The results of this study on the phenolic fractions, total phenolics, and ethanolic extracts of red oak and sugar maple leaves suggest that the oxidative activities of these leaves can be affected by their tannin composition. The oxidative activities of phenolic fractions from sugar maple were positively associated with their ellagitannin content, but negatively associated with condensed tannins and galloyl glucoses. Although these relationships were statistically significant mainly from the browning assay, regressions for the three measures of oxidative activity for each of three tannin types point toward the same overall conclusions. A positive relationship between ellagitannin concentration and phenolic oxidation rate was expected based on the unusually high rates of oxidation of purified ellagitannins at pH 10 (Barbehenn et al., 2006, this issue). However, the finding that condensed tannins can decrease the oxidation of hydrolyzable tannins was unexpected, and such interactions suggest that tannin composition in plants can have either positive or negative effects on their overall oxidative activities. This study provides a more complete explanation for the greater oxidative activity of sugar maple than red oak for caterpillars than was previously proposed (Barbehenn et al., 2005); in addition to the relatively low ratio of ascorbate/total phenolics in sugar maple, 34% of the phenolics produced by the maple trees were highly active ellagitannins. In contrast, red oak had a higher ratio of ascorbate/total phenolics (Barbehenn et al., 2005), and 71% of its phenolics were condensed tannins with low oxidative, or potentially antioxidant, activity. Only 1% of the phenolics in the red oak leaves were ellagitannins.

An important conclusion of this study is that the oxidative activities of tree leaves cannot be predicted from common measures of phenolics, such as total phenolics or total hydrolyzable tannins. Not only do the oxidative activities of the component phenolics in these measures vary tremendously, but redox reactions between phenolics (e.g., hydrolyzable and condensed tannins) can also change the oxidative activity of the mixture greatly. Dynamic methods for measuring the total oxidative activities of leaves, such as the

EPR time-course assay in this study, provide a useful overview of the complex chemical reactions that occur in the mixtures of phenolics and numerous other compounds from tree leaves. Our results suggest that more oxidatively active leaves, such as those from sugar maple, are marked by the production of semiquinone radicals, once ascorbyl radical (and hence ascorbate) levels have decreased. This pattern has been observed previously (Yamasaki and Grace, 1998; Grace et al., 1999) and reflects the instability of ascorbate at high pH, as well as the loss of ascorbate and ascorbyl radicals upon their reaction with semiquinone radicals and quinones. The higher concentrations of ascorbyl radicals in sugar maple than red oak extracts was the opposite of our expectation based on the higher ascorbate concentrations in oak leaves (Barbehenn et al., 2003b). It is possible that ascorbate oxidizes more rapidly to ascorbyl radicals in sugar maple because of a higher reaction rate between ascorbate and oxidized phenolics in extracts. The lack of observable semiquinone radicals from red oak extracts is consistent with the presence of moderate levels of condensed tannins in this species and the low levels of semiquinone radicals formed by these tannins (Barbehenn et al., 2006, this issue).

An assumption of this work is that ethanolic extracts of leaves contain the bulk of the redox-active compounds that are present in the midgut fluids of caterpillars, e.g., phenolic compounds, ascorbate, and α -tocopherol (Barbehenn et al., 2003b), and that the comparison of the oxidative activities of the two species in this study would not be changed by the inclusion of the insoluble leaf components, e.g., cell wall polymers, starch, and proteins. Some support for this assumption is provided by the results of a previous study showing that the consumption of sugar maple produces higher levels of phenolic oxidation in the midgut fluids of caterpillars than does the consumption of red oak (Barbehenn et al., 2005). Experiments with tannin-treated leaves is needed to confirm that variation in tannin composition can produce the observed differences in levels of phenolic oxidation in caterpillar midgut fluids.

The oak/maple dichotomy observed in this study is not a general pattern found in these plant taxa, because ellagitannins are found in abundance in many oak species (e.g., Haddock et al., 1982; Haslam, 1989). The individual red oak and sugar maple trees examined are unlikely to represent the full range of phenolics (both types and concentrations) found in each of these species over their wide geographical ranges and through time. Indeed, some leaf extracts from sugar maple trees in other study sites produced EPR time-course results that showed either the immediate formation of high levels of semiquinone radicals or ascorbyl radicals without the subsequent formation of semiquinone radicals (unpublished data). It is unclear whether phenolic composition and/or ascorbate concentration might explain this between-tree variation.

Low-molecular-weight phenolics interfered with the determination of the oxidative activities of tannins in some phenolic fractions in two ways: (1) highly active phenolics, such as gallic acid, can dominate the overall activities observed, and (2) less active phenolics, such as chlorogenic acid, can produce steadily increasing concentrations of secondary radicals over time (Grace et al., 1999). In some phenolic fractions, such a continuous increase in semiquinone radicals precluded our ability to measure their concentration maxima. However, the concentrations of low-molecular-weight phenolics in the crude phenolics or whole-leaf extracts from the trees in this study were at sufficiently low levels that they did not dominate the overall oxidative activities of the leaves. For example, gallic acid (0.7 mg/g in sugar maple leaves) can be calculated to contribute only 3–4% of the semiquinone concentration and approximately 11% of the browning rate of the total phenolics (Barbehenn et al., 2006, this study).

Condensed tannins can be found at high levels in many tree leaves and can deter feeding by herbivores, supporting the idea that they may have evolved, in part, as a generalized chemical defense. However, recent studies have found little support for this hypothesis in tree-feeding caterpillars (Ayres et al., 1997; Osier et al., 2000; Kopper et al., 2002). Alternatively, because there are high concentrations of condensed tannins in some leaves, they may act as antioxidants in the midgut contents of caterpillars. Thus, we raise the possibility that positive correlations between condensed tannin levels and caterpillar performance (e.g., Rossiter et al., 1988; Hemming and Lindroth, 1995) could have a substantive biochemical basis. A positive impact might be most pronounced when condensed tannins are ingested in ellagitannin-rich leaves and when the condensed tannins are themselves prodelphinidin-rich.

A prodelphinidin-rich condensed tannin had the greatest ability to decrease the oxidation of hydrolyzable tannins in this study. Other hydrolyzable tannins [cocciferin D₂, vescaligin, and gallotannins (mean MW=1396 Da)] also had substantially lower rates of browning in mixtures with the prodelphinidin-rich condensed tannin (unpublished data). Prodelphinidin subunits are distinguished by a pyrogallol (trihydroxy) substitution on the B-ring, whereas procyanidin subunits have a catechol-type B-ring. A variety of phenolics containing galloyl (trihydroxy) groups have higher redox activities than their structural counterparts containing catechol groups, e.g., flavonoids, anthocyanins, catechins, and condensed tannins (Cao et al., 1997; Guo et al., 1999; Okuda, 1999a,b; Williamson et al., 1999; Kähkönen and Heinonen, 2003). The results of this work suggest that it may be important to measure the prodelphinidin/procyanidin ratio or total prodelphinidins, and not merely total condensed tannins, to understand their impact on caterpillars.

We are unaware of studies that have compared the biological activities of purified ellagitannins, condensed tannins, and their mixtures in herbivorous insects. For example, do condensed tannins decrease the amount of oxidative damage to essential nutrients in the midgut or decrease oxidative stress in midgut tissues when co-ingested with ellagitannins? To the extent that foliar oxidative activity provides a defense against herbivores such as caterpillars, the results of this study suggest that there may be a trade-off between producing ellagitannin- or condensed tannin-rich leaves as effective defenses against different ecological challenges. Further work in these areas would provide a stronger basis for understanding the role of insect herbivory in the evolution of foliar tannin composition.

Acknowledgments This project was supported by the National Research Initiative of the USDA Cooperative State Research, Education and Extension Service grant number 2004-35302-14940 to R. Barbehenn and C. P. Constabel. Support for J.-P. Salminen and Maarit Karonen was provided by grants 204209 and 201073 from the Academy of Finland, respectively. Jonna Kenttä, Riitta Koivikko, Jaana Liimatainen, Tuuli Luomahaara, Angelica Preetz, and Victor Turhanen assisted with the isolation of tannins.

Introduction

Tannins in higher plants are broadly categorized as hydrolyzable or condensed (proanthocyanidins; Fig. 1). Hydrolyzable tannins are synthesized from galloyl glucoses, with pentagalloyl glucose serving as the precursor for both higher-molecular-weight gallotannins and ellagitannins. Whereas high-molecular-weight gallotannins contain additional galloyl groups on pentagalloyl glucose, ellagitannins contain two or more neighboring galloyl groups that are oxidatively coupled to form rigid groups such as hexahydroxydiphenoyl (HHDP) units (Okuda et al., 2000; Fig. 1). Condensed tannins are polymers of flavan-3-ols, including procyanidins and prodelphinidins (Fig. 1).

Tannins are both structurally diverse and have diverse ecological functions. They commonly comprise from 0.5% to 10% dry weight of tree leaves, but levels on the order of 20% dry weight are found in some species (Swain, 1979; Salminen et al., 2004). Because tannins are commonly present in much larger amounts than other phenolics, they generally are believed to be a major component of the chemical defenses in leaves. They can act not only as feeding deterrents but also as antimicrobial agents, ultraviolet light protectants, and possibly toxins (Swain, 1979; Hagerman and Butler, 1991; McAllister et al., 2005).

In ecological studies, separate measurements of total gallotannins and condensed tannins are occasionally made, but little attention has been paid to ellagitannins. Despite decades of research, the relative importance of different classes of tannins as antiherbivore defenses remains poorly understood. At root is a lack of understanding of the physiological mechanisms of activity in herbivores and the influence of structure on these mechanisms.

Tannins are defined, in part, by their ability to bind and precipitate proteins, and the ability of tannins to precipitate proteins remains a common assay for their potential biological activity against herbivores (e.g., Ossipov et al., 2001; Riipi et al., 2002). Although tannins do bind proteins in the physiological conditions found in vertebrate herbivores (Hagerman, 1989), this mode of action has not been supported in insect herbivores. First, surfactants in insect gut fluids prevent the formation of insoluble protein–tannin complexes (Martin et al., 1987). Second, when phenolics are present in pH conditions that exceed their pK_a values (ca. pH 9), they are ionized and lose much of their hydrogen-bonding (and protein-binding) ability (Hagerman and Butler, 1978). However, polyphenols are susceptible to oxidation at high pH (Simic and Jovanovich, 1994). Thus, in herbivores with high gut pH, such as caterpillars (Appel and Martin, 1990), one alternative mode of action for phenolic compounds is their prooxidant activity. Although many phenolics are excellent antioxidants at acidic to neutral pH (e.g., Rice-Evans et al., 1996; Hagerman et al., 1998), at high pH phenolics and their oxidation products may act as prooxidants, promoting damage to nutrients in the gut lumen and causing oxidative stress in the surrounding gut tissues (Appel, 1993; Summers and Felton, 1994; Barbehenn et al., 2005). In general, quinones are reactive and often toxic compounds in biological systems (Gant et al., 1988; Thiboldeaux et al., 1998).

Recent work comparing the oxidative activities of sugar maple (*Acer saccharum*) and red oak (*Quercus rubra*) leaves in caterpillars found elevated levels of semiquinone radicals, protein carbonyls, and total peroxides in the gut fluids of caterpillars that ingested sugar maple leaves (Barbehenn et al., 2005). This study concluded that sugar maple might have greater prooxidant activity than red oak, in part as a result of its tannin composition, especially ellagitannins. Sugar maple contained relatively large amounts of ellagitannins, along with galloyl glucoses and condensed tannins, whereas red oak contained smaller amounts of condensed tannins, but little or no hydrolyzable tannins.

To test the hypothesis that ellagitannins have greater oxidative activities than galloyl glucoses or condensed tannins, we compared the oxidative activities of a structurally diverse set of polyphenols (Fig. 4). The hydrolyzable tannins chosen for comparison represent six of the different branches of the biosynthetic pathway of hydrolyzable tannins found in higher plants (cf. Gross, 1999; Salminen et al., 2001, 2004). The galloyl glucoses examined (monogalloyl to pentagalloyl glucose) are biosynthetic precursors to gallotannins and ellagitannins. For this study, we have grouped galloyl glucoses and high-molecular-weight gallotannins together because these phenolics lack the distinctive oxidatively coupled galloyl groups present in ellagitannins. The ellagitannins examined represent a range of types, including molecules with cyclic or acyclic glucose cores, and dimers in which both types of subunits are combined. The condensed tannins examined represent molecules composed entirely of procyanidin units or largely of prodelphinidin units, and a wide range of molecular weights (Fig. 1).

The main goal of this study was to assess the extent to which different tannins might act as prooxidants in biological systems at high pH. The oxidative activities of tannins were characterized primarily by two measures: the concentration of semiquinone radicals formed and the rate of browning. A third characteristic, semiquinone radical decay rate, was also measured, but was less useful as a means of distinguishing between different groups. Measurements of semiquinone radicals and brown pigments (formed by quinones) provide two different estimates of the propensity of phenolics to form reactive oxygen species. Electron paramagnetic resonance (EPR) spectrometry measured semiquinone radicals, which are formed by the one-electron oxidation of phenolics. A browning assay was developed to provide an independent measure of the rate of phenolic oxidation to quinones following a loss of two electrons. The oxidative activities of tannins in the pH and oxygen conditions relevant to many caterpillar midgut fluids (pH 10 and low oxygen concentration; Johnson and Barbehenn, 2000) were approximated in the EPR assay, whereas the browning assay was carried out in solutions at ambient oxygen concentration. By examining the oxidative activities of three different classes of tannins, this study addressed their relative potential as plant oxidative defenses against herbivores, such as caterpillars.

Methods and Materials

Tannin Purification

1-*O*-galloylglucose (purity 91.2%), 1,6-di-*O*-galloylglucose (>99.9%), 1,2,6-tri-*O*-galloylglucose (>99.9%), and 1,2,3,6-tetra-*O*-galloylglucose (>99.9%) were isolated from leaves of *Betula pubescens* as described in Salminen et al. (2001). 1,2,3,4,6-Penta-*O*-galloylglucose (>99.9%) was purified from tannic acid (Baker) as described by Salminen and Lempa (2002). A mixture of high-molecular-weight gallotannins, including hexa- to tridecagalloylglucoses (>99.9%, mean MW 1396 Da), was isolated from tannic acid (Baker) by column chromatography with Sephadex LH-20 using the elution profile described in Salminen et al. (1999). Pedunculagin (95.8%) was isolated from leaves of *Betula nana* as described by Salminen et al. (1999, 2001). Oenothien B (>99.9%) was isolated and purified from the inflorescences of *Epilobium angustifolium* with a combination of Sephadex LH-20 and preparative high-performance liquid chromatography (HPLC) as described previously (Salminen et al., 1999, 2001). Cocciferin D₂ (94.3%) was isolated from the leaves of

Fig. 1 Structures of some examined ellagitannins, a galloyl glucose, and condensed tannins. Pentagalloyl glucose is the core metabolite of the hydrolyzable tannins, and can be further esterified with galloyl groups to yield gallotannins. Oxidative coupling of galloyl groups in galloyl glucoses and gallotannins yield ellagitannins, including pedunculagin, cocciferin D₂, vescalagin, and oenothin B. Condensed tannins are typically formed by 4→8- or 4→6-coupled flavan-3-ols such as catechin or gallicocatechin

Quercus robur, as described in Salminen et al. (2004). Vescalagin was isolated from the leaves of *Q. robur*, and included castavalonic acid as an impurity (ratio 3:1, ellagitannin purity >99.9%, approximately MW 990 Da). Castavalonic acid is a galloylated form of castalagin, an isomer of vescalagin. Compound purities were measured with HPLC coupled with a diode array detector (280 nm). Identities were confirmed by UV and mass spectra, and by nuclear magnetic resonance spectroscopy (Salminen et al., 2001, 2004, unpublished data).

Condensed tannins, i.e., procyanidin monomers to trimers (average MW=578 Da), procyanidin oligomers (average MW=1442 Da), and procyanidin polymers (average MW=2882 Da) were isolated from bark of *Pinus sylvestris* by column chromatography on Sephadex LH-20 as described in Karonen et al. (2004). Procyanidins were identified on the basis of retention times and UV and mass spectra (well-defined molecular ions and fragment ions) characteristic for procyanidins. High-molecular-weight prodelphinidin-rich condensed tannin polymers (prodelphinidin/procyanidin=55:45, average MW=9026 Da) were obtained from mountain birch leaves (*B. pubescens* ssp. *czerepanovii*). These tannins were purified by using a Sephadex LH-20 column with an elution profile as described in Ossipova et al. (2001). Prodelphinidin/procyanidin ratios and approximate molecular weights were characterized with ¹³C-NMR spectroscopy as described in Karonen

et al. (2006). Condensed tannin samples were highly pure (>99.9%), as measured by normal-phase HPLC (Karonen et al., 2006).

EPR Spectrometry

Tannin samples were weighed to the nearest microgram on a Cahn 25 Electobalance (Cahn Instruments, Inc., Cerritos, CA, USA). Solvents for EPR experiments were purged with nitrogen by bubbling them for 1 min/ml, and kept under a nitrogen atmosphere. Immediately before analysis, samples were dissolved in ethanol/double-distilled water (70:30, v/v) and kept under a nitrogen atmosphere. The stock tannin solution was serially diluted with 70% ethanol to produce final concentrations ranging from 0.5 to 3.0 mg/ml. To achieve reaction mixtures containing 20–300 μM tannin, a 20- μl aliquot of each tannin solution was added to a 2-ml centrifuge tube containing 200 μl of pH 10 carbonate buffer (70 mM), containing 10% (v/v) dimethylsulfoxide to help stabilize semiquinone radicals. A 200- μl aliquot of this mixture was placed in a quartz flat cell (Wilmad Glass Co., Buena, NJ, USA) that was pretuned in a cylindrical TM₁₁₀ cavity. EPR spectra (Fig. 2) were obtained within 30 sec of sample mixing, and recorded at room temperature with a Bruker EMX spectrometer (X-band frequency). Instrument parameters were as follows: center field, 3483 G; sweep width, 15 G; point resolution, 1024; frequency, 9.76 GHz; microwave power, 20.17 mW; gain, 5.02e^5 ; modulation frequency, 100 kHz; modulation amplitude, 1.00 G; time constant, 10.24 msec; scan rate, 0.24 G/sec. A single scan per sample was used for hydrolyzable tannins. Because of the low signal produced by condensed tannins, these were scanned five times. Hydrolyzable tannin samples were rescanned at 84-sec intervals for up to 35 min to determine the rate of radical decay, and the condensed tannins were rescanned at 7-min intervals. Because the kinetics of radical production differed among compounds, we measured the maximum semiquinone concentration produced for each compound, rather than the concentration at a fixed time after starting the reaction. Likewise, the time at which the maximum signal was produced served as the starting point for determining the rate of radical decay. The time to produce the maximum semiquinone radical concentration varied from less than 30 sec for tannins such as pedunculagin to as much as 11 min for tannins such as oenothlein. Radicals produced by purified tannins were identified as semiquinones based on comparisons of the line shapes and center field positions with EPR spectra from previous studies using similar conditions (e.g., Bors et al., 2000; Barbehenn et al., 2003). The area of each first derivative spectrum was quantified by double integration using WinEPR software (Bruker Instruments, Billerica, MA, USA). The calculated areas of condensed tannin spectra were divided by five, which accurately corrected for the higher number of scans of these samples (unpublished data). Between two and four replicate samples of separately weighed samples were run for each tannin.

Standard solutions of the stable free radical, 2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO, Aldrich Chemical Co.) were made in 70% ethanol (0.58 μM final concentration) and analyzed with EPR in pH 10 buffer using identical EPR conditions as described above. Daily measurement of TEMPO standards ($N = 2$ independent solutions/d) confirmed that the method was consistent through time, and provided a free radical standard for converting double integrals of spectra to molar concentrations. The area obtained by double integration of the spectra from TEMPO standards averaged 0.224 ± 0.006 area units per nanomolar TEMPO from 22 runs over a 4-mo period.

Fig. 2 Representative EPR spectra of ellagitannins, galloyl glucoses, and condensed tannins. (a) Oenothein B (ellagitannin). (b) Pedunculagin (ellagitannin). (c) Pentagalloyl glucose. (d) Condensed tannin oligomers. Hydrolyzable tannins were scanned three times for presentation, whereas the condensed tannin oligomer sample was scanned 30 times. Center field and field width of all spectra were 3483 and 15 G, respectively

Regressions relating semiquinone concentration and tannin concentration were plotted for each phenolic compound (Fig. 3a). The slope of each regression represents the semiquinone concentration normalized for sample concentration, and this value was used for calculating the semiquinone concentration produced by each phenolic (i.e., nM radical/ μ M phenolic). These plots also confirmed that the range of concentrations examined were within the linear range for measuring semiquinone concentrations. The rate of decay of semiquinone radicals was normalized for the effect of semiquinone concentration by using the concentration of radicals at the start of the decay period.

Phenolic Browning Assay

A spectrophotometric measure of the rate of browning of a low-molecular-weight phenolic (Misra and Fridovich, 1972) was adapted to measure the browning of tannins with a microplate reader. Samples were weighed as described above, but were dissolved in 400 μ l of 70% ethanol (nitrogen-purged), and kept under a nitrogen atmosphere until used. Purified tannins were serially diluted 1:1 with 70% ethanol to produce a series of four tannin concentrations that were kept under nitrogen. The same pH 10 buffer used for EPR was used in this assay, but it was not bubbled with nitrogen, because oxygen was necessary for the formation of brown pigments within a 3-min period. Aliquots (20- μ l, 3 replicates) of each sample solution were placed in a 96-well microplate (3 columns per run). Phenolic concentrations in the reaction mixture typically ranged from 0.01 to 0.1 mM, and oxygen concentration was estimated to be about 0.25 mM, based on saturation levels at typical room temperature and pressure. To start the reaction, 180 μ l of pH 10 buffer were added to each well with an 8-channel multiple pipetter. Absorbance was measured at 415 nm, beginning 15 sec after the addition of the buffer. Subsequent measurements were made with a kinetic protocol every 8 sec over a period of 3 min by using a Bio-Rad Benchmark microplate reader (Bio-Rad, Hercules, CA, USA). The initial, linear rate of browning

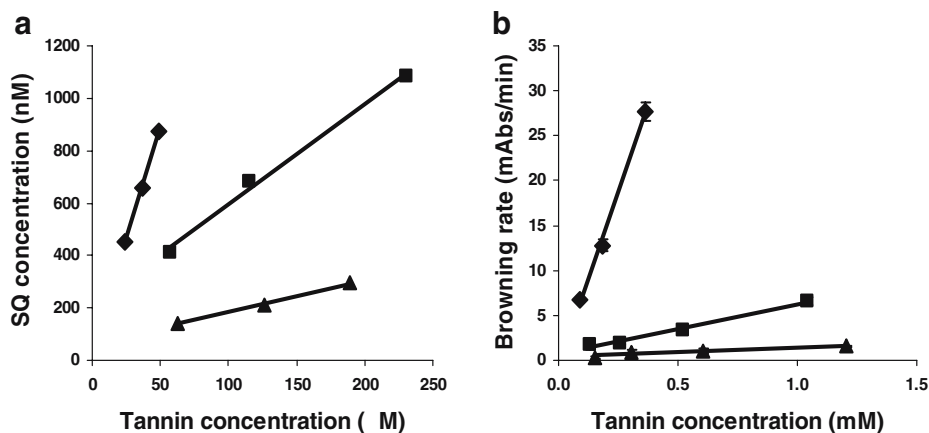

Fig. 3 Representative plots used to normalize semiquinone concentration (a) and browning rate (b) for the effect of tannin concentration. Tannins plotted include coccoiferin D₂ (ellagitannin; ♦), tetragalloyl glucose (■), and condensed tannin oligomers (▲). Slopes of these regressions represent the normalized values for each assay. Semiquinone concentrations are plotted for the single replicate analyzed per tannin concentration from one assay. Between two and three separate assays were run for each tannin. Mean browning rates are plotted from three replicate measurements per tannin concentration (\pm SEM) from one assay. Between two and seven assays were run for each tannin. Where not visible, the SEM is smaller than the symbol in (b)

(mAbs/min) was measured within the first 60 sec of the reaction. Between 2–6 replicate reactions were run for separately weighed samples. A pentagalloyl glucose standard was run on each day to confirm that measurements were consistent through time. Plots of browning rate vs. sample concentration (mM) were made for each sample to confirm that rate was a linear function of concentration for each compound (Fig. 3b). The slopes of these plots were used as the browning rates (normalized for sample concentration as mAbs/min/mM phenolic).

Statistical Analysis

The relationships between semiquinone concentration, semiquinone decay rate, and browning rate vs. the number of galloyl groups in galloyl glucoses were determined with Model II regressions (Wilkinson, 2000). The associations between semiquinone decay rate and semiquinone concentration, and between semiquinone decay and browning rates for each of the tannin groups were examined with correlations (Wilkinson, 2000). Because of non-normal data and small sample sizes, comparisons of mean semiquinone radical concentrations, semiquinone decay rates, and browning rates between tannin groups were made by using Kruskal–Wallis nonparametric tests (Wilkinson, 2000). All summary statistics are presented as the mean \pm SEM.

Results

Ellagitannins, galloyl glucoses, and gallotannins produced EPR spectra similar to those reported for other phenolics (Bors et al., 2000), with little hyperfine structure (Fig. 2). Condensed tannins produced spectra with broad line shapes and much smaller amplitudes than those of hydrolyzable tannins. The maximum semiquinone concentration produced and the rate of browning differentiated the three tannin groups (Figs. 4a,c and 6a,b). In general, ellagitannins formed the highest concentrations of semiquinone radicals, whereas galloyl glucoses and condensed tannins formed lower levels of semiquinones. Semiquinone decay rates did not differ significantly between the tannin groups, although the high decay rate of one ellagitannin, vescalagin, suggested that there may be substantial variation within this tannin group (Fig. 4b). Higher semiquinone radical concentrations were formed by more highly esterified galloyl glucoses ($R^2 = 0.88$, $P < 0.05$; Fig. 5a), the opposite of the relationship between the rate of decay of galloyl glucose semiquinones and the number of galloyl groups ($R^2 = 0.96$, $P < 0.05$; Fig. 5b).

The browning rates of ellagitannins were generally higher than those of galloyl glucoses and high-molecular-weight gallotannins, which generally browned at higher rates than did condensed tannins (Figs. 4c and 6b). Among the galloyl glucoses, browning rates decreased as the number of galloyl groups increased ($R^2 = 0.83$, $P < 0.05$; Fig. 5c). Oenothin B, the only ellagitannin tested that had both HHDP and free galloyl groups, browned more slowly than did the other ellagitannins. Among the condensed tannins, the prodelphinidin-rich polymeric condensed tannins had an unusually high browning rate. In general, tannins that formed higher concentrations of semiquinones also browned more rapidly, but there were contrary examples within the hydrolyzable tannins, such as vescalagin and oenothin B. Consistent relationships were observed for each of the three types of tannins between the measures of oxidative activity: A negative association between semiquinone radical decay rate and semiquinone concentration was observed for ellagitannins ($r = -0.88$), galloyl glucoses ($r = -0.89$), and condensed tannins ($r = -0.48$), whereas semiquinone radical

Data are presented as mean ± SEM (*N* = 2–7 assays per tannin). SQ, semiquinone radical; GG, galloyl glucose; CT, condensed tannin; PC, procyanidin; PD, prodelphinidin

Fig. 5 (a) Relationship between the number of galloyl groups on galloyl glucoses (not including high-molecular-weight gallotannins) and semiquinone concentrations ($R^2 = 0.88$). (b) Relationship between the number of galloyl glucoses and semiquinone decay rates ($R^2 = 0.96$). (c) Relationship between the number of galloyl groups on galloyl glucoses and browning rates ($R^2 = 0.83$). Galloyl glucose semiquinone concentrations and browning rates were normalized for the initial molar concentrations of the galloyl glucoses. Semiquinone decay rates were normalized for the initial semiquinone radical concentrations. Data are presented as mean \pm SEM ($N = 2-7$). SQ, semiquinone radical

decay rate and browning rate were positively associated among ellagitannins ($r = 0.69$), galloyl glucoses ($r = 0.86$), and condensed tannins ($r = 0.82$).

To relate our results both to chemical mechanisms and ecological interactions, mean semiquinone concentrations and browning rates were compared on a molar and mass concentration basis (Fig. 6a,b). Semiquinone decay rates cannot be normalized on a mass basis. Similar values were obtained when the data were normalized based on mass ($\mu\text{g/ml}$) or molarity (μM) for most of the tannins tested, as expected for compounds with an average molecular weight of 1130 Da. The prodelphinidin-rich condensed tannin (average MW= 9026 Da) was a notable exception, with a browning rate that was nine-fold lower when

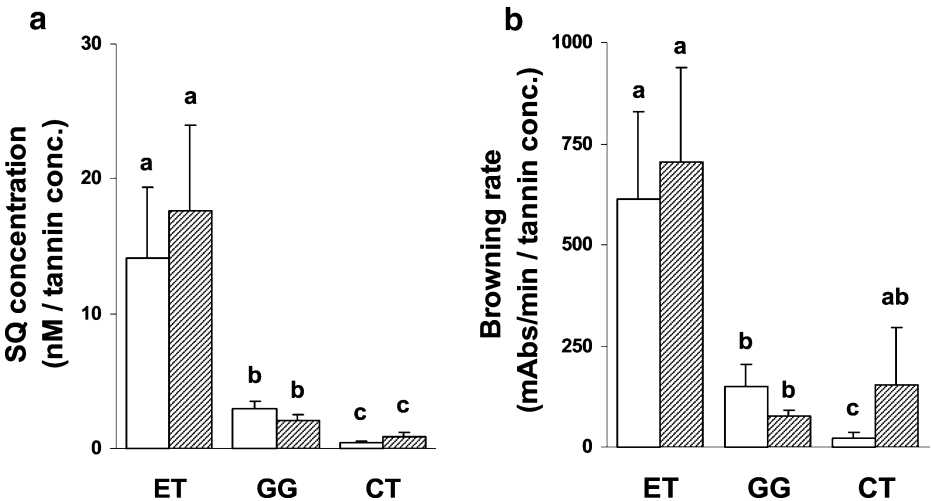

Fig. 6 Semiquinone radical concentrations (a) and browning rates (b) of ellagitannins, galloyl glucoses (including gallotannins), and condensed tannins when normalized for tannin concentration on a per mass basis ($\mu\text{g tannin/ml}$) or a molar basis. Data are presented as mean \pm SEM ($N = 4-6$). Different letters within each method of comparison indicate significant differences between tannin types. ET, ellagitannin; GG, galloyl glucose; CT, condensed tannin. \square , $\mu\text{g/ml}$ basis; ▨ , μM basis

normalized by mass concentration than when normalized by molarity. Thus, each method generally produced a similar pattern of oxidative activity among the tannin groups: ellagitannins > galloyl glucoses > condensed tannins.

Discussion

This study provides the first comparison of the oxidative activities of a wide variety of tannins at pH 10. Under these conditions, ellagitannins typically form high levels of semiquinone radicals and brown at high rates compared with galloyl glucoses, gallotannins, and condensed tannins. Because the oxidation of phenolics produces reactive oxygen species that can damage biological molecules, the results suggest that ellagitannin-rich plants have active oxidative defenses against herbivores with high gut pH. This expectation is consistent with the production of higher levels of peroxides and oxidized proteins in caterpillars that fed on sugar maple (ellagitannin-rich) compared with those that fed on red oak (condensed tannin-rich; Barbehenn et al., 2005).

An important conclusion of this study is that structural features of tannins affect their oxidative activities. Although the number of tannins examined was small, the results suggest some structure–activity mechanisms. Ellagitannins have oxidatively linked galloyl groups, which limit their ability to form resonance-stabilized radicals and potentially increase their oxidative activities (Wright et al., 1997; Bors et al., 2001b; Ito et al., 2002; Fukuhara et al., 2003; Quideau et al., 2004). Second, condensed tannins with a trihydroxyl substitution pattern on the B-ring (prodelphinidins) have greater browning rates than those with an *ortho*-dihydroxyl substitution pattern (procyanidins). This is consistent with previous findings of greater redox activity in pyrogallol- or galloyl-containing phenolics (Yoshioka et al., 1991; Cao et al., 1997; Guo et al., 1999; Okuda, 1999a,b; Fukumoto and Mazza, 2000; Mukai et al., 2005). The browning rate of gallic acid (a trihydroxyl phenol) was also 50-fold higher than that of chlorogenic acid (an *ortho*-dihydroxyl phenol; unpublished data).

In general, the EPR and browning assays produce similar rankings of oxidative activities among tannins (Fig. 6a,b). However, there are also differences between the two assays for certain compounds, e.g., oenothin B forms high concentrations of semiquinone radicals but has a low browning rate. In contrast, vescalagin forms low concentrations of semiquinones but has a high browning rate. These differences may be the result of using assays that are run under different oxygen concentrations and measure different oxidation products. EPR spectrometry measured the primary and secondary semiquinone radicals formed by phenolics under anoxic conditions, whereas the browning assay measured quinones and polymeric pigments under ambient oxygen conditions (Waite, 1976; Cilliers and Singleton, 1989; Grace et al., 1999). However, it is possible that the results of the three measures of oxidative activity are consistent with an oxidation pathway leading from phenolic to semiquinone radical to quinone. The negative correlation between semiquinone radical concentration and decay rate that was observed for each of the groups of tannins would be expected if rapid radical decay rates prevented the accumulation of high radical concentrations. Similarly, the positive correlation between semiquinone radical decay rate and browning rate that was observed for each of the groups of tannins would be expected if semiquinone radicals decayed to form brown quinones and other oxidation products. Although our data do not provide explicit support for this pathway, because radical and browning reactions were studied in different oxygen conditions, radical intermediates previously have been proposed for browning pathways for phenolics (Bors et al., 2000).

Further work is needed to explore the above relationships between measures of phenolic oxidative activity and the extent of oxidative damage to biologically important molecules. The formation of high concentrations of semiquinone radicals in a pH 10 buffer does not necessarily mean that a tannin would act as a prooxidant in a biological system. For example, although oenothin B forms high semiquinone concentrations, it might act as an antioxidant at high pH because its radicals are relatively stable (Bors and Michel, 1999). If this was the case, it would be reflected by the formation of low levels of oxidized markers, much like the formation of relatively low levels of brown oxidation products by oenothin B. In general, one would expect to find that (1) tannins with higher oxidative activities produce higher concentrations of biomarkers of oxidative damage, and (2) measures of oxidative activity that are most relevant to the mechanisms of oxidative damage are more strongly correlated with oxidative damage than are less relevant measures.

Polyphenolic compounds are often regarded as excellent antioxidants, in part because they can act as effective radical scavengers. The unusually long half-lives of the semiquinone radicals produced by tannins in the high pH, anoxic conditions that were employed in this study (1–24 min) are one indication of this potential (Pryor, 1986; Bors et al., 2001a). However, there is little in common between previous comparisons of radical scavenging by tannins and our measurements of their oxidative activities. For example, galloyl glucoses scavenged DPPH radicals in methanolic solutions at least as effectively as ellagitannins (Vuorela et al., 2005). Similarly, galloyl glucoses and monomeric ellagitannins had equivalent superoxide anion and DPPH radical-scavenging abilities (Hatano et al., 1989). In contrast, ellagitannins in our study were generally more susceptible to oxidation to semiquinone radicals and quinones than were gallotannins. The different conclusions produced by these different comparisons emphasize the need to examine phenolic activities in physiologically relevant conditions.

The high antioxidant or prooxidant activities of high-molecular-weight tannins is in part a result of the increased number of phenolic hydroxyl groups present per molecule as molecular weight increases (Hatano et al., 1989; Bors and Michel, 1999). For the lower-molecular-weight condensed tannins, radical production and browning rate are largely a function of the number of catechol B rings (Fig. 4a). However, the high-molecular-weight, prodelphinin-rich condensed tannins formed lower concentrations of semiquinone radicals and browned more rapidly than expected based solely on their degree of polymerization. Structural factors such as intramolecular resonance stabilization and coupling reactions may affect the oxidative activity of high-molecular-weight phenolics. Other features of tannins that potentially affect their oxidative activities include their redox potential and steric factors (Musso, 1967; Hodnick et al., 1988; Jovanovic et al., 1995; Chan et al., 1999; Guo et al., 1999; Mukai et al., 2005). For example, the fact that browning rate decreases linearly as the number of galloyl groups increases for the galloyl glucoses (Fig. 5c) suggests that intramolecular reactions, such as coupling, may take place rather than browning when several properly oriented galloyl groups are found on a single glucose. Further work is needed to examine the structural basis for the widely varying oxidative activities of tannins, with an emphasis on testing a larger number of examples of the different types of ellagitannins and condensed tannins.

Because both the number of phenolic hydroxyl groups and unknown structural features of tannins affect their prooxidant activities, it is not surprising that activities calculated on a mass basis yield somewhat different relationships than activities calculated on a molar basis. This was most apparent in the case of condensed tannins with high masses (e.g., 9026 Da), and would be particularly relevant in many ecological studies, in which tannin levels are

reported as a percentage of total mass. To understand the potential ecological and evolutionary significance of tannin composition, it is important to consider the impact of different tannin structural types on herbivores on a mass basis. For a given mass of tannins produced by a plant, and ingested by a caterpillar, the results suggest that ellagitannins would be most effective as oxidative defenses. By contrast, galloyl glucoses and condensed tannins would be less effective (Fig. 6a,b).

If we have correctly identified the relative reactivities of the major groups of tannins in high pH conditions, then it follows that the synthesis of substantial amounts of such different types of tannins by plants is the result of diverse selective pressures (e.g., Hagerman and Robbins, 1993; Northrup et al., 1998; Aerts et al., 1999). Our results not only point to the need to differentiate among several major groups of tannins in studies of plant–herbivore interactions, but also show that there can be a large amount of variation within the groups. Thus, some caution would be necessary when generalizing about the oxidative activities of leaves in which different tannin groups are quantified, but the composition of the tannins within each group are unknown. A better understanding of the structure–activity relationships of tannins should lead to new models for plant chemical defenses and herbivore adaptations to these defenses.

Acknowledgments This project was supported by the National Research Initiative of the USDA Cooperative State Research, Education and Extension Service grant number 2004-35302-14940 to R. Barbehenn and C.P. Constabel. Support for J.-P. Salminen was provided by grant number 204209 from the Academy of Finland. Jonna Kenttä, Riitta Koivikko, Maria Lahtinen, Jaana Liiimatainen, Tuuli Luomahaara, Angelica Preetz, and Victor Turhanen assisted with the isolation of tannins. We thank Michael M. Martin for suggesting revisions to this paper, and Jari Sinkkonen for drawing the chemical structures.

Introduction

Plant chemistry affects the behavior, distribution, performance, and population dynamics of herbivores (Frankel, 1959; Schultz, 1988; Bernays and Chapman, 1994; Seldal et al., 1994; Karban and Baldwin, 1997; Larsson et al., 2000; Shelton, 2000). Variation in chemistry among plants within a species results from genetic and environmental causes. Concentrations of many plant antiherbivore compounds, such as phenolic glycosides and condensed tannins, are under genetic control (Orians et al., 1993; Hwang and Lindroth, 1997; Lindroth et al., 2002), but also respond to environmental factors such as resource availability (Kinney et al., 1997; Lindroth et al., 1997; Orians et al., 2003).

Plant development can drive the distribution and/or performance of both pathogens and herbivores (Zagory and Libby, 1985; Kearsley and Whitham, 1989; Kearsley and Whitham, 1998; Karban and Thaler, 1999; Brennan and Weinbaum, 2001; Swihart and Bryant, 2001; Lawrence et al., 2003; Barrett and Agrawal, 2004) and can have community-level consequences (Waltz and Whitham, 1997). Well-characterized major cellular, physiological, and structural changes occur as plants develop (Cronk et al., 2002; Srivastava, 2002), but much less is known about the effects of development on plant chemistry (Edwards, 1982; Baldwin, 1999; Ohnmeiss and Baldwin, 2000). Some work has demonstrated higher levels of chemical defenses in juvenile shoots or ramets of the Salicaceae (Tahvanainen et al., 1985; Reichardt et al., 1990; Martinsen et al., 1998), but each of these studies was limited to a single tree species. Most other studies of the interaction of plant development and chemistry in trees have measured phytochemical concentrations in leaves of different ages within small saplings (e.g., Bingaman and Hart, 1993; Kleiner et al., 2003), as opposed to the variation that exists at any given time in mature, canopy-sized trees.

Here, we focus on plant development as a major source of phytochemical variation within individual trees. Developmental processes in plants can be generalized into two broad categories, ontogenetic and physiological or environmental (e.g., Lawson and Poethig, 1995). Ontogenetic variation arises from changes in gene expression in plant meristems (Poethig, 1990; Wiltshire et al., 1994, 1998; Jordan et al., 1999, 2000). It is widespread and results in changes in vegetative structures across whole-plant gradients (Jones, 1999). In contrast, environmental changes result from alteration of the local meristem environment by factors such as shading, water, and nutrient relations. This distinction is important, because only ontogenetically derived traits are heritable and subject to natural selection. Few studies have actually quantified the ontogenetic component of developmental traits that affects herbivores (but see Lawrence et al., 2003).

To assess developmentally based variation in plant chemistry, we studied the phytochemical variation in a hybrid swarm composed of Fremont and narrowleaf cottonwood (*Populus fremontii* and *P. angustifolia*, respectively), their F₁ hybrids, and complex backcrosses to narrowleaf cottonwood. Collectively, these are referred to as “cross types” (Wimp et al., 2004). Fremont cottonwood occurs at lower elevations, narrowleaf at higher elevations. The two species hybridize naturally in zones where their distributions overlap throughout the western United States (Eckenwalder, 1984), and they dominate many riparian zones in the intermountain west. The results of previous community studies performed in this hybrid system motivated several of the hypotheses of this study.

First, based on the distribution and survival of common herbivores (Kearsley and Whitham, 1989, 1998; Waltz and Whitham, 1997), we hypothesized that plant phytochemistry varies predictably within a tree across three developmental zones (juvenile ramets, juvenile zone, and mature zone). Because Waltz and Whitham (1997) showed that the juvenile zone was intermediate in its arthropod community to the mature zone and juvenile ramets, we hypothesized that it would also have intermediate phytochemistry. Second, we hypothesized that this predictable within-tree variation, which we term “developmental trajectory in phytochemistry,” has a genetic basis and would differ among cross types. Third, because different cross types support different arthropod communities in the wild and in a common garden (Wimp et al., 2005), we hypothesized that phytochemistry differs predictably among cross types (Fremont, narrowleaf, and F₁ and backcross hybrids). Last, because the leaf feeding beetle, *Chrysomela confluenta*, sequesters toxic phenolic glycosides and feeds preferentially on juvenile ramets, we predicted that juvenile ramets would be highest in phenolic glycosides.

This work is unique in that we studied phytochemical variation on multiple scales simultaneously: seasonal, within and among species, as well as within individuals, by using mature, canopy-sized trees. We document developmentally based phytochemical differences within trees that exist at any given time, as opposed to only the differences that occur as a result of aging of leaves at a given position in the tree through a growing season. Ultimately, because plant development affects whole arthropod communities (Waltz and Whitham, 1997), these findings could provide additional genetic and phytochemical mechanisms for understanding biodiversity, community structure, and ecosystem processes.

Methods and Materials

Common Garden Survey

To test the genetic basis of differences in phytochemistry among cross types, we sampled trees in a common garden established in 1991 at the Ogden Nature Center, Ogden, UT, USA. This study included 11 Fremont, 11 F₁ hybrid, 34 backcross hybrid, and 13 narrowleaf trees. The particular genotypes included were chosen as a representative sample of each cross type. Only leaves from the juvenile zone were sampled. Collection dates as well as sampling, chemical, and statistical methods were the same as for the field study, described below.

Field Survey

We studied cottonwoods growing along the Weber River in the vicinity of Ogden, UT, USA, where many population, community, and ecosystem-level studies have been conducted. We sampled leaves from trees at seven sites in the 13-km-long hybrid zone as well as from the pure species zones (one Fremont site, two narrowleaf sites) on three occasions: 21–24 May, 20–23 June, and 14–18 August 2001. At the seven sites in the hybrid/overlap zone, 2–4 of the cross types co-occurred at each site. Based on restriction fragment length polymorphism marker studies that genetically characterized the species or hybrid status of individual trees (Keim et al., 1989; Martinsen et al., 2001), our collection consisted of 10 Fremont, 14 F₁ hybrid, 13 backcross hybrid, and 13 narrowleaf trees. These were chosen based on their genetic characterization and presence of all desired developmental zones. All trees were reproductively mature in the upper crown, but juvenile at the base. Leaves were collected

from the mature and juvenile zones of all trees. All cross types, except Fremont, reproduce vegetatively by root suckering (Schweitzer et al., 2002), and leaves were also sampled from these small (<1.5 m tall) juvenile saplings that we refer to as “juvenile ramets,” reflecting their asexual origins. Thus, for the four cross types and three possible developmental zones, eleven combinations exist. Sampling from the different developmental zones of the same trees was carried out because one of our major aims was to test for and document phytochemical differences among zones of the same trees in the field.

Leaves from the mature zone were sampled with a 6-m-long pole pruner, and the reproductive status was verified by the presence of catkins and/or their scars. Each sample consisted of 15–25 leaves taken from each zone of the tree, and these leaves were collected from around the entire circumference of the canopy within that zone. Each leaf was removed by cutting at the lamina–petiole junction, and was the fifth or middle leaf from the current year’s growth to standardize leaf age. All leaf samples were frozen between blocks of dry ice and kept under dry ice until storage at -20°C . Leaves were lyophilized and ground to pass a 40-mesh screen on a Wiley Mill.

Nitrogen is often of critical importance to herbivores (Mattson, 1980; White, 1984), whereas condensed tannins and phenolic glycosides are the major secondary metabolites in the genus *Populus* (Palo, 1984; Lindroth et al., 1987). Nitrogen was measured by using an elemental analyzer (LECO, St. Joseph, MI, USA). After an exhaustive extraction of leaf tissue in 70% acetone with 1 mM ascorbate at 4°C , condensed tannins were determined with the acid butanol assay (Porter et al., 1986) by using tannins prepared from narrowleaf cottonwood as the standard (Hagerman and Butler, 1980; Waterman and Mole, 1994). Phenolic glycoside concentrations were determined by HPLC as described by Lindroth et al. (1993). The compounds salicortin and HCH-salicortin (hydroxy-cyclohexen-on-oyl-salicortin) are the major phenolic glycosides in this system (Rehill et al., 2005), but only Fremont cottonwood and F_1 hybrids contain detectable amounts of HCH-salicortin. Given this distribution, all analyses and figures for HCH-salicortin are based on data from Fremont and F_1 hybrids only. Both compounds were purified from cottonwood leaves by liquid–liquid extraction (Lindroth et al., 1986), followed by medium-pressure, “flash” chromatography (Still et al., 1978) and were used as standards. Salicortin has known antiherbivore properties (Lindroth and Hwang, 1996), and based on its structure the same is likely to be true of HCH-salicortin. Total phenolic glycosides were calculated as the sum of salicortin and HCH-salicortin. This pooled value has frequently been shown to affect herbivore preference and performance (e.g., Osier and Lindroth, 2001). All chemical measures are reported on the basis of percentage dry weight (% DW).

Data were analyzed by using repeated-measures analysis of variance [PROC MIXED, version 8, SAS (SAS Institute)] with an unstructured variance–covariance matrix and individual trees treated as subjects. Despite our explicit hypothesis for phenolic glycosides, we had no *a priori* assumptions about the trajectories of developmentally based variation for all the measured phytochemicals among all cross types. Thus, developmental zones were nested within cross type to prevent bias. Pairwise comparisons of least squares means were made with a Tukey adjustment and were considered significant when $\alpha < 0.05$.

Although some minor heteroscedasticity may have been present (e.g., compare Fremont vs. narrowleaf tannin concentrations and associated standard errors), we did not use any data transformations for several reasons. Valavanis (1959) indicates that for maximum likelihood methods (as used by SAS PROC MIXED), heteroscedasticity will not bias parameter estimates. Neter et al. (1996) and Montgomery (1997) both point out that as sample size increases, F tests approach permutation tests, which are distribution-free, and if total sample

size is not small, F tests can be considered in this light. Our total sample size was 420 observations for each chemical measured, with 50 test subjects (trees). With a sample size this large, we can invoke the Central Limit Theorem (Sokal and Rohlf, 1995), that the means of samples drawn from a population of any distribution will approach a normal distribution as sample size increases. Given the potential for somewhat ambiguous interpretation of transformed vs. untransformed data, we erred on the side of clarity of interpretation.

We used regression to make comparisons between cross types of the phytochemical shifts among developmental zones within trees. Because Fremont does not produce juvenile ramets, we used only juvenile and mature zone measures of condensed tannins, salicortin, and total phenolic glycosides in comparison among cross types. Each of these variables was regressed against the two developmental zones to determine the slope of the change (“developmental trajectory”), and slopes were compared. Thus, the slope indicates the direction and magnitude of the average change in concentration between the juvenile and mature zones of each cross type.

Results

Common Garden Survey of Phytochemical Variation

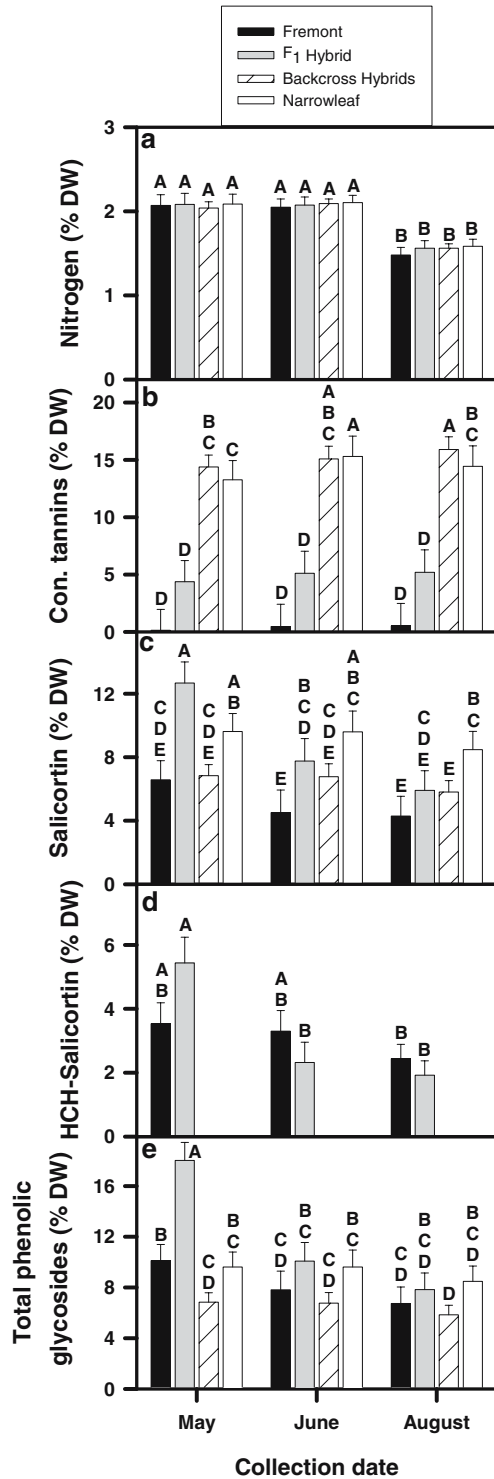

Condensed tannins, salicortin, and total phenolic glycosides in juvenile zone foliage differed significantly among cross types. Levels of seasonal variation differed widely among chemical measures and cross types.

Nitrogen concentrations were the same among cross types but did show significant seasonal variation (Table 1; Fig. 1a). Condensed tannin concentrations increased between the May and June collection dates and differed greatly among cross types (backcross = narrowleaf > F_1 = Fremont). In contrast, concentrations of salicortin decreased throughout the survey (Table 1; Fig. 1c), but also differed among cross types. These differences among cross types changed during the survey, likely as a result of different seasonal changes in each type (Fig. 1c). Concentrations of HCH-salicortin decreased during the survey (Table 1; Fig. 1d), but no consistent differences existed throughout the growing season between F_1 hybrids and Fremont cottonwood. Total phenolic glycoside concentrations, driven mostly by the concentrations of salicortin, decreased over the growing season (Table 1; Fig. 1e) and differed among cross types. Also, cross types differed in the amount of seasonal variation (see Fig. 1e).

Field Survey: Chemistry

Statistical analysis of the effects of cross type, developmental zone, and collection date on foliar chemistry showed major response patterns, and revealed numerous higher-order interactions (e.g., cross type \times zone for a particular date; see Table 2) that occasionally varied from the dominant patterns. To facilitate clear communication of these results, we emphasize the major patterns for each chemical variable.

Nitrogen levels decreased slightly over the course of the growing season (Table 2; Fig. 2a). Concentrations of nitrogen did not differ consistently among cross types or developmental zones within each cross type (Fig. 2b).

Concentrations of condensed tannins did not differ among collection dates, but did differ among cross types and developmental zones, consistent with our hypotheses. Tannin levels varied greatly (ca. 40-fold) among cross types (Table 2; Fig. 2c). Backcross hybrid foliage had the highest concentrations, narrowleaf had intermediate concentrations, and F₁ and Fremont foliage both had very low concentrations (backcross > narrowleaf > F₁ \cong Fremont; 16.7%, 10.5%, 2.3%, and 0.4% DW, respectively).

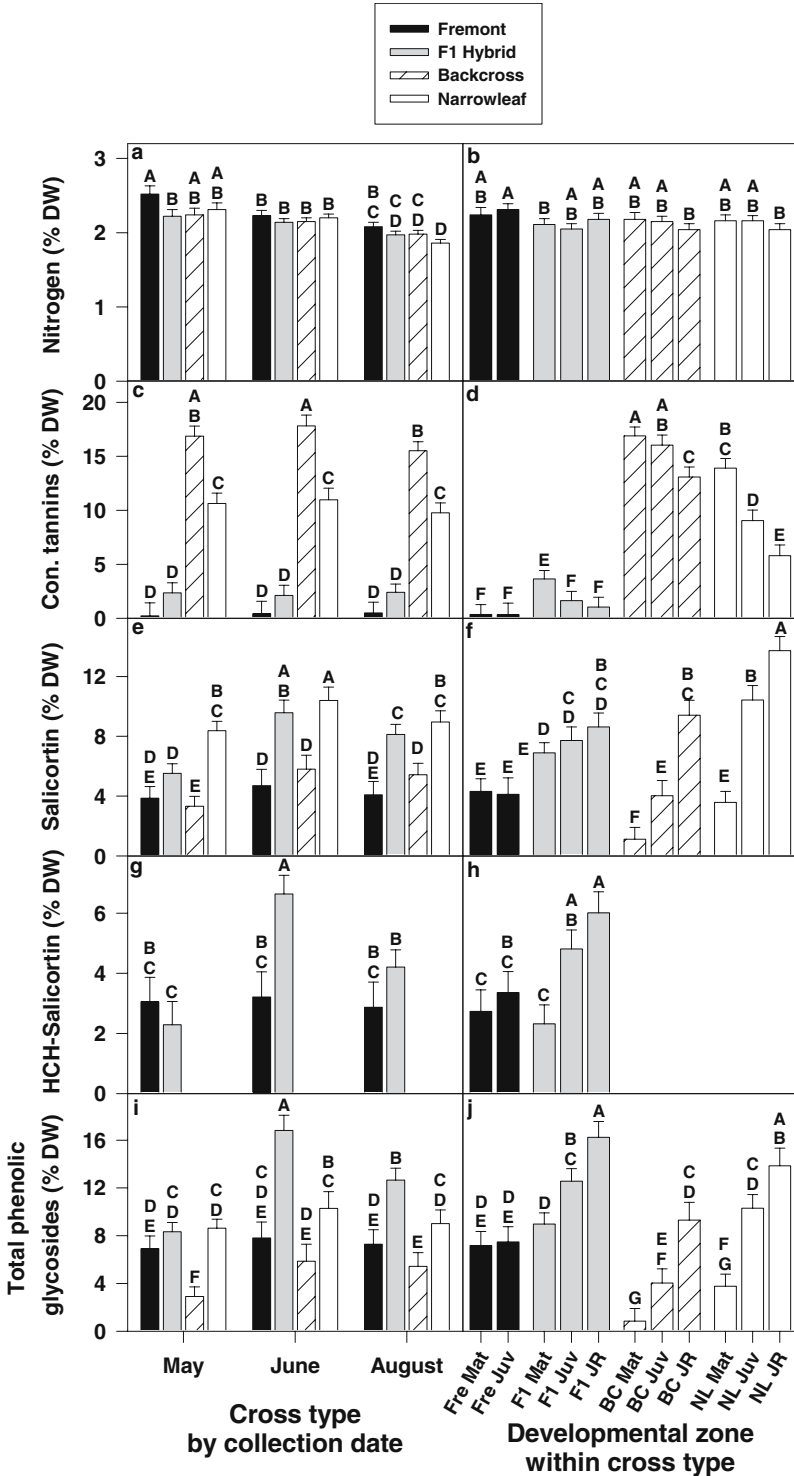

Tannin levels differed significantly among developmental zones for backcross hybrids, narrowleaf, and F₁ hybrids (Fig. 2d). These patterns among developmental zones within cross types changed seasonally (Fig. 3). Thus, relative to our initial prediction, the juvenile zone was frequently, but not always, intermediate in condensed tannin concentrations relative to the mature zone and juvenile ramets.

Salicortin concentrations showed strong seasonal variation, but as hypothesized, the levels also differed among cross types and within individual trees. Concentrations were lowest in May, peaked in June, and decreased to an intermediate level in August (Table 2; Figs. 2e and 4). Cross types separated into two groups: salicortin levels in both narrowleaf and F₁ hybrids were greater than those in backcross hybrids and Fremont (Fig. 2e).

Within all cross types except Fremont, salicortin concentrations differed among developmental zones, and the patterns were generally the opposite of those for condensed tannins (Fig. 2f). For both narrowleaf and backcross hybrids, the ranks of salicortin levels among developmental zones were the same (juvenile ramets > juvenile > mature). These results correspond well with our predictions of juvenile zone intermediacy and higher

◀**Fig. 2** Nitrogen, condensed tannin, salicortin, HCH-salicortin, and total phenolic glycoside concentrations of four cross types in the field survey. HCH-salicortin was not measured in narrowleaf and backcross foliage. The left set of panels (a, c, e, g, i) highlight differences among cross types among the collection dates for all developmental zones combined. The right set of panels (b, d, f, h, j) highlight differences among developmental zones within cross types for all collection dates combined. Cross types are abbreviated as follows: NL, narrowleaf; BC, backcross; F₁, F₁ hybrid; and Fre, Fremont. Developmental zones are abbreviated as follows: Mat, mature zone; Juv, juvenile zone; and JR, juvenile ramet. Each bar represents the least squares mean plus one standard error of the mean. Bars with different letters represent least squares means that are significantly different at $\alpha = 0.05$ using a Tukey adjustment *within the same panel only*

Fig. 3 Least squares means of condensed tannin concentrations for all developmental zones within cross types at the three collection dates. Cross types are abbreviated as follows: NL, narrowleaf; BC, backcross; F₁, F₁ hybrid; and Fre, Fremont. Data for both juvenile and mature zones of Fremont cottonwood are nearly identical, hence the designation “Fre-Both” for the superimposed lines. Differences among developmental zones for narrowleaf and both hybrid cross types account for much of the variation in the system

Fig. 4 Least squares means of salicortin concentrations for all developmental zones within cross types at the three collection dates. Cross types are abbreviated as in Fig. 3. As with condensed tannins, differences among developmental zones for narrowleaf and both hybrid cross types account for much of the variation in the system

phenolic glycoside concentrations in juvenile ramets. A similar but subtler pattern appeared in F₁ hybrids (juvenile ramets = juvenile, juvenile = mature, but juvenile ramets > mature). As with tannins, developmentally based differences varied among collection dates (see Fig. 4).

For salicortin concentrations, intraplant variation eclipsed interplant variation (Fig. 4). Whereas the greatest interplant variation encompassed a two-fold range (Fremont vs. narrowleaf, 4.2% vs. 9.3% DW, respectively), within narrowleaf salicortin concentrations varied over a four-fold range (3.6% vs. 13.7% DW, mature vs. juvenile ramet, respectively) and in backcross over an eight-fold range (1.1% vs. 9.4%, mature vs. juvenile ramet, respectively).

HCH-salicortin showed significant seasonal variation, which confounded differences in concentration among cross types. HCH-salicortin levels were higher in F₁ hybrids than Fremont in June only (Fig. 2g). Concentrations were the same between juvenile and mature foliage of Fremont, but highest in the foliage of juvenile zone and juvenile ramets of F₁

hybrids, both of which differed from F_1 mature foliage (Fig. 2h). Whereas HCH-salicortin concentrations among plants varied over a 1.5-fold range, and the difference was not statistically significant (F_1 vs. Fremont, 4.5 vs. 3.1%, respectively), within F_1 hybrids concentrations ranged over a 2.5-fold range, and the difference was statistically significant (6.2% vs. 2.5%, juvenile ramet vs. mature zone, respectively). Overall, the patterns in HCH-salicortin concentrations differed from those of condensed tannins and salicortin.

Composite concentrations of phenolic glycosides were lowest in May, peaked in June, and decreased to an intermediate level in August (Table 2; Fig. 2i), and differed significantly among cross types (Fig. 2j). Salicortin was the dominant or only phenolic glycoside contained in most foliage (ca. 66% in Fremont, 60% in F_1 hybrids, and 100% in narrowleaf and backcross hybrids). Thus, the patterns of differences among developmental zones within cross types were similar to those of salicortin, as were the shifts in the patterns among months. Narrowleaf and F_1 juvenile ramets had the greatest concentrations, whereas backcross and narrowleaf mature foliage both had the lowest. Also, as with salicortin and HCH-salicortin, intraplant variation driven by developmental trajectories exceeded interplant variation (contrast Fig. 2i with Fig. 2j).

Field Survey: Developmental Trajectories

Consistent with our prediction, developmental trajectories differed among cross types for condensed tannins and phenolic glycosides. Narrowleaf showed the greatest change in condensed tannin concentrations between juvenile and mature zones, F_1 was intermediate, and backcross and Fremont showed no change (respectively, $N = 63, 65, 74,$ and 59 ; $P < 0.05$ for all pairwise differences between slopes). A slightly different pattern was found for salicortin: narrowleaf showed the greatest change, backcross was intermediate, and F_1 and Fremont showed no change. Changes in total phenolic glycoside concentrations between juvenile and mature zones were greatest in narrowleaf, intermediate in hybrids, and least in Fremont. Overall, as predicted, the phytochemical trajectories of both the F_1 and backcross hybrids were intermediate to those of narrowleaf and Fremont cottonwood, supporting our hypothesis of an ontogenetic basis for these patterns.

Discussion

Genetic and Ontogenetic Control of Phytochemistry

The data from the common garden survey argue that both condensed tannins and salicortin (and so total phenolic glycosides) are under genetic control. Because HCH-salicortin is present only in the foliage of Fremont and F_1 hybrids (Rehill et al., 2005), but not narrowleaf or backcross hybrids, it, too, is under genetic control, at least at the level of presence/absence (likelihood ratio test: $G = 71.1, P < 0.001$). Differences among cross types in the common garden experiment (where only juvenile zone foliage was sampled) were identical (HCH-salicortin and total phenolic glycosides) or similar (condensed tannins and salicortin) to those of the juvenile zone in the field survey. It seems unlikely that field conditions, along an altitudinal gradient of the Weber River, duplicate the conditions of the common garden. The resemblance of common garden chemistry to the juvenile zone chemistry in the field would be consistent with genetic control of these secondary plant metabolites. Thus, in aggregate, the data indicate that the major defensive chemicals in this hybrid system—condensed tannins and phenolic glycosides—vary predictably among cross

types, establishing a genetic component to the phytochemical variation. The phenotypic variation in phytochemistry found among cross types in the field survey is likely to be genetically based.

