus, chemical emission rates became part of the printed GC report as specific compounds were recognized by retention time.

Bioassay Equipment

A volatile delivery system (VDS), described previously (Bartelt and Zilkowski, 1998, “new system”), was used to deliver scents. Briefly, inputs for the VDS were the airstreams

emerging (at 10 ml/min) from containers with fruit, fruit juice, or synthetic compounds. The VDS allowed up to four inputs to be controlled at once, and any of these, or any combination of these, could be quickly directed to the wind tunnel by switching a valve. Furthermore, the levels of volatiles from the four inputs could be individually adjusted, so that any level between 5% and 100% of each source could be used in the bioassay. Thus, with a small number of physical volatile sources, a wide range of combinations and doses could be tested easily.

The wind tunnel was $0.7 \times 0.7 \times 1.3$ m in size. Airflow was laminar (ca. 0.3 m/sec); incoming air was warmed with an electric space heater to maintain a temperature of 28°C to 30°C in the wind tunnel, and exiting air was exhausted from the room. Lighting was from above with four 40-W fluorescent tubes. The outlet tube from the VDS, which carried the bioassay volatiles, opened into the wind tunnel at the center of a tan, circular cardboard disk, which served as landing target for responding beetles. The disk was 8 cm diam, mounted 40 cm above the wind tunnel floor and 20 cm from the upwind end, with its plane perpendicular to the direction of air movement.

Bioassay Insects and Procedures

A culture of *C. davidsoni* was established at National Center for Agricultural Utilization Research, Peoria, with adults sent from Australia. The beetles were reared on an artificial diet (Dowd, 1987; Bartelt and James, 1994). To prepare for wind tunnel bioassays, ca. 500 to 600 adults (of mixed sex and up to 4-wk old) were transferred from food cups into a 1-l glass jar in the evening before the tests were to be run. A crumpled paper towel was placed in the jar as a walking substrate, but no food or water was provided. The following morning, beetles were transferred into the wind tunnel, and bioassays began when 50 to 100 *C. davidsoni* were consistently in flight (see Results and Discussion).

Volatile samples were evaluated in the wind tunnel within 1 or 2 hr of chemical analysis, to establish a relationship between rates of compound emission and attractiveness. A test started when the output from the VDS was directed into the wind tunnel. Beetles landing on the cardboard disk during the next 2 min were counted, and then the flow from the VDS was switched away from the wind tunnel. Beetles remaining on the disk after a test were dislodged by gentle tapping. Time between tests was typically 2 to 5 min. Bioassay sessions lasted as long as 4 to 6 hr and included as many as 60 individual tests.

The volatile treatments of an experiment (up to 10) were tested consecutively in the wind tunnel in random order. This group was considered as a block for the purpose of statistical analysis. Data were acquired for additional blocks (also randomized) during the same day or on subsequent days, as needed. The counts of landings were transformed to $\log(x + 1)$ to stabilize variance and subjected to two-way analysis of variance (ANOVA). If the overall *F* test was significant, then the means were compared by the least significant difference (LSD) method at the 0.05 level.

A control (clean air delivered by the VDS) was included in every experiment, and the bioassay standard (see above) was sometimes included as well, as a basis for measuring day-to-day changes in treatments. An index of activity (*IA*) was used for expressing relative activity of treatments: $IA = 100 \times (T - C) / (S - C)$, where *T*, *C*, and *S* are the mean counts of landing beetles during the experiment for a treatment, the control, and the standard, respectively (Bartelt and Wicklow, 1999). *IA* expresses the attractiveness of a treatment as a percentage of the attractiveness of the standard, after correcting for the baseline (control) response. By definition, *IA* for the standard is 100, and *IA* for the control is 0.

Beetles were removed from the wind tunnel by allowing them to enter cups of diet set on the floor (typically complete within 1 hr). After at least 2 d of feeding, beetles could be reused in the bioassay. By alternating among several sets of insects, bioassays could be run each day. Newly emerged adults were added to the groups to replace dead ones as needed. The wind tunnel floor was swept with a vacuum cleaner, and the walls were wiped down with water between uses.

Field Experiments

Synthetic food attractant (SFA) was evaluated in Australia by one of us (M.S.H.) in two field experiments. Both were conducted in peach orchards (variety T204) in the Goulburn Valley, Victoria, Australia. The population of *Carpophilus* spp. was relatively low during the first experiment (December 2–13, 2002); fruit on the trees was green during this period. The second experiment (February 18 to March 21, 2003) was carried out after harvest at an orchard with a higher beetle population; some overripe and rotting fruit was still present on the ground.

The experiments included three treatments: The first was SFA (120 ml of an aqueous solution of ethanol, 35 mg/ml; ethyl acetate, 0.094 mg/ml; 3-methyl-1-butanol, 0.060 mg/ml; acetaldehyde, 0.051 mg/ml; 2-methyl-1-propanol, 0.027 mg/ml; and 2-methyl-1-butanol, 0.010 mg/ml). The second was a higher dose of the synthetic attractant (SFA10X), which was 120 ml of an aqueous solution prepared in the same way as SFA but the amount of each compound was 10 times greater. SFA and SFA10X were held in 200-ml glass jars. The third treatment was 120 ml of fermenting apple juice (FAJ), which was known to be attractive to the beetles (Mansfield and Hossain, 2004) and served as a standard for comparison. The traps were Magnet™ funnel traps (23 × 17 cm) and were hung at a height of 1.5 m. Each trap contained one bait jar, covered with fine mosquito net to exclude beetles, and a piece (1 cm²) of dichlorvos-impregnated insecticidal plastic strip.

Each test was set up as a 3 × 3 Latin square replicated twice ($N = 6$ for each treatment). Trap spacing was 20 to 24 m (traps in every fourth tree), and randomization was carried out at the beginning of each experiment. During the first experiment, all baits were replaced and trapped beetles were removed daily or on alternate days. During the second experiment, traps were serviced twice weekly. Trap catches were estimated volumetrically (200 beetles/ml), and species composition was determined (Dobson, 1954, 1964), based on a sample of 500 beetles per trap, or on the entire trap catch if it was <500. Trap catches were transformed to $\log(x + 1)$ to stabilize variance, and statistical analysis was carried out by using Genstat 5.42 (Genstat Committee, 2002). The Latin square design was subjected to ANOVA, using a repeated-measures model. Both treatment main effects and treatment-by-time interactions were fitted. Individual means were compared by *t*-tests when significant *F* values were obtained. The two field experiments were analyzed separately.

Results and Discussion

Initial Bioassay Observations

Responses of *C. davidsoni* in the wind tunnel were similar to results with *C. humeralis* (e.g., Bartelt and Zilkowski, 1998). Beetles initially crawled into corners and became motionless. However, with the lights on and the temperature at 28°C to 30°C, they began to fly spontaneously after 1 to 2 hr. Then, for as long as 4 to 6 hr, typically 50 to 100 beetles

would be airborne at any instant, even in the absence of attractants. Bioassay experiments were conducted only when this level of flight activity existed.

When an attractant was directed into the wind tunnel through the VDS, a characteristic response usually began within 20 to 30 sec. A “cloud” of hovering beetles formed at a location about 0 to 30 cm downwind of the paper disk and volatile outlet. Beetles slowly began to alight on the disk, and this landing activity intensified as the test continued. Beetles on the disk walked rapidly, and some attempted to enter the VDS outlet tube (prevented by a small-diameter opening). When the flow of volatiles from the VDS was turned off, the cloud of hovering beetles dissipated almost instantly and most of those on the paper disk took flight within a minute.

Beetles responded to the bioassay standard (containing acetaldehyde, ethanol, and ethyl acetate; see above). During 2 mo of bioassays, the standard mixture and control were compared 68 times, usually as part of larger experiments. Mean numbers of landings per 2-min test were 56.7 (\pm 28.5 SD) and 0.5 (\pm 0.6 SD), respectively (paired *t*-test on transformed counts, $t = 16.3$, $P < 0.001$). The absolute numbers of beetles responding to any treatment, including the standard mixture, differed somewhat between days and even from hour to hour because of variation in numbers of beetles in the wind tunnel, numbers actually in flight, and other factors. Blocking of experiments compensated for this variability.

Chemical Analysis and Attractiveness of Fruit Juice and Fruit

A key capability in this study was that airstreams from volatile sources could be both chemically analyzed and behaviorally evaluated within 1 or 2 hr, before an ephemeral volatile source had time to change. Thus, the chemical emission rate from a sample (in ng/min) became the chemical delivery rate into the wind tunnel, and a direct relationship could be established between chemical composition and behavior.

A typical GC profile for fermenting peach juice is shown in Fig. 1 (upper panel), and the chemical identifications, emission rates, and bioassay results are summarized in Table 1. This material was highly active in the wind tunnel, attracting nearly twice as many beetles as the standard. All six of the tested intact peaches and nectarines were demonstrably attractive in the wind tunnel, but attractiveness increased dramatically as the fruits became ripe or overripe (subjectively categorized by taste, smell, and softness). Correspondingly, chemical emissions became more abundant and more complex with ripening. GCs for two typical examples are shown in Fig. 1. Corresponding chemical identifications, emission rates, and bioassay results are summarized in Table 1. Based on bioassay landings, an unripe peach was about one fourth as attractive as the standard, whereas the overripe peach was over twice as attractive. All of the whole pieces of fruit showed the same general trend, but there were differences in the amounts and identities of compounds, especially the esters (data not given).

A property of this SPME method is that sensitivity increases dramatically with molecular weight (Bartelt, 1997; Pawliszyn, 1997), and this property must be kept in mind as chromatograms are examined; the largest GC peak does not necessarily represent the most abundant chemical. In the upper panel of Fig. 1, for example, the GC peak for ethyl octanoate (**15**) is far larger than that for acetaldehyde (**1**); yet, the actual emission rate for ethyl octanoate was less than one tenth of that for acetaldehyde (Table 1). Nevertheless, acetaldehyde (the most volatile analyte in this study) was still detectable by SPME whenever there was enough to elicit a behavioral response.

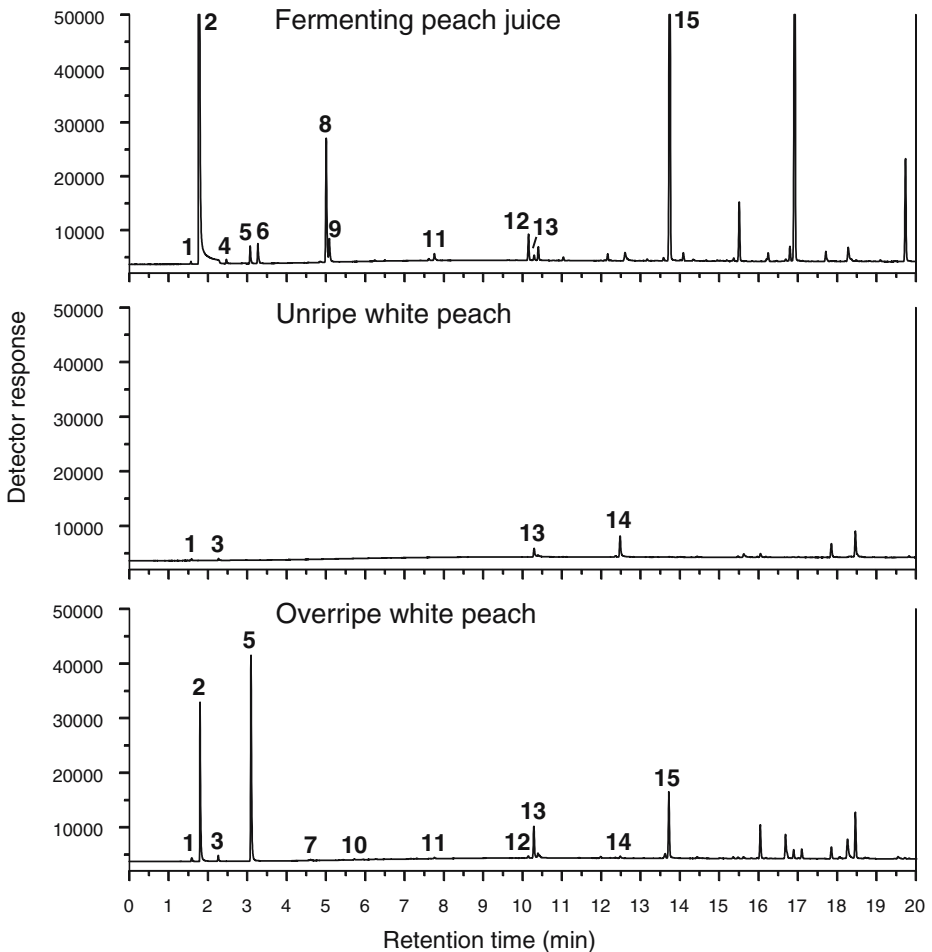

Fig. 1 SPME-GCs for three example sources of volatiles. Peak identifications as in Table 1

Clearly, a variety of volatile blends can be highly attractive to *C. davidsoni* (Fig. 1; Table 1). We used the fermenting juice as the primary model for developing a practical beetle attractant because canned peach juice was always available for laboratory work, whereas the fresh peaches were seasonal.

Effect of Fermentation Time on Activity and Chemistry of Fermented Juice

The chemical analyses and bioassay responses for fermenting peach juice of various ages are summarized in Table 2. Samples were generally similar with respect to volatile composition and bioassay activity, regardless of the length of time after inoculation, but the greatest activity and highest amounts of emitted esters and ethanol occurred after 1 to 2 days of fermentation. The peach juice used in the experiment showed some evidence of fermentation even before the addition of yeast, based on the amount of ethanol emitted, but no microbiological examination was made.

Synthetic mixtures that would mimic peach juice after 1 to 3 days of fermentation were prepared. There were at least 50 compounds emitted from fermented juice, but most of

Table 1 Emission rates of volatiles from fermented peach juice (1 d after inoculation), unripe peach, and overripe peach and corresponding bioassay activity

esters (a total of 10, see below) would be sufficient to account for the attraction of *C. davidsoni* to fermenting peach juice and that it would not be necessary to include all natural constituents.

Simulation of Fermenting Juice

Four simulations of fermenting peach juice are summarized in Table 3, with the natural juice and synthetic blend being matched as closely as possible with respect to 9 or 10 compounds and delivered at the 100% rate by the VDS. The bioassay comparisons were all favorable, and no differences between natural juice and synthetic blend were significant ($P > 0.6$).

A dose–response comparison was carried out for one simulation (set 3, see Fig. 2). The ANOVA model included terms for dose (five levels), volatile sample (two levels), dose-by-sample interaction, and replication of the experiment (“block”, four levels). Differences among the doses were dramatic ($F = 102$, $df = 4$ and 25 , $P < 0.001$), and response decreased smoothly as dose decreased. The responses to the synthetic blend were slightly lower than to the natural juice ($F = 4.54$, $df = 1$ and 25 , $P = 0.04$), but there was no good evidence that the lines in Fig. 2 were not parallel ($F = 0.88$ for the dose-by-sample interaction, $df = 4$ and 25 , $P = 0.49$). Two extreme data points (synthetic blend at 25% and 5% of maximum dose in the initial replication) were omitted from the analysis ($P < 0.005$ for outlier test).

The subtle difference between the curves for natural juice and synthetic blend was explored further with regression analysis, using $\log(x + 1)$ -transformed response data and \log -transformed doses. A single quadratic dose–response model was applied to both volatile samples, allowing, in addition, for differences among the four blocks ($R^2 = 0.927$ for this model, residual mean square = 0.0068). [The joint F statistic for the linear and

Table 3 Emission rates of compounds (ng/min) for four fermenting peach juice samples and the synthetic mixtures prepared to simulate them and corresponding bioassay comparisons

Fig. 2 Wind tunnel response to doses of a sample of fermenting peach juice and the synthetic blend prepared to simulate it. The various doses were generated by the VDS. Means ($N = 4$, except $N = 3$ for the synthetic blend at 25% and 5%) and standard errors (bars) were based on ANOVA after transformation of counts to $\log(x + 1)$, but the values were back transformed for presentation here. See text

quadratic terms, fitted last, was 198 ($df = 2$ and 32, $P < 0.001$), but subsequent addition of cubic and quartic terms gave no further significant improvement ($F = 2.06$, $df = 2$ and 30, $P = 0.15$). Then, the dose values for the synthetic blend were systematically adjusted until residual error for the model was minimized; conceptually, this process slid the curve for the synthetic blend in Fig. 2 along the X axis until it matched that for the natural juice as closely as possible. The minimum error was achieved when the doses for the synthetic blend were 86% of those for the natural juice (R^2 increased to 0.933 and residual mean square decreased to 0.0062, a residual error that was even smaller than in the initial ANOVA model, which was 0.0064). The calculated effective dose (86% of the natural juice) agreed remarkably well with the actual difference in total emission rates shown in Table 3 (83%), nicely accounting for the offset of the curves in Fig. 2.

More importantly, the well-behaved dose–response for set 3 suggested that the favorable bioassay comparison of natural and synthetic sources for all sets in Table 3 was genuine, rather than being an artifact of a “saturated” bioassay.

Importance of Components and Blend Optimization

Whereas the blend of 10 compounds was sufficient to account for the attractiveness of the fermenting juice, it was unknown if all 10 were necessary. Thus, the blend (specifically, set 4 in Table 3) was considered further in two portions, the five components formulated in water and the five formulated in oil. The GC traces of the natural model and the aqueous and oil synthetic formulations are shown in Fig. 3, and corresponding bioassay data are given in Table 4. The water formulation was strongly attractive by itself, but it was not as

Fig. 3 SPME-GCs showing a sample of fermenting peach juice 1 day after inoculation and the synthetic formulations (aqueous part and oil part) that together simulate the natural sample. Peak identifications as in Table 1

attractive as the whole blend. The oil formulation was barely attractive on its own, but it synergized the aqueous formulation, and the synthetic combination was as attractive as the natural juice sample. The same trend was seen for all four simulation blends described in Table 3 (data not shown).

The water formulation was examined further by preparing corresponding samples that contained just acetaldehyde, ethanol, or the three higher alcohols (2-methyl-1-propanol, 3-methyl-1-butanol, and 2-methyl-1-butanol; Fig. 4). When bioassayed individually, in pairs, or all together, it was clear that all three samples contributed to attraction (Table 5, upper portion). The best response was when the entire water formulation was reconstructed. However, no clear answer was obtained about the relative importance of the three higher alcohols (Table 5, lower portion). Adding any one of 2-methyl-1-propanol, 3-methyl-1-butanol, or 2-methyl-1-butanol to a blend of acetaldehyde plus ethanol elicited a response that was significantly greater than to just acetaldehyde plus ethanol. However, the response caused by adding all three at once was not obviously different from that caused by adding

^c Emission rate for ethanol (**2**) 30,000 ng/min.

^d Higher alcohols = 2-methyl-1-propanol (**6**) + 3-methyl-1-butanol (**8**) + 2-methyl-1-butanol (**9**). Emission rates for **6**, **8**, and **9** were 83, 210, and 42 ng/min, respectively.

^e Emission rate for 2-methyl-1-propanol (**6**) 68 ng/min.

^f Emission rate for 3-methyl-1-butanol 200 (**8**) ng/min.

^g Emission rate for 2-methyl-1-butanol (**9**) 27 ng/min.

just one of them. Given that all three of the compounds would be inexpensive to use, we decided to retain all three in the final blend.

Finally, the oil-soluble components were considered. From Table 4, the nonpolar components from fermenting peach juice were of marginal importance, but such components were generally more abundant in overripe fruit (Table 1) and efforts to enhance the blend further were guided by this finding. Bioassays with additional esters are summarized in Table 6. Ethyl acetate was the most effective of the treatments, and this was added to the blend for field testing. Because ethyl acetate is a small, relatively polar ester, it is moderately soluble in water. Therefore, it was possible to formulate all six blend components in water solution. Figure 5 shows an SPME-GC analysis of the final aqueous blend, along with the measured emission rates and concentrations of components in the water.

The final six-component blend is chemically similar to the three-component bioassay standard that was (arbitrarily) used when the research began. The final blend is more attractive than the bioassay standard, calculated from comparisons in the tables, although it contains lower amounts of the three components possessed in common (ethanol, acetaldehyde, and ethyl acetate). The three additional, higher alcohols present in the final

* For 10 ml solution under standard laboratory conditions

Fig. 5 SPME-GC of the final synthetic blend used for field tests and the corresponding compound emission rates and solution composition

blend (Fig. 5) clearly contribute to attractiveness, despite their low levels. Overall, the intense behavioral response to the minute amounts of airborne chemicals was remarkable.

Field Study

Carpophilus davidsoni was the dominant species, accounting for >95% of the trap catches, and all results below refer to this species. In the first test (Fig. 6, left side), there were overall differences in trap catch among the three attractants ($F = 10.4$, $df = 2, 6$, $P = 0.011$). Catches for SFA10X (untransformed mean of 10.3 beetles per trap per day) were larger ($P < 0.05$) than those for SFA or FAJ (untransformed means of 5.6 and 7.0, respectively), but the SFA and FAJ were not significantly different from each other. From analysis of variance, the treatment-by-day interaction was significant ($F = 2.48$, $df = 10, 75$, $P = 0.013$), indicating that the ratios of catches among treatments were not statistically consistent from day to day. However, the interaction had a relatively minor effect on trends in Fig. 6 (e.g., SFA10X always had the highest or second highest trap catch). On two of the eight test dates (December 5 and 6), all trap catches were zero due to cold weather; these days were omitted from the analysis because they gave no information about treatment differences.

The results for the second test were more dramatic, both in terms of trap catch and treatment differences (Fig. 6, right side; for treatment effect, $F = 97.0$, $df = 2, 6$, $P < 0.001$). The overall means for SFA10X, SFA, and FAJ were 206.3, 37.7, and 18.3 beetles per trap per day, respectively, after back transformation, and all of the treatment differences were significant ($P < 0.001$). Once again, the treatment-by-day interaction was significant ($F = 6.22$, $df = 16, 120$, $P < 0.001$) but was minor relative to main treatment effects (e.g., SFA10X was superior during each interval of the experiment; see Fig. 6). Key results were that the synthetic blends were at least as effective as FAJ throughout, and that the higher dose of the synthetic attractant was more attractive. For the range of doses tested, no saturation or inhibitory effect was seen.

The differences in results between the two field tests remain unexplained. The beetle population was lower during the first test, which at least partially accounted for the smaller trap catches, and different weather conditions likely contributed as well. More

Fig. 6 Average number of *Carpophilus* beetle caught in traps baited with different co-attractants during two tests in orchards. Test 1 was before fruit coloring (December 2–13), and test 2 was after fruit harvest (February 19–March 21)

interesting was the dramatic preference for the high dose of synthetic attractant in the presence of a dense, highly responsive beetle population. The practical potential of the synthetic blend is clear.

Relationship to Previous and Future Research

The results were similar to conclusions for previously studied *Carpophilus* spp.. Qualitatively, the attractant blend for *C. davidsoni* from this study (Fig. 5) included many or all of the same compounds as blends developed previously for *C. hemipterus* (Smilanick et al., 1978; Phelan and Lin, 1991), *C. lugubris* (Lin and Phelan, 1991), and *C. humeralis* (Bartelt and Wicklow, 1999; Bartelt and Zilkowski, 1998). The common thread is a general responsiveness to blends of volatiles associated with fermenting fruit or food products, including ethanol, acetaldehyde, and various other alcohols and esters. Considerable plasticity is apparent in composition of attractive blends, but use of blends rather than single compounds is always advantageous. Further improvements in attractiveness are likely possible by adding still other components, by adjusting blend proportions, or by increasing overall dose. Research is continuing to incorporate the synthetic blend into the killing station concept for practical beetle control. A key remaining need is a more practical formulation method than the water solutions used here that will still allow the six components to be released at appropriate rates.

Acknowledgments The authors thank Sorn Norng for some statistical analyses and Robert Bennet for technical assistance. We also thank Mamun Hossain and David Williams for constructive review of the manuscript and Horticulture Australia, Ltd., and the Department of Primary Industries, Victoria, for providing the financial support for the field portion of this work.

Based on this study, a new attractant system for green lacewings is being developed for both domestic and international markets.

Keywords Hoverfly · Attractant · Pheromone · Iridodial · Methyl salicylate · 2-phenylethanol · Nepetalactone · Nepetalactol · 1-tridecene · GC–EAD · Field flight behavioral assay

Introduction

Lacewings (Chrysopidae) are important predators of aphids and other soft-bodied insects (New, 1975; Tauber et al., 2000). Furthermore, because of their commercial availability and resistance to insecticides, green lacewings are also among the most commonly released predators for augmentative biological control (Ridgway and Murphy, 1984; Tulisalo, 1984; Aldrich, 1999). However, methods are still needed to retain the predators near augmentation sites and/or to attract wild predators to target areas (Baker et al., 2003).

Lacewings are attracted to semiochemicals from different trophic levels, including host plant volatiles (Flint et al., 1979; Zhu et al., 1999, 2005; Hooper et al., 2002); herbivore-induced plant volatiles, such as methyl salicylate (MS; James, 2003a,b, 2006; James and Price, 2004); and sex pheromones of scale insects (Mendel et al., 2003) and aphids (Boo et al., 1998, 2003; Hooper et al., 2002). In particular, some lacewings are attracted to certain isomers of nepetalactone and nepetalactol, which are components of aphid pheromones and are also found in the catnip plant (Lamiaceae: *Nepeta cataria* L.; McElvain et al., 1941). Recently, we identified a male-produced pheromone from the goldeneyed lacewing, *Chrysopa oculata* Say, the first pheromone for any lacewing (Zhang et al., 2004). The synthetic pheromone, (1*R*,2*S*,5*R*,8*R*)-iridodial (IRI; Chauhan et al., 2004), outperformed all other reported attractants for the green lacewings in the genus *Chrysopa*, and has potential for manipulating lacewings for pesticide-free control of garden and agricultural pest insects (Zhang et al., 2004).

Chrysopa nigricornis Burmeister is a large green lacewing distributed throughout the United States (Agnew et al., 1981). Similar to *C. oculata*, both the adults and larvae are predacious. It is the most common green lacewing species in the U.S. Pacific Northwest and is a useful component of integrated pest management programs in tree and vine crops such as hops (James, 2003a). To develop a pheromone-based attractant for this beneficial insect, we carried out a series of experiments in 2004 that focused on (1) pheromone production and perception in *C. nigricornis* with gas chromatographic–electroantennographic detection (GC–EAD) and gas chromatographic (GC)–mass spectrometric analyses; (2) field testing the newly identified pheromone and other known lacewing semiochemicals, such as MS, *Z,E*-nepetalactone (*ZE*-lactone), *Z,E*-nepetalactol (*ZE*-lactol), 2-phenylethanol (2PE), and various combinations of these compounds in garden and orchard environments; and (3) dispenser technology, including dispenser types and the duration of attraction.

Methods and Materials

Adult Insects and Preparation of Extracts

Adult lacewings for GC–EAD and GC–mass spectrometric analyses were collected during summer 2004 from either sticky Delta traps or nonsticky grapefruit-shaped plastic traps in

Spokane, WA. Lacewings recovered quickly from sticky surfaces of the traps and were still viable for EAD recordings. *C. nigricornis*, *C. oculata*, *C. coloradensis* Banks, and the common green lacewing, *Chrysoperla plorabunda* (Fitch; = *carnea*) were collected for EAD recordings, but only male *C. nigricornis* were collected from nonsticky traps for dissection and GC–mass spectrometer. Adults of these lacewings were processed within 6 to 20 hr of capture for GC–EAD and GC–mass spectrometric analyses. Adult male *C. nigricornis* were anesthetized with CO₂, eviscerated under tap water, and their thoracic cuticle was separated from their abdominal cuticle so that each body portion could be extracted individually in 50 µl of methyl *tert*-butyl ether. No head extracts were made because no glands had been previously reported from the heads of lacewings. All extracts were kept at –20°C until they were analyzed.

Gas Chromatographic–EAD and GC–Mass Spectrometric Analyses

Lacewing extracts and chemical standards were analyzed in splitless mode with a Varian CP-3800 GC equipped with a polar column (CP-Wax 52CB; 1.0 µm film thickness, 30 m × 0.53 mm i.d., Varian, Inc., Middelburg, the Netherlands), and a 1:1 effluent splitter that allowed simultaneous flame ionization detection and EAD of the separated volatile compounds. Helium was used as the carrier gas, and the injector temperature was 220°C. The column temperature was 30°C for 2 min, rising to 240°C at 10°C/min, and then held for 10 min. The outlet for the EAD was held in a humidified airstream flowing at 0.5 m/sec over an antennal preparation. EAD recordings were made by using silver wire-glass capillary electrodes filled with Beadle-Ephrussi Ringer (Zhang et al., 2000) on freshly cut antennae. The antennal signals were stored and analyzed on a PC equipped with a serial IDAC interface box and the program EAD version 2.5 (Syntech, Hilversum, the Netherlands). Antennally active peaks in the lacewing extracts were identified with a GC–mass spectrometer (Varian CP-3800 GC coupled to a Varian Saturn 2000 mass selective detector) operated in split mode (1:10) with a CP-Wax 52CB column (0.25 µm film thickness, 60 m × 0.25 mm i.d., Varian, Inc.), programmed at 30°C for 2 min, increasing to 240°C at 10°C/min, and then held for 10 min. Compounds were identified by comparison of mass spectra and retention times to those of authentic standards. In addition, EAD responses from male antennae of the four species noted above were recorded to a synthetic mixture (100 ng/µl each) containing five *C. oculata*-produced compounds (1-tridecene, nonanal, nonanol, nonanoic acid, and IRI); three compounds associated with aphid prey [(1*R*,4*aS*,7*S*,7*aR*)-nepetalactol, (4*aS*,7*S*,7*aR*)-nepetalactone (both sex pheromone components), and (4*aS*,7*S*,7*aS*)-nepetalactone (non-pheromone compound)]; and three herbivore-induced plant volatiles [MS, (*Z*)-3-hexenyl acetate (Z3HA), and benzaldehyde (BA)].

Chemical Standards

1-Tridecene (97%), 1-nonanol (97%), skatole (98%), MS (99%), 2PE (99%), Z3HA (98%), and BA (99.5%) were obtained from Aldrich Chemical (Milwaukee, WI); nonanal (99%) and nonanoic acid (98%) were from Emery Industries (Cincinnati, OH). (4*aS*,7*S*,7*aR*)-Nepetalactone and (4*aS*,7*S*,7*aS*)-nepetalactone are often referred to as *Z,E*- and *E,Z*-nepetalactone, respectively, in the literature (e.g., Hooper et al., 2002). *Z,E*-lactone (98%), *E,Z*-nepetalactone (96%), (1*R*,4*aS*,7*S*,7*aR*)-nepetalactol [ca. 90% *Z,E*-isomer (Hooper et al., 2002) with ca. 2% impurity of iridodial isomers], and the lacewing pheromone, IRI [80%; with 20% of (1*R*,2*S*,5*R*,8*S*)-iridodial as an impurity] were isolated or synthesized as described by Chauhan et al. (2004).

Field Trapping

Field-trapping experiments were carried out from early May through the end of September 2004 in either garden or small orchard environments in Spokane by using Pherocon VI traps (Trécé, Inc., Adair, OK) with removable sticky inserts. Traps were hung 1.0 to 1.5 m above the ground on either garden stakes or the branches of cherry (*Prunus*)/apple (*Malus*) trees ca. 5 to 10 m apart within each trap line. For each trapping experiment, two sets of traps (each set contained all treatments) were deployed with treatments allocated randomly to their initial trap positions within a set. The treatments were then systematically rotated among trap positions within a set after each replicate so that treatments appeared at least once per location (Latin-square design; Byers, 1991). To minimize positional effects, lacewing collections and trap rotations were carried out when two or more lacewings were caught in any trap. Each replicate lasted several days to 1 wk, depending on lacewing flight activity. The sticky inserts were taken to the laboratory to record species, gender, and catch.

Experiment 1 (May 7–August 3, 2004) was conducted to determine potential response to the newly discovered lacewing pheromone [from *C. oculata* (Zhang et al., 2004) and *C. nigricornis* (this article)], IRI (5 mg loaded onto rubber septa inserted into a 1.5-ml open plastic centrifuge tube; release rate not determined because of the low quantities emitted and the difficulty of applying the gravimetric method), and three other reported lacewing kairomone attractants, MS [2 g in a 12-mil (≈ 0.31 mm) polyethylene (PE) bag, Associated Bag Company, Milwaukee, WI, USA; 40×50 mm, with felt; with a release rate of ca. 30 mg/day, measured gravimetrically at 20 to 23°C in the laboratory], Z3HA (2 g in 4-ml open glass vial with 1/2 cotton ball; ca. 25 mg/day, measured gravimetrically at 20°C to 23°C in the laboratory), and 2PE [2 g in a 3-mil (≈ 0.076 mm) PE bag (40×50 mm) with felt; ca. 5 mg/day], in a full factorial experiment design with a total of 16 treatments (i.e., all individual compounds and all binary, ternary, and quaternary combinations). Each compound was loaded in a separate dispenser; thus, combinations have higher total releases than the individual treatments. Trap set 1 was deployed at a blackberry field (ca. 0.2 ha) in the Strawberry Hill Farm owned by Mr. Fallstorm that was surrounded by mixed pine (*Pinus*) forests. Trap set 2 was set up in Christensen's Cherry Orchard (ca. 0.4 ha) with typical agricultural land surroundings.

Experiment 2 (May 7–July 7, 2004) was similar to experiment 1, but tested BA [2 g in a 12-mil (≈ 0.31 mm) PE bag (40×50 mm) with felt; ca. 35 mg/day] in addition to the previous four individual compounds, along with selected combinations for a total of eight treatments. This study occurred in an urban setting in two smaller residential gardens (Florionovich and Rosengrant) in Spokane Valley, WA (one set of traps in each garden).

Experiment 3 (July 28–August 24, 2004), with a total of six treatments, compared the responses to IRI with ZE-lactone, *Z,E*-nepetalactol, the combination of IRI with MS (5 mg of each compound loaded onto rubber septa), and a commercial product, Benallure™ (Gardens Alive Inc., Lawrenceburg, IN, USA). This study occurred at Strawberry Hill Farm described above.

Experiment 4 (June 22–July 27, 2004), with a total of six treatments, tested the aging effect of IRI (5 mg) on rubber septum dispensers (aged from 0 to 5 wk). The dispensers were aged at ca. 20°C to 23°C in the laboratory hood with mild airflow (ca. 0.3 m/sec); the study occurred at Strawberry Hill Farm described above.

Experiment 5 (August 5–September 30, 2004) with a total of seven treatments, tested the aging effect of the combination of IRI (5 mg) and MS (1.5 g) in 6-mil (≈ 0.16 mm) PE bags (20×50 mm; with felt; aged from 0 to 5 wk). Fresh IRI (5 mg) rubber septum dispenser

[0(RS)] was included as a positive control. The study occurred at Christensen's Cherry Orchard described above.

Experiment 6 (September 1–30, 2004), with a total of four treatments, tested the response to IRI (5 mg), MS (1.5 g), and their combinations, using PE bag type dispensers (6-mil \approx 0.16 mm; 20 \times 50 mm; with felt; ca. 50 mg/d release for MS; release for IRI unknown). Combinations included IRI + MS-1, where both compounds were loaded in one PE bag and IRI + MS-2, where the two compounds were loaded in separate PE bags. The study occurred at Christensen's Cherry Orchard described above.

Statistical Analysis

For each experiment, data from the two sets of traps were pooled for statistical analysis because no block effects were found. Because of heterogeneity of variances among treatments, trap catch data (number of lacewings caught/trap/wk) were analyzed using the non-parametric Kruskal–Wallis ANOVA on rank test, followed by the Student–Newman–Keuls all pairwise comparison to separate means (Zar, 1984). The total trap catches between *C. nigricornis* and *C. oculata* within each experiment were compared by the χ^2 goodness of fit test at $\alpha = 0.05$.

Results

Gas Chromatographic–EAD and GC–Mass Spectrometric Analyses

Gas chromatographic–EAD analyses of extracts of thoracic and abdominal cuticle of male *C. nigricornis* (both forms: the western form with the entire antenna pale-white; the eastern form with the basal third of antenna dark; Penny et al., 2000) indicated no EAD responses by male antennae to any peaks from abdominal extracts (Fig. 1c), whereas two peaks from thoracic extracts elicited significant antennal responses by males of both forms (Fig. 1c; females were not available for testing). The two EAD-active compounds were identified as 1-tridecene and IRI by comparison of the mass spectra and retention times to those of authentic standards (for details, see Zhang et al., 2004). Other major components from the thoracic extracts were (*E*)-5-undecene, a C_{13} -hydrocarbon with two double bonds, 2-methylpropanoic acid, *N*-3-methylbutylacetamide, 2-methyl-1-*H*-indole, and skatole (3-methyl-1-*H*-indole), all of which elicited no EAD response (Fig. 1). GC–EAD analyses with male *C. nigricornis* antennae using synthetic mixtures showed that nonanal, MS, and IRI elicited higher EAD responses than did nonanol, 1-tridecene, *ZE*-nepetalactone, *EZ*-nepetalactone, *ZE*-nepetalactol, BA, or 2PE (Table 1). A similar EAD response pattern was also found for male *C. coloradensis*; however, its antennal responses to IRI were relatively weak compared with those of *C. nigricornis*. Antennae of male *Cl. plorabunda* showed similar EAD responses to most of the compounds in the synthetic mixture, but were unresponsive to IRI and its (8*S*)-stereoisomer (Table 1).

Field-Trapping Experiments

At least four species of green lacewings, *C. nigricornis* (both western and eastern forms; >75%), *C. oculata* (ca. 24%), *C. coloradensis* (<2%), and *Cl. plorabunda* (rare) were caught in the various treatments of all experiments. In addition, other beneficial insects,

such as the brown lacewing, *Hemerobius ovalis* Carpenter (total catch, 10), the hoverfly, *Metasyrphus americanus* (Weidemann; total catch, 100), and a few convergent lady beetles, *Hippodamia convergens* (Guérin-Méneville), were captured in the traps.

In experiment 1 (at Strawberry Hill Farm and Christensen's Cherry Orchard), a total of 495 *C. nigricornis* males and 192 *C. oculata* males were caught. More *C. nigricornis* were captured than *C. oculata* ($\chi^2 = 134$, $df = 1$, $P < 0.001$). There was an effect of treatment for males of both species (*C. nigricornis*: $H = 215.6$, $df = 15$, $P < 0.001$; *C. oculata*: $H = 149.7$, $df = 15$, $P < 0.001$), and traps baited with IRI alone or combined with other test compounds caught more males of both species than did unbaited traps (Fig. 2). MS, Z3HA, and 2PE alone were inactive. No females of either species were captured.

In experiment 2 (Florianovich and Rosengrant residential gardens), a total of 10 *C. nigricornis* males and 106 *C. oculata* males were caught and there was a treatment effect for both species (*C. nigricornis*: $H = 19.8$, $df = 7$, $P = 0.006$; *C. oculata*: $H = 68.3$, $df = 7$, $P < 0.001$). Again, traps baited with IRI alone or its binary combination with MS or BA were attractive to males of both species, whereas MS, Z3HA, 2PE, and BA were inactive when presented alone (Fig. 3). In contrast to experiment 1, traps baited with IRI alone or mixtures containing IRI caught more *C. oculata* than *C. nigricornis*, which may have been because of the habitat differences between the experimental sites ($\chi^2 = 79.1$, $df = 1$, $P < 0.001$).

In experiment 3 (Strawberry Hill Farm), 155 *C. nigricornis* males and 48 *C. oculata* males were caught. More *C. nigricornis* were captured than *C. oculata* ($\chi^2 = 56.4$, $df = 1$, $P < 0.001$). There was a treatment effect for both species (*C. nigricornis*: $H = 56.4$, $df = 5$, $P < 0.001$; *C. oculata*: $H = 44.8$, $df = 5$, $P < 0.001$). IRI attracted more males of both lacewing species than did ZE-lactol (Fig. 4). The number of *C. nigricornis* males in ZE-

Bars with the same letter within the same species indicate means that are not significantly different ($P > 0.05$), Kruskal–Wallis ANOVA on ranks, followed by the Student–Newman–Keuls all pairwise comparison test

Fig. 3 Captures of male *C. nigricornis* and *C. oculata* in traps baited with MS, IRI, Z3HA, 2PE, BA, and selected binary combinations; at Florianovich and Rosengrant residential gardens, Spokane Valley, WA, May 7 to July 7, 2004. Bars with the same letter within the same species indicate means that are not significantly different ($P > 0.05$), Kruskal–Wallis ANOVA on ranks, followed by the Student–Newman–Keuls all pairwise comparison test

Fig. 4 Captures of male *C. nigricornis* and *C. oculata* in traps baited with IRI, ZE-lactol, ZE-lactone, IRI + MS, and the commercial lacewing/lady beetle attractant, Benallure™ at Strawberry Hill Farm, Spokane, WA, July 28 to August 24, 2004. Bars with the same letter within the same species indicate means that are not significantly different ($P > 0.05$), Kruskal–Wallis ANOVA on ranks, followed by the Student–Newman–Keuls all pairwise comparison test

Fig. 5 Captures of *C. nigricornis*, *C. oculata*, and *C. coloradensis* in traps baited with aged PE bag dispensers loaded with 5 mg of IRI and 1.5 g of MS compared with the attraction to fresh rubber septa [0 (RS); loaded only with 5 mg IRI] at Christensen’s Cherry Orchard, Spokane, WA, August 5 to September 30, 2004. Bars with the same letter for *C. nigricornis* indicate means that are not significantly different ($P > 0.05$), Kruskal–Wallis ANOVA on ranks, followed by the Student–Newman–Keuls all pairwise comparison test. No further pairwise comparisons were made for *C. oculata* and *C. coloradensis* because no significant treatment effects were detected by ANOVA

Fig. 6 Captures of *C. nigricornis*, *C. oculata*, and the hoverfly, *M. americanus*, in traps baited with IRI, MS, and their binary blends in PE bag dispensers (IRI + MS-1: in the same PE bag; IRI + MS-2: in two separate PE bags) at Christensen's Cherry Orchard, Spokane, WA, September 1 to 30, 2004. Bars with the same letter within the same species indicate means that are not significantly different ($P > 0.05$), Kruskal–Wallis ANOVA on ranks, followed by the Student–Newman–Keuls all pairwise comparison test. No further pairwise comparisons for *M. americanus* took place because no significant treatment effects were detected by the ANOVA

lactol-baited traps was higher than that in the unbaited traps. ZE-lactone and the commercial attractant, Benallure™, were both inactive. Interestingly, addition of MS to IRI increased the trap catches for *C. nigricornis*, but not for *C. oculata* (Fig. 4).

In experiment 4 (Strawberry Hill Farm), all traps baited with 5 mg of IRI on rubber septa aged from 0 to 5 wk caught males of both *C. nigricornis* (59) and *C. oculata* (32). More *C. nigricornis* were captured than *C. oculata* ($\chi^2 = 8.01$, $df = 1$, $P = 0.005$), but there was no treatment effect in the experiment for either species (*C. nigricornis*: $H = 7.9$, $df = 5$, $P = 0.16$; *C. oculata*: $H = 9.04$, $df = 5$, $P = 0.11$).

In experiment 5 (Christensen's Cherry Orchard), traps baited with variously aged PE bag dispensers containing 5 mg of IRI plus 1.5 g of MS caught a total of 1150 *C. nigricornis*, 109 *C. oculata* males, 28 *C. coloradensis* males, 57 *M. americanus*, and 26 *H. convergens*. The ratio of eastern/western forms of *C. nigricornis* in the traps was ca. 1:3. More *C. nigricornis* were captured than *C. oculata* ($\chi^2 = 861$, $df = 1$, $P < 0.001$). There was a treatment effect in the experiment for *C. nigricornis* ($H = 30.1$, $df = 6$, $P < 0.001$), but not for *C. oculata* ($H = 1.56$, $df = 6$, $P = 0.96$) or *C. coloradensis* ($H = 10.2$, $df = 6$, $P = 0.12$). All *C. nigricornis* captured during the August and early September were males; however, from mid to late September, 23 out of the 63 caught (mostly the western form) were females. Trap catches for *C. nigricornis* seemed to decrease with the lure age (Fig. 5), but this decline was not statistically significant. The 0- to 5-wk-old PE bag dispensers were significantly (five to six times) more attractive to *C. nigricornis* than were the fresh IRI rubber septa dispensers [0(RS)], although the total loading of IRI was the same. Thus, the PE bag dispensers loaded with IRI and MS should stay attractive for at least 5 wk in the field.