The data do not constitute direct experimental evidence for genetic control of phytochemistry in the mature zone of the canopy, because the common garden study was carried out only with juvenile zone foliage. However, any uncertainty that this might introduce to our conclusions should be considered in the following light. First, if chemistry in the mature zone is under less genetic control than chemistry in the juvenile zone for all cross types, we would have expected a less consistent pattern of changes between developmental zones within cross types, given environmental heterogeneity in the field survey. Second, most plant secondary metabolites appear to be under at least some level of genetic control (Hamilton et al., 2001). Last, even if chemistry in the mature zone is more phenotypically plastic than that in the juvenile zone, and the observed differences between juvenile and mature zones occur as a result of microenvironmental variation, the increase in phenotypic plasticity would still constitute an ontogenetic shift in the control of chemistry, because phenotypic plasticity itself can be considered a trait under genetic control (Callahan et al., 1997).

In the field survey, although the specific patterns differed among phytochemicals, the overall pattern is of predictable changes both within an individual tree and among different cross types. In total, these changes constitute evidence for ontogenetically based developmental trajectories of phytochemistry in this *Populus* system. Several lines of evidence support this conclusion. First, plant development affected phytochemistry as much or more than other variables normally emphasized in phytochemical studies, such as seasonal variation. Second, although some or all of the cross types co-occurred at most of the field sites, different cross types exhibited major differences in both their phytochemistry and the developmental trajectories of specific phytochemicals. These findings argue for a genetic basis to both phytochemistry and developmental trajectory. Third, the magnitude of change both within an individual tree and among cross types was great, e.g., up to 40-fold differences in concentration. Fourth, condensed tannins, salicortin, and HCH-salicortin show drastically different patterns of change among cross types, indicating that the changes do not occur purely because of resource availability for secondary plant metabolites. Finally, in both studies, nitrogen concentrations showed little variation, whereas the other phytochemicals varied greatly. This argues against any changes in condensed tannins or phenolic glycosides as a result of differences in available nitrogen, leading to potential protein competition with phenolic metabolites (Jones and Hartley, 1999). Because these phytochemicals are ecologically important, the developmental trajectories have the potential to affect populations, communities, and ecosystems.

Plant Developmental Trajectory

We refer to predictable, developmentally based changes in plant traits (such as the phytochemistry we measured) as a plant's "developmental trajectory." For the sake of analysis, we concentrated on differences between the lower (juvenile) vs. upper (mature) portions of the canopy, and used the slope of the difference between these zones of the tree as a metric. The use of such a linear measure does not imply that all developmentally based changes occur in a gradual, linear fashion, or that all the traits of a given plant species change in the same manner or extent with development. Rather, this slope is intended only as a readily comprehensible means of referring to the change between developmental zones of the same cross type (if they occur), and of comparing the extent of change among cross

types. Further, we acknowledge that many developmentally based changes occur outside the scope of our measure (between juvenile and mature zones of a canopy sized tree). However, we concentrated on these developmental zones as a result of the potential major community and ecosystem consequences (most of a tree's biomass is in these zones) and for uniformity of comparison, because Fremont cottonwoods have no juvenile ramets.

We found striking differences in trajectories among cross types. Fremont cottonwood exhibits no significant trajectory, whereas narrowleaf cottonwood exhibits the steepest trajectory, and the hybrids are generally intermediate. The intermediate hybrid trajectories suggest an additive genetic mechanism to the phytochemical variation and argue that it has a genetic (i.e., ontogenetic) rather than environmental basis.

Developmental Trajectories and Community Structure

The findings suggest a potential phytochemical basis for the distribution of two herbivores in this system with known community effects, *Pemphigus betae*, a galling aphid, and *C. confluens*, a leaf-feeding beetle. For example, for *C. confluens*, which prefers to feed on juvenile ramets (Kearsley and Whitham, 1989), tannin levels explain ca. 50% of the variation in larval weight gain (Rehill et al., unpublished data), consistent with our finding of lower tannin concentrations in juvenile ramets. Concurrently, the foliage of juvenile ramets is also highest in phenolic glycosides, which larvae sequester and convert to their own defenses (Martinsen et al., 1998).

Developmental variation in phytochemistry may be one mechanism that could cause pronounced differences in arthropod communities associated with different developmental zones of the same tree, and this leads to two predictions: First, the greater the chemical differences among developmental zones, the greater the difference in the respective communities among those zones; Second, because phytochemistry differs among developmental zones, arthropod diversity in a stand of trees is a combination of the interplant genetic diversity (Wimp et al., 2004) as well as the intraplant ontogenetic diversity (see also Kearsley and Whitham, 1989, 1998; Waltz and Whitham, 1997; Lawrence et al., 2003). At present, we know of no studies on the relationship between developmental trajectories and herbivore communities. However, for both *Quercus velutina* and *Q. alba*, condensed tannin concentrations are higher in leaves of the upper canopy vs. those of the understory, and they explain ca. 25% of the variation in leaf-chewing insect community composition (Forkner et al., 2004).

Developmental Impacts on Ecosystem Processes

The marked increase in condensed tannin concentrations in mature foliage of narrowleaf and backcross trees, as well as the modest increase in F₁ hybrids, may have ecosystem consequences. Condensed tannins influence decomposition in this (Driebe and Whitham, 2000) and many other systems (Hattenschwiler and Vitousek, 2000; Hattenschwiler et al., 2003; Schweitzer et al., 2004). Increased tannin levels in the mature zone, which usually represents the majority of foliar mass in mature trees, may represent a means of controlling nitrogen cycling in the immediate environment of the tree (Northup et al., 1998; Van Breemen and Finzi, 1998; Kraus et al., 2003). Such control may be particularly advantageous to clonally propagating cross types, such as narrowleaf and backcrosses, as well as other clonal tree species (i.e., those that reproduce vegetatively), such as aspen (*Populus tremuloides*). Because leaves from ramets within a clone are more likely to fall and decompose under another member of the same clone (genotype) than nonclonal species

(i.e., an area effect), we predict that clonal species will undergo more pronounced developmental shifts in phytochemistry than will nonclonal species. Aspen has been found to have similar developmentally based chemical shifts to narrowleaf (Donaldson et al., 2006).

Evolutionary Pressures Leading to Genetic and Ontogenetic Differentiation

The reciprocal trajectories of phenolic glycosides (decreasing with maturity) and condensed tannins (increasing with maturity) in narrowleaf, backcross, and F_1 hybrids could represent a selective regime shaped by competing pressures (similar to aspen, Donaldson et al., 2006). Intense herbivory in the early life and lower portion of a tree's canopy may be balanced by the need to control nutrient cycling. This ensures adequate resources once sexual reproduction has begun. Such a pattern of competing selection pressures would be consistent with the shift from higher to lower phenolic glycosides from juvenile to mature foliage (better defended leaves in the lower canopy against herbivory) and the opposite trend for condensed tannins (thus, altering rates of decomposition and nitrogen mineralization).

The difference in the developmental trajectories of two congeneric trees (narrowleaf and Fremont cottonwoods) that have been in close proximity and/or had overlapping distributions for at least 12 million years (Eckenwalder, 1984) emphasizes that patterns of ontogenetic shifts in plant chemistry may be widespread. Phylogenetic constraints, however, seem unlikely to explain the flat trajectory of Fremont cottonwood. Selection pressures differ among environments for multiple reasons, such as the extent of herbivory, the costs of producing different defenses, and the availability of required resources such as minerals. Therefore, it seems likely that different selective regimes have led to different developmental trajectories. Developmental trajectories can be under genetic control (Wiltshire et al., 1998; Jordan et al., 1999), and variation in developmental trajectories within species may be an adaptation to environmental heterogeneity (Jordan et al., 2000).

The findings prompt a methodological caveat. Some studies of heritability compare traits of seedlings with those of mature trees. However, we have demonstrated major differences in ecologically important traits among the developmental zones of mature trees. Based on these data, if developmental trajectories of phytochemistry apply throughout the life of a tree, then the foliar chemistry of seedlings, and, therefore, resistance to natural enemies, may differ substantially from the mature zone of large trees. This may give an inaccurate representation of the genetic component of the studied traits, as others have suggested (Cornelissen et al., 2003).

Finally, given the established role of plant quality along with the potential for within-plant variation to affect herbivores (Stockhoff, 1993; Suomela and Ayres, 1994; Shelton, 2000), it is clear that developmental trajectories of phytochemistry could be important in regulating herbivore populations, structuring communities, and influencing ecosystems. More mechanistic studies are required to evaluate the community- and ecosystem-level importance of ontogenetically based chemical variation by linking the performance and distribution of keystone herbivores to plant chemistry. Such studies are a focus of continuing research with this hybrid system.

Acknowledgments We thank Jack Donaldson and Michael Stevens for stimulating discussions and the Ogden Nature Center, Ogden, UT, for accommodating our common gardens and providing an opportunity to educate the public on the conservation value of cottonwoods and riparian habitat. Shane Anderson, Matthias Dahnert, Kate Larson, Amanda Thompson, and Gina Wimp assisted with leaf collection, and Lindsay Wieczorek, Heidi Barnhill, and Kelly Crouner helped with chemical analyses. The comments of two anonymous reviewers greatly improved the manuscript. This research was supported by NSF grants DEB-0078280 and DEB-0425908.

Plants defend themselves against herbivores by using various mechanisms, including chemical ones, and defense has frequently been found to be most intense during the juvenile stage (Kozłowski, 1971; Bryant and Kuropat, 1980; Bryant et al., 1983; Reichardt et al., 1984; Tahvanainen et al., 1985; Mauricio, 2000). Boreal tree species, for example, have chemical defenses against feeding by moose, hares, and voles (e.g., Tahvanainen et al., 1985, 1991a), and the phenolic compounds found in birch (Hegnauer, 1989) are used in defense against herbivores (Palo, 1985; Palo et al., 1985; Tahvanainen et al., 1991a, b). They have been reported to affect food preferences of bank voles *Clethrionomys glareolus* (Hjältén et al., 1996), and phenolic substances on the base of birch bark may affect their palatability to voles (Rousi et al., 1993). However, there have been no studies of the role of phenolic compounds in birch seedlings as a defense against voles.

Voles of the genus *Microtus* are common in boreal forests at the early successional stage in Northern Fennoscandia (Hansson, 1977), but their population densities undergo cyclical fluctuations (Hansson and Henttonen, 1988). Their diet consists primarily of grasses, sedges, and forbs (Myllymäki, 1977; Ostfeld, 1985), but they also gnaw tree seedlings and saplings, and are an important cause of tree seedling mortality, especially during high-density years (Byers, 1984; Rousi et al., 1990; Hansson, 1977). For voles, tree seedlings are a poor-quality food source (Stenseth et al., 1977; Harju and Tahvanainen, 1997; Iason and Van Wieren, 1999) so they browse on them mainly in winter, when their preferred food sources are scarce (Rousi et al., 1993).

Voles seem to be selective when they feed on tree seedlings. Pusenius et al. (2002) found that field voles, *Microtus agrestis*, discriminated between different genotypes of silver birch, *Betula pendula*, seedlings, preferring to attack genotypes that had achieved competitive dominance in dense populations, i.e., those with the highest growth rate. Vole preference also correlated negatively with the genotypic mean of resin droplet density, suggesting that the chemistry of seedling bark is a factor in their choice. However, resin droplets are mostly found at the top of the *B. pendula* seedlings (Tahvanainen et al., 1991b) with fewer droplets in the lower part of the stems (Rousi et al., 1990; Bryant and Julkunen-Tiitto, 1995), where voles usually feed (Tahvanainen et al., 1991b; Rousi et al., 1997). On the other hand, both the upper and lower parts of the seedlings have similar concentrations of phenolics (Taipale et al., 1994) and we wanted to see whether these are responsible for variation in birch resistance to vole attack.

Variation in the size of seedlings on a spatial scale relevant to foraging voles (Hansson, 1968; Pusenius and Viitala, 1993) can be produced by intraspecific competition through at least two different mechanisms. First, in the process of becoming established, seedlings may be exposed to different existing local densities, yielding different mean seedling sizes among local patches, according to the self-thinning rule (Westoby, 1984; Crawley, 1997). Second, the differential success of individual seedlings within patches of competing seedlings may give rise to size differences, especially in high-density patches with asymmetrical competition (Weiner et al., 2001).

Production of secondary compounds is thought to be costly to a plant's energy and nutrient budget (Bryant and Julkunen-Tiitto, 1995), possibly even limiting its growth potential, and there is thus a potential trade-off between defense and growth (Rhoades, 1979). The costs of resistance are hypothesized to increase under resource-limiting conditions (Weis and Hochberg, 2000), so concentrations of defense compounds may vary with the density of competitors and the ability to acquire resources in competitive conditions, largely determined by seedling size (e.g., Tiffin, 2002).

The effect of intraspecific interactions on plant susceptibility to herbivores has been little studied (Hjältén et al., 1994). There have been several studies of the secondary chemistry of

silver birch (e.g., Laitinen et al., 2000, 2002), but nothing is known about the effects of intraspecific competition on the secondary chemistry of birch stems. This study focuses on intraspecific competition between silver birch seedlings and its effects on phenolic compounds, growth, and palatability to field voles. We studied the effects of the intensity of competition, as indicated by seedling density, and the effects of competitive success within populations, as indicated by seedling size, on quality and susceptibility to vole attacks. We asked the following questions: (1) How does intraspecific competition affect the growth of silver birch seedlings? (2) Do intraspecific interactions affect secondary chemistry and nitrogen content of the stems of the seedlings? (3) Do potential quality changes caused by intraspecific interactions affect the food selection of voles?

Methods and Materials

Birch Seedling Experiments

The study site was located in Punkaharju, southeastern Finland (61°41'N, 29°20'). Silver birch (*B. pendula*) seedlings were grown from a mixture of seeds collected from 27 randomly chosen, open-pollinated trees growing in a naturally regenerated birch forest. Seeds were sown in early May 2001 in peat pot trays, which disintegrate 3–4 wk after being planted, allowing plant roots to grow freely into the soil. Each tray was 0.4 × 0.6 m and consisted of 130 hexagonal pots, or cells, 5.1 cm wide and 7.5 cm deep in rows of 10. Homogenized peat (Kekkilä M6) was pressed into the cells and watered. Two days later, a mixture of seeds was sown randomly onto the trays. Sowing was carried out in a greenhouse to exclude external seeds. There was no artificial lightning or heating in the greenhouse, and the trays were watered as necessary. Five wk after sowing, trays were placed, still intact, onto a strip of bare soil in an abandoned field, and the seedlings were left to grow in natural conditions for one growing season. They were not watered, but weeds were removed from around them.

The seedlings established in each tray, or plot, constituted an experimental population. These populations were subsequently randomized for different treatments. Seedling populations were divided into two groups of 24, which were located close to each other. One group was subjected to a density manipulation (DM) experiment: Seedlings were thinned to obtain populations with different predominant heights. Densities chosen were based on prior experience (e.g., Pritinen et al., 2003) such that no significant size–hierarchy or seedling mortality would occur during the experiment. The other group was subjected to a competitive success (CS) experiment: A seedling density was allowed that was high enough for a clear size–hierarchy to be formed. In the DM experiment, thinning started about 2 wk after sowing, when the seedlings had established themselves. Seedlings were thinned to three different densities: low (one seedling in every other cell, 65 seedlings per plot, 270/m²), moderate (one seedling per cell, 128 seedling per plot, 533/m²), and high (two seedlings per cell, 260 seedlings per plot, 1083/m²). In thinning the populations to their final densities, we selected seedlings located at the centers of the cells. Where cells contained no seedlings or only weak ones, seedlings were transplanted from nearby cells. Each treatment was applied to eight randomly selected plots.

In the CS experiment, seedlings were not thinned at all. At the end of the growing season, the mean density was 429 per plot (1787/m²), which was 1.7 times greater than the highest density in the DM experiment. The processes of producing these densities were

different, and there was almost no mortality in the DM experiment, whereas mortality was high in the CS experiment.

The Vole Feeding Experiments

The voles used in the feeding experiments were trapped at Konnevesi, central Finland, in August 2000 (see Puseenius et al., 2002). They were housed in a 6×12 m outdoor enclosure containing nesting boxes and hay bales to provide shelter. Vegetation within the enclosure included natural food plants (Teivainen et al., 1986).

Our aim was to study whether voles choose among different-sized seedlings when the size difference is due to (1) density differences among stands, or (2) variable competitive success in a high-density population. Thus, we conducted two feeding experiments in the fall, when the seedlings were in winter dormancy. In the first, we allowed voles to choose among seedlings grown at the three different densities of the DM experiment. We constructed 15 replicated 0.4×0.6 m stands, each containing 10 randomly chosen seedlings from each of the three treatments, transplanted with their entire root ball. Each stand was enclosed within a 0.8×0.8 m sheet metal pen. One vole was introduced into each pen and allowed to feed. We monitored the feeding closely and recorded the order in which the three different classes of seedlings were attacked. The experiment was halted when at least two thirds of the seedlings had been attacked.

In the second experiment, we allowed voles to choose among different-sized seedlings from the CS experiment. Sixteen 0.4×0.6 m experimental stands were constructed, each containing 10 dominant, 10 medium, and 10 subordinate seedlings (see below). The other experimental conditions were identical to those of the first experiment.

Measurements

Seedlings from the DM experiment were harvested after the growing season, and their biomass, height, and root biomass were measured. Seedlings from the CS experiment were harvested in November, after the vole feeding experiment, when they were in winter dormancy. Because the ground was already frozen, it was not possible to recover roots. We randomly sampled seedlings from three distinct categories identified by their size in relation to the prevailing canopy within each experimental stand. The size–hierarchy categories were as follows: subordinate (well below the prevailing canopy), intermediate (prevailing canopy), and dominant (well above the prevailing canopy). We measured the height of the seedlings. The mean heights (\pm standard deviation) of dominant, intermediate, and subordinate seedlings were 15.2 ± 3.6 , 12.6 ± 2.3 , and 8.8 ± 0.9 cm, respectively.

Chemical Analysis

Sampling and Measurement of the Seedlings We randomly sampled two individual seedlings from eight different plots for each of the studied densities (DM experiment) and size–hierarchy categories (CS experiment). The total number of sampled seedlings in each case was 48: 3 densities \times 8 plots per density \times 2 seedlings per plot (DM experiment) and 3 size–hierarchy categories \times 2 seedlings per category per plot \times 8 plots (CS experiment).

Seedlings were collected for stem analysis in November, when the leaves had fallen off and they were in winter dormancy. All seedlings were stored in paper bags and left to dry at room temperature for 2–3 wk until the stems were dry and then stored in a freezer (-20°C).

Air drying was used on the basis of previous studies (e.g., Julkunen-Tiitto and Tahvanainen, 1989; Keinänen and Julkunen-Tiitto, 1996; Keinänen et al., 1999; Mutikainen et al., 2000; Julkunen-Tiitto and Sorsa, 2001). Forty-eight seedlings were taken randomly from the density experiment for measurements of their physical properties. They were taken from the ground with their roots intact and air-dried as described above. The dry weight of the roots and stems and the height of the stems were measured.

Stem Extraction Each stem sample was taken from two seedlings from each plot with the same density (DM experiment) or size category (CS experiment). A piece of stem (5 cm long) was cut 4 cm from the base of both seedlings and combined. Any buds were removed without breaking the stem. Stems were cut into 5 mm pieces, weighed, put into a 50 ml centrifuge tube, and stored in a freezer (-20°C). For extraction, 10 ml of methanol were added, the sample was homogenized for 2 min with an Ultra-Thorax homogenizer, and it was incubated on ice for 15 min. The residue was extracted three more times. Methanol was evaporated with a vacuum evaporator, and the dry sample was redissolved in 8 ml of methanol. Aliquots of 2 and 1 ml were taken for HPLC analyses and condensed tannins, respectively. The extraction residue was air-dried overnight and stored in a freezer. The internal standard was recorsin, which was added at the beginning of the extraction procedure (480 μg , ca. 99%, Ega-Cheme). The internal standard showed 74.9% recovery in the DM experiment and 74.8% in the CS experiment, respectively.

Colorimetric Test for Condensed Tannins The amounts of condensed tannins were determined with the colorimetric test (e.g., Porter et al., 1986., Julkunen-Tiitto and Sorsa, 2001). Condensed tannins were estimated as proanthocyanidins. The stem dry sample was redissolved in 1 ml of methanol. Six ml of butanol-HCl and 200 μl of iron reagent were then added to 100 μl of the stem sample. Samples were hydrolyzed in boiling water for 50 min and cooled. Absorbance at 550 nm was measured. Condensed tannins purified from *Betula nana* leaves were used as a standard.

HPLC Stem phenolic compounds were analyzed by HPLC. The HPLC system was a Hewlett-Packard HP 1050 instrument (Avondale, PA, USA) with a quaternary pump, a vacuum degasser, an autosampler, a thermostatic column oven, and a photodiode array detector (HP 1040A) combined with an HP Chemstation. A 3- μm HP Hypersil ODS column (60 \times 4.6 mm i.d.) was used. The solvents were aqueous 1.5% tetrahydrofuran + 0.25% orthophosphoric acid (A) and methanol (B). The solvent gradient was as follows: 0–5 min 100% A; 5–10 min 85% A, 15% B; 10–20 min 70% A, 30% B; 20–30 min 65% A, 35% B; 30–50 min 50% A, 50% B; 50–55 min 100% B; 55–60 min 100% A (Julkunen-Tiitto and Sorsa, 2001). The flow rate was 2 ml/min, and the injection volume 20 μl . The column oven was set at 30°C . The analysis was monitored at 220, 270, 280, 320, and 360 nm.

The phenolic compounds identified were quantified with commercial standards: myricetin-3-*O*-rhamnoside (Apin Chemicals, Oxon, UK) for myricetin derivatives, quercetin-3-*O*-glucoside (Extrasynthèse, Genay, France) for all quercetin and rhamnetin derivatives, kaempferol-3-*O*-rhamnoside (Extrasynthèse, Genay, France) for all kaempferol derivatives, chlorogenic acid (Aldrich, Steinheim, Germany) for cinnamic acid derivatives, salidroside (a gift from H. Prof. Thieme, Germany) for rhododendrine derivatives, and platyphylloside.

Eighteen individual compounds were found in stems (Fig. 1; Table 1). Identification of the compounds was based on comparisons of retention times and spectral characteristics (Keinänen and Julkunen-Tiitto, 1998). The compounds were grouped on the basis of their

Fig. 1 HPLC chromatogram of stem phenolic compounds monitored at 320 nm

chemical derivatives. Stem phenolics were grouped as flavonol glycosides, chlorogenic acid derivatives, catechine derivatives, rhododendrin derivatives, platyphylloside, cinnamic acid derivative, and monocoumarylstragalol (Table 1). The total concentration of the phenolics was calculated by adding the concentrations of condensed tannins and individual compounds together.

Nitrogen Analysis The total nitrogen content of dried stems was analyzed. Stem samples of 40–190 mg were taken from directly above the part that had been taken for phenolic extraction and cut into smaller pieces (1–2 mm). Samples were analyzed with a nitrogen analyser (Leco FP-528). The Leco Corn Flour calibration sample (1.7% N \pm 0.03) was used as a standard.

Statistical Analyses

The effects of density on seedling height and stem and root biomass were analyzed by multivariate analysis of variance (MANOVA). Effects of density and competitive success (seedling size category) on the concentrations of individual chemical compounds and groups of compounds in the stems were analyzed by MANOVA. These groups included phenolics from the HPLC analysis that were categorized on the basis of their chemical derivatives, and condensed tannins. Where MANOVA revealed a significant effect of treatment, we made corresponding univariate ANOVAs. In addition, we analyzed the effects of density and competitive success on the total concentration of phenolics, summed across individual compounds, by univariate ANOVA. The normality of residuals for each compound and compound group was tested with the Kolmogorov–Smirnov test, and compounds with normally distributed concentrations were included in the MANOVA. The *F*-values of the MANOVAs were converted from Pillai's trace statistics. Certain compounds were detected in only one or two samples, or not at all, resulting in non-normal distributions for these compounds (Table 1). The effect of treatment on the concentrations of these was tested with Kruskal–Wallis nonparametric ANOVA, using Bonferroni-adjusted significance level to compensate for the large number of tests. Pairwise differences in height, biomass, and chemistry between different densities or height classes were assessed using a *post hoc* test (Bonferroni). The vole feeding preferences were tested with Friedman's nonparametric ANOVA. All analyses were conducted using the SPSS statistical package for Windows 11.0 (SPSS, Inc.).

Table 1 The detected phenolic compounds, their retention times and significances *B. pandula* obtained from univariate tests

Compound	Retention time (min)	DM		CS	
		<i>P</i>	Bon	<i>P</i>	Bon

Condensed tannins				0.115	

The analyses of compounds with non-normally distributed concentrations were performed with Kruskal–Wallis test and include a Bonferroni-corrected significance. The significances with no Bonferroni correction are based on univariate ANOVAs performed after a significant MANOVA. Significances are lacking in the case of a nonsignificant MANOVA. Bon: Bonferroni-corrected significance; DM: density manipulation experiment; CS: competitive success experiment.

Results

Density, Biomass, and Height Root and stem biomass, root-to-shoot ratio, and stem height varied among the populations grown at different densities created by thinning (MANOVA, $F_{8,38} = 6.90$, $P < 0.0005$). Univariate *F*-tests indicated a significant ($P < 0.05$) effect of density for all variables. All measures of seedling size decreased with increasing density. Root biomass differed between all studied densities (Bonferroni multiple comparison, $P < 0.05$; Fig. 2a). Stem biomass differed between low and moderate, and low and high densities (Bonferroni multiple comparison, $P < 0.05$; Fig. 2b). The differences in root and stem biomass between high-density and low-density seedlings were 2.5- and 2.0-fold, respectively. Root–shoot ratio and stem height differed between low densities and high densities, and between moderate densities and high densities (Bonferroni multiple comparison, $P < 0.05$; Fig. 2c and 2d). The mean height of seedlings from the CS experiment was less than that of DM seedlings, being 12.2 ± 2.6 cm, which was less than

the mean height of seedlings from the highest density (15.1 ± 3.9 cm) in the DM experiment. ($t = 3.39$, $df = 62$, $P < 0.01$; Fig. 2d).

The Effects of Density on the Secondary Compound and Nitrogen Concentrations of Stems MANOVA did not indicate any effect of density on concentrations of phenolic compounds in stems in the DM experiment ($F_{26,20} = 0.82$, $P = 0.69$), and density had no effect on the concentrations of the individual compounds with non-normal distributions (Kruskall–Wallis ANOVA with Bonferroni-adjusted significance levels, $0.05/7 = 0.0071$; Table 1). Neither was there any effect of density on the concentrations of groups of phenolic compounds (MANOVA, $F_{16,30} = 1.35$, $P = 0.24$). We also compared total phenolic concentrations, summed across individual compounds, in the seedlings grown at different densities. Density had an effect on the concentration of total phenolics in stems (ANOVA, $F_{2,21} = 4.64$, $P = 0.021$; Fig. 3a). Seedlings from low densities had higher concentrations of total phenolics than those from moderate or high densities (Bonferroni multiple comparisons, $P < 0.05$). The effect of density on nitrogen concentrations (% dry weight) in stems was marginally nonsignificant ($F_{2,21} = 2.83$, $P = 0.081$; Fig. 4a).

The Effects of Seedling Size on the Chemical Composition of Stems In the CS experiment, seedling size had a significant effect on the concentrations of total phenolics (ANOVA, $F_{2,21} = 6.56$, $P = 0.006$). The highest concentration of total phenolics occurred in the tallest seedlings and the lowest in the smallest ones (Fig. 3b). Nitrogen concentrations (%) varied among seedlings of different size classes (ANOVA, $F_{2,21} = 4.51$, $P = 0.023$). The highest nitrogen concentrations were found in the smallest seedlings and vice versa (Fig. 4b).

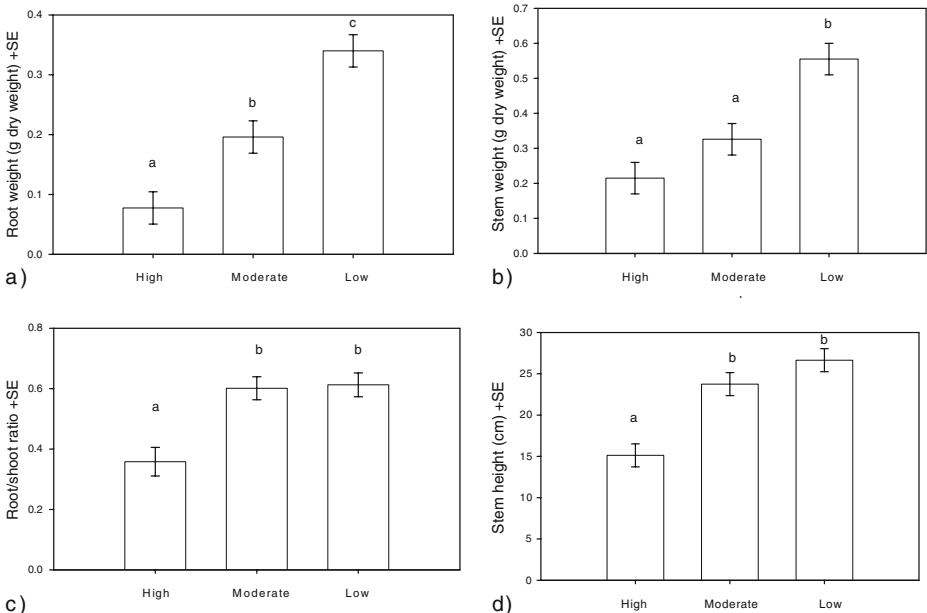

Fig. 2 Root weight (a), stem weight (b), root/shoot ratio (c), and stem height (d) in the three different densities of DM experiment. The means represented by bars with a same letter do not differ from each other (Bonferroni, $P < 0.05$)

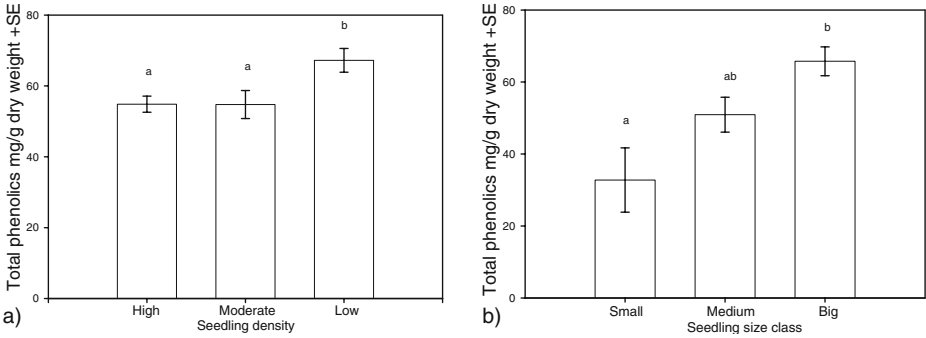

Fig. 3 Total phenolics concentration in stems: (a) DM experiment and (b) CS experiment seedlings

Hence, the pattern of variation in nitrogen in relation to density was the opposite of that observed for phenolic compounds.

Concentrations of phenolic compounds of stems varied among seedlings of different size–hierarchy categories (MANOVA, $F_{22,24} = 3.18$, $P = 0.003$). Univariate F -tests of the individual compounds (Table 1) and pairwise comparisons (Bonferroni, $P < 0.05$) revealed that the concentrations of catechin glycoside increased with seedling size (there were significant differences between all size classes). Concentrations of (+)-catechin, rhododendrin (2), and chlorogenic acid (A, B) were lower among small seedlings than among medium and large ones. The concentrations of rhododendrin aglycone were lower among small and medium seedlings than among large ones and the concentrations of hyperin, quersetin-3-glucoside, and platyphylloside were lower among small seedlings than among large ones. Seedling size had no significant effects on the concentrations of non-normally distributed individual compounds (Kruskal–Wallis ANOVA, Bonferroni-adjusted significance level $0.05/10 = 0.005$; Table 1). The concentrations of different compound groups also differed between the different-sized seedlings (MANOVA, $F_{16,30} = 2.42$, $P = 0.018$). Univariate F -tests indicate that there were differences in chlorogenic acids, flavonol glycosides, rhododendrins, catechins, and platyphylloside, but not condensed tannins, monocoumarylstragalol, and cinnamin acid derivative. In general, tall seedlings had higher concentrations than medium-sized or small ones (Fig. 5a–d).

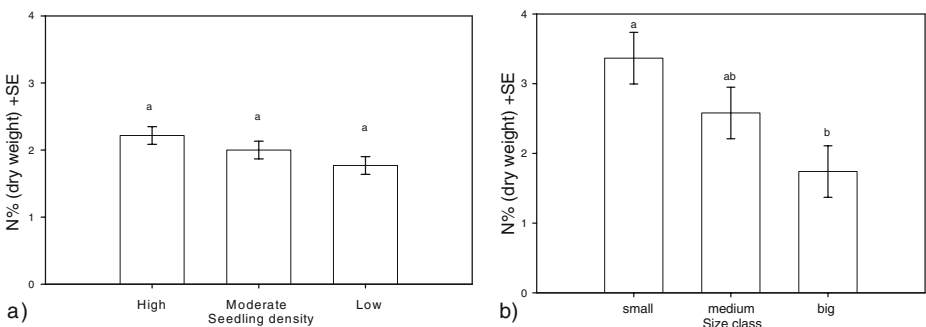

Fig. 4 Nitrogen content (% dry weight) in DM experiment (a) and in CS experiment (b) seedlings

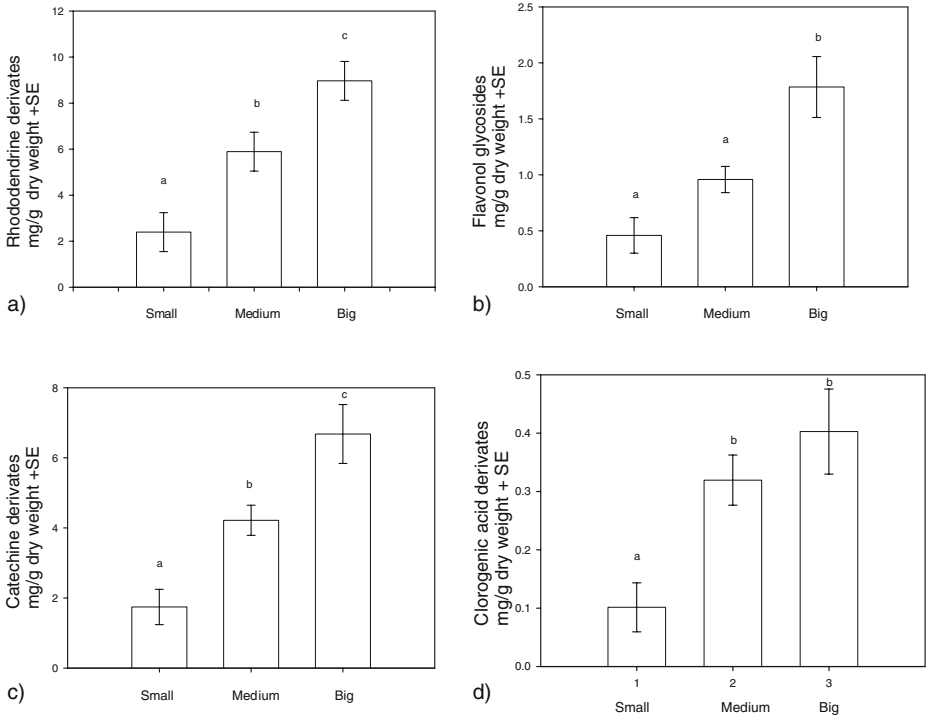

Fig. 5 Concentration (mg/g) of rhododendrin derivatives, catechin derivatives, flavonol glycosides, and chlorogenic acid derivatives in CS experiment seedlings

Vole Feeding Preferences Voles did not select among seedlings grown at different densities (Friedman’s nonparametric ANOVA, $\chi^2 = 0.93$, $N = 15$, $df = 2$, $P = 0.63$; Fig. 6a), but they preferred large seedlings to small seedlings from the CS experiment (Friedman’s nonparametric ANOVA, $\chi^2 = 7.12$, $N = 16$, $df = 2$, $P = 0.029$; Fig. 6b).

Fig. 6 Vole preference in DM (a) and CS (b) experiments

Discussion

We studied the extent to which size variation generated by variable population density and variable competitive success within high-density populations is related to the chemical quality and herbivore susceptibility of silver birch seedlings. Intraspecific competition reduced the growth of juvenile birches, as indicated by the negative relationship between population density and seedling size. Population density had an effect on stem total phenolics, but no effect on the concentrations of individual phenolic compounds, groups of phenolic compounds, or total nitrogen. Voles also did not show any preference between seedlings grown at different densities.

Large, competitively dominant seedlings generally had higher concentrations of phenolic compounds and lower concentrations of nitrogen than small, competitively inferior seedlings. Voles preferentially attacked large seedlings when these were offered along with small ones. Thus, the relationship between feeding preference and nitrogen and/or secondary compound concentrations was not in accordance with the expected role of these constituents as factors affecting plant susceptibility to herbivores (e.g., Stephens and Krebs, 1986; Marquis and Batzli, 1989; Hjäältén et al., 1994).

The observed decrease in seedling size with increasing density was as predicted on the basis of yield density curves constructed for several plant species (e.g., Silvertown and Charlesworth, 2001). Biomass tended to decrease more rapidly than height with the increase of density from low (270 seedlings/m²) to moderate (533 seedlings/m²), suggesting that the seedlings prioritized allocation for growth in height and thus the ability to intercept light. The intense competition in the populations of the CS experiment resulted in a considerable degree of variation in height and also in mortality, which was not observed in the DM experiment. Patterns of variation observed in the CS experiment are characteristic of asymmetrical competition, which is particularly liable to occur when seedlings compete for light (Weiner et al., 2001). Seedlings from the CS experiment were also smaller at mean height than those from the DM experiment, indicating that competition was more intense in the former.

There were significant variations in the concentrations of individual phenolic compounds among the different-sized seedlings from the CS experiment: Tall seedlings had higher concentrations than smaller ones. Moreover, seedlings from the low-density treatment in the DM experiment, i.e., the largest seedlings, had higher concentrations of total phenolics than those from moderate- and high-density treatments. This is consistent with the notion that resource competition constrains the production of chemical defenses (Cipollini and Bergelson, 2002). Stamp et al. (2004) have shown that the concentration of allelochemicals is inversely related to the intensity of competition. On the other hand, variation in nitrogen concentrations showed the opposite pattern to that found in carbon-based phenolic compounds. Nitrogen concentrations increased with decreasing seedling size in the CS experiment and tended to be highest in seedlings at the highest density, i.e., the smallest seedlings, of the DM experiment. These patterns in covariation of seedling size and concentrations of phenolics and nitrogen suggest that the growth of small seedlings was limited by the availability of light, and the growth of taller seedlings was limited by shortage of nitrogen. Nutrient availability is known to affect growth and resistance traits (Herms and Mattson, 1992; Tiffin, 2002). The CNB hypothesis predicts that if nutrient deficiency limits growth more than photosynthesis, it leads to the accumulation of carbon-based secondary chemicals (Bryant et al., 1988). It is likely that large seedlings had better access to light than smaller ones and were better able to synthesize carbon-based compounds. Several studies have shown that the concentration of phenolic compounds

increase under high light conditions (Larsson et al., 1986; Lavola, 1998; Lavola et al., 2000). Small, probably more shaded seedlings suffered from a shortage of light and a low potential to produce carbon-based compounds via photosynthesis. Consequently, these seedlings were unable to utilize the available nitrogen, which then accumulated (Rousi et al., 1993).

Plant defense is thought to be metabolically costly, and a trade-off between growth and defense has been proposed (Rhoades, 1979; Herms and Mattson, 1992). The positive relationship between phenolic concentrations and plant size observed in the present study seem to contradict this idea and differential access to light among different-sized seedlings is likely to be important here. In competitive conditions, variation in the acquisition of resources is a factor that can mask potential trade-offs. If the acquisition of resources is more variable than variability in allocation to different traits, a positive correlation is likely to be observed between the two traits in spite of the trade-off between them (Van Noordwijk and De Jong, 1986). Thus, we suggest that the differential competitive success associated with differential growth results in differential nutrient balance and differences in the concentrations of secondary metabolites.

In the DM experiment, the size differences between seedlings from the three densities were not associated with such clear differences in chemistry as the size differences resulting from competitive success in the CS experiment. The effect of competition on the chemical quality of the seedlings was not as evident as its effects on their physical characteristics. It is likely that competitive success was affected by seedling genotype: Previous studies of silver birch seedlings have revealed genotypic variation in both growth (e.g., Viherä-Aarnio and Velling, 2001; Pusenius et al., 2002; Pritinen et al., 2003) and chemistry (Keinänen et al., 1999; Laitinen et al., 2000, 2002), so the size differences and associated differences in chemistry observed in the CS experiment may have resulted from genotypic differences. It has been noted that random birch families have different growth rates in competitive conditions (Pusenius et al., 2002; Pritinen et al., 2003) and it is possible that seedlings that grew taller in the CS experiment were of certain genotypes. In the DM experiment, size differences as a result of different densities were probably not related to genotypic variation, and the assortment of genotypes within each of the groups of different size may have been wider than in the CS experiment.

The vole feeding experiments showed no preferences between seedlings grown at different densities. This is consistent with the findings of Hjältén et al. (1994). However, voles did choose between different-sized seedlings from the CS experiment, preferring the tallest ones. A study by Pusenius et al. (2002) showed that field voles preferentially attacked competitively dominant, fast-growing genotypes of silver birch seedlings, and other mammalian browsers, such as moose and deer, prefer large seedlings (for a review see Price, 1991; Shabel and Peart, 1994). Fast-growing plants seem to have relatively fewer fibres than slow-growing ones and this might make them more palatable to voles (e.g., Iason and Van Wieren, 1999), but it does not explain the differential results of the experiment with CS and DM seedlings. Again, this might be because of differences in genotype composition among different-sized seedlings in the CS experiment, but not in the DM experiment. However, the results pertaining to the relationship between chemistry and seedling size, i.e., the highest amounts of phenolics and lowest amounts of nitrogen in the largest seedlings, conflict with previous findings on the relationship between plant chemistry and the food preference of voles (Bergeron and Jodoin, 1987; Marquis and Batzli, 1989).

In summary, we can say that growth and biomass of the silver birch seedlings studied were affected by stand density. The resulting differences in seedling size were associated with differences in concentration of total phenolics, but they did not affect the feeding

preferences of voles. However, size differences resulting from differential competitive success were more clearly associated with variation in nitrogen concentrations and the concentration of various secondary compounds. Voles also selected seedlings that were successful in competition. Differences in the set of characteristics associated with size variation in relation to density variation vs. variation in competitive success were possibly related to genotypic differences in competitive success (Pusenius et al., 2002). Our results suggest that the ecological consequences of size variation may be contingent on the mechanism that created the variation.

Introduction

In the early 1980s, the horse chestnut leafminer, *Cameraria ohridella* (Lep., Gracillariidae), was observed for the first time in Macedonia, near Ohrid Lake (Deschka and Dimic, 1986). Since that outbreak, *C. ohridella* spread rapidly and is now established throughout central Europe (Skuhrovy, 1999; Hellrigl, 2001; ˇSefrova, 2003). The larval stages of this insect mine in leaves of the horse chestnut *Aesculus hippocastanum* (Sap., Hippocastanaceae). The eggs are deposited singly on veins of the upper leaf surface. The insect develops within leaves through one to five feeding larval stages, two prepupal stages, and one pupal stage (ˇSefrova and Skuhrovy, 2000; Freise, 2001; De Prins et al., 2003; Zunke and Doobe, 2003; John e et al., 2005). Larvae of the first feeding stage (L1) create a 1- to 3-mm-long mine parallel to the leaf vein. The second feeding stage (L2) enlarges the mine to a nonuniform circle with a diameter of approximately 3 mm, which is broadened to 8 mm by the third stage (L3). Older feeding larvae (L4, L5) broaden the mines so much that one mine can cover several square centimeters. In early larval stages (L1–L3), leaf veins limit the expansion of mines. During development of late larval stages (L4, L5), leaf veins are destroyed and, in heavy infestations, mines merge and can totally cover the leaf surface. Larvae in early stages are considered to be of the “sap-sipping” type, whereas those in late stages are of the “tissue-feeding” type (Pschorn-Walcher, 1994).

The origin of this invasive insect species is still unknown (Freise et al., 2002). Moreover, it is not known whether the horse chestnut tree is the original host plant or whether *C. ohridella* performed a host shift (Hellrigl, 1999). The sex pheromone of the moth was identified by Svatoš et al. (1999). In this study, the olfactory basis of oviposition site selection by *C. ohridella* was examined. The insect has three generations (spring, summer, and autumn) in Central Europe (Pschorn-Walcher, 1994; Hellrigl, 1999; Skuhrovy, 1999). At high population densities, the mining larvae are able to completely destroy the leaf surface (Tomiczek and Krehan, 1998; Gilbert and Gregoire, 2003). During the development of the first generation in spring, the host leaves are green and the trees are flowering (John e et al., 2003). The second and third generations encounter increasingly damaged leaf tissue caused by mining conspecifics and decreasing green leaf area suitable for oviposition. Because of these factors, the moths of various generations encounter different olfactory environments. The odor patterns of green and damaged leaves were analyzed by gas chromatography-mass spectrometry (GC-MS) and GC-electroantennographic detection (GC-MS/EAD). Identified compounds were provided to the insect antennae in dilution series to examine quantitative antennal responses of moths. In bioassays, leaves of *A. hippocastanum* infested with different larval stages and with different degrees of browning were tested for their possible effect on adults. Moreover, oviposition choices by female moths were tested in two choice tests, by using green leaves treated with single compounds induced by larval mining in leaves, and that elicited responses from antennae of adult moths.

Methods and Materials

Locations and Trees

Between July 2002 and October 2004, leaves for odor sampling were taken from trees in Goettingen (Lower Saxony, Germany, 8°C mean annual temperature, 600–700 mm rainfall).

Trees were situated in different types of locations: directly in the city (sealed soil), in a suburban area (grassland), and in a meadow surrounded by forest. Microclimatic conditions and removal of foliage were monitored.

Sampling of Volatiles

Odor samples for GC-MS/EAD analysis were obtained by using the closed-loop stripping analysis (CLSA) method (Boland et al., 1984). At each location, leaf volatiles from three trees of *A. hippocastanum* were sampled three times during the appearance of *C. ohridella* adults and once before and after each generation. From 2002 till 2004, there were three generations per year in Goettingen. For collection of volatiles, five leaves per tree were taken from different branches. Volatiles released in response to stress or attack by phytophagous insects can be released locally at the site of damage or systemically from other parts of the plant (Röse et al., 1996; Dicke, 1999). To rule out position effects within one tree, one branch pointing in each direction (north, south, west, and east) was chosen. The fifth leaf was taken from near the trunk of the tree. Five leaves per tree were put into a single 250-ml glass flask with ground glass joints. The degree of browned, mined leaf surface was noted for each leaf (rating: 0%, 1–5%, 6–10%, 11–30%, 31–50%, 51–70%, 71–90%, and 91–100%). Leaves with 0% leaf browning were checked to ensure that no larvae were developing in the tissue. It was not possible to open mines to remove the larvae and their associated products without complete destruction of the leaf. Thus, during collection of volatiles, the larvae remained inside their mines. Stainless steel capillaries (1 mm ID) were fed through the stoppers (PTFE) of the flasks. Miniature pumps (type DC12/16NK; Fürgut, Tannheim, Germany) were used to circulate air from the flasks to adsorbent traps (type “LR”; CLSA-Filter, Daumazan sur Arize, France). Traps consisted of glass tubes (6 cm long and 0.3 mm ID) loaded with 1.5 mg charcoal. The sampling time for leaf odor was 45 min at a flow rate of 1 l/min. Volatiles were eluted from the traps with 75 μ l solvent ($\text{CH}_2\text{Cl}_2/\text{MeOH}$, 2:1, Suprasolv-quality; Merck/VWR, Darmstadt, Germany). After elution, the samples were stored at -80°C . In May 2004, in addition to leaf odor, floral volatiles were obtained by the same method, with a few modifications. Thus, flowers were enclosed in a plastic roasting bag (Melitta GmbH, Minden, Germany) directly on the trees and volatiles were sampled for 4 hr (11:30 AM–3:30 PM; flow rate, 1 l/min).

GC-MS/EAD System

Samples were analyzed by coupled GC-MS/EAD (Weissbecker et al., 2004), using a 6890N gas chromatograph (Agilent, Palo Alto, CA, USA) and a 5973N mass spectrometer (Agilent). The GC was equipped with a split/splitless (S/SL) injector and an HP-5MS column (Agilent; 30 m, 0.25 mm I.D., film thickness 0.25 μm). A GRAPHPACK 3D/2 flow splitter (Gerstel, Mülheim, Germany) was used to split the effluent from the column into a capillary (1 m long, 0.1 mm ID) leading to the MS and another (1 m long, 0.15 mm ID) leading to the EAD. The restriction capillaries resulted in an equal split of the gas flow into the two setups.

A modified “olfactory detector port” (ODP-2; Gerstel; Weissbecker et al., 2004) guided the capillary out of the GC oven within a flexible heating sleeve. Volatiles eluted from the column into a flow of helium make-up gas, and then were mixed with humidified air (23°C, 80% RH). The airflow (flow rate, 400 ml/min) was directed through the flow tube (15 cm long, 6 mm ID, PTFE) to the insect antennae preparation that was housed in a PTFE detector cell.

Excised antennae of *C. ohridella* were placed into an antenna holder milled from a perspex disc (Färbert et al., 1997). The origins of the moths used were noted so that possible differences in electrophysiological responses among individuals from different locations could be traced. Within the holder, the ends of the antennae contacted an electrolyte solution that provided electrical contact to a pair of Ag/AgCl electrodes. EAD potentials were amplified by a factor of 100 with a high-impedance amplifier (input impedance 100 M Ω ; Prof. Koch, Kaiserslautern, Germany) containing a built-in low-pass filter set to a cutoff frequency of 1 Hz to suppress the ubiquitous electrical supply frequency of 50 Hz. An additional high pass filter set at a cutoff frequency of 0.01 Hz was used to suppress drift of the EAD signal. The amplified and filtered signal was digitized by using a 35900E A/D converter (Agilent) and recorded by the GC ChemStation software (Agilent).

Analytical Conditions

One- μ l aliquots of the samples were injected into the S/SL injector (temperature, 250°C). The GC oven was programmed from 50°C for 1.5 min, then 6°C/min to 200°C; hold for 5 min. Helium was used as carrier gas (1 ml/min, 24 cm/sec). The GC-MS interface was held at 280°C. The heating sleeve of the ODP was set to 230°C. The MS used electron impact ionization (EI) at 70 eV, in scan mode (35–300 mass units, 2.78 scans/sec). For preliminary peak identification, the NIST mass spectral library (National Institute of Standards and Technology, Gaithersburg, MD USA) and the MassFinder 3.0 software (Hochmuth, 2004) together with the library “Terpenoids and Related Constituents of Essential Oils” (König et al., 2004) were used. Subsequently, the spectra and retention times of compounds were compared with those of synthetic standards, and identifications were confirmed by coinjection. To ensure the identification of compounds, the collected samples and standards were also analyzed with an HP-INNOWax column (Agilent, 30 m, 0.25 mm ID, film thickness 0.25 μ m) using the GC-MS method and the same analytical parameters as the HP-5MS column. Tables 1 and 2 include information about the sources of synthetic standards used for identification. The identification of the tentatively identified compounds was based only on a match of library spectra to the mass spectra, which were measured in our samples, on both columns. The synthetic standards of (*E,E*)- α -farnesene and (*E*)-4,8-dimethyl-1,3,7-nonatriene were gifts from Roman Kaiser, Givaudan, Switzerland and Wilhelm Boland, Max Planck Institute Jena, Germany, respectively.

Electroantennogram Dose–Response Series

Dose–response series were measured by manual injection of odor standards into an air stream passed over the antennae of *C. ohridella* mounted in an electroantennogram (EAG) setup. The origins of the moths used were noted as in the GC-MS/EAD measurements. Odor standards were produced from dilution series of the respective compounds in paraffin oil (Uvasol quality, Merck/VWR). Small pieces of filter paper (2 cm²; Schleicher & Schuell, Dassel, Germany) were soaked with 100 μ l of the standard dilution. The filter paper then was put into a 10-ml glass syringe (Poulten & Graf GmbH, Wertheim, Germany). Inside the air volume of the syringe, the odorant accumulated at a concentration proportional to the concentration of the substance in the solution and its vapor pressure according to Henry’s law. A reproducible stimulus could be supplied by puffing 5 ml of air over the antenna (Schütz et al., 1999). The resulting signals were amplified (100 \times). Details (purity and source) of substances tested on insect antennae are shown in Tables 1 and 2. For the compounds (*E*)- β -caryophyllene and (*E/Z*)-linalool oxide, (furanoid) racemic mixtures were used.

Table 1 Leaf volatile compounds that appear throughout the entire year, and flower odorant compounds of *A. hippocastanum*

The total leaf surface of every twig was about 1000 cm². Twigs with the following degrees of infestation were used for the bioassays:

- Twigs with leaves, 10 wk after termination of leaf development and infested by early larval stages (eggs, L1–L3): the twigs were taken from five trees treated with the systemic insecticide Confidor WG 70 (active ingredient imidacloprid, 70%; Bayer CropScience, Monheim, Germany) via soil application [0.28 g/cm diam of the stem at breast height (DBH)]. The emerging larvae bored into the leaves and started mining, but most died in the L1 stage without causing any browning on the leaves.
- Twigs with uninfested leaves, directly after termination of leaf development: the leaf material originated from seedlings dug out in February. The development of the shoots was delayed for 3 mo in a cooling chamber at 5°C. Neither eggs nor larval stages of *C. ohridella* were observed on these plants.
- Twigs with leaves that had a browning ratio of 70–90% caused by late larval stages (L4, L5) of *C. ohridella*.

For the two-choice tests, two twigs were arranged in 5-l jars filled with water within a cage (200 × 100 × 130 cm) consisting of a wooden frame and base, a polyester net (mesh size, 0.5 mm), and two glass doors in the front. The distance between the twigs was 150 cm. The lighted cage (1000 lx) was situated in a room (29°C, 45% RH) without windows or airflow. Before the experiment, adults were captured from different locations in Goettingen and

chilled in a dark chamber at 5°C overnight. In each assay, 200 moths were released in groups of 20 individuals in the middle of the cage. After an orientation phase of 20 min, all insects that were sitting on plants were counted.

In further two-choice tests with treated and control twigs, compounds identified by GC-MS/EAD were tested for influence on oviposition. The twigs originated from *A. hippocastanum* trees treated with Confidor WG 70 via soil application (0.28 g/cm DBH; see above). They were checked for fungal infection and larval mining activity. Only twigs without fungal infection or necrosis were selected for bioassays. To rule out position effects, two equally sized twigs were taken from the same branch. Filter paper covering 30–50% of the leaf surfaces was fixed to each leaflet with a needle (Fig. 1). The filter paper of one twig was soaked with a paraffin oil solution of an odorant, whereas the filter papers on the second twig were treated with paraffin oil only as a control. Thus, the volatile pattern of healthy leaves was superimposed with additional odorant compounds. The selected concentration of odorant compounds was near the inflection point of the respective EAG dose–response curves (10^{-3} v/v in paraffin oil). Fresh odor solution was added to the filter papers at the beginning of a bioassay and replenished every 6 hr (nonanal [19], decanal [12], benzaldehyde [7]) or every 12 hr (control, 1,8-cineole [8], benzyl alcohol [15], 2-phenylethanol [11], methyl salicylate [16], enantiomeric (*E*)- β -caryophyllene [14], (*E,E*)- α -farnesene [17], (*E/Z*)-linalool oxide (furanoid, enantiomeric mixture of isomers) [9, 10] and (*E,E*)-2,4-hexadienal [18]; numbered as in Tables 1 and 2) to maintain the concentration of compounds at the appropriate level. After 6 or 12 hr, before fresh odorant solution was added, the amount of the tested compound had decreased by approximately 50%. In a lighted (1000 lx) cage (180 × 75 × 75 cm), the two twigs were arranged in 5-l glass jars filled with water and 120 cm apart (Fig. 1). The cage was made out of a wooden frame, stainless steel screen (mesh size of 0.7 mm), and glass, with two glass doors in the front. The cage was situated in a dark room without air flow at 26°C and 50% relative humidity. At the beginning of each assay, 250 moths captured outdoors were released in the middle of the cage. The fresh eggs on the leaves were counted after 24 hr (nonanal, decanal, benzaldehyde) or 48 hr (all other compounds).

Statistical Analyses

The amounts of single compounds emitted from different browned leaves after mining by *C. ohridella* were analyzed with the Kruskal–Wallis *H* test ($\alpha = 0.05$; Lozán and Kausch, 1998). The data were not normally distributed ($\alpha = 0.05$; Shapiro–Wilks test; Lozán and Kausch, 1998). The analyses were carried out by using Statistica 6.1 software (StatSoft,

Fig. 1 Schematic of experimental setup for oviposition bioassay. A filter paper treated with odorant compound dissolved in paraffin oil (10^{-3}) or only paraffin oil (control) was fixed on every leaflet with a needle

Inc., 2003). To optimize the dilution of odor compounds in choice tests, a sigmoid function $y = A_2 + (A_1 - A_2)/(1 + (X/X_0)^P)$ was fitted to the dose–response curves using the Origin 7 software (OriginLab, 2002), where A is the EAG response amplitude, X is the dilution of the odor, and X_0 is the dilution at the point of inflection. In addition, the detection limit was determined via statistical analyses of EAG dose–response curves, using the Mann–Whitney U test ($\alpha = 0.05$; Lozán and Kausch, 1998; Statistica 6.1; StatSoft, Inc., 2003). In all bioassays, statistical analyses were carried out with χ^2 test 2×2 tables ($\alpha = 0.05$; Lozán and Kausch, 1998) using Statistica 6.1 software (StatSoft, Inc., 2003). Statistical comparisons were made only between the two twigs in one cage and not between the several variants.

Results

Analysis of Volatiles

In 2003, the mean annual temperature in the city was 16.0°C, 1°C higher than in the forest. A mean annual relative humidity of 69.1% was measured in the forest, which was 1% higher than in the city. In 2003, in both locations, temperatures of up to 35°C were reached. No significant differences in the profiles of volatiles were found as a result of microclimate or location. The profiles of volatiles of control trees treated with Confidor WG 70 was not different from that of untreated healthy trees.

During the spring bloom of *A. hippocastanum*, flower scent compounds such as (*E/Z*)-linalool oxides (furanoid) [9, 10] (enantiomeric composition not determined) and benzaldehyde [7] were emitted by trees and mixed with leaf odor (Table 1). The leaf odor

Fig. 2 Quantification of volatiles released by *A. hippocastanum* leaves infested with *C. ohridella* larvae. Compounds are shown in order of increasing retention times and labeled as in Tables 1 and 2: [7] benzaldehyde; [8] 1,8-cineole; [9,10] (*E/Z*)-linalool oxides (furanoid)*; [11] 2-phenylethanol; [12] decanal; [13] tridecane; [14] (*E*)- β -caryophyllene*; [15] benzyl alcohol; [16] methyl salicylate; [17] (*E,E*)- α -farnesene; [18] (*E,E*)-2,4-hexadienal; [19] nonanal. Twenty measurements were taken for each compound, 10 per bar (Kruskal–Wallis test, $\alpha = 0.05$; n.s. = not significant; ** $p < 0.01$; *** $p < 0.001$). Error bars indicate the standard error. Benzaldehyde (1.0×10^{-6}) [7] is equivalent to 0.22 ng/l air. *Enantiomeric composition not determined

compounds listed in Table 1 were released throughout the season by both uninfested and damaged leaves, independently of the mining degree.

Infestation by *C. ohridella* caused significant changes in the pattern of volatiles released by *A. hippocastanum* leaves. After oviposition and during development of early larval stages (L1–L3), plants started to produce additional alcohols, aldehydes, phenolics, and terpenes (Table 2). Mining by late larval stages (L4, L5) and severe loss of green leaf area caused the release of tridecane [13], (*E/Z*)-linalool oxides (furanoid) [9, 10] (enantiomeric composition not determined), and aldehydes, such as decanal [12] and (*E,E*)-2,4-hexadienal [18] (Table 2). The amount of released volatiles increased with progressive larval development (Fig. 2). Leaves infested by late larval stages and with a high ratio of browned to green area released a higher total number and amount of compounds than leaves infested by early larval stages (Fig. 2).

Electrophysiological Analyses

Because of microclimatic conditions, moths emerged 1 wk (first generation) or 2 wk (second and third generations) earlier in the city than in the forest. Moths collected from the different locations showed no differences in their olfactory responses to leaf volatiles. The response of the insects' antennae to the leaf odor of control trees treated with Confidor WG 70 was not different from the response to untreated trees.

Fig. 3 GC-MS/EAD recording from antenna of *C. ohridella* in response to leaf volatiles of *A. hippocastanum* released in spring (first generation). The leaves were not browned by larval feeding. Upper, inverted trace: electroantennogram response. Lower trace: total ion chromatogram. Compounds labeled as in Tables 1 and 2: [2] (*Z*)-3-hexen-1-yl acetate; [3] hexyl acetate; [4] (*E*)-2-hexen-1-yl acetate; [8] 1,8-cineole; [9] (*E*)-linalool oxide (furanoid)*; [10] (*Z*)-linalool oxide (furanoid)*; [12] decanal; [20] (*E*)-4,8-dimethyl-1,3,7-nonatriene; [21] unknown; [22] unknown. *: Enantiomeric composition not determined

In spring, flower scent compounds were released in large amounts. These compounds were found in leaf odor samples too. These compounds included (*E/Z*)-linalool oxides (furanoid) [9, 10], 1,8-cineole [8], and decanal [12], and were detected by antennae of *C. ohridella* (Fig. 3). Green leaf volatiles of *A. hippocastanum* that were released throughout the year (Table 1), including (*Z*)-3-hexen-1-ol [1] (Fig. 4), (*Z*)-3-hexen-1-yl acetate [2] (Figs. 3 and 4), hexyl acetate [3] (Figs. 3 and 4), and (*E*)-2-hexen-1-yl acetate [4] (Figs. 3 and 4) elicited the strongest responses from *C. ohridella* antennae. (*Z*)-3-Hexen-1-yl acetate [2], hexyl acetate [3], and (*E*)-2-hexen-1-yl acetate [4] coeluted using the HP-5MS column. Other leaf volatiles that elicited antennal responses in each generation were (*Z*)-3-hexen-1-yl isovalerate [5] and (*Z*)-3-hexen-1-yl valerate [6] (Fig. 4).

Changes in leaf odor pattern induced by larval mining were detectable by moths. Additional compounds released by leaves after oviposition and during development of early larval stages (L1–L3), such as benzyl alcohol [15], 2-phenylethanol [11], and methyl salicylate [16], were detected by the moths (Fig. 4). Decanal [12], (*E,E*)-2,4-hexadienal [18], nonanal [19], and tridecane [13] were released by leaves affected by mining of late larval stages and severe loss of green leaf area. These compounds also elicited antennal responses (Fig. 4). In addition, the insect antennae responded to sesquiterpenes, such as (*E*)- β -caryophyllene [14] (enantiomeric composition not determined), and (*E,E*)- α -farnesene [17]. (*E*)-4,8-Dimethyl-1,3,7-nonatriene [20] also elicited antennal responses (Figs. 3 and

Fig. 4 GC-MS/EAD recordings of *C. ohridella* in response to leaf volatiles of *A. hippocastanum* released in summer (second generation). The leaf surface of *A. hippocastanum* was browned by mining of late larval stages. Upper, inverted trace: electroantennogram response. Lower trace: total ion chromatogram. Compounds labeled as in Tables 1 and 2: [1] (*Z*)-3-hexen-1-ol; [2] (*Z*)-3-hexen-1-yl acetate; [3] hexyl acetate; [4] (*E*)-2-hexen-1-yl acetate; [5] (*Z*)-3-hexen-1-yl isovalerate; [6] (*Z*)-3-hexen-1-yl valerate; [11] 2-phenylethanol; [12] decanal; [13] tridecane; [14] (*E*)- β -caryophyllene*; [15] benzyl alcohol; [16] methyl salicylate; [17] (*E,E*)- α -farnesene; [18] (*E,E*)-2,4-hexadienal; [19] nonanal; [20] (*E*)-4,8-dimethyl-1,3,7-nonatriene; [23] unknown; [24] unknown. *: Enantiomeric composition not determined

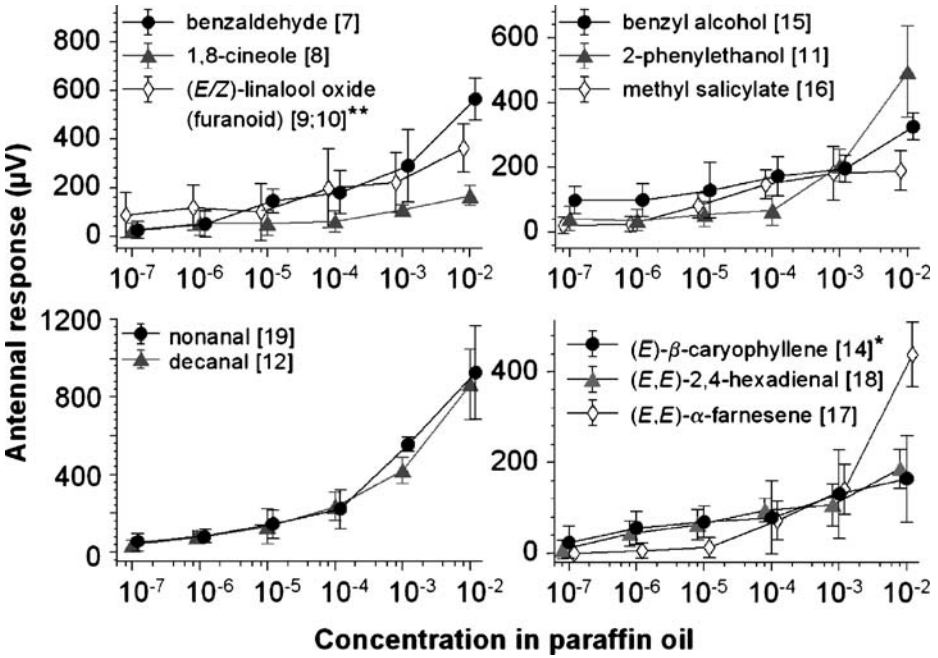

Fig. 5 Electroantennogram dose–response curves of floral odors, and compounds induced by larval mining in leaves, stimulating *C. ohridella* antennae. Compounds labeled as in Tables 1 and 2. Puffs of 5 ml of air were loaded with reference standards of plant odors (pulses 0.5 sec, minimum three animals, number of puffs = 10). Each point represents the mean of antennal response. Standard deviations are indicated as error bars. Data points are slightly shifted along the x-axis to avoid overlap of the error bars; *: racemic mixture; **: enantiomeric mixture of isomers

4), but no correlation was found between the occurrence of this compound and larval mining by *C. ohridella*.

The absolute sensitivity of the antenna toward identified compounds was determined with commercially available standards (Tables 1 and 2). (*E*)-β-Caryophyllene and (*E/Z*)-linalool oxides (furanoid) were tested as enantiomeric mixtures. The EAG dose responses

Fig. 6 Total number of *C. ohridella* adult sitting on differently infested and browned leaves of *A. hippocastanum* in two-choice tests: (a) leaves infested with early larval stages (eggs, L1–L3, destroyed leaf tissue less than 5%); (b) uninfested leaves; (c) leaves browned by late larval stages (L4, L5) of *C. ohridella* (destroyed leaf tissue 70–90%); (χ^2 test, $\alpha = 0.05$; n.s. = not significant; *** $p < 0.001$)

obtained after stimulation with reference standards in dilution series are depicted in Fig. 5, focusing on compounds emitted from flowers and leaves after leaf mining. The highest EAG responses of all compounds tested were observed in response to the aldehydes nonanal [19] and decanal [12], with amplitudes between 800 and 1000 μV for the 10^{-2} dilution. At the 10^{-3} dilution level, 2-phenylethanol [11], benzaldehyde [7], benzyl alcohol [15], (*E/Z*)-linalool oxides (furanoid) [9, 10], and methyl salicylate [16] elicited responses with amplitudes between 150 and 300 μV . In the 10^{-3} dilution series, 1,8-cineole [8], (*E*)- β -caryophyllene [14], (*E,E*)- α -farnesene [17], and (*E,E*)-2,4-hexadienal [18] evoked low responses, with amplitudes of about 100 to 150 μV . The antennal responses to (*E,E*)- α -farnesene [17] and 2-phenylethanol [11] increased strongly from the 10^{-3} dilution to 10^{-2} dilution.

Bioassays

In two-choice tests, the responses of moths to leaf odors of healthy leaves, leaves infested by early larval stages (L1–L3), and browned leaves with late larval stages (L4, L5) were

Fig. 7 Percentage of eggs laid by *C. ohridella* on leaves of *A. hippocastanum* in two-choice tests. A filter paper covering 30–50% of the leaf surface was fixed on each leaflet with a needle. The filter papers of one twig were treated with paraffin oil (Control), and the other one was treated with volatile substances in paraffin oil (solution 10^{-3} ; Treated). Compounds are listed based on their retention time, appearance during larval feeding, and are labeled according to Tables 1 and 2 (χ^2 test, $\alpha = 0.05$); n.s. = not significant; *** $p < 0.001$). *: Enantiomeric mixture; **: enantiomeric mixture of isomers

compared. A control experiment with two twigs infested by early larval stages resulted in a uniform distribution of adults ($p > 0.05$, χ^2 test; first bioassay, Fig. 6). The responses of moths to leaves infested by early larval stages and healthy leaves were not significantly different ($p > 0.05$, χ^2 test; second bioassay). In contrast, fewer moths were found on browned leaves with late larval stages than either leaves infested by early larval stages or healthy leaves ($p < 0.001$, χ^2 test; third and fourth bioassays, Fig. 6).

Single compounds were tested for their influence on oviposition. The control bioassay with paraffin oil-treated leaves resulted in a uniform dispersal of eggs ($p > 0.05$, χ^2 test; Fig. 7). Compounds induced by mining of various larval stages of *C. ohridella* could be grouped as follows: compounds without any discernable effect, compounds resulting in preferential oviposition, and compounds resulting in reduced oviposition. Benzaldehyde [7] and enantiomeric (*E*)- β -caryophyllene [14], induced by early larval stages, resulted in more oviposition than the control ($p < 0.001$, χ^2 test). In contrast, leaves treated with benzyl alcohol [15] and 1,8-cineole [8] received less oviposition than controls ($p < 0.001$, χ^2 test). Methyl salicylate [16], 2-phenylethanol [11], and (*E,E*)- α -farnesene [17] had no effect on oviposition ($p > 0.05$, χ^2 test; Fig. 7). Leaves treated with (*E,E*)-2,4-hexadienal [18], a compound that appeared during late larval stages, received more oviposition than controls ($p < 0.001$, χ^2 test). In contrast, the mixture of (*E/Z*)-linalool oxides (furanoid) [9, 10] and decanal [12] reduced the number of eggs laid ($p < 0.001$, χ^2 test), whereas nonanal [19] had no effect in comparison to controls ($p > 0.05$, χ^2 test).

Discussion

Aesculus hippocastanum trees bloom during the flight period of the first *C. ohridella* generation. Flower scent is emitted in high amounts and may serve for long-distance host plant finding (Visser, 1986; Bernays and Chapman, 1994). The bioassays presented here examined the intermediate and short distance effects on oviposition, that is, from branch to branch in one tree and from position to position on one leaf. Detection over longer distances was not examined. Besides encountering flower scent, moths of the first generation also encounter green undamaged leaves. Green leaf volatiles are important cues used by phytophagous insects in their search for host plants and selection of oviposition sites (Visser and Avé, 1978). Volatiles induced by mining do not play any important role in mediating oviposition by the first generation.

In contrast, the adults of the second and third generations are confronted with an increasing degree of mining damage and a decreasing proportion of green leaf tissue. Totally browned leaves, caused by larval mining, are frequently encountered by the third generation (Tomiczek and Krehan, 1998; Gilbert and Grégoire, 2003). Larval mining by *C. ohridella* causes significant changes in the profile of volatiles of horse chestnuts. Some of the compounds produced in infested leaves are typically found in flowers as well. Changes in the odor profiles of plants as a result of herbivore infestation can modify the responses of conspecific herbivores in different ways. For instance, the cabbage looper moth, *Trichoplusia ni*, avoids cabbage plants infested by conspecifics (reviewed by Dicke and Vet, 1999). In contrast, potato leaves infested with Colorado potato beetle larvae (Bolter et al., 1997) or adults (Schütz et al., 1997) attract host-searching Colorado potato beetles. For *C. ohridella*, the ratio of green to browned leaf surface is important, with fewer adults being found on browned leaves infested with late-stage conspecifics and a high ratio of destroyed leaf tissue. This result indicates that moths may avoid intraspecific competition for the same

food resources or poor quality hosts. The odor pattern of healthy leaves is modified by several odorant compounds produced in response to herbivore infestation; the odor pattern of leaves infested with late larval stages and a high ratio of destroyed leaf tissue shows additional compounds compared to leaves with early infestation stages. When leaves of *A. hippocastanum* were treated with single odorant compounds, these compounds elicited different effects on the number of eggs oviposited by *C. ohridella* females.

(*E*)- β -Caryophyllene, tested as the enantiomeric mixture, and benzaldehyde released by flowers and larval-damaged leaves of *A. hippocastanum*, resulted in increased levels of oviposition on treated leaves. (*E,E*)-2,4-Hexadienal, which is only emitted by leaves infested with late larval stages and a high ratio of brown to green leaf tissue, also enhanced oviposition. This compound may indicate increasing oxidative stress in leaf tissue infested with late stage larvae (Schütz, 2001). Thus, attractive compounds can be used for host location and recognition in spring (first generation, flowers). Compounds indicating the feeding activities of conspecifics may also help to identify the correct oviposition substrate (second and third generations, leaves), as was suggested for the Colorado potato beetle (Bolter et al., 1997; Schütz et al., 1997).

In contrast, 1,8-cineole and benzyl alcohol resulted in decreasing levels of oviposition on treated leaves. These compounds are known to act as defenses in plant herbivore systems. For instance, 1,8-cineole, which has antimicrobial effects (Zhu et al., 2005), is known to be induced as a plant defense against herbivores (reviewed by Langenheim, 1994). High concentrations of 1,8-cineole in plants can inhibit feeding by insects (Steinbauer and Wajura, 2002) and act as a repellent (Matsuki et al., 2001), as shown for Christmas beetles on eucalyptus. Benzyl alcohol is also known to be induced by herbivore infestation, for example, in the cases of red spotted spider mites on lima beans (Hopke et al., 1994) and psylla infestation on pear leaves (Scutareanu et al., 1997). Decanal and (*E/Z*)-linalool oxides (furanoid, tested as an enantiomeric mixture of isomers), which were released by leaves with high ratios of brown tissue because of infestation with late larval stages, also decreased the oviposition of females. Like (*E,E*)-2,4-hexadienal, these two compounds may indicate increasing oxidative stress in damaged leaf tissue due to decay processes in cells (Schütz, 2001). Decanal is known to be induced by mechanical and herbivore damage (Schütz et al., 1997; Weissbecker et al., 1999; Dicke et al., 2003) and by senescence of old leaves (Schütz, 2001). Because compounds with both positive and negative effects were emitted at the same time, further studies should focus on mixtures of these compounds on oviposition and the effect of these compounds on larval development. Furthermore, Our study investigated the chiral compounds (*E*)- β -caryophyllene and (*E/Z*)-linalool oxide (furanoid) as enantiomeric mixtures. Insects can selectively respond to different isomers and enantiomers in physiological experiments as well as in bioassays (Hobson et al., 1993; Zhang et al., 2003). Therefore, it is necessary to investigate these compounds with defined isomeric and enantiomeric purity in future experiments, and the results presented here should be interpreted with care.

The volatile compounds 2-phenylethanol, (*E,E*)- α -farnesene, and methyl salicylate, which act as defense compounds in host trees, did not influence the number of eggs laid. These compounds were recorded as present in odors released by herbivore-damaged plants and are utilized by predators (Dicke et al., 1990; Weissbecker et al., 1999; Maeda and Takabayashi, 2001) as well as parasitic wasps (De Moraes et al., 1998) to locate prey and hosts. No specialized parasitoid or predator for the leaf miner has been found to date, even in the area of first observation of *C. ohridella* (Freise et al., 2002; Grabenweger et al., 2005). 2-Phenylethanol and (*E,E*)- α -farnesene were perceived by the insect antennae, but did not affect oviposition. Methyl salicylate is involved in the induction of acquired resistance in

tobacco plants as an airborne signal (Shulaev et al., 1997). The compound was perceived by the insect antennae, but also did not affect oviposition. The observed high infestation rates produce up to 100% leaf browning in *A. hippocastanum* trees, and the defense status of leaves seems to have no effect on the host suitability for *C. ohridella*. Instead, insufficient food resources due to destroyed leaf tissue by conspecifics are probably the cause of high larval mortality, especially in autumn (Deschka, 1994; Freise, 2001; Kindl et al., 2002; Grabenweger, 2003). So far, the observed natural mortality of *C. ohridella* on *A. hippocastanum* leaves is low (Johné, 2001; Grabenweger, 2003). The lack of an effective defense by *A. hippocastanum* against infestation by *C. ohridella* might be one major cause of the invasive success of the insect.

In summary, our study demonstrated that adult *C. ohridella* were able to detect alterations in patterns of leaf volatiles induced by oviposition and larval mining by conspecifics. These alterations of leaf odor pattern affected the oviposition of the adults. Despite moths avoiding leaves highly browned by larval feeding, they did not display a reduction in oviposition to all single volatile compounds induced by larval mining. The preference for green and only slightly browned leaves ensures oviposition sites with satisfactory food resources for developing larvae, while also minimizing intraspecific competition.

Acknowledgments A.B. Johné was supported by the evangelisches Studienwerk “e. V. Villigst”. We are grateful to Wolfgang Gießle (City of Goettingen), Volker Meng (forest botanical garden of Georg August University), and Martin Levin (Revierförsterei Hainberg) for appropriation of trees, to Roman Kaiser, Givaudan, Switzerland, for the gift of (*E,E*)- α -farnesene, and to Wilhelm Boland, Max Planck Institute Jena, Germany, for the gift of (*E*)-4,8-dimethyl-1,3,7-nonatriene. We thank the members of our Institute Miriam Rameckers, Jörg Berger, Kira Duntemann, Reinhold Dankworth, and Ulrike Eisenwiener for their assistance. Moreover, thanks to Stefan Schwab for literature. We also appreciate the useful suggestions of the anonymous reviewers.

We recently reported that lepidopteran eggs and neonates contain significant amounts of JA (Tooker and De Moraes, 2005). We detected JA in each of nine lepidopteran species that we screened; this JA may have accumulated from the larval diets of the ovipositing mothers, although we found evidence that some lepidopteran species may have synthesized JA *de novo* because the unfed neonates of some species contained significantly greater amounts of JA than the eggs (Tooker and De Moraes, 2005).

The quantities of JA that we measured in lepidopteran eggs and neonates did not appear to be directly related to the amounts of JA in the larval diets of the parents—species that consumed the diets with the highest JA concentrations had relatively low levels of JA (Tooker and De Moraes, 2005). In this work, we expand our previous analyses of JA in lepidopterans and investigate the relationship between JA levels in the diets of caterpillars and in the insects themselves. We reared the generalist caterpillar *Heliothis virescens* (Fabricius) (Noctuidae) on artificial diets with differing JA concentrations, collecting frass and regurgitant and dissecting fifth instar larvae. We also collected similar samples from caterpillars reared on lines of transgenic tobacco with different capabilities of producing JA.

Methods and Materials

Insect Samples We reared the generalist herbivore *H. virescens* on three artificial diets with different concentrations of JA and on lines of transgenic tobacco that have been shown to have different capabilities of producing JA in response to insect attack. For the artificial diet experiment, we reared *H. virescens* larvae from eggs (USDA, Tifton, GA, USA) to second instar in an incubator (16:8 L:D; 25:22°C, day:night; 65% RH) on a casein-based artificial diet. When larvae reached the second instar, we starved them for 24 hr and transferred them to one of three casein-based diets that differed only in their JA concentration ($N = 30$ caterpillars per concentration). The control or “low” concentration diet was not supplemented with JA but contained $\sim 2 \mu\text{g JA/g FW}$ because diet ingredients derived from plant material (e.g., wheat germ and cellulose powder) or seaweed (e.g., agar) can contribute significant amounts of JA to diets, including our casein diet (Tooker and De Moraes, 2005, unpublished data); therefore, the use of a true “control” diet that did not contain JA did not appear possible. This concentration of $2 \mu\text{g JA/g}$ falls within the range of JA concentrations that have been reported for damaged plants (Royo et al., 1999). The medium concentration diet was supplemented to achieve $\sim 200 \mu\text{g JA/g}$, an amount similar to that used experimentally by others (Li et al., 2002). The “high” concentration diet was supplemented to $2000 \mu\text{g JA/g}$, a concentration that greatly exceeds JA levels reported for plants and might provide insight into how caterpillar process excess JA. The supplemental JA was synthesized from methyl jasmonate (Sigma-Aldrich, St. Louis, MO, USA; Farmer et al. 1992), and added to diets in an ethanol solution; an equal amount of ethanol was added to the low concentration diet.

For the transgenic tobacco study, we grew from seeds three lines of tobacco that have been shown to differ in their capability to produce JA in response to insect damage: OX-434, C17, and NahG (for details, see Felton et al., 1999). We reared *H. virescens* from eggs to the second instar (as above), then starved them for 24 hr and transferred them to diet cups containing leaf tissue. Caterpillars were monitored daily, and fresh tissue was added at least every other day.

In both experiments, we collected regurgitant with a pipette from fourth instars by gently squeezing their heads. Regurgitant was pooled and boiled for 3 min to destroy enzymatic activity and stored at -80°C until processing (see below). When larvae reached the fifth

instar (2–4 d postmolt), we collected frass and dissected caterpillars (10 per diet) on ice, collecting the labial salivary glands, gut, and remainder of the body into three separate FastPrep[®] tubes (Qbiogene, Carlsbad, CA, USA). We transferred boiled regurgitant (20 μ l/sample; 5 samples per diet) to FastPrep[®] tubes whereas frass and insect tissues were collected directly into the tubes. Tubes of known mass containing 1 g of Zirmil beads (1.1 mm; Saint-Gobain ZirPro, Mountainside, NJ, USA) were weighed to determine the mass of samples and stored at -80°C . We also collected for analysis samples of artificial diet as well as tobacco leaves that had been excised and caterpillar-damaged in diet cups for 24 and 48 hr (5 samples per line per time point; samples were processed individually, but the data were pooled to produce a representative mean per line). For the tobacco experiment, we also collected adult moths (6–10 per line) and the eggs they laid (10 samples each containing 10 eggs). We collected males and females after eggs had been laid. For the remainder of this article, we refer to the various insect tissues (e.g., salivary gland, gut, body, adults, eggs), regurgitant, and frass collectively as “tissues” to avoid awkward prose.

Extraction and Quantification of JA To extract and detect JA, we used a previously described method (Tooker and De Moraes, 2005) that was modified slightly from Schmelz et al. (2003, 2004). Briefly, we derivatized the carboxylic acid to its methyl ester, which was isolated by using vapor phase extraction and analyzed by GC-MS with isobutane chemical ionization by using selected-ion monitoring. For details on quantification and controls, see Tooker and De Moraes (2005).

To normalize the data and stabilize variance, we square-root- or natural log-transformed our data (artificial diet and tobacco data, respectively) and compared mean amounts of JA among and between samples by ANOVA, testing differences between diets and tissues as planned comparisons with the LSD means separation test (Statistix, 2003).

Results and Discussion

We detected JA in all tissues of caterpillars reared on the artificial diets and tobacco lines (Fig. 1). Retention times and mass spectra of meJA recovered from diets and tissues matched the pure standard, confirming the identity of JA in our samples. Moreover, we did not recover meJA in the absence of the derivatization agent, verifying that the methyl ester we measured was derivatized from JA and was not itself present in samples.

By adding supplemental JA, we created diets with three distinct JA concentrations (Fig. 1a; ANOVA, $F_{2,14} = 154.1$, $P < 0.001$). The final concentrations of our medium and high concentration diets exceeded our targets; however, the final concentration of diets is not as important as the differences between diets and the concentrations of JA in caterpillar tissues. Caterpillars reared on each of the three artificial diets had significant differences across their tissues (Fig. 1a). Those reared on the “low” diet had guts, bodies, frass, and regurgitant containing amounts of JA statistically similar to that found in the diet (LSD, $P > 0.05$), but the amount of JA found in salivary glands was significantly enriched above that of the diet and the other tissues (Fig. 1a; LSD, $P < 0.05$). For caterpillars reared on medium and high diets, frass contained significantly greater concentrations of JA than the diets, suggesting that JA was not metabolized but passed through the digestive tract unaltered (Fig. 1a). Moreover, guts of caterpillars reared on these high-concentration diets had significantly less JA than was found in frass and regurgitant, which includes foregut contents, indicating that JA is removed to the frass or is somehow bound while moving

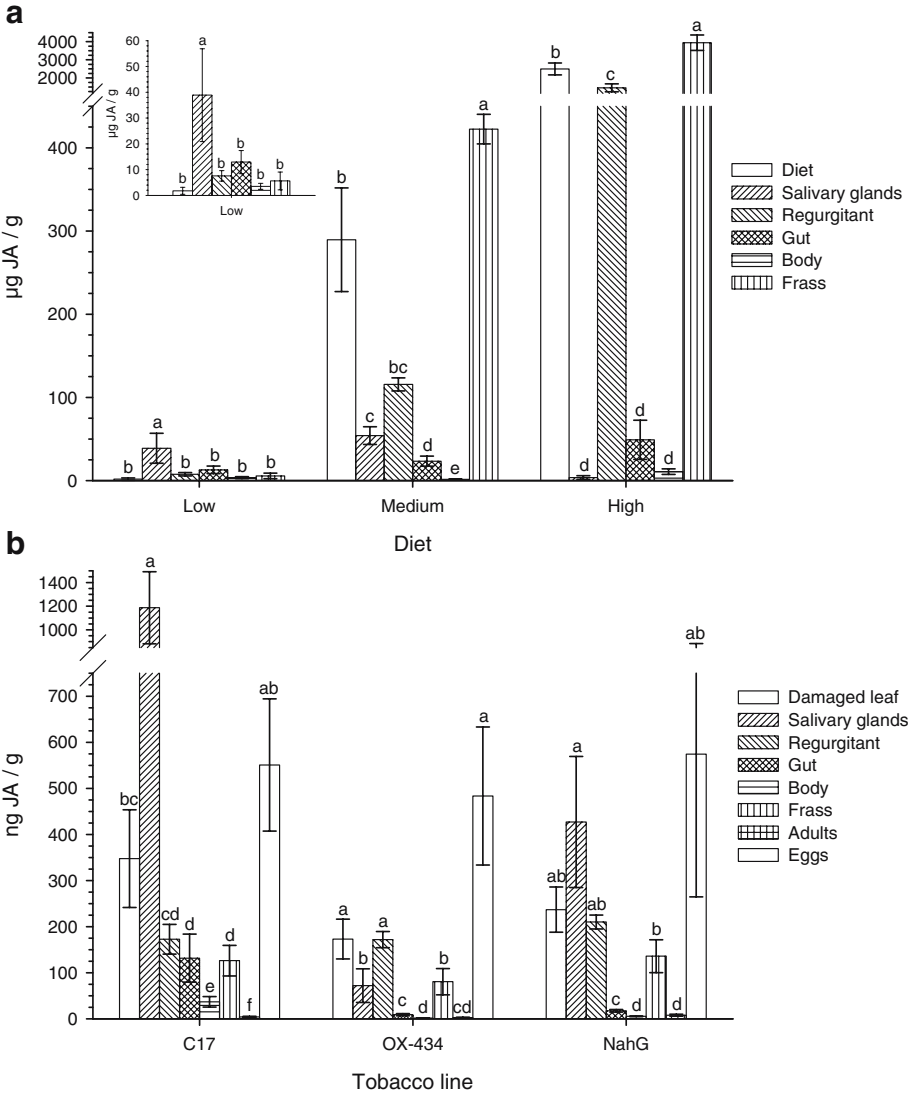

Fig. 1 Jasmonic acid (JA) detected in tissues of *H. virescens* caterpillars reared on (a) artificial diets with different concentrations of JA (inset shows details from caterpillars reared on low diet; within-diet ANOVA comparisons: low concentration— $F_{5,27} = 8.45, P < 0.001$; medium concentration— $F_{5,26} = 44.6, P < 0.001$; high concentration— $F_{5,27} = 44.3, P < 0.001$). (b) Lines of transgenic tobacco (within-line ANOVA comparisons: C17— $F_{7,76} = 23.9, P < 0.001$; OX-434— $F_{7,69} = 45.1, P < 0.001$; NahG— $F_{7,72} = 15.3, P < 0.001$). Data shown are untransformed. Within each diet, tissues marked with different letters are significantly different from each other (LSD $P < 0.05$; see text for details on statistics)

through the midgut. Caterpillars on both supplemented diets also produced regurgitant that tended to have higher concentrations of JA than those found in salivary glands and was enriched in JA significantly above gut samples, likely reflecting recently devoured diet in the foregut, which is expelled when caterpillars regurgitate. For medium and high diets, body samples (comprising mainly cuticle and fat body) contained relatively low

concentrations of JA (Fig. 1a). Caterpillars reared on the high concentration diet consumed more than those fed medium and low diets (5.8 ± 0.2 , 4.2 ± 0.3 , and 4.2 ± 0.2 g, respectively; ANOVA, $F_{2,73} = 13.9$, $P < 0.001$), indicating that the greater levels of JA in “high” larvae were a function of both diet and amount consumed. Moreover, greater consumption of this “high” diet may indicate that JA concentration alone can trigger increased consumption by insects in response to induced defenses; however, this finding should be interpreted with caution because of the unrealistic amount of JA in the high concentration diet.

The three lines of transgenic tobacco contained similar amounts of JA (ANOVA, $F_{2,29} = 2.2$, $P = 0.14$), an unexpected finding given previous work with these lines (Felton et al., 1999); however, we did not use intact plants, and the detached leaves may have had diminished capacities to respond to herbivory relative to leaves remaining on plants. Nevertheless, our results clearly indicate that caterpillars feeding upon plants with lower JA concentrations (relative to our artificial diet experiment) accumulate JA in their tissues (Fig. 1b).

Caterpillars reared on each of the three tobacco lines showed statistical differences in JA concentrations across tissues (Fig. 1b). Moreover, tissues from caterpillars reared on each diet showed similar patterns of differences across all three tobacco lines. First, C17 and OX-434 caterpillars had JA levels in frass that were significantly lower than concentrations found in damaged leaves, and NahG caterpillars showed a similar trend (Fig. 1b). These results suggest that caterpillars reared on plant tissue retained proportionally more of the JA they ingested than caterpillars reared on supplemented artificial diets whose frass had concentrations greater than those of their diet (Fig. 1a). Second, guts contained significantly less JA than the damaged leaves, again suggesting that JA is excreted in the frass or bound and made unavailable. Third and similar to the diet-reared caterpillars, levels of JA in body tissue were relatively low, implying that JA was not harbored in the exoskeleton or fat body. Fourth, adult moths (males and females were combined into one group because they had similar JA concentrations) contained relatively little JA, whereas the eggs they produced contained amounts statistically similar to those found in their tobacco diets (Fig. 1b). These results may indicate that adults provision their eggs with JA obtained from their diet, but could also indicate that moths synthesize JA and incorporate it into eggs. Because we did not collect moths upon eclosion, we can not make this distinction.

Caterpillars reared on the three tobacco lines also showed some significant differences across lines despite their similar in-plant levels of JA, suggesting that features of the individual lines influenced JA accumulation in insects. For example, significantly different amounts of JA accumulated in salivary glands of caterpillars reared on the three diets (Fig. 1b; C17 > NahG > OX-434; ANOVA, $F_{2,29} = 23.3$, $P < 0.001$). These results contrast with those from our artificial diet experiment where we found consistent amounts of JA in salivary glands across diets (ANOVA, $F_{2,14} = 1.7$, $P = 0.22$) despite large differences in the JA content of the diets (Fig. 1a). It is unclear why JA accumulates in insect salivary glands, although host plants might benefit from the incorporation of JA into insect saliva, as it is an important trigger of plant defensive responses. In this case, selection on caterpillars would be expected to favor suppressing accumulation, but JA might be retained due to physiological constraints or some countervailing benefit to the insect. The adaptive significance of JA accumulation in insect salivary glands will likely remain unclear until the physiology of accumulation and the role of accumulated JA in interactions with the host plant are better understood.

Our previous work indicated that JA could be present in lepidopteran eggs and neonates (Tooker and De Moraes, 2005). The data we present here demonstrate that JA is

consistently present in various insect tissues. When diets contained high amounts of JA, jasmonate accumulated in insect tissues, but caterpillars voided large quantities. When diet concentrations were lower as with our transgenic tobacco experiment, caterpillars appeared to retain JA and excreted relatively low amounts. Significant amounts of JA accumulated in the salivary glands, a notable result given the importance of this tissue to insect–plant interactions (Felton and Eichenseer, 1999) and the role of JA as a signaling molecule in the induction of plant defense responses. Further research on the mechanisms of JA accumulation and its physiological roles is needed to determine the adaptive significance of JA in salivary glands and other insect tissues.

Acknowledgements We thank J. Saunders, A. Conrad, and C. Wagner for logistical support, E. Bogus for technical assistance, C. Delphia for performing dissections, and M. Mescher, G. Felton, J. Engelberth, and two anonymous reviewers for helpful comments on the manuscript. The project was supported by the USDA National Research Initiative (#2002-35302-12375), the David and Lucile Packard Foundation, and the Beckman Foundation.

Previously, we questioned the importance of (\pm)-catechin (hereafter referred to as catechin) in spotted knapweed's invasion (Blair et al., 2005). Specifically, we (1) found published techniques to be unrepeatable, (2) found levels of catechin production more than an order of magnitude less than previously reported, (3) showed that a species described as sensitive to catechin (*Festuca idahoensis*) only exhibited slightly reduced growth at concentrations 10 times higher than previously reported to cause 100% mortality, and (4) found no measurable catechin at two spotted knapweed sites in Montana, USA. In regards to this last point, it was noted that the soil samples were collected in the late fall, when plants may be less likely to be actively producing the root exudate. This paper addresses this issue by sampling and analyzing soil from three knapweed-infested sites during the summer and fall.

Methods and Materials

Spotted knapweed is a self-incompatible Eurasian biennial or perennial that threatens grassland diversity and productivity across western North America (Roché and Roché, 1991). Spotted knapweed is commonly called *C. maculosa* in North America; however, there remains much confusion regarding the nomenclature. There are two cytotypes of the plant, which are treated either as separate species or as subspecies. *Centaurea maculosa* Lam. has been used for both the diploid and tetraploid form. The diploid form has been synonymized with *Centaurea stoebe* L. spp. *stoebe* (Ochsmann, 2000). The tetraploid has been referred to as *C. biebersteinii* DC or *C. stoebe* L. spp. *micranthos* (Gmelin ex Gugler) Hayek. Ochsmann (2000) argues that the *C. stoebe* name takes priority. The *C. stoebe* species group consists of several taxa of uncertain status that are difficult to distinguish morphologically. Herein, we refer to the plant by its common name, spotted knapweed.

Knapweed-Infested Field Sites and Sampling Protocol

Three field sites were sampled through time to assess catechin production over the course of a growing season (see Table 1 for site characteristics). The soil around five, randomly selected spotted knapweed plants was sampled from 3 to 5 cm depth using 6 cm diam cores. Three cores were taken adjacent to and directly under the knapweed crown for a total of 6 cores per plant, pooled, and mixed. Bulk soil samples (200 g) were collected from outside the three infested sites to serve as control soils. All samples were frozen within 1 h of collection and shipped on ice to Colorado State University, where they were stored at -20°C until analysis.

Quantitation of Catechin in Soil

We extracted and analyzed catechin in the soils using HPLC following protocol of Blair et al. (2005). We used field soils fortified with 5 ppm catechin to assess extraction efficiencies.

Catechin Persistence in Wet vs. Dry Soil

Because catechin was found above trace levels in August only (see results below), we conducted an additional experiment to evaluate the persistence of catechin in these field soils. Based on previous work (Blair et al., 2005), we hypothesized that catechin may have been able to build up in August because the soils were quite dry, but that it would degrade if

^f less than 0.1 ppm catechin; the number in parentheses refers to the number of cores with trace catechin out of 5.

the soils were moist. We tested this hypothesis using soil from the cores with the highest naturally occurring catechin concentrations from the Nelson and Jens August samples and soils from control areas of these sites fortified at 5 ppm catechin. We moistened samples of 5 g of soil ($N = 3$ per sample) with 1 ml water and allowed them to sit at room temperature in the dark for 24 h. As positive controls, un-moistened soils with natural or fortified catechin ($N = 3$ per sample) were subject to the same environment. Catechin was quantitated as above. The percent soil moisture from each field site through time was determined by drying approximately 5 g overnight at 105°C and comparing mass before and after.

Results

Quantitation of Catechin in Soil

Recovery efficiencies across the three sites through time averaged $80.3 \pm 9.4\%$ (mean \pm SE). The detection limit of our method was 0.02 ppm, well below previously reported levels of catechin found in the field, and much lower than what has been suggested to be biologically active. Catechin was found in all soil cores at the two sites sampled in August (Nelson and Jens) (Table 1). Only 14% of the other soil cores had detectable trace levels of catechin (<0.11 ppm) (Table 1).

Catechin Persistence in Wet vs. Dry Soil

The naturally occurring catechin was not detectable in the Nelson and Jens soil samples 24 h after they were moistened. Similarly, only 22% and 6% of the catechin was recovered from the moistened fortified Nelson and Jens control soils, respectively. However, the naturally occurring catechin from the same Nelson and Jens cores remained detectable in the un-moistened controls (Nelson = 1.83 ± 0.21 ppm and Jens = 2.9 ± 0.5 ppm). Fortified control soils behaved similarly; 81.4% and 74.8% of the catechin was recovered from the un-moistened Nelson and Jens control soils, respectively.

These data support our hypothesis that the amount of detectable catechin found in these soils through time can be explained by field soil moisture levels. The two sites that had detectable catechin in August 2005 were among the three with the lowest soil moisture levels of any samples (Table 1).

Discussion

We found catechin in field soils at levels three orders of magnitude lower than have previously shown to be toxic (Blair et al., 2005). Additionally, based on the research herein and our previous work, we believe that it is unlikely that catechin will persist in the field at levels necessary to influence plant distributions. Blair et al. (2005) found catechin to be highly unstable at neutral and basic pH in both water and soil, and even in acidic soils if they were moist. In this study, we found that catechin degraded rapidly in moistened soils from the low or trace amounts naturally present to undetectable (<0.02 ppm). We hypothesize that our inability to find catechin even when the soil moisture was relatively low (i.e., Nelson 7-5-2005, soil moisture $\approx 5\%$) suggests that sporadic precipitation may prevent a build-up of the compound in the soil via the chemical process of degradation and/or enhanced microbial activity.

Our finding of low or undetectable levels of catechin from field-collected soils are in sharp contrast to the recent reports of catechin found in the field at levels ranging from ~1,550 to 3,300 ppm on average, with a single high value reported at 7,100 ppm (also from Montana, USA) (Bais et al., 2003; Perry et al., 2005; Thelen et al., 2005). It is plausible that differing sites will have varying amounts of catechin, as soil characteristics and microbes will greatly influence the stability and persistence of this compound. However, we are not confident in the accuracy of the remarkably high concentrations reported in these papers. They used a methanol extraction technique that we found to yield between 0 and 17% extraction efficiency with 6 different soil types fortified with 10 ppm catechin (Blair et al., 2005). If extraction efficiency is similar for higher levels of catechin and was on the high end of this range for their soils (e.g., 20%), then their estimates would increase 5-fold to approximately 7,750 to 16,500 ppm, or 7.8 to 16.5 mg of catechin per gram of soil (Bais et al., 2003; Perry et al., 2005; Thelen et al., 2005). Given that our data here suggest catechin is not likely to build up in the soil due to precipitation, this seems like a physiologically unreasonable amount for a plant to produce, and still have carbohydrates remaining for growth and maintenance.

While catechin may be toxic to plants at high concentrations, this study adds to the case that it is unlikely to be a strong force in the successful invasion of spotted knapweed. We predict that rainfall will never allow the chemical to attain toxic levels. However, this research does not rule out the possibility that spotted knapweed is allelopathic, and we suggest that future energies be directed at assaying additional putative allelochemicals.

Acknowledgment We would like to thank Celestine Duncan for collecting the soil samples.

Introduction

Assessing the effects of plant defenses on insect herbivores has challenged chemical ecologists for a long time. Although numerous studies have investigated the role of chemical defenses in plant–herbivore interactions, the impact of specific compounds on insect herbivores is often hard to discern. Results obtained from insect feeding studies with intact plants that show quantitative or qualitative differences in putative defense compounds are frequently difficult to interpret, because the plants tested differ in a number of chemical and morphological parameters besides the defensive compounds of interest. These difficulties can be circumvented by the use of pure compounds added to artificial diets, but only if an artificial diet is available for the insect to be studied and the defense compounds can be isolated in sufficient quantity and purity for testing. Furthermore, the compounds must be soluble in the diet and chemically stable during the experiment. Unfortunately, artificial diet studies often do not adequately mimic the way chemical defenses are stored within the plant, and insect feeding behavior and physiology may be different on artificial diets than on intact plants (Wittstock et al., 2003). The effects of chemical defenses that are formed from inactive precursors upon insect feeding are particularly difficult to investigate in artificial diet studies, since it is hard to simulate the conversion to active forms in a way that is spatially and temporally similar to what occurs in the intact plant. In addition, if the active form is added directly to the artificial diet, the sensory response of insects may be completely different from that towards the inactive precursors the insects normally encounter when searching for a feeding site, and the insects may even completely avoid feeding on the test diet.

One of the most intensely studied examples of an activated chemical defense in plants is the glucosinolate–myrosinase system of the Brassicaceae and related plant families (Matile, 1980; Fig. 1). The defensive function of this system has been attributed to the isothiocyanates that are released from the parent glucosinolates by hydrolytic enzymes called myrosinases, upon tissue damage. However, besides isothiocyanates, other hydrolysis products can also be formed, namely nitriles, thiocyanates, and oxazolidinethiones (Schlueter and Gmelin, 1972; Hasapis and MacLeod, 1982; MacLeod and Rossiter, 1985). The formation of nitriles depends on the presence of protein factors known as epithiospecifier proteins (ESPs) and is restricted to certain plants and specific ecotypes within a species (Tookey, 1973; Petroski and Kwolek, 1985; Lambrix et al., 2001). Thus, the same glucosinolate can be hydrolyzed to different products depending on the presence or absence of ESP.

Numerous studies have been conducted to elucidate the ecological role of the different types of glucosinolate hydrolysis products (Lichtenstein et al., 1962; Chew, 1988; Stoewsand, 1995; Rask et al., 2000; Tierens et al., 2001; Buskov et al., 2002). However, these investigations have been fraught with difficulties. On the one hand, testing the effects of glucosinolate hydrolysis products by using intact plants with different profiles of hydrolysis products is problematic because plant properties other than hydrolysis products, such as leaf morphology, nutritional content, or other defensive compounds, may also vary (Nielsen et al., 2001). On the other hand, testing the effects of isolated glucosinolate hydrolysis products with artificial diets or other substrates has also proved to be a challenging task. Apart from the fact that only a few of these compounds are available in

Fig. 1 The glucosinolate–myrosinase system. Upon damage of plant tissue, glucosinolates are hydrolyzed by myrosinases yielding glucose and unstable aglycones. The aglycones spontaneously rearrange into isothiocyanates, the most common class of glucosinolate hydrolysis products. In some plants, epithiospecifier proteins (ESPs) redirect glucosinolate hydrolysis towards the formation of nitriles. If there is a terminal double bond in the amino acid derived side chain, the sulfur atom released from the thioglucosidic bond during nitrile formation is captured in a thiirane ring resulting in epithionitrile formation

pure form, they differ in their solubility and volatility as well as their potential to react with other diet components, thus making the results of comparative feeding tests difficult to interpret. A notable alternative might be the recently reported incorporation of isothiocyanates into an artificial diet by microencapsulation (Agrawal and Kurashige, 2003), a technique that should be feasible for other glucosinolate hydrolysis products as well.

The availability of molecular tools for the model plant *Arabidopsis thaliana* (Brassicaceae) has facilitated the identification of genes that control glucosinolate biosynthesis and hydrolysis (Mikkelsen et al., 2000; Wittstock and Halkier, 2000; Hansen et al., 2001; Kroymann et al., 2001; Lambrix et al., 2001; Reintanz et al., 2001). These advances have opened the possibility to specifically manipulate glucosinolate levels and to introduce biosynthetic pathways that lead to the accumulation of new defensive compounds by genetic engineering (Bak et al., 2000; Petersen et al., 2001; Tattersall et al., 2001). In this study, we generated transgenic lines of *A. thaliana* that differ from wild-type plants only in the type of glucosinolate hydrolysis that is formed upon tissue damage in order to investigate the effects of different types of hydrolysis products on insect herbivores. While isothiocyanates are highly toxic to insect herbivores (Seo and Tang, 1982) including

specialized feeders on glucosinolate-containing plants (Agrawal and Kurashige, 2003), less is known about the defensive function of nitriles. In one of the few studies that have been carried out to compare the effects of nitriles and isothiocyanates with intact plants, larvae of the generalist lepidopteran *Trichoplusia ni* preferred nitrile-producing over isothiocyanate-producing plants when they were allowed to choose among recombinant inbred lines of *A. thaliana* (Lambrix et al., 2001). However, these lines differed in their glucosinolate profile as well as the type of hydrolysis products; both factors significantly affected herbivory by *T. ni* (Lambrix et al., 2001). Therefore, additional feeding trials that use intact plants engineered to differ only in the type of hydrolysis products formed upon tissue damage are required to compare directly the toxicity of nitriles and isothiocyanates to insect herbivores. To produce such transgenic lines, we transformed plants of the ecotype Columbia-0 devoid of ESP expression with a construct containing the ESP cDNA from the ecotype Landsberg *erecta* (*Ler*) under the control of the strong constitutive cauliflower mosaic virus 35S (CaMV35S) promoter. Overexpression of ESP led to strongly enhanced formation of nitrile products at the expense of isothiocyanates upon glucosinolate hydrolysis. To test the value of these transgenic lines in insect feeding trials and to answer the question whether the presence of ESP has an impact on insect performance, we carried out bioassays with the model generalist insect herbivore *Spodoptera littoralis* (Lepidoptera: Noctuidae).

Methods and Materials

Plant and Insect Culture

Arabidopsis thaliana plants were grown on soil in a controlled environment chamber (21°C, 55% relative humidity, and 100 $\mu\text{mol m}^{-2} \text{s}^{-1}$ photosynthetically active radiation) for 4–5 wk. The photoperiod was 10:14 hr light/dark.

Eggs of *S. littoralis* were obtained from Syngenta Crop Protection AG (Stein, Switzerland), and were kept at a temperature between 20°C and 22°C until hatching.

Intact Glucosinolates and Glucosinolate Hydrolysis Products Used as Enzyme Substrates and Standards for Analysis

Allylglucosinolate was purchased from Sigma-Aldrich, 4-hydroxybenzylglucosinolate was obtained from Bioraf Danmark (Copenhagen, Denmark). Allyl isothiocyanate (3-isothiocyanatoprop-1-ene) and allyl cyanide (but-3-enenitrile) standards were obtained from Fluka (Taufkirchen, Germany); propyl isothiocyanate (1-isothiocyanatopropane) was from Sigma-Aldrich Chemie (Schnellendorf, Germany); benzonitrile was from Merck (Darmstadt, Germany).

Cloning of ESP

To obtain the full-length ESP cDNA (GenBank, accession number AF416787), 1.3 μg RNA extracted from rosette leaves of *A. thaliana*, ecotype Landsberg *erecta* (*Ler*) were transcribed into cDNA by using Superscript II Reverse Transcriptase (Invitrogen, Karlsruhe, Germany), according to the manufacturer's instructions. The ESP cDNA was amplified from the reaction by polymerase chain reaction (PCR) using the forward

primer (5'-GCAGCCATGGCTCCGAC) and the reverse primer (5'-TCATCTAGAT-TAAGCTGAATTGACCGCATAG). The PCR reaction was done in a total volume of 50 μ l PCR buffer containing 2.5 units *Pwo* DNA Polymerase (Roche Molecular Biochemicals, Mannheim, Germany), 1 mM MgSO₄, 1 μ l of the reverse transcriptase reaction, 100 μ M dNTPs, and 50 pmol of each primer. After incubation for 3 min at 94°C, 30 cycles of 94°C for 30 sec, 60°C for 50 sec, and 72°C for 60 sec were carried out. The PCR product was digested with *Nco*I and *Xba*I and ligated into the pTrc99A vector (Amersham Pharmacia Biotech, Freiburg, Germany). The correct insert sequence was verified by sequencing.

Generation of Transgenic Plants

After subcloning into the pYX223 vector (Ingenius, Abingdon, Oxon., UK) by using *Nco*I and *Sal*I, the ESP cDNA was cloned into the *Eco*RI/*Xba*I-digested pRT101 vector (Töpfer et al., 1987) downstream of the CaMV35S promoter. The *Pst*I-digested expression cassette was then transferred into the pPZP221 vector (Hajdukiewicz et al., 1994). *Agrobacterium tumefaciens* strain PGV38 c58 transformed with this construct or the empty pPZP221 vector was used to transform *A. thaliana* ecotype Col-0 by floral dip (Clough and Bent, 1998). For selection of positive transformants, seeds were germinated on MS medium containing 2% (w/v) sucrose, 0.9% (w/v) agar, and 100 μ g/ml gentamycin. Independent homozygous lines with a single T-DNA insertion were chosen based on the segregation of gentamycin resistance. Three independent lines that overexpress the ESP cDNA (35S:ESP 2.6, 37.3, 38.1) were characterized in the T3 generation, as were three independent vector control lines (pPZP221 7.1, 8.2, 36.1). Insect feeding trials were done with T4 generation plants.

Glucosinolate Analysis

For quantification of glucosinolates, 10–15 mg freeze-dried leaf material were ground to a fine powder in a paint shaker (Kliebenstein et al., 2001b) and extracted with 1.5 ml 80% (v/v) methanol for 5 min at room temperature before 50 μ l 1 mM 4-hydroxybenzylglucosinolate were added as internal standard. Insoluble material was pelleted by centrifugation at 2500 \times g for 10 min, and the supernatants were loaded on columns containing 0.4 ml of a 10% (w/v) suspension of DEAE Sephadex A25 in H₂O. Columns were washed with 1 ml 80% (v/v) methanol, 1 ml water, and 1 ml 0.02 M MES buffer (pH 5.2), before 50 μ l of sulfatase solution were applied (Hogge et al., 1988). After incubation at room temperature overnight, desulfated glucosinolates were eluted with 2 \times 0.8 ml 60% (v/v) methanol, dried at 50°C in a nitrogen stream, and then redissolved in 0.4 ml water. Samples were analyzed by high-performance liquid chromatography (HPLC) on an Agilent HP1100 Series instrument equipped with a C-18 reversed phase column (LiChrospher RP18ec, 250 \times 4.6 mm, 5 μ m particle size) by using a water (solvent A)–acetonitrile (solvent B) gradient at a flow rate of 1 ml min⁻¹ at 25°C (injection volume 50 μ l). The gradient was as follows: 1.5% B (1 min), 1.5–5% B (5 min), 5–7% B (2 min), 7–21% (10 min), 21–29% (5 min), 29–43% (7 min), 43–100% (0.5 min), 100% B (2.5 min), 100–1.5% B (0.1 min), and 1.5% B (4.9 min). The eluent was monitored by diode array detection between 190 and 360 nm (2-nm interval). Desulfoglucosinolates were identified based on comparison of retention times and UV absorption spectra with those of known standards (Reichelt et al., 2002). Results are given as μ mol (g dry weight)⁻¹ calculated from the peak areas at 229 nm relative to the peak area of the internal standard using the relative response factors 2.0 for aliphatic and 0.5 for indole glucosinolates. These relative response factors were evaluated in our laboratory to give more

accurate results than previously published relative response factors (Fiebig and Arens, 1992; Wathelet et al., 2004). The remarkable differences of relative response factors of certain glucosinolates published by different groups are likely due to considerable differences in the hygroscopic properties of the glucosinolates.

Plant Extracts for Detection of ESP Protein, Measurements of Enzyme Activities and Glucosinolate Hydrolysis Products

Crude plant extracts were prepared from rosette leaves of *A. thaliana* by grinding 500 mg of leaf material with 500 μ l of 50 mM MES buffer, pH 6.0. After incubation at room temperature for 5 min, samples were centrifuged at 10,000 \times *g* and 4°C for 10 min. The supernatants were kept on ice before they were used for measurements of ESP and myrosinase activities, hydrolysis products from internal glucosinolates and total isothiocyanates as described below. The protein content of the extracts was determined with the Pierce BCA Protein Reagent (Perbio Science Deutschland GmbH, Bonn, Germany) using bovine plasma γ -globulin (Biorad, Munich, Germany) as a standard.

ESP Assay

To assay ESP activity, 100 μ l plant extract were incubated with 1 mM allylglucosinolate in 50 mM MES buffer (pH 6.0) in a total volume of 500 μ l at room temperature for 1 hr. After addition of 50 μ l benzonitrile (100 ng/ μ l in methanol) as an internal standard, the samples were extracted with 2 \times 750 μ l dichloromethane. The combined organic phases were dried over Na₂SO₄, concentrated to about 100 μ l in a nitrogen stream, and analyzed by gas chromatography (GC) with flame ionization detection (FID) using an Agilent 6890 series gas chromatograph with an HP5MS column (30 m \times 0.25 mm \times 0.25 μ m), splitless injection at 200°C (injection volume 1 μ l), and the following temperature program: 35°C for 3 min, 12°C/min to 96°C, 18°C/min to 150°C, 60°C/min to 300°C, and 4-min final hold. Identity of the products was verified by GC-mass spectrometry (GC-MS) (Lambrix et al., 2001) in comparison with authentic standards and published MS spectra (Spencer and Daxenbichler, 1980). Products were quantified as previously described (Lambrix et al., 2001). ESP activity was expressed as the amount (nmol) of 3,4-epithiopropylcyanide formed from allylglucosinolate per min and mg protein. Under the conditions described above, 3,4-epithiopropylcyanide formation by ESP was linear with time for 2 hr using plant extracts of the ecotype *Ler*.

Myrosinase Assay

Myrosinase assays were carried out in 50 mM MES buffer, pH 6.0, with 1 mM allylglucosinolate and 25 μ l of plant extract in a total volume of 100 μ l. After incubation at 37°C for 30 min, the reaction was stopped by boiling (95°C for 5 min). Samples were centrifuged at 10,000 \times *g* for 5 min, and 90 μ l of the supernatant were used for glucose determination using the Glucose GOD/PAP Kit from Randox (Crumlin, UK). Absorbance was measured at 500 nm against the absorbance of samples incubated without allylglucosinolate. The amount of glucose formed by myrosinase was calculated based on a calibration curve obtained with a glucose standard solution. Myrosinase activity was expressed as the amount (nmol) of glucose formed per minute and mg total protein. Under standard assay conditions, glucose formation as a measure for myrosinase activity was linear with time for at least 50 min.

Analysis of Glucosinolate Hydrolysis Products in Plant Extracts

Crude plant extracts (200 μ l) to which 30 μ l benzonitrile (100 ng/ μ l in methanol) as internal standard had been added were extracted with dichloromethane and analyzed by GC-FID and GC-MS as described above for ESP assay mixtures. The temperature program used was 45°C for 3 min, 12°C/min to 96°C, 18°C/min to 150°C, 60°C/min to 270°C, and 3-min final hold. Quantification of the hydrolysis products of 4-methylsulfinylbutylglucosinolate was carried out as previously described (Lambrix et al., 2001).

Determination of Total Isothiocyanates in Plant Extracts

Total isothiocyanates were quantified after cyclocondensation with benzene-1,2-dithiol (Zhang et al., 1996). Plant extract (30 μ l), 20 μ l 1 M Tris-HCl, pH 8.5, and 150 μ l H₂O were mixed and equilibrated to room temperature before 200 μ l of 10 mM benzene-1,2-dithiol (Fluka) in methanol were added. Conversion of benzene-1,2-dithiol to benzo[1,3]dithiol-2-thione was accomplished by incubation for 1 hr at 65°C. The samples were centrifuged at 16,000 \times g for 3 min to pellet precipitate, and a 50- μ l aliquot of the supernatant was analyzed by using an Agilent 1100 series HPLC (Agilent Technologies) with an Supelcosil LC18 column (150 mm \times 2.1 mm \times 5 μ m, Supelco) and an isocratic elution with 85% (v/v) methanol. The eluates were monitored at 365 nm by a UV detector, and the area of the benzo-1,3-dithiole-2-thione peak was integrated. Total amounts of isothiocyanates were calculated based on a calibration curve done with propyl isothiocyanate.

Western Blotting

A rabbit polyclonal antibody against ESP was raised by using the synthetic peptide H₂N-RDENRNFENFRSYDTV-CO-NH₂, which corresponds to the amino acids 94–109 of the native protein N-terminally coupled with keyhole limpet hemocyanin as a carrier (Eurogentec, Seraing, Belgium). Proteins from 100 μ l plant extract were concentrated by trichloroacetic acid precipitation. The protein pellets obtained by centrifugation at 10,000 \times g and 4°C for 30 min were dissolved in SDS sample buffer, boiled for 5 min, separated on 12% Tris-SDS-PAGE gels, and transferred to nitrocellulose membranes (Schleicher & Schuell, Dassel, Germany). Membranes were blocked with 2% nonfat dried milk powder in TTBS [20 mM Tris-HCl, pH 7.5, 150 mM NaCl, 0.1% (v/v) Tween 20] for 30 min before addition of the anti-ESP antibody serum (1:10,000 diluted with TTBS, containing 2% dry milk powder). After incubation at 4°C overnight and washing with TTBS (3 \times 7 min), the secondary antibody (antirabbit IgG alkaline phosphatase conjugate; Sigma, 1:10,000) was added in TTBS, containing 2% nonfat dried milk powder. Membranes were incubated at room temperature for 1 hr, washed with TTBS (3 \times 7 min), and rinsed with detection buffer (100 mM Tris-HCl, pH 9.5, containing 100 mM NaCl and 5 mM MgCl₂). Detection was carried out with 0.085 μ g/ml nitroblue tetrazolium and 0.17 μ g/ml 5-bromo-4-chloro-3-indolyl phosphate in detection buffer.

Insect Feeding Trials

To investigate the performance of *S. littoralis* on the ESP-expressing Arabidopsis lines (35S: ESP 2.6, 37.3, 38.1), the vector control lines (pPZP221 7.1, 8.2, 36.1) and Col-0 wild-type plants, larvae were reared from hatching to pupation on 5-wk-old plants (T4) of each line.

The parameters recorded were the larval weight gain, time until pupation, the pupal weight, the duration of the pupal stage, and the proportion of successful adult emergence.

Each experiment was started with 50 neonate larvae on 20 plants per line. Plants and insects were placed in a controlled environment chamber with a 16:8 hr light/dark photoperiod, 70% relative humidity, and a constant temperature of 22°C. The weight of each larva was recorded every day starting from day 8, when the larvae were transferred to fresh plants for the first time. To ensure sufficient food supply, larvae were transferred to new plants 5–6 additional times depending on their consumption rate. As a consequence of the enormous food consumption by larvae of later stages and for other practical reasons, we reduced the number of individuals per plant line in two steps. About 10 d after hatching, the 15 smallest and the 15 biggest individuals of each group were removed. A further reduction to 10 larvae per plant line was accomplished in the same way 2 d later. This reduced the variability within groups. Only individuals with a growth rate close to the medial growth rate of larvae on a particular plant line were investigated throughout their entire development. Two days after pupation, the pupae were removed from the soil and placed on Whatman paper in small, ventilated plastic vessels. The emergence of adults was monitored everyday for a period of 20 d. At three time points during the experiment, two uninfested plants of each transgenic line as well as two uninfested wild-type Col-0 plants grown at the same time and under the same conditions as the plants used to feed *S. littoralis* were harvested to analyze glucosinolate hydrolysis products as described above. The entire feeding experiment was carried out three times with different sets of plants. All data were analyzed using Sigmapstat (Systat Software Inc., Richmond, CA, USA). Means were tested for significant differences by one-way ANOVA with a Bonferroni test (all pairwise comparisons) or by Kruskal–Wallis ANOVA followed by Dunn's test (all pairwise comparisons) when the data did not show normal distribution.

Results

To create plants for insect testing that differ only in the type of glucosinolate hydrolysis products formed upon tissue disruption, we transformed the Col-0 ecotype of *A. thaliana*, an ecotype known to be devoid of functional ESP (Fig. 2a; Lambrix et al., 2001), with the ESP cDNA from *A. thaliana*, ecotype *Ler*, under the control of the CaMV35S promoter. Three independent ESP-overexpressing lines (35S:ESP 2.6, 37.3, and 38.1) as well as three independent control lines carrying the empty pPZP221 vector (pPZP221 7.1, 8.2, and 36.1) were characterized in comparison to the Col-0 wild-type. Plants of the transgenic lines did not differ from wild-type plants with regard to growth habit and leaf morphology. In addition, no changes in growth rate or development were observed. From each line, 10 plants of the T3 generation were analyzed and compared to Col-0 wild-type plants grown at the same time.

Transformation with the 35S:ESP construct altered the levels of ESP protein and activity. In Western blot experiments performed with an anti-ESP antibody, comparable levels of ESP were detected in plants of the three ESP-overexpressing lines and the *A. thaliana* ecotype *Ler* (Fig. 3). However, ESP was not detected in the Col-0 wild-type and in the vector control lines (Fig. 3a). To test for ESP activity, allylglucosinolate was added to plant extracts as substrate for the hydrolysis reactions. In crude extracts of Col-0 wild-type plants and vector control lines, allylglucosinolate was hydrolyzed almost exclusively to the corresponding isothiocyanate; only traces of the simple nitrile were detected (data not shown). In contrast, the hydrolysis of allylglucosinolate was redirected towards epithioni-

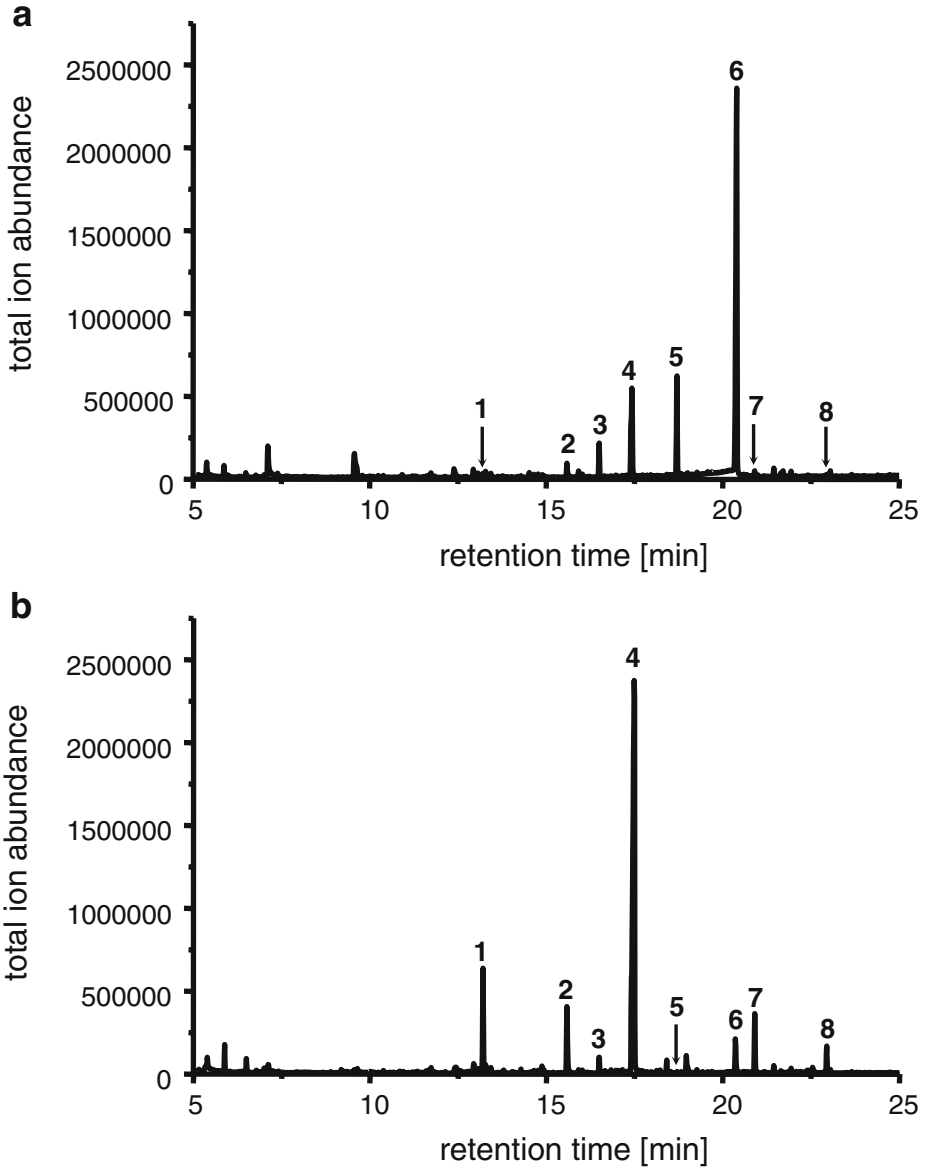

Fig. 2 Glucosinolate hydrolysis products in leaf autolysates. For qualitative analyses, aqueous leaf macerates of an *A. thaliana*, ecotype Col-0, wild-type plant (a) and a 35S:ESP plant (b) were extracted with CH₂Cl₂. Depicted are GC-MS traces of the CH₂Cl₂ phases. **1:** 5-Methylsulfinyl-pentanenitrile (nitrile product of 4MTB); **2:** 4-methanesulfinyl-butyronitrile (nitrile product of 3MSOP); **3:** 1-isothiocyanato-4-methylsulfinyl-butane (isothiocyanate product of 4MTB); **4:** 5-methanesulfinyl-pentanenitrile (nitrile product of 4MSOB); **5:** 1-isothiocyanato-3-methanesulfinyl-propane (isothiocyanate product of 3MSOP); **6:** 1-isothiocyanato-4-methanesulfinyl-butane (isothiocyanate product of 4MSOB); **7:** indole-3-acetonitrile [(2,3-dihydro-1*H*-indol-3-yl)-acetonitrile]; **8:** 4-methoxy-indole-3-acetonitrile [(4-methoxy-2,3-dihydro-1*H*-indol-3-yl)-acetonitrile]. 3MSOP: 3-methylsulfinylpropyl-glucosinolate; 4MSOB: 4-methylsulfinylbutylglucosinolate; 4MTB: 4-methylthiobutylglucosinolate

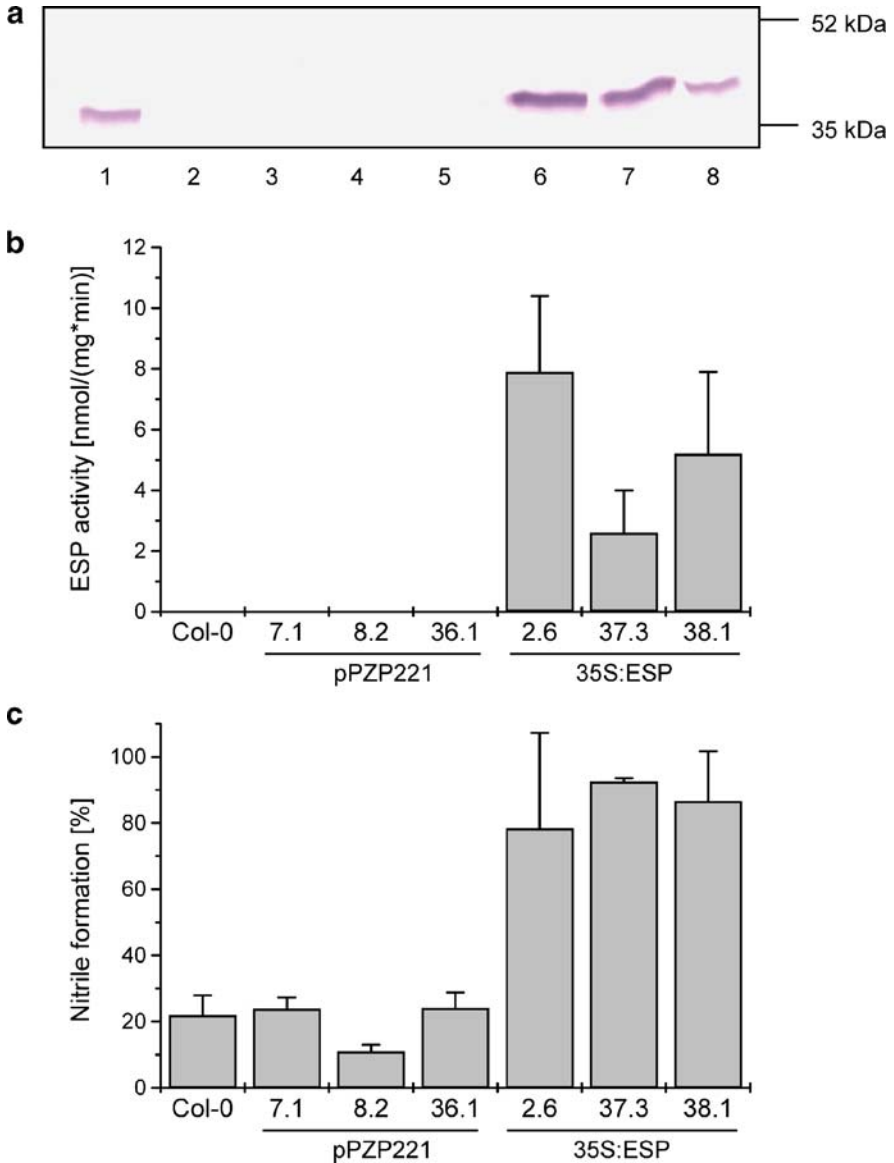

Fig. 3 ESP abundance, ESP activities and nitrile formation in the transgenic *A. thaliana* lines. (a) Proteins from crude leaf extracts were concentrated by trichloroacetic acid precipitation, separated by SDS-PAGE, and analyzed by Western blotting using a polyclonal antibody against ESP from *A. thaliana*, Ler. lane 1, *A. thaliana*, Ler; lane 2, *A. thaliana*, Col-0; lane 3, pPZP221 (7.1); lane 4, pPZP221 (8.2); lane 5, pPZP221 (36.1); lane 6, 35S:ESP (2.6); lane 7, 35S:ESP (37.3); lane 8, 35S:ESP (38.1). (b) ESP activity in leaf extracts was assayed in 50 mM MES buffer, pH 6.0, containing 1 mM allylglucosinolate. Activities of ESP are expressed as the amount (nmol) of 3,4-epithiopropylcyanide formed per minute and mg protein. Data are the mean \pm SD ($N = 7-10$). (c) Hydrolysis products formed from internal glucosinolates in crude leaf extracts of *A. thaliana* Col-0 wild-type plants and plants of the transgenic lines were analyzed by GC-FID after extraction with dichloromethane. Nitrile formation is expressed as the amount (nmol) of nitrile derived from 4-methylsulfinylbutylglucosinolate, the major leaf glucosinolate in *A. thaliana* Col-0, as a percentage of the total amount (nmol) of hydrolysis products formed from this glucosinolate. Data are the mean \pm SD ($N = 7-10$)

trile formation in the ESP-overexpressing lines (Fig. 3b). The ESP activity in the plants of the 35S:ESP lines 2.6, 37.3, and 38.1 was 7.9 , 2.6 , and $5.2 \text{ nmol min}^{-1} (\text{mg protein})^{-1}$, respectively. These levels of ESP activity exceeded the activity of ESP in leaf extracts of *A. thaliana* ecotype *Ler* by a factor of 2–6 (data not shown).