In experiment 6 (Christensen's Cherry Orchard), a total of 61 *C. nigricornis* (41 males and 20 females), 18 *C. ocellata* males, and 28 *M. americanus* were captured during September 2004. More *C. nigricornis* were captured than *C. ocellata* ($\chi^2 = 23.4$, $df = 1$, $P < 0.001$). There were treatment effects for *C. nigricornis* ($H = 7.8$, $df = 3$, $P = 0.049$) and *C. ocellata* ($H = 9.32$, $df = 3$, $P = 0.025$), but not for *M. americanus* ($H = 1.87$, $df = 3$, $P = 0.60$). IRI (5 mg in PE bag dispenser) alone or combined with MS in the same PE bag (IRI + MS-1) or in separate PE bags (IRI + MS-2) were significantly more attractive to *C. nigricornis* than was MS alone (Fig. 6). No synergistic effect on *C. nigricornis* and *M. americanus* was found between IRI and MS; however, the combination of these two compounds in separate PE bags caught significantly more *C. ocellata* than did the IRI or MS alone (Fig. 6). More work is needed to confirm the effects of MS (with or without IRI) on both lacewing species.

Discussion

(1R,2S,5R,8R)-Iridodial was recently discovered as a male-produced pheromone of the goldeneyed lacewing, *C. ocellata*, and is believed to be produced in elliptical glands abundantly distributed between the third and eighth abdominal sternites of the males (Zhang et al., 2004). Our current study indicates that IRI is also a male-produced (females were not available for chemical analysis) pheromone for the green lacewing, *C. nigricornis*. It elicited an EAD response, and attracted conspecific males into traps. It also attracted some females late in the season. In contrast to *C. ocellata*, IRI was detected in *C. nigricornis* males from thoracic extracts, rather than from abdominal cuticle extracts. Thus, we expect pheromone-producing glands in the thorax of this species. Another antennally active compound from thoracic extracts of *C. nigricornis* males, 1-tridecene, was not field tested in the current study because it was reported as one of the defensive compounds produced in the thoracic glands of *C. ocellata* and reduced the numbers of *C. ocellata* males captured in IRI-baited traps (Zhang et al., 2004).

In addition to the responses of *C. nigricornis* and *C. ocellata*, a few males of *C. quadripunctata* (Zhang et al., 2004) and *C. coloradensis* (this article) were captured in the pheromone-baited traps. It is not known if these two species also use IRI or its isomers as pheromone components. The low-trap catches might be a result of either extremely low populations in the test areas or missing pheromone component(s) in the treatments. Recently, males of a Eurasian green lacewing species, *C. septempunctata* Wesmael, were also found to be strongly attracted to synthetic IRI (Zhang et al., 2006). Two other common green lacewing species from the genus *Chrysoperla*, *Cl. plorabunda* (= *C. carnea*) and *Cl. rufilabris* Burmeister, did not respond to IRI antennally or behaviorally in this and in a previous study (Table 1; Zhang et al., 2004).

Methyl salicylate is reportedly an attractant for both sexes of *C. nigricornis* and *C. ocellata* (James, 2003a, 2006) along with several other beneficial insects (James and Price, 2004). James and Price (2004) also recently found evidence for recruitment and retention of beneficial insects in grapes and hops by using controlled-release dispensers of MS, in Prossor, WA. However, in our study, in Spokane, WA, ca. 300 km northeast of Prossor, MS was inactive alone, but in a few instances enhanced the responses of *Chrysopa* spp. to IRI. MS alone and its binary blend with IRI attracted another beneficial insect, the hoverfly, *M. americanus*. Surprisingly, the commercial lacewing/ladybeetle attractant, Benallure™, did not catch any lacewings or other beneficial insects in our experiments. ZE-lactol was slightly

attractive to *C. nigricornis* and *C. oculata*, which might be because of the presence of small amount of IRI as an impurity, whereas ZE-lactone was inactive at the release rate tested.

If, indeed, some sympatric *Chrysopa* species share IRI as a pheromone component, there might be cross-attraction between species, which might undermine species isolation. However, earlier studies on acoustical communication of green lacewings showed that chrysopids produce species-specific, low-frequency, substrate-borne vibrations that guide the conspecifics to one another on a plant (Henry, 1982). Comparative acoustical studies of *Chrysoperla* versus *Chrysopa* species indicated that *Chrysoperla* spp. [*C. rufilabris*, *C. carnea* (Stephens), and *C. downesi* (Smith)] are more dependent on acoustic signals for mating success than are *Chrysopa* spp. (*C. oculata* and *C. chi* Fitch; Henry, 1979, 1980a, b, c). Thus, species of *Chrysoperla* rely on acoustic communication with no obvious role for pheromones, whereas *Chrysopa* species communicate with pheromones at long range and, to a lesser extent than *Chrysoperla*, with species-specific acoustic signals at short range for courtship and isolation from sympatric species. Adults of *Chrysopa* (*sensu stricto*) are predacious, whereas adults of *Chrysoperla* are phytophagous (Principi and Canard, 1984), suggesting that predation in the adult stage somehow favors chemical communication or selects against communication by substrate vibration.

Surprisingly, no females of *C. oculata* were caught during any of our current tests nor in the experiments carried out by Zhang et al. (2004), although antennae from the females were as sensitive to IRI and other male-produced compounds as were the antennae of males (Zhang et al., 2004). Sweep netting and live insect counting at a soybean field in 2004 at Beltsville, MD, showed that IRI not only attracted *C. oculata* males, but also females to the pheromone-baited plots (Chauhan et al., unpublished data). However, unlike males, the females did not completely approach and enter the traps, possibly because females call males acoustically at close range or females require male-produced, species-specific acoustical signals for close-range communication. Similar to *C. oculata*, no females of *C. nigricornis* were captured in IRI-baited traps during the summer season; however, in the early fall (September), some *C. nigricornis* females were captured in IRI or IRI/MS-baited traps.

Our field testing indicated that the lacewing pheromone, IRI, loaded onto either rubber septa or its binary blend with MS in PE bags remained attractive for at least 5 wk in the field during the mid-summer season for both *C. nigricornis* and *C. oculata*. Synthetic lacewing pheromone IRI or its combination with MS (the herbivore-induced plant volatile) attracts and retains both male and female lacewings to treated areas, which will probably elevate the local lacewing population (Chauhan et al., unpublished data). Furthermore, the more males attracted to the treated area, the more natural pheromone would be released by males, further strengthening attraction and potentially enhancing biological control. Moreover, IRI and MS or their binary blend also attract many other beneficial insects, such as hoverflies, lady beetles, and predatory bugs (James and Price, 2004 and this article). Based on this study, a new lacewing attractant/trap system is being developed for both domestic and international markets. This product will have potential for manipulating natural or artificially augmented populations of lacewings and other beneficial insects to enhance biological control of garden, agricultural, and forest pest insects.

Acknowledgments We thank Dr. Oliver S. Flint, Jr. (Section of Entomology, Smithsonian Institution, Washington D.C.) and Dr. N. D. Penny (Department of Entomology, California Academy of Sciences, San Francisco, CA) for identifications of lacewings and other insect species; and Mr. Fallstrom, Mr. Christensen, Mr. Florianovich, and Mr. Rosengrant (in Spokane, WA) for allowing us to carry out our field-trapping experiments on their property.

stereomeric purity >94% showed the highest attractivity. The presence of 5% of the *Z,Z* isomer in the lure did not induce any synergistic or inhibitory effect, and the alcohol precursor of the pheromone was inactive. The results show that use of a stereomerically pure pheromone may not be necessary in pest control strategies.

Introduction

Sweet potato, *Ipomoea batatas* (L.) Lam., is one of the seven most important food crops worldwide, with an estimated annual production of 115 million metric tons (FAO, 1984). It is grown in more than 100 countries with 98% of the world production proceeding from developing countries (Jansson and Raman, 1991). One of the most important constraints that limit sweet potato production worldwide are the pre- and postharvest losses from insect feeding, especially the sweet potato weevils *Cylas formicarius* (Fabricius), *C. puncticollis* (Boheman), and *C. brunneus* (Fabricius) (Jansson and Raman, 1991). *C. formicarius* [= *C. f. elegantulus* (Summers)] abounds in more than 50 countries in tropical and subtropical regions and is the most devastating pest of sweet potato worldwide (Chalfant et al., 1990). In response to insect feeding, sweet potato tissue produces toxic sesquiterpenes that induce an extremely bitter taste in the roots, rendering it unfit for consumption (Akazawa et al., 1960; Sato et al., 1981). For this reason, even low population densities may cause devastating crop losses, i.e., yield losses of between 60% and 100% in many developing countries. Owing to the cryptic character of these weevils, insects are difficult to control with conventional insecticides, and growers in many countries have tried to reduce populations primarily by cultural practices and, more recently, through biological control (Jansson, 1991).

The sex pheromone of *C. f. elegantulus* was identified by Heath et al. (1986, 1988) as (*Z*)-3-dodecenyl (*E*)-2-butenolate (**1**) from a laboratory-reared colony. In this paper, we present the pheromone analysis of feral insects from Cuba, the first scanning electron microscopy (SEM) studies on insect antenna, new electrophysiological and behavioral responses to the pheromone in a double dual-choice olfactometer, and activity of several pheromone formulations in the field.

Methods and Materials

Insects

Weevils were collected in infested sweet potato fields near the Instituto de Investigaciones Fundamentales (INIFAT; Santiago de las Vegas, Cuba). They were sexed, fed with commercial sweet potato, and sent to Barcelona, Spain, for pheromone analysis and biological and electrophysiological activity. They were kept in a climatic chamber on a 16:8 L/D photoperiod.

Solid Phase Microextraction

Commercial fibers of polydimethylsiloxane (7 and 100 μm thickness) (Supelco Inc., Bellefonte, PA, USA) were previously conditioned in a Carlo Erba 6000 gas chromatograph

at 250°C injector temperature for 1 hr. The fiber was introduced into a Teflon-coated screw-top glass vial containing batches of 26–90 virgin females. Volatiles emitted by the insects were adsorbed for 24 hr at room temperature and desorbed in the injector port of a ThermoQuest gas chromatograph coupled to a Trace MS ThermoQuest mass selective detector. The gas chromatography (GC) conditions used were injection in splitless mode on an HP-5 MS capillary column (30 m × 0.25 mm ID × 0.25 μm) at 60°C for 5 min, and then programmed to 230°C at 5°C/min. The GC-mass spectrometry (MS) was run under SIM mode of ions of m/z 166, 138, 96, 87, and 69.

Chemicals

Synthesis of pheromone **1** was carried out by esterification of (*Z*)-3-dodecen-1-ol (**2**), which was prepared from MOM-protected 3-butyn-1-ol (**3**) (Scheme 1). A solution of 4-methoxymethoxy-1-butyne (**3**) (0.5 g, 4.3 mmol) in anhydrous tetrahydrofuran (THF) (3.5 ml) was cooled to −20°C. Then, a freshly prepared 0.5 M solution of LDA (8.8 ml, 4.3 ml) was slowly added. The solution was stirred for 10 min at −20°C and 1 hr at room temperature. A solution of 1-bromooctane (0.83 g, 4.3 mmol) in a mixture of anhydrous THF (2 ml) and anhydrous 3,4,5,6-tetrahydro-2-(1*H*)-pyrimidinone (DMPU) (3 ml) was added, and the mixture stirred for 3 hr. THF was evaporated under vacuum, and the residue was poured over ice/water. Organic material was extracted with hexane, washed with water, and dried (Na₂SO₄). After evaporation of the solvent, the residue was purified by flash column chromatography over neutral alumina III to obtain the condensation product **4** (0.6 g, 65%) in pure form. ¹H NMR δ 4.65 (s, 2H, OCH₂O), 3.61 (t, $J = 6.9$ Hz, 2H, CH₂O), 3.37 (s, 3H, CH₃O), 2.46 (tt, $J = 6.9$, $J' = 2.4$ Hz, 2H, C ≡ CCH₂), 2.14 (tt, $J = 6.9$, $J' = 2.4$ Hz, 2H, CH₂C ≡ C), 1.46 (m, 2H, CH₂CH₂C ≡ C), 1.26 (br, 10H, 5CH₂), 0.87 (t, $J = 6.7$ Hz, 3H, CH₃) ppm. ¹³C NMR δ 95.5, 80.9, 77.3, 65.8, 54.5, 31.1, 28.5, 28.4, 28.3, 28.1, 21.9, 19.6, 17.9, 13.8 ppm. MS (EI) m/z (%): 226 (M⁺, 1). Elem. Anal. Calcd. for C₁₄H₂₆O₂: C, 74.28, H, 11.58; Found: C, 74.22, H, 11.56. A mixture of compound **4** (0.211 g, 0.93 mmol), MeOH (2 ml), and 12 M HCl (0.21 ml) was stirred at room temperature for 24 hr. The solvent was evaporated and

i: LDA/THF; ii: BrC₈/THF-DMPU; iii: HCl 12M/MeOH; iv: H₂, Lindlar cat/quinoline/hexane; v: crotonyl chloride/CH₂Cl₂

Scheme 1 Synthesis of pheromone **1** by esterification of (*Z*)-3-dodecen-1-ol (**2**)

the residue was extracted with CH_2Cl_2 and washed with NaHCO_3 sat solution. Usual workup and purification by flash column chromatography over neutral alumina III furnished compound **5** (0.153 g, 91%). IR ν 3340, 2220 cm^{-1} . ^1H NMR δ 3.67 (dt, $J = J' = 6.3$ Hz, 2H, CH_2O), 2.43 (tt, $J = 6.3$, $J' = 2.4$ Hz, 2H, $\text{C} \equiv \text{CCH}_2$), 2.15 (tt, $J = 7$, $J' = 2.4$ Hz, 2H, $\text{CH}_2\text{C} \equiv \text{C}$), 1.81 (t, $J = 6.3$ Hz, 1H, OH), 1.48 (m, 2H, $\text{CH}_2\text{CH}_2\text{C} \equiv \text{C}$), 1.26 (br, 10H, 5 CH_2), 0.88 (t, $J = 6.75$ Hz, 3H, CH_3) ppm. ^{13}C NMR δ 82.7, 76.2, 61.3, 31.8, 29.2, 29.1, 28.9, 28.8, 23.1, 22.6, 18.7, 14.05 ppm. MS (EI) m/z (%): 182 (M^+ , 2). Alkynol **5** (0.59 g, 3 mmol) was hydrogenated with Lindlar (Pd-CaCO_3) catalyst (20 mg) in hexane (3 ml) and two drops of quinoline at atmospheric pressure and room temperature. The reaction was monitored by GC with an HP-5 capillary column (0.33 μm , 25 m \times 0.20 mm ID). The crude was filtered through Celite, and after usual workup, compound **2** (0.54 g, 91%) was obtained with a stereomeric purity Z,E 99/1. IR ν 3334 cm^{-1} . ^1H NMR δ 5.56 (m, 1H, $\text{HC}=\text{}$), 5.35 (m, 1H, $=\text{CH}$), 3.64 (t, $J = 6.5$ Hz, 2H, CH_2O), 2.33 (c, $J = 6.5$ Hz, 2H, $=\text{CCH}_2$), 2.05 (c, $J = 6.6$ Hz, 2H, $\text{CH}_2\text{C}=\text{}$), 1.70 (s, 1 H, OH), 1.26 (br, 12H, 6 CH_2), 0.87 (t, 3H, $J = 6.75$ Hz, CH_3) ppm. ^{13}C NMR δ 133.6, 124.9, 62.3, 31.9, 30.8, 29.7, 29.5, 29.3, 29.2, 27.4, 22.7, 14.1 ppm. MS (EI) m/z (%): 184 (M^+ , 0.4), 166 ($\text{M}^+ - \text{H}_2\text{O}$, 12). A mixture of crotonyl chloride (0.19 ml, 2 mmol) and alcohol **2** (0.3 g, 1.6 mmol) was dissolved in CH_2Cl_2 (3 ml) and cooled to 0°C. Pyridine (0.16 ml, 2 mmol) in CH_2Cl_2 (3 ml) was added dropwise to the solution, and the mixture was stirred at 0°C for 1 hr (Heath et al., 1986). Usual workup and purification over flash column chromatography on silica gel yielded compound **1** (0.23 g, 57%), as a mixture of isomers (3*Z*)-**1** and (3*E*)-**1** with the *E* stereochemistry of the double bond at the acid side and the isomer containing the two double bonds with *Z* stereochemistry in 94:1:5 ratio, respectively. IR ν 1724, 1660, 968 cm^{-1} . ^1H NMR δ 6.97 (dq, $J = 15.6$, $J' = 6.9$ Hz, 1H, $\text{OCCH} = \text{CH}$), 5.84 (dq, $J = 15.6$, $J' = 1.75$ Hz, 1H, $\text{OCCH} = \text{CH}$), 5.50 (m, 1H, $\text{HC}=\text{}$), 5.35 (m, 1H, $=\text{CH}$), 4.12 (t, $J = 6.75$ Hz, 2H, CH_2O), 2.40 (m, 2H, $=\text{CCH}_2$), 2.03 (m, 2H, $\text{CH}_2\text{C}=\text{}$), 1.87 (dd, $J = 6.9$, $J' = 1.75$ Hz, 3H, $=\text{CCH}_3$), 1.26 (br, 12H, 6 CH_2), 0.88 (t, $J = 7.0$ Hz, 3H, CH_3) ppm. ^{13}C NMR δ 166.6, 144.6, 132.9, 124.3, 122.7, 63.7, 31.9, 29.6, 29.5, 29.3, 27.3, 26.9, 22.7, 18.0, 14.1 ppm; MS (EI) m/z (%): 166 ($\text{M}^+ - \text{CH}_3 - \text{CH} = \text{CH} - \text{COOH}$, 76).

For field tests, samples of 3-dodeceny (*E*)-2-butenate were prepared as mixtures of (3*Z*)- and (3*E*)-dodeceny crotonate in several ratios through Wittig reaction of 3-hydroxypropyltriphenylphosphorane with nonanal, or by reaction of methylenetriphenylphosphorane with ethylene oxide followed by metallation and Wittig reaction with nonanal (Maryanoff et al., 1985).

Scanning Electron Microscopy

The head of a freshly sacrificed weevil was cut, fixed on a stub with conductive glue, air-dried, and metalized. Observations were performed on a Jeol JSM 840 SEM at 5 eV.

Electrophysiological Activity

Electroantennogram (EAG) responses were recorded under standard techniques by using a pair of glass microelectrodes filled with Ringer's saline (Guerrero et al., 1986). The tip of the antenna club was cut off, the reference electrode was introduced into the base of the head, and the recording electrode was slipped into the open tip of the antenna. A flow of humidified air (900 ml/min) was continuously directed over the antenna, and olfactory stimuli were delivered by puffing air (300 ml/min) with a CS-1 stimulus generator (200 ms

duration; Syntech, Hilversum, The Netherlands) through a Pasteur pipette directly into the main stream of the air. The pipette contained a small filter paper on which several amounts (0.001–1 μg) of the pheromone were deposited. All experiments were performed with the synthetic pheromone **1** having the highest stereochemical purity (mixture of isomers *Z,E* and *E,E* in a 98:2 ratio). Control puffs (pure air) were intercalated between two consecutive pheromone stimuli to determine the real depolarizations to the attractant. Responses from the antenna were amplified (1000 \times), filtered (DC to 1 kHz) with an IDC 02 interface (Syntech), digitized on a PC, and analyzed with the EAG 2.6 program (Syntech).

Olfactometer Bioassay

For behavioral studies, a dual-choice olfactometer consisting of two methacrylate-based plates of 20 \times 20 cm adjusted to each other by four plastic screws was built. The upper plate contained a hole (diam 5.5 cm) in the center that allowed us to suck out the air of the system via an ordinary vacuum pump. The vacuum allowed volatiles from the vials to reach the test insects, which had been initially placed in groups of 4–5 in the center of the chamber. Each of the four olfactometer sides had an outlet with a Tygon[®] hose adjusted to a glass vial. Each vial contained a piece of paper impregnated with a bait (pheromone) or blank (hexane) so that the two baited vials were surrounded by two control vials in an alternate form. The number of insects that reached each arm of the olfactometer was counted, and the percentage of responses with regard to the total number of insects was calculated. The apparatus was rotated 90 $^\circ$ after each assay so that the vials occupied all four possible positions in each assay. By rotating the system, any photokinetic side effect induced by indirect light coming into the chamber was avoided. The experiments were performed in the dark, and the chamber was thoroughly cleaned with 96% ethanol after every assay. To establish the optimum response of males, 10 insects were released and their responses to 10 ng pheromone recorded at different times of the scotophase. Eight replicates were done for each assay. Responses of males of the 6th hr into the scotophase to several pheromone doses (0.1 to 10,000 ng) were also recorded, and 10 replicates with 10 insects/replicate were run for each dose. For comparison, the activity of a commercial sample (50 ng) was also determined (12 replicates with 10 insects/replicate).

Field Tests

Field experiments were conducted in 1-ha infested sweet potato fields at the Cuban Institute of Tropical Agricultural Research (Santiago de las Vegas, Cuba) (July–August 2000–2001). The traps were made with the materials available in the country. Two thick 50-cm-long iron bars supported an open square iron box at an approx. height of 45 cm from the floor. Two opposite sides of the box were covered with a plastic sheet impregnated with Tanglefoot[®]. The roof of the trap was cardboard covered with aluminum foil, from which a thin wire was suspended with a rubber septum (Aldrich, Milwaukee, WI, USA) loaded with 1 mg of the formulation. In the lower part of the trap and ca. 10 cm from the ground, another plastic sheet impregnated with Tanglefoot[®] helped to increase trap catch. The distance between the traps was 15 m. The insects caught were counted daily for 1 mo, and the traps were rotated once a week. Traps were randomly placed within the plots, and 3 replicates per formulation were considered. Septa loaded with hexane served as controls. For the tests, formulations were designated in terms of the stereochemical purity of the pheromone used; and thus, for instance, a formulation *Z,E/E,E* 95:5 refers to a bait containing a mixture of the two isomers (*Z,E*)-**1** and (*E,E*)-**1** (the letters refer in this order to the stereochemistry of the double bond at the alcohol side and the acid side, respectively) in 95:5 ratio.

Statistical Analysis

Behavioral data were analyzed by the χ^2 homogeneity test ($P < 0.05$). EAG depolarizations were analyzed by Student's t -test ($P < 0.05$). Field data were transformed ($\sqrt{x + 0.5}$) and analyzed for significance via Student's t -test ($P < 0.05$).