In parallel with the *in vitro* ESP assays, the outcome of glucosinolate hydrolysis *in vivo* was tested in the *A. thaliana* lines overexpressing ESP. Col-0 wild-type plants (Figs. 2a and 3c) and pPZP221 control transformants (Fig. 3c) mainly produce isothiocyanates with a small percentage of nitriles. For example, 4-methylsulfinylbutylglucosinolate, the major glucosinolate present in the Col-0 ecotype (Kliebenstein et al., 2001a; Table 1), was approximately 80% converted into the corresponding isothiocyanate and 20% converted to the corresponding nitrile (Fig. 3c). However, in the ESP-overexpressing lines, glucosinolates were predominantly hydrolyzed to nitriles (Figs. 2b and 3c). In the case of 4-methylsulfinylbutylglucosinolate, more than 90% was converted into the corresponding nitrile (Fig. 3c). Moreover, increased amounts of indole glucosinolate-derived nitriles were detected in autolysates prepared from 35S:ESP plants compared to autolysates from Col-0 wild-type plants (Fig. 2). Measurements of the total amount of isothiocyanates present in plant extracts confirmed this trend, showing that leaf autolysates prepared from plants of the three 35S:ESP lines were significantly reduced in isothiocyanate content as compared to plants of the control lines (Table 2).

With respect to the parent glucosinolates, no quantitative or qualitative changes were detected in the ESP-overexpressing lines or the control transformant lines compared to Col-0 wild-type plants (Table 1). Myrosinase activity was also not altered in the 35S:ESP lines or the control lines (Table 2).

To investigate the differential effects of isothiocyanates and nitriles on the development of a generalist insect herbivore, larvae of *S. littoralis* were reared on wild-type *A. thaliana*

Table 1 Glucosinolate Content of the Transgenic *A. thaliana* Lines

Table 2 Total Isothiocyanate Levels and Myrosinase Activities in the Transgenic *A. thaliana* Lines

Plant line	Total isothiocyanates [nmol (mg protein) ⁻¹]	Myrosinase activity [nmol (min mg protein) ⁻¹]
Col-0	38.5 (±17.8)	13.7 (±3.7)
pPZP221 (7.1)	38.5 (±4.4)	11.2 (±1.5)
pPZP221 (8.2)	24.7 (±4.5)	14.2 (±4.4)
pPZP221 (36.1)	41.3 (±7.1)	11.3 (±1.8)
35S:ESP (2.6)	6.8 (±10.2)	18.7 (±7.7)
35S:ESP (37.3)	1.9 (±1.4)	11.5 (±2.0)
35S:ESP (38.1)	6.8 (±9.4)	11.2 (±3.0)

Total amounts of isothiocyanates formed from the internal glucosinolates were quantified in crude leaf extracts by HPLC after cyclocondensation with benzene-1,2-dithiol. Myrosinase activities in leaf extracts were measured based on the amount of glucose released from allylglucosinolate added as a substrate. Data are mean ± SD ($N = 7-10$).

Col-0, on plants of the 35S:ESP lines 2.6, 37.3, and 38.1, and on the vector control lines (pPZP221 7.1, 8.2, and 36.1). On average, larvae that were allowed to feed on plants of the 35S:ESP lines gained weight faster than the larvae on Col-0 wild-type plants or plants of the control lines during the first 10 d of development (Fig. 4). We found this effect to be significant for one and two, respectively, of the tested 35S:ESP lines in two out of three independent experiments. In the second section of the feeding experiment, larvae with growth rates close to the medial growth rate were reared until pupation on the same plant lines. The larvae that were fed on plants of the 35S:ESP lines reached the stage of pupation on average about a day earlier than on the control plants. This effect was significant for all tested lines in experiment A and for one 35S:ESP line in experiment B (Table 3). The pupal weight, the duration of the pupal stage, and the proportion of successful emergence of adults from the pupae were unaffected by the type of plant fed upon (Table 3). These results were consistent over three independent experiments conducted with the same lines, each using a different set of plants grown at different times. For each feeding trial, uninfested replicate plants of the Col-0 wild-type and the transgenic lines grown in parallel were analyzed for glucosinolate hydrolysis products. The results were consistent with those presented in Figs. 2 and 3c.

Discussion

As a damage-activated defense, the glucosinolate–myrosinase system is particularly difficult to simulate in insect feeding trials. In several studies that have been carried out to compare the impact of different types of glucosinolate hydrolysis products on insect herbivores, toxic effects have been most frequently demonstrated for isothiocyanates (Lichtenstein et al., 1962; Blau et al., 1978; Seo and Tang, 1982; Agrawal and Kurashige, 2003), whereas nitriles are generally considered to be less harmful to insects (Wittstock et al., 2003). Nevertheless, many glucosinolate-containing plant species as well as some ecotypes of *A. thaliana* possess an ESP and so form nitriles instead of isothiocyanates upon herbivore damage. To elucidate why plants should alter their glucosinolate hydrolysis product profile in this manner, more studies comparing the effects of nitriles and isothiocyanates derived from the same glucosinolates on insect herbivores are needed. Here, we used the molecular tools available for the model plant *A. thaliana* to specifically

Fig. 4 Growth rates of *S. littoralis* larvae on the different transgenic plant lines. In three independent experiments a–c, the weight of *S. littoralis* larvae reared on *A. thaliana* Col-0 wild-type plants, on the control lines pPZP 7.1, 8.2, and 36.1, or on the 35S:ESP lines 2.6, 37.3, and 38.1 was measured about 10 d after hatching. Growth rates presented are mean values \pm SD ($N = 37\text{--}47$). Mean values were tested for significant differences ($P < 0.05$) by Kruskal–Wallis ANOVA followed by Dunn’s test for all pairwise comparisons. Significant differences are indicated by different letters. n.d.: not determined

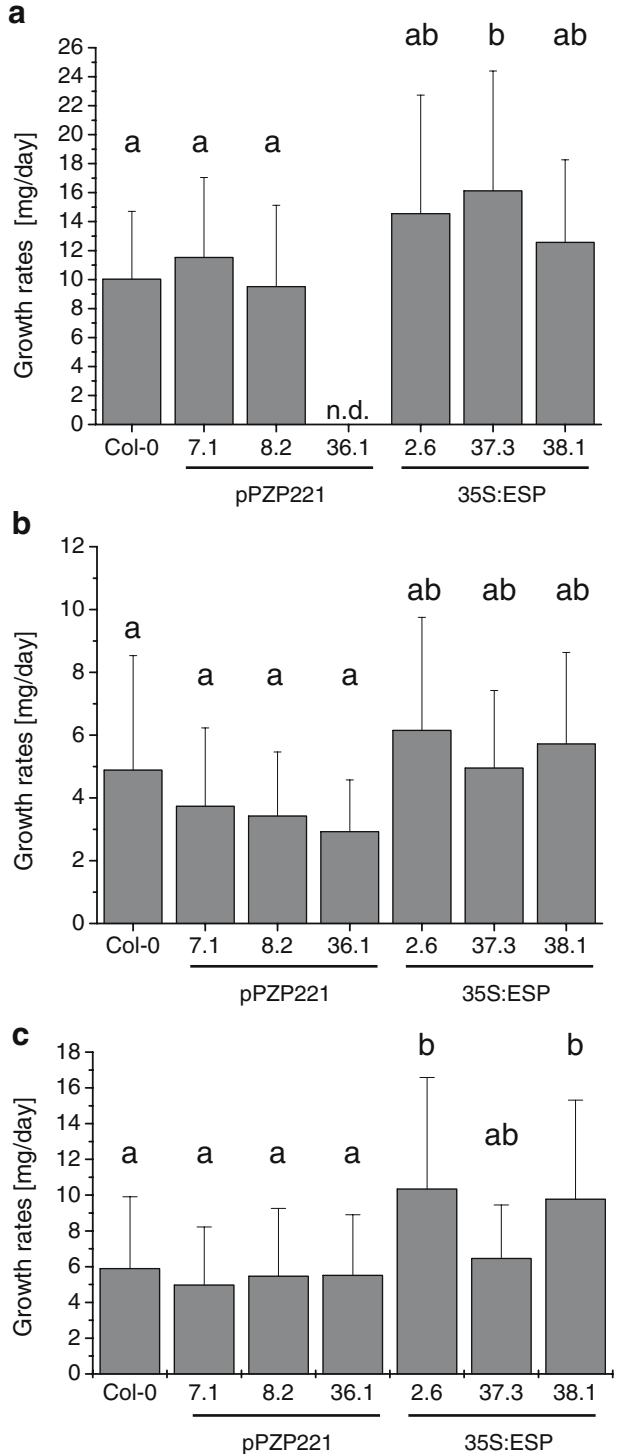

Table 3 Performance of *S. littoralis* on the Transgenic *A. thaliana* Lines

Developmental parameter	Experiment	N	Col-0	pPZP221			35S:ESP		
				(7.1)	(8.2)	(36.1)	(2.6)	(37.3)	(38.1)

Pupal weight [mg]	A	8–10	364± 47	392± 12	364± 49	388± 28	358± 31	362± 44	347± 46
	B	8–10	389± 39	373± 42	386± 29	379± 37	394± 36	354± 26	385± 39
	C	8–10	353± 41	333± 52	377± 44	359± 41	357± 29	335± 29	357± 35
Successful adult emergence (%)	A	6–9	75	100	100	100	90	70	80
	B	8–10	100	100	100	90	90	100	100
	C	7–10	100	100	90	88	90	100	100

The time until pupation, the duration of the larval stage, the pupal weight, and the proportion of successful adult emergence were recorded for those larvae that had growth rates close to the medial growth rate at days 10 and 12 after hatching (for details see [Methods and Materials](#)). Data obtained in three independent experiments (A–C) are presented as means ± SD. Values followed by different letters (a–d) are significantly different ($P < 0.05$) in one-way ANOVA followed by a Bonferroni test for all pairwise comparisons (¹) or in Kruskal–Wallis ANOVA with Dunn's test for all pairwise comparisons (²). N: number of larvae.

manipulate the outcome of glucosinolate hydrolysis *in planta* in a background where the parent glucosinolate profile is unchanged, and used the genetically altered lines in feeding trials with a generalist insect herbivore.

The transgenic lines with constitutive expression of the ESP cDNA from *A. thaliana* Ler in the Col-0 background had readily detectable levels of ESP protein and activity (Fig. 3), and formed predominantly nitriles from glucosinolates instead of the corresponding isothiocyanates (Figs. 2 and 3). Although it has been questioned whether or not ESP can efficiently promote the formation of simple nitriles from nonalkenyl aliphatic glucosinolates under natural conditions (Zabala et al., 2005), nitrile formation from 4-methylsulfinylbutylglucosinolate, the dominant glucosinolate in these plants, reached 100% of the total hydrolysis products formed from this glucosinolate in some of our transformants (Fig. 3c).

The value of these nitrile-forming lines for insect bioassays would be greatest if they differed from the isothiocyanate-forming wild-type in no trait other than glucosinolate hydrolysis. The defensive function of the glucosinolate–myrosinase system against insect herbivores is influenced by changes in glucosinolate concentration and composition as well as the level of myrosinase activity in the plant tissue (Giamoustaris and Mithen, 1995; Stowe, 1998; Li et al., 2000). However, none of these parameters was changed in uninfested plants of the three ESP-overexpressing lines generated in this study compared to

wild-type plants. Furthermore, the ESP-overexpressing lines were not different from wild-type controls in growth and morphology. Therefore, these nitrile-forming transgenic lines are ideal tools to dissect the role of glucosinolate hydrolysis in plant–insect interactions away from that of other parameters of the glucosinolate–myrosinase system.

To investigate the differential effects of isothiocyanates and nitriles on a generalist herbivore, larvae of *S. littoralis* were reared on the different transgenic *A. thaliana* lines, and their development was monitored until the emergence of the adult moths. *S. littoralis* has frequently been used in toxicity tests as a model organism because its larvae are known to be extremely polyphagous and rather insensitive to a broad range of pesticides. In the present study, young larvae of *S. littoralis* gained weight faster on the ESP-overexpressing lines compared to the control lines and to Col-0 wild-type plants (Fig. 4). Faster growth in early instars affected the duration of the larval stage. Of the larvae with medial growth rates on ESP lines, control lines, and wild-type plants at days 10 and 12, those reared on nitrile-forming lines had a tendency to pupate earlier than those reared on the other plant lines (Table 3). However, these effects were only significant in up to two out of three independent experiments. The type of glucosinolate hydrolysis products formed had no impact on the average pupal weight of medial individuals, the duration of their pupal stage, or the proportion of successful adult emergence. An extended larval stage is presumed to be a disadvantage for insects due to an increased risk of attack from predators and parasitoids, unless it leads to enhanced weight or fecundity (which was not the case in our study). Our results extend previous work on the detrimental effect of isothiocyanates performed with intact plants, plant extracts, and artificial diets (Bartelt and Mikolajczak, 1989; Li et al., 2000; Agrawal and Kurashige, 2003). However, considering the large differences in hydrolysis product formation between the tested control and 35S:ESP lines (Fig. 3), the effects of the different plant diets on the growth of *S. littoralis* larvae were surprisingly weak and were, moreover, only observed for young larvae. These findings might be explained by the induction of detoxification pathways for isothiocyanates in young larvae that may counteract the defensive potential of these compounds. The alternative hypothesis, that herbivory triggers plant responses that balance the effect of the transgene, will be tested in future investigations.

Because the presence of ESP and the subsequent formation of nitriles did not have negative effects on the performance of *S. littoralis*, a role for ESP in direct defense against generalist insect herbivores seems unlikely. Nevertheless, the effects of isothiocyanates vs. nitriles need to be further investigated in comparative bioassays with other generalist insect herbivores as well as with insect species that are specialized feeders on glucosinolate-containing plants. Moreover, the transgenic lines created here will allow the investigation of several alternative functions for ESP, including the possibility that nitriles act as defensive compounds against pathogens, as inhibitors of insect oviposition, or as attractants to herbivore enemies.

Acknowledgments We thank Andrea Bergner for technical assistance, Michael Reichelt for providing intact glucosinolates, and the Max Planck Society for financial support. Two anonymous reviewers are thanked for their valuable comments.

Introduction

Complex phenotypes that contribute to plant fitness in natural and agricultural environments, such as herbivore and pathogen defense, can be dissected by using quantitative genetic and molecular methods. Perhaps more than in any other plant family, studies of defense in the Brassicaceae have identified mechanisms, quantitative trait loci (QTL), and candidate genes that contribute to resistance, tolerance, and avoidance of enemies in *Arabidopsis thaliana* and *Brassica* (Rask et al., 2000; Wittstock and Halkier, 2002; Koornneef et al., 2004). Two herbivore defense characteristics that have been intensively investigated are glucosinolate (GS) composition and trichome density (Mauricio 1998; Agrawal 1999; Traw 2002; Traw and Dawson, 2002a; Strauss et al., 2003). While it is often true that more GS and more hairy leaves confer greater resistance against insect herbivory, these functional relationships are not found for all plant–herbivore interactions. To understand the ecology and evolution of plant defense, the contribution to resistance of phenotypic and genetic variation in candidate defense traits must be assessed for relevant ecological contexts.

In the model *A. thaliana*, differences among accessions in GS, trichomes, and herbivore resistance have been functionally dissected in laboratory and common garden experiments (Mauricio and Rausher, 1997; Mauricio 1998; Jander et al., 2001; Kliebenstein et al., 2001b, 2002; Lambrix et al., 2001; Kroymann et al., 2003; Weinig et al., 2003a,b; Symonds et al., 2005). In contrast, little is known about the ecological interactions of different accessions in their native, usually human-disturbed environments (Arany et al., 2005). Recently, attention has turned to closely related nonmodel *Arabidopsis* species in which many of the tools developed for *A. thaliana* can be applied, but which differ in their biological characteristics (Nasrallah et al., 2002; Bert et al., 2003; Clauss and Koch, 2006). Comparative studies within the Brassicaceae also enable us to ascertain whether findings in the model are more generally true. In *A. lyrata*, the genetic basis of variation in trichome production (glabrous or hairy) and trypsin proteinase inhibitors has been investigated (Karkkainen and Agren, 2002; Clauss and Mitchell-Olds, 2003; Karkkainen et al., 2004), and GS diversity has been surveyed (Windsor et al., 2005). Because populations of perennial and self-incompatible *A. lyrata* are geographically well-defined, persistent, and subject to little human disturbance, the ecological and evolutionary context of plant–herbivore interactions can be established *in situ*. An appropriate scale at which to study species interactions and adaptive evolution of plant defense in *A. lyrata* is within local, polymorphic populations (Clauss and Mitchell-Olds, 2003, 2006; Clauss and Koch, 2006).

Quantitative genetic experiments can be used to estimate the genetic architecture of defense. From one central European population of *A. lyrata*, we collected 51 naturally occurring genotypes for the parental generation of a sires-nested-within-dam crossing design. Because genetic architecture can change with plant age and environmental conditions, we estimated heritabilities and genetic correlations from phenotypic measurements of GS and trichome density for the F1 generation in years 1 and 3. Furthermore, we estimated the heritability of herbivore resistance and the contribution of candidate defense traits to resistance for *A. lyrata* in four herbivory contexts. In growth chamber resistance assays, three lepidopteran herbivores (*Plutella xylostella*, *Pieris brassicae*, and *Trichoplusia ni*) were employed that differ in their digestive physiologies, and are thus expected to respond differently to chemical and morphological defenses. All three taxa are common herbivores on Brassicaceae, and *P. xylostella* is a dominant herbivore on *A. lyrata* in Scandinavia (Løe 2006). We also assessed herbivore resistance in a common garden where 3-yr-old plants were subject to feeding by the chrysomelid *Phyllotreta cruciferae* and diverse other herbivores.

Methods and Materials

Study Species and Focal Population *Arabidopsis lyrata* is a self-incompatible perennial herb found in the temperate biomes of Eurasia and North America. The North American and European subspecies were previously called *Arabis lyrata* (L.) and *Arabis petraea* (L.) Lam. or *Cardaminopsis petraea* Hill, respectively. We follow O’Kane and Al-Shehbaz (1997) and Koch et al. (2001) in referring to these species as *Arabidopsis*, and focus on the European subspecies *A. lyrata* subsp. *petraea*, hereafter *A. lyrata*. We conducted our investigation on a population of *A. lyrata* collected near Plech, Bavaria, Germany ($N > 1000$; 49°54’99”N; 11°30’64”E; same as KOCH, Pfaffenhofen b. Neuhaus, Bavaria, Germany, leg. KOCH; Koch et al., 2001) for which all tested individuals were diploid ($2N=16$; sample size=60). Analyses of multilocus diversity patterns indicate that the Plech population is genetically diverse, largely random mating, and significantly differentiated from nearby populations (Clauss et al., 2002; Clauss and Mitchell-Olds, 2003, 2006). In the course of these studies, seeds were collected from maternal plants distributed throughout the Plech population (see Clauss and Mitchell-Olds, 2006 for details). In September 2000, seeds from 51 of the maternal seed families were germinated, and one seedling per family was grown to reproductive maturity in a growth chamber.

Quantitative Genetics Study Year 1: Laboratory Fifty-one reproductively mature *A. lyrata* plants were randomly assigned to one of 17 triads, in which two plants designated as sires were each crossed to one designated dam plant. This resulted in 17 pairs of full sibships, each sharing a dam. The F1 seeds were placed into Petri dishes, subject to 4°C chilling for 4 wk, germinated, and 30 single plants per cross were transferred into 7-cm pots in February 2002 (34 full sibships × 30 plants = 1020). Plants were grown in the growth chamber under short day conditions (light: 11 hr, 22°C, 60% RH; dark: 13 hr, 15°C, 50% RH). Plants were rerandomized within the same growth chamber every 6 wk, fertilized ca. every 3 mo [1.2 ml Compo Sana (NPK, 5-5-6) fertilizer/l], and periodically cleaned of senescent leaves. For traits measured on these F1 plants throughout the next 3 yr, we estimated genetic variance components, broad-sense heritability, and genetic correlations (see below). We employed a sires-within-dams mating design (Pilson 1996) for several reasons. (1) We obtain an estimate of genetic variation with lower sampling variance than paternal half-sib experiments of equal size. (2) This design examines variation among sires that is not contaminated by maternal effects, which are a genuine concern in most designs. (3) In random mating populations, the covariance of parent and offspring actually includes a portion of the epistatic variance, hence epistasis contributes to short-term evolutionary responses to natural selection. (4) Finally, partitioning of genetic variance into additive, dominance, and epistatic components is entirely contingent on allele frequencies, which will fluctuate whenever variation is determined by a finite number of loci. For these reasons, we chose a design that provides optimal control for maternal effects at a given sample size and estimates broad-sense genetic variance of ecologically important traits from a large random sample of the natural population.

At 8 wk, leaves were harvested to determine constitutive GS composition, trichome density, specific leaf area (SLA), and leaf dry matter content (LDMC). Glucosinolate extraction and purification followed the basic sephadex/sulfatase *Arabidopsis* protocol previously described (Hogge et al., 1988), with adjustment for sampling in a 96-well format (Kliebenstein et al., 2001b), for ca. 0.1 g of fresh leaf tissue harvested from the most recent fully expanded leaves on each plant. Plants were uninduced, and leaves were harvested

directly into liquid nitrogen to minimize breakdown of GS by the enzyme myrosinase. Each 96-well plate represented a block to which 94 *A. lyrata* plants were randomly assigned, together with one sample from a single *A. thaliana* Ler-0 plant (0.1 g wet weight) as a positive control and one empty negative control. Forty microliters of the GS extract were run on a reverse-phase column (LiChroCART 250-4 RP19e; Hewlett-Packard, Waldbronn, Germany) on a Hewlett-Packard 1100 series high-performance liquid chromatography (HPLC) machine. Compounds were detected at 229 nm and separated using the 60-min program described by Kliebenstein et al. (2001b). All GS have previously been identified by MS and NMR analysis (Kliebenstein et al., 2001b; Reichelt et al., 2002). HPLC peaks were called based on retention time and UV absorption spectrum. For ca. half of the samples, we added a known amount of an internal standard (4-hydroxybenzyl GS=sinalbin) before extraction, which allowed us to calculate the concentrations for all GS compounds in micromole per gram dry weight. The concentration was calculated from HPLC peak areas using response factors computed for pure desulfo-GS standards at 229 nm (Brown et al., 2003), and recalculated for sinalbin. The relationship between leaf wet and dry weights was ascertained from the measurement of LDMC below. GS concentrations were log-transformed before analyses.

For analysis of ratios of GS compounds, peak areas from all samples, with and without internal standard, were used after correction for response factors. Ratios among compound classes were calculated to reflect enzyme function at key steps in GS biosynthesis involving side-chain modification and side-chain elongation (Kliebenstein et al., 2001b). Three ratios were calculated to reflect aspects of aliphatic side-chain modification (RMT, RMS, RPropenyl; Table 1). RMT is the ratio of all aliphatic compounds other than methylthio GS over methylthio GS, regardless of chain length. RMS is the ratio of the sum of 2-propenyl and 3OHP GS over all methylsulfinyl GS. RPropenyl is the ratio of 3OHP over 2-propenyl GS. Three ratios were calculated that quantify variation in aliphatic side-chain elongation for which the *MAM* locus (containing *methylthioalkylmalate synthase* genes) has been identified in *A. thaliana* and proposed as a candidate in *A. lyrata*: (1) R3MAM is the ratio of all >3 carbon length GS over C3 chain length GS; (2) R6MAM is the ratio of all >6 carbon length GS over C6 chain length GS, and (3) R7MAM is the ratio of 8 over 7 carbon length GS (Table 1; Kliebenstein et al., 2001b; Kroymann et al., 2001, 2003; Heidel et al., 2006). These ratios are closely related to product/substrate ratios, and high values indicate that the conversion from shorter to longer carbon chain length by the *MAM*-encoded enzymes is more efficient. The following two ratios reflect indole GS modifications: (1) I3MR1 is the ratio of 4MO13M plus 1MO13M over I3M, and (2) I3MR2 is the ratio of 4MO13M over 1MO13M (Table 1). Finally, we calculated the ratio of total aliphatic to total indole GS, which reflects the ratio of methionine over tryptophan amino acid precursors in the GS skeleton (aliphatic/indole; Table 1). GS ratios were not transformed before analysis.

For three fully expanded, nonsenescent leaves per individual, we measured the number of trichomes in the first full field of view below the leaf tip at 5× magnification with a dissecting microscope (area=0.1257 cm²). For each of these leaves, one leaf disk with an area of 0.1963 cm² was then taken from just below the leaf tip, weighed immediately, dried at 50°C for 48 hr, and weighed again to calculate SLA (dry weight/area) and LDMC (dry weight/wet weight).

Insect feeding bioassays were separated by ca. 6 mo, allowing the plants to grow new uninduced leaves. We conducted resistance bioassays using three lepidopteran herbivore species known to feed on *A. thaliana* and other Brassicaceae, with well-established laboratory populations. Performance of two specialist insect species, *Plutella xylostella* (Yponomeutidae) (PX) and *Pieris brassicae* (Pieridae) (PB), and the generalist *Trichoplusia*

ni (Noctuidae) (TN) was assessed on each *A. lyrata* plant. Differences in the performance of individual insects feeding on different *A. lyrata* individuals reflect the plant's resistance to herbivory in a way that integrates many characteristics. Differences among plant sibships in insect performance, host choice, and plant damage reflect the degree to which these resistance-related traits are genetically based.

In June 2002, 897 plants were divided into three randomized blocks for the *P. xylostella* (diamondback moth) assay. The *Plutella* larvae originate from line G88 (Cornell University, USA) and were reared on artificial diet (Shelton et al., 1991), from which they were removed 16 hr prior to the experiment. On d 1, for each plant in block 1, four leaves were cut and placed into a Petri dish (diam 9 cm) together with five third instars of *Plutella*. The petri dishes were kept in the growth chamber with short day conditions, and larvae had no additional food source. Four fresh leaves from the same plant were added to each Petri dish every 2 d until the last larva pupated. Feeding trials for blocks 1, 2, and 3 were each offset by 1 d. After pupation was complete, Petri dishes were maintained at 50% RH with a day/night cycle of 11/13 hr, 25% full light, and 26°C/19°C until *Plutella* adults emerged. We recorded the number of adults out of five that emerged when feeding on each plant. Plants from which fewer *Plutella* adults emerged were considered more herbivore-resistant.

The assay of *P. brassicae* (cabbage white butterfly) performance was conducted by allowing one larva to feed on each *A. lyrata* plant for 7 d in February 2003. A total of 751 plants were divided into four randomized blocks reflecting the bench position in the growth chamber. Second instars, ordered from Seritech (Warwickshire, UK), were allowed to develop for 5 d on *Brassica oleraceae* leaves before being starved overnight, individually weighed, and placed on *A. lyrata* plants. Plants were widely spaced to prevent *Pieris* from moving between individuals, and soapy water in the trays below the plants prevented other excursions. Larvae were frozen immediately after removal from the plant for later weighing. For each plant, we measured the growth rate of the resident larvae (ratio of biomass after to before feeding). The amount of leaf damage due to feeding by *Pieris* was estimated in gross categories reflecting no, little, and extensive tissue removal (0, 1, and 2; PB damage). The architectural complexity of the 1-yr-old *A. lyrata* plants with many leaves and side rosettes prevented a more exact quantification of feeding damage. Plants on which *Pieris* larvae grew less or which were less damaged were more herbivore-resistant.

The assay of *T. ni* (cabbage looper) performance was conducted in July 2003. Eggs of *Trichoplusia* were ordered from Benzon Research Inc. (Carlisle, PA, USA), and larvae were raised on cabbage looper diet (BioServe, Frenchtown, NJ, USA) for 1 wk. Second instars were starved overnight, weighed, and then placed on 546 *A. lyrata* plants divided into three randomized blocks in the growth chamber. Plants were widely spaced, and soapy water in the trays below the plants prevented larvae from reaching other plants. Larvae were removed from the plants after 3 d of feeding, immediately frozen, and weighed. *Trichoplusia* larvae were mobile, with ca. 50% leaving their resident plant. Each plant was scored as having a larva that remained and accepted the host (acceptance=1) or rejected the host and left (acceptance=0). Larval growth rate was calculated only for those accepting the host (departing larvae entered the soapy water below the plants and could not be accurately weighed). Finally, we scored the amount of leaf damage for each plant in gross categories as above (0, 1, and 2). Plants that were accepted less as hosts, had lower *Trichoplusia* larval growth, or experienced less plant damage were more resistant.

Quantitative Genetics Study Year 3: Common Garden In October 2003, we transplanted all F1 plants (now 21 mo old) into four randomized blocks in an experimental field plot near Jena, central Germany, located approx. 180 km north of the original *A. lyrata* Plech population in southern Germany (Clauss and Mitchell-Olds, 2006). Winter survival was >98%, and we measured trichome density and GS composition of new growth in May–June 2004 as described above with the following modifications. Tissue for GS extraction (ca. 0.1 g wet weight) was weighed after freeze-drying. Because GS concentration was lower in these 3-yr-old plants, we doubled the injection volume to 80 μ l. Furthermore, we shortened the HPLC program to 44 min to eliminate only the later minutes of the run where no GS peaks are observed in *A. lyrata* (8 min gradient from 1.5% to 5.0% [v/v] acetonitrile, 2 min gradient from 5.0% to 7.0% [v/v] acetonitrile, 25 min gradient from 7.0% to 42.0% [v/v] acetonitrile, 1 min gradient from 42.0% to 92.0% [v/v] acetonitrile, 5 min at 92.0% [v/v] acetonitrile, and 1 min gradient from 92.0% to 1.5% [v/v] acetonitrile), and a final 1 min at 1.5% (v/v) acetonitrile).

We counted the number of trichomes within only 0.25 \times of the leaf area described above because trichome density was greater for the plants in the common garden. On June 16, 2004, we scored the extent of unmanipulated herbivore damage for each plant (0, 1, and 2, as above).

Analyses All analyses were based on the same set of 34 sibships (17 dams each crossed with two sires), with some variation in the number of offspring measured per cross (average $N=20$). Phenotypic correlations were calculated among GS compounds and trichome density with Spearman correlation coefficients. The relationship between defense-related phenotypes and *A. lyrata* resistance to *Plutella*, *Pieris*, *Trichoplusia*, and naturally occurring herbivores in the common garden was quantified by using multiple regression analysis with the logarithms of aliphatic and indole GS amounts, the logarithm of trichome density, and SLA as independent variables. For each analysis, we employed the subset of individuals for which standard-corrected GS concentrations were available, and which had no missing data. Further, the analysis of *Trichoplusia* larval growth rate included only plants on which larvae remained resident and accepted the host.

Genetic variance components were estimated within an analysis of variance framework for each variable separately, using raw data or data transformed by log, square root, or arcsine square root as appropriate to give rise to an approximately normal distribution of

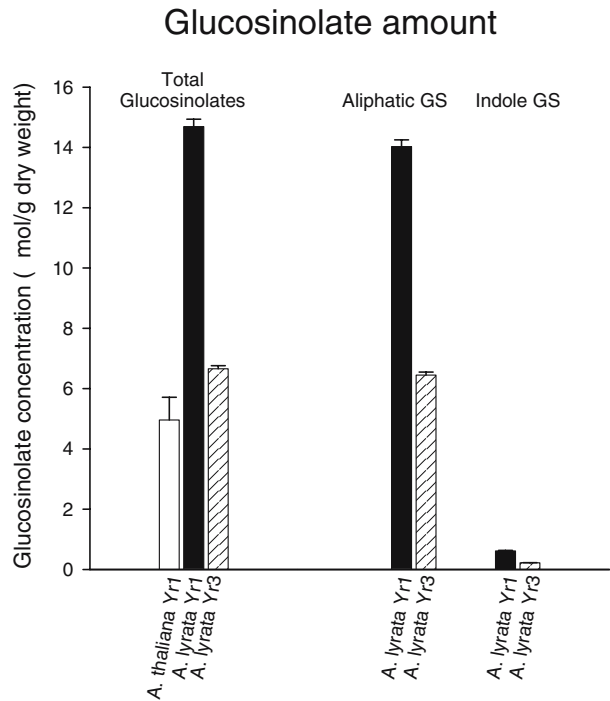

residuals. For each variable, we used the residuals of a model including block effects to estimate the magnitude and significance of the variance components associated with dams and sires nested within dam from PROC MIXED with restricted maximum likelihood estimation (SAS Institute Inc., Cary, NC, USA; see Table 1 for sample sizes). For PB larval growth, PB plant damage, TN larval growth, TN host acceptance, TN plant damage, and Field damage, we used a noniterative unbiased estimator (MIVQUE0 in PROC MIXED; SAS Institute Inc.). We report broad sense heritabilities (H^2) calculated as four times the sire variance component. Sire-based estimates of genetic correlation are free of maternal effects but may include dominance and epistatic effects as well as additive genetic variance (see above). For PX emergence, we report significance of H^2 from a random effects analysis of dam and sire nested within dam that treated PX emergence as Poisson distributed response variable using PROC GENMOD with a log link function (SAS Institute Inc.). For TN acceptance, we report significance from a similar random effects analysis that treated TN acceptance as binomially distributed response variable using PROC GENMOD with a logit link function.

Genetic correlations among pairs of traits with nonzero sire variance components were calculated as follows. In the context of the variance component analysis for each trait above, we estimated breeding values for each dam and sires within each dam (sireA and sireB), using empirical best linear unbiased prediction (BLUP; Littell et al., 1996). BLUP estimates are more accurate than sire family means because they use all information available, and thus are not biased by environmental effects, as are family means (e. g., Agrawal et al., 2002). We then calculated the difference between the breeding values of sireA and sireB (sireA–sireB) for each dam. Genetic correlations among traits were estimated by Spearman rank correlation of the sire breeding value differences (hereafter sire-based correlations). We also calculated genetic correlations among the dam breeding values of selected traits using Spearman rank correlation analysis (dam-based correlations). Dam-based genetic correlations are calculated from a larger number of offspring per family ($N=40$ on average), may sample unique genotypes from the original populations not compared in the sire variance analysis, and may include maternal effects.

Results

Phenotypic Variation The sample size, mean, standard deviation, and units for the raw data of all traits measured while plants were in the growth chamber (yr 1 and 2) and after they were transplanted to the common garden (yr 3) are given in Table 1. The glucosinolate phenotype of *A. lyrata* was composed of aliphatic GS derived from methionine (>96%) and indole GS derived from tryptophan amino acid precursors (4%) (Fig. 1). All compounds identified in *A. lyrata* have also been found in natural accessions of *A. thaliana*, and comparison with 8-wk-old rosettes of *A. thaliana* Ler-0 demonstrated that young *A. lyrata* plants had a slightly higher overall concentration of GS (Fig. 1, but see Kliebenstein et al., 2001b for variation among accessions). The single most dominant GS compound in 8-wk-old *A. lyrata* rosettes was the aliphatic 3OHP, followed by 7MSOH, and the indole I3M (Table 1). Phenotypic correlations among different GS compounds were generally positive (Table 2). The total GS concentration decreased from 14.7 $\mu\text{mol/g}$ dry weight in yr 1 to 6.7 $\mu\text{mol/g}$ dry weight when plants were remeasured in the common garden in yr 3 (Fig. 1 and Table 1). Overall GS profiles were correlated between years ($r_{\text{spearman}}=0.812$, $P<0.001$, $N=11$; Table 1; Fig. 1), and individual GS compound amounts and ratios were positively

Fig. 1 GS concentrations measured at 8 wk in the growth chamber (yr 1, solid bars) and 28 mo in a common garden (yr 3, striped bars) for *A. lyrata* subsp. *petraea* from Plech, Germany. GS content was also assessed for 8-wk-old *A. thaliana* (Ler-0) in the laboratory (open bar)

correlated for 612 individuals measured in both yr 1 and 3 (r_{spearman} ranged from 0 to 0.378, significant in 17 out of 23 cases; Table 3).

The distribution of trichome counts was continuous and unimodal, with no completely glabrous plants. Whereas rosette leaves on young plants in yr 1 had, on average, 27 trichomes/cm², plants in yr 3 growing in the common garden had 127 trichomes/cm². The phenotypic correlation in trichome density among years was positive ($r_{\text{spearman}}=0.149$, $P<0.001$, $N=585$).

The relationship between defense-related phenotypes and *A. lyrata* resistance was quantified using multiple regression analysis. Less than 5% of the phenotypic variance in resistance traits was explained by four independent defense-related variables (aliphatic GS, indole GS, trichome density, and SLA; Table 4). Trichome density, but not GS characteristics, significantly reduced adult emergence in the specialist *Plutella* (Table 4). Resistance to *Pieris* was not explained by any of the independent variables tested. For the generalist herbivore, *Trichoplusia*, indole GS negatively affected larval growth and reduced leaf damage by feeding (Table 4). Interestingly, plants with higher aliphatic GS experienced greater feeding damage by *Trichoplusia*. In the common garden, plants with more trichomes and more aliphatic GS experienced less leaf damage by herbivores (Table 4). The most common leaf herbivore in the common garden experiment was the crucifer specialist flea beetle, *Phyllotreta cruciferae* (Chrysomelidae, Coleoptera; $N=458$ during 30 min of herbivore scans conducted eight times between May 15 and September 30, 2004; Claus, unpublished data).

Single Trait Heritability Total indole GS concentration was significantly heritable in yr 1 and 3 (Fig. 2). In contrast, variation in total aliphatic GS had no significant genetic basis.

Spearman correlation coefficients significant after sequential Bonferroni adjustment with family-wise alpha=0.05 are indicated in bold.

When GS were broken down into their individual compounds and ratios among compound classes, 3 of 11 GS concentrations and 8 of 9 GS ratios were significantly heritable in yr 1 (Fig. 2). After sequential Bonferroni corrections (Holm, 1979), one GS concentration (7MTH) and three ratios (RMT, R6MAM, and aliphatic/indole) remained significant (Table 1). Although there was an average decline in GS heritability of 50% from yr 1 to 3, indole GS were less affected than aliphatics (Fig. 2). Two indole GS showed significant heritability in yr 3, as did two long-chain aliphatic GS (7MTH, 8MSOO) and three ratios (R6MAM, I3MR2, and aliphatic/indole). After sequential Bonferroni correction, no GS heritabilities in yr 3 were significant (Table 1).

Trichome density was significantly heritable in yr 1, but not in yr 3 (Table 1). Specific leaf area, but not LDMC, was heritable in yr 1 (Table 1).

Resistance bioassays demonstrated significant genetic variation in one aspect of resistance to *Plutella* (adult emergence) and to *Trichoplusia* (host acceptance) (Table 1). There was no significant genetic basis to variation in *Pieris* larval growth or to the amount of tissue damage inflicted by *Pieris* and *Trichoplusia* (Table 1). In the common garden in

R7MAM	-0.85	0.09	1.000

For phenotypic (lower left) and genetic (upper left) correlations, sample sizes were $N=794$ and 14 in (A), and $N=805$ and 17 in (B), respectively.

Spearman correlation coefficients significant after sequential Bonferroni adjustment with family-wise $\alpha=0.05$ are indicated in bold.

yr 3, damage to plants by herbivores was pervasive but did not show a significant genetic basis (Table 1).

Genetic Correlations Significant positive genetic correlations among GS compounds were observed for 6MSOH, 7MSOH, and 8MSOO in yr 1 (Table 2) and between 7MSOH and 8MSOO in yr 3 ($r_{\text{spearman}}=0.811$, $P<0.001$). Genetic correlations among aliphatic chain length ratios in yr 1 showed that while R3MAM and R6MAM were positively correlated, both varied negatively with R7MAM (Table 5A). A strong negative genetic correlation was also seen between R3MAM and R7MAM in yr 3 (Table 5B). Between yr 1 and 3, genetic correlations among GS amounts and ratios were generally positive, but not significant (Table 3). Dam-based estimates of genetic correlations were more strongly positive (Table 3). Cross-year genetic correlations were not significant for trichome density (sire-based: $r_{\text{spearman}}=0.353$, $P=0.165$, $N=17$; dam-based: $r_{\text{spearman}}=0.348$, $P=0.171$, $N=17$). A significant genetic correlation between trichomes and GS was seen only for trichome density and indole GS in yr 3 ($r_{\text{spearman}}=0.645$, $P=0.005$, $N=17$; Fig. 3). Although biochemical and physical defenses can be correlated as the result of common induction (e.g., Agrawal 2000; Traw and Dawson, 2002b), we found no evidence of positive phenotypic correlations between trichomes and GS in yr 3 ($r_{\text{pearson}}=-0.019$, $P=0.582$, $N=784$).

Resistance to different herbivores was genetically correlated with different defense mechanisms. Here, we focus on selected GS compounds and ratios that were highly and/or consistently heritable across years, and also included total aliphatic and total indole GS to facilitate comparison with other studies. *Plutella* emergence was negatively genetically correlated with SLA (Table 6) and trichome density ($r_{\text{dam-based}}=-0.596$, $P=0.012$, $N=17$). Host-plant damage due to feeding by *Pieris* was significantly correlated with one ratio of aliphatic GS chain lengths (R6MAM), but not with the amount of GS (Table 6). *Trichoplusia* host acceptance showed a significant negative genetic correlation with indole

Fig. 2 Heritability of GS amounts (A) and ratios (B) for *A. lyrata* subsp. *petraea* Plech in the laboratory at 8 wk (yr 1, dark bars) and in the common garden at 28 mo (yr 3, gray bars). Abbreviations and calculation of ratios are given in Table 1 ($*P<0.05$, $**P<0.01$)

Fig. 3 Genetic correlation between indole GS concentration and trichome density for *A. lyrata* subsp. *petraea* Plech in yr 3 in the common garden

GS, primarily reflecting the main indole compound, I3M (Table 6). The growth rate of *Trichoplusia* larvae remaining on their host plant was also negatively correlated with indole GS ($r_{\text{spearman}} = -0.529$, $P = 0.029$, $N = 17$). Considering only the two resistance assays with significant heritabilities, there was a significant positive genetic correlation between resistance to the specialist *Plutella* and to the generalist *Trichoplusia* ($r_{\text{spearman}} = 0.520$, $P = 0.032$, $N = 17$). However, genetic correlations have notoriously large standard errors (Falconer, 1989, p. 317), and all tests reported for resistance were no longer significant after sequential Bonferroni correction.

Discussion

The diverse GS profiles observed in *A. thaliana* and other species in the Brassicaceae arise largely from biosynthetic modifications in type and length of GS side chains and in regulatory steps that determine the amino acid precursors for the GS skeleton (Wittstock and Halkier, 2002; Kliebenstein et al., 2005; Grubb and Abel, 2006). Although *A. lyrata* spp. *petraea* is closely related to the model *A. thaliana* and the subject of an increasing number of comparative investigations, little is known about glucosinolates in this out-crossing perennial herb. We report 11 aliphatic and indole GS compounds in *A. lyrata*, all of which have previously been identified in natural accessions of *A. thaliana* and other *Arabidopsis* species (Table 1; Kliebenstein et al., 2001b; Windsor et al., 2005). The single most abundant compound in the *A. lyrata* GS profile was the short chain aliphatic 3-hydroxypropyl GS (>86%). GS profiles remained similar across years and environmental conditions, even though the overall concentration declined twofold in 3-yr-old plants (Fig. 1; Tables 1 and 3). Age-dependent decreases in GS concentration are also seen in *A. thaliana* and *Brassica* (Fahey et al., 2001; Brown et al., 2003; Lambdon et al., 2003). Within a single population of *A. lyrata*, we found significant and independent genetic variation for amounts and ratios of GS compounds (Table 1, Fig. 2). Studies of GS in *A. thaliana* have so far focused exclusively on natural genetic variation among populations or accessions (e.g., Kliebenstein et al., 2001b). Somewhat unexpectedly, heritabilities for indole GS in *A. lyrata* were high and less affected by differences in plant age and environment than aliphatic GS (Fig. 2). Indole GS are considered to be the dominant inducible compounds in the Brassicaceae and generally have lower heritabilities (Agrawal et al., 1999; Kliebenstein et al., 2001a; Traw 2002; Mikkelsen et al., 2003). Below, we address (1) the genetic basis of GS variation in *A. lyrata* in relation to candidate enzymes and genes identified in *A. thaliana*, and (2) the contribution of GS composition and trichome density to herbivore resistance in *A. lyrata*.

Elongation of the carbon side chain of the base amino acid is the first step in biosynthesis of *Arabidopsis* aliphatic GS. The allelic state of the *GS-Elong* locus determines the distribution of carbon chain lengths observed in methionine-derived aliphatic GS, and contains two or three directly repeated paralogous sequences in *A. thaliana* encoding MAM (Kroymann et al., 2003). The chain elongation phenotype can be quantified by ratios of longer to shorter chain GS (Kliebenstein et al., 2001b), and all three ratios reflecting the putative function of the MAM enzyme in *A. lyrata* were significantly heritable (Fig. 2). Indeed, a cosegregation test for the F1 progeny from several of the same families used in this study suggests that the *MAM* locus is responsible for segregating variation in chain length ratios in *A. lyrata* (Heidel et al., 2006). Interestingly, both the phenotypic and genetic correlations among MAM ratios are positive between R3MAM and R6MAM, but negative for R7MAM (Table 5). This suggests that while overall the amounts of long chain GS are positively correlated to one another (Table 2), a high conversion of 3-carbon and 6-carbon GS was associated with a low conversion of 7-carbon GS. This negative correlation has also been observed in *A. thaliana* (Kliebenstein et al., 2001b).

Genetic control of side-chain modifications converting methylthioalkyl to methylsulfanylalkyl GS has been attributed to the *GS-OX* locus (Giamoustaris and Mithen, 1996; Kliebenstein et al., 2001c). The GS ratio quantifying this modification step in *A. lyrata* was significantly heritable (RMT; Fig. 2, Table 1). Although *GS-OX* is variable in *A. thaliana* and has been subject to QTL mapping, a single underlying gene has not been unambiguously identified (D. Kliebenstein, personal communication). Ratios corresponding

to the carbon chain modification functions of *AOP2* and *AOP3* candidate loci (Kliebenstein et al., 2001c) did not vary genetically in the Plech population of *A. lyrata* (RMS and RPropenyl in Table 1). In contrast, the heritability of the ratio of methionine to tryptophan-derived GS was significant (aliphatic/indole; Fig. 2), and the corresponding QTL in *A. lyrata* appears to contain *CYP79F1* and *CYP79F2* (Heidel et al., 2006). Mutants in these two cytochrome P450 genes affect the ratio of indole to aliphatic GS and are involved in chain elongation for aliphatic GS biosynthesis (Chen et al., 2003).

Our investigation of the natural quantitative genetic variation for GS in *A. lyrata*, and a companion paper showing a molecular genetic basis for variation in GS carbon chain elongation (Heidel et al., 2006) exemplify the possibilities for functional genetic research in nonmodel systems. Beyond the natural variation observed among accessions of *A. thaliana*, populations of closely related species represent further biological complexity and the opportunity to understand the causes and consequences of variation in function (Clauss and Koch 2006).

GS compounds are an important plant defense against many insect herbivores. However, the strength of resistance conferred by GS, the most effective GS compounds, and the role of other defense-related traits can vary when different plants and herbivore species interact. Below, we infer defense function from the phenotypic covariance structure between defense-related traits and plant resistance in four different herbivory experiments. Given equivalent exposure to herbivores, plants with less feeding damage or plants on which insects had reduced performance were considered more resistant. Future experiments manipulating individual defense traits are necessary to confirm the conclusions from our correlative study.

The specialist herbivore *P. xylostella* is restricted to feeding on Brassicaceae and possesses a detoxification mechanism for GS–myrosinase defenses (Ratzka et al., 2002). Commensurate with the detoxification physiology of this insect, performance of *Plutella* was not related to GS composition but significantly reduced on *A. lyrata* individuals with greater trichome density (Table 4). Leaf morphological characteristics, and in particular trichome density, have been previously shown to contribute to resistance to herbivores in *A. thaliana* and *Brassica* spp. (Agren and Schemske, 1993; Mauricio, 1998). Defenses outside the GS–myrosinase system are expected to play an important role in resistance to herbivores specialized on Brassicaceae.

Larvae of butterflies in the genus *Pieris* feed primarily on plants in the Brassicaceae and related families, and have been the focus of a large number of ecological and functional investigations of plant–insect interactions (Renwick and Lopez, 1999; Agrawal and Kurashige, 2003). Although *Pieris rapae* larvae can respond to GS-containing diet by redirecting enzymatic breakdown in the gut to favor formation of less toxic products (Wittstock et al., 2004), larval performance can be reduced by the presence of GS and their breakdown products (e.g., isothiocyanates) under some conditions (Agrawal and Kurashige, 2003; Rotem et al., 2003). GS and isothiocyanates can also serve as stimulants for feeding and oviposition in *Pieris* (Renwick and Lopez, 1999; Rask et al., 2000; Fahey et al., 2001; Renwick, 2002). For *A. lyrata*, we observed no phenotypic relationships between GS, isothiocyanates, or leaf morphological traits with *Pbrassicae* larval growth or plant damage (Table 4; PB plant damage vs. total isothiocyanates; $r_{\text{spearman}} = 0.005$, $P = 0.911$, $N = 493$; Clauss, unpublished data).

Trichoplusia ni is a generalist herbivore that feeds on a variety of plant species, including members of the Brassicaceae, but is sensitive to the particular composition of GS and their breakdown products (Jander et al., 2001; Lambrix et al., 2001; Kliebenstein et al., 2002). A higher indole GS phenotype in *A. lyrata* was associated with in reduced *Trichoplusia* larval growth and feeding damage (Table 4). There was no effect of trichome

density on resistance to the generalist *Trichoplusia*. A role for indolic GS in defense against pathogens and insect herbivores has been previously suggested (Hopkins et al., 1998; Brader et al., 2001; Reymond et al., 2004). It was unexpected that rather than confer resistance against *Trichoplusia* (Raybould and Moyes, 2001; Kliebenstein et al., 2002), the dominant aliphatic GS in *A. lyrata* had a weak *positive* phenotypic relationship with feeding damage (Table 4).

In the common garden, the crucifer flea beetle, *P.cruciferae*, was the most common herbivore, and *A. lyrata* plants with more trichomes and more aliphatic GS experienced less leaf damage (Table 4).

In summary, we found that *A. lyrata* resistance was conferred by both indole GS amount and trichome density, and that aliphatic GS amount had a defensive as well as a stimulatory role. The contribution of these defense traits to resistance was dependent on the experimental herbivory context.

Phenotypic variance and covariance are shaped by both genetic and environmental factors. Although variation in trichome density had a genetic basis when measured in the laboratory ($H^2=0.33$), there was a fivefold increase in density when the experiment was transferred to the common garden. Plants of the same age maintained in the growth chamber showed no change in trichomes (Clauss, personal observation). The environmental conditions in the common garden caused not only an increase in the mean trichome phenotype, but also an increase in the environmental variance component, which resulted in a dramatic decline in trichome heritability ($H^2=0.03$, where $H^2 = \text{Var}_{\text{Gen}}/(\text{Var}_{\text{Gen}} + \text{Var}_{\text{Env}})$). Interestingly, density in the common garden (127 trichomes/cm²) was more representative of plants growing in the natural Plech field population (111 trichomes/cm², SD=69.9, N=45). The high trichome density in the Plech population is in contrast with the observation that *A. lyrata* individuals of many Swedish populations are lacking any hairs and are completely glabrous both under field and greenhouse conditions (Karkkainen et al., 2004). A single locus with simple Mendelian inheritance (GLABROUS1) has been proposed for the glabrous/trichome-producing polymorphism (Karkkainen and Agren, 2002). However, when trichomes are present in *A. lyrata*, trichome density appears to be under polygenic control as indicated by the significant heritability observed for trichome density in the laboratory for Plech, and the continuous unimodal distribution of F1 phenotypes (results not shown). Regardless of the genetic basis, the dramatic changes in phenotype for trichomes and GS seen over the course of development under different environmental conditions (Tables 1 and 3) emphasize the importance of ecologically relevant experimental conditions when interpreting the role of trait variation in biological interactions (Conner et al., 2003).

Considering the genetic components of variation, the heritability of individual traits and genetic correlations among traits reflect past evolutionary processes such as natural selection, drift, migration, recombination, and mutation. For the *A. lyrata* Plech population, we found genetic variation in GS and trichome defense traits as well as in resistance to *Plutella* and *Trichoplusia* (Table 1 and Fig. 2). Although balancing selection, frequency-dependent selection, and heterozygote advantage can contribute to the maintenance of genetic variation in some interaction-related traits (Stahl et al., 1999; Mauricio et al., 2003; Charlesworth, 2006), the importance of these selective processes for herbivore defense within populations of perennial plants such as *A. lyrata* remains to be shown. Because genetic variation in defense can be hidden from selection by high environmental variance and age-dependent changes in heritability (Fig. 2; Charmantier and Garant, 2005; Charmantier et al., 2006), future studies in *A. lyrata* must also address the possibility that substantial nearly neutral diversity in functional characteristics might segregate in old and stable glacial relict populations (Clauss and Mitchell-Olds, 2003, 2006).

When genetic polymorphisms in defense traits cause variation in resistance, we expect genetic correlations to reflect this functional relationship. One aspect of leaf morphology, biomass per leaf area (SLA), had a negative genetic correlation with *Plutella* emergence (Table 6). Although not primarily involved in defense, traits affecting leaf toughness can influence herbivore feeding and thus resistance to herbivory. Sire-based genetic correlations between trichome density and *Plutella* emergence were not significant, suggesting that the significant relationships we observed between trichomes and resistance in phenotypic and dam-based analyses were not due to genetic differences. Indole GS concentration was negatively genetically correlated with host acceptance by *Trichoplusia* and the growth rate of larvae (Table 6), confirming the defensive role for indole GS observed in the phenotypic data. Two GS ratios were significantly correlated with resistance, suggesting that the relative GS composition, in addition to the amount, can be of ecological importance (Table 6). Such genetic correlations in a population-level survey motivate further functional investigations employing crosses of divergent genotypes, QTL mapping, and testing of candidate genes underlying ecologically important traits (e.g., Kroymann et al., 2003; Heidel et al., 2006).

Genetic correlations can also affect the future response to selection across generations. Models of multispecies interactions predict that positively correlated resistances contribute to a “diffuse” coevolutionary dynamic where plant defense evolves in response to a whole suite of attackers (Hougen-Eitzman and Rausher, 1994). A weak positive genetic correlation between resistance to the specialist *Plutella* and to the generalist *Trichoplusia* was observed in *A. lyrata*. In the natural Plech population of *A. lyrata*, single long-lived plants (>10 yr) experience attack by many different herbivore species throughout their lifetime (Clauss, unpublished data). Correlated resistance against multiple herbivores could be beneficial when individual herbivores species are rare and the composition of the herbivore community varies among months and years (Clauss, unpublished data). Interestingly, the observed correlation in resistance was not mediated via a shared response to GS, but rather might reflect an underlying positive genetic correlation between trichome density and indole GS concentration (Fig. 3). If trichomes and GS defend *A. lyrata* plants against multiple herbivores and are positively genetically correlated, why has natural selection not swept all genetic variation in these traits to fixation? In the common garden, we observed a negative correlation between plant size and total GS concentration (Clauss, unpublished data), which might indicate a resource-related trade-off that imposes limits on selection for increased defense (Bergelson and Purrington, 1996; Mauricio and Rausher, 1997; Mauricio 1998). In *A. lyrata*, we can now test hypotheses concerning the ecological and evolutionary processes that shape functional genetic variation within stable and persistent populations of a perennial plant species.

Acknowledgments The authors thank D. Kliebenstein, M. Reichelt and A. Figuth for technical advice, and J. Bishop and J. DeMeaux for helpful comment on an earlier version of the manuscript. Financial support was provided by the Max-Planck Gesellschaft.

achieved by wounding the plants and applying herbivore regurgitant or elicitors such as jasmonates (JA) to the damaged sites (Turlings et al., 1993a; Hopke et al., 1994; Halitschke et al., 2001). Induced volatile blends vary considerably in quantity and quality with plant species or variety (Takabayashi and Dicke, 1996; Krips et al., 2001; Fritzsche-Hoballah et al., 2002; Degen et al., 2004; Van Den Boom et al., 2004; Bukovinszky et al., 2005), which may reflect in differences in attractiveness to the natural enemies of herbivores (Krips et al., 2001; Fritzsche-Hoballah et al., 2002; Bukovinszky et al., 2005). However, little to nothing is known about the consequences of these differences among plant genotypes for the effectiveness of the natural enemies in the field.

Nilaparvata lugens is one of the most important rice pests. It feeds on the phloem and causes a decrease in leaf area, plant height, dry weight, leaf and stem nitrogen concentration, chlorophyll contents, and photosynthetic rate (Rubia-Sanchez et al., 1999; Watanabe and Kitagawa, 2000), which subsequently results in yield loss. Previous studies have shown that *N. lugens* attack or JA treatment alters the volatile profiles of rice plants, and these volatiles are strongly attractive to the egg parasitoid *Anagrus nilaparvatae* (Lou et al., 2005a,b), a major natural enemy of the rice planthoppers (Cheng and He, 1996). Moreover, the parasitism of *N. lugens* eggs by *A. nilaparvatae* on plants that were surrounded by JA-treated plants is more than twofold higher than on control plants in the greenhouse and field (Lou et al., 2005a), implying that augmenting the release of rice-produced attractants has the potential to enhance the effectiveness of the parasitoid in the control of *N. lugens*. This should be testable, as the volatiles released from different rice varieties in response to *N. lugens* infestation show distinct differences in attraction of the parasitoid (Ma et al., 2004). In this work, we performed such tests, whereby we compared the volatile emissions of various rice varieties after JA induction, as well as their attractiveness to *A. nilaparvatae* in the laboratory and field.

Methods and Materials

Plant Growth

Rice varieties used in this study were TN1, IR26, IR64, Xiushui 63, Bing 97-34, and Bing 97-59, whose genetic backgrounds are described in Table 1. Of these varieties, both IR26 and IR64 contain the *Bph1* gene (Zhu et al., 2004), a resistance-related gene to biotype one of *N. lugens*, and share several parents in their pedigrees; the other four are all susceptible to *N. lugens*, and three (Xiushui 63, Bing 97-34, and Bing 97-59) have a similar genetic background (Table 1). Pregerminated seeds were sown in a greenhouse, and after 20–25 d,

Table 1 Genetic background of six rice varieties

Variety	Genetic background
TN ₁	DGWG/Tsai Yuan Chan
IR26	IR24/TKM6; containing <i>Bph1</i> gene
IR64	...IR24/TKM6...IR5657-33-2-1/IR2061-465-1-5-5; containing <i>Bph1</i> gene
Xiushui 63	Shan 41r/Bing 8961//Bing 8961(M)
Bing 97-34	Bing 8961/Bing 93390
Bing 97-59	Bing 9147/Bing 9117//Bing 88122(M)/3/Xiushui 63(F)

“/,” “//,” and “/3/” indicate the first, second, and third hybridization, respectively. For each cross, the female parent is listed first unless otherwise specified. F, female parent; M, male parent.

seedlings were transplanted into small clay pots [8 cm (diam) × 10 cm (height)] each with one plant, or big clay pots (16 × 10 cm) each with three plants. In the latter, plants were arranged in an equilateral triangle 8 cm apart. Plants were watered daily, and each pot was supplied with 10 ml of nutrient solution ($\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, 0.5 g/l; $\text{K}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, 0.125 g/l; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.125 g/l; K_2HPO_4 , 0.125 g/l; FeCl_2 , 0.005 g/l) every 3 d. All plants were placed in a controlled climate room that was maintained at $23 \pm 2^\circ\text{C}$, 70% r.h. and 18 hr photophase (25,000 lx). Twenty-five to 30 d after potting, plants were used for experiments. Plantings were continued at regular intervals so that enough of suitable age were available for all experiments.

Insects

The *N. lugens* culture was originally obtained from the China National Rice Research Institute (CNRRI), Zhejiang, and maintained on Shanyou 63 rice plants (susceptible to *N. lugens*) in a greenhouse. Late instar nymphs of *N. lugens* were captured from the greenhouse and reared on potted Shanyou 63 rice plants, which were confined in plastic cages (11 × 40 cm). Caged rice plants were maintained in a controlled climate room at $28 \pm 2^\circ\text{C}$, 12 hr photophase, and 70–80% r. h. Newly emerged adults of *N. lugens* were collected daily and fed on potted fresh Shanyou 63 rice plants. With this procedure, *N. lugens* adults of uniform age were obtained.

A laboratory colony of the egg parasitoid *A. nilaparvatae* was started from individuals trapped in rice fields in Hangzhou, using Shanyou 63 rice plants with *N. lugens* eggs as bait. The colony was propagated on *N. lugens* eggs in rice shoots enclosed in glass tubes (2.5 × 20 cm), which were kept in a controlled climate room at $28 \pm 2^\circ\text{C}$, 12 hr photophase, and 70–80% r.h. Each day, newly emerged wasps were collected into clean glass tubes (2.5 × 20 cm) with access to both water and honey solution, and held for at least 2 hr to ensure mating. From the second generation onwards, female parasitoids were used in experiments less than 24 hr after emergence.

Plant Treatment

Potted plants (1 or 3 per pot) were washed with running water. They were individually damaged with a needle at the lower and upper positions of the rice stems, each with 200 pricks. They were subsequently treated by applying 20 μl of 10 mM jasmonic acid in 50 mM sodium phosphate buffer (titrated with 1 M citric acid until pH = 8) at each damage site (JA). In a previous study, we found that JA treatment induces the release of volatiles in rice, resulting in the attraction of the parasitoid (Lou et al., 2005a). Plants were treated at 17:00 hr, and then the plants were placed in a controlled climate room that was maintained at $28 \pm 2^\circ\text{C}$, 12 hr photophase, and 80% r.h. Fifteen hours after treatment, i.e., at 8:00 hr the next day, plants were used for experiments.

Collection, Isolation and Identification of Volatile Compounds

The volatile collection system has been described in detail (Turlings et al., 1998). It basically consists of six vertically placed cylindrical glass tubes (9.5 cm i.d., 54 cm high). A split Teflon plate with a hole in the center at the base of a cylinder was filled loosely around the plant stem, allowing the separation of the aerial part of the plant, in the cylinder, from the pot, which remained outside (Turlings et al., 1998). Purified and humidified air was pushed into each cylinder at a rate of 1 l/min and passed over the plant. Around the base of

each cylinder, just above the Teflon disk, eight openings served as ports that could hold the collection traps. Only one port was used during an experiment. For collections, air was pulled (0.8 l/min) through a Super-Q adsorbent trap (Heath and Manukian, 1992), whereas the rest of the air was vented out through the hole in the bottom, thus preventing outside, impure air from entering. The automated part of the collection system (Analytical Research System, Gainesville, FL, USA) controlled the flow through the trap. The climate chamber (CMP4030; CONVIRON, Winnipeg, Manitoba, Canada) in which the collection cylinders were housed was kept at 17.5°C; due to heat irradiation, the temperature inside the cylinders was $23 \pm 3^\circ\text{C}$. During the light cycle, light intensity was about 20,000 lumen/m².

Volatiles emitted from plants of the six varieties that were wounded and treated with JA were collected. Collections started immediately after the lights were turned on, 15 hr after treatment, and lasted 4 hr. After each collection, traps were extracted with 150 µl of methylene chloride (Lichrosolv.; Merck, Whitehouse Station, NJ, USA) and 200 ng of *n*-octane and nonyl acetate (Sigma, Buchs, Switzerland) in 10 µl of methylene chloride were added to the samples as internal standards. Collections were replicated six times for each variety.

Analyses were done with an HP 6890 series gas chromatograph equipped with an automated on-column injection system (HP G1513 A) and a flame ionization detector. A 3-µl aliquot of each sample, was injected onto an apolar SE-30 capillary column (30 m, 0.25 mm i. d., 0.25 µm film thickness; Alltech, Deerfield, IL, USA) that was preceded by a deactivated retention gap (5 m, 0.25 mm i.d.) and a deactivated precolumn (30 cm, 0.530 mm). Helium (24 cm/sec) was used as carrier gas. After injection, the column temperature was maintained at 40°C for 3 min, increased to 230°C at 8°C/min, and held at 230°C for 9.5 min. The detector signal was processed with HP GC Chemstation software. Compounds were identified by comparison of GC retention times with those from our previous studies (Lou et al., 2005a) and those of authentic standards.

Olfactometer Bioassay

Responses of *A. nilaparvatae* females to rice volatiles were measured in a Y-tube olfactometer. The olfactometer consisted of a Y-shaped glass tube (1 cm diam). The base and the two arms of the Y tube were all 10 cm in length. Each arm was connected to an odor source container (a glass cylinder, 6 × 46 cm). An airstream was generated and was divided in two, and each secondary airstream was led through a flowmeter, a tube with active charcoal, a humidifier bottle, and one of the odor containers. Subsequently, the two airstreams were led through the two arms of the Y-tube olfactometer at 150 ml/min. The Y-tube olfactometer was placed in a box painted white with an artificial light source consisting of two 20-W fluorescent lamps placed in front of the box. All bioassays were conducted between 09:00 and 17:00 hr. During experiments, the temperature in the room was maintained at 25–28°C.

The six varieties were divided into three groups on the basis of the volatiles profiles that they emitted after JA treatment (Table 2; Fig. 2): group 1 (TN1), group 2 (IR26 and IR64), and group 3 (Bing 97-34, Bing 97-59, and Xiushui 63). To compare attractiveness among and within these groups, we selected the following five pairs for olfactometer tests: IR26 vs. IR64, Bing 97-59 vs. Xiushui 63, TN1 vs. IR26, Bing 97-59 vs. IR26, TN1 vs. Bing 97-59. Fifteen hours after JA treatment, 10 individually potted plants of each variety were cut off at soil level, their cut stems wrapped in wet cotton, and the plants of one variety were placed into one of the odor source containers. Mated female parasitoids were introduced individually into the base tube of the Y-shaped olfactometer and given 10 min to walk towards the end of one of the arms. A choice for an odor source was defined as a female crossing a line 7 cm after the division of the base tube and remaining there for at least 1 min.

^aData represent the mean amount (% of IS peak area) of six replications. Different letters in the same row indicate significant differences among treatments ($P < 0.05$, Fisher LSD *post-hoc* tests).

^b(E)-4,8-Dimethyl-1,3,7-nonatriene.

^c(3E,7E)-4,8,12-Trimethyl-1,3,7,11-tridecatetraene.

If a parasitoid did not make a choice within 10 min, this was recorded as “no response.” After two females were tested, the olfactometer tube was washed with 98% alcohol and heated at 80°C for several minutes. To eliminate the effects of asymmetrical bias, connections of the two arms of the olfactometer to the odor source containers were exchanged after testing of two females, and the odor source containers were exchanged and supplied with a new set of plants after testing of eight females. For each odor source combination, at least 48 females were tested. All females that were tested made a choice.

Field Experiment

To obtain plants with *N. lugens* eggs, plants of the variety Shanyou 63 were individually infested for 1 d with 10 gravid *N. lugens* females that were confined to the plants in two parafilm bags at the upper and lower positions of the stems. Of these plants, two were chosen with about 80–100 1-d-old *N. lugens* eggs, and they were transplanted to a pot into the center of a triangle of three plants of a particular variety, which had been wounded and treated with 10 mM JA 15 hr earlier (Fig. 1A). Five pots for each of the varieties—TN1, IR26, IR64, Bing 97-59, and Xiushui 63—were placed at five locations in a rice field (20 m wide, 35 m long; rice variety Jialeyou 2) as shown in Fig. 1B. Hence, each location included five pots, each of them with JA-treated plants of a different variety. Two days after the plants were introduced into the rice field, they were transferred to the controlled climate room at $28 \pm 2^\circ\text{C}$, 12 hr photophase, and 80% r.h. Each pot of plants was confined to an 11×40 cm plastic cage (after herbivores, predators, and parasitoids had been removed). Five days later, the plants were cut off at soil level and dissected under a microscope to record the total and parasitized *N. lugens* eggs by using the method described in Lou et al. (2005a). This experiment was done two times (July 6 and September 27, 2005).

Fig. 1 Design of potted plants for field experiment (A) and arrangement of plants in a rice field (B). Letters a, b, and c represent three plants that were arranged in an equilateral triangle 8 cm apart and were wounded and treated with $40 \mu\text{l}$ of 10 mM JA in 50 mM sodium phosphate buffer (pH = 8); d and e are two plants of variety Shanyou 63, each with 80–100 *N. lugens* eggs, which were planted into the center of the triangle. Numbers indicate locations, and each location included five pots of plants, each with JA-treated plants of one of the five varieties: TN1, Bing 97-34, Xiushui 63, IR26 or IR64

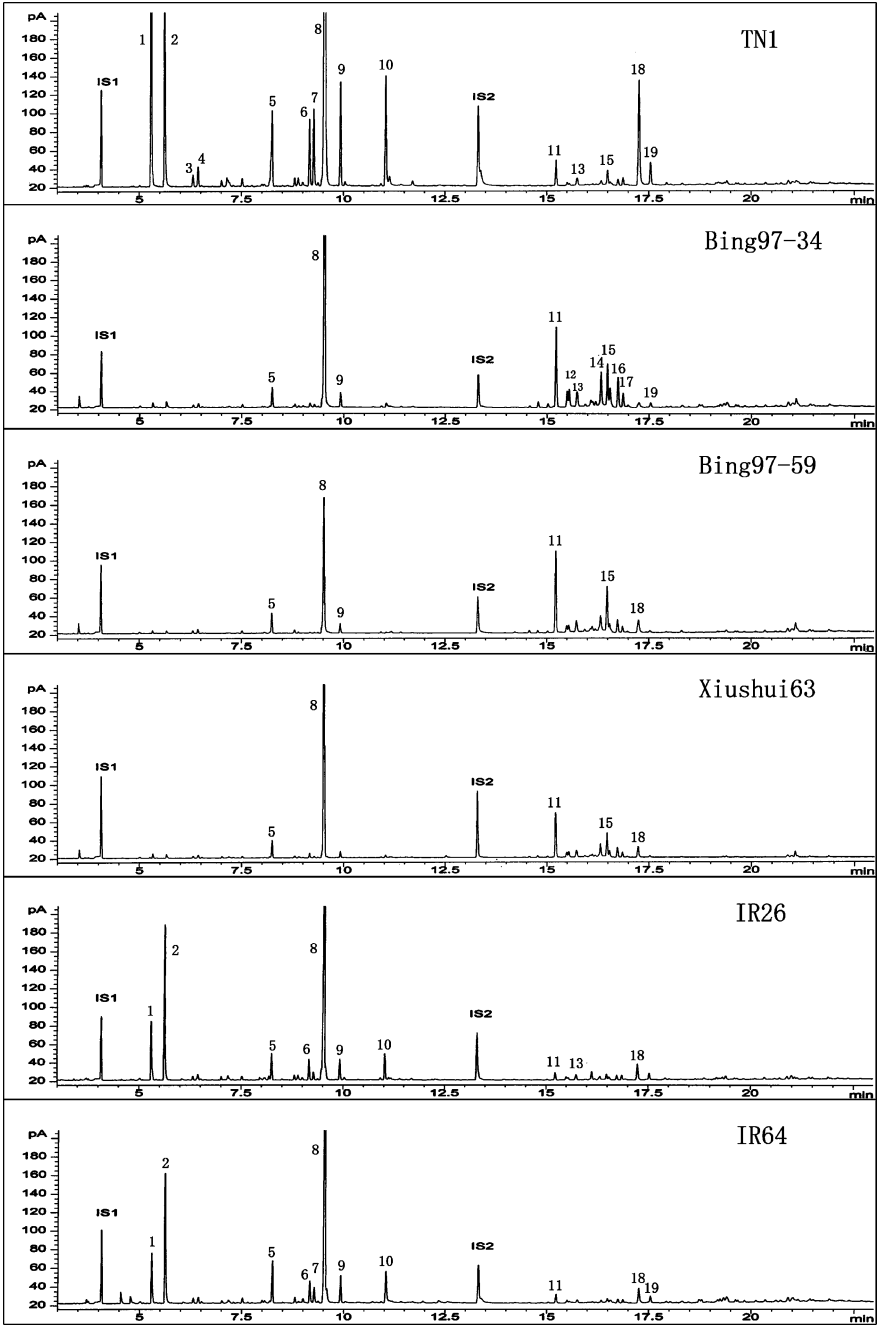

Fig. 2 Typical chromatograms obtained from headspace collections from JA-treated rice plants of rice variety TN1, Bing 97-34, Bing97-59, Xiushui 63, IR26 and IR64. 1, 2-Heptanone; 2, 2-heptanol; 3, unknown 1; 4, unknown 2; 5, limonene; 6, unknown 3; 7, unknown 4; 8, linalool; 9, (*E*)-4,8-dimethyl-1,3,7-nonatriene; 10, methyl salicylate; 11, β -caryophyllene; 12, (*E*)- α -bergamotene; 13, unknown 5; 14, unknown 6; 15, unknown 7; 16, *n*-heptadecane; 17, unknown 8; 18, (*E*)-nerolidol; 19, (*3E,7E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene

Data Analysis

Differences in behavioral responses of the parasitoid to pairs of JA-induced rice volatiles of various varieties were determined by χ^2 tests. To test for differences in parasitism among varieties, we used the Friedman rank sum test. Comparison of the data on plant volatiles were analyzed by analysis of variance (ANOVA) after the data were log-transformed. If the ANOVA analysis was significant ($P < 0.05$), Fisher LSD *post-hoc* tests to detect significant differences among groups were conducted. Data were analyzed with Statistica (Statistica, SAS, Institute Inc., Cary, NC, USA).

Results

Volatiles Comparison

The analyses revealed significant differences in volatile profiles emitted from JA-treated plants of the six varieties (Table 2; Fig. 2). The total amount emitted from TN1 was significantly (from 2.84 to 3.53 times) higher than those from the other five varieties, whereas no differences in total amounts were found among the remaining varieties. The volatile profiles of the six varieties could be roughly divided into three groups. The first group represented the volatiles released from TN1 plants, which, in addition to the total amount, had the highest amount of compounds 2-heptanone, 2-heptanol, limonene, linalool, (*E*)-4,8-dimethyl-1, 3, 7-nonatriene, (*E*)-nerolidol, (*3E,7E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, and unknowns **1**, **2**, **3**, and **4** (Table 2; Fig. 2). The second group consisted of varieties IR64 and IR26 plants. In this group, plants usually released intermediate amount of 2-heptanone, 2-heptanol, and unknown **4**, and the lowest levels of (*E*)- α -bergamotene, *n*-heptadecane, and unknowns **6** and **8**. The third group included Bing 97-34, Bing 97-59, and Xiushui 63 (Table 2; Fig. 2). They usually had the highest levels of β -caryophyllene, (*E*)- α -bergamotene, *n*-heptadecane, unknowns **5**, **6**, **7**, and **8**, and the lowest levels of 2-heptanone, 2-heptanol, unknown **4**, methyl salicylate and (*3E,7E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (Table 2; Fig. 2).

Olfactometer Bioassay

We compared the choices of female *A. nilaparvatae* when offered pairs of odors within groups and between groups. When the parasitoid was exposed to volatiles from pairs of

Fig. 3 Number of *Anagrus nilaparvatae* female adults attracted by volatiles released from JA-treated plants of pairs of varieties: plants were used 15 hr after they were wounded and treated with 40 μ l of 10 mM JA in 50 mM sodium phosphate buffer (pH = 8). Asterisks indicate significant differences between members of a pair ($P < 0.05$, χ^2 test)

Fig. 4 Mean (\pm SE) parasitism rates (%) of *Nilaparvata lugens* eggs by *Anagrus nilaparvatae* in the field on Shanyou 63 rice plants of that were surrounded by JA-treated plants of variety TN1, Bing 97-59 (B97-59), Xiushui 63 (XS63), IR26, or IR64. Plants were placed in the field for 2 days on September (A, $N = 5$) or October (B, $N = 5$), 15 hr after they were wounded and treated with 40 μ l of 10 mM JA in 50 mM sodium phosphate buffer (pH = 8). The differences in parasitism among the varieties were determined by Fieldman rank sum test

varieties within a particular group (IR64 vs. IR26 or Bing 97-59 vs. Xiushui 63), they showed no preference (Fig. 3). However, in two cases, significant preferences were observed between varieties from different groups (Fig. 3). Parasitoids preferred TN1 (group 1) and Bing 97-59 (group 3) over IR26 (group 2), but were equally attracted to TN1 and Bing 97-59 (Fig. 3).

Field Experiment

In the first field experiment, no significant difference was found in parasitism of *N. lugens* eggs on Shanyou 63 plants that were surrounded by JA-treated plants of different varieties (Fig. 4A). However, in the second experiment, there were significant differences (Fig. 4B). These reflected the differences in attractiveness of the varieties that had been observed in the olfactometer experiments (Fig. 3). Parasitism was highest on plants that were surrounded by TN1, followed by those on plants that were surrounded by Bing 97-59 (85.3% of that surrounded by TN1) and Xiushui 63 (76.0% of TN1), and lowest on plants surrounded by IR26 (50.4% of TN1) and IR64 (54.2% of TN1) (Fig. 4B).

Discussion

Varietal or genotypic differences in herbivore-induced volatiles have been recorded for several plant species (Loughrin et al., 1995; Turlings et al., 1998; Krips et al., 2001; Degen et al., 2004). Here, we show such differences in induced profiles among rice varieties (Table 2; Fig. 2). The assignment of the varieties to different groups on the basis of the induced volatile profiles (Table 1; Fig. 2) is consistent with the genetic backgrounds of these varieties (Table 1). For instance, varieties Bing 97-34, Bing 97-59, and Xiushui 63, all of which have a Bing 8961 parent in their pedigrees, shared similar profiles (Fig. 2). The sharing of parents such as IR24 and TKM6, which is the case for IR26 and IR64, also resulted in similar profiles, confirming that the volatiles emitted from varieties are genetically determined.

Volatiles released from both TN1 and Bing 97-59 were more attractive to the parasitoid than those from variety IR26, whereas TN1 and Bing 97-59 were equally attractive (Fig. 3). Moreover, the parasitoid did not distinguish between the volatiles from IR26 and IR64, and those from Bing 97-34 and Bing 97-59 (Fig. 3). A comparison of their profiles (Table 2) does not provide much insight into which compounds may have been responsible for the observed differences in attractiveness. Linalool is a candidate that is attractive to *A. nilaparvatae* (Lou, 1999). 2-Heptanone, 2-heptanol, and methyl salicylate seem less likely to be important because they were released in considerable amounts by some of the least attractive varieties. The importance of specific plant volatiles for attraction of natural enemies is documented. For example, the lacewing (*Chrysopa carnea*), a predator of small insects, was caught more in traps containing β -caryophyllene than in traps that contained caryophyllene oxide, bisabolene, or limonene (Flint et al., 1979). When exposed to individual chemicals in an olfactometer, the predatory mite *Phytoseiulus persimilis* was attracted to linalool, methyl salicylate, (*E*)- β -ocimene, and (3*E*)-4,8-dimethyl-1,3,7-nonatriene (Dicke et al., 1990). (*E*)- α -Bergamotene increased *Manduca sexta* egg predation rates on *Nicotiana attenuata* by a generalist predator *Geocoris pallens* (Kessler and Baldwin, 2001). Recently, Kappers et al. (2005) demonstrated that the predatory mite *P. persimilis* is attracted by (*E*)-nerolidol or (3*E*)-4,8-dimethyl-1,3,7-nonatriene released from transgenic *Arabidopsis thaliana* plants. Similarly, transformation of *Arabidopsis* with a sesquiterpene synthase gene from maize resulted in the constitutive release of a blend of sesquiterpenes, which made the transformed plant attractive to a parasitoid of lepidopteran larvae, but the parasitoid had to learn the volatiles during an oviposition experience (Schnee et al., 2006). In general, the identities of key attractants for parasitoids remain largely unknown (D'Alessandro and Turlings, 2006), and common herbivore-induced compounds may not be as important for attraction as usually assumed (D'Alessandro and Turlings, 2005).

We have previously shown that parasitism rates of *N. lugens* eggs by *A. nilaparvatae* on plants surrounded by JA-treated plants are significantly higher than those surrounded by control plants (Lou et al., 2005a). Here, we compared the effect of JA-treated plants of various rice varieties on parasitism. The clear and significant differences found in the second field experiment nicely matched the differences in attraction of the parasitoid that were found in the olfactometer bioassay. The average percentage parasitism (55.82 ± 2.63) in the first field experiment was significantly higher than that (38.29 ± 2.27) in the second time ($t = 5.05$, $df = 48$, $P < 0.001$). This suggests a higher population density of the parasitoid in the field during the first field experiment. Parasitoids may interfere with each other intraspecifically or interspecifically, and the degree of interference increases with the increase in population density. Parasitoids and predators may also use volatiles to avoid intraspecific or interspecific competition (Janssen et al., 1995, 1997; Fatouros et al., 2005). Therefore, stronger interference among parasitoids under high population density might explain why there was no difference in parasitism rates among varieties in the first field experiment. From the results of the second experiment, however, it is clear that rice varieties with appropriate volatile profiles might enhance the effectiveness of the parasitoid in the field.

Many parasitoids have a keen ability to learn to respond to a specific odor by associating the odor with hosts or host feces (Lewis and Tumlinson, 1988; Vet and Groenewold, 1990; Turlings et al., 1993b). The parasitoids used here had emerged from *N. lugens* eggs on plants of variety Shanyou 63, and they had been in contact with this host plant before they were tested. The field experiments with potted plants were conducted in fields with the variety Jialeyou 2, on which the parasitoids would also have had experiences during the experiment. It is possible that the observed differences in attraction and parasitism were due to similarities or differences in volatile profiles between the *N. lugens*-infested rice varieties

that the wasps experienced and the JA-treated experimental plants. We did not compare the volatile profiles of these varieties, and an effect of learning cannot be ruled out. This does not interfere, however, with the general conclusion that differences in volatile profiles and preferences for certain odors can be used to enhance the parasitism rate of *A. nilaparvatae*.

Only few studies have demonstrated the importance of herbivore-induced odor emissions outside the laboratory (Scutareanu et al., 1997; De Moraes et al., 1998; Thaler, 1999; Kessler and Baldwin, 2001; Lou et al., 2005a; Rasmann et al., 2005). One of those studies (Rasmann et al., 2005) also shows that the effectiveness of the natural enemies in the field can be enhanced by planting crop varieties that emit the appropriate volatile signal(s) from their roots. The results reported here represent a first example of how varietal differences in leaf volatiles affect tritrophic interactions in the field, implying that induced rice volatile emissions can be manipulated to enhance the control potential of egg parasitoids.

Acknowledgments We thank Wenwen Song, Guoxin Zhou, and Xia Wang for assistance with laboratory work. Key words *Adelges tsugae* · chemical indicators · GC/MS · eastern hemlock · hemlock woolly adelgid · phenology · plant resistance · SPME · terpenes · terpenoids · *Tsuga canadensis*

Introduction

The genus *Tsuga* (hemlock trees) consists of nine species, two in eastern North America, two in western North America, and five in Asia (Farjon, 1990). The Asian and western North American hemlock species are considered resistant to the hemlock woolly adelgid, *Adelges tsugae* Annand, whereas the eastern North American species are susceptible to feeding by the adelgid, resulting in a slow decline in tree health and eventual tree death (McClure et al., 2001). The hemlock woolly adelgid (HWA) is an introduced pest to North American hemlock. The predominant eastern North American species is *T. canadensis* (L.), with pockets of *T. caroliniana* Engelm. in the Southern Appalachians. We previously examined the terpenoid profiles of seven species [*T. caroliniana*, *T. canadensis*, *T. chinensis* (Franch.) E. Pritz., *T. diversifolia* (Maxim.) Mast., *T. heterophylla* (Raf.) Sarg., *T. mertensiana* (Bong.) Carriere, and *T. sieboldii* (Carriere)] by solid-phase microextraction (SPME) sampling with gas chromatography/mass spectrometry (GC/MS) analysis in the headspace of a single needle of mature foliage (Lagalante and Montgomery, 2003). Data reduction by principal component analysis (PCA) revealed a “species” component and a “resistance/susceptibility” component. Examination of factor loadings of individual terpenoids within the resistance/susceptibility component revealed 13 terpenoids with statistically significant ($P < 0.05$) factor loadings.

While our previous study provided a foundation for understanding the role of terpenoid chemistry in species level resistance to HWA, this study focused on how the patterns of terpenoids vary in time and space within the susceptible species, *T. canadensis*. Although the needle is the most convenient and consistent place to sample for comparing terpenoid variation among hemlock species, it is not the exact location where the adelgid feeds. The adelgid crawler (a newly hatched nymph that is the only mobile stage on eastern hemlock) settles at the base of the needle and inserts a stylet bundle (a feeding tube three times its body length) just below the leaf abscission layer into the leaf cushion. It technically feeds on nutrients in the stem wood and the xylem ray parenchyma tissue rather the leaf needle (Young et al., 1995). The needle possesses a single resin canal along the ventral side of the midrib; however, defined resin canals are absent in the woody tissue (Farjon, 1990). Therefore, it is important to compare the terpenoid chemistry in the needle and the leaf cushion.

The lifecycle of the HWA consists of two parthenogenetic generations per year on hemlock. The spring generation (progrediens) develops between March and June, and the overwintering generation (sistens) develops between June and March, with overlap of the two generations in the late spring. Between June and mid-July, hatched crawlers of the sistens generation settle preferentially at the base of the current year’s growth needles and insert their stylet bundles into the immature leaf cushion. They do not feed during this period; instead, they enter summer diapause (estivation). In October, when the weather cools, estivation is broken and feeding commences, and the sistens’ nymphs mature over the winter to produce the progredien generation the following spring (McClure, 1987). The progredien generation crawlers settle preferentially on the same age tissue on which their sistens’ parents fed. Generally, both generations of the adelgid feed on foliage that is mature, but less than 14 mo old at the tip of the branch. In the late spring and early summer, the sistens crawlers

move onto the new foliage, settle, and enter diapause. Thus, there are “winter” and “spring” feeding periods on mature foliage separated by a “summer” nonfeeding period on immature foliage.

The current study examined how the terpenoids in the foliage of *Tsuga canadensis* vary: (1) temporally during three feeding periods of the HWA, (2) spatially between the new growth and the previous year’s growth, and (3) spatially between the needle and leaf cushion tissues. The spatial and temporal results obtained are interpreted in relation to the settling preferences and feeding of the HWA on eastern hemlock.

Methods and Materials

Plant Material Samples were collected from June 2003 to May 2004 from a hemlock stand located at Lake Scranton (41.3858°N, 75.6286°W) in Scranton, PA, USA. The area around Lake Scranton possesses hemlock stands that span the entire range of HWA population densities, from dense conspicuous infestations where branches are covered with white ovisacs to stands that are visually uninfested. A stand of healthy hemlock with a light infestation (possessing only a few visible ovisacs scattered among trees in the stand) on the eastern shore of the lake was selected as a sampling site. This particular stand was selected because the vast majority of branches were devoid of adelgid or other pests, yet a neighboring stand (approximately 0.5 km closer to the lakeshore) possessed moderate to heavy levels of adelgid where we could observe the settling behavior of the crawlers of the 1st instar nymph stage. Thus, our analytical results are based on the terpenoid present in healthy hemlock, presumably devoid of induced host-plant responses from adelgid wounding.

Hemlock trees, approximately 10 m in height, were tagged within the sampling site, and the peripheral 10 cm of foliage was periodically clipped from branches lying approximately 2 m above ground level. Due to time constraints imposed by the analytical method, one of the six trees was sequentially sampled each day to provide a single branch clipping for analysis. The clipped branch was immediately placed in a polyethylene bag in a cooler on ice packs and taken to the laboratory. Dissection and analysis were initiated <1 hr postsampling. Although the buds started opening in mid-May 2003, needle dissections were not possible on the tiny (3 mm), pliant, bright green foliage. Thus, sampling was delayed until June when the shoot had elongated to an average of 2 cm and the needle length had reached 10 mm. Initially, about 5 samples were collected each week, with the sampling frequency decreasing in November when the 2003 foliage had visually matured (turned dark green). Sampling was terminated when bud break occurred for the 2004 year’s growth in May.

Sample Preparation On each sampling date, 6 samples were analyzed from one hemlock twig; 2 samples were needles representing new growth (2003), 2 samples were needles representing the previous year’s growth (2002), 1 sample comprised 5 combined, new growth (2003) leaf cushions, and 1 sample comprised 5 combined, previous year’s growth (2002) leaf cushions. The samples were collected, prepared, and analyzed for terpenoids on the same day. This method minimized extraneous influences on comparisons between the two types of tissue and the two foliage ages.

We define the twig as a branch tip consisting of the linear length from the tip back to the start of the previous year’s growth, ignoring any lateral shoots. The needle and leaf cushion (pulvinus) are separated by an abscission layer (Fig. 1). In hemlocks, as in most conifers,

Fig. 1 Photograph indicating the cuts performed in the leaf cushion dissection. Arrows indicate the direction of cuts and numbers are referred to in the text. A removed leaf cushion is shown in the inset picture

the leaf or needle consists of the blade and a very short petiole. During the sampling period, the abscission layer was distinct in both young and mature tissue. The leaf cushion is the thickened base below the abscission layer that remains after the leaf falls off the stem. The leaf cushion is technically part of the woody stem tissue and contains the nutrient laden ray parenchyma cells that the adelgid penetrates with its stylet bundle during feeding.

Under a stereoscope at 40 \times , 2 needles from the 2002 growth and 2 from the 2003 growth were broken cleanly away from the leaf cushion at the leaf abscission layer with a stainless steel scalpel. Using the same shoot from which the needles were taken, 5 needles representing the previous year's growth (2002) and 5 representing new growth (2003) were selected for leaf cushion dissection. The needles were removed at the leaf abscission layer as described above. The needle portion was discarded, and two cuts were made with a stainless-steel scalpel (Fig. 1). The first cut (arrow 1) was made along the twig from the distal to the basal end of the leaf cushion. The second (arrow 2) was made perpendicular to the first cut at the bend denoting the base of the leaf cushion. On the mature previous year's growth, the leaf cushion is distinctly darker brown than the light-tan stem, thus allowing a visual cue for the second cut. On immature needles, the distinct visual color difference does not exist, and so the placement of the cut was made at the same relative angle and position used for dissecting mature tissue. The five leaf cushions from new growth (2003) and five cushions from previous year's growth (2002) were collected in two separate 4-ml screw-top vials and capped with PTFE/silicone septa (VWR Scientific, Pittsburgh, PA, USA). Five leaf cushions were necessary to produce a measurable terpenoid profile, owing to the reduced amount of plant volatiles in the leaf cushion as compared to the needle that contains a foliar canal where the resins are concentrated.

SPME/GC/MS Analysis We used a headspace SPME sampling procedure for both the needle and leaf cushion analyses (Lagalante and Montgomery, 2003). The GC/MS conditions were identical except a splitless injection was used for the individual sample containing 5 leaf cushions. The same 51 compounds previously quantified by Lagalante and Montgomery (2003) were identified from a mass spectrum database search (Varian NIST MS database, 1998, and IMS terpene library, 1992), and on the basis of their measured retention indices as compared to the retention indices reported using an equivalent DB-5 column (Adams, 2001). The area under an identified peak was integrated

by using a single m/z fragment from the total ion spectrum for each compound. The m/z fragment was the most intense ion in the mass spectrum that was provided from our previously published work. Relative, as opposed to absolute, amounts (area percent) of an individual compound were calculated from the ratio of the peak area for an individual compound, relative to the total peak area for all identified compounds in a chromatogram.

On a given day, the SPME/GC/MS analyses were performed on 6 samples from a single twig as described above. Fifty-one terpenoids were measured for each of the 6 samples on each sampling day. Of the 51 terpenoids, 28 were present in amounts that averaged <0.1%, and these were not included in the statistical analysis.

Statistical Analysis There were 11 sampling days during the first “spring” period (June 10 to July 14, 2003), 10 sampling days during the second “summer” period (July 15 to October 14, 2003), and 15 sampling days during the third “leaf-off” period (October 15, 2003 to May 10, 2004). This division of periods is made to correspond to distinct aspects of the adelgid’s life history on hemlock: spring, summer, and leaf-off. Spring is when the progrediens generation crawlers select feeding sites, generally settling on the current year’s growth and immediately feeding and completing development in about 2 mo. Summer is when the sistens generation crawlers settle on the new, current year growth but enter diapause. Leaf-off is when the sistens generation feeds and develops.

We used a three-way ANOVA in the general linear model (GLM) procedure of Systat 11 (Systat Software, Richmond, CA, USA) to examine influence of the three factors: (1) *tissue* (needle or leaf cushion), (2) *age* [current year (2003) or previous year (2002) growth], and (3) *period* (spring, summer, leaf-off) and their interactions. Each twig sample within the seasonal periods was treated as a block, and, thus, twig is nested within tissue. *F*-tests were performed on the main effects and the interactions and *P* values were evaluated at the 0.05 significance level (95% confidence interval). Systat Software was also used to conduct PCA on the symmetric correlation matrix of the terpenoids in order to collapse the variability into a few components so that meaningful relationships could be identified.

Classical multidimensional scaling (CMDS) was used to calculate distances among the four “spatial” components (two ages and two tissues) for each twig sample by using all the terpenoids listed in Table 1. The distance matrix was calculated by using a cityblock measure (Manhattan distance) and the *pdist*, *eigval*, and *cmdscale* commands with Matlab® Statistics Toolbox 5.2 software (MathWorks, Natick, MA, USA). This analysis was then separated into the period components to show how the “spatial” relationships change temporally. The scaling analysis was repeated by using global nonmetric multidimensional scaling (GNMDS) and Bray–Curtis coefficient distance to ensure that the obtained results were consistent with the CMDS procedure, and not dependent on the type of MDS or distance variable used. Since the results of the GNMDS agreed with those of the CMDS, they are not included here.

Results

Visually, the new growth progressed from a bright green, pliant needle in May to a dark green, hardened needle in November. By November, the new, current year’s growth of both the needle and leaf cushion were visually identical to the previous year’s growth needles and leaf cushion. The twig also had matured and hardened, although it was not nearly as hard as the previous year’s growth. This visual maturation coincides with the sistens generation crawler breaking estivation and commencing feeding.

Table 1 Terpenoid percentages (Least squares means and Standard errors) and significance tests of the three factors: Age (Previous or Current year's growth), Period of the year (Spring, Summer, Leaf-off) and Tissue (Needle or Leaf cushion)

Period	Spring		Summer		Leaf-off		Spring		Summer		Leaf-off		Age × Period × Tissue <i>F</i> (<i>P</i>)	Age × Period × Tissue <i>F</i> (<i>P</i>)	Age × Period × Tissue <i>F</i> (<i>P</i>)

Table 1 summarizes the mean values (with standard error) of the percentages and the statistical tests associated with the variables measured for the terpenoids. Additional terpenoids not listed in Table 1 were present at levels below 0.1% and could not be reliably quantified. There were significant main effects and interactions for most of the measurable terpenoids. The data are complex and patterns are not readily visualized. For instance, isobornyl acetate, the most abundant terpenoid, is at higher levels in the new growth needles and at lower levels in the new growth leaf cushions during the spring and summer periods. During the leaf-off period when the foliage has visually matured, the percentages of isobornyl acetate are similar in both the needles and cushions in both the current and previous year's growth. The statistical tests indicate that the needle and leaf cushion tissues are not different generally, but do differ from each other within age and period. Hence, the isobornyl acetate content in the needles and leaf cushions depends on the age of the foliage and the time of the year. Although inferences can be drawn from Table 1 for other terpenoids by visual inspection, ordination analysis provided a more objective and powerful method to discern the terpenoid inter- and intrarelations.

CMDs was used to assess the relationships among the two tissues and two age growth classes in each of the three time periods, based on the composition of all 23 terpenoids (Fig. 2). This approach demonstrates three key patterns relating host chemistry and adelgid feeding. First, the ordination shows that the chemical composition of both old and new needles is similar, and that the variation in chemical composition within and between both groups is relatively small. In other words, needles vary little spatially or temporally. This is not the case for leaf cushions. For the leaf cushion, there are two patterns. The leaf cushions are widely scattered and in separate groups, and this changes with the time period. The widely scattered points for the leaf cushions in both the spring and summer periods indicate that the adelgid crawlers of both generations encounter a highly unpredictable chemical mixture. In the last period, by leaf-off, the scatter for the leaf cushions is greatly reduced and data points coincide with those for the needles.

PCA was used to identify which individual terpenoids are varying in similar patterns and which may be phytochemically important. The correlation matrix was analyzed by using the 23 terpenoids in the 138 tissue and age samples as variables for the PCA. Next, dummy variables for the age, period, and tissue factors were introduced in order to more easily identify which factors were influencing the component loadings. Introducing the dummy variables had little influence on the loading of the terpenoids. The initial run produced six latent roots (eigenvalues) greater than 1.0 and explained 73% of the total variance. It was difficult to find meaning in so many components, so the components were limited to three (Table 2). First, second, and third components accounted for 30.3%, 14.3%, and 9.7% of the total variance, respectively (54.7% total).

The first component (Table 2) seems to be most associated with the tissues. There are nine terpenoids with high, positive loadings (>0.5). Table 1 indicates that these are generally higher in the needles than in the leaf cushions. There are four terpenoids with negative loading (<-0.5), and these have higher levels in the leaf cushions than in the needles. This pattern among these fourteen terpenoids with positive or negative high loadings is often reversed in the current growth tissues in the spring period. This was identified in the second component, which is interpreted as the interaction between the age and period factors. There are high, positive loadings for isobornyl acetate and piperitone, and high, negative loadings for myrcene and germacrene D. The third component represents a weak relationship that may be represented by the interaction among all three factors in the statistical model (age, period, tissue). The high positive loading terpenoids (*o*-cymene, viridiflorene, δ -cadinene, and γ -cadinene) have higher percentages in leaf

Fig. 2 Classical multidimensional scaling ordination as a function of the terpenoid composition of each sample: 2002 leaf cushion (Δ), 2003 leaf cushion (\blacktriangledown), 2002 needle (\circ), and 2003 needle (\bullet). The positions were simultaneously calculated for all samples and then separated into time periods of June 6–July 14 (spring), July 15–October 14 (summer), and October 15–May 10 (leaf-off)

cushions than needles except during the leaf-off period. This pattern is reversed for the high negative loading terpenoids isobornyl acetate and sabinine. Except for isobornyl acetate, the terpenoids with the higher loadings in this component are generally present in the samples at <1.0%. The importance of these low-level terpenoids is uncertain because in the PCA analysis the mean is subtracted across the data dimensions; hence, the PCA analysis does not consider the overall level of the terpenoid in the eastern hemlock.

Table 2 Values of component loadings for the three factors and 23 terpenoids on the three components of the PCA

We identified six terpenoids considering components 1 and 2 together, and plotted their means in Fig. 3. Here, the focus was on comparison of the tissues on which the adelgid feeds (denoted with an \times) with the other tissues. Although the adelgid does not feed on needles, we hypothesized that we could use them as a means to probe host–insect chemical interactions, as the terpenoid levels in needles are more readily analyzed. Although there was not an exact match between terpenoid percentages between the two tissues, levels were similar. Furthermore, all plots in Fig. 3 show that during adelgid feeding periods in the leaf cushion, the tissue that is being fed upon has a stable percentage of the terpenoid.

Myrcene levels in the leaf cushion, but not the needles, were elevated in the immature foliage shortly after shoot extension. Myrcene dramatically increased to become a dominant terpenoid in the leaf cushion during the period over the summer months and decreased by leaf-off to endogenous levels present in previous year's growth tissues. The other dominant terpenoids in the leaf cushion were isobornyl acetate and germacrene D. In November, the needle took on a dark green color and a dramatic hardening of the cushion was evident. Thus, the visual physical maturation of new growth coincided with the chemical maturation of the new growth as well as with the conclusion of estivation and the beginning of the sistens feeding period. Throughout this time period, myrcene levels in the needles remained equivalent to the current and previous year's growth needles.

The period behavior of the sesquiterpene germacrene D in leaf cushions was similar to that of myrcene in leaf cushions. However, unlike myrcene, slightly elevated levels of

Fig. 3 Select terpenoid percentages (mean±standard deviation) as a function of the period factor grouped according to tissue and clustered by age: current year's (2003) growth (■), previous year's (2002) growth (□). The symbol × indicates a period and tissue fed upon by the hemlock woolly adelgid

germacrene D were also found in needles during the spring period. Once again, by approximately November 2003, the levels of germacrene D decreased to levels that are indistinguishable from the new and previous year's growth in both areas of tissue. The monoterpene, α -pinene behaved similarly to germacrene D, as indicated by its 2nd component PCA loading. As indicated by a positive 1st component loading, α -pinene is slightly more abundant in needles than leaf cushions.

Isobornyl acetate is the predominant volatile chemical constituent of both the needle (40–45%) and leaf cushion (50–55%) in mature tissue. In spring, new growth needle tissue, isobornyl acetate levels are increased relative to old growth needle tissue while the leaf cushion tissue exhibits a depletion in isobornyl acetate compared to previous year leaf cushions. Although at lower relative percentages, α -humulene, and piperitone display depletion in the leaf cushion similar to isobornyl acetate as indicated by their 2nd component PCA loading.

Discussion

The objective of this study was to determine if temporal and spatial variations in percentages of volatile terpenoids in eastern hemlock are linked to the biological life cycle of the HWA. The HWA positions itself distally to the leaf abscission layer but the stylet bundle is inserted proximally to the leaf abscission layer. Electron micrographs reveal that the 1.04- to 1.27-mm stylet bundle penetrates in the proximal direction of the twig and not in the distal direction of the needle tip, terminating in the ray parenchyma cells located within the leaf cushion (Young et al., 1995). A statistically detectable temporal and spatial variation of germacrene D and isobornyl acetate exists within the leaf cushion. In our previous work, PCA identified germacrene D as a compound with a high factor loading in the resistance/susceptibility component of an interspecies comparison among worldwide *Tsuga* (Lagalante and Montgomery, 2003). Comparison of germacrene D levels in the needles among seven species of *Tsuga* revealed that elevated percentages are found in species that are considered resistant to mortality from the HWA as compared to susceptible species (21.65% in *T. mertensiana* and 10.58% in *T. sieboldii*). Also, isobornyl acetate levels in these *Tsuga* species are elevated in the susceptible species. Unlike germacrene D, isobornyl acetate may function as a potential attractant to the HWA.

If these terpenoids have the ability to attract or deter HWA, then settling preferences may be distinguishable between the sistens and progrediens generations of the adelgid. Generally speaking, terpenoids are often toxic or repellant to insects due in part to their ability to inhibit acetylcholinesterase in the neuromuscular junction (Harrewijn et al., 2001). Although monoterpenes do not act on the acetylcholine receptor directly, they can function as competitive inhibitors through binding with acetylcholine. Additionally, HWA, like many herbivorous insects, harbors symbiotic microorganisms that are essential to its survival (Shields and Hirth, 2005). Such symbionts may be susceptible to antibiotic effects of terpenoids.

The crawler phase of the 1st instar of both the sistens and progrediens generations is the only stage of adelgid on hemlock that is capable of selecting feeding sites. Thus, variation in terpenoid levels during each generation's crawler stage may influence settling preferences and survival. For the sistens generation, depending on local climate and elevation, crawler settling generally occurs by mid-July, at the end of the "spring" period. If the sistens crawler settles on new growth, it is likely to encounter a different terpenoid profile in needle and leaf cushion tissue. Depending on the health of the tree, sistens crawlers will settle preferentially on new growth in July (McClure, 1991). However, they do not feed during the summer but instead enter estivation until cooler weather in October when estivation is broken. The adelgid then feeds over the colder winter months and matures to produce up to 300 eggs by April. Following initial high colonization on new growth foliage, the production of the next year's new growth will be severely inhibited, forcing colonization on previous years growth and a subsequent population crash (McClure, 1991).

Most aphids and adelgids avoid mature tissues and feed preferentially on new growth, possibly because older foliage has lower levels of nutrients and higher levels of allelochemicals (Miles, 1990). The primary content of the parenchyma cells of softwoods are steryl esters, fats, and waxes, whereas the canal resin is primarily composed of terpenes and terpenoids (Back, 2002). The salivary sheaths of aphid and adelgid stylet bundles may be able to seal off cell ruptures along the feeding path to avoid plant chemical defenses and wounding responses by absorbing allelochemicals before the undamaged, surrounding cells can be signaled (Miles, 1987, 1990). Since the function of the parenchyma cells is to store metabolites that are mobilized for new growth the following spring, the parenchyma cells of the new growth tissue should not possess high nutrient levels until mid-fall. Thus, the sistens crawlers could not detect high nutrient levels to select an optimal feeding site during stylet probing in July.

Given the general unsuitability of older growth foliage, one might conjecture that a seasonal chemical signal may serve as an indicator of tissue suitability during the period when the adelgid probes leaf cushion tissue with its stylet bundle. The spring emergence of western spruce budworm (*Choristoneura occidentalis* Freeman) larvae has been associated with the annual cycle of select foliar monoterpenes in Douglas-fir (*Pseudotsuga menziesii* (Mirb.) Franco) as an indicator, not the cause, of foliage suitability (Nealis and Nault, 2005). Similarly, elevated relative levels of either myrcene or germacrene D detected while probing leaf cushions may be indicators to settle on new growth tissue that will be nutrient-rich during fall. Although myrcene and germacrene D were identified as potential deterrents to HWA in our previous study, the adelgid estives with its stylet inserted, but does not actually feed during summer when these chemicals are elevated; thus, any possible toxic effects are avoided. By the time feeding commences in mid-October, terpenoid levels in new growth tissues have been reduced to background endogenous levels.

Studies linking terpenoid composition to HWA infestation levels are limited to a single reported study in which correlations were made between the volatile emission from eastern hemlock and adelgid population levels between August 20 and August 28, 2001, in a nursery plot in Blacksburg, VA, USA (Broeckling and Salom, 2003). These researchers reported that in respect to the relative percentage of individual terpenoids, there was a stronger correlation with adelgid population levels than with foliage age, although the two variables were not independent of one another. The hemlock trees selected in our study were healthy, displaying no outward signs of even moderate adelgid infestation. Thus, we would not have observed this density-dependent feedback with volatile emissions from the previous year's growth tissues.

Unlike the sistens generation, the progrediens generation 1st instar crawler does not have a choice of settling on new or previous year's growth because all the foliage is mature in March. From April to June, the progrediens generation crawlers will feed in the previous year's growth tissue that has a more stable composition of terpenoids. Interestingly, if the population of overwintering sistens is high on the shoot, the progrediens crawlers appear to survive better on the older growth, more proximal on the shoot. The progrediens crawlers mature to produce approximately 50 eggs that will become the sistens generation. Late hatching progrediens crawlers also have the possibility of settling on new foliage. Unfortunately, we could not sample this new growth (immediately post bud-break in May) due to difficulties in dissecting the pliant, young plant tissue. Therefore, the temporal and spatial variations in terpenoid levels in this study are more open to interpretation for the sistens generation.

Mortality of progrediens crawlers on new growth foliage is in agreement with our previous PCA assertion that identified myrcene and germacrene D as potential chemical deterrents (Lagalante and Montgomery, 2003). Unlike the sistens crawler that settles on

new growth and estivates, a progrediens crawler that settles on new growth immediately begins feeding on the immature leaf cushion and may ingest elevated levels of the potentially toxic myrcene and germacrene D. Although we did not separate enantiomers on a chiral GC column, germacrene D isomers are reported in volatile chemical communications in the aphids *Euceraphis punctipennis* (Zetterstedt) (Francis et al., 2005) and *Therioaphis maculate* (Buckton) (Bowers et al., 1977). (–)-Germacrene D elicited a strong repellent response in *Sitobion avenae* (F.) although (+)-germacrene D isomer elicited no response (Bruce et al., 2005). High concentrations of limonene and myrcene in Douglas-fir deter *A. cooleyi* (Gillette) (Stephan, 1987), and high concentrations of myrcene and piperitone in Sitka spruce [*Picea sitchensis* (Bong.) Carr.] deter several species of aphids (Jackson et al., 1996). Thus, it is reasonable to hypothesize that elevated relative levels of select terpenoids in new growth of eastern hemlock leaf cushion tissue would promote mortality in the progrediens generation of *Adelges tsugae* that settles on new foliage. Likewise, if isobornyl acetate is a chemical attractant for HWA, decreased relative levels in new growth leaf cushions may promote stylet insertion in cushions from the previous year's growth where levels of isobornyl acetate are elevated (Fig. 3). This chemical cue would promote survival of the progrediens generation crawler on previous year's growth, as levels of the all terpenoids are already reduced to endogenous levels during the progrediens crawler stage. The crawler stage of *Adelges piceae* (Ratzeburg) on *Abies balsamea* (L.) continually touch the bark surface with their antennae until settling, suggesting that the crawler is possibly seeking a stimulus from parenchyma cells (Bryant, 1974).

A detailed study of HWA fecundity and population levels as related to settling preferences may further elucidate the role of temporal and spatial chemical variation in levels of terpenoids and their role in resistance/susceptibility to adelgid infestation. Visual maturation of the eastern hemlock foliage was coincident with the levels of all volatile terpenoids reaching the endogenous levels found in the previous year's tissues. We conclude that deviations from endogenous levels for isobornyl acetate, myrcene, and germacrene D have biological implications in relation to the feeding periods of the hemlock woolly adelgid on eastern hemlocks.

exploring their potential in controlled scientific studies (Lewis et al., 1999). Plant alkaloids are a diverse group of compounds in both structure and function. While there are numerous examples of alkaloids currently utilized in both medicine and industry, considerable potential remains for novel molecules from natural resources.

α -Solasonine and α -solamargine (Fig. 1) are the two dominant steroidal glycoalkaloids (GAs) extracted from plants belonging to the Genus *Solanum* (Ripperger, 1995). Composed of a lipid core and a trisaccharide carbohydrate moiety, they differ only in that α -solamargine terminates in two rhamnose sugars, positioned on the 2' and 4' carbons of the bridging D-glucose sugar, whereas solasonine has a rhamnose and glucose in the 2' and 3' positions of D-galactose, respectively (Fig. 1). α -Solasonine and α -solamargine have shown cytotoxicity against protists, fungi, and various tumor cell lines *in vitro* and *in vivo* (Kupchan et al., 1965; Cham et al., 1987; Fewell et al., 1994; Chataing et al., 1998).

The importance of the carbohydrate moiety in mediating the effects of solasonine and solamargine has been repeatedly confirmed (Roddick et al., 1990, 1992). Studies on cytolytic effects of GAs on Hep3B and Sarcoma 180 tumor cell lines implicated interactions

Fig. 1 Structures of solamargine and solasonine

between rhamnose-specific binding proteins (RBPs) on the target cell surface and the terminal rhamnose sugars of the alkaloids (Cham and Daunter, 1990). Separate experiments using the Hep3B cell line found that rhamnose-specific interactions led to the induction of apoptotic mechanisms through tumor necrosis factor (TNF) signaling (Chang et al., 1998). The importance of rhamnose in toxicity against phytoparasitic nematodes has also been confirmed (Udalova et al., 2004).

A 1:1 mixture of α -solasonine and α -solamargine demonstrated synergistic cytotoxic effects on tumor cells (Cham et al., 1987). Similar effects were reported in antifungal studies (Fewell et al., 1994). In the first study, mixtures effectively killed tumor target cells at concentrations significantly lower than with either alkaloid alone. This was taken as an indication of distinct, but cooperative pathways for α -solasonine and α -solamargine function. Experiments testing the efficacy of this 1:1 mixture against S180 sarcoma tumors in mice found an increase in animal survival rate compared to controls deprived of alkaloid (Cham and Daunter, 1990). Subsequent studies reported that the administration of exogenous L-rhamnose significantly reduced survival in S180 challenged mice that received such treatments, suggesting that competitive inhibition of RBPs on the tumor cell surface attenuated the uptake of the alkaloids. A formulation of this compound is currently marketed under the trade name Curaderm as a topical treatment of premalignant and malignant skin cancers in humans (Cham et al., 1987).

Trypanosoma cruzi is a zoonotic hemoflagellate protozoan parasite and the etiologic agent of Chagas disease in humans. Current therapy for *T. cruzi* infection depends on synthetic drugs such as nifurtimox and benznidazole, which are only effective during the acute stage and are frequently associated with severe side effects. One complicating factor in drug development has been that different *T. cruzi* strains and lifecycle stages have not been consistent in their susceptibility to pharmacologic compounds (Chena et al., 2005).

When tested against the EP strain of *T. cruzi* *in vitro*, α -solamargine induced cytolysis of epimastigotes (EMs) (Chataing et al., 1998). In these experiments, α -solasonine was roughly half as effective, suggesting a role for the terminal rhamnose sugars in parasite killing. The same study showed that hydrolysis of the glycosidic residue reduced α -solamargine's anti-parasitic activity, further supporting a role for the carbohydrate moiety in mediating cytolysis. The authors stated that they observed differences in the responses between EMs and bloodstream form trypomastigotes (BSFs) upon exposure to α -solamargine. Although they failed to provide data in support of this statement, they suggested that stage-specific membrane constituents are important in susceptibility to these alkaloids.

This report assesses the efficacy of α -solasonine and α -solamargine against two distinct *T. cruzi* genotypes. We also evaluated lifecycle stage susceptibility over a range of solasonine and solamargine concentrations, as well as the effects of 1:1 compounding on parasite cytolysis. The role of rhamnose in mediating parasite attrition is also investigated through competitive inhibition experiments.

Methods and Material

Alkaloid Purification and Preparation

α -Solasonine and α -solamargine were extracted and purified from the fruits of *Solanum khasianum* by previously described procedures (Cipollini and Levey, 1997a). The purity of each was verified by high-performance liquid chromatography (HPLC) as described by Bushway et al. (1986). Authenticated preparations of α -solasonine and α -solamargine for

quality control monitoring during chromatography and HPLC procedures were obtained from Plantech (Reading, UK). Each alkaloid was separately freeze-dried and stored at -20°C until use. For culture, the purified alkaloids were initially dissolved in dimethyl sulfoxide (DMSO) at a concentration of 7 mg/ml. For preparation of 1:1 SM/SL, an equal weight ratio of solasonine and solamargine were combined and dissolved in DMSO as above. Alkaloid solutions were diluted to working concentrations in complete Dulbecco's modified Eagle's medium (cDMEM) for assays involving BSF stages, whereas those requiring EMs were diluted in complete liver infusion tryptose broth (cLIT) (Powell and Kuhn, 1980).

Parasites and Cultures

The type I Brazil strain (BS) and a type II North American isolate (LI) of *T. cruzi* were routinely maintained by serial passage in BALB/c mice or in cLIT. BSF parasites were routinely obtained by coculturing with DH-82 canine monocytes in cDMEM at 37°C , 5% CO_2 . EMs were recovered from log growth phase cLIT cultures.

Cytotoxicity Assay

For cellular toxicity assays, 96-well tissue culture plates were seeded with 100 μl of cDMEM containing 2×10^4 BSF stages. EM stages were prepared in cLIT and diluted to $1 \times 10^6/\text{ml}$. Stock solutions of alkaloids were prepared by dissolving in DMSO at 5–7 mg/ml. The appropriate amount of stock alkaloid solution was added to media to achieve the desired final concentration (0–500 $\mu\text{g}/\text{ml}$) in each well. To account for any potential toxic effects of DMSO, control cultures were incubated with media containing equal concentrations of this reagent. Preliminary experiments showed DMSO to be of negligible toxicity at the concentrations used. DMSO did not synergize with the alkaloids to affect parasite attrition. Cultures in cDMEM were maintained at 37°C , 5% CO_2 ; those in cLIT were kept in an environmental chamber at 27°C . Each well was microscopically examined at 1, 24, 48, or 72 hr, and the mean number of surviving parasites was calculated from counts made throughout three separate microscopic fields of view (400 \times). This value was used to obtain percentage of surviving parasites, expressed as viability, as compared to DMSO-matched controls. One hundred percent viability was set at the lesser value between the initial seeded concentrations or DMSO control culture viability at the appropriate time point. This was done to minimize the exaggeration of alkaloid-dependent parasite attrition due to proliferation in control cultures.

Competitive RBP Inhibition

To test the role of rhamnose-binding proteins in solasonine and solamargine toxicity against *T. cruzi*, cytotoxicity assays were performed as described above with the addition of exogenous L-rhamnose (Sigma, St. Louis, MO, USA) to the media to achieve final concentrations of 50 or 500 mM. Results are expressed as described above.

Statistical Analysis

The Bonferroni all-pairwise comparisons test of cells (Statistix 8.0) following factorial ANOVA was used to assess statistical differences among treatment groups. All experiments were performed at least three times.

Results

Strain Susceptibility

Cytotoxicity assays performed on BSFs and EMs demonstrated that the BS and LI strains were equally susceptible to the effects of α -solamargine and α -solasonine (Table 1, Experiment 1). In BSF cultures at 24 hr, significant attrition was noted for both the BS and LI at titers as low as 10 $\mu\text{g/ml}$ of α -solamargine (Fig. 2a). These titers reduced culture viability to approximately 37% of the DMSO controls lacking α -solamargine. Increasing α -solamargine concentrations to 20 $\mu\text{g/ml}$ reduced parasite survival to approximately 8% for both strains. Concentrations of 40 $\mu\text{g/ml}$ resulted in the clearance of BSFs entirely from culture. Similar results were obtained with α -solasonine except that concentrations approximately twice higher were required to elicit effects equivalent to those of α -solamargine (Fig. 2a).

Similar results were found with EMs cocultured with each alkaloid (Fig. 2b). Significant EM attrition was observed at 10 $\mu\text{g/ml}$ of α -solamargine, where reductions in viability of approximately 23% (BS) and 25% (LI) were measured. Increasing the concentrations of α -solamargine to 30 $\mu\text{g/ml}$ decreased parasite survival for both strains to less than 20%.

As noted for BSF stage parasites, α -solasonine titers had to be increased approximately 1.5–2 times to elicit cytotoxic effects in EM cultures similar to those of α -solamargine.

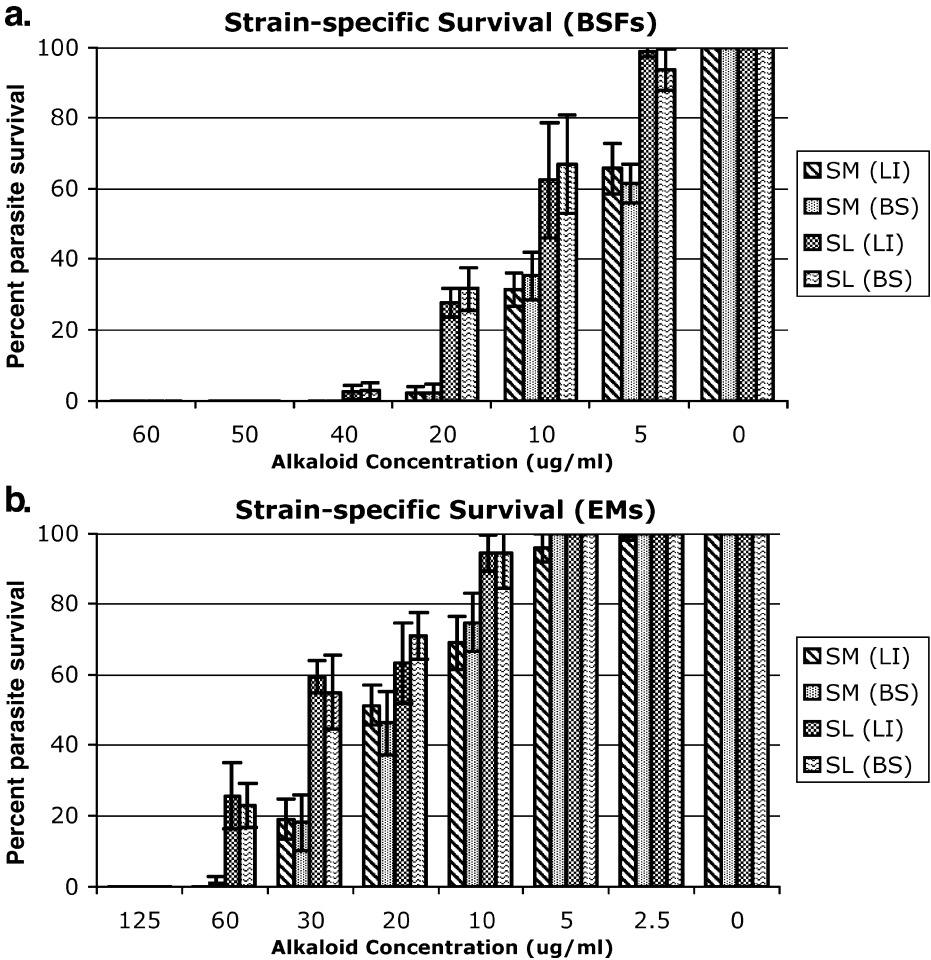

Fig. 2 Susceptibility of the Brazil strain (BS) and Lemur isolate (LI) of *Trypanosoma cruzi* to solasonine (SL) and solamargine (SM). (a) Shows the effects of the alkaloids on blood stream forms (BSFs) and (b) on epimastigotes (EMs). Parasites were cocultured for 24 hr in media containing the appropriate alkaloid at concentrations ranging from 0 to 125 $\mu\text{g/ml}$. For each treatment, parasite survival (mean \pm SD) was calculated as a percentage of the DMSO-matched control cultures. Each value is derived from three independent counts

While statistically significant differences could be attributed to both the concentration and type of alkaloid, no differences in susceptibility could be attributed to parasite strain (Table 1, Experiment 1). These assays suggested higher resistance for the EM stage as compared to BSFs, but given the differences in initial parasite concentrations and media constituents such conclusions cannot be wholly supported.

Since it was determined that the BS and LI strains were equally susceptible to the effects of α -solamargine and α -solasonine, subsequent experiments were limited to the more easily cultured Brazil strain.

Timed Assay

Cytotoxicity assays were performed and culture viability evaluated at 1, 24, and 48 hr to establish the timing of parasite attrition and potential recovery. Assays carried out on BSFs showed that the majority of attrition occurred within the first hour of exposure (Fig. 3a). When cultured at concentrations of α -solamargine $\geq 20 \mu\text{g/ml}$, viability declined rapidly with cultures cleared of parasites within 24 hr. α -Solamargine at 5–10 $\mu\text{g/ml}$ showed an initial decline in BSF viability at 1 hr, followed by a steady increase over 48 hr. Significant decreases were also apparent in EM cultures as early as 1 hr after exposure at all concen-

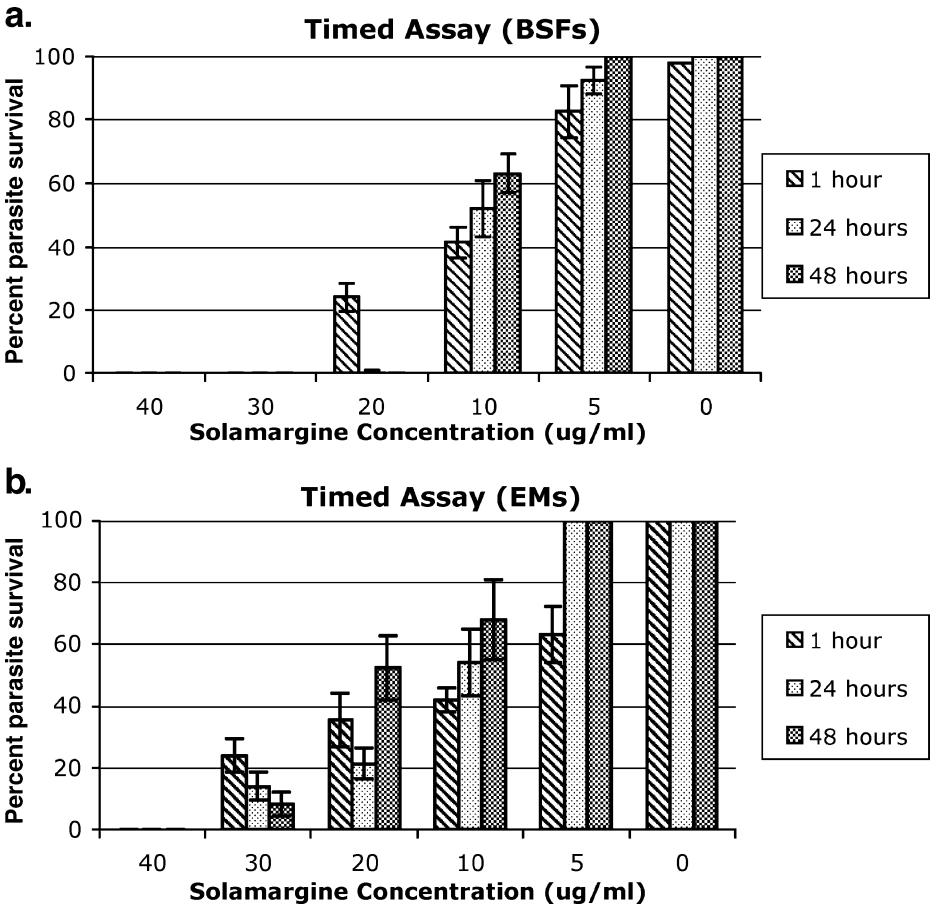

Fig. 3 Timing of attrition induced by different concentrations of solamargine on (a) blood stream forms (BSFs) and (b) epimastigotes (EMs) of the Brazil strain of *Trypanosoma cruzi*. The number of parasites (mean \pm SD) surviving at each concentration after 1, 24, and 48 hr of culture was calculated as a percentage of the DMSO matched controls. Each value represents three independent counts. Pairwise comparisons test of cells identified homogenous groups as follows (Group: concentration/time): (A) 0/1, 0/24, 0/48, 5/24, 5/48; (B) 10/48, 5/1, 10/24, 20/48; (C) 10/24, 20/48, 10/1; (D) 20/48, 10/1, 20/1; (E) 10/1, 20/1, 30/1; (F) 20/1, 30/1, 20/24; (G) 30/1, 20/24, 30/24, 30/48; (H) 30/24, 30/48, 40/1, 40/24, 40/48

trations of α -solamargine tested (Fig. 3b). At concentrations of α -solamargine ≥ 40 $\mu\text{g/ml}$, viability was reduced to zero by 1 hr, whereas those containing 30 $\mu\text{g/ml}$ continued to decline through all time points measured. When alkaloid titers were reduced to 20 $\mu\text{g/ml}$ or lower, cultures initially declined but demonstrated signs of recovery as measured by increases in parasite numbers and activity. Rosettes of replicating EMs were frequently visible by 48 hr in these cultures. Results obtained from EM and BSF cocultured with α -solasonine gave results similar to those with α -solamargine, except for the previously noted requirement for higher alkaloid concentrations to obtain the same effects (data not shown).