Results and Discussion

(*Z*)-3-Dodecenol (**2**) has been documented as a candidate trail-following semiochemical for several termite species (Argenti et al., 1994) as well as the major component of the trail-following pheromone of the fungus-growing termite *Macrotermes annandalei* (Peppuy et al., 2001). In an attempt to develop a simple procedure of preparation of (*Z*)-3-dodecenol (**2**) that could be adapted and scaled up in Cuba for larger treatments, a similar procedure to that described by Lo et al. (1992) was developed. In our case, we protected 3-butyn-1-ol as the corresponding MOM ether (**3**) instead of the tetrahydropyranyl (THP) derivative (Lo et al., 1992) since MOM compounds are simpler and provide NMR spectra that are easier to interpret than THP ethers. Therefore, MOM-protected butynol **3** was alkylated with 1-bromooctane in THF–DMPU in the presence of LDA [the alkylation reaction with sodamide as base in ammonia (Lo et al., 1992) failed in our hands] to provide acetylenic derivative **4** in 65% yield. When MeLi or *n*-BuLi was used as base, 1-dodecen-3-yne was obtained as by-

The mass spectrum was run in SIM mode of selected ions (see text). GC conditions: injection in “splitless” mode at 60°C for 5 min and then program to 230°C at 5°C/min

product in 10 – 30% yield. This compound has not hitherto been described in such a process, but a similar case was reported when the THP-protected 1-butynol was subjected to alkylation for the synthesis of the sex pheromone of the tomato pest *Scrobipalpaloides absoluta* (Svátos et al., 1993). Hydrolysis of the MOM group followed by partial hydrogenation with Lindlar catalyst/quinoline furnished dodecenol **2** in good overall yield (53.8%) and excellent

stereochemistry (*Z/E* 99:1). Esterification of alcohol **2** with crotonyl chloride/pyridine in CH_2Cl_2 (Heath et al., 1986) afforded the expected pheromone **1** in 57% yield.

Characterization of the Pheromone

Because of the expected low contents/release of pheromone in sweet potato weevil females of other origins (Heath et al., 1986), solid-phase microextraction (SPME) was considered for identifying the pheromone. The first report of the utilization of SPME in pheromone analysis was in monitoring the diel rhythm of emission of airborne volatiles from the sugar cane weevil *Metamasius hemipterus* (Malosse et al., 1995). Since then, other examples of applications have been reported (Frérot et al., 1997; Rochat et al., 2000; Peppuy et al., 2001).

In our case, analysis of an extract of volatiles from 90 virgin females, adsorbed for 24 hr on a 100 μM fiber, by GC-MS under SIM conditions of ions of *m/z* 166, 138, 96, 87, 69 confirmed the presence of the pheromone **1** when compared with an authentic sample (Fig. 1). The selected ions had been previously noted as major or characteristic fragments in the ms of the synthetic pheromone (Lo et al., 1992). The amount of pheromone present in the volatile extract was estimated as 1.8 ng, i.e., 20 pg of pheromone emitted per female every 24 hr. Trials to detect the pheromone by rubbing the syringe over the abdomen of virgin females were unsuccessful. Likewise, an SPME extract of 30 female volatiles gave no response when using the male antenna as detector [GC-electroantennographic detection

Fig. 3 Dose-response depolarizations of *Cylas formicarius elegantulus* male antennae to several amounts of pheromone **1**. Error bars are standard errors. Bars followed by the same letter are not significantly different (Student's *t*-test, $P < 0.05$)

(EAD)], probably as a result of the high threshold and low EAG amplitude shown by this insect.

Electrophysiology

Male and female antennae comprise a scape, a pedicel, and a flagellum with nine subsegments. The first eight subsegments of the flagellum are short, whereas the last one is considerably larger. This last distal subsegment is club shaped in females and elongated in males. The following types of sensilla were found on the male distal flagellum segment: sensilla trichoidea type 1 (ST1) as long hairs of 100–150 μm; sensilla trichoidea type 2 (ST2) as short hairs of 50–60 μm; sensilla basiconica type 1 (SB1) as thick pegs of 20–25 μm; sensilla basiconica type 2 (SB2) as curved pegs of 10–15 μm, and sensilla basiconica type 3 (SB3) as thin and straight short pegs of 15–20 μm (Fig. 2). The same types were observed on female antennae, but ST1 are less abundant than on male antennae. Sensilla chaetica were also found on the first eight flagellum subsegments in both sexes. Although we did not run single sensillum recordings to confirm that sensilla trichoidea house the olfactory receptor neurons for pheromone detection, we may assume that ST1 are probably the most likely sites for pheromone detection for the following reasons: (1) the pheromone is emitted by females; (2) only males are attracted by the pheromone both in the laboratory and in the field; (3) male antennae show sensitivity to the pheromone on EAG but not female antennae; and (4) ST1 are more abundant in male antennae.

EAG responses of a male antenna to the synthetic pheromone 1 were generally small, as expected from such a type of antenna, but typical depolarizations of 0.6–0.8 mV were nevertheless obtained with puffs on 1 μg of pheromone. A dose–response plot with puffs on 0.001–1 μg of pheromone is shown (Fig. 3), with higher doses inducing higher

Fig. 4 Responses of *Cylas formicarius elegantulus* males to 10 ng of synthetic pheromone 1 at different times of the scotophase compared with control (hexane). Bars followed by the same letter are not significantly different (χ^2 homogeneity test, $P < 0.05$)

depolarizations as expected. Female antennae did not show any response even at a 100- μ g dose.

To determine the specificity of the crotonate ester on the antennal response, the formate, acetate, propionate, and butyrate esters of (*Z*)-3-dodecenol were prepared by standard methods (not shown), and their possible electrophysiological activity was tested. None of the analogues elicited EAG responses from male antennae, which demonstrates the key role played by the crotonate function on pheromone activity. In this regard, negligible attractant activity in the field by the butyrate ester has also been reported (Heath et al., 1991).

Behavior

To assess the behavioral response of males to the synthetic pheromone, we developed a double dual-choice olfactometer based on a four-armed bioassay designed by Vet et al. (1983) to measure olfactory responses of hymenopterous parasitoids. Preliminary experiments showed that the insects made the best choice between pheromone and blank vials after exposure for 3 min. We found that the difference in response to pheromone and control generally increased with the time of the scotophase, being highest at the 8th hr (70% of insects walked to the pheromone vials vs. 30% that moved towards control vials) (Fig. 4). Nevertheless, the responses were significantly different from the 4th hr, indicating that the maximum activity of males was between the 4th and the 8th hr of scotophase.

As regards the effect of pheromone dose, low amounts of pheromone (0.1–1 ng) induced no behavioral preference for any particular arm of the olfactometer. However, higher doses, particularly 50–1000 ng, elicited significantly higher responses (70–75%) on males orienting to the two sources (Fig. 5). Higher doses (10,000 ng) inhibited male response. The

Fig. 5 Responses of *Cylas formicarius elegantulus* males to several pheromone doses at the 6th hr of the scotophase compared with control (hexane). Bars followed by the same letter are not significantly different (χ^2 homogeneity test, $P < 0.05$)

Fig. 6 Number of *Cylas formicarius elegantulus* males caught in traps baited with different pheromone formulations. Bars containing the same letter are not significantly different according to the Student's *t*-test ($P < 0.05$). Tests were performed in infested sweet potato fields in Santiago de las Vegas (Cuba) (July–August 2000, 2001)

commercial pheromone (Pherobank, Wageningen, The Netherlands) induced males at the same level of preference (70%) vs. control as our synthetic material (results not shown).

One drawback of the system could be the confined space in which insects are exposed to stimuli. This can be offset by using a sufficient number of individuals and replicates to obtain statistically significant responses. In addition, although in our olfactometer insects had to choose between two pheromone vials and two blanks (50% choice); in principle, our system could also allow them to discriminate between one, two, or three odors simultaneously. Moreover, the setup could determine the effect of the stimulus (attraction or repellency).

Field Tests

A number of reports on the attractiveness of the pheromone in the field have been described (Talekar and Lee, 1989; Jansson et al., 1990, 1992; Mason et al., 1990; Yasuda et al., 1992; Pillai et al., 1994). Here, we studied the effect of the stereomeric purity of the pheromone. We found in the first-year experiments that the formulation of the highest stereochemical purity was the most effective. The commercial sample (mixture of isomers *Z,E* and *E,E* in a 98:2 ratio) caught more males than the formulation with the same mixture of isomers in a 92:8 ratio, which in turn was more active than formulations with a blend of isomers in ca. 40:60 ratio (Fig. 6).

In the following year, although formulations containing the *Z,E* isomer in the range 94–98% were as active as the commercial pheromone, the bait containing a blend of the *Z,E* and *E,E* isomers in a 40:60 ratio was again inferior. In both experiments, as noted previously by other authors, a clear correlation between the content of the *Z,E* isomer with activity was apparent. The pheromone sample containing 5% of the *Z,Z* isomer induced no synergistic or inhibitory effect, and the alcohol precursor of the pheromone was inactive. These results contrast with those of Jansson et al. (1992) who reported that pheromone purities between 75% and 98% did not consistently affect weevil collections in traps, although some significant effects of purity were observed when trap counts were lower. In line with our results, Yasuda et al. (1992) reported that the activity of the synthetic pheromone was not inhibited by the addition of up to 10% of the *E,E* isomer. We suggest that the use of a stereochemically pure pheromone may not be necessary for future pest control strategies, and that formulations containing the active *Z,E* isomer with 94–95% stereomeric purity may be preferable owing to their easier availability and lower cost.

In summary, the sex pheromone of feral sweet potato weevil of a Cuban population has been confirmed as (*Z*)-3-dodecenyl (*E*)-2-butenate, as previously reported from a laboratory-reared colony (Heath et al., 1986). The synthetic compound elicited electrophysiological and behavioral activity in the laboratory and was highly attractive in the field, highlighting its potential utilization for pest control on the island. In this context, it is worth noting that the utilization of the pheromone in an IPM strategy in India has resulted in a considerable reduction of damage, leading to an increased production of marketable tubers by 53% (Pillai et al., 1993).

Introduction

The pine weevil, *Hylobius abietis* (L.) (Coleoptera: Curculionide), is a severe pest of newly planted forest trees in large parts of Europe and Asia (Långström and Day, 2004). Adult weevils girdle and kill planted conifer seedlings by feeding on the bark of the stem (Day et al., 2004). If no countermeasures are taken, this frequently results in more than 80% seedling mortality in the first two years after planting (Örlander and Nilsson, 1999; Petersson and Örlander, 2003). The *H. abietis* problem is generally managed by treatment of seedlings in the plant nursery with a relatively persistent insecticide (Långström and Day, 2004). However, several European countries currently strive to abandon this insecticide usage. Novel ways to handle the *H. abietis* problem are, therefore, urgently needed.

H. abietis appears to avoid feeding on root bark close to where their eggs have been laid, thus indicating the presence of a deterrent substance that may be useful in conifer seedling protection (Nordlander et al., 2000; Bylund et al., 2004). Furthermore, antifeedant activity has been demonstrated in a methanol extract of female feces, which are placed over the egg during oviposition (Nordlander et al., 2000; Borg-Karlson et al., 2006). For identification of the active compounds, a feces extract was fractionated and the fractions were bioassayed by using both sexes of *H. abietis* (Borg-Karlson et al., 2006). In the most active fraction, oxygenated aromatic compounds, presumably originating from lignin, were identified. These and a number of structurally related compounds had an antifeedant effect when tested separately.

Among other substances, benzoic acid derivatives were found in the active extract fractions (Borg-Karlson et al., 2006). Initial work with this group of substances shows that *H. abietis* responds selectively to variations in the chemical structure of the isomers tested, and that the biological activity is related to the functional groups present and to the positions of the substituents on the aromatic ring. Similarly, the 10 isomers of methyl hydroxy-methoxybenzoate differ considerably in their antifeedant effects on *H. abietis* (Legrand et al., 2004). This emphasizes the importance of investigating the various isomers of potential antifeedants.

The rationale for research on structure–activity relationships is derived from studies in which the correlations between biological activity of plant growth regulators and chemical structure were analyzed (Hansch et al., 1963). The original approach was based on the assumption that chemical properties of the analogs are optimized for the compound to enter a cell and reach receptors where biological responses are triggered. The methodology has been applied for insecticides, (Hansch and Fujita, 1964), photosynthesis inhibitors (Hansch and Deutsch, 1966), and drug design (Topliss, 1972). Several structure–activity studies on insect antifeedants have previously been reported (e.g., Luteijn and DeGroot, 1981; Fischer et al., 1990; Ley et al., 1991; Luthria et al., 1993; Morimoto et al., 1999).

Antifeedant effects observed with *H. abietis* may result from activation of a number of receptors. Therefore, new analogs may result in increased antifeedant activity via one receptor, but may counteract the effect via another receptor. However, large differences in activity between close structural analogs show that this approach can be used to find promising antifeedants.

With the practical application that we have in mind (protection of conifer seedlings), we are not only interested in finding the most active chemical structure, but also in minimizing the cost of treatment. For example, we may find a commercially available analog having a lower biological activity than the most active substance, but available at a lower price. Specific properties of the compounds may be crucial when the compound is applied in the field (e.g., the melting point may be important for successful application and adherence to

the plant), or lower volatility may be necessary for persistence of the protective effect. An antifeedant compound might be physiologically detrimental to the seedling, either by penetrating through the bark or by being taken up by the roots (e.g., if the compound is leaking out from the formulation in which the compound is attached to the plant). Given these potential pitfalls, it is crucial to have more than one candidate antifeedant compound. It is also possible that two or more compounds may combine synergistically.

The potential of using antifeedants to protect seedlings against *H. abietis* damage has been previously demonstrated in field tests with methyl 3,5-dimethoxybenzoate (Nordlander et al., 2000) and with ethyl 2,3-dibromo-3-phenyl-propanoate, a substance identified in the bark of lodgepole pine, *Pinus contorta* Douglas ex Loudon (Bratt et al., 2001). In contrast, more volatile olfactory repellents, e.g., the monoterpenoid carvone, have provided poor protective effects against *H. abietis* damage in field tests (Schlyter et al., 2004), notwithstanding the strong antifeedant effect found in laboratory bioassays (Salom et al., 1994; Klepzig and Schlyter, 1999). In general, we hypothesize that the results of laboratory antifeedant assays should predict the results of field assays, but for use in the field, suitable dispenser matrices need to be developed to formulate the antifeedant for optimal activity. This is a complex issue that is beyond the scope of this paper.

This study was aimed at increasing our understanding of the physicochemical properties responsible for the antifeedant effects of benzoic acid derivatives on *H. abietis*. We also hoped to optimize any such effects in order to facilitate the development of an efficient method of protecting conifer seedlings from feeding damage by *H. abietis*. To these ends, we tested 55 structurally related compounds for antifeedant effects against *H. abietis* in a laboratory bioassay.

Methods and Materials

Collection and Maintenance of *H. abietis*

Both sexes of *H. abietis* were collected during spring migration at a sawmill in southern Sweden, where they landed in large numbers in response to massive emissions of attractive conifer volatiles. After collection, *H. abietis* were stored in darkness at 10°C and provided with fresh Scots pine, *Pinus sylvestris* L., branches or stems with tender bark as food. These storage conditions interrupted the reproductive development of the weevils, so that females did not begin to oviposit until about 1 week after they had been transferred to the experimental conditions, i.e., a light regime of 18:6 hr (L/D) at 22°C. This transfer was made at least 10 days before *H. abietis* was used in the following bioassay.

Feeding Bioassays

The compounds were tested on *H. abietis* by using a two-choice laboratory bioassay (Bratt et al., 2001). Fresh pieces of *P. sylvestris* twigs (50 mm long, 15 mm diam) were split, and each half (=test twig) was wrapped in aluminum foil. In each test twig, two sharp-edged metal rings (5 mm diam) were punched 25 mm apart through the foil and into the bark. The rings and the pieces of aluminum foil inside them were removed. The thin outer layers of corky bark inside the two circular areas on the surface of the twig were also carefully removed with a scalpel. Thereafter, new rings were fitted into the bark around the two exposed areas, and 100 µl of a 50-mM methanol solution of the compound to be tested were applied on the bark in one of the two rings. In the other ring, 100 µl of pure methanol

were added for control. When the solvent enclosed by the metal rings had evaporated and/or absorbed into the wood, the metal rings were removed. Each test twig was placed on moistened filter paper in a 142-mm-diam Petri dish, with one weevil in each dish for 24 hours (Fig. 1). The assay was replicated 20 times for both females and males. Weevils were all in the reproductive phase of their life cycle and were starved for 24 hours before the test period. Each weevil was used only once. Bioassays were conducted under a light regime of 18:6 (L/D) at 22°C. The amount of feeding on the treatment and control area of each test twig was recorded at the end of the bioassay. There was generally no significant difference in response between the sexes, and the data presented were therefore pooled.

The effects of the various treatments are described by two variants of the antifeedant index (AFI) (Blaney et al., 1984): $100 \times (C - T)/(C + T)$. (1) In AFIa, C represents the mean area of the control surfaces consumed and T represents the mean area of the treated surfaces consumed. (2) In AFIn, C represents the number of the control surfaces with feeding scars and T represents the number of the treated surfaces with feeding scars. Hence, AFIa is a measure that captures the reduction in feeding, whereas AFIn is a measure of complete inhibition of the initiation of feeding on the treated area. The two indices were fairly well correlated, but AFIa tended to be higher than AFIn because the antifeedant substances generally affected both the initiation of feeding and the amount of plant material consumed if feeding had started. For both indices, positive values (up to a maximum of 100) reflect an antifeedant effect, whereas negative values (down to a minimum of -100) indicate a stimulant effect. Statistical differences in feeding/no feeding between treatment and control were tested for each substance with Fisher's exact test of a 2×2 table: $*P < 0.05$, $**P < 0.01$, $***P < 0.001$.

Test Compounds

The origins of the compounds tested are given in Tables 1, 2, 3, and 4. Final purities of all compounds ranged from 96% to 99%, and, if necessary, compounds were purified by preparative chromatography (Baeckström et al., 1987) or flash chromatography on silica gel (Merck 60, 0.040–0.063 mm; Merck, Darmstadt, Germany). The compounds were synthesized from their corresponding carboxylic acids by method A, B, or C (see [Synthesis](#) below). Isopropyl benzoate (entry 27, Table 2) was obtained by method D, a transesterification using alkaline conditions (see [Synthesis](#) below). As can be seen in the

Fig. 1 *Hylobius abietis* on test twig with exposed treatment and control areas

^a Purchased from Sigma - Aldrich.

^b Synthesis was reported in Legrand et al. (2004).

^c Purchased from Lancaster Synthesis Co.

^d Prepared from the corresponding carboxylic acids by refluxing in the alcohol with H_2SO_4 as a catalyst.

^e Prepared from the corresponding carboxylic acids by reaction with DCC and DMAP and the alcohol in CH_2Cl_2 .

Method A Esters were prepared from the corresponding carboxylic acids by refluxing in the alcohol with H_2SO_4 as a catalyst. For a typical procedure: methyl 2,3,4-trimethoxybenzoate (Table 4, entry 69). 2,3,4-Trimethoxybenzoic acid (500 mg, 2.36 mmol) was dissolved in methanol (20 ml), and a few drops of H_2SO_4 were slowly added to the stirred reaction mixture. The mixture was heated, and refluxed until the reaction was completed by thin layer chromatography. After cooling, solvent was removed under reduced pressure (10–20 mm Hg). The residue was taken up in CH_2Cl_2 , and washed twice with brine. The organic layer was dried over MgSO_4 , and the solvent was evaporated, leaving methyl 2,3,4-trimethoxybenzoate as a colorless oil (450 mg, 84%).

Method B Esters were prepared from the corresponding carboxylic acids (1.5 eq.) by reaction with 1.5 eq. dicyclohexylcarbodiimide (DCC) and 0.1 eq. *N,N*-dimethylaminopyridine (DMAP) and the alcohol or thiol in CH_2Cl_2 . For a typical procedure: (3*E*)-hexen-1-yl 3,5-dimethoxybenzoate (Table 2, entry 24). 3,5-Dimethoxybenzoic acid (545 mg, 3.00 mmol) was dissolved in a solution of CH_2Cl_2 (5 ml) containing DCC (618 mg, 3.00 mmol) and DMAP (24 mg, 0.2 mmol). (3*E*)-Hexen-1-ol (200 mg, 2 mmol) was added to the reaction mixture, which was then stirred overnight at room temperature. The white precipitate was filtered off and the solvent evaporated. The crude product was purified by liquid chromatography on silica gel by using an eluting gradient of EtOAc in hexane (1.25%, 2.5%, 5.0%, 7.5%, 10.0%, 15.0%, 20.0%, 30.0%, 50.0%, and 80.0% via a constant volume mixing chamber) to give (3*E*)-hexen-1-yl 3,5-dimethoxybenzoate (262 mg, 50%).

Method C *N*-Ethyl 3,5-dimethoxybenzamide (Table 1, entry 17) was prepared by stirring 3,5-dimethoxybenzoyl chloride (300 mg, 1.50 mmol) in a solution of 70% ethylamine in water (10 ml). After stirring overnight, the crystals were filtered off, and subjected to chromatography. The product amide was analyzed by NMR and the yield was 111 mg (35%).

Method D An example of the transesterification procedure is given for isopropyl 2,4-dimethoxybenzoate (Table 2, entry 27). Sodium (0.1 g, 4.3 mmol) was dissolved in 7.5 ml isopropanol, and a solution of methyl 2,4-dimethoxybenzoate (403 mg, 2.06 mmol) in 10 ml isopropanol was added. The reaction mixture was stirred at room temperature overnight. Then, 20 ml of EtOAc were added, and the organic phase obtained was washed twice with H_2O and once with a saturated NH_4Cl solution. The organic phase was dried over magnesium sulfate and evaporated to give isopropyl 2,4-dimethoxybenzoate (220 mg, 48%) as a yellow oil.

Method E Methyl 2-hydroxy-6-methoxybenzoate (Table 4, entry 53) and methyl 3-hydroxy-5-methoxybenzoate (Table 4, entry 57) were synthesized from the commercially available symmetric 2,6-dihydroxy- and 3,5-dihydroxybenzoic acids (Legrand et al., 2004). The acids were esterified and then *O*-monomethylated by using methyl iodide in the presence of a weak base (K_2CO_3) in MeOH. Analytical data from these two benzoates were identical with those previously reported (Hoffmann and Pete, 2001; Kühnert and Maier, 2002). The syntheses of the methyl hydroxy-methoxybenzoates (Table 4, entries 56, 58, and 59) were executed by a regioselective protection-deprotection synthetic sequence (Legrand et al., 2004).