Synergistic Effects of 1:1 SM/SL Compound

As tested here, a 1:1 compound of α -solasonine and α -solamargine failed to increase parasite attrition (Fig. 4), although significant differences were noted between each of the three alkaloid preparations tested (Table 1, Experiment 3). The 1:1 mixture was consistently measured as being between that of pure α -solasonine and pure α -solamargine in attrition for both BSFs (Fig. 4a) and EMs (Fig. 4b). α -Solamargine was significantly more effective at eliminating BSFs than the 1:1 mixture at concentrations of 5, 10, and 30 $\mu\text{g/ml}$. α -Solasonine was less effective than either the 1:1 mixture or α -solamargine at 10 and 20 $\mu\text{g/ml}$, with titers of α -solasonine at 10 $\mu\text{g/ml}$ decreasing culture viability by 13% as compared to 36% and 62% for the 1:1 mixture and α -solamargine respectively. Results from coculture of EMs with the 1:1 mixture were consistent with those from BSF assays, eliciting attrition levels between that of α -solasonine and α -solamargine (Fig. 4b).

L-Rhamnose Inhibition Assays

The role of RBPs in mediating cytotoxicity was tested *in vitro* by performing assays in the presence or absence of 50 mM L-rhamnose as a competitive inhibitor. In both the BSF and EM cultures, L-rhamnose failed to significantly increase parasite survival over those cultured with either alkaloid alone (Table 1, Experiment 4). Increasing the final concentration of L-rhamnose to 500 mM generated nearly identical results, with no significant effect on parasite survival (data not shown).

Discussion

T. cruzi strain-specific characteristics are largely associated with the clonal expansion of geographically isolated populations (Revollo et al., 1998). The drug resistance demonstrated in some *T. cruzi* isolates has been correlated largely to such strain specificity (Andrade et al., 1985). α -Solasonine and α -solamargine as tested in this study were effective at inducing cytolysis in both a South American derived type I strain (BS) and a North American type II isolate (LI). This, coupled with previously cited studies, suggests that these compounds are cytolytic against biologically diverse *T. cruzi* strains. This characteristic was also extended to the different lifecycle stages, with both BSFs and EMs rapidly cleared in the presence of either alkaloid, although requiring different titers (Fig. 2). Concentrations as low as 10 $\mu\text{g/ml}$ of α -solamargine drastically reduced culture viability within 1 hr. We routinely observed significant attrition within 5–15 min of the addition of alkaloid, especially at higher concentrations (>40 $\mu\text{g/ml}$). α -Solamargine was significantly more effective at killing all stages tested than solasonine, which required 1.5–2 \times the concentration of alkaloid.

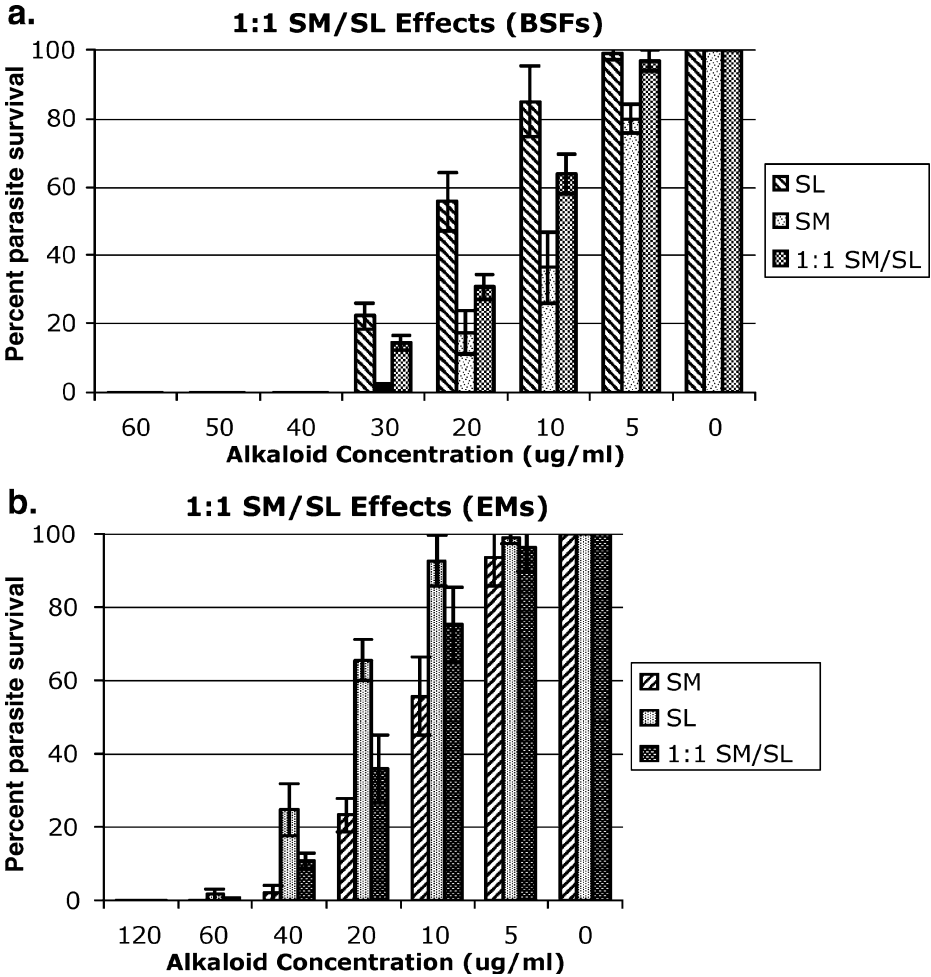

Fig. 4 Cytolytic effects of a 1:1 compound (1:1 SM/SL) of solamargine (SM) and solasonine (SL) on (a) blood stream form trypanosomes (BSFs) and (b) epimastigotes (EMs) of *Trypanosoma cruzi*. Parasites were incubated for 24 hr in the presence of various concentrations of solasonine, solamargine, or the 1:1 compound. Surviving parasites were calculated as a percentage (mean ± SD) of those in DMSO-matched controls. Each value represents three independent counts. Pairwise comparisons test of cells identified homogenous groups as follows (Group: concentration/alkaloid): (A) 0/sm, 0/sl, 0/1:1, 5/sl; (B) 5/1:1, 10/sl; (C) 10/sl, 5/sm; (D) 5/sm, 10/1:1; (E) 10/1:1, 20/sl; (F) 10/sm, 20/1:1; (G) 30/sl, 20/sm, 20/1:1; (H) 30/sl, 20/sm, 30/1:1; (I) 30/1:1, 30/sm; (J) all other comparisons

Although experiments with metacyclic stage parasites found they were cleared from culture at concentrations of alkaloid similar to BSFs, the rapid increase in EMs at lower alkaloid concentrations in these cultures made the data difficult to interpret.

As demonstrated by the reduced titers required by α-solamargine vs. that for α-solasonine, the carbohydrate moiety clearly plays a significant role in the cytolytic properties of these compounds against *T. cruzi*. What is less certain is the mechanism by which the carbohydrates participate. The efficacy of solamargine, with two terminal rhamnose sugars, exceeded both that of 1:1 SM/SL and α-solasonine, in a manner correlated to the relative

amounts of rhamnose in each preparation (Fig. 3). Opposed to the previously cited results in tumor models, the medial efficacy of the 1:1 SM/SL compound as compared to its parent alkaloids discounts the role of separate mechanisms for α -solasonine and α -solamargine for killing. Despite the evidence that rhamnose likely plays a role in antitrypanocidal activity, the inability to competitively inhibit parasite death with exogenous L-rhamnose argues against a direct role for RBPs (Fig. 4). Any suggested requirement for a bivalent rhamnose-dependent receptor would fail to explain the efficacy of solasonine, albeit at somewhat higher concentrations.

We can only speculate that the positioning of the terminal sugars in α -solamargine are sterically more favorable to binding with the parasites mucin-rich cell surface than those of α -solasonine (Ferguson, 1997). Once bound in sufficient concentrations, the alkaloid's lipid moiety would induce cytolysis through hydrophobic interactions with membrane sterols (Roddick et al., 1992, 2001). The difference in the susceptibility noted between EMs and BSFs would be explained by stage-specific differences in membrane constituents, as described by Chataing et al. (1998). The ability to mimic the effects of α -solamargine with higher doses of solasonine likely reflects a dose-dependent increase in bound alkaloid at the cell surface. This would also explain the medial response observed with 1:1 SM/SL and the mechanistic independence from RBPs.

We note that the alkaloids used in this study were derived from ripe fruits of a *Solanum* species that is most likely dispersed by mammals. There have been numerous hypotheses put forth to explain the allocation of secondary metabolites in ripe fleshy fruits (Cipollini and Levey, 1997a; Cipollini, 2000), including the retention of high levels of glycoalkaloids in fruits of some *Solanum* species (Cipollini and Levey, 1997b). The appearance of secondary metabolites in ripe fleshy fruits seems paradoxical in that such fruits are presumably adapted for dispersal by vertebrates yet may contain levels of secondary metabolites that may be toxic or deterrent to vertebrates. Among the hypotheses put forth to explain this phenomenon is the suggestion that high levels of certain secondary metabolites may be necessary to prevent consumption/destruction of fruits by organisms that do not consequently disperse seeds. This "directed toxicity" hypothesis maintains that such chemicals should not have profound effects on vertebrate seed dispersers at normal consumption levels. Considering this hypothesis, we suggest that phytoparasitic organisms may have contributed to selective pressures favoring the retention of high levels of glycoalkaloids in ripe fleshy *Solanum* fruits.

The typical route of transmission for *T. cruzi* and the closely related *T. rangelii* depends on the feeding patterns of the hemophagic reduviid bug. It is likely that, as with most hemophagic arthropods, reduviid bugs are evolutionarily derived from forms that fed upon plant phloem (Grimaldi and Engel, 2005). Other members of the order Hemiptera are phloem feeders and remain important plant pests (Bonjour et al., 1993). Maturing fruits are often targeted by phloem-feeding hemipterans, probably as a consequence of the fruit's role as a carbohydrate sink (M. Cipollini, personal observation). Coincidentally, there are species of trypanosomes, such as *Phytomonas serpens*, that parasitize *Solanum* species. An evolutionary relationship between *P. serpens* and *T. cruzi* has been demonstrated through antigenic cross-reactivity in the mouse model (Bregano et al., 2003). *T. cruzi* is also known to contain a unique pyrophosphatase within their acidocalcisomes that thus far has only been found in plants (Scott et al., 1998). This supports the hypothesis that the trypanosomes that infect animals likely evolved from those that once parasitized plants. Alkaloids such as α -solasonine and α -solamargine may have evolved as a strategy to inhibit parasitism in these plants. High concentrations of these alkaloids in the fruits in particular could: (1) deter feeding by phloem-feeding insects, (2) deter growth of phytoparasitic trypanosomes, and (3) inhibit vertical transmission of phytoparasites to the plant's progeny during seed develop-

ment. One consequence would be that vertebrate seed dispersers could benefit by consuming *Solanum* fruits containing glycoalkaloids.

The hypothesis that animals can self-medicate through strategic feeding upon specific plants or plant parts has been supported by several studies (Hart 1990; Huffman and Caton, 2001; Vitazkova et al., 2001). In the context of our study, it has been suggested that the maned wolf (*Chrysocyon brachyurus*) specifically seeks out *S. lycocarpum* fruits in Brazil and may thus suffer reduced rates of parasitism (Courtenay 1994). Being “medicinal” might be a factor that attracts vertebrates to feed upon certain fruits, including those of *Solanum* species, and thus disperse the seeds. Although there is little experimental evidence that addresses these hypotheses, the potential for coevolution of reduviid feeding strategies with trypanosomes and consequent effects upon vertebrate fruit consumers presents a promising area for investigation. In general, consideration of the evolutionary context of natural products may guide the search for antiparasitic compounds with limited acute vertebrate toxicity and appropriate therapeutic indices. Given their requirement to be eaten by vertebrates, ripe fleshy fruits may be ideal incubators of such compounds in plants.

Introduction

Plants are attacked by a broad array of herbivores and pathogens. Damage to plant tissue may have a profound impact on host plant physiology. In response to herbivore attack, plants have evolved a number of defense mechanisms including physical and chemical barriers, as well as inducible defenses (e.g., Maleck and Dietrich, 1999; Stotz et al., 1999; Ratzka et al., 2002; Rostas et al., 2002).

Many secondary plant metabolites function as repellents or toxins that can reduce feeding by nonadapted herbivores and force adapted herbivores to invest in detoxification (Baldwin et al., 2001). In many cases, however, herbivores evoke a variety of active plant responses, including the induction of defensive secondary metabolites and shifts in plant metabolism. Some responses may be specifically induced by herbivores, while others lack that specificity with regard to the inducing agent. Similarly, the effects of plant responses can be specific depending on the herbivore species (Baldwin and Preston, 1999). Such specificity, in relation to the diversity of abiotic and biotic stress, may have adaptive value.

Plants initiate wound-response pathways when attacked by insects. For instance, feeding by the tobacco hornworm (*Manduca sexta*) stimulates mitogen-activated protein kinase systemically within a few minutes in tomato (Stratmann and Ryan, 1997). Signal transduction pathways in plant defense mechanisms respond differently to different insect species. Therefore, herbivory is thought to cause a profound effect on the plant metabolome. Previous studies have demonstrated alterations of plant metabolism under herbivory. Mauricio and Rausher (1997) as well as Shonle and Bergelson (2000) have shown that total glucosinolate concentration in *Arabidopsis thaliana* and concentration of two individual alkaloids in *Datura stramonium* are under selection pressure by insects. Furthermore, feeding damage of leaf-chewing insect larvae results in the production of a wide variety of volatile organic compounds including mono- and sesquiterpenes, sulfides, (iso)thiocyanates, and others. The ratios among herbivore-induced monoterpenes and sesquiterpenes may vary considerably among plant varieties. The proportion of monoterpenes attains nearly 50% of the total volatile organic compounds emission spectrum in intact white cabbage plants, but remains below 25% in herbivore-damaged plants (Geervliet et al., 1997; Gouinguene et al., 2001). Emission of certain volatiles is enhanced in the plants damaged by their specialist herbivores compared to those damaged by generalists (Vuorinen et al., 2004). Rostas et al. (2002) demonstrated that herbivory by the chrysomelid beetle (*Phaedon cochleariae*) on Chinese cabbage (*Brassica rapa* spp. *pekinensis*) reduces the sucrose concentration of leaves and increases the amounts of indole glucosinolates as well as the total anthocyanins. Yet, these studies have been limited to specific groups of metabolites. Information on the alteration of the whole metabolome of plants under herbivory is necessary.

Examination of the metabolome, however, is a complex task due to the large number of metabolites and different tissues, including special storage organs, with different metabolite complements. It is unlikely that a single analytical method will yield information about all

the metabolites in a plant. Diversity in volatility, polarity, solubility, and chromatographic behavior requires multiple methods. Therefore, a wide spectrum of rapid and reproducible chemical analysis techniques should be used that require only simple sample preparation (Choi et al., 2004a).

^1H NMR can meet these requirements. This method provides metabolic fingerprints with good chemical specificity for compounds containing elements with a nonzero magnetic moment, and can simultaneously detect all proton-bearing compounds such as carbohydrates, amino acids, fatty acids, amines, esters, ethers, and lipids (Sumner et al., 2003). Several studies on plant metabolite profiling utilizing ^1H NMR have been done. For example, Ward et al. (2003) distinguished various ecotypes of *A. thaliana* by using ^1H NMR and multivariate analysis. Choi et al. (2004b) found metabolites that were present in different concentrations in phytoplasma-infected *Catharanthus roseus* leaves vs. healthy leaves, and these could be identified by using one-dimensional (1D) and two-dimensional (2D) nuclear magnetic resonance (NMR) spectroscopy followed by principal component analysis (PCA).

Although ^1H NMR is a powerful tool, it has some disadvantages due to low resolution and overlapping signals when applied to mixtures. Thus, when working with complex mixtures, it is essential to reduce the spectral overlap. 2D NMR is an attractive alternative. The use of 2D NMR adds information on the correlation between resonances by dispersing the signals in an extra dimension. The problem of overlap decreases, thereby facilitating the assignment procedure (Nilsson et al., 2004). In particular, 2D J-resolved NMR spectroscopy is helpful because of its relatively short measuring time and reliability for the quantification of metabolites in mixtures.

The present study investigated the metabolomic differentiation of *B. rapa* leaves damaged by two different instars of the crucifer specialist *Plutella xylostella* L. (Lepidoptera: Yponomeutidae), and the generalist *Spodoptera exigua* Hubner (Lepidoptera: Noctuidae), compared to control leaves. For two reasons, we would expect a reaction of the plant specific to larval age. First, young instars are not very mobile and dispersive in comparison to older, and they are, therefore, less easily repelled. Thus, instar-specific differences in induced defense mechanisms could be adaptive. Second, the natural enemies attracted by plants might be different for young and old instars. Therefore, we might expect differences in the induced metabolome.

2D J-resolved NMR spectroscopy coupled with PCA was applied to achieve a more complete interpretation of the ^1H NMR spectra and to discriminate the metabolic differences between the damaged and the healthy leaves.

Methods and Materials

Plant and Insect Materials Turnip (*B. rapa*) plants were grown from seed (commercial seed, Herfstraap Goldana 60773) in a growth chamber (16:8 hr L/D photoperiod, 20°C day/15°C night, RH 70%) in pots (11 cm diam) containing a mixture of 50:50 dune sand/peat. Plants used for the experiments were 2 mo old. Larvae of generalist herbivore, the beet armyworm (*S. exigua*), were reared in a growth chamber on artificial diet. Larvae of the specialist, the diamondback moth (*P. xylostella*) were obtained from the Department of Entomology, Wageningen University, Wageningen, The Netherlands (reared on *Brassica oleracea* L.)

Insect Feeding Experiment Herbivore feeding damage was caused by 48 hr feeding. The following numbers of larvae were transferred to a single leaf: in *P. xylostella*, either 8 2nd- or 8 4th instars; in *S. exigua* either 4 2nd- or 4 4th instars. Five plants were used to analyze

effects of local infestation. For analyzing systemic effects of feeding damage, 2 2nd- or 4th instars of *P. xylostella*, or 2 2nd- or 4th instars of *S. exigua* were placed on 1 leaf of the different plants for 48 hr. Five plants were used.

The particular leaf to which larvae were transferred was covered with a plastic bag. Small holes were made in the bag to provide air circulation. Plants with larvae were placed in transparent plastic cylinders (30 cm diam, 50 cm high). Additional plants were used as controls ($N = 5$) and were kept under the same conditions. Locally damaged and systemic leaves (only the 4th to 7th true leaves) from each treated plant and control plant were harvested. Each leaf sample was separated from the veins, ground into fine powder in liquid nitrogen, and immediately stored at -80°C until needed for analysis.

Extraction of Plant Materials Each sample was freeze-dried. Fifty mg of dry material were transferred to a 10-ml centrifuge tube. After addition of 1.5 ml of 50% methanol- d_4 in buffer (90 mM KH_2PO_4 , pH = 6.0) containing 0.05% trimethyl silyl propionic acid sodium salt (TSP; w/v), the mixture was vortexed at room temperature for 1 min, ultrasonicated for 15 min, and centrifuged at 13,000 rpm at 25°C for 20 min. Each NMR sample consisted of 800 μl of the supernatant.

NMR Measurements ^1H NMR and J-resolved spectra were recorded at 25°C on a 400-MHz Bruker AV-400 spectrometer operating at a proton NMR frequency of 400.13 MHz. The window functions were optimized. The resulting spectra were manually phased and baseline-corrected, and calibrated to TSP at 0.0 ppm, all by using XWIN NMR (version 3.5, Bruker). Two dimensional J-resolved ^1H NMR spectra were acquired by using 16 scans per 32 increments that were collected into 16 K data points, with spectral widths of 5.208 kHz in F2 (chemical shift axis) and 50 Hz in F1 (spin–spin coupling constant axis). A 1.0-sec relaxation delay was employed, giving a total acquisition time of 14.52 min. Data sets were zero-filled to 512 points in F1, and both dimensions were multiplied by sine-bell functions prior to double complex FT. J-resolved spectra tilted by 45° , symmetrized about F1, and then calibrated, all using XWIN NMR (version 3.5, Bruker). Data were exported as the 1D projection (F2 axis) of the 2D J-resolved spectra. ^1H – ^1H COSY, TOCSY, heteronuclear single quantum correlation (HSQC), and heteronuclear bond correlation (HMBC) were measured at 600 MHz Bruker DMX-600 spectrometer operating at a proton NMR frequency of 600.13 MHz. The COSY spectra were acquired with a 1.0 sec relaxation delay, 6361 Hz spectral width in both dimensions. The HSQC spectra were obtained with a 1.0-sec relaxation delay, and 6361 Hz spectral width in F2 and 27,164 Hz in F1. The HMBC spectra were recorded with the same parameters as the HSQC spectrum, except for 30,183 Hz of spectral width in F2. The TOCSY spectra were acquired with a 1.0-sec relaxation delay and 6361 Hz spectral width in both dimensions.

Data Analysis The ^1H NMR and the J-resolved projection spectra were automatically reduced to ASCII files by using AMIX (v. 3.7, Bruker Biospin). Spectral intensities were scaled to TSP and reduced to integrated regions of equal width (0.04 ppm) corresponding to the region of δ 0.40–10.00. The region of δ 4.7–5.0 was excluded from the analysis because of the residual signal of water, and the region of citric acid, malic acid, and succinic acid in δ 2.8–2.5 was bucketed by 0.1 ppm to avoid the problems due to chemical shifts of these compounds that depend on concentration. PCAs were performed with the SIMCA-P software (v. 10.0, Umetrics, Umeå, Sweden).

Results

Identification of Metabolites in NMR Spectra The congestion of ^1H NMR spectra due to signal overlapping is to a great extent solved by using 2D J-resolved spectra (Fig. 1). Based on the 2D J-resolved spectra together with other 2D NMR spectra including ^1H – ^1H COSY, HSQC, and HMBC, a number of individual metabolites in *B. rapa* leaves were identified.

The amino acids region in the spectra showed the signals of alanine, threonine, valine, and glutamine. Resonance of alanine at δ 1.48 (d, J = 7.2 Hz, H-3) correlates with δ 3.72 (H-2) in the COSY spectrum and with δ 51.6 (C-2) and δ 176.8 (C-1) in the HMBC spectrum. The threonine signal at δ = 1.33 (d, J = 6.6 Hz, H-5) correlates with δ 4.28 (H-4) and with δ 66.6 (C-4) in the HMBC spectra. Valine signals at δ 1.04 (d, J = 8.0 Hz, H-4) and δ 1.01 (d, J = 8.0 Hz, H-5) show COSY correlation with δ 2.31 (H-3) and HMBC correlation with δ 30.3 (C-3) and δ 61.3 (C-2). Resonance of glutamine at δ 2.13 (m, J = 9.2 Hz, H-3) shows correlations with δ 2.47 (H-4) and δ 3.76 (H-2) in the COSY spectrum, and those with δ 55.8 (C-2), δ 178.7 (C-5), and δ 180.1 (C-1) in the HMBC spectrum. Other compounds detected in this region are α -linoleic acid analogues at δ 0.97 (t, J = 7.5 Hz). A downfield-shifted terminal methyl signal at δ 0.97, when compared with that of general fatty acids at δ 0.94, was identified as a signal of α -linoleic acid analogues including jasmonates by comparison of fatty acid reference compounds. Resonances of malic acid were detected at δ 2.80 (dd, J = 11.2 Hz, 6.6 Hz) and δ 2.63 (dd, J = 11.2 Hz, J = 4.7 Hz), which correlate with H-2 at δ 4.32 in COSY spectra. In the HMBC spectra, those signals show correlations with δ 70.1 (C-2), δ 177.5 (C-1), and δ 179.2 (C-4). Signals found in the sugar region were attributable to sucrose at δ 5.40 (d, J = 3.9 Hz), α -glucose at δ 5.16 (d, J = 3.0 Hz), β -glucose at δ 4.57 (d, J = 7.9 Hz), and the fructose moiety of sucrose at δ 4.22 (d, J = 8.8 Hz). These assignments were confirmed by 2D NMR spectra including J-resolved, COSY, HSQC, and HMBC, and by the comparison of reference compounds.

Apart from those ubiquitous compounds, phenylpropanoids were also detected in *B. rapa* leaves. Recently, we found that major phenolic metabolites of *B. rapa* leaves were malate-conjugated phenylpropanoids including caffeoyl, coumaroyl, feruloyl, and sinapoyl malates (Liang et al., 2006). Each phenylpropanoids malate can be identified by the ^1H NMR signals of H-8 (Liang et al., 2006). Sinapoyl malate (Fig. 2) shows a clear doublet at δ 6.45 (d, J = 16.0 Hz, H-8). The other signals of this compound are detected at δ 6.99 (s, H-2 and H-6) and H-7 at δ 7.66 (d, J = 15.9 Hz, H-7), respectively. Feruloyl malate (Fig. 2) signals are also present in the phenolic region as a major phenolic metabolite: H-7 at δ 6.48 (d, J = 15.9 Hz), H-8 at δ 7.66 (d, J = 15.9 Hz), H-2 at δ 7.25 (d, J = 2.0 Hz), H-6 at δ 7.03 (dd, J = 2.0 Hz, 8.2 Hz), and H-5 at δ 6.89 (d, J = 8.2 Hz). Correlation between H-7–H-8, and H-2–H-3 of the compound is clearly shown in the COSY spectrum. As minor phenolic metabolite, a flavonoid similar to kaempferol was detected. Signals at δ 6.46 (d, J = 2.1 Hz, H-6), δ 6.73 (d, J = 2.1 Hz, H-8), δ 7.79 (d, J = 8.8 Hz H-2' and H-6'), and δ 6.93 (d, J = 8.8 Hz H-3' and H-5') indicate kaempferol analogue.

Signals from an olefinic glucosinolate, gluconapin (Fig. 2), are identified in the 2D J-resolved spectrum (Fig. 3a) in which the anomeric proton from the attached sugar is detected at δ 4.93 (d, J = 9.7 Hz). In the HMBC spectrum, the characteristic correlation is equivocally present. The signal of the anomeric proton of the glucose is correlated with carbon in the ^{13}C NMR spectrum at δ 163.2 (Fig. 3b). Signals from H-2 of gluconapin were observed at δ 2.79 (d, J = 6.4 Hz), H-3 at δ 2.47 (d, J = 6.4 Hz), H-4 at δ 5.14 (ddd, J = 5.0 Hz, J = 4.0 Hz, J = 1.9 Hz), H-5 at δ 5.91 (ddd, J = 10.3 Hz, J = 3.0 Hz, J = 3.1 Hz). In the COSY spectrum, H-2, H-3, H-4, and H-5 are continuously correlated with each other. Those

signals correlate with carbons at δ 33.9, δ 28.9, δ 137.9, and δ 116.6, respectively, in the HSQC spectrum.

Effect of Herbivory from Different Larval Stages PCA analysis was performed to discriminate between different larval stages of the same species of insect on locally and systemically induced leaves. Projected J-resolved spectra to F2 axis were used for the PCA analysis to increase resolution and overcome the complexity of 1D ¹H NMR spectra. The degree of spectral complexity in the projected J-resolved spectrum is significantly reduced compared to the true 1D data set. We applied this enhanced resolution obtained from the projected J-resolved spectra to monitor metabolic changes in the plants. In spite of the enhanced resolution in J-resolved spectra, a disadvantage is that for strongly coupled spin systems, such as in glucose, glutamine, and glutamic acid, spectral artifacts can arise in J-resolved spectra (Foxall et al., 1993; Nicholson et al., 1995). Such artifacts were included in the PCA as an additional resonance for the metabolites (Viant 2003).

Figure 4a shows that the metabolomes of the local leaves attacked by generalist herbivory are different in young vs. old instars. On locally damaged leaves, the metabolomic profile induced by 2nd generalist instars is separated by PC2 from the control and 4th instar. The loading plot of PC2 and PC3 shows that herbivory of 2nd generalist instars on local leaves increased the level of glucose, ferulic acid, and gluconapin, whereas feeding by the 4th instars caused an increase in levels of alanine and sinapoyl malate.

Figure 4b shows a comparison of the metabolites of systemic leaves attacked by 2nd and 4th generalist instars. The score plot of PC2 and PC3 (Fig. 4b) shows a strong separation. Using a loading plot of PCA, the metabolic difference of the 2nd instar induced *B. rapa* leaves might be ascribed to an increase in glucose, feruloyl and sinapoyl malate when

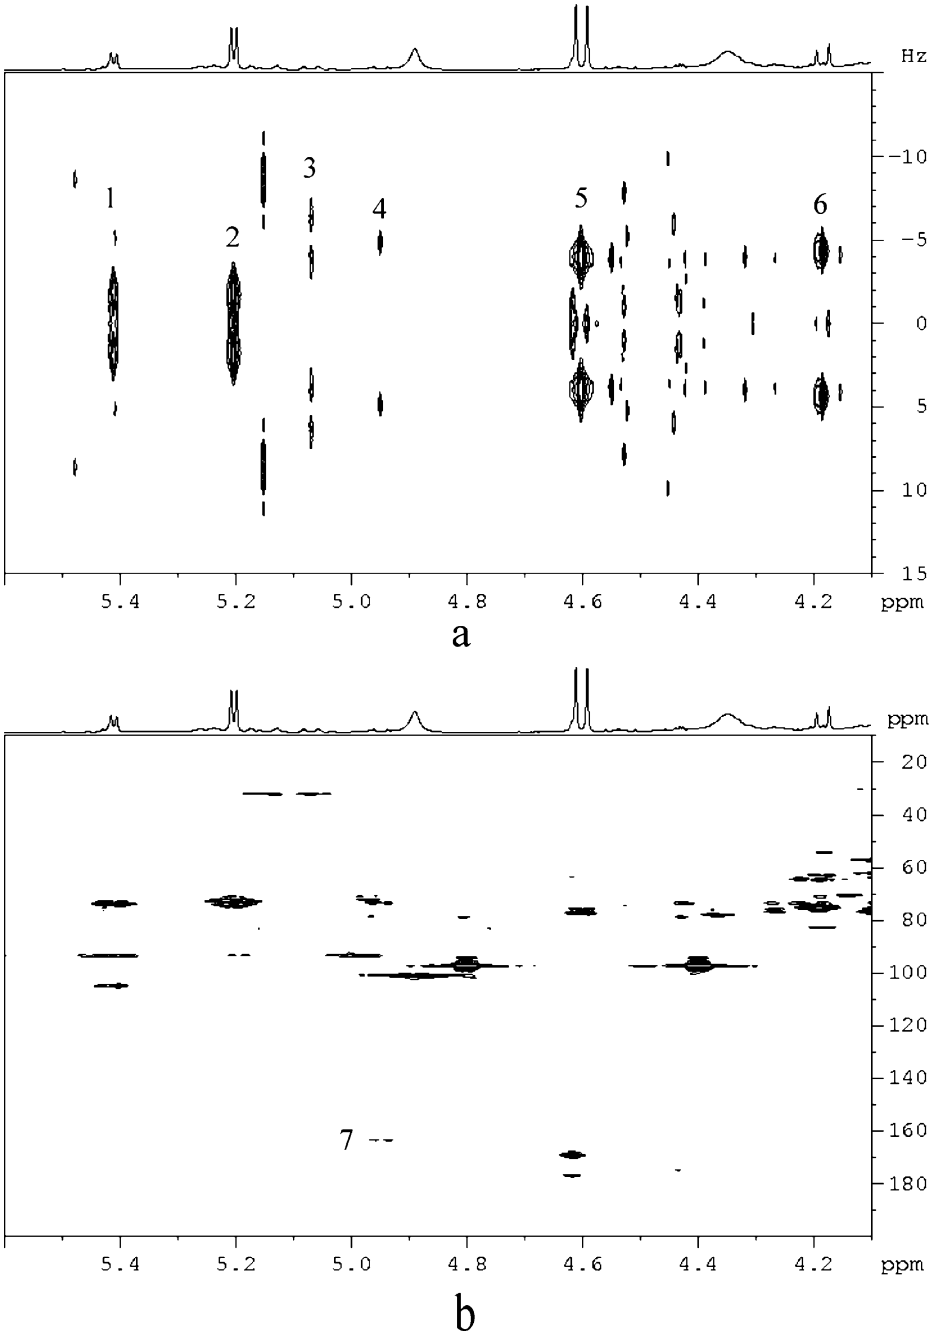

Fig. 3 2D J-resolved (a) and HMBC spectrum (b) of *Brassica rapa* leaves samples in the range of δ 4.0–5.6. 1: H-1 of sucrose; 2: H-1 of α -glucose; 3: H-2' of feruloyl and sinapoyl malate; 4: H-1' of gluconapin; 5: H-1 of β -glucose; 6: H-1' of fructose moiety of sucrose; 7: HMBC correlation between H-1' and C-1.

compared to the control and the 4th instar induced leaves. Feeding by 4th instars was found to induce the highest accumulation of gluconapin and sinapoyl malate in plants.

Figure 4c shows the score plot of PC2 and PC3 of specialist herbivory of different instars on local leaves. Second specialist instars increased levels of glucose, feruloyl and sinapoyl malate, and gluconapin, whereas 4th instars stimulated the plants to accumulate more sucrose.

When comparing the effects of herbivory by 2nd and 4th instar specialists on systemic leaves, PCA analysis showed that when compared with the control, herbivory stimulated plants to synthesize more gluconapin, glucose, feruloyl malate, sinapoyl malate, and threonine (Fig. 4d).

(a) 1: Control; 2: local induction of the second instar of the generalist; 4: local induction of the fourth instar of the generalist. (b) 1: Control, 6: systemic induction of the second instar of the generalist; 8: systemic induction of the fourth instar of the generalist. (c) 1: Control; 3: local induction of the second instar of the specialist; 5: local induction of the fourth instar of the specialist. (d) 7: Systemic induction of the second instar of the specialist; 9: systemic induction of the fourth instar of the specialist.

Discussion

We showed that plants respond specifically to herbivory of different instars. Changes in both primary and secondary metabolites occurred in response to different types of herbivory. In particular, *B. rapa* leaves showed different metabolic responses against young (the 2nd) vs. old (the 4th) larvae both of the generalist *S. exigua* and the specialist *P. xylostella*. In reality, young instars of herbivorous insects are not very mobile and dispersive in comparison to old instars. In a certain area of the leaves, the lower mobility of young instars might cause greater damage than that induced by old ones. In both the generalist and specialist larvae, the metabolic alterations induced by younger instars were larger than those of the older. Score values of *B. rapa* leaves attacked by 4th instars are closer to control plants than the those damaged by 2nd instars (Fig. 4a–c). When considering the metabolic pattern of locally damaged *B. rapa* leaves and systemic ones, clear differences were detected, however, in both the local and systemic leaves in the level of phenolics (ferulic acid and sinapic acid) and a glucosinolate (gluconapin).

Although their precise role is not yet understood, phenolics play a role in plant defense. Ferulic and sinapic acid might be involved in guaiacyl and syringyl lignin biosynthesis of *Arabidopsis* (Stout and Chapple, 2004). The modification of cell walls induced by the lignin synthesis may play a role in the defense mechanism. Also, ferulic acid is reported to significantly reduce the incidence of powdery mildew in susceptible (Mustang) and tolerant (Flamingo) cucumber (*Cucumis sativus*) cultivars (Daayf et al., 2000), and it has shown significant antifungal activity against a fungal pathogen, *Sclerotium rolfsii* (Sharma and Singh, 2003). Grant and Langevin (2002) stated that together with sinapic acid, ferulic acid acts as an oviposition deterrent to spruce budworm (*Choristoneura fumiferana*).

Several studies have shown that herbivore feeding damage induces glucosinolate biosynthesis in Brassicaceae. Glucosinolates and their catabolites have wide-ranging biological activities, from feeding deterrence for generalist insects to oviposition stimulation for specialists (Halkier and Du, 1997, Ratzka et al., 2002) and an involvement in the interaction between Brassicaceae with their microbial and fungal pathogens (Doughty et al., 1996) and nematodes (Zasada 2003). We showed in this study that when attacked by insects, *B. rapa* produced an olefin glucosinolate, gluconapin, that is known as one of the most abundant glucosinolates in Brassicaceae. Together with 4-hydroxyglucobrassicin, it accounts for more than 80% of the total glucosinolates in *B. campestris* and *B. rapa* accessions (Peiwu et al., 1999).

The use of 2D NMR spectroscopy is promising for the analysis of complex mixtures of compounds in plant material. Problems of overlap can be decreased, so that the assignments are easier. In particular, J-resolved 2D NMR spectra were helpful because of their relatively short measuring time and the reliability for the assignments of metabolites present in a mixture compared to other 2D NMR methods. When combined with principal component analysis (PCA), the discrimination of peaks can be easily assigned and used to distinguish effects of different types of herbivory.

Acknowledgment Financial support from the Netherlands Education Centre (STUNED Scholarship 2003) for Heru Tri Widarto is highly acknowledged. We also acknowledge Henk Nell for rearing *S. exigua* larvae.

detached from the flower and adhered to the fly's dorsum. In this unique mutualistic association, both species receive direct reproductive benefits—the flower's pollinarium is transported for cross pollination, and the fly is offered a bouquet of phenylpropanoids (synomone) that it consumes, converts, and/or sequesters as sex pheromonal components, thus enhancing sexual attraction and mating success.

Introduction

A number of orchid species in the genus of *Bulbophyllum* (Orchidaceae: subfamily Epidendroideae, subtribe Bulbophyllinae) exhibit an elaborate floral architecture, in addition to characteristic floral fragrances, that attract and bring specific pollinators to the right position for effective pollination. Some of the species, here called “fruit fly orchids,” selectively attract fruit flies of the genus *Bactrocera* (Diptera: Tephritidae) with specific floral volatiles that act as a synomone. It has been reported that the ginger orchid (*Bu. patens* King) flower releases a ginger essence—zingerone, as a floral synomone that attracts fruit flies sensitive to both methyl eugenol (ME) and raspberry ketone (RK)—inclusive of both pestiferous and nonpestiferous species (Tan and Nishida, 2000). In addition, flowers of *Bu. apertum* Schltr. (subspecies *verrucatum*) release RK that attracts RK-sensitive *Bactrocera* species (Tan and Nishida, 2005). Furthermore, the fruit fly orchid flower (*Bu. cheiri* Lindl.) possesses several phenylpropanoids, of which the major component is ME. It attracts male flies of *Bactrocera papayae* Drew and Hancock that assist in its pollination (Tan et al., 2002; Nishida et al., 2004). [It is noted that *B. papayae* is neither a distinct biological nor genetic species different from the Oriental fruit fly, *B. dorsalis* (Hendel) (Naeole and Haymer, 2003; Tan, 2003) and henceforth it is referred to as *B. dorsalis*.] The fruit fly orchid also attracts males of *B. carambolae* Drew and Hancock, *B. umbrosa* (Fabricius), and the hybrid of *B. dorsalis* × *B. carambolae*. None of the above species produces nectar; hence the question of the reward for attracted fruit flies remains unanswered. Flies consume and then either convert the chemical attractant into male sex pheromonal component(s)—in the case for ME-sensitive species, or directly sequester the attractant as part of a male pheromone system in the RK-sensitive species (Nishida et al., 1988, 2004; Tan, 2000; Tan and Nishida, 1995, 1998, 2000, 2005; Tan et al., 2002). Hence, for the three *Bulbophyllum* species—*Bu. patens* King, *Bu. apertum*, and *Bu. cheiri* Lindl.—the respective floral attractants are themselves the rewards for the attracted flies.

The majority of the *Bulbophyllum* species are epiphytes found in the virgin pan-tropical forest (Vermeulen, 1991) in lower montane forest at ca. 1000 m above sea level. The vinaceous orchid, *Bu. vinaceum* Ames & C. Schweinf., is a rare epiphytic plant, that is endemic to the highlands of Borneo Island, such as the Crocker Range and Mt. Kinabalu of Sabah, East Malaysia. Its name is derived from the Latin word “vinaceus” (for dark wine red) (Vermeulen, 1991) due to its deep wine-red colored, single-flowered inflorescence. Its resupinate flower (with lip turned downwards) has a protruding and stiff hamulus (pollinia stalk), whose function is unknown (Rasmussen, 1985), and a “spring loaded” hinged lip that is always held in a closed position (presumably protecting its sexual organs). The flower has a mild sweet scent resembling that of an ester and strongly attracts males of *B. dorsalis*.

The objectives of this paper are to investigate: (1) the behavior of fruit fly visitors and determine species identity of attracted flies; (2) the process of pollinarium removal as well as to determine the role of floral hamulus and the constantly closed lip; (3) the chemical constituents in floral fragrance that attract fruit flies; and (4) the content of phenylpropanoids in various floral organs and rectal gland of fruit fly visitors.

Methods and Materials

Observations of Flies on flowers

Observations of orchid flowers and plants were conducted in Kundasang (ca. 1800 m at the foothill of Mt. Kinabalu), Sabah, East Malaysia, and in Tanjung Bungah (lowland <200 m above sea level), Penang (plants originally obtained from Kundasang). Fly attraction was observed continuously from 07:00 to 17:00 hr on the day a flower bloomed. Investigations of pollinarium removal by a fruit fly were conducted when the first fly visited and fed on a newly opened flower; this process was videotaped whenever possible. Attention was paid to the role of the floral lip (labellum) and hamulus during pollinarium removal. To confirm that fruit flies were attracted to the flower via scent and not visually via floral color or form, certain investigations were performed with the fully developed bud covered with a piece of black mosquito wire netting; the flower was covered at dawn before it bloomed. After observation, flies on the flowers were collected in clear plastic bags, and their respective species identity was confirmed, if necessary, under 40× magnification. To ascertain floral response to lower light intensities especially during the night, newly bloomed flowers were left on the plant for further observation (after exposure to fruit flies). Observations were conducted on at least three flowers.

Instruments

Volatile components were analyzed via gas chromatography-mass spectrometry (GC-MS) using an HP 5989B mass spectrometer coupled with an HP 5890 series II plus gas chromatograph equipped with an HP-5MS capillary column (30 m×0.25 mm, 0.25 μm film thickness) programmed from 60°C (1 min holding) to 280°C at a rate of 10°C/min. Quantification of volatiles was done on an HP 4890A gas chromatograph using an HP-1MS capillary column (20 m×0.25 mm, 0.25 μm film thickness) and programmed from 80°C (1 min holding) to 280°C at a rate of 10°C/min; the GC was equipped with a total ion monitor and flame ionization detection (FID) using internal standards [1-tetradecanol or ethyl 4-(3,4-dimethoxyphenyl)-propanoate].

Headspace Sampling

Volatile components from *Bu. vinaceum* flowers were collected during the day by using a glass jar (250 ml) with a filtered air inlet at the bottom end—connected to an aquarium pump (air flow regulated at ca. 20 ml/min)—and an outlet at the top end—directly connected to a TENAX column (packed with 100 mg in a glass tube). The TENAX column was replaced every 2 hr and washed with 0.5 ml ethanol. The resulting eluate was partially concentrated under reduced pressure (20 mmHg, <20°C) and then subjected to GC-MS and GC-FID analyses, with 1-tetradecanol as an internal standard.

Extraction of Floral Volatiles

Bu. vinaceum plants were originally collected in Kundasang, Sabah, and grown under outdoor conditions in a home garden in Tanjong Bungah, Penang, Malaysia, to obtain the blossoms. Flowers were plucked within 4 hr of blooming (07:00–9:00 hr), weighed, and immersed in sufficient redistilled ethanol in a 20-ml glass vial, and then used for GC quantifications. For individual floral organs (petals, lateral and medial sepals, lip, and column), each part was carefully removed from a freshly bloomed flower (within 3 hr after it bloomed and not exposed to fruit flies), weighed, and soaked in sufficient ethanol in a 5-ml glass vial for quantification of ME.

Extraction of Volatiles from Fruit Flies

Ten wild flies, which were observed feeding on the floral tissues of *Bu. vinaceum* flower, were captured in the orchid habitat in Kundasang, Sabah (October 1, 2002). Flies (captured in the afternoon) were kept alive until the evening (ca. 6 hr—sufficient time to incorporate and sequester the phenylpropanoids into the rectal pheromone glands)—and then dissected. The rectal gland from each fly was removed and individually soaked in ethanol (0.25 ml in 1-ml vial). Each fly body received the same treatment. A laboratory-reared male (18 d old, and not previously exposed to any phenylpropanoids) of *B. dorsalis* was processed in a similar manner after feeding 10–20 min on a flower of a potted *Bu. vinaceum* plant in Penang (October 2003) and kept alive for 24 hr before rectal gland extraction.

Authentic Samples

Eugenol and methyl eugenol were purchased from Tokyo Chemical Industries (Osaka, Japan). 2-Allyl-4,5-dimethoxyphenol, eusarone (5-allyl-1,2,4-trimethoxybenzene), *cis*- and *trans*-coniferyl alcohol, and *trans*-3,4-dimethoxycinnamyl alcohol were synthesized as previously described (Tan and Nishida, 1998; Nishida et al., 2004).

Results

Fruit Fly Species

In the highlands of Kundasang, males of two sibling species belonging to the *B. dorsalis* complex—*B. dorsalis* (most abundant) and *B. unimacula* Drew and Hancock visited flowers of *Bu. vinaceum*. Many males were observed feeding on a single flower and at times, the flower was completely covered with attracted flies (>20). The number of visitors dwindled towards dusk. Of the 10 flies captured from a single flower for rectal chemical analysis, eight were *B. dorsalis* and two were *B. unimacula*; all were male.

A similar phenomenon was observed in the lowland (nonendemic area), but with one or two individuals of *B. umbrosa* and *B. carambolae* occasionally joining the abundant *B. dorsalis* and the wild hybrid (between *B. dorsalis* and *B. carambolae*; Wee and Tan, 2005). Besides being major agricultural pests, all three are ME-sensitive species that are known to respond to ME and have been captured in ME baited traps (Tan and Lee, 1982). No other organism or insect visited the flower. When a flower was covered with fine black wire netting—through which neither the shape nor the color of the flower can be distinguished—flies landed on the netting and were observed to frantically search before settling on the

area of netting nearest to the flower. This indicated that they were attracted by the fragrance and not the floral color or shape. No female flies were attracted to the flower, irrespective of time or location.

Pollinarium Removal

An attracted fly usually landed in the general vicinity of the flower before climbing onto a petal or sepal to begin probing and feeding on the floral surfaces. The fly seemed able to detect a higher concentration of the attractant located on the inner side of the floral lip, and hence eventually headed towards the lip and climbed onto it. This hinged ovately shaped lip is always in its “closed” position (Fig. 1a and b) thus protecting the sexual organs. Should the fly climb onto the lip, particularly the area towards the tip, its weight was enough to pivot the lip into its open position (Fig. 1c). This exposed the bulbous swelling of the hamulus protruding from the gynostemium (Fig. 1d) that is always facing the flower’s reproductive organs. Due to the location of the attractant on the lip and the lip’s architecture—a concave or U-shaped channel—the fly eventually aligned itself along the longitudinal axis on the adaxial side of this ovate lip (Fig. 1d). It continued to lap up chemicals on the lip with its proboscis, and as this was depleted, it moved further in towards the base. After the fly passed the point of instability, at about the midpoint of the lip’s length, the “spring loaded” lip suddenly sprang back to its closed position (in less than 0.04 sec). This pitched the fly headfirst into the column cavity. On the fly’s parabolic flight path into the cavity, it brushed forcefully against the sticky bulb of the hamulus. The relatively long and stiff hamulus acted like a crowbar to force out or dislodge the pollinia from the anther leaving behind just the anther cover. Hence, the whole pollinarium (hamulus and pollinia) was detached from the anther and adhered to the fly’s dorsum.

Apparently shocked and shaken, the fly retreated from its temporary confinement between the closed lip and the floral column—by backing out towards the tip of the lip, hence pivoting the lip open again. Figure 1e and f shows the fly exiting the flower with the hamulus and the pollinia (ca. 2 mm from the surface of the fly’s thorax) stuck to it. The whole process of actual pollinarium dislodgement from the anther and its adhesion to the fly was precise, smooth, and nearly instantaneous—occurring in less than 1 sec (as determined from video footage). Once free, the fly either took off (one in five observations) or dismounted from the lip and continued to settle on the flower (Fig. 1f) while intermittently feeding, resting, preening, and cleaning its proboscis for 6–40 min if left undisturbed—until satiation. In the latter situation, no self-pollination was observed.

As the fly dismounted or took off from the opened lip, the lip immediately sprang back to its normal closed position (in less than 0.02 sec—the speed of a single frame of the video clip). In all five cases observed, it was the first fly that landed on the flower that removed the pollinarium; and because there is only one pollinarium, subsequent flies regardless of number were just visitors (>35 fruit flies per flower/d) feeding on floral fragrance on all parts of the flower.

The flower partially closed at night. This process took several hours beginning in late afternoon nearing sunset. The partially closed flower reopened with its petals and sepals spread out again the next day (10:00–12:00 hr).

Identification of Phenylpropanoids

Figure 2 shows a typical gas chromatogram (GC-MS trace) of *Bu. vinaceum* whole-flower extracts, exhibiting eight phenylpropanoid peaks, which were identified as eugenol (**1**),

methyl eugenol (**2**), eusarone (5-allyl-1,2,4-trimethoxybenzene) (**3**), 2-allyl-4,5-dimethoxyphenol (**4**), *cis*-coniferyl alcohol (**5**), *trans*-coniferyl alcohol (**6**), *trans*-3,4-dimethoxycinnamyl alcohol (**7**), and *trans*-3,4-dimethoxycinnamyl acetate (**8**) by direct comparison of GC-MS data with those of authentic samples.

Methyl eugenol (**2**) and *trans*-coniferyl alcohol (**6**) were the most abundant components in all samples of *Bu. vinaceum* flowers (Fig. 3). Besides the phenylpropanoids, 3,4-dimethoxybenzoic acid was also detected in varying quantities (not quantified) in these samples.

1. Compound **1** (eugenol) GC: Rt (min) 11.10; *m/z*(%) 164(100, M⁺), 149(35), 137(17), 131(24), 121(14), 104(14), 103(22), 91(16), 77(19).
2. Compound **2** (methyl eugenol) GC: Rt (min) 11.67; MS: *m/z*(%) 178(100, M⁺), 163(33), 147(18), 135(10), 107(21), 103(20), 91(21), 77(9).
3. Compound **3** (eusarone). GC: Rt (min) 13.77; MS: *m/z*(%) 208(100, M⁺), 193(53), 177(20), 165(14), 133(10), 124(10), 105(7), 91(9), 77(7).
4. Compound **4** (2-allyl-4,5-dimethoxyphenol). GC: Rt (min) 14.33; MS: *m/z*(%) 194(100, M⁺), 179(87), 163(9), 151(12), 123(31), 91(17), 77(12), 69(12).
5. Compound **5** (*cis*-coniferyl alcohol). GC: Rt (min) 14.93; MS: *m/z*(%) 180(70, M⁺), 152(15), 147(10), 137(100), 124(42), 119(23), 103(15), 91(32), 77(19).
6. Compound **6** (*trans*-coniferyl alcohol). GC: Rt (min) 15.67; MS: *m/z*(%) 180(82, M⁺), 152(10), 147(10), 137(100), 124(48), 119(24), 103(12), 91(31), 77(14).
7. Compound **7** (*trans*-3,4-dimethoxycinnamyl alcohol). GC: Rt (min) 16.08; MS: *m/z*(%) 194(97, M⁺), 177(14), 165(17), 161(23), 152(19), 151(100), 138(55), 119(16), 107(12), 91(33), 77(28).
8. Compound **8** (*trans*-3,4-dimethoxycinnamyl acetate). GC: Rt (min) 17.40; MS: *m/z*(%) 236(100, M⁺), 193(41), 177(59), 165(31), 146(59), 138(18), 119(10), 105(10), 103(10), 91(16), 77(9), 43(26).

Headspace Analysis

Emanation of methyl eugenol (**2**) was confirmed by GC-MS analysis of the headspace of a whole flower of *Bu. vinaceum* (diagnostic ion mass chromatogram: *m/z* 178, 163, 147, 107, 103, and 91; Rt = 11.67 min). Although the exact emission rate could not be determined due to low recoveries, methyl eugenol emanation from a flower (1 and 2 d old) was roughly

◀ **Fig. 1** Flowers of *Bulbophyllum vinaceum* showing the role of “spring-loaded” lip before and after pollinarium removal by a fruit fly, *Bactrocera dorsalis*. Bar=1 cm. (a) Flower with closed lip—snapped at an angle to show anther with partially hidden yellow pollinia. Hinged lip (yellow arrow) in a normal closed position, exposing its whitish ligament—“spring loaded” hinge (white arrow). (b) A male fruit fly feeding on floral volatiles near the base of closed lip that hides the floral anther and stigma. (c) Floral lip forced open by the weight of a male fruit fly (on the right edge of lip) to expose the protruding opaque bulbous swelling of hamulus (white arrow) attached to the partially exposed yellow pollinia underneath the anther cover (yellow arrow). (d) A male fruit fly perched on the floral lip before being toppled into the column cavity to remove pollinarium. Only at this instance that the bulbous swelling of the hamulus (white arrow), attached to yellow-orange pollinia partially hidden by anther cover (yellow arrow), is exposed. (e) Lateral view of flower with posterior view of male fruit fly, bearing the freshly removed pollinarium [consisting of a pollinium package (white arrow) supported by hamulus/pollinia stalk (pink arrow)], ready to dismount from the opened lip. A pollinium package has two lobes—each with a pair of pollinia. (f) Lateral view of the male fruit fly, bearing the freshly removed pollinarium, on the back of medial sepal

Fig. 3 Contents (μg/flower) of phenylpropanoid volatiles in flowers of *Bulbophyllum vinaceum* (N=11). Compounds 1–8 as in Fig. 2

Fig. 4 Weights of various floral parts of *Bulbophyllum vinaceum* ($N=4$)

estimated in a range of 10–100 ng/2 hr. No other phenylpropanoid analogs contained in the flower tissues were detected.

Distribution of Phenylpropanoids in Floral Organs

The average weight for each of the five floral parts, i.e., petals, lateral and medial sepals, lip, and column is shown in Fig. 4; the mean concentration (ppm) of individual components in each organ was obtained to compare the relative quantities among the various floral parts (Fig. 5). Although the lip was the lightest in weight, its relative concentrations of the major compounds (2, 4, 6, and 8) were highest among the five organs. These compounds were detected in lower quantities in the petals. Eugenol (1) was found almost exclusively in the petals.

Fig. 5 Concentrations (ppm) of phenylpropanoids in each floral part ($N=3$). Compounds 1–8 as in Fig. 2

Accumulation of Floral Volatiles in Rectal Glands

A laboratory-reared virgin male of *B. dorsalis*, which received the pollinarium on his thorax after voracious feeding on *Bu. vinaceum* flower, sequestered 2.3 and 3.0 μg of compounds **4** and **6**, respectively, in the rectal glands.

Of the 10 males captured on a *Bu. vinaceum* flower under natural conditions in Sabah, eight flies were identified as *B. dorsalis* and two as *B. unimacula*. Among the *B. dorsalis* males, six of them possessed relatively low quantities of compound **4** ($0.51 \pm 0.18 \mu\text{g}/\text{male}$) and a trace amount of **6** (less than $0.10 \mu\text{g}/\text{male}$), whereas the other two possessed 24.5 and 45.7 μg of compound **4**, and 0.5 and 4.9 μg of compound **6**, respectively. Both *B. unimacula* males captured on the same flower possessed a trace amount (approx. $0.03 \mu\text{g}$) of **4**, and 0.99 and 0.49 μg of **6**, respectively, in addition to large quantities of two sesquiterpenic compounds tentatively identified as β -caryophyllene and humulene. These flies appeared to have obtained large quantities of the sesquiterpenes from other plant sources prior to visiting *Bu. vinaceum*.

Discussion

Both *Bu. vinaceum* and *Bu. apertum* flowers have architectures that include prominently protruding hamuli and hinged floral lips. According to Rasmussen (1985), the function of the prominent hamulus for *Bu. ecorutatum* (= *Bu. apertum*) is unknown. However, observations of *Bu. vinaceum* presented here demonstrate the function of the hamulus as a “crowbar” to pry the pollinia out of its protective anther cover.

The morphology of the floral lip in *Bu. apertum*—except for the fact that it is hinged—is like any other petal, i.e., in the open position. Hence, the reproductive organs are always exposed and can be easily or accidentally removed by any part of the fly. Furthermore, the pollinarium once removed can just as easily be deposited anywhere on the petals or medial sepals of the same flower, leading to a total wastage of pollen (Tan and Nishida, 2005). Hence, the function of the “spring loaded” ovately shaped floral lip of *Bu. vinaceum*—always in the closed position—presumably is to protect the pollinarium from accidental removal.

A weight comparison of the portions of the *Bu. vinaceum* lip on either side of the hinge/pivot point demonstrated the presence of a nominal spring restoring force that retains the lip in its normally closed position (Tan, unpublished data). Based on two different methods of calculations performed on preserved flowers, the rotational force required to catapult the fly to the observed velocities was estimated to be between 117 and 122×10^{-9} N m (Tan, unpublished data). Additionally, the fact that the highest concentration of chemical reward occurs on the adaxial side of the lip ensures that an attracted fly will eventually end up here.

Of all the other *Bulbophyllum* species studied so far, this catapulting lip and stiff crowbar-like hamulus is unique to *Bu. vinaceum*. In contrast, other *Bulbophyllum* species, which possess flexible stipes instead of hamuli, such as *Bu. macranthum*, *Bu. cheiri*, and *Bu. patens*, have floral lips that act like seesaws and are normally in an open position. In *Bu. macranthum*, the slippery inner edges of the lateral sepals cause the fly to fall onto the lip, which then tips into the closed position sending the fly—abdomen first—into the column cavity (Ridley, 1890). For *Bu. cheiri* and *Bu. patens*, the floral lip is also usually in an opened position seesawing gently with the breeze. The fly settles on the lip to feed on chemical attractant, and as it moves past the point of imbalance the lip tilts suddenly to a closed position. Thus, for these two species, the fly is sent headfirst into the column cavity

(Tan and Nishida, 2000; Tan et al., 2002). The only other species investigated with a hamulus is *Bu. apertum* (Tan and Nishida, 2005). However, in this flower the hamulus is exposed because of the absence of a spring loaded lip; instead, it has a small triangular seesaw lip that is not large enough to protect the flower's sexual organs.

In *Bu. vinaceum*, the speed of pollinarium detachment and precision of attachment to the fly's dorsum is remarkable. This dynamic process is likely assisted by the stiff hamulus, which allows the momentum of the catapulted fly to be converted into a force that pries out the pollinia from the anther. Conversely, pollinarium removal in *Bu. baileyi* is a much slower process, taking at least 4 orders of magnitude longer (up to 46 min). In this process, the fly adheres to the stipes of the pollinarium, which is attached to the anther, and is hence suspended from the pollinarium. It has to struggle vigorously with wing and leg movements, occasionally clinging onto the small seesaw lip, in order to free itself, and thus, in the process, loosens the pollinia from the anther (Tan, unpublished observation). The adhesion of the *Bu. baileyi* pollinarium to the fly is so strong, that it is believed to be permanent, as reported by Smythe (1969), where a fly—after depositing the pollinia onto the stigma of another flower—remained attached to the pollinarium and suspended from the stigmatic surface until death.

Methyl eugenol (**2**) and *trans*-coniferyl alcohol (**6**) are the two volatile components with the highest concentrations in *Bu. vinaceum* flowers, accompanied by a series of related phenylpropanoids (**1**, **3**, **4**, **5**, **7**, and **8**). However, in another methyl eugenol-producing species, the fruit fly orchid, *Bu. cheiri*, the floral content of **2** varies from 85% to 90% of the total phenylpropanoid volatiles, with some minor ingredients similar to those found in *Bu. vinaceum* (Tan et al., 2002; Nishida et al., 2004). While **2** is known as a potent male attractant for *B. dorsalis*, compounds **4** and **6** and their derivatives **7** and **8** are moderate attractants for male flies and induce compulsive feeding behavior (Tan and Nishida, 1998; Khoo et al., 2000). Compounds **4** and **6** quickly build up in the rectal glands, when the male flies ingest **2** (Nishida et al., 1988). In contrast, if males are fed artificially either with compounds **4** or **6**, these compounds are sequestered unchanged in the rectal glands (Nishida et al., 2004). Compounds **7** and **8** are hydrolyzed by the flies to **6** after ingestion (Nishida et al., 1997). Both rectal compounds **4** and **6** serve as a sex pheromone and attract females during the courtship period at dusk (Tan and Nishida, 1998; Khoo et al., 2000). Thus, the phenylpropanoid cocktail in the *Bu. vinaceum* flower provides both intact pheromone materials (**4** and **6**) and their precursors (**2**, **7**, and **8**) to the male flies. According to the headspace analysis, methyl eugenol (**2**) was the major volatile. The emission rate is sufficient to attract male *Bactrocera* flies to the flower as the flies are extremely sensitive to this compound (ca. 1 ng spotted on a TLC plate was able to attract one or two native *B. dorsalis* males in the field; Tan, unpublished data). It is likely that the flower emits only a small amount of **2** that acts as a long distance signal, and then, provides a variety of less volatile compounds (e.g., **4**, **6**, **7**, and **8**) in its floral tissues that guide the attracted fly towards the lip area where the concentration of phenylpropanoid ingredients is the highest. This demonstrates that the floral volatiles act as synomone in this interaction in which both flies and orchid flowers gain reproductive benefits, i.e., the flower's pollinarium is transported for pollination, and the male fruit fly is rewarded with the chemicals that are used for the production of its sex pheromone (Tan and Nishida, 2000; Tan et al., 2002).

The behavioral and physiological activities (or functions) of phenylpropanoids (**1**–**8**) found in *Bu. vinaceum* flowers—evaluated from previous work on *B. dorsalis* (Nishida et al., 1988, 1997; Tan and Nishida, 1998; Khoo et al., 2000) are as follows: compounds highly attractive to males: **2**; compounds moderately attractive to males: **4**, **6**, **7**, and **8**; compounds marginally attractive to males: **1**, and **3**; compounds with potent phagostimulant activity toward males: **2**,

4, 6, 7, and 8 (5 not tested); compounds sequestered into the male rectal organ after ingestion of methyl eugenol (2): 4 and 6; compounds biotransformed to coniferyl alcohol (6) in the crop after ingestion: 2, 7, and 8; compounds attractive to females during courtship period as a sex pheromone: 4 and 6.