Results and Discussion

When interpreting our results, we have specifically focused on the importance of four types of structural features for antifeedant activities: (1) the functional groups (Table 1); (2) the carbon chain length of the parent alcohol moieties in benzoic esters (Table 2); (3) the

structures of the substituents on the aromatic rings (Table 3); (4) the patterns of substituents (Table 4). Antifeedant activities (AFIa and AFIn values) were compiled and compared for these four categories of structural features with the aim of demonstrating the effect of each structural feature by itself (Tables 1, 2, 3, 4).

Effect of Functional Group on Antifeedant Activity (Table 1)

Functional groups of benzoic acid derivatives were important for antifeedant activity. Benzoic acids *per se* seemed to have weak activity or none at all, whereas the corresponding methyl esters generally were highly active (compare entries 1 vs. 2, 3 vs. 4, 5 vs. 6, 7 vs. 8, and 15 vs. 16). Because some methyl phenylacetates (entries 9–14) also possess antifeedant activities, the carbonyl moiety does not need to be directly attached to the aromatic ring. These examples show that aromatic carboxylic acids are relatively poor antifeedants in comparison with their ester analogs. For example, both 3,5- and 2,5-dimethoxy isomers of methyl phenylacetate are good antifeedants (entries 12–13), whereas 3,5-dimethoxyphenylacetic acid (entry 11) is not (Table 1). Test results of the secondary benzamide (entry 17), thioester (entry 18), and benzyl alcohol (entry 19) show that the functional group does not need to be an ester moiety for a compound to have antifeedant activity.

Effect of Benzoic Ester Parent Alcohol Moiety on Antifeedant Activity (Table 2)

Esters with a short alkyl chain from the parent alcohol had relatively high antifeedant activities (entries 21, 25–28), whereas esters with bulkier substituents from the parent alcohol had relatively low activities (entries 20, 22–24).

Effect of Aromatic Ring Substituents on Antifeedant Activity (Table 3)

Comparisons of monosubstituted benzoates revealed that monomethoxylated benzoates were generally better antifeedants than the corresponding monohydroxylated benzoates (Table 3, entries 29 and 30 vs. entries 31 and 33). A methyl benzoate substituted with a long alkyl chain (e.g., entry 34) showed no significant antifeedant activity.

Comparison of disubstituted benzoates revealed that methoxy-substituted benzoates generally give better antifeedants than hydroxy-substituted benzoates (Table 3, entries 36 vs. 39; 40 vs. 43; 46 vs. 48). The hydroxy–methoxy analogs (Table 3, entries 38, 41, 42, and 47) were relatively good, in contrast to the corresponding dihydroxybenzoates (Table 3, entries 36, 40, and 46), which were not significantly active. Dimethoxy-substituted benzoates (entries 39, 43, and 48) possessed some of the highest antifeedant activities among substances tested. The connection of two adjacent oxygen atoms via a methylene group did not yield high antifeedant activity (entry 44).

Relative to the dimethoxy analog, the activities of methyl benzoates were lower when they were substituted with strong electron-withdrawing substituents like the nitro group (Table 3, entry 50 vs. 48). Halogen substituents (bromo or chlorine) also resulted in lower antifeedant capacity of methyl benzoates (e.g., a dibromo derivative, entry 49 or a monochlorobenzoate, entry 45). The result with the lipophilic 3,5-dimethyl analog (entry 51) discouraged us from further testing of even more hydrophobic analogs.

Effect of Aromatic Ring Substituent Pattern on Antifeedant Activity (Table 4)

Given that monomethoxylated benzoates were some of the most efficacious antifeedants, we evaluated the effect of the position of the methoxy groups on the activity. Derivatives with the methoxy group in the *meta*- or *ortho* positions are superior to those with the methoxy group in the *para* position (Table 3, entries 31–33). Hydroxy–methoxybenzoates with hydroxy groups in *ortho* positions (Table 4, entries 52–55) had moderate to high antifeedant activities, and methyl 2-hydroxy-3-methoxybenzoate showed the highest activity in this class. We hypothesize that this may be correlated to hydrogen bonding between the *ortho*-hydroxy and adjacent carbonyl group. The other hydroxy–methoxybenzoates (entries 56–61), showed no, low, or moderate antifeedant activities. The results of the assays of these compounds did not indicate an optimal substitution pattern, although the weevils exhibited a remarkable selectivity in their responses to close structural analogs. For example, there was almost no antifeedant activity from the 5-hydroxy-2-methoxy analog (entry 56), whereas the 2-hydroxy-5-methoxy analog (entry 55) was highly active. This also supports the hypothesis that hydrogen bonding between *ortho*-hydroxy and carbonyl groups is important for antifeedant activity.

The activities of benzoates with two dimethoxy groups (entries 63–67) vary but are generally high, with the exception of the 2,6-analog (entry 67). The somewhat higher antifeedant activity of the 2,4-analog (entry 63), compared with the 3,5-dimethoxy analogue (entry 62) in the 50-mM concentration was consistent even when tested at lower concentrations (25 and 5 mM; unpublished results). An attempt to find a compound with an even higher activity than that of methyl 2,4-dimethoxybenzoate (entry 63) by adding a third methoxy substituent in position 6 failed completely (entry 68). Other derivatives with a third methoxy or hydroxy group also showed no significant antifeedant effect (entries 69–71). Some aromatic compounds related to the ones tested here are emitted by sporulating fruiting bodies of tree-decaying fungi, e.g., anisole, benzaldehyde, methylanisate, and methyl 4-methoxyphenylacetate (Rösecke et al., 2000; Rösecke and König, 2000). The ecological significance of these substances to *H. abietis* females may be that they indicate that the host is infested with fungi and in a state of decay, thus making it unsuitable for oviposition (von Sydow, 1993). If compounds such as anisole and methyl (4-methoxyphenyl)acetate were tested, the response might be similar to that of the deterring signals from substances in *H. abietis* feces [i.e., methyl (2,4-dimethoxyphenyl)acetate (Table 1, entry 14), or 3-methylanisole, AF1a 35, AF1n 23, which was tested in Borg-Karlson et al., 2006].

In summary, This study has revealed the following structural criteria for benzoic acid derivatives that have high antifeedant activity against *H. abietis*:

1. The functional group of the benzoic acid derivative is apparently not critical as long as it is not a –COOH group.
2. The carbon chain of the parent alcohol in the ester derivative must be short.
3. The optimal substituents are methoxy groups. Longer alkoxy groups do not result in more effective antifeedants. Nitro and hydroxy groups are seemingly too polar, whereas halogens and methyl groups are apparently too lipophilic to be effective.
4. Two substituent patterns seem to give optimal antifeedant effects. First, in hydroxy–methoxy derivatives, the hydroxy group should be situated in the *ortho* position and adjacent to the carbonyl group (Table 4, entries 52–61). Second, all dimethoxy derivatives, except the 2,6-dimethoxy derivative, possess good antifeedant activities. Inductive or resonance effects are apparently not important for antifeedant activity, as both the *ortho*–*para*-2,4-dimethoxy analog (entry 63) and the *meta*-3,5-dimethoxy

analog (entry 62) had high activity relative to most other structures tested. No substituent pattern can be declared to be optimal.

Additionally, esters or amides formed from a short parent alcohol and with two small alkoxy substituents on the aromatic ring lead to high antifeedant activity for *H. abietis*. Long carbon chains in the substituents or from the parent alcohol portion of the ester reduce the antifeedant effect and hydroxy substituents reduce the activity except when the hydroxy group is in the *ortho* position.

Several benzoic acid derivatives had strong antifeedant effects against *H. abietis* in the laboratory feeding tests. Five compounds tended to have at least as high, or even higher, antifeedant activity than methyl 3,5-dimethoxybenzoate, which previously had been identified as a potent antifeedant in laboratory and field tests (Nordlander et al., 2000). These new, highly effective antifeedants are methyl 2,4-dimethoxybenzoate, isopropyl 2,4-dimethoxybenzoate, methyl 2-hydroxy-3-methoxybenzoate, methyl (3,5-dimethoxyphenyl) acetate, and methyl (2,5-dimethoxyphenyl)acetate. Further tests at lower concentrations are needed to evaluate their relative potentials as *H. abietis* antifeedants. Field assays measuring volatility, stability, and physiological effects on seedlings will be necessary to assess the usefulness of these five antifeedants for seedling protection.

Acknowledgments We thank Anoma Mudalige and Henning Henschel for chemical syntheses and Olle Terenius for assistance with the bioassays. Introduction

Plant bugs of the genus *Lygus* feed on meristematic tissues of plants, causing shedding of buds, blooms, seeds, and fruit (Debolt and Patana, 1985). There are at least nine species of *Lygus* bugs of economic importance in the northern hemisphere (Kelton, 1975), of which *Lygus hesperus* Knight is the most abundant in western North America (Clancy and Pierce, 1966; Kelton, 1975). The species is polyphagous, damaging cotton, alfalfa, and strawberries, and it is found on over 100 species of plants in 24 families (Scott, 1977; Blackmer et al., 2004). Several species in the genus, including *L. hesperus*, use a sex pheromone released by the female (Scales, 1968; Strong et al., 1970; Graham, 1987, 1988; McLaughlin, 1996). Several research groups have tried to identify the sex pheromone components of *L. hesperus* and *Lygus lineolaris* (prevalent in eastern United States) so far without success (Aldrich et al., 1988; Ho and Millar, 2002; Wardle et al., 2003).

Aldrich et al. (1988) extracted metathoracic scent glands and trapped airborne volatiles from *L. hesperus* and the sibling species *L. lineolaris* and found similar ratios of hexyl and (*E*)-2-hexenyl butyrate in males and females. (*E*)-4-Oxo-2-hexenal was also detected in glands of male *L. hesperus* and in both sexes of *L. lineolaris*. More recently, Ho and Millar (2002) found significant quantities of hexyl butyrate, (*E*)-2-hexenyl butyrate, (*E*)-2-hexenal, and 1-hexanol in solvent extracts of *L. hesperus* glands. These compounds, as well as lower amounts of additional components, were also found in aerations of the macerated adults. Although the sexes differed somewhat in the ratios of some components, each sex had all of the components. Field testing of all binary combinations of 16 components detected in aerations failed to attract either sex. Electroantennographic responses of each sex to 15 of the compounds indicated that both sexes can detect a wide range of compounds, including those from the macerated adults. Ho and Millar (2002) did not ascribe any biological function to the volatiles other than to suggest that one or more could be components of a sex pheromone blend.

Wardle et al. (2003) investigated volatile emissions from the sibling species *L. lineolaris* with the same goal of identifying a sex pheromone. They found that both sexes had large amounts of hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-2-hexenal, with considerably more (*E*)-4-oxo-2-hexenal than in *L. hesperus* (compared with $\leq 1\%$ by Ho and Millar, 2002) as collected by Porapak Q traps. The adults were crowded together in a mass at the bottom of a glass tube to induce high rates of volatile release. Wardle et al. (2003) suggested that the volatiles may act as an alarm pheromone or as chemical defenses against predators; however, no experiments were carried out to test these hypotheses.

The objectives of this study were to (1) induce releases of volatiles from both sexes of *L. hesperus* and identify the compounds and their relative amounts, (2) compare these to amounts in solvent extracts of individual insects, and (3) test volatile compounds for intraspecific alarm functions and for defensive functions against two species of ants. A further objective was to look for compounds unique to females that might be sex pheromone components.

Methods and Materials

Induced Release of Defensive Chemicals from Adult Tarnished Plant Bugs and Behavioral Effects

Unless otherwise stated, *L. hesperus* (collected from Maricopa, AZ, USA) was reared in the laboratory on green beans and synthetic diet (Rodriguez-Saona et al., 2002; Blackmer et al., 2004). Sexes were separated by the presence or absence of an ovipositor groove. Volatile chemicals from male and female *L. hesperus* were collected from the headspace by solid-phase microextraction (SPME). Individual *L. hesperus* were chilled so that they did not release volatiles under stress when transferred to 2-ml glass vials with Teflon liners with a 0.5-mm hole, allowing insertion of the SPME needle. A 65- μ m Carbowax-divinylbenzene SPME fiber (Supelco, Bellefonte, PA, USA) was inserted into the vials for 10 min to collect background volatiles that were then desorbed in the GC–MS injection port at 250°C for 5 min. In some experiments, a vial was opened and forceps were used to grab the leg of an adult for about 10 sec (molestation) to induce defensive emissions, the vial was recapped, and volatiles were collected for 10 or 120 sec by SPME.

Gas chromatography–MS analysis of volatiles collected on SPME fibers was carried out with a Varian 3900 GC with a 30 m \times 0.25 mm ID column coated with 0.25 μ m CP-Sil 8 CB (Varian CP5860). Helium carrier gas was programmed for constant flow (1.2 ml/min). The injection at 250°C was splitless for 5 min (then split 20:1), whereas the oven/column temperature was held at 40°C during the same period before increasing at 5°C/min to 180°C. Thereafter, temperature increased at 20°C/min to 250°C and was held for 5 min. Compounds in GC effluents were analyzed with a Varian Saturn 2100D MS using the NIST02 and Wiley7 spectral libraries and comparison to commercial standards (all >98% purity, Aldrich Chemical Co. and Bedoukian Research, Danbury CT, USA), except (*E*)-4-oxo-2-hexenal (>98%, synthesized by H.D. Pierce Jr. and provided by R. Gries, Burnaby, B.C., Canada) and pentyl butyrate (previously identified by Ho and Millar, 2002).

In bioassay experiments, harvester ants, *Pogonomyrmex rugosus* Emery, and native fire ants, *Solenopsis xyloni* McCook, from Phoenix, AZ, were placed in 2-ml vials with an adult bug until the ant initiated an attack, whereupon SPME collection was performed for 1–2 min. The behavioral and lethal effects of saturated vapors of hexyl butyrate (50 μ l in 125-ml closed bottle) or 0.5 μ l direct applications of hexyl butyrate on *P. rugosus* were observed every 30 min for 1 min over an 8-hr period. Adults of *L. hesperus* grasped with forceps were presented within a few millimeters of resting *L. hesperus* nymphs and adults for several seconds to determine if any alarm behavior could be induced.

Quantification of Volatile Chemicals in Adult Tarnished Plant Bugs

Adult *L. hesperus* reared in the laboratory or collected on September 8, 2004, in Maricopa, AZ, from the field (wild) were extracted individually, with 100 μ l pentane with an internal standard of ethyl heptanoate (1 ng/ μ l, Aldrich). Adults were cooled to 3°C and dropped into solvent contained in a 100- μ l conical vial and crushed with a blunt, nickel-plated tapestry needle (Prym-Dritz Corp., Spartanburg, SC, USA). The solvent was immediately sucked off the mashed insect and placed in a new vial and analyzed within a few days by GC–MS. Leaving the crushed cadaver in solvent caused degradation of (*E*)-4-oxo-2-hexenal (see Results). The metathoracic glands of three 10-d-old individuals of each sex were dissected under water and extracted as above. The column and temperature program used for analysis

of solvent extracts were the same as for SPME above, but the flow was splitless for 0.75 min before being split 60:1 for 4.25 min (thereafter 20:1) and was maintained an additional 10 min at 250°C.

For quantification of various volatile chemicals in solvent extracts of *L. hesperus*, the total ion chromatogram peak areas at the respective retention times were compared with areas of the internal standard (ethyl heptanoate) and adjusted for the MS response factor sensitivities of identified compounds. The MS chromatogram areas of the three major compounds, hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal from adults were usually large and needed correction for nonlinear MS responses. This was carried out by multiplying the peak areas by a correction function (*Y*) before comparison to the internal standard. This function was determined by GC–MS for a concentration curve of each compound (0.1, 1, 10, 100, 1000 ng/μl) and regressing *X* (observed MS peak area at each amount) with *Y* (predicted peak area from linear extrapolation of the area for 1 ng times the number of nanograms injected divided by *X*) to obtain a best-fitting function (e.g., for hexyl butyrate: $Y = 0.862 + 0.0002593X^{0.5}$, $R^2 = 0.995$). Differences between means of chemical amounts were analyzed by *t*-tests, and linear and nonlinear regressions were performed on scatter plots of individual *L. hesperus* weights or adult age after last instar ecdysis vs. amounts of volatile compounds (Sokal and Rohlf, 1995; Statistica 5.1 by StatSoft, Inc.).

To determine the amounts of volatile compounds in each sex as they matured sexually (Strong et al., 1970), a large cohort of newly emerged adults from the laboratory colony were separated by sex and kept separately until extraction. In other experiments, adults of both sexes were kept together for known times until extraction. Individual weights of 16 males and 16 females from the laboratory colony were taken on a Mettler balance (precision of 0.1 mg) and each was extracted to determine if volatile compound amounts varied with weight.

Initial Discharge Percentage of Volatile Chemicals

The initial discharge percentage (IDP) is defined as the percentage of volatile chemical secretion that is discharged from an insect due to an initial molestation stimulus. Because extraction destroys the insects, a group of adults was split and individuals of one cohort were extracted for volatiles to obtain a mean (\bar{A}), and this was compared with the mean of the other cohort (\bar{B}) after they had discharged chemicals due to molestation. SPME collection (2 min, described above) and GC–MS were used to verify whether members of group B released volatiles before their extraction. After SPME, the molested adults were removed from the 2-ml vial and aired out for 12 min before extraction. The volatile secretion was defined as the sum of amounts of hexyl butyrate and (*E*)-2-hexenyl butyrate because the latter did not fully separate by GC on the column used. Because age plays a role in amounts of volatiles, 10-d-old males and females of the two cohorts were extracted to determine the IDP for volatile compounds:

$$\text{IDP} = \frac{\bar{A} - \bar{B}}{\bar{A}} \cdot 100 \quad (1)$$

Amounts of Volatile Compounds and their Cross-Correlations

In addition to the three major volatiles, six additional compounds were commonly identified in adults older than 2 d of age. Correlation matrices (Statistica) were carried out

on the quantified amounts of the nine compounds in individual males and females from the three major experiments (maturation, IDP, and weight variation).

Results

Induced Release of Volatiles from Adult Tarnished Plant Bugs and Behavioral Effects

Resting *L. hesperus* adults did not release SPME-detectable amounts of any volatiles in 10-min periods ($N = 6$). However, briefly grabbing one of the legs of an adult bug with fine forceps induced the immediate discharge of volatile compounds as determined by SPME and GC–MS ($N = 8$ of each sex, IPD experiment). Relative amounts of the compounds hexyl butyrate, (*E*)-4-oxo-2-hexenal, and (*E*)-2-hexenyl butyrate released were estimated from SPME peak areas corrected for MS responses and normalized, yielding $100 \pm 13\%$ ($\pm SE$), $44 \pm 9\%$, and $4 \pm 0.5\%$, respectively, from females and $83 \pm 18\%$, $37 \pm 9\%$, and $3 \pm 0.5\%$ from males.

Pogonomyrmex rugosus ($N = 4$) and *S. xyloni* ($N = 3$) ants placed individually with a bug in 2-ml vials usually spent a few minutes in searching/escape movements before opening their mandibles and grasping the bug in an attack. Immediately after this, the ant jerked its head away and violently began running. Thereafter, SPME for 10 sec showed high concentrations of the volatile components of the adult bug (similar to grabbing with forceps above) as well as smaller amounts of an alarm pheromone from *P. rugosus* (4-methyl-3-heptanone; McGurk et al., 1966). The ants and *L. hesperus* were removed from the vials after SPME and none appeared adversely affected. However, one *P. rugosus* after being irritated by the defensive secretion repeatedly attacked and killed the bug, and then the ant's movements became spasmodic. This ant was removed a few minutes later and recovered but had permanent damage to its antennae as evidenced by lack of movement. Two *S. xyloni* ants that attacked *L. hesperus* were left in the vials and died within 4 hr, whereas the adult bugs survived for more than 15 hr.

Pogonomyrmex rugosus ants exposed singly in 125-ml bottles to saturated vapors of hexyl butyrate for 8 hr showed no behavioral or toxic effects compared with a control group in similar bottles ($N = 6$ each group). However, topical application of $0.5 \mu\text{l}$ of neat hexyl butyrate caused violent escape behaviors by the ant that within seconds turned into spasms ($N = 6$). All treated ants recovered apparently normal motor behavior within an hour. None of the *L. hesperus* adults ($N = 5$) held by forceps and presented within a few millimeters of resting nymphs and adults elicited any movement or alarm behavior ($N = 8$ for each group for each held adult). All five forceps-held adults discharged average amounts of butyrates as indicated by SPME and solvent extraction.

Quantification of Volatiles in Adult Tarnished Plant Bugs

When adult *L. hesperus* were placed in pentane, they released a fluid as seen by refractive changes. (*E*)-4-Oxo-2-hexenal amounts (Y) declined rapidly with time (X) in the solvent extracts (e.g., $13.9 \mu\text{g}$ initially, 19% left after 75 min, 0.4% left after 4 hr) when the crushed cadaver remained in the solvent ($Y = e^{3-0.24\sqrt{x}}$, $R^2 > 0.99$, $N = 4$). This also caused a more gradual loss over several weeks of hexyl butyrate and (*E*)-2-hexenyl butyrate (as well as the internal standard). The loss of (*E*)-4-oxo-2-hexenal occurred rapidly in pentane as well as in diethyl ether and acetone. In the same cadaver extract, γ -caprolactone

[5-ethylidihydro-2-(3*H*)-furanone] was not detected initially but accumulated over time ($Y = -0.002 + 0.00085X$, $R^2 > 0.99$, $N = 4$; e.g., 0.22 μg after 4 hr, 1.23 μg after 24 hr). In contrast, if the solvent extract was sucked off the macerated bug and placed in a new vial, then (*E*)-4-oxo-2-hexenal and the esters were stable in solvent for weeks and γ -caprolactone did not accumulate. Using the decanting method, sample extracts were usually analyzed within a day or two of preparation to ensure the accuracy of quantification. The solvent extraction was efficient because a second extraction with 100 μl pentane performed on a few individuals recovered <1% of the material recovered in the first extraction.