The reason why *Bu. vinaceum* flowers produce such an assortment of phenylpropanoids—in addition to the most attractive compound (2)—is puzzling. The less volatile phenylpropanoids may function as short-range attractants (olfactory) or phagostimulants (gustatory) to arrest male flies, at the same time securing the endowment of the pheromone precursors to the faithful pollinators. Although the flower produces components 4 and 6, which attract and arrest females during courtship and hence would serve as specific “female attractants,” the flower has never been observed to attract female fruit flies—not even during dusk when females are the most sensitive to these chemicals. This absence of attracted females despite the presence of female attractants is an unusual phenomenon—perhaps, it is because floral emission rate of compounds 4 and 6 declines through the day. Furthermore, it is possible that some of the compounds are simply by-products of other processes and, as such, do not have an explicit (or evolved) function in fly attraction. Hence, at this point, we do not have a conclusive answer for the function(s) of all the compounds produced by *Bu. vinaceum*. However, we believe that the original mutualistic interactions between *Bu. vinaceum* and its “true” partner (probably *B. dorsalis*) could shed some light. The hypothesis that the flower and its true partner coevolved, thus allowing the flower to blend the fly’s favorite cocktail in order to charm the male fruit flies is currently being investigated.

Acknowledgments We express our thanks to Jaap J. Vermeulen of National Herbarium Netherlands, Leiden Branch for useful information on *Bu. vinaceum*. This work was partially supported by the Grant-in-Aid for Scientific Research from JSPS (No. 15405022) and a Grant-in-Aid for the 21st Century COE Program for Innovative Food and Environmental Studies Pioneered by Entomomimetic Sciences, from the Ministry of Education, Culture, Sports, Science and Technology of Japan. We also thank Diogo Ezequiel and Kayin Dawoodi for their work on dynamic flower mechanisms.

Introduction

Phytoecdysteroids (PE) are plant secondary compounds that include more than 200 molecules (Dinan et al., 2001). One of the most common is 20-hydroxyecdysone (20E). Phytoecdysteroids are found in about 5–6% of the species in most plant genera (Dinan 1998). Since PEs are found in primitive plants such as ferns, it was assumed that these secondary compounds appeared very early in plant evolution. PEs are structural analogs of the molting hormone of insects and are usually considered as defensive compounds against insects. Sensitive species living on plants with low levels of PEs, such as *Bombyx mori* or *Pectinophora gossypiella* (Kubo et al., 1983), are disturbed in their growth and food intake when PEs are incorporated into their diet (Tanaka and Takeda, 1993). *Manduca sexta*, which feeds on *Solanaceae* where some species contain significant level of ecdysteroids, is tolerant to PEs (Dinan 1998). Other polyphagous species are resistant, such as several Noctuidae including *Spodoptera littoralis* (Blackford et al., 1996).

Given the large botanical distribution of PEs, we hypothesize that phytophagous insects have been confronted with these defenses for a long time and that they may have evolved different strategies to cope with them. One way to escape PE intoxication by larvae or juvenile stages is to avoid exposure. This hypothesis is supported by the observation that several larval Lepidoptera are able to avoid feeding on plants or diets treated with PEs (Tanaka et al., 1994; Marion-Poll and Descoins, 2002). This is true even for resistant species such as *S. littoralis* since neonate larvae avoid PE-treated diet (Marion-Poll and Descoins, 2002). This avoidance is mediated by deterrent taste neurons that detect PEs at a low threshold (Ma 1969; Tanaka et al., 1994; Descoins and Marion-Poll, 1999). If PEs exert a selection pressure on phytophagous insects, one would expect females to avoid laying eggs on plants producing them in order to maximize the survival chances of their progeny and, thus, limit exposure of neonate larvae to the toxicant.

How could females achieve such detection? An obvious strategy would be to use the same type of taste receptors as those expressed in larvae, in order to detect PEs on plants' surfaces or within their tissues. To begin testing whether this strategy could be used in polyphagous insects, we chose the European grapevine moth (EGVM) *Lobesia botrana* Denis & Schiffermüller (Tortricidae, Lepidoptera) as a model insect. Although this species is best known as a major pest of grapes, it has been found on more than 20 plant species including rosemary, olive trees (only flowers), privet, or *Daphne gnidium*, which is sometimes considered as its ancestral host plant (Bovey 1966; Maher 2002; Thiéry 2005; Maher and Thiéry, 2006). In this species, first instars can hardly disperse and would not be able to compensate female mistakes (Torres-Vila et al., 1997; Thiéry and Moreau, 2005;). Female decisions to oviposit on different plants or different phenological stages of grapes (Thiéry and Gabel, 2000; Maher et al., 2001) have a strong influence on the fitness of future larvae. Except for grapes, most of the host plants of *L. botrana* are toxic or known for their pharmacological use, but none has been reported to produce PEs in large amounts (Dinan, personal communication). We expect all stages of EGVMs to be sensitive to PEs and possibly to avoid them, a view that is supported by earlier observations on larvae that showed that PEs, and particularly 20E, added to the diet, caused numerous abnormalities in growth, development, and metamorphosis (Mondy et al., 1997). Behavioral studies and electrophysiological observations indicated that larvae do detect PEs from plant extracts, in their diets, by using their taste receptors (Mondy et al., 1999).

In this work, we examined the feeding behavior and oviposition responses of EGVM to 20E and evaluated the sensory responses of taste sensilla of fifth instar and adult females to 20E. In doing so, we described the distribution of the contact chemoreceptors present on the

foreleg of the females of this species, and propose to segregate these taste receptors into three functional groups, based on their responses to a limited set of stimuli.

Methods and Materials

Insects A colony of *L. botrana* issued from insects sampled in Sauternes vineyard in 1998, was reared on a semisynthetic diet (Maher, 2002) at INRA Bordeaux. They were maintained without diapause at $22 \pm 1^\circ\text{C}$ under a 16:8 L/D photoperiod and at 60–65% relative humidity. Electrophysiological and behavioral observations were performed on adults from this strain in 2002–2004 and on larvae in 2005.

Chemicals 20-Hydroxyecdysone was purified from *Leuzea carthamoides* (95% min purity with minor ecdysteroids mixtures of polypodine B, ajugasterone C, and inokosterone; SciTech, Prague, Czech Republic, and R. Lafont, Univ. Paris 6). It was dissolved in ultrapure water or in ethanol according to the different bioassays. For electrophysiology, test solutions were dissolved in 10^{-4} M potassium chloride (KCl, Prolabo) to ensure proper electrical conductivity. 20E was used at concentrations ranging from 10^{-8} to 10^{-3} M for electrophysiological recordings and 10^{-7} to 10^{-2} M for behavioral tests.

Two-Choice Feeding Experiments To determine 20E effects on the feeding behavior of *L. botrana* larvae, two-choice tests were conducted. Two disks of artificial food were placed diametrically opposed on the bottom of a plastic Petri dish. The size of the food disk and of the feeding arenas (Petri dish) varied according to the stage of the larvae (L2=8 mm diam \times 2 mm high food disks into a 3-cm-diam Petri dish; L3=12 mm diam \times 2 mm high food disks into a 5.5-cm-diam Petri dish). One disk was treated with 20E 10^{-3} M in ethanol (12 μl for L2 and 22 μl for L3) and the other with ethanol only (control disk). Given the volume of the diet offered to the larvae, this corresponds to 49 $\mu\text{g}/\text{cm}^3$. A control test was conducted each time in parallel using disks treated with solvent only. Assuming that the solvent had evaporated after 30 min, four larvae starved for 4 hr were introduced into the center of each arena. We measured the number of larvae located on the disks or within a radius of 1 cm around the disks, after 2, 24, 48, and 72 hr. These experiments were repeated 15 times (240 larvae tested). The results were analyzed with nonparametric statistics. Preferences between treated and nontreated disks were compared by using the Wilcoxon test (WX). To determine if there was an increase or a decrease in the deterrency, the number of larvae placed onto or close to the treated disk at different times was analyzed with the Mann–Whitney (MW) test.

Oviposition Tests Oviposition responses of gravid females of *L. botrana* were examined by using a two-choice bioassay (Maher and Thiéry, 2004a). Test solutions were sprayed onto rows of four glass spheres (diam: 1.6 cm, spaced by 2 cm), placed on a glass plate (75 \times 25 mm). Each row was treated either with 0.5 ml of diluted 20E (ranging from 10^{-7} to 10^{-2} M) or with 0.5 ml of pure water (control). These spheres were dried in an incubator at 40°C for 90 min. Given the size of the spheres, the resulting concentration of 20E ranged from 0.8 ng to 80 $\mu\text{g}/\text{cm}^2$. Two rows of spheres, spaced by 6 cm, were placed into the bottom of a plastic box. This box was covered with baize, which prevents oviposition on the experimental area except on the spheres. After introducing a single female per box, each box was closed with a veil and placed into an environmental chamber maintained at 16:8 L/D photoperiod

and 23°C. Females were removed 16 hr later, and the number of eggs deposited on the spheres was counted.

Experiments were done on 3–4 day old females. Recently emerged females and males (less than 12 hr) were grouped one night in a cage. Females were isolated the following night in glass tubes and checked for oviposition in the morning. We used only females that laid eggs during this first night. By using this procedure, more than 90% of females were ready to oviposit during the experiments. Experiments that started at 4 P.M. were run on individual females with a minimum of 20 females per dose.

Oviposition scores were compared with nonparametric statistics. The total number of eggs laid during one experiment was compared by using the MW test. The preferences between treated and nontreated items in each experiment were compared by the WX test. For control experiments, the spheres were arbitrarily assigned a label A or B before experiments. Pilot experiments showed that the females ignored such labels. For convenience, data are presented in the text as mean±SE of the mean.

Electrophysiology Recordings from fifth instars were obtained from isolated heads, mounted on a reference silver electrode. The preparation was oriented in such a way that the galea was extruded, thus giving access to the lateral and medial sensilla styloconica.

Adult females were briefly narcotized with carbon dioxide, decapitated by using fine scissors, and then fixed onto a polystyrene block. A reference electrode, filled with Ringer's solution, was inserted into the abdomen. One of the prothoracic legs was taped to the support in order to expose the sensilla from the ventral side of the fifth tarsomere. Recordings were performed on sensilla chaetica type b (Maher and Thiéry, 2004b) by capping them with a capillary tube (10 µm tip diam) containing the test solution, filled just before recording.

Electrical signals were recorded with an amplifier (TastePROBE DLP-02; Syntech, Hilversum, the Netherlands) with automatic offset compensation (Marion-Poll and Van der Pers, 1996) and further amplified and filtered (CyberAmp, 320, Axon Instruments; gain: 1000; eight poles Bessel band-pass filter: 0.1–30 to 2800 Hz). Data were recorded and stored on a computer with a 16-bit A/D conversion card (DT9803; Data Translation, USA) under the control of a custom software, dbWave (Marion-Poll 1996). Each recording lasted 2 sec and was triggered by a pulse delivered by the amplifier on the initial contact of the electrode with the sensillum. Recordings were analyzed by using dbWave, in order to detect and sort spikes according to their amplitude and shape using interactive procedures. Responses to the different stimuli were evaluated by counting the total number of spikes during the first sec of the recording.

Series of recordings were done with 10^{-4} M KCl (also used as electrolyte of nonconductive solutions) and followed by an ascending series dilutions of 20E (10^{-8} to 10^{-3} M step 10). Consecutive stimuli on a sensillum were applied with an interval of at least 2 min in order to avoid adaptation. For adults, the position of each recorded sensillum was carefully noted in order to compare our results with earlier observations (Maher 2002; Maher and Thiéry, 2004b; Maher et al., 2006).

Results

Two-Choice Feeding Experiment Larvae preferentially fed on nontreated disks rather than on disks treated with 20E (Fig. 1). The difference was highly significant for all observation times for L2 and L3 larvae. Both instars spent significantly more time on or close to the food disk (treated or not) than wandering elsewhere, except during the first 24 hr. Mann–

Fig. 1 Behavioral choices of second and third instars of *Lobesia botrana* between two food disks treated or not with 20E. White bars: control diet (solvent alone); black bars: treated diet (20E 10^{-3} M). Bars indicate the number of larvae (mean±SEM) found on or close to each disk at 2, 24, 48, and 72 hr after the start of the experiments. $N=15$ (with four larvae each). Wilcoxon test, 20E vs. control * $P<0.05$, ** $P<0.01$

Whitney test showed that there was no increase or decrease in deterrence according to time. In the control tests (using disks with only solvent), L2 and L3 larvae fed equally on both disks.

Sensitivity of Larvae to 20E In fifth instars, a strong activity in response to 20E was found in the medial and lateral sensilla (Fig. 3). Responses originated from one cell that increased its activity from 10 to 80 spikes sec^{-1} , respectively, for 10^{-5} to 10^{-3} M of 20E (Figs. 2 and 3). At lower concentrations (10^{-6} and 10^{-5} M), the response was initiated after a latency of 50–100 ms as in the adults.

Fig. 2 Response samples of fifth instar lateral sensilla to 20E 10^{-4} M and 10^{-3} M. Trace duration = 1 sec. Vertical bar = 1 mV, horizontal bar = 100 ms

Fig. 3 Electrophysiological responses of fifth instars to ascending concentrations of 20E. Black squares: responses from medial sensilla styloconica; Open triangles: responses from the lateral sensilla styloconica. Each data point represents the average number of action potentials during the first second of the recordings (mean \pm SEM; $N=10$ stimulations)

Oviposition Tests Females laid fewer eggs on treated glass spheres (T) than on nontreated ones (NT) at intermediary doses of 20E, namely, 10^{-6} M (T: 8.1 ± 6.9 vs. NT: 16.7 ± 9.8 ; WX, $P=0.003$), 10^{-4} M (T: 4.7 ± 6.9 eggs vs. NT: 19.1 ± 14.9 eggs; WX, $P<0.001$) and 10^{-3} M (T: 5.2 ± 8.6 eggs vs. NT: 16.5 ± 15.1 eggs, WX, $P<0.001$). This was not the case for low 20E concentrations (10^{-7} M) nor for the highest (10^{-2} M), where the scores were not statistically different between the treated and untreated spheres (10^{-7} M: T: 14.5 ± 10 vs. NT: 20.2 ± 8.6 ; 10^{-2} M: T: 11.2 ± 8.2 vs. NT: 15.1 ± 14 (Fig. 4). The behavioral threshold to 20E is close to 10^{-6} M, a concentration that corresponds to 30 ng of 20E per sphere or 0.037 ng per mm^2 . In addition, the total number of eggs deposited on both glass spheres is significantly reduced at concentrations higher than 10^{-6} M (Mann Whitney: NT vs. 10^{-6} M: $P=0.002$; NT vs. 10^{-4} , $3 \cdot 10^{-4}$ M: $P=0.008$).

Tarsal Taste Sensilla On the ventral side of the fifth tarsomere, adults of both sexes bear a ring of 10 sensilla and four medial sensilla that were described as sensilla chaetica type I, or “sensilla b” (Maher, 2002; Maher and Thiéry 2004b). Although they look morphologically

Fig. 4 Behavioral choices of females *L. botrana* given a choice between glass surrogates treated or not with 20E (from 10^{-7} to 10^{-2} M). Number of eggs laid by one female according to the substrate ($N>20$). Wilcoxon test: 20E vs. control $**P<0.01$, $***P<0.001$

identical, they diverge in their responses to KCl. We propose to distinguish three groups among them (Fig. 5):

- (a) Group I sensilla (Fig. 6a) that fires a few spikes of large amplitude at the beginning of the stimulation (amplitude = 1.5–2 mV; 1.7 ± 0.2 spikes sec^{-1} (average \pm SEM), $N=32$).
- (b) Group II sensilla responds tonically with a single class of spikes (0.3 mV; 57.2 ± 2.7 spikes sec^{-1} , $N=27$).
- (c) Group III sensilla (Fig. 6b) that responds phasitonicly with two classes of spikes: one of large amplitude (1–2 mV; 2.6 ± 0.3 spikes sec^{-1} , $N=6$ recordings) and a second one of smaller amplitude (0.2 mV; 48.4 ± 6.4 spikes sec^{-1}). On some recordings, this second cell started to fire after a variable delay.

The large amplitude spikes observed at the beginning of the recordings (Fig. 6a, b) differ from the activity of mechanoreceptors. When a deflection was imposed on the hair by moving the capping electrode laterally, these mechanoreceptors elicited spikes of much smaller amplitude (1–2 mV) superimposed on a downward deflection of the baseline during the bending (data not shown). Only sensilla of group II responded to 20E; therefore, all subsequent recordings were performed on them.

Sensitivity of Adults to 20E Although two spike amplitudes were observed in the responses of group II sensilla to 20E, we consider that only one neuron was activated (Fig. 7a, b). One neuron consistently fired spikes of medium amplitude (0.3–0.4 mV), but its activity did not vary with changes of 20E concentration (Fig. 8a), except by a small decrease of activity at 10^{-3} M (46.5 ± 3.02 spikes sec^{-1}). This cell fired also in the presence of NaCl or of sugars (data not shown).

A second cell fired spikes of smaller amplitude (0.2–0.3 mV) in the presence of 20E, starting at concentrations of 10^{-8} or 10^{-7} M, depending on the preparation. Its activity increased with 20E concentration, ranging from 8.25 ± 1.61 spikes sec^{-1} at 10^{-7} M to a maximum of 22.5 ± 2.79 spikes sec^{-1} at 10^{-5} M (Fig. 8b). Its response decreased from 10^{-4}

Fig. 6 Response samples of “b” sensilla to 10^{-4} M KCl: (a) sensilla from group I; (b) sensilla from group III. Trace duration=1 sec. Vertical bar=400 μ V; horizontal bar=60 msec

to 10^{-3} M. The responses were tonic and regular over the observation period (2 sec). At low concentrations of 20E, it started to fire with a delay of 200–300 ms. This delay shortened at higher concentrations of 20E.

Discussion

In this work, we demonstrate that *L. botrana* adults and larvae can detect 20E. Electrophysiological recordings indicate that taste receptors responding to 20E are present

Fig. 7 Response samples of sensilla chaetica b to (a) 10^{-4} M KCl and to (b) 10^{-7} M 20E. Trace duration = 500 msec; vertical bar=400 μ V; horizontal bar=50 msec. Spikes amplitudes fall into two classes: medium-amplitude spikes (class 0) are observed in both types of recordings; small-amplitude spikes (class 1) are observed only in the presence of 20E

Fig. 8 Electrophysiological responses of sensilla chaetica type I (sensilla b—group II) to 10^{-4} M KCl and to ascending concentrations of 20E. (a) White diamonds: responses from class 0 spikes (of medium amplitude). (b) Black triangles: responses from class 1 spikes (of small amplitude). Each data point represents the average number of action potentials during the first second of the recording (mean \pm SEM; $N=12-25$ recordings)

in both stages, and our behavioral studies show that 20E has a deterrent effect on feeding and oviposition. These observations are new because the impact of phytoecdysteroids has been mostly evaluated on larval insects. Using behavioral and toxicity tests on larvae, Blackford and Dinan proposed that species can be rated as sensitive, semitolerant, or tolerant to PEs (Blackford et al., 1996, 1997; Blackford and Dinan, 1997a, b, c). Our own observations on second and third instars as well as former studies on *L. botrana* (Mondy et al., 1997) suggest that this species is sensitive to 20E. These behavioral responses are probably mediated by taste neurons located in the lateral and the medial sensilla of the maxillary palps in which we recorded vigorous and sustained monocellular responses to 20E, at a threshold of 10^{-5} M.

Because larvae are sensitive to 20E, we expected adults to avoid ovipositing on a substrate in the presence of 20E. This hypothesis was tested by monitoring eggs laid on berry surrogates treated with 20E. We observed that 20E-treated berries were avoided and that females laid fewer eggs in the presence of 20E. The most effective concentration of 20E was 10^{-4} M, which is equivalent to 6.3 μg of 20E per sphere, i.e., 0.8 μg of 20E per cm^2 . At higher concentrations of 20E, discrimination between treated and nontreated spheres was less effective. The total number of eggs deposited during the observation period decreased with 20E in a dose-dependent manner, even at higher doses when females did not seem to discriminate between treated and nontreated surfaces.

As in larvae, detection of 20E in adults is certainly mediated by taste sensilla. We studied taste sensilla located on the distal tarsi. From the 16 sensilla present on the ventral

side of the last tarsus of the prothoracic legs, only four were found to house a neuron stimulated by 20E. This neuron fired spikes of small amplitude and responded with a detection threshold of 10^{-7} M. Its response was maximal at 10^{-5} M and decreased slightly at higher concentrations. This decrease is probably attributable to adaptation and to our experimental protocol, because we presented 20E as a series of increasing concentrations. It is likely that we would need to respect resting intervals longer than 2–3 min at these high doses. While 20E stimulated this cell firing small amplitude spikes, a second cell was present in the recordings, characterized by spikes of medium amplitude. Its firing activity did not change in the presence of 20E, except at high concentrations where its activity decreased. This cell could correspond to the ubiquitous water cell found in many taste sensilla of other insects (Inoshita and Tanimura, 2006).

Our anatomical and electrophysiological observations complete earlier descriptions of taste tarsal sensilla in *L. botrana* (Maher, 2002; Maher and Thiéry, 2004b; Maher et al., 2006). By using KCl and 20E as test stimuli, the responses of these taste receptors could be classified into three groups, with only group II sensilla responding to 20E. It remains to be determined if group I–III sensilla respond to other deterrent compounds or if group II sensilla are specialized in triggering an avoidance behavior. The functional arrangement of these tarsal sensilla is reminiscent of what we found with *Ostrinia nubilalis* (Marion-Poll et al., 1992; Marion-Poll and Calas, unpublished data) and with *Drosophila melanogaster* (Meunier et al., 2003), where only a subset of the tarsal sensilla are sensitive to a given deterrent molecule. This means that behavioral decisions taken in the presence of deterrent compounds is taken from integration of responses from several types of sensilla from one or more appendages.

Although similar taste cells responding to 20E have been found in *L. botrana* larvae, as well as in larvae of several other species of Lepidoptera (Ma, 1969; Tanaka et al., 1994; Descoins and Marion-Poll, 1999; Marion-Poll and Descoins, 2002), it is the first time that responses to this compound have been demonstrated in adult Lepidoptera. We postulated that if 20E presented a negative effect on growth and development of the larvae of *L. botrana* (Mondy et al., 1997), this ecdysteroid could be perceived by adults and particularly females as a deterrent compound for oviposition. That females could detect deterrents avoided by larvae is ecologically relevant, since females are much more mobile than larvae. A similar situation was observed in *Trichoplusia ni*, where oviposition of adult females was deterred by toosendanin, a limonoid from the bark of *Melia azedarach*, which inhibits feeding of larvae of this species (Akhtar and Isman, 2003).

Although we have examined the effect of 20E on adults only in regard to oviposition, and have speculated that detection of 20E is relevant in avoiding plants that would lessen the chance of larvae survival, it is still possible that 20E could impact directly on adults, a hypothesis that was not tested in this work. Adults may need to avoid ingesting phytoecdysteroids present in the nectar of flower or from guttation liquids, especially considering that the maturation of the oocytes requires 20E. Avoiding 20E has been noted in Heteroptera, where 20E was found to deter drinking in three species among four tested (Schoonhoven and Derksen-Koepfers, 1973).

The ecological significance of 20E avoidance in the European grapevine moth may have to be considered in a broader frame than the relations between the EGVM and its host plants. Given the number of plants producing PEs in different genera and scattered observations in the literature concerning the detection of PEs, it is possible that PEs have been conserved in many phytophagous insect species, not only in larvae as discussed by Blackford and Dinan (1997a), but also in adult insects.

Acknowledgements We thank René Lafont (University Paris VI) for his gift of 20E and many scientific discussions. We also thank Andrée Berthier for excellent technical assistance and Claire Barthe who contributed to behavioral experiments on adults. This work was supported by an INCO-DEV program SUSVEG-ASIA, and by the Comité Interprofessionnel des Vins de Bordeaux.

Introduction

Low levels of nutrients and high concentrations of plant secondary metabolites (PSMs) often make it difficult for herbivores to meet their daily nutritional requirements. Therefore, most herbivores have adapted a generalist strategy to foraging, eating many different types of plants to meet their nutritional requirements and reduce toxic effects of PSMs (Freeland, 1991; Dearing et al., 2000; Marsh et al., 2003; Sorensen and Dearing, 2003). Out of more than 1000 mammalian herbivores known, only about 1% are considered dietary specialists, obtaining most or all of their nutritional requirements from one plant source (Freeland 1991; Dearing et al., 2000). Specialist herbivores have likely coevolved with their forage plant, developing detoxification pathways specific to its PSMs (McArthur et al., 1991; Marsh et al., 2003; Sorensen and Dearing, 2003; Sorensen et al., 2004).

Monoterpenes are bitter-tasting volatile oils, many of which are responsible for the characteristic aromatic odors of plants such as sagebrush, *Eucalyptus* spp., and conifers (Harborne, 1991). They act as feeding deterrents (Sinclair et al., 1988; Gershenson and Croteau, 1991; Meyer and Karasov, 1991), and at higher concentrations can cause acidosis (Cork and Foley, 1991), destroy or inhibit growth of rumen flora (Nagy et al., 1964; Burritt et al., 2000), irritate mucous membranes, cause neurotoxicity, diuresis and nephritis (Dearing et al., 2000), and require animals to spend additional energy in detoxification (Sorensen et al., 2005). In some instances, terpenes themselves may not be toxic, but as volatile compounds act as an easy-to-detect cue for more potent PSMs they are associated with, such as formylated phloroglucinol compounds (FPCs), lactones, and phenolics (Radwan et al., 1982; Bray et al., 1991; Lawler et al., 1999).

Although most animals avoid eating large amounts of plants that contain toxic PSMs, some animals specialize on them. Koalas (*Phascolarctos cinereus*) and the greater glider (*Petauroides volans*) feed almost exclusively on *Eucalyptus* spp., known to have high levels of terpenes, tannins, and FPCs (Lawler et al., 1998; Moore and Foley, 2000; Marsh et al., 2003). Other herbivores also rely on terpene-containing plants, but to a lesser extent. For example, the terpene-containing juniper (*Juniperus monosperma*) comprises 80–95% of the diet of the Stephen's woodrat (*Neotoma stephensi*; Dial, 1988). Likewise, pygmy rabbits (*Brachylagus idahoensis*) are restricted to deep-soil sagebrush-steppe habitat, consuming up to 99% of their diet in big sagebrush (*Artemisia tridentata*) in winter and up to 50% in summer (Green and Flinders, 1980b; Thines et al., 2004), despite high concentrations of terpenoids (6–23%), and monoterpenes (1–4%) in particular (White et al., 1982b; Meyer and Karasov, 1991). Although little is known about PSMs other than terpenes and sesquiterpenes in sagebrush, 10 coumarins (Shafizadeh and Melnikoff, 1970; Brown et al., 1975) and 13 flavonoids (Brown et al., 1975; Thines, 2006) have been identified.

Several wildlife species, such as mule deer (*Odocoileus hemionus*; Cluff et al., 1982), pronghorns (*Antilocapra americana*; Ngugi et al., 1992), and black-tailed jackrabbits (*Lepus californicus*; Uresk, 1978), consume sagebrush as a portion of their seasonal diet, but no other known mammal depends on sagebrush as extensively for food as does the pygmy rabbit. Consuming moderate amounts of sagebrush (15–50% of the diet) causes digestive upset, reduced rumen motility, rumen lesions, rumenitis, and even death in mice, mule deer, sheep, and cattle (Johnson et al., 1976; White et al., 1982b; Harborne, 1991). Therefore, sagebrush is generally considered toxic to mammals, especially livestock (Burritt et al., 2000).

Although sagebrush dominates 1.1 million km² of the western United States and Canada (Meyer and Karasov, 1991), pygmy rabbits only occupy patchily distributed deep soil habitats dominated by tall, dense big sagebrush (Green and Flinders, 1980a). However,

much of this small (400–500 g), burrowing rabbit's habitat within the Great Basin of the western United States has been degraded, fragmented, and converted to other uses such as agriculture for over a century (McAllister, 1995; Federal Register, 2003). An evolutionarily distinct population of pygmy rabbits in the Columbia Basin of Washington has been listed as endangered by the U.S. Fish and Wildlife Service (USFWS; Federal Register, 2003), and USFWS has received petitions for listing the species range-wide (Federal Register, 2005). However, little is known about the extent to which pygmy rabbits depend on sagebrush for food, how they cope with a diet high in terpenes, and their requirements for energy and nitrogen (N).

In this study, we examined the nutrient requirements of pygmy rabbits and their propensity and ability to select and consume sagebrush. As a comparison, we also examined nutritional requirements and sagebrush consumption by eastern cottontail rabbits (*S. floridanus*), a larger leporid that is considered a dietary generalist, but is also known to occasionally inhabit the sagebrush-steppe region with pygmy rabbits (McAllister, 1995). We expected pygmy rabbits to eat more sagebrush relative to their size than cottontails when sagebrush was offered alone and as part of a mixed diet. We expected them to voluntarily eat enough sagebrush to meet their energy requirements and maintain body mass, and to obtain more digestible nutrients from sagebrush, but less from nonsagebrush foods, than cottontails. Finally, we expected both pygmy rabbits and cottontails to eat more sagebrush as the quality and quantity of other diet items declined.

Methods and Materials

To examine energy and protein requirements and fiber tolerances of pygmy rabbits, we conducted digestion trials with 2–5 adult pygmy rabbits (451 ± 15 g) from populations found in Idaho. All had been born in captivity as part of a captive breeding program at the E.H. Steffen Center at Washington State University (WSU). As a comparison, we also used 3–4 adult eastern cottontails (1209 ± 70 g), captured on the WSU campus. Standard husbandry practices and the experimental protocol were approved by the WSU Institutional Animal Use and Care Committee (#3097). When not used in experiments, animals were housed on soil in large outdoor pens or in stainless steel rabbit cages indoors, and fed a maintenance diet consisting of one or more completely balanced pelleted rabbit diets (e.g., LabDiet[®] 5326 Hi Fiber Rabbit, PMI Nutrition International, Brentwood, MO, USA; Bunny Basics/T[®], Oxbow Pet Products, Murdock, NE, USA). They were also fed a mix of fresh forbs and sagebrush grown in our greenhouse without pesticides, and only supplemented with N for fertilizer. Tap water, trace mineral block, and the pelleted rations were provided *ad libitum*.

In January–March 2003–2005, we conducted total-collection, single-diet digestion trials using a series of seven pelleted diets and sagebrush grown in the greenhouse and outside (Table 1). Cottontails participated in three of the pelleted trials and the greenhouse sagebrush trial. The diets ranged in fiber [24–55% neutral detergent fiber (NDF)] and N content (0.5–4.5%) (Table 1). During the trials, animals were housed individually in stainless steel digestion crates with Dri-Dek[®] flooring (Kendall Products, Naples, FL, USA) and plastic nest boxes in a covered barn. Electric heaters maintained the air temperature outside the crates at an average daily temperature that ranged from 0 to 5°C. The digestion trials lasted from 3 d (sagebrush) to 5 d (pellets) following a 10-d pretrial during which the animals were gradually introduced to the trial food by increasing its contribution to the diet, and acclimated to stainless steel digestion crates. At the end of each trial,

Table 1 Composition of pelleted rations and sagebrush (*Artemisia tridentata*) fed to captive pygmy rabbits (*Brachylagus idahoensis*) and eastern cottontails (*Sylvilagus floridanus*)

animals were moved back to their original pens and weaned back onto their maintenance diets during a 10-d post trial. Animals were weighed before, at least once during, and after each digestion trial. Food and water were offered *ad lib*, and a mineral block was provided. If an animal lost more than 20% of its pretrial body mass, it was removed from the trial.

During the sagebrush trials, fresh sagebrush was offered in the morning and augmented twice during the day as needed. To ensure that sagebrush diets were homogenous, sagebrush was grown in a dedicated greenhouse or food plot outside. Greenhouse sagebrush was grown from seed in individual containers, and watered daily. Greenhouse seedlings used in trials were 2–3 mo old and about 20 cm tall. Sagebrush grown outside in food plots were 3-yr-old shrubs that had originated from greenhouse seedlings. Only current annual growth was collected, the woody component of sagebrush was minimized, no flowers or inflorescences were included, and all leaves were consistent in size and age. Sagebrush was harvested each day immediately before feeding from several flats in the greenhouse or at least six shrubs outside. Orts were collected, weighed, and corrected for dry matter (DM), then subtracted from the forage given the previous day to determine daily DM intake (DMI) of each animal.

Feces fell to mesh screens placed below each digestion crate, urine was funneled into bottles containing ≈ 5 ml of HCl to maintain a $\text{pH} < 7$ and reduce loss of N as ammonia. Each day, the pH of urine (before it reached the HCl) was measured with a pH meter or pH paper between 0700 and 0800 hr. The remainder of the urine was collected daily and stored at -20°C . Samples of the food, feces, and orts were dried daily at 100°C for 24 hr to determine DM content. Additional samples of food and feces were dried at 60°C for 3 d and ground to pass a 1-mm screen and pooled at the end of the 3- to 5-d trial for later nutritional analysis. Samples of sagebrush intended for terpene analyses were harvested from at least six plants between 1000 and 1130 hr to avoid diurnal and interplant variation in terpene concentration (Nicholas, 1973) and stored at -40°C . We made composites of samples intended for tannin analysis from at least six plants, froze them at 20°C , and freeze-dried them before grinding.

We measured the gross energy content of food, feces, and urine by using bomb calorimetry (Table 1). Fiber composition of food and feces was determined from sequential detergent analysis (Goering and Van Soest, 1970) with filter bags, sodium sulfite, and alpha

amylase (Ankom Fiber Analyzer 200/220®; Ankom Technology, Fairport, NY, USA) to determine NDF, acid detergent fiber (ADF), and acid detergent lignin (ADL; Table 1). Kjeldahl analysis and a carbon–nitrogen analyzer (TruSpec®; LECO Corporation, St. Joseph, MI, USA) was used to determine N content of feces, food, and urine. Crude protein (CP) content (%) was estimated as 6.25 times the N content (Robbins, 1993). The capacity of condensed and hydrolyzable tannins to bind proteins in food was determined by the bovine serum albumin (BSA) method (Martin and Martin, 1982).

To extract volatile terpenes from whole plant tissue of greenhouse and outside sagebrush, we used direct simultaneous steam distillation pentane extraction of the frozen (−20°C) plant material with a Likens–Nickerson apparatus (J&W Scientific, Folsom, CA, USA). In this process, we combined plant material with 100 ml deionized water, boiled it for 20 min, and collected distillate in 25 ml of pentane with a standard added to the pentane. After drying and weighing the distilled plant material, we diluted the distillate with pentane (200 µl of sample with 800 µl of pentane) and quantified the components by comparing detector response with a standard of known quantity using capillary gas chromatography (GC) on a Hewlett-Packard 5890 Series II GC equipped with a flame ionization detector (at 230°C), 7673 A autosampler, and a ZB5 column (30 m × 0.25 mm i.d.; Phenomenex, Torrance, CA, USA) using hydrogen (13 psi head pressure) as the carrier gas. Cool on column injection (40°C) was used with a temperature program starting at 40°C, ramped at 10°C/min to 250°C, and then programmed at 40°C/min to 300°C. Data were analyzed by using Chrom Perfect Spirit v. 5.5.2 (Justice Laboratory Software, Denville, NJ, USA). We identified components of the distillate by comparing their mass spectra with spectra from the NIST02 Mass Spectral Library with Windows Search Program v.2.0 (National Institute of Standards and Technology, Gaithersburg, MD, USA). GC-mass spectrophotometry (GC-MS) was performed on a Hewlett-Packard 5840A-5985B MSD system (at 70 eV) using a ZB5 column (30 m × 0.25 mm i.d.; Phenomenex, Torrance, CA, USA) with the same temperature program as described for GC analysis.

Metabolic fecal nitrogen (MFN, g N/100 g feed) for pygmy rabbits was estimated as the negative y -intercept of the line of regression of digestible N (g N/100 g feed) against dietary N (%) for all foods. True N (%) was determined by the slope of this regression line. Similarly, the y -intercept of the regression line of urinary N (mg N/kg^{0.75}/d) against dietary N intake (mg N/kg^{0.75}/d) was used to estimate the endogenous urinary N (EUN, mg N/kg^{0.75}/d). The x -intercept of the regression line for N balance (N ingested – N excreted, mg N/kg^{0.75}/d) against dietary N intake (mg N/kg^{0.75}/d) estimated maintenance N requirements (the amount of N an animal must consume to counteract the minimum constant losses from feces and urine) of pygmy rabbits and cottontails. Minimum dietary protein requirements were derived from the equation [(EUN + MFN (DMI) – 6.25)/DMI/0.74] (Robbins, 1993). Because none of the diets had enough tannins to precipitate proteins in BSA analysis, all diets were included, but only animals gaining mass or losing <1% of their pretrial body mass per d of the trial were included in these analyses. We compared digestible N, urinary N, and N balance among pygmy rabbits and cottontails with analysis of covariance.

Maintenance energy requirements for both pygmy and cottontail rabbits in small cages were estimated from the x -intercept of the regression of average daily change in body mass as a function of digestible energy intake (DEI; kJ/kg^{0.75}/d), where DEI was the product of DMI (g/kg^{0.75}/d), gross energy content of the food (kJ/g), and apparent energy digestibility (AED, %) for each diet. The slope of this line represented body mass change per unit of additional energy intake. We compared intake and digestibility among foods between pygmy rabbits and cottontails by using a two-way analysis of variance with interactions, with Tukey's multiple comparison test at $\alpha = 0.05$.

To compare intake of sagebrush by pygmy rabbits and cottontails as a function of the amount and nutritional quality of supplemental foods, we ran a series of single- and double-choice experiments. In these experiments, we measured the rabbits' voluntary consumption of sagebrush grown in the greenhouse and outside as we varied the amount of high-quality (pellet 1: high N, low fiber) or low-quality (pellet 2: low N, high fiber; Table 1) pellets offered. We used two to three pygmy rabbits and three cottontails for these experiments. Our first experiments determined the amount of sagebrush and high- or low-quality pellets consumed when each was offered *ad lib*. In subsequent experiments, we offered rabbits pellets at 50% and 25% of their *ad lib* intake of pellets and measured sagebrush consumption. We also measured sagebrush consumption when no supplementary pellets were offered, and consumption of greenhouse and outside sagebrush when offered together with 15% of their *ad lib* consumption high-quality pellets. Because of its limited availability, we only conducted experiments with outside sagebrush with 50% *ad lib* intake of both high- and low-quality pellets for both rabbit species, and with greenhouse sage/15% pellets and no pellets for pygmy rabbits.

Food offered was weighed and corrected for DM, and orts were collected, weighed, and subtracted to determine the dry mass of pellets and sagebrush consumed. For trials with both sagebrush types, we separated the food offered and refused into stems and leaves to account for any possible differences in preference for plant parts. We compared DMI and DEI of greenhouse sagebrush consumed by pygmy rabbits and cottontails, and the relationship between urine pH and sagebrush consumption, by using analysis of covariance, with species and pellet quality as class variables and dry mass of pellets consumed as a covariate. Additionally, we compared voluntary intake of greenhouse and outside sagebrush by pygmy rabbits and cottontails when fed 50% of their *ad lib* intake of low- and high-quality pellets by using analysis of variance, and paired *t*-tests.

Results

Energy and Protein Requirements

Pygmy rabbits required 750.8 kJ DE/kg^{0.75}/d and cottontails required 549.2 kJ DE/kg^{0.75}/d to maintain their body mass when residing in small cages between 0°C and 5°C (Fig. 1). Pygmy rabbits had an MFN of 7.5 g N/kg feed (Fig. 2), and an EUN of 22.9 mg/kg^{0.75}/d (Fig. 3). True N digestibility was 88%. They required at least 306.4 mg N/kg^{0.75}/d for

Fig. 1 Body mass gain as a function of digestible energy intake of captive pygmy rabbits (PR, solid line) and cottontail rabbits (CT, dashed line) when consuming pelleted rations and sagebrush (*Artemisia tridentata*, circled points). Daily digestible energy requirements are found at the intersection of the regression lines with the *x*-axis

Fig. 2 Mean apparent digestible nitrogen of captive pygmy rabbits (PR) and cottontail rabbits (CT) as a function of dietary nitrogen for pelleted rations and sagebrush (*A. tridentata*, circled points). Metabolic fecal nitrogen is the negative y -intercept

maintenance (Fig. 4). Cottontails had a similar digestible N ($F = 1.13, P = 0.32$), N balance ($F = 0.80, P = 0.39$), and urinary N ($F = 0.02, P = 0.90$) relative to dietary N or N intake to pygmy rabbits (Figs. 2, 3, and 4). Based on their EUN and MFN, when pygmy rabbits eat >9 g DM/d, they require a minimum of 7% CP in their diet.

Digestibility of Foods

Pygmy rabbits digested DM, apparent energy (AE), neutral detergent solubles (NDS) and NDF of the high-quality diet (pellet 1), and NDS and NDF of the low-quality diet (pellet 2), to a lesser extent than the larger cottontails (all $P < 0.05$, Table 2). However, the two rabbit species digested high-quality pellets and greenhouse sagebrush equally (all $P > 0.05$, Table 2). Both pygmy and cottontail rabbits digested DM, AE, and NDF to a greater extent when eating high-quality pellets and greenhouse sagebrush than when eating low-quality pellets (all $P < 0.05$, Table 2). Pygmy rabbits achieved a lower DM digestibility (DMD) and AED on outside sagebrush than on high-quality pellets and greenhouse sage, but greater than that on low-quality pellets ($P < 0.05$, Table 2). Both pygmy and cottontail rabbits digested NDF as a function of the proportion of indigestible of the cell wall (i.e., ADL) similarly to other small hindgut fermenters, and to a lesser extent than ruminants and large

Fig. 3 Mean urinary nitrogen as a function of nitrogen intake of captive pygmy rabbits (PR) and cottontail rabbits (CT) consuming pelleted rations and sagebrush (*A. tridentata*, circled points). Endogenous urinary nitrogen is the y -intercept of the regression line

Fig. 4 Mean nitrogen balance as a function of total nitrogen intake of captive pygmy rabbits (PR) and cottontail rabbits (CT) consuming pelleted rations and sagebrush (*A. tridentata*, circled points). Minimum nitrogen requirements are found at the x -intercept

hindgut fermenters (Fig. 5). However, they digested NDF of greenhouse sagebrush better than expected from its ADL content, and better than the other diets (all $P < 0.05$; Table 2, Fig. 5).

A greater proportion of energy consumed was excreted in the urine of both pygmy rabbits ($\bar{X} = 9.5 \pm 2.4\%$) and cottontails ($\bar{X} = 14.1 \pm 2.7\%$) when eating sagebrush than when eating high-quality or low-quality pellets ($\bar{X}_{\text{pygmy rabbits}} = 0.7 \pm 0.2\%$, $\bar{X}_{\text{cottontails}} = 2.8 \pm 0.2\%$, $F = 9.87$, $P < 0.001$). Pygmy rabbits and cottontails excreted in their urine the same proportion of energy consumed when eating greenhouse sagebrush ($F = 0.53$, $P = 0.52$). In contrast, the proportion of ingested energy excreted in the feces when consuming sagebrush was lower than the amount excreted when eating low-quality pellets (all $P < 0.05$), and lower than (i.e., pygmy rabbits eating greenhouse sagebrush, $P < 0.05$) or equivalent to (i.e., pygmy rabbits eating outside sagebrush and cottontails eating greenhouse sagebrush, both $P > 0.05$) the energy excreted when eating high-quality pellets. Pygmy rabbits and cottontails excreted in feces the same proportion of ingested energy when eating greenhouse sagebrush ($F = 4.12$, $P = 0.14$).

Terpene Content of Sagebrush

Using GC and GC-MS, we identified six major peaks (mostly monoterpenes) present in the greenhouse and outside sagebrush (Table 3). Greenhouse sagebrush had over twice the total concentration (% DM) of terpenes of the outside sage, and among the major peaks, had more than twice the amount of artemiseole, 1,8-cineole/eucalyptol, and methyl santolinate, and 10 times more santolina epoxide than did the outside sagebrush. However, greenhouse sagebrush had only half the camphor of outside sagebrush (Table 3). Camphor made up nearly 50% of the major distilled volatile oils of the outside, but only 12% of the greenhouse, sagebrush.

Voluntary intake of sagebrush and pellets

When only pellets were offered, pygmy rabbits ate the same dry mass and digestible energy (DE) relative to their metabolic body mass ($\text{kg}^{0.75}$) as did cottontails (both $P > 0.05$, Table 2). Both pygmy ate more mass of low- than high-quality pellets ($F = 24.4$, $P = 0.001$), but consumed equivalent DE ($F = 0.19$, $F = 0.67$, Table 2).

An asterisk denotes significant difference between PR and CT on each diet, and different letters denote significant differences among diets within a column ($\alpha=0.05$). WSU: Washington State University.

Fig. 5 Mean digestibility of neutral detergent fiber (NDF) of pygmy rabbits and cottontail rabbits as a function of the proportion of acid detergent lignin (ADL) in the cell wall of pelleted rations and sagebrush (*A. tridentata*, circled points) they consumed. Data for ruminants, large hindgut fermenters, large hindgut fermenters, and small hindgut fermenters are provided for comparison (Robbins, 1993)

Regardless of the amount of high- and low-quality pellets offered, pygmy rabbits voluntarily consumed more greenhouse sagebrush than cottontails relative to their metabolic body mass ($F = 5.72$, $P < 0.001$, Table 4). For example, pygmy rabbits ate five times more greenhouse sagebrush relative to their size than cottontails did when given *ad lib* access to both high-quality pellets and sagebrush (Table 4). However, sagebrush comprised only $8.1 \pm 2.5\%$ DM consumed by pygmy rabbits when offered with *ad lib* high-quality pellets, and $14.8 \pm 2.5\%$ when offered with *ad lib* low-quality pellets. Cottontails ate sagebrush as $0.7 \pm 0.2\%$ of their diet when eating high-quality pellets and $1.8 \pm 0.8\%$ when eating low-quality pellets. Both pygmy rabbits and cottontails ate more greenhouse sagebrush relative to their metabolic body mass when offered low-quality than high-quality pellets at 50% and 25% *ad lib* ($F = 37.85$, $P < 0.001$). For example, pygmy rabbits doubled their intake of sagebrush when offered 25% *ad lib* of low-quality pellets than when offered 25% *ad lib* of high-quality pellets (Table 4). Both rabbit species ate more greenhouse sagebrush as the amount of either type of pellet offered declined ($F = 30.22$, $P < 0.001$, Table 4).

When offered together with 50% *ad lib* intake of both high- and low-quality pellets, pygmy rabbits and cottontails ate a similar amount of greenhouse and outside sagebrush ($t < 6.48$, $P > 0.08$, Table 4). However, when no supplementary pellets were offered, pygmy

rabbits ate three times more dry mass of greenhouse sagebrush than outside sagebrush ($t = 5.01, P = 0.02$, Table 4).

When consuming all mixed diets of pellets and sagebrush, pygmy rabbits acquired about twice the DEI of cottontails relative to their metabolic body mass (all $F < 12.77$, all $P < 0.02$; Fig. 6). By voluntarily eating more greenhouse sagebrush, both pygmy rabbits and cottontails achieved a higher total DEI when eating mixed diets (at 50% and 25% *ad lib*) including low-quality pellets than those that included high-quality pellets (both $F > 10.49$, both $P < 0.02$). As the DEI of pellets decreased, so did the total DEI of cottontails ($F = 25.77, P < 0.001$) when offered greenhouse sagebrush *ad lib*. However, pygmy rabbits ate enough greenhouse sagebrush to maintain their total DEI as their DEI of pellets varied from 100% to 0% of their diet ($F = 4.26, P = 0.11$; Fig. 6). However, when pellet intake was restricted to 25–50% *ad lib*, pygmy rabbits voluntarily ate enough sagebrush to meet between 67% and 110% of their requirements, and met only 30% of their requirements when eating outside sagebrush alone. In contrast, cottontails only met their daily DE requirements when given *ad lib* access to low- and high-quality pellets alone and with *ad lib* access to sagebrush (Fig 6). Cottontails met only 67% of their daily energy requirements on greenhouse sagebrush alone, and when pellets were restricted to 25–50% *ad lib*, they only ate enough sagebrush to meet 35–67% of their DE requirements. However, mass gain during the mixing trials was not consistently related to pellet type, pellet amount, sagebrush type, or rabbit species ($F = 2.05, P = 0.11$).

When offered *ad lib* access to both greenhouse and outside sagebrush together with 15% of their *ad lib* intake of high-quality pellets, pygmy rabbits ate five times more leaves of greenhouse ($\bar{X} = 50.82 \pm 3.2\text{g}$) than outside sagebrush ($\bar{X} = 10.35 \pm 1.4\text{g}$, $t = 6.73, P = 0.003$). Pygmy rabbits ate the same proportion of leaves and stems of greenhouse and outside sagebrush ($t = 1.52, P = 0.20$).

Fig. 6 The amount of digestible energy (DEI) of greenhouse (GH) and outside (OS) sagebrush (*Artemisia tridentata*) voluntarily consumed by pygmy rabbits (PR) and cottontails (CT) each day when offered different amounts of a high-quality (HQ) or low-quality (LQ) grain-alfalfa pelleted. The diagonal lines indicate the amount of additional energy in sagebrush pygmy rabbits (solid line) and cottontail rabbits (dashed line) would have to consume to meet their daily energy requirements and maintain body mass when eating pellets

Fig. 7 pH of urine when in relation to the dry mass of greenhouse (GH) and outside (OS) sagebrush (*Artemisia tridentata*) eaten by captive pygmy rabbits (PR) and cottontail rabbits (PR) when offered *ad libitum*, and when consuming diets of high-quality (HQ) or low-quality (LQ) pelleted grain-alfalfa offered *ad libitum*

pH of Urine

When consuming high-quality pellets, low-quality pellets, and greenhouse sagebrush alone *ad lib*, pygmy rabbits and cottontails had the same urine pH ($F = 2.66$, $P = 0.13$), even when including DMI of sagebrush as a covariate ($F = 0.06$, $P = 0.53$; Fig. 6). Both had a higher urine pH when eating high-quality pellets than low-quality pellets, and a lower urine pH when eating only greenhouse sagebrush than either pellet ($F = 27.38$, $P < 0.001$; Fig. 7). Despite eating about half the total mass of outside sagebrush, the urine pH of pygmy rabbits was lower when eating outside sagebrush than when eating greenhouse sagebrush ($t = 5.0$, $P = 0.01$; Fig. 7).

Discussion

Pygmy rabbits had relatively high energy and low protein requirements. Daily energy expenditure (i.e., basal metabolic rate + activity + thermoregulation + heat increment, kJ/d) tends to scale as $591.6 \text{ kJ/kg}^{0.75}$ for eutherian mammals (Robbins, 1993). When living in small cages, the daily energy requirement of our 1.2-kg cottontails ($549.2 \text{ kJ/kg}^{0.75}/\text{d}$) was consistent with this scaling, and consistent with Rose, (1973), who found energy requirements of eastern cottontails to range from $531\text{--}607 \text{ kJ DE/kg}^{0.75}/\text{d}$ when ambient temperature ranged from 10°C to 20°C . Likewise, snowshoe hares (*L. americanus*, 1.5 kg) needed only $510 \text{ kJ/kg}^{0.75}$ (Holter et al., 1974) to maintain their body mass. In contrast, pygmy rabbits (0.45 kg) required DE of $750.8 \text{ kJ/kg}^{0.75}/\text{d}$ to maintain their mass in small cages, 27% more than predicted from the scaling relationship for eutherian mammals, and 36% higher per unit metabolic mass than eastern cottontails. Similarly, when measuring oxygen consumption of pygmy rabbits under different thermal conditions, Katzner et al. (1997b) found that pygmy rabbits had a higher resting metabolic rate than other eutherian mammals relative to metabolic body mass. McNab, (1988) showed that small herbivores such as lagomorphs tend to have higher basal metabolic rates relative to their size than other mammals, and that energy requirements for small folivores scale with body mass^{0.545}. The lower critical temperature for pygmy rabbits is $15\text{--}20^\circ\text{C}$ (Katzner et al., 1997b); thus they were always expending 18% more energy than they would at thermal neutrality during our

feeding trials, which were conducted at 0–5°C. Because of their larger size, the thermal neutral zone of cottontails is predicted to be two times wider than that of pygmy rabbits (Katzner et al., 1997b); thus cottontails may not have had to expend as much energy to keep warm in our trials.

Not only do pygmy rabbits have a higher energy requirement relative to body mass than similar mammals, their behavior and habitat demand that they acquire additional energy from their food, especially in winter. They do not hibernate, and they live in cold, exposed sagebrush-steppe rangelands in the northwestern United States. Additional activity and cold temperatures increases the energy expenditure of cottontails by 30–60% (Rose, 1973) and pygmy rabbits by up to 60% (Katzner et al., 1997b). Sagebrush, despite its terpene concentration, has a high DE content, especially relative to grass, one of the few other foods available in the winter. For example, NDF content of two common grass species in pygmy rabbit habitat in the Columbia Basin of Washington ranged from 67% in summer to 78% in winter, whereas sagebrush in the same area contained only 36–47% NDF (Thines et al., 2004). However, the detoxification of terpenes and other PSMs in sagebrush likely increases energy demands further, as evidenced by the high energy content of urine while eating sagebrush. Sorensen et al., (2005) found that woodrats ate more, increased energy intake, and reduced their basal metabolic rate and activity when eating high-terpene juniper diets. Therefore, many herbivores that specialize on plants with high levels of PSMs have developed energy conservation methods, such as low reproduction (e.g., woodrats, *Neotoma* spp.; Meyer and Karasov, 1991) and low metabolic rates, requiring them to eat less (e.g., arboreal marsupials, Cork and Foley, 1991). On the other hand, the small body size of pygmy rabbits is advantageous in eliminating PSMs from the body. The steady-state plasma concentration of toxins scales with body mass^{0.39}; thus, small animals maintain lower concentrations of toxins in their bodies than large animals and can ingest more relative to their size (Freeland, 1991). Therefore, the size of pygmy rabbits, the smallest leporid in North America, may be an adaptation to excreting toxins, thus allowing them to consume large amounts of sagebrush.

Although pygmy rabbits have a relatively high energy requirement, they seem to have a lower N requirement (306.5 mg N/kg^{0.75}/d) than many other mammals. Their N balance falls below the mean for eutherian mammals (582 ± 235 mg/kg^{0.75}/d; Robbins, 1993), such as blacktailed jackrabbits (950 mg/kg^{0.75}/d; Nagy et al., 1976). However, herbivorous marsupials that specialize on terpene and tannin-containing foods, such as ringtail possums (290 mg/kg^{0.75}/d) and koalas (275 mg/kg^{0.75}/d), have similar N requirements to pygmy rabbits (Robbins, 1993).

Pygmy rabbits have an MFN of 7.5 g N/kg feed, which is within the normal range for mammals (1–9 g N/kg feed; Robbins, 1993). This MFN is also within the range found in other lagomorphs such as blacktailed jackrabbits (4.6 g N/kg feed; Nagy et al., 1976), domestic rabbits (*Oryctolagus cuniculus*, 8.0 g N/kg feed; Slade and Robinson, 1970), and snowshoe hares (9.1 g N/kg feed; Holter et al., 1974). EUN was 22.9 mg/kg^{0.75}/d, lower than that of the average nonruminant eutherian mammal (160 ± 22 mg N/kg^{0.75}/d), such as blacktailed jackrabbits (128 mg/kg^{0.75}/d; Nagy et al., 1976). However, the lowest excretion of urinary N we measured on pygmy rabbits eating low N diets was 97 mg/kg^{0.75}/d (Fig. 3). Thus, the standard method for estimating EUN may have underestimated EUN for pygmy rabbits.

When eating more than 9 g DM/d, pygmy rabbits require a diet of at least 7% CP, which is similar to the minimum dietary protein requirements of nonruminant eutherians and browsing ruminants (Robbins, 1993). The National Research Council, (1977) recommends that domestic rabbits be fed a diet with a CP content (6.25 N) of 13–18% for maintenance,

and a dietary level of 16% CP is considered adequate for growth and reproduction. Sagebrush in the greenhouse (18%), outside (15.6%), and in pygmy rabbit habitat in the Columbia Basin (9.5–11.4%; Thines et al., 2004) had at least twice the CP content of grasses (3.6–5%) available in native habitat (Thines et al., 2004.), and is adequate to meet the requirements for domestic and pygmy rabbits.

The smaller pygmy rabbits generally digested foods less efficiently than the larger cottontails, large hindgut fermenters, and ruminants (Fig. 5). Because smaller herbivores have a higher metabolic rate relative to their fermentation capacity (i.e., size of ceca), they have a faster throughput of ingesta and less efficient digestion of plant fiber (Demment and Van Soest, 1985). Fiber digestibility of pygmy rabbits and cottontails in our study was generally consistent with that of European rabbits (*O. cuniculus*; Kuijper et al., 2004) and snowshoe hares (Holter et al., 1974).

Despite terpenes in sagebrush, both pygmy rabbits and cottontails digested the NDS of sagebrush and pelleted diets equally, and pygmy rabbits digested the NDS of greenhouse and outside sagebrush similarly (Table 2). Furthermore, both digested the NDF of greenhouse sagebrush better than the pelleted diets without terpenes or other PSMs, even relative to the indigestible portion of the cell wall (Table 2, Fig. 5). Outside sagebrush was poorly digested, yet had a lower content of terpenes overall. Because sagebrush did not precipitate BSA, the biological activity of any condensed tannins in sagebrush was likely too low to affect digestibility. These findings suggest that terpenes and other PSMs in sagebrush do not reduce fiber or soluble digestion in either rabbit species, and that pygmy rabbits, which “specialize” on sagebrush, do not seem to have developed a mechanism for digesting this high-terpene food better than the generalist cottontail. Specific monoterpenes are known to be toxic to rumen microorganisms *in vitro* at 0.7–1.3 $\mu\text{l/ml}$ and reduce *in vitro* and *in situ* digestibility (Schwartz et al., 1980; Welch and Pederson, 1981). However, nearly 80% of terpene concentration of sagebrush is lost by the time it reaches the stomach of pygmy rabbits (White et al., 1982b) and the rumen of mule deer (Cluff et al., 1982), likely through evaporative losses during chewing and eructation. Terpenes may also be absorbed into the bloodstream from the digestive system before they can influence digestibility of forages. Therefore, concentrations of monoterpenes in the digestive system of pygmy rabbits feeding on sagebrush are likely not high enough to reduce digestibility (White et al., 1982b; Gershenson and Croteau, 1991).

On the other hand, urine pH of both cottontails and pygmy rabbits declined and urinary energy increased when sagebrush was added to the diet, indicating that consuming sagebrush incurs a metabolic cost to rabbits. However, the specialist pygmy rabbit did not have a consistently higher urine pH or lower urinary or fecal energy than the generalist cottontail, suggesting that pygmy rabbits may not have an increased capacity to avoid or metabolize terpenes or other PSMs. They had a lower urine pH when consuming solely outside sagebrush, which had a lower overall monoterpene content but a higher content of camphor, which is known to deter feeding by lagomorphs eating conifers (Rodgers et al., 1993). Outside sagebrush may also have had higher levels of unmeasured PSMs.

Both pygmy rabbits and cottontails were able to meet their DE requirements by increasing their DM intake of pellets as the nutritional quality of pellets declined. To do this, pygmy rabbits consumed more relative to their body mass than cottontails did, increasing DM intake from 9.6% of body mass on high-quality pellets to 14.0% on low-quality pellets, whereas cottontails increased from 5.3% to 8.2% of their body mass when shifting from high- to low-quality pellets (Table 2). When the amount of either type of pellet was restricted, both chose to eat more sagebrush, but cottontails did not consume

enough additional sagebrush to meet their energy requirements (Fig. 6). Regardless of the amount and quality of pellets offered, pygmy rabbits ate more sagebrush overall, and in relation to energy requirements, than did cottontails. However, when allowed free access to pellets containing a DE content similar to sagebrush, they selected pellets over sagebrush, which comprised only 8% of their diet. Under the same conditions, sagebrush comprised only 0.7% of the cottontails' diets. When offered low-quality pellets containing only half the protein and 60% of the DE content of sagebrush, pygmy rabbits increased their use of sagebrush to 15%, and cottontails to 1.8%, but sagebrush still did not make up a substantial portion of the diet of either rabbit. Likewise, Stephen's woodrats, a terpene specialist, consumed twice as much juniper (27% of diet) as did whitethroat woodrats (*N. albigula*), a generalist (10%), when given *ad lib* access to a control diet with a low N content (1.25%) and high ADF (23%) similar to juniper (Dearing et al., 2000).

Like our captive rabbits, wild pygmy rabbits in native habitats expand their use of sagebrush from 11–50% in early summer, when alternative forages are more available and of higher nutritional quality, to 72–98% in the winter, when grasses and forbs are rare and less nutritious (Green and Flinders, 1980b; Thines et al., 2004). In contrast, domestic lambs (generalist foragers) actually ate more (Villalba and Provenza, 2005) or the same amount (Burritt et al., 2000) of a terpene-containing food as the energy and protein content of an alternative food increased. Therefore, the presence of high-quality foods in the environment may either decrease or increase diet breadth used by generalist and specialist herbivores.

Despite the lower fiber content of the outside sagebrush, pygmy rabbits chose to eat less of it when offered alone and when offered with 50% *ad lib* high- and low-quality pellets than of greenhouse sagebrush. In addition, pygmy rabbits ate five times more greenhouse sagebrush than outside sagebrush when they were simultaneously offered. Pygmy rabbits may have preferred greenhouse sagebrush because it contained nearly twice the protein content and was more digestible, despite its higher fiber content (Tables 1 and 2). Although the greenhouse sagebrush had higher monoterpene levels overall than outside sagebrush, and had higher levels of all specific terpene compounds identified except camphor, the specific effects of these terpenes and other PSMs on preference and digestion in pygmy rabbits is unknown. White et al., (1982a) found no relationship between total monoterpenoid content and dietary preference of sagebrush by pygmy rabbits, but pygmy rabbits did prefer plants from individual populations, and preference was negatively correlated with the monoterpene α -thujone (not found in our sagebrush samples). However, urine pH was lower when our pygmy rabbits ate solely outside sagebrush than solely greenhouse sagebrush, suggesting that the terpenoid compounds or other PSMs in the outside sagebrush required more detoxification, and thus may have been a less desirable food choice. Similarly, snowshoe hares preferred mature white spruce (*Picea glauca*) over juvenile white spruce that contained four times more camphor, and camphor added to pellets deterred feeding by captive hares (Sinclair et al., 1988).

The terpenoid content of both types of sagebrush we fed our pygmy rabbits likely differed to some degree from sagebrush consumed in their native habitat. Monoterpene concentration in sagebrush varies greatly with climate, soils, age, season, genetics, and plant part (Welch and McArthur, 1981; Gershenzon and Croteau, 1991; Zhang and States, 1991). Total terpene content measured in wild sagebrush varies from 0.37% to 3.7% DM, and the composition of terpenoids, such as α -thujone, camphor, α -pinene, 1,8-cineole, β -thujone, and terpineol, differs among populations, individuals, and plant parts (Welch and McArthur, 1981; Cluff et al., 1982; White et al., 1982a). For example, camphor content of oils distilled from sagebrush varies from 0% to 70.3% dry mass (Welch and McArthur, 1981). The reproductive structures and new growth, which we fed to pygmy rabbits in our

experiments, generally have higher levels of monoterpenoids than older, structural components (Gershenzon and Croteau, 1991). Our greenhouse sagebrush was fertilized with N, whereas the outside sagebrush was not, which might explain, in part, the higher N content and the different terpenoid composition (Gershenzon and Croteau, 1991). Similarly, when white spruce was grown in a nursery, it had about 30% less camphor than wild white spruce seedlings (Rodgers et al., 1993). Snowshoe hares selectively ate more nursery-grown white spruce than naturally regenerated spruce seedlings, and in most cases avoided the naturally regenerated spruce all together. Plants growing in low light and poor soil are expected to invest in carbon-based defenses, whereas those grown in fertile soils and high light (e.g., greenhouses) are more likely to invest in N-based defenses (Rodgers et al., 1993).