Logarithmic regression of amounts of (*E*)-4-oxo-2-hexenal produced in *L. hesperus* of different adult ages showed nearly identical curves for males and females (female: $Y = 1.19 + 1.54\ln X$, $R^2 = 0.72$, $P < 0.001$, $N = 13$; male $Y = 1.15 + 1.56\ln X$, $R^2 = 0.69$, $P < 0.001$, $N = 13$; Fig. 1). Pooling data of adults aged 8 to 19 d gave a mean of 5.6 μg per male and 5.1 μg per female of (*E*)-4-oxo-2-hexenal (not significantly different, $t = -0.39$, $df = 39$, $P = 0.70$). However, females produced more hexyl butyrate ($Y = 4 + 6.64\ln X$, $R^2 = 0.67$, $P < 0.001$) and (*E*)-2-hexenyl butyrate ($Y = 0.44 + 0.58\ln X$, $R^2 = 0.77$, $P < 0.001$) than males ($Y = 3.3 + 3.52\ln X$, $R^2 = 0.77$, $P < 0.001$; $Y = 0.29 + 0.20\ln X$, $R^2 = 0.58$, $P = 0.003$, respectively). Pooling data from days 8 to 19 gave a mean of 22 μg hexyl butyrate per female, significantly more than the 13 μg per male ($t = 2.39$, $df = 39$, $P = 0.02$). Females had a mean of 1.9 μg (*E*)-2-hexenyl butyrate, significantly more than the 0.8 μg in males ($t = 3.77$, $df = 39$, $P < 0.001$).

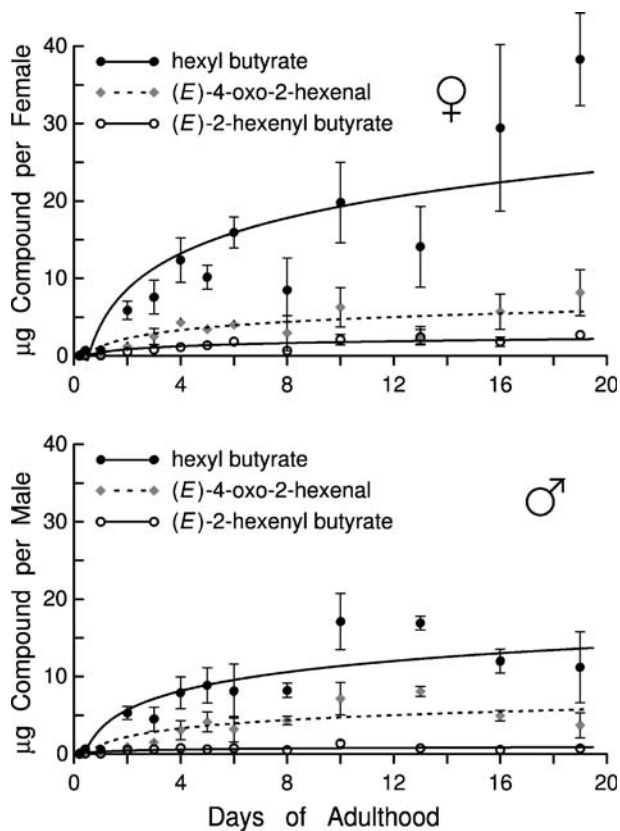

The amounts of (*E*)-4-oxo-2-hexenal and the pooled butyrates [hexyl and (*E*)-2-hexenyl butyrate] increased in relation to fresh weight of females reared in the laboratory (Fig. 2). In wild females, linear regression gave positive slopes but none were significant ($P > 0.05$), although hexyl butyrate had an $R^2 = 0.63$ ($N = 6$). In laboratory females, only the slope of (*E*)-4-oxo-2-hexenal was significant ($P = 0.01$) with an $R^2 = 0.37$. Combining the two butyrates (Fig. 2), because they did not separate fully by GC, gave a regression for laboratory females of $Y = -9.47 + 1.44X$, $R^2 = 0.18$, $N = 16$, suggesting a weak correlation and positive slope, although not significant ($P = 0.1$). The amounts of the volatile compounds in males showed no relationship with weight and had a high variation similar to females (Fig. 2). All regressions of male weight and amounts of volatiles (wild $N = 10$, laboratory $N = 16$) gave R^2 values of < 0.01, and none of the slopes were significantly different from 0 (Fig. 2).

No significant differences in body weight were found between laboratory and wild males, but the mean weight of laboratory females was greater than wild females ($t = 3.84$, $df = 20$, $P = 0.001$; Table 1). Laboratory females weighed more than laboratory males ($t = 15.19$, $df = 30$, $P < 0.001$) and wild females weighed more than wild males ($t = 4.93$, $df = 14$, $P < 0.001$). No significant differences in the amounts of (*E*)-4-oxo-2-hexenal, hexyl butyrate, and (*E*)-2-hexenyl butyrate were found between sexes of laboratory or wild adults (Table 1, Fig. 2), or between laboratory and wild adults of the same sex, except for wild males that had less (*E*)-4-oxo-2-hexenal than laboratory males ($t = 2.39$, $df = 24$, $P = 0.025$). Metathoracic glands dissected from laboratory males and females had comparable amounts of volatiles to those in whole bodies from other experiments (Tables 1 and 2).

Initial Discharge Percentage of Volatiles

Females had an IDP of 84% for (*E*)-4-oxo-2-hexenal and 59% for the combination of hexyl butyrate and (*E*)-2-hexenyl butyrate (Fig. 3). Males had an IDP of 66% for (*E*)-4-oxo-2-

Fig. 1 Amount of volatile compounds in male and female *L. hesperus* in relation to age in days after their final ecdysis (laboratory colony, March 2003). Each point and brackets represent a mean \pm SE ($N = 4$)

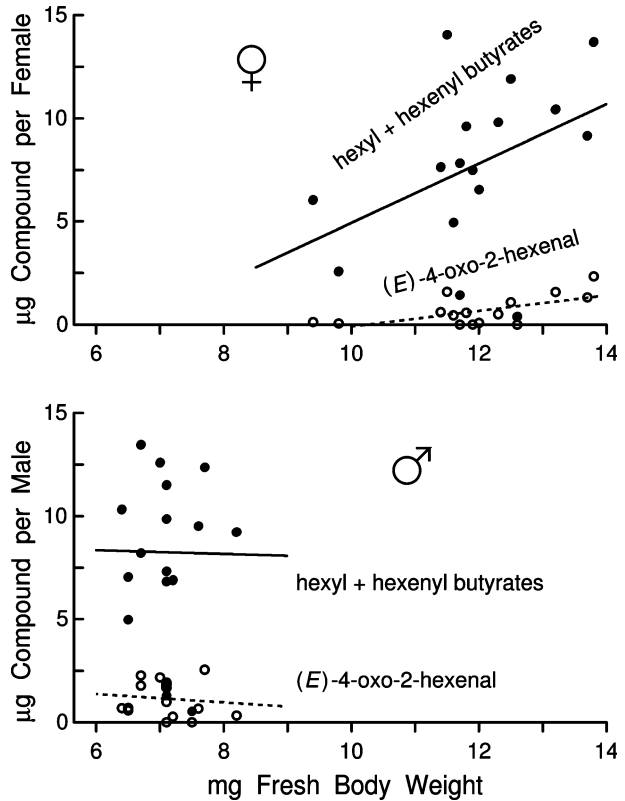

hexenal and 32% for hexyl butyrate plus (E)-2-hexenyl butyrate. Molested/discharged males and females contained lower amounts of the major volatiles than the nonmolested cohort, but only (E)-2-hexenyl butyrate in molested males ($t = 2.97$, $df = 14$, $P = 0.010$), and only hexyl butyrate in molested females ($t = 2.44$, $df = 14$, $P = 0.028$) were significantly less. Of the six minor constituents, most were less in molested males: (E)-2-hexenal (20%, as percentage of unmolested in Table 2, IDP experiment), 1-hexanol (45%), compound X (49%), pentyl butyrate (35%), and (Z)-3-hexenyl butyrate (50%). However, levels of hexyl acetate (130%) were higher in molested males. Compound X eluted at 12.15 min and had MS major fragments (m/z) of 56, 57 (base), 85, and 86. In females, compound X (25%), pentyl butyrate (36%), (Z)-3-hexenyl butyrate (30%), and hexyl acetate (70%) were reduced after molestation, whereas (E)-2-hexenal (237%) and 1-hexanol (234%) increased. However, of the minor constituents, only pentyl butyrate and (Z)-3-hexenyl butyrate were significantly less after discharge in both sexes (all $P < 0.01$).

Amounts of Volatiles and their Cross-Correlations

In addition to the three major volatiles presented earlier, six additional minor compounds were quantified in adults (8 d or older) from the maturation, IDP, and weight experiments

Fig. 2 Amounts of volatile compounds in relation to fresh body weight of 10-d-old adult male and female *L. hesperus* reared in the laboratory (August 2004, $N = 16$ each sex)

presented above to investigate biosynthetic aspects (Table 2). As adults aged, the ratios of the six minor components to the three major ones remained relatively constant (data not shown). No compounds were detected in 5-hr-old adults, but by 10 hr of age, (*E*)-2-hexenal, 1-hexanol, (*E*)-4-oxo-2-hexenal, hexyl acetate, (*Z*)-3-hexenyl butyrate, hexyl butyrate, and (*E*)-2-hexenyl butyrate were evident in small amounts. By 1 d of age, in addition to these compounds, males had pentyl butyrate and an unidentified compound X,

^a Chemicals listed in order of retention time, 8, 8.8, 12.15, 12.5, 14.2, 17, 19.8, 20.05, and 20.15 min, respectively.

^b Asterisks in male columns indicate mean was significantly different from corresponding female mean (*t*-test, **P* < 0.05 or ***P* < 0.01).

Fig. 3 Mean amounts of volatile compounds in cohort groups of male and female *L. hesperus* after being molested (grasping a leg in forceps) to induce discharge of volatiles as detected by SPME, or not molested (control). Lines above bars represent +SE (bugs from laboratory colony, June 2004, $N = 8$ for each bar)

whereas by day 2, both sexes had all compounds in Table 2. A comparison of means of the nine compounds in adult males vs. females indicated no significant differences between the sexes for compound X, (*E*)-4-oxo-2-hexenal, pentyl butyrate, and (*Z*)-3-hexenyl butyrate. Significant differences were found for (*E*)-2-hexenal, 1-hexanol, hexyl acetate, hexyl butyrate, and (*E*)-2-hexenyl butyrate, with females having more of each of these compounds on average (Table 2).

The correlation matrices of nine compounds in the defensive secretion of males and females (Table 3) gave a higher number of significant correlations ($P < 0.05$) among 36 possible pairings for each sex than expected of a null hypothesis. Of these pairings, 12 were significant for males (33%) and 19 for females (53%), much higher than the expected two correlations for each sex based on a 5% level of significance. All of the significant correlations were positive, suggesting that many of the nine compounds were involved in biosynthesis of the defensive secretion. There were 25 corresponding correlations for males and females that were similar in regard to significance (69.4%) and 11 cases where the significance levels differed between the sexes. The two major butyrates and (*E*)-4-oxo-2-hexenal were significantly correlated between themselves in each sex. By pooling males and females, significant positive correlations were found between all possible comparisons of 1-hexanol, (*E*)-2-hexenal, (*E*)-4-oxo-2-hexenal, hexyl butyrate, and (*E*)-2-hexenyl butyrate (data not shown).

Discussion

Wardle et al. (2003) suggested that the function of hexyl butyrate and other volatiles released by agitated *L. lineolaris* could be either as an alarm pheromone or as defensive allomones, but no experiments were carried out with predators. In the present study, alarm behavior was not elicited in nymphs or adults of *L. hesperus* when presented with conspecifics releasing defensive secretions. Alarm pheromones are likely to evolve only when related individuals live in aggregations, such as with social insects or aphid colonies (Byers, 2005). It is possible that unrelated individuals could exploit defensive emissions of others as a warning of predatory danger, but this apparently has not evolved in *L. hesperus*. I also exposed adults of *L. hesperus* to two native species of ants found in fields near infestations of the bug. The adult bugs attacked by ants released a volatile secretion composed mainly of hexyl butyrate, (*E*)-4-oxo-2-hexenal, and (*E*)-2-hexenyl butyrate that

apparently caused agitated movements and avoidance by the predator. These reactions were probably the result of direct contact with the secretion because application of hexyl butyrate (at high doses) elicited violent reactions, whereas ants showed no behavioral changes or toxicological effects during 8-hr exposure to saturated vapors of the compound. Stink bugs (Heteroptera: Pentatomidae) release similar volatile compounds such as (E)-2-decenyl acetate and (E)-2-decenal that deter feeding by birds and lizards (Krall et al., 1999).

Wardle et al. (2003) collected volatiles from disturbed *L. lineolaris* females for 1 hr on Porapak Q and determined that they released 23.6 μg of hexyl butyrate, 8 μg of (E)-2-hexenyl butyrate, 1.8 μg of (E)-4-oxo-2-hexenal, 0.7 μg of (E)-2-hexenal, and 0.4 μg of 1-

hexanol per bug-hour (100%, 34%, 7.5%, 3.2%, 1.7%, respectively). These compounds were also released in the present study from *L. hesperus*, but because the methods of the two studies differ, the compound ratios are not comparable. In this study, SPME exposure for 2 min was used to collect compounds in the vapor phase in which the more volatile (*E*)-hexenal, 1-hexanol, and (*E*)-4-oxo-2-hexenal should have volatilized more completely from the insect surface in the first few minutes after discharge than less volatile components such as hexyl butyrate and (*E*)-2-hexenyl butyrate. Thus, it seems more appropriate to compare the extracted amounts of females in this study (100%, 8%, 18%, 2%, 1%, respectively; Table 2) and assume they are discharged in the same proportions as would be collected by absorbent over a 1-hr period. Ho and Millar (2002) found all of the major and minor compounds (Aldrich et al., 1988) in aerations of macerated females as those presented here but in somewhat different ratios (100%, 4.5%, 1%, 10%, and 10%), possibly caused by degradation of some components during the 22-hr aerations. They also showed that heptyl butyrate placed on bugs was hydrolyzed to 1-heptanol. Significant positive correlations among many of the defensive components (Table 3) suggest that they are involved in biosynthesis and hydrolysis in an equilibrium that could be altered during aeration of macerated bugs (Ho and Millar, 2002) or even during solvent extractions if the bug remains to provide catalytic sites. The present experiments show that quantification is optimized by immediate decanting of solvent from the macerated bug followed by analysis within 2 d.

The most significant difference between studies was the low percentage of (*E*)-4-oxo-2-hexenal (1.2% in females and 0.05% in males) found by Ho and Millar (2002) compared with the 18% and 30% in the present study (Table 2). Also, they did not detect this compound in pentane extracts of metathoracic glands, rather only hexyl butyrate, (*E*)-2-hexenyl butyrate, (*E*)-2-hexenal, and 1-hexanol. However, in gland extracts of both sexes, the author found large amounts (0.5 to 6 μg) of (*E*)-4-oxo-2-hexenal, hexyl butyrate, and (*E*)-2-hexenyl butyrate with small amounts (4 to 30 ng) of 1-hexanol, compound X, pentyl butyrate, and (*Z*)-3-hexenyl butyrate. Earlier, Aldrich et al. (1988) found small amounts of (*E*)-4-oxo-2-hexenal in female metathoracic glands but detected none in males. Again, the most probable explanation for the discrepancy is that (*E*)-4-oxo-2-hexenal breaks down rapidly in solvent when the macerated gland or whole bug is present. Therefore, (*E*)-4-oxo-2-hexenal seems to be more important to the blend of defensive components than suggested from earlier data (Aldrich et al., 1988; Ho and Millar, 2002). Studies of semiochemical identification could miss important compounds if catalytic sites in the biological material remain active in solvent to alter chemical structures before analyses are carried out. Conversely, generation of artifacts through prolonged exposure of extracts to tissues, such as the production of gamma-caprolactone in this study, may complicate analyses.

Ho and Millar (2002) did not ascribe any biological function to the volatiles released by *L. hesperus* other than to suggest that one or more could serve as components of a sex or aggregation pheromone. However, they did not find any differences between the sexes that would suggest sex pheromone components nor were any two-way blends attractive in the field. The present study did not find any significant differences between the sexes either, but does demonstrate the defensive role of the secretions. The volatile components in recently eclosed adults are negligible but then increase with age, in agreement with results for hexyl butyrate in Ho and Millar (2002, their Fig. 1). Several studies (Scales, 1968; Strong et al., 1970; Graham, 1987, 1988; McLaughlin, 1996) provided convincing evidence that virgin females are attractive to males, but identification of *L. hesperus* sex pheromone components has so far been elusive for a number of possible reasons as discussed in Ho and Millar (2002).

The quantities of the hexyl and (*E*)-2-hexenyl butyrates and (*E*)-4-oxo-2-hexenal increased with an increase in weight of laboratory-reared females (Fig. 2). These 10-d-old females had mated with males and were producing eggs as observed during maceration in solvent. In contrast, male size did not appear to affect compound amounts (Fig. 2). It is unknown why young adults contain no defensive allomones for about 1–2 d after molting (Fig. 1) and, thus, are more vulnerable to predators than adults. Resources are probably needed more for maturation processes during this time than for biosynthesis of allomones.

Relatively few studies have reported increased semiochemical content as a function of body weight or size. Amounts of aggregation pheromone components of a bark beetle (Birgersson et al., 1988) and male butterfly courtship pheromone components (Sappington and Taylor, 1990) were not correlated with weight or size (0–3% of variation explained). Pureswaran and Borden (2003) found no relationship between body size and aggregation pheromone components of mountain pine beetles but did find a positive relationship for antiaggregation components. Byers (2005) found that as first instar to adult cotton aphid weights increased over a 60-fold range, the amounts of alarm pheromone, (*E*)- β -farnesene, found in all stages were positively related (66% of the variation in pheromone amounts explained by increases in weight). *Lygus hesperus* produces microgram quantities of defensive allomones compared with nanogram amounts of pheromones in bark beetles and aphids (Birgersson et al., 1988; Pureswaran and Borden, 2003; Byers, 2005). Thus, results for *L. hesperus* suggest that in insects producing large amounts of defensive allomones, the costs can be enough to manifest a positive relationship with size even in adults that vary less in weight compared with all developmental stages (e.g., aphids).

Acknowledgments I thank Dan Langhorst and LeAnne Elhoff for maintaining the colonies of tarnished plant bugs; LeAnne Elhoff for technical assistance; and Jackie Blackmer, Hollis Flint, and the Journal's review process for helping improve the manuscript.

Introduction

Frogs that are able to sequester alkaloids into skin from arthropod prey possess an important evolutionary advantage; they not only afford themselves chemical protection without expending energy to produce such defensive compounds, but also exploit a nutrition niche that other species may reject as bitterly distasteful and dangerous (dietary data not shown). Such ingested alkaloids are known nematocides, insecticides (including antimosquito), and neurotoxins, and provide these frogs with protection against a wide range of possible foes (Daly et al., 1999, 2005 and references therein). More than 800 lipophilic alkaloids from 24 classes, designated in boldface by molecular weight and distinguishing letter (e.g., **251O**; Fig. 1) (Daly et al., 2005), have been documented in certain frog genera from five families. Most genera within these families do not have alkaloids, and thus the traits for alkaloid sequestration and storage in skin glands, along with specialization on ants, has likely arisen multiple times in evolution (Clark et al., 2005 and references therein).

Such poison frogs include *Mantella* of Madagascar (Mantellidae), *Dendrobates*, *Epipedobates*, and *Phyllobates* of Central and South America (Dendrobatidae), *Melanophryniscus* of South America (Bufonidae), *Pseudophyrne* and, to some extent, *Geocrinia* of Australia (Myobatrachidae; see Smith et al., 2002), and to a lesser extent, one *Limnonectes* species of Thailand (Ranidae; see Daly et al., 2004, 2005). Multiple feeding experiments with certain captive-born poison frogs revealed that: (1) dietary alkaloids are usually sequestered unchanged; (2) some chemical modifications of ingested alkaloids exist; and (3) sequestered alkaloids are retained in frogs' skin glands for several years (Smith et al., 2002; Daly et al., 1997, 2003). Many of these "poison frog alkaloids" are also known from tropical and/or temperate ants, mites (Takada et al., 2005), millipedes, beetles, and plants (reviewed in Eisner et al., 1978; King and Meinwald, 1996; Leclercq et al., 2000; Daly et al., 2005; Laurent et al., 2005). In Madagascar, a siphonotid millipede and three ant subfamilies, some of which were confirmed frog prey, contained alkaloids in common with sympatric *Mantella* (Clark et al., 2005); however, putative sources of some of these same alkaloids occur in different ant subfamilies in the Neotropics (see Jones et al., 1999). Further related research on occurrence and pharmacology of alkaloids in poison frogs and their prey is reviewed in Daly et al. (1999, 2005), Saporito et al. (2004), Clark et al. (2005) and Daly (2005).

Fig. 1 Representative structures of select minor and major alkaloids detected in *Mantella* frogs of the Ranomafana region, suspected or confirmed to be of arthropod origin

Daly (1982; see Table 22) and his colleagues (Myers and Daly, 1980; Daly et al., 1990, 1992, 1994a, b, 1996, 2002) have demonstrated that the alkaloid content of pooled frog skins vary by population/locality. Myers et al. (1995) reported variability between frogs, with two individual *Dendrobates granuliferus* skins at each of three locales in Costa Rica; also, at one of these locales two individual and one 30-skin samples of microsympatric *D. pumilio* tentatively revealed that the two species are similar in alkaloid content. Saporito et al. (2006) also discuss variation in alkaloids recovered from 70 individual *D. pumilio* skins. Mebs et al. (2005) made methanolic extracts from 81 individual *Melanophryniscus montevidensis* toads from Uruguay, to reveal by quantitative gas chromatography-mass spectrometry (GC-MS) that there was variation among individuals and populations in the amount of both pumiliotoxin **251D** and the nonalkaloid phenolic hydroquinone.

We previously reported that within a locality, sympatric individuals of two *Mantella* species had similar alkaloid profiles (see supporting information online and Table 1 in Clark et al. 2005). Here, we explore patterns of variation for >80 alkaloids detected in individual *Mantella* poison frogs. Individual variation within or among poison frog species

of a region may reveal important aspects of community ecology; thus, we report the detailed alkaloid content (profiles) of 22 individual *Mantella* frogs of three species sampled from four localities in the Ranomafana region of southeastern Madagascar (Fig. 2), alongside data on frog size and “snapshot” prey consumption. Alkaloid profiles from *M. baroni* collected at two of these localities in 1989 and 1993 are compared to frogs from the 2003 expedition.

Fig. 2 *Mantella* individuals were sampled in and near Ranomafana National Park at riparian locales indicated by solid circles (after map in Bradt, 1999)

Methods and Materials

Field Collections

Materials and methods are described in detail in Clark et al. (2005). Briefly, riparian *Mantella madagascariensis*, *M. baroni*, and *M. bernhardi* were collected in March and April 2003 at localities in moist forests of the Ranomafana region in southeastern Madagascar (Fig. 2). Localities included Ampasimpotsy (Ampa, disturbed forest fragments, 550 m; 21° 28.796'S, 47°33.424'E), Vatoharanana (Vato, old-growth primary forest, 1100 m; 21°17.444' S, 47°25.569'E), Sahavondrona (Saha, disturbed roadside forest, 1100 m; 21°15.450'S, 47° 21.609'E), and both sides of the Kidonavo stream at Vohiparara (Vohi 1 and 2, disturbed roadside forest, 1100 m; 21°13.587'S, 47°22.193'E). Ampa is 25–34 km away from the other three localities, which are clustered 4–9 km from one another within Ranomafana National Park (Fig. 2). In addition, temporal variations in the alkaloid content of *M. baroni* were assessed with samples collected at Vato (December 1989, 10 combined skins) and Saha (January 1993, 17 combined skins); these two samples were provided by John W. Daly (National Institutes of Health), and previously described in Daly et al. (1996).

Sample Preparation and Analyses by Gas Chromatography-Mass Spectrometry

Eighteen *Mantella* frogs were skinned into methanol, and alkaloid fractions were made following the methods of Daly et al. (1994b). These and other frog voucher specimens were deposited and the stomach contents removed at the American Museum of Natural History (AMNH, A168355–A168393) and the University of Antananarivo, Department of Animal Biology (UADAB #1–8). Additional exudates were collected from four live frogs by using a TAS (purchased from Jacqueline Grant, and described in Grant and Land, 2002) and a methanol-laced Kim-wipe; these frogs were rinsed in water and released unharmed. Skin alkaloid fractions and TAS extracts were individually analyzed for alkaloids on a Micromass™ GC-time of flight (TOF)-MS in CI (with 100% NH₃) and EI modes with a ramp of 10°C/min from 100 to 280°C, with oven maintained at 100°C for the first 5 min and at 280°C for the final 5 min. The MS libraries of Daly et al. (1999, 2005) were used to identify over 80 known alkaloids in *Mantella* sampled at Ranomafana in 2003, and the two *M. baroni* standards of Daly et al. (1996) provided retention times of known alkaloids for comparison. Based only upon their relative abundance (RA) in EI mode, these alkaloids are reported in Table 1 as trace (RA < 10%), minor (10% < RA < 70%), or major alkaloids (RA > 70%; see chromatograms in Supplementary Information); although not absolutely quantitative, any possible ionization biases should be consistent among all samples tested.

Statistical Analyses

Statistics were performed with SPSS v. 13. A *t*-test was used to compare the mean alkaloid diversity of Vohi *M. baroni* sampled by TAS vs. full-skin extraction, and to compare means of both frog size [snout–vent length (SVL)] and number of prey between *M. bernhardi* and *M. baroni*. A linear regression was used to evaluate the relationship between frog size and number of prey within the Vohi locality. A *partial correlation* for all *Mantella*,

controlled for by locality, was used to evaluate the relationship of SVL with both the number of prey and individual frog skin-alkaloid diversity. One-way analysis of variance (ANOVA) was used to compare mean alkaloid diversity per frog among all four localities, among the three localities of constant (1100 m) elevation, and between frogs of the two elevation groups. *K*-Means cluster analysis was performed on 22 *Mantella* frogs by using all alkaloids requesting four clusters, and was followed by a cross-tabulation between the cluster membership and the localities.

Results and Discussion

Variation in Alkaloid Content of Individual Frogs, within and among Localities

Cluster analysis revealed that the three *M. baroni* and 1989 standard from Vato represent a distinct group based on the specific alkaloid content of the resident individual frogs (see Cluster groups at bottom of Table 1), indicating that frogs within a locality are more similar to one another compared to frogs from different localities. Seven of nine frogs from both sides of the Kidonavo stream at Vohi clustered in another group of individuals, indicating little variation at this fine spatial scale (Table 1). The other two Vohi frogs clustered in a third unique group, demonstrating little difference in alkaloid profiles of microsympatric *Mantella* species. Frog individuals from the two most disturbed locales clustered exclusively in another group, including all four frogs from moderately disturbed Saha and all six frogs from the disturbed forest fragments of Ampa; these two localities also had the lowest mean number of alkaloids per frog and the six individuals with the fewest alkaloids (Table 1).

Out of the 91 alkaloids in Table 1, 26 were detected in only a single frog individual, 16 were detected in multiple frogs from a single locality, and 11 were detected in multiple individuals from two localities. Vohi 1 and 2 are separated only by the 2- to 4-m-wide Kidonavo stream, and frogs from these sites contained many alkaloids in common (e.g., **207N**, **251D**, **265N**, **273A**); 21 alkaloids were present on both sides of the Kidonavo stream, and the other 38 were only detected in frogs from either Vohi 1 or Vohi 2 (Table 1; of these 38 alkaloids, 25 were found only in a single frog). Of the 91 alkaloids, 26 were detected in only one of the various 22 frogs sampled, and may represent rare prey. The fact that Vohi samples contain 25 of these 26 unique (in one of 22 frogs) alkaloids suggests this intermediately disturbed site may have an elevated number of rare arthropod-source species. Alkaloids appearing in more than one frog that are limited to one locality include: **217B** and **223B** at Ampa; **151B**, **195B**, **207N**, **251R**, and **275E** at Vohi; **273A'** at Saha; and **207J**, **209I**, **223C**, **223M**, **243D**, **255B**, **307F''**, and **307F'''** at Vato. These results also suggest that frogs within a locality are more similar in terms of alkaloid content compared to frogs from different localities. Alkaloids that appear in the majority of frogs from only two localities in 2003 include **203A**, **205A**, **207A**, **219F**, **221I**, **223H''**, **241F**, **245C**, **265N**, **291E**, and **293D** (Table 1).

The distribution and amount of particular alkaloids in individual *Mantella* frogs should reflect how abundant the leaf-litter source arthropod is in the environment. Although frog sequestration efficiency varies among alkaloid classes (see Daly et al., 2003), such sequestration biases should be constant among *Mantella* sampled in this study. For example, alkaloids such as **251O** and **217B** were found in all or most of the 22 individuals (Table 1, Fig. 1); these alkaloids are likely common in frogs because the source arthropod is particularly abundant in the region, so it was not surprising that the endemic ant source species for these common alkaloids was discovered (Clark et al., 2005). As-yet-undetermined arthropod sources for **217A**, **233A**, and **325A** are also likely widely distrib-

uted across the entire region, whereas sources of **231A**, **275C**, and **307G** appear limited to localities within Ranomafana Park boundaries (see Table 1). Ampa is relatively far from the three 1100-m localities and has an elevation of only 550 m. This suggests that the arthropod sources of **231A**, **275C**, and **307G** could be limited to higher elevations. In fact, previous work indicates ant species assemblages and diversity do vary with elevation (Fisher, 1998).

Ants were the most numerous taxon in *Mantella* stomach samples (>67%), and individuals of the same ant species were often collected in the same stomach sample (Table 4 of Clark et al., 2005; unpublished data of V.C.C. and B.L.F.). This is not surprising, because ants are colonial and locally abundant. Based on this data, and the fact that most of the more commonly distributed and “major/minor” alkaloid classes reported here are known from some ant source, the majority of common “minor/major” alkaloids in Table 1 are suspected to be sequestered from dietary ants. The cooccurrence in most frogs of related pumiliotoxin alkaloids **309A** and **325A** (see Fig. 1, Supplementary Information, and Table 1) suggests a possible common alkaloid-source-ant/symbiotic mite for these two alkaloids. Alternatively, *Mantella* could possibly have a hydroxylase to convert **309A** into **325A**, as evidence for frog hydroxylases has been suggested by alkaloid-feeding experiments with captive-born *Dendrobates* spp. (Daly et al., 2003) and *Pseudophryne* spp. (Smith et al., 2002). In one *Mantella* individual, SpiroP **236'** was considerably more abundant than **236** (see Supplementary Information chromatogram for frog #U4), similar to the relative abundance of these spiropyrolizidines reported for the putative source millipede of Clark et al. (2005).

Frog Size and Prey Consumption

M. baroni in this study had an average SVL of 25.5 ± 2.2 mm ($N = 15$), with a range of 22–30 mm identical to a report by Vences et al. (1999) (Table 1). *M. bernhardi* SVLs ranged from 19 to 22 mm in Vences et al. (1999); however, the seven specimens in this study ranged from 17 to 22 mm with an average SVL of 19.9 ± 2.0 mm. *M. baroni* are significantly larger than *M. bernhardi* (t -test, $P < 0.001$), and based on the number of prey per preserved dissected stomach, the larger *Mantella* species consumes more prey (34.7 ± 14.8 prey/frog for 12 *M. baroni* vs. 16.6 ± 11.4 prey/frog for 7 *M. bernhardi*; t -test, $P = 0.009$, from Table 1 data). Furthermore, when performing a regression on one species within a locality, we find a linear relationship for *M. baroni* from Vohi, indicating that larger frogs consumed more prey (slope = 4.949, $P = 0.031$, $R^2 = 0.832$). A partial correlation for the 22 *Mantella*, controlled for by locality, also revealed that frog SVL is positively correlated with both the number of prey (correlation = 0.642, $P = 0.004$) and the total number of alkaloids per frog (correlation = 0.525, $P = 0.025$).

All dietary data represent a “snapshot” of what each specimen ate in the morning of its collection—frogs were preserved within 30 min of capture. In addition to consuming more, and thus probably a greater diversity of prey, it is also likely that some larger prey (that might contain unique alkaloids) are only consumed by larger frogs. Of the 609 *Mantella* stomach arthropods identified by Clark et al. (2005), the two largest prey items were recovered from *M. baroni* (data not shown).

Frog Alkaloid Diversity and Habitat Disturbance

The lower alkaloid diversity (average of 12.0 alkaloids/frog) at Ampa as compared to any other locality could merely be a reflection of the reduced arthropod consumption observed in this smaller species (Table 1, see above). An alternative explanation is suggested by the

notable link between frog alkaloid diversity and observed forest disturbance. The pristine primary forest of Vato is located within Ranomafana Park boundaries and contained *Mantella* with an average of 28.7 known alkaloids per frog (Table 1). Secondary roadside forest localities at the edges of Park boundaries yielded frogs with an intermediate diversity of skin alkaloids (average of 14.5 and 20.2 alkaloids/frog at Saha and at Vohi, respectively). The mean number of alkaloids per frog (mean frog alkaloid diversity) differed: (1) among the three localities of 1100-m elevation (ANOVA, $F = 6.304$, $P = 0.012$, $Eta^2 = 0.492$); (2) more significantly among all four localities (ANOVA, $F = 10.133$, $P < 0.001$, $Eta^2 = 0.628$); and (3) between the two elevation groups, whether (ANOVA, $F = 8.388$, $P = 0.009$, $Eta^2 = 0.295$, $n = 22$) or not (ANOVA, $F = 7.547$, $P = 0.013$, $Eta^2 = 0.284$, $n = 21$) the *M. madagascariensis* data point was included in the analysis. The Eta^2 value suggests that locality differences account for 62.8% of the observed variation in mean frog alkaloid diversity among the four localities.

Fragmented Ampa is clearly the most disturbed forest, with fragments surrounded by rice fields and other agriculture (VCC personal observation; also Rabemananjara et al., 2005). Only 20 different known alkaloids were detected in the six frogs from Ampa, as compared to more than 28 different alkaloids at each of the other localities; this is particularly striking since fewer frogs were sampled at most other localities (Table 1). Fragmentation could lower diversity of alkaloid-source arthropods by eliminating critical microhabitats. Invasive ants can also lower insect diversity in fragmented lowland forests (Fisher et al., 1998; Fisher, 2005). Although confounded by distance, variation in elevation, and frog size/species, this pattern suggests that future conservation research should aim to understand the impact of forest fragmentation on ant assemblages, as invasive ants might decrease the variety of alkaloid-source arthropods available to *Mantella* in Madagascar. Such a scenario could also be imagined for unrelated poison frogs of convergent ecosystems on other continents.

Temporal Variation in Alkaloid Content at Two Localities

Of the 30 alkaloids we detected in the January 1993 Saha 17-skin sample, 15 were absent from the 2003 Saha frogs and four of these were absent from all of the 2003 frog samples (Table 1). Similarly, on average 40% of alkaloids detected in each of the other three localities had been detected in the 1993 Saha sample; 1993 Saha shows little more resemblance to 2003 Saha (15/30 alkaloids) than to Vato (16/33), Vohi (22/59), or Ampa (7/20) frogs in 2003, and 1993 Saha even grouped with the Vohi frogs in the *K*-means cluster analysis (Table 1). In contrast, of the 27 alkaloids we detected in the December 1989 Vato 10-skin sample, only five were absent from Vato and three of these were absent from samples representing the entire region 14 yr later; 11 alkaloids were detected in 2003 Vato but not in 1989 Vato frogs. A comparison of 1989 Vato to different 2003 localities revealed that 1989 Vato shares more alkaloids (66%) with 2003 Vato than with any other locality—only about 33% of 1989—Vato alkaloids were detected in frogs from each of the other localities (17/59 at Vohi, 10/28 at Saha, and 7/20 at Ampa; see Table 1).

Alkaloids not reported in Daly et al. (1996) that are detected here include **151B**, **197E**, **217A**, **223H**, **233A**, **251N**, **251O**, **291E**, **293D**, **307G**, and **323E** in the 1993 Saha sample, and **151B**, **197B**, **251O**, **255B**, **257D**, **271B**, **275C**, **291E**, **293D**, **307A**, **309C**, **323E**, and **325A** in the 1989 Vato sample; these differences are likely a result of the greater sensitivity of the GC-TOF-MS used in this study as compared to the quadrupole GC-MS used in 1996.

Frogs retain their alkaloids for several years in captivity (Daly et al., 1997, 2003 and references therein), so it seems unlikely that the observed temporal variation was influenced

by seasonal variation in time of collection (December/January, the start of the rainy season, vs. March/April, the end of the rainy season). Rather, these results might indicate that the arthropod assemblage was relatively constant in the undisturbed primary forest of Vato, whereas disturbed roadside Saha had undergone a shift in the arthropod community. Disturbance and fragmentation of habitat could decrease the availability of alkaloid-containing prey and pose a possible threat to *Mantella* survivorship. This point is further supported by the observation that the two frog individuals with highest skin-alkaloid diversity both came from pristine Vato, and the six frog individuals with the lowest skin-alkaloid diversity were from disturbed roadside Saha and disturbed Ampa forest fragments (Table 1). A potential threshold diversity for alkaloid-containing arthropods required to maintain wild populations of poison frogs has not yet been determined.

Nonlethal Collection of Frog Skin Alkaloids with the TAS

There is no significant difference in the mean number of frog skin alkaloids detected using a nonlethal TAS vs. the traditional method (Daly et al., 1994b) of lethal full-skin extraction (*t*-test, $P > 0.05$, CI contains zero, for eight *M. baroni* of Vohi). The single TAS frog sample acquired at Saha contained more detectable known alkaloids than two skin samples and fewer alkaloids than one skin sample from Saha. However, quantitative detection by a flame-ionization GC-MS revealed that only 25% of the amount of each alkaloid is recovered with the TAS as compared to full-skin extraction (John W. Daly, personal communication). Based on our results, future investigations on frog alkaloid profiles should rely on the nonlethal TAS, especially when sampling endangered amphibians (listed on CITES appendices). The TAS is particularly useful for obtaining defensive compounds from frogs as it elicits a predator response in the frogs. The resulting TAS extract requires no further chemical workup, yet yields clean gas chromatograms consisting primarily of alkaloids.

Conclusions

Our data suggest that frog alkaloid profile variation is attributable to differences in arthropod assemblages among localities, and as such may give an indication of local ecosystem health. Specifically, variation in frog skin alkaloids appeared: (1) greatest among frog individuals of more geographically distant localities that varied in elevation and size of resident species; (2) lower among individuals from geographically close localities at the same elevation; and (3) lowest among *Mantella* individuals within a locality. In a comparison of frog alkaloid samples over a 10- or 14-yr period, alkaloid turnover, and thus presumably alkaloid-source arthropod turnover, was high in a disturbed locality and low in the pristine primary forest locality.

As all alkaloids in Malagasy poison frogs appear to be obtained from their diet, the local distribution of alkaloid-containing arthropods is likely key to variations in frog skin-alkaloid content among and within localities. Also, larger frog species consume more and larger prey and this increased arthropod sampling likely contributes to greater alkaloid diversity observed in frog skin. Further ecological studies on variation in poison frog alkaloids should use the TAS to evaluate in greater detail factors that might affect alkaloid diversity, such as habitat disturbance and elevation, frog gender, and especially frog age/size. Greater numbers of sympatric *Mantella* species should also be analyzed for variation in their defensive skin chemistry; only one *M. madagascariensis* was compared to several sympatric *M. baroni* (Clark et al., 2005; current study).

It appears that the alkaloid content of Malagasy poison frogs is most affected by locality, and that poison frogs continue to accumulate alkaloids as they age. This poison collection may reach some maximum diversity dependent on the assemblage of alkaloid-source species in the frogs' local habitat and/or individual territories. Because the alkaloids sequestered by frogs vary considerably in toxicity, it is to the frogs' advantage to acquire as many different defensive chemicals as possible. Accordingly, frogs living in particularly arthropod-rich habitats could obtain more dietary alkaloids.

Habitat quality and local arthropod diversity appear to affect how well poison frogs are chemically defended. Therefore, habitat disturbance and fragmentation might decrease *Mantella* survivorship or even exclude the poison frogs altogether *via* selective pressures. Future studies need to address this relationship and determine the threshold of alkaloid-containing arthropods required in habitat suitable for *Mantella* poison frogs.

Acknowledgments We thank Elizabeth E., Sandra P., and William S. Clark, John W. Daly, Jerrold Meinwald, Helian Ratsirarson, Aimee Razafiarimalala, and Justin Solo for their help, anonymous reviewers for critical readings of this manuscript, Christopher J. Raxworthy for discussions, Julián Faivovich for frog dissection training, and Florio Arguillas and Françoise Vermeulen for statistical consulting at Cornell. This work was supported by National Science Foundation Grants DEB-9984496 (to C.J. Raxworthy) for VC Clark's 2003 fieldwork, DEB-0344731 (to B.L.F. and P.S. Ward) for arthropod processing, and CHE-0216226 to Prof. Koji Nakanishi for GC-TOF-MS acquisition and partial support of L.A. The UADAB, Association Nationale pour la Gestion des Aires Protégées, Direction Generale des Eaux et Forêts, Madagascar Institute pour la Conservation des Ecosystèmes Tropicaux, and California Academy of Sciences team in Antananarivo facilitated activities in Madagascar, and Columbia University (including Edward Bass for Biosphere 2) and the American Museum of Natural History provided research support in the United States.

Introduction

Tannins are commonly considered dominant defensive compounds in the leaves of many tree species. Temperate deciduous trees, for example, produce tannins ranging from 0.5% to 20% dry weight (Swain, 1979; Ossipov et al., 2001; Salminen et al., 2004). Terrestrial plant tannins are classified as condensed tannins (polymers of flavan-3-ols) or hydrolyzable tannins. Within the hydrolyzable tannins are galloyl glucoses and gallotannins (gallic acid esters of glucose or other polyols) and ellagitannins. The ellagitannins, which are distinguished by the presence of oxidatively coupled galloyl groups, were recently found to have unusually high oxidative activities (Barbehenn et al., 2006, this issue). Tannins in this relatively unexplored group formed higher concentrations of semiquinone radicals and browned at higher rates compared with other hydrolyzable and condensed tannins.

The leaves of many trees contain mixtures of hydrolyzable and condensed tannins (e.g., Baldwin et al., 1987; Kinney et al., 1997; Salminen et al., 2004), but the potential impact of tannin composition on herbivores is poorly understood. Research on the roles of phenolic compounds in protecting leaves from insect herbivores has focused on their oxidative activities (Appel, 1993; Summers and Felton, 1994; Barbehenn et al., 2005). Phenolic oxidation produces reactive oxygen species, which have the potential to damage essential nutrients and/or cause oxidative stress in herbivores (Summers and Felton, 1994; Bi and Felton, 1995, 1997; Barbehenn et al., 2005). The oxidation of ingested phenolics is minimized in caterpillars by co-ingested ascorbate, suggesting that the oxidative activities of leaves depend on the ratio of phenolics to ascorbate (Felton and Duffey, 1992; Barbehenn et al., 2001, 2003a, 2005). However, if the oxidative activities of different phenolics vary greatly, then the oxidative activities of leaves would also depend on phenolic composition and not merely on total phenolic and ascorbate levels.

A major goal of this study was to examine the importance of phenolic composition on the oxidative activities of tree leaves. Previous work showed that sugar maple leaves have greater oxidative activity when ingested by caterpillars than do red oak leaves (Barbehenn et al., 2005). Here, we examined the association between tannin composition and oxidative activities in maple leaf phenolic fractions, which contain a wide range of tannin mixtures. Our initial expectation was that the oxidative activities of leaves could be predicted from the sum of the activities of their component phenolics. However, it is also possible that redox reactions among phenolics could change the overall rate of oxidation of their mixtures (e.g., Hoover et al., 1998). The potential for chemical interactions among tannins was examined with two hydrolyzable tannins in mixtures containing one of four types of condensed tannins: monomeric to trimeric procyanidins, oligomeric and polymeric procyanidins, or polymeric prodelphinidin-rich condensed tannins.

Oxidative activity was measured at pH 10 (representative of many caterpillar midguts), and was defined by three parameters: semiquinone radical concentration, the rate of decay of these semiquinones, and the rate of browning of phenolics. Electron paramagnetic resonance (EPR) spectrometry was used to measure semiquinone radicals (one-electron oxidation products of phenolics). A UV-visible spectrophotometric assay was used to measure the rate of formation of brown pigments (quinones and quinoidal polymers) that are produced by oxidized phenolics (Richard-Forget and Gauillard, 1997). Although the EPR assay (anoxic) is more relevant to the chemistry of the midgut fluids of many insect herbivores (Johnson and Barbehenn, 2000), the browning assay (ambient oxygen) was developed as a relatively simple assay that would provide a second, independent measure of oxidative activity.

Phenolic compounds from ingested leaf tissues are present in herbivore gut fluids in much more complex chemical mixtures than are phenolics in crude or semipurified solvent

extracts from plants. It would be most relevant to measure the oxidative activities of phenolics in the gut fluids of animals that have ingested them. However, a useful approximation of the oxidative activities of ingested phenolics can be obtained by examining whole-leaf extracts. Therefore, we used EPR spectrometry to develop a time-course assay for quantifying the relative oxidative activities in ethanolic extracts of leaves.

This study examined three questions aimed at explaining the large differences between the oxidative activities of red oak and sugar maple leaves: (1) Does tannin composition affect the oxidative activities of tree leaves? (2) Do chemical interactions between tannins affect the oxidative activities of mixtures of tannins? (3) Are the oxidative activities of whole-leaf extracts useful for comparing tree leaf quality?

Methods and Materials

Extraction and Analysis of Leaf Phenolics

Leaves used were from three tagged red oak and sugar maple trees on the University of Michigan campus in Ann Arbor, MI, USA. The same trees have been used in a series of experiments (Barbehenn et al., 2003a, b, 2005). Branch tips were cut from the sunny side of the trees (June 22, 2004) and immediately placed in flasks of water. Within 1 hr, the midribs were removed, and the leaves were freeze-dried and air-mailed to Turku, Finland. Leaves were combined within species (19.2 g red oak and 17.3 g sugar maple) and ground into a homogeneous powder with an IKA Labortechnik A10 mill (Janke & Kunkel GmbH, Staufen, Germany). To identify and quantify the complete phenolic compositions, leaf powder (20 mg) from each species was extracted with 800 μ l of 70% acetone (containing 0.1% ascorbic acid) for 1 hr. The extraction was repeated $\times 4$, and the extracts were pooled. Acetone was removed with an Eppendorf concentrator 5301 (Eppendorf AG, Hamburg, Germany), and the remaining aqueous extract was freeze-dried. The freeze-dried sample was dissolved in 600 μ l of water and filtered (0.45 μ m). Using high-performance liquid chromatography and a diode array detector (HPLC-DAD), hydrolyzable tannins were quantified in pentagalloyl glucose equivalents (280 nm), flavonoids in quercetin equivalents (349 nm), chlorogenic acids in chlorogenic acid equivalents (315 nm), coumaroylquinic acids in coumaric acid equivalents (315 nm), and the remaining phenolics (other than condensed tannin) as gallic acid equivalents (280 nm; Salminen et al., 1999). Monomeric to trimeric condensed tannins were quantified by reverse-phase HPLC, and total condensed tannins were estimated with the acid-butanol assay (Ossipova et al., 2001), with purified birch leaf condensed tannins as a standard.

Foliar Phenolic Fractions

The bulk of the powdered sugar maple leaves was extracted with 70% acetone (5 \times 500 ml). Extracts were combined, and the acetone was rotary evaporated. After centrifugation (10 min, 2500 \times g, room temperature), the supernatant solution was freeze-dried. The crude phenolic extract from sugar maple leaves was separated into nine fractions using a Sephadex LH-20 column (Salminen et al., 1999). The following series of solvents was used sequentially to elute each fraction: water (150 ml), water (350 ml), 30% aqueous methanol (500 ml), 50% methanol (500 ml), 10% acetone (200 ml), 30% acetone (500 ml), 50% acetone (500 ml), 70% acetone (500 ml), and 85% acetone (500 ml). Each fraction was analyzed by HPLC-

DAD, rotary evaporated, and freeze dried. The 50–85% acetone fractions had similar, tannin-rich compositions. To examine these fractions further, they were combined, dissolved in 40 ml of water, and applied to a Sephadex LH-20 column. Twelve fractions were collected with a graded series of aqueous acetone solvents, ranging from 10% acetone to 85% acetone (500 ml each). Phenolics in each fraction and subfraction were identified and quantified as described.

EPR Assay for Oxidative Activity

Pedunculagin, pentagalloyl glucose, and condensed tannins were isolated as described previously (Barbehenn et al., 2006, this issue). Crude phenolics, phenolic-containing fractions, and purified tannins were weighed to the nearest microgram on a Cahn 25 Electobalance (Cahn Instruments, Inc., Cerritos, CA, USA). Immediately before analysis, each sample was solubilized in 70% aqueous ethanol, which was prepared with nitrogen-purged, double-distilled water and ethanol (each bubbled for 1 min/ml). Solubilized samples were further diluted to produce a series of three concentrations per sample. The range of concentrations varied from sample to sample to produce semiquinone levels that were in a linear range (e.g., sample final concentrations of 0.2–0.7 mg/ml). EPR assays were carried out as described previously (Barbehenn et al., 2006, this issue), with the exception that one scan per sample was run. Samples were scanned for an additional period of time (up to 45 min) to determine the linear rate of semiquinone decay. One replicate was run for each sample. Radicals were identified by comparison of the line shapes and center field values with EPR spectra of semiquinone radicals formed by phenolic and ascorbic acid standards (Barbehenn et al., 2003a, 2006). Standard solutions of the stable free radical, 2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO, Aldrich Chemical Co.) were run to confirm that the method was consistent through time, and to provide a free radical standard for converting double-integrals of spectra to a concentration basis (in nM; Barbehenn et al., 2006, this issue). Plots were made of semiquinone concentration vs. sample concentration for each series of concentrations. The slope of the regression line represents the semiquinone concentration (nM) normalized for sample concentration (mg/ml). The rate of decay of semiquinone radicals was normalized by using the semiquinone radical concentration present at the start of the decay period.

Phenolic fractions from sugar maple that contained elevated levels of gallic acid ($N = 5$) or that did not produce a useable time-course ($N = 2$) were not included in correlation analyses. Semiquinone decay rates were positively correlated with gallic acid content ($r = 0.77$), and inclusion of these fractions obscured correlations between tannin content and oxidative activity. In two sugar maple fractions, no EPR data were obtained because the semiquinone radical concentration continued to increase for over 45 min, i.e., no decay rate or maximum semiquinone radical concentration could be obtained. Correlations between the tannin composition of leaf fractions and semiquinone radical concentrations were only examined in sugar maple because of the lack of hydrolyzable tannins in red oak.

Phenolic Browning Assay

The browning of phenolics in an alkaline solution was used to compare the rate of oxidation of purified tannins and crude extracts (Barbehenn et al., 2006, this issue). Final sample concentrations typically ranged from 0.01 to 0.1 mg/ml of 70% aqueous ethanol (nitrogen purged). At least three replicate reactions were run from separately weighed samples, as well as a pentagalloyl glucose standard to confirm that measurements were consistent

through time. Sample concentration was plotted against browning rate for each sample, and the slope of each regression represents the browning rate normalized for sample concentration.

The unusually high rate of browning of gallic acid (Barbehenn et al., 2006, this issue) could potentially dominate the overall oxidative activity of sugar maple fractions containing gallic acid ($N = 5$). As expected, there was a strong correlation between gallic acid content and the browning rates of sugar maple fractions ($r = 0.97$). Therefore, correlations between tannin content and oxidative activity excluded samples containing gallic acid to examine the effects of tannins more clearly. Other low-molecular-weight phenolics could potentially have a similar strong effect on the oxidative activities of phenolic fractions. However, chlorogenic acid, one of the major low-molecular-weight phenolics, had only 1% of the rate of oxidation of gallic acid (on a mg/ml basis; Barbehenn et al., 2006, this issue).

Effects of Condensed Tannins on Hydrolyzable Tannin Oxidation Rates

The EPR assay was used to measure semiquinone concentrations from pedunculagin (0.046 mg/ml, final concentration) and pentagalloyl glucose (0.091 mg/ml) in the presence or absence of condensed tannins (0.046 and 0.091 mg/ml). Pedunculagin was chosen as an example of an oxidatively active ellagitannin, and pentagalloyl glucose as a less-active gallotannin precursor (Barbehenn et al., 2006, this issue). A lower concentration of pedunculagin than pentagalloyl glucose was used to produce semiquinone concentrations in the linear range for pedunculagin, whereas a higher concentration of pentagalloyl glucose helped to measure changes in its smaller semiquinone concentrations with greater accuracy. Four types of condensed tannins were used: monomeric to trimeric, oligomeric and polymeric procyanidins, and polymeric prodelphinidin-rich condensed tannins. Condensed tannins (2.0 mg/ml) were solubilized in oxygen-free 70% ethanol immediately before use. A 1.0 mg/ml condensed tannin solution was prepared by diluting the 2.0 mg/ml solution 1:1 with 70% ethanol. A 20- μ l aliquot of the hydrolyzable tannin solution was mixed with a 20- μ l aliquot of the condensed tannin solution, or 70% ethanol (control). An aliquot (20- μ l) of the tannin mixture was then mixed with 200 μ l of the pH 10 buffer, and the EPR spectrum was obtained (Barbehenn et al., 2006, this issue). Each condensed tannin and hydrolyzable tannin was examined alone to determine mean concentrations of semiquinone radicals. Each treatment was examined using 4–6 measurements (replicates) with independently weighed tannin samples. The ratios of condensed tannin/ellagitannin and condensed tannin/hydrolyzable tannin were chosen to encompass those found in trees such as sugar maple. Due to the length of each experiment, each of the four condensed tannins were examined with both hydrolyzable tannins on separate days. TEMPO standards ($N = 2$) were run on each day, and used to confirm that day-to-day variation in EPR measurements had a negligible effect on the results. In the absence of condensed tannins, semiquinone concentrations from replicate hydrolyzable tannin measurements were divided by the mean semiquinone concentration, defining the expected value as 100 percent (Table 3). Expected values for semiquinone concentrations in tannin mixtures were calculated from the sum of the semiquinone concentrations from the tannins that were examined separately in each experiment.

The browning assay was used to measure the effect of each of the four condensed tannins on the rate of browning of pedunculagin and pentagalloyl glucose. The experimental design was the same as described for the EPR assay, with the following exceptions: A total of 80 μ l of each tannin mixture was prepared, from which three

replicate 20- μ l aliquots were placed in a 96-well microplate. pH 10 buffer (180 μ l, ambient oxygen level) was added to start these reactions. Thus, tannin final concentrations were slightly higher in the browning assay than in the EPR assay. Either four or five replicate measurements were made for each treatment (tannin concentration and mixture). Pentagalloyl glucose browning rates were measured in each run to ensure that day-to-day variation was negligible.

EPR Time-Course Assay on Whole-Leaf Extracts

Fresh red oak and sugar maple leaves ($N = 3$ trees/species) were ground under liquid nitrogen and extracted in nitrogen-purged ethanol (6 ml) in June and July 2003, as described previously (Barbehenn et al., 2005). Phenolics from the same trees were analyzed in this study, but were sampled in 2004. Extracts were stored at -80°C under a nitrogen atmosphere in plug-seal screw-cap centrifuge tubes. Leaf extracts stored in this manner appear to remain stable for a period of at least 4–7 months (Barbehenn et al., 2003b), but neither the stability of the phenolics over longer time periods nor the potential effects of ethanolysis on phenolic composition were examined (Mueller-Harvey, 2001). Aliquots (20 μ l) were taken from each extract, mixed with the pH 10 buffer (200 μ l), placed in a flat cell, and observed with EPR, as described above. EPR was used to identify the radicals formed (ascorbyl or semiquinone) in each sample and to follow their concentrations over a 45-min period. Samples were rescanned at five-min intervals. Spectra were identified and quantified, as described above. As ascorbyl radical levels in sugar maple samples decayed and semiquinone radicals formed, a spectrum in which small amounts of both radicals were present was formed. These intermediate spectra were regarded as 0 nM for each radical type due the difficulty of quantifying small amounts of these radicals in mixtures. TEMPO radical standards were used to calculate ascorbyl and semiquinone radical concentrations (Barbehenn et al., 2006, this issue). The fresh weight of each leaf sample was used to standardize radical concentrations, i.e., radical concentration/mg. Ascorbyl radical decay rates were normalized for ascorbyl radical concentrations by dividing them by the ascorbyl radical concentration at the start of the time course.

Statistical Analyses

The relationships between the percentage of three groups of tannins in sugar maple phenolic fractions and the oxidative activities of these fractions were examined with linear regressions (Wilkinson, 2000). The effects of condensed tannins on hydrolyzable tannin semiquinone radical concentrations and browning rates were examined by two-way ANOVA (SAS; PROC MIXED procedure), using hydrolyzable tannin type, condensed tannin type, and condensed tannin concentration and their two-way and three-way interactions in the model (SAS, 2000). The percent of the expected oxidation rate was calculated as the actual rate of oxidation (semiquinone concentration or browning rate) divided by the sum of the browning rates for the condensed tannin and hydrolyzable tannin when measured alone. The percent of expected values for pedunculagin and pentagalloyl glucose controls (i.e., without added condensed tannin) were calculated as the individual variate/mean, with the mean expected rates of pure hydrolyzable tannins defined as 100%. Data from both EPR and browning assays were arcsin square root transformed to fit a normal distribution. Pairwise multiple comparisons were made using the differences of least-square means (PROC MIXED) to test *a priori* hypotheses for concentration effects (i.e., control oxidation > 0.05 mg/ml > 0.10 mg/ml). In each ANOVA analysis, the main

effects and interactions were significant ($P < 0.001$), and specific comparisons of interest are reported in Results. All summary statistics are presented as the mean \pm SEM.

Results

Red oak and sugar maple leaves contained distinctly different classes and concentrations of phenolics (Table 1). Red oak contained approximately one fourth the amount of total phenolics found in sugar maple leaves. The bulk of the tannins in red oak were condensed tannins, with little ellagitannin and no galloyl glucoses found. Sugar maple contained substantial amounts of ellagitannins and condensed tannins, as well as a wide range of galloyl glucoses. Neither species contained high-molecular-weight gallotannins (i.e., galloyl glucoses larger than pentagalloyl glucose). Further characterization of the low-molecular-weight condensed tannins showed that red oak and sugar maple contained 0.5 and 2.5 mg/g monomeric–trimeric condensed tannins, respectively. The crude phenolics from red oak produced broad, weak semiquinone radical spectra, similar to those of oligomeric and polymeric condensed tannins (Barbehenn et al., 2006 this issue). The crude phenolics and

phenolic fractions from sugar maple produced semiquinone radical spectra with line shapes that were similar to spectra from hydrolyzable tannins (Barbehenn et al., 2003a, 2006).

The overall oxidative activities of sugar maple and red oak phenolics were compared with three measures: semiquinone concentration, semiquinone decay rate, and browning rate. Each of these measures was significantly higher in sugar maple phenolics than in red oak phenolics ($P < 0.05$; Table 2).

Significant regressions relating tannin composition and the rate of browning were observed in phenolic fractions from sugar maple leaves (Fig. 1a,b,c). Browning rates increased as the percentage of ellagitannins in the fractions increased ($R^2 = 0.76$, $P < 0.001$). By contrast, the rate of browning decreased as the percentage of condensed tannins in these fractions increased ($R^2 = 0.74$, $P = 0.001$), and browning rates also decreased as the percentage of galloyl glucoses increased ($R^2 = 0.41$, $P = 0.034$). Similarly, the relationship between each of the three types of tannins and semiquinone decay rates showed the same direction of association as did browning rates, i.e., increasing with higher ellagitannin content ($R^2 = 0.29$, $P = 0.14$), decreasing with higher condensed tannin content ($R^2 = 0.62$, $P = 0.012$), and decreasing with higher galloyl glucose content ($R^2 = 0.23$, $P = 0.19$). Although not statistically significant, the association between each of the three types of tannins and semiquinone concentrations also showed the same direction of association as did browning rates and semiquinone decay rates ($R^2 = 0.10$ – 0.23).

Ellagitannin and condensed tannin levels were themselves negatively correlated in the maple fractions ($r = -0.73$), suggesting that lower oxidation rates in condensed tannin-rich fractions could either be caused by a direct effect of condensed tannins on oxidation rates or the result of decreased concentrations of ellagitannins in fractions that were rich in condensed tannins. Therefore, the direct effects of condensed tannins on hydrolyzable tannin oxidation rates were tested to understand the basis for the negative relationship between condensed tannins and oxidative activities in phenolic fractions from maple leaves. Semiquinone radical concentrations from pedunculagin (ellagitannin) and pentagalloyl glucose were significantly decreased in the presence of all four types of condensed tannins tested (Table 3). The expected concentrations of semiquinones from pedunculagin were decreased between 17% and 90% by an equal concentration of condensed tannins, and decreased by 29–92% by twice the concentration of condensed tannins, a small, but significant decrease from the higher condensed tannin concentration ($P = 0.015$). Similarly, pentagalloyl glucose formed lower concentrations of semiquinone radicals in the presence of equal or greater concentrations of condensed tannins ($P < 0.001$; Table 3). Condensed tannins decreased semiquinone concentrations from pentagalloyl glucose by 42–85% and 74–91% by an equal concentration or twice the condensed tannin concentration, respectively. Thus, condensed tannins had a greater antioxidant effect on pentagalloyl glucose than on pedunculagin ($P < 0.001$). Prodelphinidin-rich condensed tannins were the

Data are presented as mean ± SE from four or five independent measurements. Different letters indicate significant differences between means within each tannin combination. Browning rates for procyanidin (PC) monomers-trimers, oligomers, procyanidin polymers, and prodelphinidin (PD)-rich (55%) polymers averaged 0.3, 0.2, 0.0, 5.1 mAbs/min, respectively, at 0.05 mg/ml, and averaged 0.3, 0.6, 0.1, 7.7 mAbs/min at 0.10 mg/ml.

most effective antioxidants for both types of hydrolyzable tannins ($P < 0.001$ for each condensed tannin comparison). The condensed tannins themselves formed relatively low levels of semiquinones (Table 3).

Condensed tannins had a wide range of effects on the rates of browning of the hydrolyzable tannins (Table 4). The expected rates of browning of pedunculagin and pentagalloyl glucose were decreased by 54–76% by prodelphinidin-rich condensed tannins

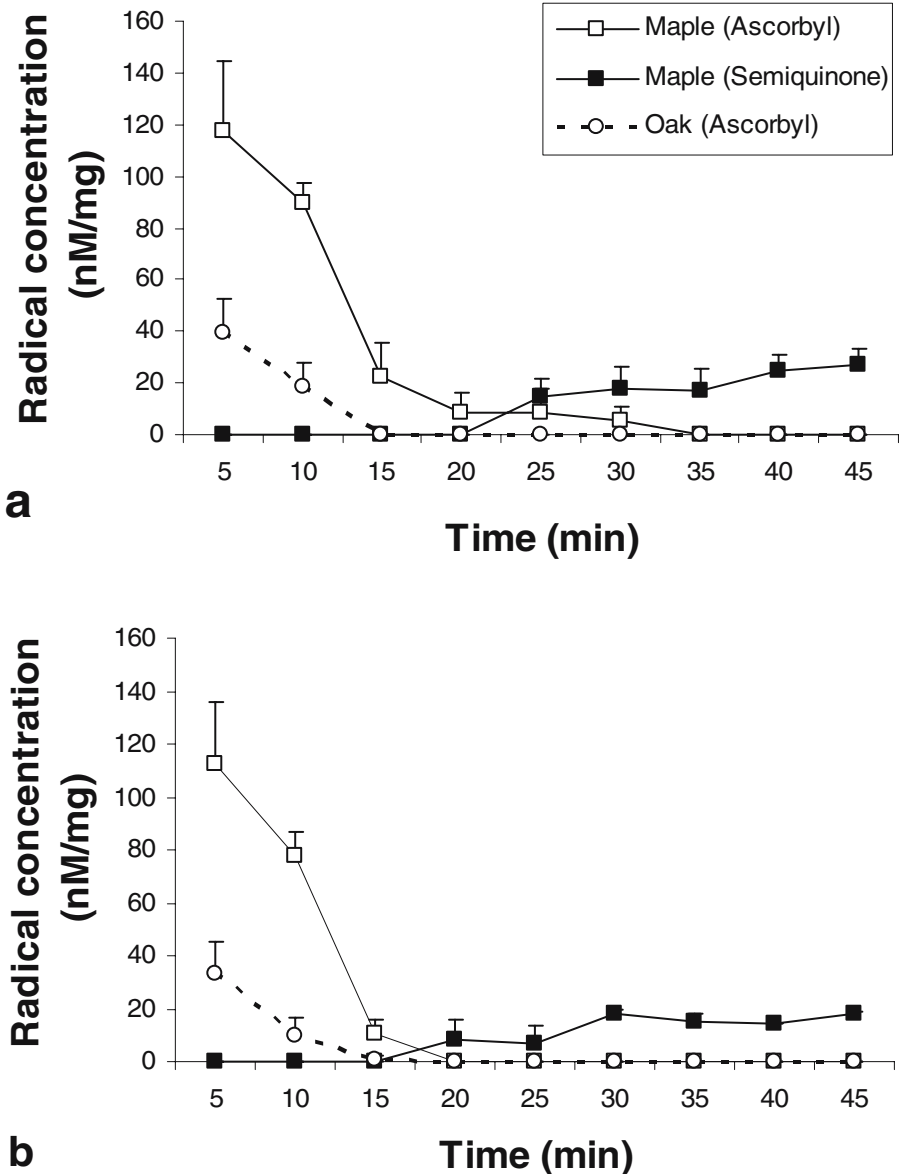

Fig. 2 EPR time-course analyses of ethanolic extracts of red oak and sugar maple leaves in June (a) and July (b) 2003. The same trees were used in 2003 as were used for chemical analyses and measurement of oxidative activities in 2004 in this study. Radical concentrations are presented on a leaf fresh weight basis

($P < 0.001$). Oligomeric and polymeric procyanidin condensed tannins had significant, but weak, antioxidant effects on both hydrolyzable tannins. Low-molecular-weight condensed tannins had a striking prooxidant effect on the hydrolyzable tannins, increasing the browning rate of pedunculagin by 36–86% ($P < 0.005$) and increasing the browning rate of pentagalloyl glucose by 229–269% ($P < 0.001$). Condensed tannins themselves generally had low browning rates, adding little directly to the overall expected rates (Table 4). Prodelphinidin-rich condensed tannins were an exception, having both a markedly higher browning rate than the other condensed tannins, as well as the greatest antioxidant activity.

When red oak leaf extracts from June were examined at pH 10 with EPR, ascorbyl radicals were observed (Fig. 2a). Concentrations of ascorbyl radicals decreased over a 15-min period, but semiquinone radicals were not detected during the following half hour. Similar results were observed from extracts of leaves from July (Fig. 2b). Extracts of sugar maple leaves initially produced ascorbyl radicals at concentrations that were 3.0- to 3.3-fold higher than those from red oak (Fig. 2a,b). When normalized for the initial radical concentration, the rates of decay of ascorbyl radicals during the first 15 min of the assay were similar in the extracts of maple and oak in June (0.45 and 0.48 nM/mg/min, respectively) and July (0.41 and 0.50 nM/mg/min, respectively). However, after ascorbyl radical concentrations fell below detectable levels, only sugar maple extracts produced increasing concentrations of semiquinone radicals.

Discussion