Because pygmy rabbits sacrificed protein and DE in their diet when they selected low-quality pellets over sagebrush in our experiments, and because wild pygmy rabbits decreased their use of sagebrush when other nutritious forages were available in the spring (Thines et al., 2004), pygmy rabbits do not seem to be constrained by the type of obligatory relationship with sagebrush that animals like koalas have with *Eucalyptus* spp. (Marsh et al., 2003). Sagebrush clearly exacts a cost to its specialist forager. However, because pygmy rabbits ate more sagebrush than cottontails and were able to meet their DE requirements while feeding exclusively on sagebrush, they have likely adapted mechanisms to keep the costs of ingesting terpenes relatively low. Adaptations for dealing with PSMs include avoiding ingesting them, reducing their absorption from the gut, and detoxifying them in the liver (McArthur et al., 1991).

Nonspecialist and specialist foragers alike often avoid PSMs by carefully selecting individual plants and plant parts (Zhang and States, 1991; Lawler et al., 1998; Dearing et al., 2000; Marsh et al., 2003). For example, small herbivores such as mountain hares (*L. timidus*), black-tailed jackrabbits, and woodrats often discard young leaves and eat the stems of plants, which have lower concentrations of PSMs but also have lower N and DE content (Gershenzon and Croteau, 1991; Meyer and Karasov, 1991; Palo et al., 1992). Pygmy rabbits ate leaves and stems in proportion to availability when eating greenhouse and outside sagebrush, but when given the opportunity during pretrials, we noticed that cottontails tended to eat stems and discard leaves of sagebrush.

Specialist herbivores may have more transporter proteins or transporter proteins more specific to a particular PSM, which move PSMs out of cells and into the intestinal lumen, thus reducing absorption of PSMs into the circulation (Sorensen et al., 2004). For example, the specialist Stephen's woodrat had lower blood levels of α -pinene, a terpene in juniper, and excreted 40% more in the feces than did the generalist whitethroat woodrat (Sorensen and Dearing, 2003; Sorensen et al., 2004). If absorbed, PSMs can be eliminated from the bloodstream through enzymatic reactions in the liver that add a functional group or conjugate the PSM to change its solubility (McArthur et al., 1991; Dearing et al., 2005). However, even specialist herbivores that encounter PSMs in their normal diet have a threshold, albeit higher than the generalists, to the amount of PSMs that can be processed and will not voluntarily ingest terpenes above a crucial daily amount (Boyle et al., 1999; Marsh et al., 2003; Boyle and McLean, 2004). This threshold is caused, in part, by the finite tolerance of the kidney for excreting acidic metabolites produced during detoxification (Freeland and Janzen, 1974; Foley, 1992; McLean et al., 1993; Foley et al., 1995). Therefore, urine pH is a general indicator of overall detoxification processes. Dearing et al., (2000) found that urine pH declined from about 8.7 when a generalist and specialist woodrat consumed a nonterpene control diet, to about 7.7 on a juniper diet. The specialist, which had a slightly higher pH when consuming juniper, may have produced metabolites that were less acidic, or were able to buffer the acidic metabolites better than the generalist. In our study,

urine of both pygmy rabbits and cottontails declined to a similar degree from a nonterpene pelleted diet to a sagebrush diet (Fig. 7). However, specialist pygmy rabbits did not maintain a higher urine pH on greenhouse sagebrush than generalist cottontails did.

In summary, pygmy rabbits have a relatively high metabolism and moderately low N requirement, and can acquire high levels of DE from sagebrush that dominates their natural habitat. However, their low voluntary intake of sagebrush in the presence of low-quality non-terpene foods and their increased excretion of acids and energy in the urine when consuming sagebrush suggests that consuming sagebrush exacts a cost even for this “specialist”. However, because pygmy rabbits voluntarily consumed more sagebrush than cottontails regardless of the quantity and quality of supplementary foods, these small rabbits likely detoxify the monoterpenes and other PSMs better than the generalist rabbit species that overlap their range. Any “obligate-like” relationship between pygmy rabbits and their deep soil sagebrush habitat (Green and Flinders, 1980b) likely occurs not only because pygmy rabbits are better competitors for sagebrush as forage, but also because this habitat provides cover suitable for thermoregulation and hiding (Katzner and Parker, 1997a; Katzner et al., 1997b), and reproductive habitat suitable for digging natal burrows (Rachlow et al., 2005). Future studies examining behavioral and physiological responses to individual monoterpenes and other PSMs in sagebrush and detoxification pathways will enhance our understanding of the tolerances and requirements of this unique rabbit.

Acknowledgments We thank J. Jackson for help collecting data and caring for rabbits, G. K. Rademaker for raising sagebrush, and B. Davitt, R. Croteau, K. Ringer, and R. Goodwin for helping to analyze sagebrush for tannins and terpenes. J. Sorensen provided helpful comments on the manuscript. Support for this project came from Washington Department of Fish and Wildlife.

Keywords Stemborer · Maize · Sorghum · Hostlocation · Electrophysiology · Volatiles · GC-MS · Push–pull

Introduction

The stemborers *Busseola fusca* Fuller (Noctuidae) and *Chilo partellus* Swinhoe (Pyralidae) are economically important pests on maize (*Zea mays* L.) and sorghum (*Sorghum bicolor* (L.) Moench) crops in Africa, causing losses in yield of 20–80%, depending on the pest population density and the phenological stage of the crop at infestation. Larvae of these species are polyphagous and attack a wide range of cultivated and wild plants belonging to three families—Poaceae, Cyperaceae, and Typhaceae (Khan et al., 1997a). Studies have shown that the high diversity of wild grasses surrounding farmers' fields in sub-Saharan Africa are important in stemborer management (Khan et al., 1997a,b; Khan and Pickett, 2004). Although most of these grasses are hosts for the stemborers and, indeed, elicit higher levels of oviposition than maize or sorghum, subsequent larval survival is poor (Khan et al., 2004, 2006). These aspects have been exploited in the development of “push–pull” strategies for stemborer control, in which gravid females are repelled from the main crop by a repellent intercrop (“push”) and simultaneously attracted to a trap crop (“pull”) planted around the field (Khan et al., 2000, 2001; Khan and Pickett, 2004). The latter comprise a number of wild hosts, including Napier grass, *Pennisetum purpureum* Schumach., which are considerably more attractive to gravid females than the crop itself (Ndemah et al., 2002; Rebe et al., 2004).

In a previous study on volatiles from maize, sorghum, and Napier grass, six key compounds were identified as mediating host location and oviposition by gravid stemborer females (Khan et al., 2000). However, the occurrence of these compounds in all of the hosts investigated would not appear to account for the differential attraction/oviposition observed in the laboratory and field. To address this question, a comparative analysis was conducted of the electrophysiologically active components of the volatiles from four host plants, the cultivated crop plants maize and sorghum, and two wild grasses, Napier grass (*P. purpureum*) and blue thatching grass (*Hyparrhenia tamba* (Steud.) Stapf).

Methods and Materials

Insects

Pupae of *B. fusca* and *C. partellus* were obtained from cultures maintained at the International Centre of Insect Physiology and Ecology's (ICIPE) Thomas Odhiambo Campus, Mbita Point, Kenya, that originated from colonies collected from maize and sorghum stubbles in farmers' fields in that vicinity. They were maintained at a temperature of 20°C with a 16-hr photophase and an 8-hr scotophase. Newly emerged moths were separated from pupae everyday to keep track of the age of adults and provided with 10% sugar solution as a food source. Females (2–7 d old) were used in all experiments.

Plants

Plant species used were maize, *Z. mays* (Western Seed Company Hybrid 502), sorghum, *S. bicolor* (var. Gadam), Napier grass, *P. purpureum* (originally obtained as cuttings from

Kenya), and blue thatching grass, *H. tamba* (obtained as seeds from South Africa). Seeds were sown individually for maize and sorghum, or in a group for *H. tamba*, in plastic pots filled with compost. *P. purpureum* was grown from cut stems planted in compost, 2–3 plants in a pot. Plants were grown in a glasshouse under controlled conditions, with a 16-hr photophase and an 8-hr scotophase; relative humidity was 60% and temperature was 27–30°C during the photophase and 22–25°C during the scotophase. Natural lighting was supplemented with sodium lamps (SON-T, 600 W) that gave photosynthetically active radiation of approximately 300 $\mu\text{mol m}^{-2} \text{sec}^{-1}$ at bench height. Plants used in experiments were 19–27 d old, although the ages of plants from the same species were within 1–2 d of each other. Comparably sized plants of each species were used.

Chemicals

Synthetic compounds were purchased from commercial sources (Aldrich, Fluka, or Lancaster Synthesis) or were samples of compounds that had been previously synthesized at Rothamsted by methods described in the literature—(*E*)-ocimene (Gaoni 1977; Chou et al., 1984); (*E*)- β -farnesene (Kang and Kim, 1986); (*E*)-4,8-dimethyl-1,3,7-nonatriene; (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (Maurer et al., 1986). All were $\geq 95\%$ as the designated geometric isomer.

Collection of Volatiles from Intact Plants

Volatile compounds were collected by entrainment of intact plants by using portable equipment developed at Rothamsted (Agelopoulos et al., 1999; Birkett et al., 2003). To avoid causing plant stress by transfer, all entrainments were performed at the site where the plants were being grown. Part of the plant was enclosed in an open-bottomed glass cylinder (100 mm o.d. \times 600 mm length), and the bottom was closed with two semicircular aluminum plates that fitted closely together except for a hole in the middle that fitted, but not tightly, around the plant. The holes were circular openings (diam 2 cm for *H. tamba* and 1 cm for *P. purpureum* and *S. bicolor*) or an elliptical opening of (2 \times 1.3 cm (for *Z. mays*). Into any large gaps between the plates and the stem(s) was packed silanized and baked glass wool. Air, purified by passage through an activated charcoal filter, was pumped into the vessel, through a port in one of the aluminum plates at 1.2 lmin^{-1} , and volatiles were collected on Porapak Q (0.05 g) packed into a glass tube (80 mm \times 5 mm o.d.) inserted into a collection port at the top of the vessel. Air was drawn out through the collection tube by another pump at 1 lmin^{-1} , the differential flow rates eliminating the risk that unfiltered air could be drawn into the vessel from outside, while obviating the need for an injuriously tight seal around the plant stem(s). In general, volatiles were collected for 10–12 hr starting at the 4th hr of the photophase. All connections were made with PTFE tubing and ferrules, and as much as possible the equipment, especially the glassware, was heated at 180°C for at least 2 hr before use. Porapak Q tubes were washed with redistilled diethyl ether and conditioned at 140°C with filtered nitrogen pumped through for 10 hr before use.

Gas Chromatography of Volatiles

Collected volatiles were eluted from the adsorbent with freshly distilled diethyl ether (500 μl) and concentrated to 50 μl under a slow stream of nitrogen. These solutions of plant volatiles were stored at -10°C until analysis. Gas chromatography (GC) of the solutions was carried out on both polar (DB-wax, 30 m \times 0.23 mm i.d. \times 0.5 μm film thickness) and

nonpolar (HP-1, 50 m×0.32 mm i.d.×0.52 μm film thickness) capillary columns using an HP6890 GC (Agilent Technologies, UK) fitted with a cool-on-column injector and a flame ionization detector (FID). The oven was kept at 30°C for 1 min, heated at 5°C min⁻¹ to 150°C, and then 10°C min⁻¹ to 250°C (220°C for the wax column), where it was maintained for 20 min. Tetradecane (10 ng μl⁻¹, 1 μl) was added to 10 μl of the sample as an internal standard, and three to four aliquots were analyzed.

Electrophysiology

Electroantennogram (EAG) recordings were made from four to nine *B. fusca* and *C. partellus* females for each compound tested. The Ag–AgCl glass electrodes were filled with saline solution (composition as in Maddrell 1969, but without glucose). An antenna was excised and suspended between the two electrodes. The tip of the terminal process of the antenna was removed to ensure a good contact. Responses were measured in mV deflections, and the signals were passed through a high-impedance amplifier (UN-06, Syntech, The Netherlands) and analyzed with a customized software package (Syntech).

Stimulus Delivery

The delivery system, with a filter paper in a disposable Pasteur pipette cartridge, has been described previously (Wadhams et al., 1982). The stimulus (2 sec duration) was delivered into a purified airstream (1 lmin⁻¹) flowing continuously over the preparation. Solutions (10⁻¹ g ml⁻¹ and decadic dilutions) of pure synthetic compounds were made in distilled hexane, with the exception of indole, which was dissolved in diethyl ether, and applied (10 μl) to a filter paper strip. The solvent was allowed to evaporate for 45 sec before the strip was placed in the cartridge. The control stimulus was hexane (10 μl) or diethyl ether (10 μl) in the case of indole. Presentation of compounds was randomly ordered, and fresh cartridges were prepared immediately before each stimulation. A standard of 4-allylanisole (10⁻⁵ g) was applied at the beginning and at the end of each experiment and between groups of five to six compounds, to monitor the condition of the antennal preparation. Responses were normalized with respect to the standard by subtracting the value for the hexane control and expressing this result as a percentage of the response to the standard.

Coupled Gas Chromatography-Electroantennography (GC-EAG)

The coupled GC-electrophysiology system, in which the effluent from the GC column is simultaneously delivered to the antennal preparation and the GC detector, has been described previously (Wadhams 1990). Separation of the volatiles was achieved by injecting 1–2 μl of sample onto a nonpolar column (HP-1, 50 m×0.32 mm i.d.×0.52 μm film thickness) by using an AI 93 GC equipped with a cold on-column injector and an FID. Oven temperature was maintained at 40°C for 2 min and then programmed at 5° min⁻¹ to 100°C, and then at 10°C min⁻¹ to 250°C. The carrier gas was hydrogen. Simultaneous records of the EAG and FID responses were obtained with commercial software (Syntech, Netherlands) installed on a computer.

Coupled Gas Chromatography-Mass Spectrometry A capillary GC column (50 m×0.32 mm i.d., HP-1) fitted with an on-column injector was directly coupled to a mass spectrometer (VG Autospec, VG Analytical, UK). Ionization was by electron impact at

70 eV, 250°C. Oven temperature was maintained at 30°C for 5 min and then programmed at 5°C min⁻¹ to 250°C. Tentative identification by gas chromatography-mass spectrometry (GC-MS) was confirmed by peak enhancement with authentic samples (Pickett 1990).

Statistical Analysis

Statistical analysis was run by using SPSS for Windows (SPSS 1989–2001) with values of $P < 0.05$ accepted as significant. Mean EAG responses (% of response to standard) to the tested compounds were calculated, and significant differences between *B. fusca* and *C. partellus* were established by performing *t*-tests.

Results

GC-EAG analysis of the volatiles from all four host plant species, using both insect species, detected a total of 43 electrophysiologically active components (Table 1), of which 41 were chemically characterized by at least two of the following methods: (1) GC-MS analysis, (2) comparison of Kovat's index (KI) on both nonpolar (HP-1) and polar (DB-wax) columns with the indices of synthetic standards, (3) coinjection with authentic standards on both columns. A GC-EAG trace showing responses of *B. fusca* to volatiles from *H. tamba* is shown in Fig. 1. Electrophysiological activity, in either *B. fusca* or *C. partellus* female antennae, of 37 of these compounds was confirmed by EAG with authentic standards (Fig. 2). Authentic samples of α -pinene (**11**), limonene (**20**), linalool (**26**), and β -caryophyllene (**39**) used in these studies were racemic.

The majority of physiologically active compounds detected by GC-EAG were common to all four plant species, although there are significant differences in the levels produced by the different hosts (Table 1). Of particular note are the large variations in the amounts of (*Z*)-3-hexen-1-yl acetate, methyl salicylate, (*E*)-4,8-dimethyl-1,3,7-nonatriene, β -caryophyllene, and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene. Two of the compounds eliciting GC-EAG activity were not identified (**2** and **9**). Neither of them was present in the headspace of *Z. mays*. Compound **2** was shown by GC-MS to be present in trace quantities in *P. purpureum*, *H. tamba*, and *S. bicolor*, although GC-EAG responses to the volatiles of these plants were obtained only from *B. fusca*. Compound **9**, detected only in the *H. tamba* and *S. bicolor* samples, elicited GC-EAG responses from both stemborers.

The identified compounds fall into several distinct groups: aliphatic compounds, which include the well-documented green leaf volatiles; aromatic compounds; and terpenoids, which can be subdivided into monoterpenoids, sesquiterpenes, and tetranorterpenes. The relative amounts of all identified compounds in each plant species and grouped within these chemical classes are shown in Table 1. Overall, wild hosts produced significantly higher levels of physiologically active compounds than either *Z. mays* or *S. bicolor*. These differences relate particularly to the elevated production by the wild hosts of the green leaf volatiles, hexanal, (*E*)-2-hexenal, (*Z*)-3-hexen-1-ol, (*Z*)-3-hexenyl acetate, and indole. Only in the cases of α -pinene (**11**), (*E*)-ocimene (**22**), and 4-ethylbenzaldehyde (**30**) did either of the cultivated hosts (in both instances, *Z. mays*) show higher levels than the wild hosts.

Dose–response studies with 4-allylanisole, over the range 10⁻⁶ to 10⁻³ g, showed no significant differences in absolute EAG amplitudes between *B. fusca* and *C. partellus* females (Fig. 3). This compound was therefore chosen as the standard for all subsequent

Table 1 (Continued)

Compound	<i>P. purpureum</i> (<i>N</i> =5)	<i>H. tamba</i> (<i>N</i> =3)	<i>S. bicolor</i> (<i>N</i> =4)	<i>Z. mays</i> (<i>N</i> =2)
Total volatiles	294.8	186.5	103.4	70.3

Compound numbers refer to the order in which they were eluted from an HP-1 GC column. Samples were collected for 10–12 hr (starting from the 4th hr of the photophase). The amounts of volatiles are estimated based on the total area under the reported peaks compared with the peak area of the internal standard (100 ng). nd: below the detection limits of 0.05 ng.

^aThe optical isomers of these compounds were not characterized.

electrophysiological studies with authentic samples. Mean EAG response to the 4-allylanisole standard (10^{-5} g) was, for *B. fusca*, $-0.75 \pm \text{SE } 0.05$ mV, and for *C. partellus*, $-0.79 \pm \text{SE } 0.07$ mV. Of the electrophysiologically active compounds, the aldehydes octanal, nonanal, and decanal elicited the strongest relative EAG response (Fig. 3). This was particularly the case for *B. fusca*, and significant differences in relative EAG responses between *B. fusca*

Fig. 1 Coupled GC-EAG with female *Busseola fusca* using volatiles entrained from *Hyparrhenia tamba*. Upper trace: GC of *H. tamba* volatiles; lower trace: EAG response from *B. fusca*. Major EAG-active peaks are marked (see Table 1)

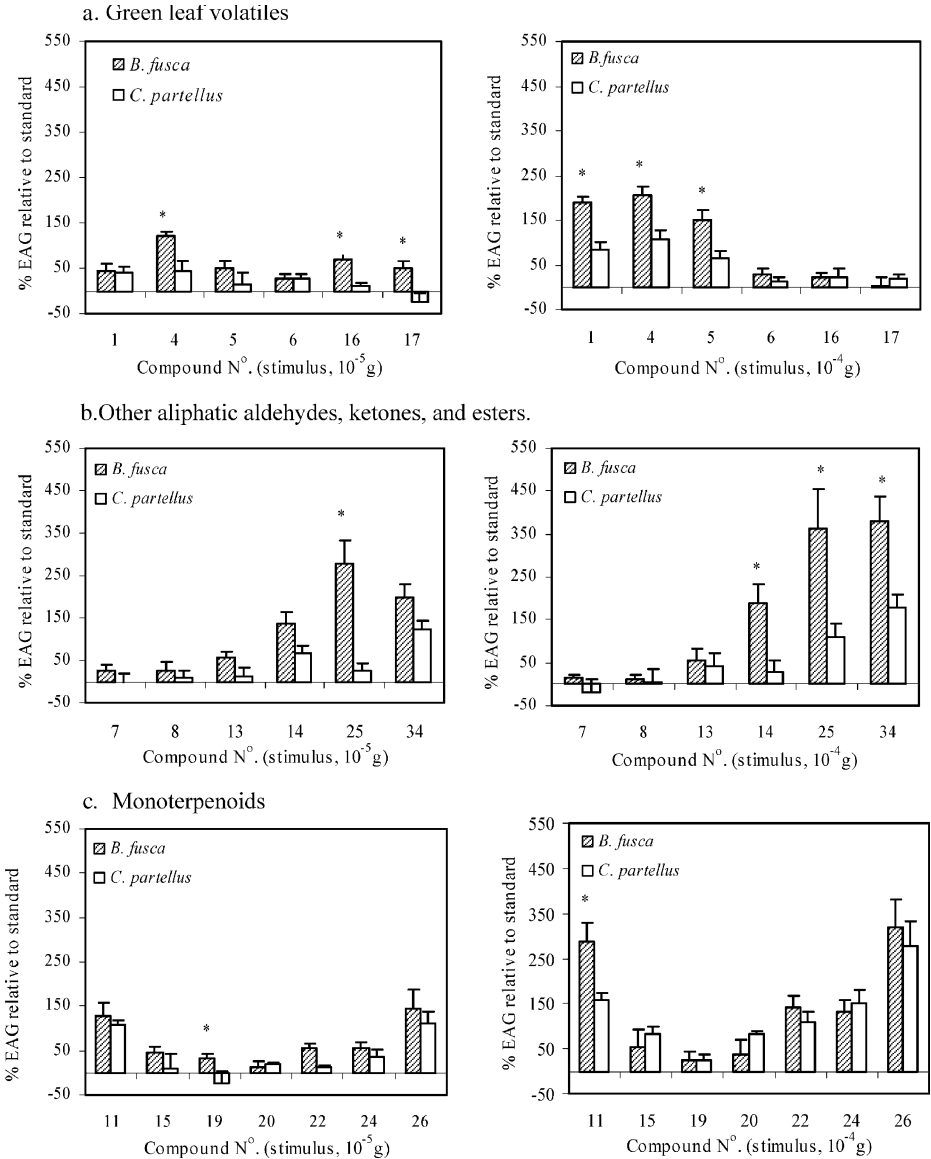

Fig. 2 Electrophysiological activity for *Busseola fusca* and *Chilo partellus*, relative to that of 4-allylanisole (10^{-5} g), of authentic compounds; asterisk indicates a significant difference between the responses of the two species ($P < 0.05$)

and *C. partellus* were observed for these aldehydes and for the green leaf volatiles hexanal, (*E*)-2-hexenal, (*Z*)-3-hexenyl acetate, and hexyl acetate. In all cases, with the exception of α -humulene, where significant differences in relative EAG responses were observed between the two stemborers, the strongest responses were elicited from *B. fusca* (Fig. 2).

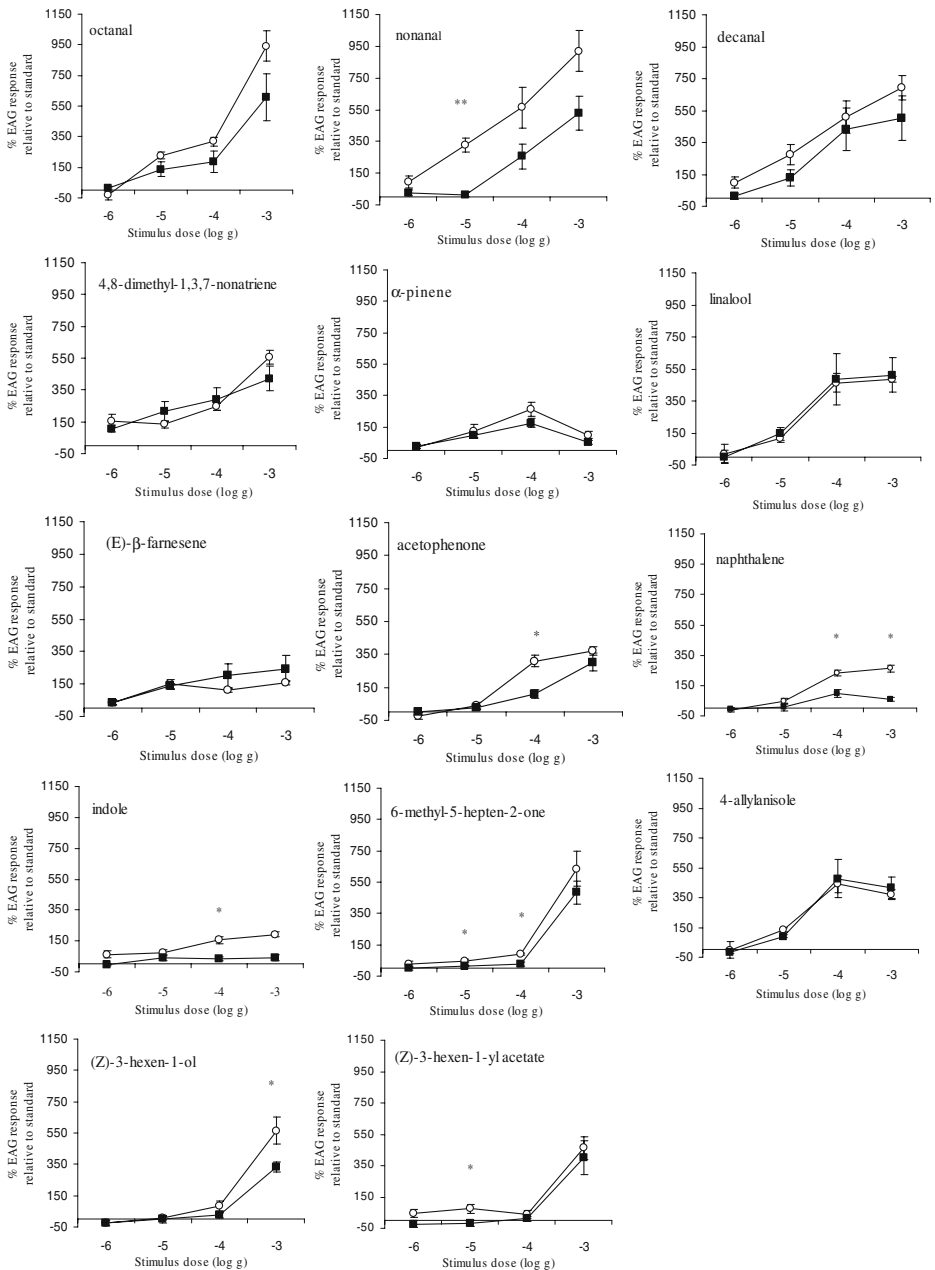

Fig. 3 Dose–response curves of electrophysiological activity, relative to that of 4-allylanisole (10^{-5} g), for *Busseola fusca* (○) and *Chiloptartellus* (●); asterisk indicates a significant difference between the responses of the two species ($P < 0.05$)

Discussion

The differential oviposition preference of *C. partellus* and *B. fusca* for the wild host grasses, used as trap crops, over the cultivated crop plants is essential in the “push–pull” system of stemborer control. While an earlier investigation identified six compounds used in host location by these stemborer moths (Khan et al., 2000), the results did not explain the insects’ preference for the wild hosts. The results of this more comprehensive study may assist in our understanding of the reasons for that behavior. However, differences between the climatic and soil conditions in East Africa and in a UK glasshouse may affect the quantities and ratios of emitted volatiles, although it is unlikely that such differences would cause qualitative changes in secondary metabolism.

Coupled GC-EAG showed the presence of 43 active compounds (Table 1), 41 of which were subsequently identified by GC-MS and cochromatography. The activities were confirmed by EAG with authentic compounds, which showed significant differences in the relative responses of the two species of stemborer to a number of compounds. Of particular interest are the differences in response to some of the green leaf volatiles (Fig. 2a), especially (*Z*)-3-hexen-1-yl acetate, which is one of the major components in the volatiles from the two wild hosts, particularly *P. purpureum* (Table 1). The aliphatic aldehydes **4** and **5** (Fig. 2a) and **14**, **25**, and **34** (Fig. 2b) also produce significant differences between the responses of the two species of insects. In all cases, it is *B. fusca* that is more sensitive. In fact, in all cases where there was differential peripheral sensitivity, with the exception of α -humulene (**42**), compounds elicited a greater relative EAG response in *B. fusca* than in *C. partellus* (Fig. 2). It is possible that the coevolution of *B. fusca* with three of the four plant species has resulted in a greater sensitivity to the volatiles from them than in the introduced species, *C. partellus*, which has coevolved with none of them.

Six key compounds, octanal (**14**), nonanal (**25**), linalool (**26**), naphthalene (**31**), 4-allylanisole (**33**), and eugenol (**37**), were identified in a previous study (Khan et al., 2000) as mediating host location and oviposition by gravid stemborer females. However, this is the first time that volatiles from the wild host, *H. tamba*, have been investigated and shown to include the same compounds. In the present work, electrophysiologically significant levels of octanal (**14**), nonanal (**25**), and linalool (**26**) were found in the volatiles obtained from all cultivated and wild hosts (Table 1). However, electrophysiologically significant levels of 4-allylanisole (**33**) and eugenol (**37**) were found only in the wild hosts, *P. purpureum* and *H. tamba*, and *S. bicolor*. EAG activity associated with naphthalene (**31**) was not found in the *Z. mays* samples. Although these results are in contrast to previous studies, which showed GC-EAG activity in volatile samples from *Z. mays*, *P. purpureum*, and *S. bicolor* to be associated with 4-allylanisole (**33**), eugenol (**37**), and naphthalene (**31**) (Khan et al., 2000), this difference may simply reflect differences in overall levels of volatiles used in the two GC-EAG studies. Authentic samples of all three compounds were found to elicit significant EAG responses from both *C. partellus* and *B. fusca* antennae (Fig. 2d).

Within the four host plant species, only the semiochemicals produced by *Z. mays* have been studied in any detail, and largely from plants under stress, either biotic or abiotic. A number of studies have investigated the induction of volatiles in *Z. mays* by herbivore damage (Turlings et al., 1998a; Ngi-Song et al., 2000; Degen et al., 2004), simulated herbivore damage (Bernasconi et al., 1998; Turlings et al., 1998b), or mechanical damage (Ngi-Song et al., 2000) and compared them with those from undamaged plants. In this context, it is particularly interesting to find the production, from undamaged plants, of large quantities of (*E*)-4,8-dimethyl-1,3,7-nonatriene (**27**) and (*E,E*)-4,8,12-trimethyl-1,3,7,11-

tridecatetraene (**43**), and from *Z. mays*, (*E*)-ocimene (**22**), as these compounds are normally associated with stress (Table 1) (Loughrin et al., 1994; Takabayashi et al., 1995), although there were no other signs of stress in any of the plants. (*E*)-4,8-Dimethyl-1,3,7-nonatriene (**27**) has been shown to reduce oviposition by gravid stemborer females and also to attract parasitoids (Turlings et al., 1990, 1991, 1995; Khan et al., 1997b; Gouinguéné et al., 2001), which makes its high production by the wild trap crop hosts surprising.

Most of the large difference in the overall production of electrophysiologically active volatiles (Table 1) between cultivated and wild hosts was associated with the production of green leaf volatiles (Table 1), possibly suggesting a key role for these compounds in host location. Although the EAG responses to these compounds were relatively low (Fig. 2a and 3), they are present in the volatiles at higher concentrations than most others (Table 1). The green leaf volatiles, in particular, hexanal (**4**), (*E*)-2-hexenal (**5**), (*Z*)-3-hexen-1-ol (**6**), and (*Z*)-3-hexen-1-yl acetate (**16**), also show a marked diel periodicity, extremely large increases in their production occurring during the 1st hr of the scotophase (Chamberlain et al., 2006). This also supports the hypothesis that they could be important compounds in locating oviposition sites for stemborers, since this is the period when most host-locating flights take place (Päts 1991).

The overall trend for *B. fusca* to be more responsive to the compounds than *C. partellus* is highlighted in the case of the unknown compound with a Kovats Index of 743 (**2**). Although this was shown by GC-MS to be present in all the hosts except *Z. mays* (Table 1), it only gave a GC-EAG response with *B. fusca*, indicating a significant differential acuity between the two stemborer species. In this context, *B. fusca* has co-evolved with *P. purpureum*, *H. tamba*, and *S. bicolor*, whereas *C. partellus* is an introduced species in Africa. Work will continue on elucidation of the structure of both unknown compounds.

Although plant volatiles are known to play a key role in host location by phytophagous insects (reviewed in Bernays and Chapman, 1994; Dethier 1982; Visser 1986, 1988; Pickett et al., 1998; Bruce et al., 2005;), the ability to detect a kairomone at the peripheral level does not necessarily mean that the component is associated with host plant recognition. To address this issue, further laboratory behavioral assays and field studies with these compounds are required. Nevertheless, this study provides insights into possible host location kairomones used by these two species of stemborers and into the differential attraction/oviposition between cultivated and wild hosts observed in the field. In particular, it provides some essential scientific input required for the sustainability of the “push–pull” strategy.

Introduction

The multicolored Asian lady beetle, *Harmonia axyridis* (Pallas) (Coleoptera: Coccinellidae), is an effective predator of aphids and other soft-bodied insect pests in pecan, apple, and citrus ecosystems (Tedders and Schaefer, 1994; Brown and Miller, 1998; Michaud, 2002; Brown, 2004) during the spring and summer. Lady beetles play an important role as biological pest control agents. Nonetheless, they are considered a nuisance pest when they overwinter in North American homes. In autumn, adults leave feeding sites in agricultural and urban landscapes and search for overwintering sites. Attics, wall voids, and other inaccessible locations in houses and man-made structures are often selected (Nalepa et al., 1996; Schaefer, 2003). Odors emanating from beetles in infested locations can lead to allergic rhinoconjunctivitis (Yarbrough et al., 1999; Ray and Pence, 2004). As a defense, *H. axyridis* adults secrete hemolymph from their joints when roughly handled (King and Meinwald, 1996; Laurent et al., 2002). This secreted hemolymph can stain furniture and draperies, and gives off an unpleasant odor.

In recent years, *H. axyridis* has become a concern to grape growers and the wine industry. The inadvertent crushing of beetles with grapes releases defensive compounds (e.g., pyrazines) resulting in off-taste wines (Cudjoe et al., 2005). Production of beetle-tainted wines has been reported in several wineries in the northeastern United States and southern Canada (Pickering et al., 2004, 2005).

A potential approach to managing this useful, but problematic insect is by implementing a push–pull strategy. Such an approach relies on using environmentally friendly repellents to push beetles away from structures or grape clusters during the fall, and attractants (possibly aggregation pheromones) to pull beetles into outdoor traps (Riddick et al., 2000; Riddick and Aldrich, 2004). To begin the process of detecting and identifying volatiles that function as attractants or aggregation pheromones, research was initiated to compare airborne chemicals released from living male and female lady beetles.

Gas chromatography/mass spectrometry (GC/MS) is a common analytical technique used to identify volatile analytes and MS offers sensitivity for the detection of compounds that are in trace amounts. However, GC and GC/MS alone can not always handle sample matrices directly, and sometimes extraction and preconcentration is necessary prior to analysis. To study the chemical profile of beetle odors, we utilized two sample introduction techniques. Solid phase microextraction (SPME) was developed in the early 1990s as a means of extracting and preconcentrating pollutants in water samples (Arthur and Pawliszyn, 1990; Zhang and Pawliszyn, 1993), but has also been used for the study of airborne insect pheromones (Malosse et al., 1995). SPME involves absorption/adsorption of volatiles and semivolatiles in a sample matrix to be fused onto a chemically coated fiber. Direct desorption of the extracted compounds into the GC column occurs in the heated injection port of the GC system. In contrast, trapped whole air sampling, a modified EPA TO-14 type methodology (Environmental Protection Agency, 1989), is similar to SPME. However, a variable volume of air is removed from the sample and preconcentrated by

absorption/adsorption depending on the chemical composition of the trapping material in the trap. The trap temperature is rapidly raised to allow desorption, and a series of valves allows the carrier gas to sweep through the trap that is now in line with the GC column. Both of these techniques allow living subjects to be tested in a more natural, less-stressed environment. The solvent-free environment is unique to these techniques, and their sensitivity allows reduced sampling time over traditional methods. Both whole air and SPME extraction are time-saving procedures, which reduce stress to the insects and allows the investigation of their normal pheromone production. Traditional methods often involve solvent extractions and direct injection into a GC port via a syringe (Malosse et al., 1995; Agelopoulos and Pickett, 1998; Al Abassi et al., 1998; Robbins et al., 2003; Zhang and Aldrich, 2003; Cudjoe et al., 2005).

The primary objective of this study was to develop a useful, sensitive method for detection and identification of volatile chemicals emitted by live lady beetles.

Methods and Materials

Insect

Cultures *H. axyridis* adults were purchased from Rincon-Vitova Insectaries Inc. (Ventura, CA, USA) and placed at random into one of two polypropylene cages (30 × 30 × 30 cm, 24 mesh size, Bug Dorm 1™; MegaView Science Education Services Co., Ltd., Taiching, Taiwan), provisioned with food (pure honey, apple slices, lepidopteran eggs) and sterile water on cotton wads at the base of each cage. Both cages contained mixed sexes of beetles of unknown age. Cages were kept inside a plant growth chamber (at 10°C, 60–68% RH, 12-hr photophase).

Fig. 1 Environmental sampling chamber. This is a 1-l plexiglas cylindrical container, encircled with copper tubing connected to a water bath to control temperature. A small, mesh-covered, battery-operated fan is housed inside the chamber to maintain homogeneous air circulation. The chamber is equipped to accept SPME fibers and an air tube for whole air sampling

Fig. 2 Total ion chromatograms. These total ion chromatograms, obtained via GC/MS, represent air samples from with the Environmental Sampling Chamber containing 3 g lady beetles. (1) Whole air sampling of females, (2) whole air sampling of males, (3) SPME sampling of females, and (4) SPME sampling of males. Shaded peak shows an area of difference between males and females and major analyte was identified as β -caryophyllene

Fig. 3 Spectral match of the shaded peak to the NIST Library using data acquired on ion trap MS

Sample Preparation

H. axyridis adults were separated by gender, and approximately 3.0 g (101 males, 83 females) of insects were placed in the environmental sampling chamber for analysis. Mass was used to normalize weight discrepancy between sexes. The sampling chamber was essentially a modified, plexiglass (1 l) capillary syringe (Fig. 1). Once placed in the chamber, beetles were allowed to acclimate for 8 hr. All GC/MS sampling was performed at 24°C; temperature was kept constant throughout by circulating tap water from a water bath and through copper tubing, encircling the chamber. A small battery-operated fan was placed inside the chamber to maintain constant air circulation. A screen was placed around the fan to prevent beetles from contacting the fan blades.

A 1.0 mg/ml stock standard solution of pure β -caryophyllene dissolved in acetone was prepared and used for confirmation of analyte identification. Aliquots of these solutions were immediately sealed and kept in the refrigerator. Fresh standards were always used prior to each analysis, and all chemicals were obtained from Sigma-Aldrich.

(2) Spectral difference between the raw MS spectra and the NIST Library match. (3) NIST Library match spectra identifying and confirming the compound as caryophyllene

Sample Collection

A 75- μm carbonex/polydimethylsiloxane fiber (SPME, SupelcoTM), 1 cm in length, was used for volatile sequestration. Prior to extraction, the fiber was conditioned for 30 min in the injection port of the GC at 250°C. The fiber was allowed to absorb at 24°C for 2 hr and desorb for 3 min at 200°C.

A Tenax-G-Trap (Varian Chromatography Systems, Walnut Creek, CA, USA) was used for the whole air sampling. The trap was held at 4°C for 12.5 min, while 40 ml/min of sample air were collected yielding a total volume of 500 ml. Desorption of the trap was at 180°C for 2.5 min and then baked at 200°C for 20 min.

GC/MS Separation

A Varian Star 3600 GC with helium as a carrier gas passing through a Restek Rtx-Volatiles column (60 m \times 0.32 mm, with a 1.5- μm film) coupled with the Varian Saturn 2000 GC/MS with wave board technology, which has the NIST library installed, was used for identification. Regardless of the sampling technique, the initial GC oven temperature (40°C) was held for 3 min and then ramped to 260°C at 20°C min⁻¹, and then held for another 11 min. Electron impact ionization (EI) or chemical ionization (CI) of the analytes was achieved by using the Saturn 2000, with a scan range of 60–250 m/z and scan time of 0.45 scan/sec. For confirmation and identification of the analytes, a Finnigan MAT 95 XL Magnetic GC/MS operating at 5000 resolution was utilized based on this instrument's extreme sensitivity and spectral resolution. The column in this magnetic sector GC/MS was a Phenomenex ZB5 (30 m \times 0.25 mm, with a 0.25 μm film). Helium was used as the carrier gas, and the system was equipped with the NIST library. The higher resolution system used electron impact with a MS scan range of 50–250 m/z and a scan time of 1 sec/decade.

Chiral Separation

Racemic β -caryophyllene was resolved by GC on a Cyclodex-BTM capillary column (30 m \times 0.25 mm i.d.; 100°C for 3 min, to 117°C at 1°/min; Advanced Separation Technologies, Inc., Whippany, NJ, USA). Since neither the plus enantiomer nor the racemic β -caryophyllene are

commercially available (Fricke et al., 1995), it was necessary to prepare racemic β -caryophyllene. This was accomplished by converting α -humulene [(*E,E,E*)-2,6,6,9-tetramethyl-1,4,8-cycloundecatriene; Fluka Chemical Corp., Ronkonkoma, NY, USA] to (\pm)- β -caryophyllene according to Greenwood et al. (1968).

Results

A comparison of volatiles emitted by male and female live beetles was achieved by using SPME and trapped whole air sampling techniques (Fig. 2). Differences in the total ion chromatograms between sexes, independent of the sampling technique, were evident. The shaded area in Fig. 2 highlights one of these areas of difference and indicates a compound that is present only in females. The identification of the analyte was obtained by a combination of comparisons with the NIST Library (Figs. 3 and 4) and by comparing the retention time with known standards (Table 1), which were analyzed by ion trap and magnetic sector GC/MS (Fig. 4). The analyte was β -caryophyllene. β -Caryophyllene (bicyclo[7.2.0]undec-4-ene 4,11,11, trimethyl-8-methylene) has a molecular weight of 204. The gaseous emissions from the same lady beetle population were analyzed three times at 2-d intervals. The average retention time run on the Ion trap MS was 20.191 ± 0.005 min for the whole air sampling and 19.812 ± 0.070 min for the SPME sampling. When pure caryophyllene was run with the same methodology, average retention times were 20.191 ± 0.003 and 19.901 ± 0.192 min, respectively, for whole air and SPME. There is greater variation in the retention times for the SPME method compared to whole air methodology. This can be attributed to the automation of the whole air method that reduces the human error and increases precision when compared to manual SPME technique.

The mass spectrum (Fig. 3) shows a fragmentation pattern with major ions of m/z 161, 133, 105, and 91, and gives a spectral probability of 79.3%. The match with β -caryophyllene also shows other terpene compounds that share these ions, and therefore higher-resolution GC/MS was utilized for absolute identification. The Magnetic Sector, equipped with the NIST library, confirmed β -caryophyllene as the analyte when compared with pure standard at retention time of 11.126 min. Figure 4 reveals little spectral difference between the raw analyte MS spectra and the NIST reference.

The racemic mixture of β -caryophyllene was resolved with near-baseline separation, exhibiting two peaks eluting at 16.9 and 17.2 min. ($-$)- β -Caryophyllene eluted at 17.2 min, establishing that the earlier eluting enantiomer was ($+$)- β -caryophyllene (Fig. 5). Coinjection experiments of an aeration sample of ~ 500 male and female *H. axyridis* adults (73 h/75 μ l CH_2Cl_2) with (\pm)- β -caryophyllene and ($-$)- β -caryophyllene established that caryophyllene from *H. axyridis* consisted solely of the ($-$)-enantiomer with no trace of ($+$)- β -caryophyllene.

Discussion

This work demonstrates an innovative approach in which compounds emitted by live laboratory reared beetles, in an environmentally controlled chamber, can be analyzed with two different sampling methods. Environmental chamber design along with the development and sensitivity of the sampling techniques allows for the analysis of beetle odors without subjecting the insects to undue stress. Traditional methods have involved solvent extractions that use charcoal filters, with lady beetles packed in a small cylindrical tube for

several days (J.R. Aldrich, unpublished data). These tight quarters, in the absence of food and water, can cause unintentional die-off of some of the test beetles. The induced stress may impact the profiles of emitted volatiles. Instead of several days, our sampling time is reduced to a matter of hours, and the sample size can be reduced to ensure a more natural production of emitted volatiles.

The sampling methods removed only a small aliquot of air from the environmental chamber and did not comprehensively deplete air supply. The sensitivity of the procedure can be enhanced by withdrawing larger volumes of chamber air. This was a variable volume system in which the flow rate and/or time could be changed to facilitate the desired sensitivity of the analysis. In contrast, SPME fibers could be introduced into smaller chambers, reducing headspace, and thereby concentrating the volatiles and increasing sensitivity. This increase in sensitivity will play a greater role as we identify more peaks in the chromatography profile in order to isolate the aggregation pheromone.

The sampling methods produced similar chromatograms that showed marked differences between laboratory-reared male and female beetles. A combination of retention time, GC/MS analysis with NIST library searching, complemented by higher-resolution GC/MS allowed for the identification of one analyte. This was identified as β -caryophyllene and was exclusively emitted by the females. Preliminary data from field collected beetles exhibit similar results (A.E. Brown, unpublished data).

Isoprenoids play a major role in governing the behavior of other insects (Birkett and Pickett, 2003). For example, the boll weevil is attracted to cotton plants (Hedin et al., 1973), and the female is sexually attracted to the male by airborne volatiles (Tumlinson et al., 1969). In both cases, the attracting compounds are terpenes. β -Caryophyllene has been isolated from female boll weevils and serves as an attractant under certain conditions (Minyard et al., 1969). β -Caryophyllene serves as an attractant in other species, including the Colorado potato beetle (Khalilova et al., 1998), the carrot fly (Guerin et al., 1983), the damson hop aphid (Campbell et al., 1993), and the green lacewing (Flint et al., 1979). Plant-derived (–)- β -caryophyllene inhibits the response of the lady beetle, *Coccinella septempunctata* L., to aphid alarm pheromone [(E)- β -farnesene] in olfactometer bioassays (Al Abassi et al., 2000).

The detection of the (–)-enantiomer of β -caryophyllene in airborne volatiles from *H. axyridis* females was determined by chiral column GC and by comparison of the elution sequence of the racemic mixture. The minus enantiomer is commonly found in a variety of plant species (Nazaruk et al., 2002).

This study demonstrates that volatiles emitted from live laboratory-reared beetles can be analyzed by using SPME or whole air sampling coupled with GC/MS. These sampling techniques show differences in volatile and semivolatile organic chemicals emanating from *H. axyridis* males and females. Future studies might include lowering the temperature of the environmentally controlled chamber to mimic the natural conditions within overwintering aggregations. Although SPME fiber desorption appeared to be more sensitive than whole air sampling, the latter is presently more compatible with automated real-time analysis. Unattended automated analysis will allow us to study the physiological responses of *H. axyridis* to changes in temperature, light, and humidity.

Acknowledgments Ralph Dollar, Rezwan Hague, Mary Catherine Tate, Elizabeth Wray, and Bart H.J. van den Berg provided technical assistance in the laboratory. We thank Jim Oliver (retired, USDA-ARS) for help with the organic synthesis, and Steven Grossman and Thomas Nebeker for reviewing an earlier version of the manuscript.

Introduction

Spider mites are common plant pests that feed mostly on leaves. A typical symptom of spider mite feeding is the presence of small, slightly colored scars. The color of scars induced on kidney bean leaves by the spider mite *Tetranychus kanzawai* Kishida (Acari: Tetranychidae) can be categorized as red or white (Yano et al., 2003). After applying bidirectional selection to the color of the leaf scars in two strains of this mite, Yano et al. (2003) found that the scars became uniformly red in one strain and white in the other (hereafter called “Red” and “White” strains). Reciprocal and backcrosses between the strains suggested that the Red genotype was fully dominant over the White, and that the color of leaf scars induced by *T. kanzawai* was controlled by a single locus (Yano et al., 2003).

Herbivory by spider mites induces several defensive responses in infested plants, including the emission of volatiles that attract natural enemies of the mites (e.g., Sabelis et al., 1984; Dicke, 1994), and the expression of defensive genes in the plant (e.g., Ozawa et al., 2000). Differences in the color of leaf scars by the Kanzawa spider mite would also be a result of differences in the induced responses of kidney bean plants.

Jasmonic acid (JA) is one of the endogenous signals involved in eliciting induced direct defense against herbivores and pathogen in plants (Creelman and Mullet, 1997; Wasternack and Parthier, 1997). It is also considered to be one of the important factors involved in induced indirect defense, i.e., the production of herbivore-induced plant volatiles (HIPVs) that attract carnivorous natural enemies of the herbivore (Boland et al., 1995; Dicke et al., 1999; Gols et al., 1999; Ozawa et al., 2000, 2004; Schmelz et al., 2003). The other plant-signaling pathway involved in induced defense is the salicylic acid (SA) signaling pathway, which is known to be involved in induced direct defense against pathogens (Ryals et al., 1996; Durner et al., 1997). Ozawa et al. (2000) showed that both the JA and SA signaling pathways are involved in the production of lima bean plant volatiles induced by the two-spotted spider mite, *Tetranychus urticae*.

The objective of this study was to determine whether intraspecific variation in *T. kanzawai* differentially affects induced defensive responses in lima bean plants. Using Red and the White strains from a field-collected population of *T. kanzawai*, we studied whether the two strains differentially induce defensive responses. We investigated the expression of genes coding pathogenesis related (PR) proteins that are under the control of either the JA or SA signaling pathways. The amounts of SA in intact leaves and those infested by either the Red or the White strains were measured. We also analyzed the headspace volatiles from lima bean leaves infested by each strain to investigate whether the induced defensive response of leaves against each strain differentially affects the production of HIPVs.

Methods and Materials

Plant and Mites Lima bean plants (*Phaseolus lunatus* L.) were grown in soil in a climate-controlled greenhouse (25 ± 2°C, 60–70% RH, 16L–8D). We used plants with two fully expanded primary leaves (10–13 d old) for all experiments.

Herbivorous Kanzawa spider mites (*T. kanzawai*) were collected from hydrangea, *Hydrangea macrophylla* (THUNB. Ex MURRAY) SER. f. *macrophylla*, at Ami, Ibaraki (36°1'N, 140°12'E), on April 27, 2004. Collected mites were transferred onto detached lima bean leaves (ca. 100 mites per leaf), and the leaves were pressed onto water-saturated cotton in Petri dishes (90 mm diam, 14 mm deep; hereafter referred to as “leaf disks”). We placed the disks in transparent plastic containers under controlled conditions ($25 \pm 2^\circ\text{C}$, 60–70% RH, 16L–8D).

Bidirectional Selection of Pure Mite Strains To obtain pure mite strains that induced either red or white leaf scars, we selected individual mites based on the color of the scars that they induced on lima bean leaves, following the method of Yano et al. (2003) with minor modification. The population collected from *H. macrophylla* was used as a base population for the following selection experiment. Adult females (100–120) were randomly selected from the base population and individually isolated on 10×10 mm bean leaf squares on water-saturated cotton in Petri dishes. These squares were cut from intact lima bean leaves. Females were allowed to feed for 4–6 d. The observed scar colors were classified as either red or white. The 10 females that induced the most distinctive red scars and the 10 females that induced the most distinctive white scars on the leaf squares were selected. The selected females were grouped according to the induced scar color and transferred to a fresh leaf square for oviposition. Generated mites were allowed to randomly mate and produce the next generation that became the base population for the second selection. We repeated this procedure for more than eight generations. They were called Red strain and White strain.

Mode of Inheritance To examine the mode of inheritance responsible for scar color variation and gene induction, we conducted reciprocal crosses according to the method of Yano et al. (2003). Three randomly selected teleiochrysalis females of each strain were separately introduced onto a 10×10 mm leaf square, together with an adult male of the opposite strain. We randomly selected female hybrids. The color of the scar induced by the hybrid female was determined, as described above. For gene expression analysis, we placed 20 hybrid females on each detached primary leaf. After 24 hr of infestation, total RNA was isolated from the leaf by the same procedure as described in the “RT-PCR Analysis” section, below.

Performance Index of Adult Females The number of eggs produced within a certain period is used as a performance index in *T. kanzawai* (Gomi and Gotoh, 1996). Teleiochrysalis females from each of the Red and White strains were collected and after 1 d the newly emerged females were individually transferred onto a 10×10 mm leaf square. We counted the number of eggs laid by each female within 1, 3, and 7 d. We also conducted the same experiment with adult females that were randomly collected from the mite colony, because we used such mites in the following experiments.

RT-PCR Analysis We detached a primary leaf with the petiole from intact lima bean plants (10–13 d old) and immediately transferred it into a vial (10 ml) containing distilled water. We separately placed 20 adult females of Red and White strain on a detached leaf and allowed them to feed for 24 and 72 hr. We also placed 120 females of White and 5 females of Red strain separately on a detached leaf and allowed them to feed for 24 hr, in order to compare the induction levels of the two strains. Total RNA was isolated from leaves using a RNeasy Plant Mini Kit (Qiagen, Valencia, CA, USA). First-strand cDNA was synthesized from 1 µg of total RNA by using AMV reverse transcriptase XL (TaKaRa, Kyoto, Japan)

and Oligo dT-Adaptor Primer (TaKaRa) according to the manufacturer's instructions. Negative controls were used in experiments in which the reverse transcriptase was omitted. The first-strand cDNA was amplified using *TaKaRa Ex Taq* DNA polymerase (TaKaRa) and the following gene-specific primers (Arimura et al., 2000): for the acidic chitinase gene, 5'-AGCAACAACGTTAATGTTGC-3' and 5'-CTTGCACCATCTATCTCTTC-3'; for the basic chitinase gene, 5'-CTCAGCGCCCTCATATCCAG-3' and 5'-GATGCGGTCTTG AACCTGC-3'. Polymerase chain reaction (PCR) conditions were as follows: 95°C for 30 sec; 30 cycles (acidic chitinase) or 20 cycles (basic chitinase) of 95°C for 30 sec, 55°C for 30 sec, and 72°C for 1 min. The PCR products and total RNA (4 µg) were separated in a 1.5% agarose gel by electrophoresis and detected by staining with ethidium bromide. No PCR product was amplified in control amplifications that lacked reverse transcriptase.

Measurement of SA and Salicylic Glycoside (SAG) We placed 20 *T. kanzawai* females on each detached leaf and allowed them to feed for 24 hr. SA was then extracted from the leaves and quantified according to the method of Malamy et al. (1992), with minor modification. Half a gram of lima bean leaves was ground in 5 ml of 90% (v/v) methanol and centrifuged at 10,000 × *g* for 15 min. The pellet was back extracted with 5 ml of 100% methanol and centrifuged again. Methanol extracts were combined and dried at 40°C under vacuum. Extracts were resuspended in water at 80°C. The extracts were equally divided into two tubes: one for SA and the other for SAG measurements. An equal volume of 0.2 M sodium acetate (pH 4.5) was added to each tube. For the SAG measurement, 5.5 units of β-glucosidase (Sigma) were added into the tube and incubated at 37°C overnight, whereas for the SA measurement, the sample was incubated under the same conditions but without the enzyme. After digestion, samples were acidified to pH 1–1.5 with HCl. Free SA was extracted into 2 volumes of cyclopentane/ethyl acetate/isopropanol 50:50:1. The organic extract was dried and analyzed with a high-performance liquid chromatography (HPLC) system equipped with a spectrofluorescence detector (model RF-550A; Shimadzu, Kyoto, Japan) under the following conditions: column, Inertsil ODS-3 (GL sciences, 4.0 × 150 mm); column temperature, 40°C; mobile phase, 23% (v/v) methanol in 20 mM sodium acetate (pH 5.0); flow rate, 1 ml/min; excitation wavelength, 313 nm; emission wavelength, 405 nm.

Recovery rate of SA was determined by using SA (Wako Pure Chemical Industries, Ltd., Osaka, Japan) standard that was added into the crude methanol extracts (SA standard sample). As a negative control, methanol extracts without the SA standard were also prepared. After the partial purification described above, the amount of SA was analyzed with HPLC. Recovery rate of SA (73.4%) was determined by subtracting SA amount in the negative control from the SA standard sample.

Analysis of Headspace Volatiles We placed 5 or 20 *T. kanzawai* adult females on a detached leaf, allowed them to feed for 72 hr, and then collected headspace volatiles from two leaves. The leaves were placed in a 2-l glass bottle with two nozzles; one was connected to an air cylinder and the other was connected to a glass tube packed with Tenax TA adsorbent (100 mg, mesh 20/35). Pure air gas from the cylinder was drawn into the glass bottle, and volatile compounds from the headspace of the bottle were collected with Tenax TA for 1 hr at a flow rate of 100 ml/min. The collected volatile compounds were analyzed by GC-MS (GC: Hewlett Packard 6890 with HP-5MS capillary column: 30 m long, 0.25 mm I.D., and 0.25 µm film thickness; MS: Hewlett Packard 5973 mass selective detector, 70 eV) equipped with a thermal desorption cold trap injector (TCT; CP4010; Chrompack, Middelburg, The Netherlands). Headspace volatiles collected on Tenax-TA were released from the adsorbent by heating in the TCT at 220°C for 8 min within a flow of

He gas. The desorbed compounds were collected in the cold trap unit of the TCT (SIL5CB-coated fused silica capillary) at -130°C . Flash heating of the cold trap unit provided sharp injection of the compounds into the capillary column of the gas chromatograph to which the cold trap unit was connected. The oven temperature of the GC was programmed to rise from 40°C (5 min hold) to 280°C at $15^{\circ}\text{C}/\text{min}$. Headspace volatiles were identified by comparing their mass spectra with those of the database (Wiley7N and Wiley275) and by comparison of their retention times and mass spectra with those of authentic compounds or volatile compounds from lima bean leaves infested with *T. urticae*.

Statistics *t*-Tests were used to compare the numbers of eggs laid by the Red and the White strain ($N = 27\text{--}30$), and the ion intensities of each headspace volatile compound emitted from lima bean leaves infested with the two mite strains ($N = 6\text{--}8$). Tukey's HSD test was used to determine significant differences among treatments in the experiments for endogenous salicylic acid and salicylic glycoside (SAG) analyses ($N = 4$).

Results

Bidirectional Selection of Red and White Strains After nine mite generations of bidirectional selection based on leaf scar color, the color induced by each strain became uniformly red or white (Fig. 1). To examine the mode of inheritance responsible for the color variation, reciprocal crosses between the two strains were performed. Almost all female hybrids from the reciprocal crosses of Red female \times White males ($N = 20$) and White female \times Red male ($N = 18$) induced red scars. Only one female from each cross induced an ambiguously colored scar. These results showed that the Red genotype was fully dominant over the White genotype.

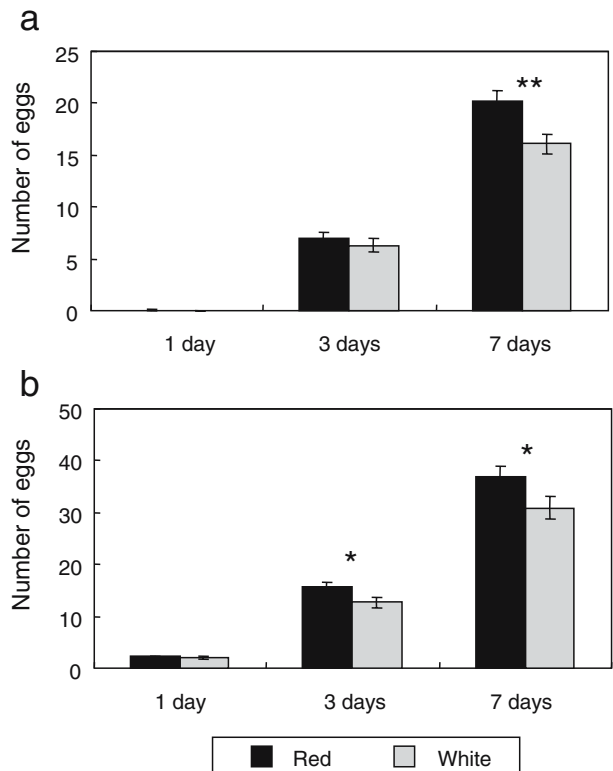

Fig. 1 Photographs showing the scar colors induced on lima bean leaves by the Red (left) and White (right) strains of *Tetranychus kanazawai*. Each stain was allowed to feed for 1 day. Bars = 1 cm

Performance Index of Adult Females The numbers of eggs laid by newly emerged females from teleiochrysalis within 1 and 3 d were not significantly different between the Red and White strains ($P > 0.05$, *t*-test; Fig. 2A), but the number of eggs laid by Red females within 7 d was higher than that of White females ($P = 0.003$, *t*-test; Fig. 2A). Similarly, the number of eggs laid by randomly collected adult females within 1 d was also not different between the two strains ($P > 0.05$, *t*-test; Fig. 2B), but the numbers of eggs laid by randomly collected Red females within 3 and 7 d were higher than those of White strain females ($P = 0.031$ for 3 d and $P = 0.049$ for 7 d, *t*-test; Fig. 2B).

Expression Profiles of Defensive Genes Induced by Red and White Strains We compared the expression of two defensive genes, acidic and basic chitinase, in lima bean leaves when infested by either the Red or the White strain (Fig. 3). In intact lima bean leaves, no expression of acidic chitinase was observed, whereas a slight expression of basic chitinase was observed. As the intact leaves were detached from the plant, the leaves had some injury stress, and this is likely to be one of the reasons why the slight induction of basic chitinase in intact leaves was detected.

The expression of the acidic chitinase gene was observed in lima bean leaves infested by 20 Red females (Red 20) for 1 d. The expression was further up-regulated after 3 d of infestation. Conversely, we could not detect the expression of acidic chitinase gene in lima bean leaves infested by 20 White females (White 20) for 3 d. The expression of basic chitinase was up-regulated in both Red- and White-infested leaves in 1 d. The expression was further up-regulated in both strains infested leaves at 3 d after damage.

Fig. 2 The total numbers of eggs laid by the Red and White strains within 1, 3, and 7 d by using newly emerged females (a) and randomly collected females (b). Two White strain newly emerged females and one Red strain and one White strain random collected females died on day 7, and so only eggs laid by these mites in 1 and 3 d were included in the data set. Error bars represent standard errors ($N = 27-30$). $**P < 0.01$, $*P < 0.05$ (*t*-test)

Fig. 3 Acidic and basic gene expression in lima bean leaves in response to feeding by Red and White scar strains of *Tetranychus kanazawai*. Acidic and basic chitinase gene expression in lima bean leaves was investigated by RT-PCR analysis. Twenty females of Red (Red20) and White (White20) strains were used for infestation. RNA was collected 1 (1d) and 3 d (3d) after infestation. rRNA was used as a loading control

Next, we studied the effects of the number of Red and White mites on the expression of both basic and acidic chitinase genes (Fig. 4). The expression of acidic chitinase gene was up-regulated when the number of Red mites was increased from 5 to 20. Likewise, the expression of acidic chitinase gene was also up-regulated when the number of White mites was increased from 20 to 120. The level of the expression of acidic chitinase in White 120 was lower than Red 20, based on the RT-PCR band intensity. Basic chitinase showed the same dose-dependent up-regulation in both strains. The expression of basic chitinase in White 120 and Red 20 leaves was similar according to the RT-PCR band intensity.

When lima bean leaves were infested by 20 female hybrids from the reciprocal crosses of either Red female \times White male or White female \times Red male, we observed increased acidic chitinase gene expression, which was at the same level as that in leaves infested by 20 Red females (Fig. 4).

Levels of Endogenous Salicylate The concentration of SA in leaves infested by Red females was higher than those in either intact leaves or in leaves infested by White strain ($P < 0.05$, Tukey–Kramer’s HSD; Fig. 5A). The amount of SAG showed the same trends between intact leaves, leaves infested by Red females and those infested by White females ($P < 0.05$, Tukey–Kramer’s HSD; Fig. 5B).

Headspace Volatiles of Leaves Infested by either Red or White Strains We recorded seven compounds in the headspace of lima bean leaves infested with 5 or 20 females of either Red or White strain for 72 hr. Uninfested control leaves either did not emit or barely emitted

Fig. 4 Effects of the number of mites and their genetic background on defensive gene expression in lima bean leaves. Numbers after strain names and in parentheses represent the number of females used for infection. Red × White F1 and White × Red F1 represent the hybrids of reciprocal crosses between the Red and White stains. Plants were infested for 1 d. rRNA was used as a loading control

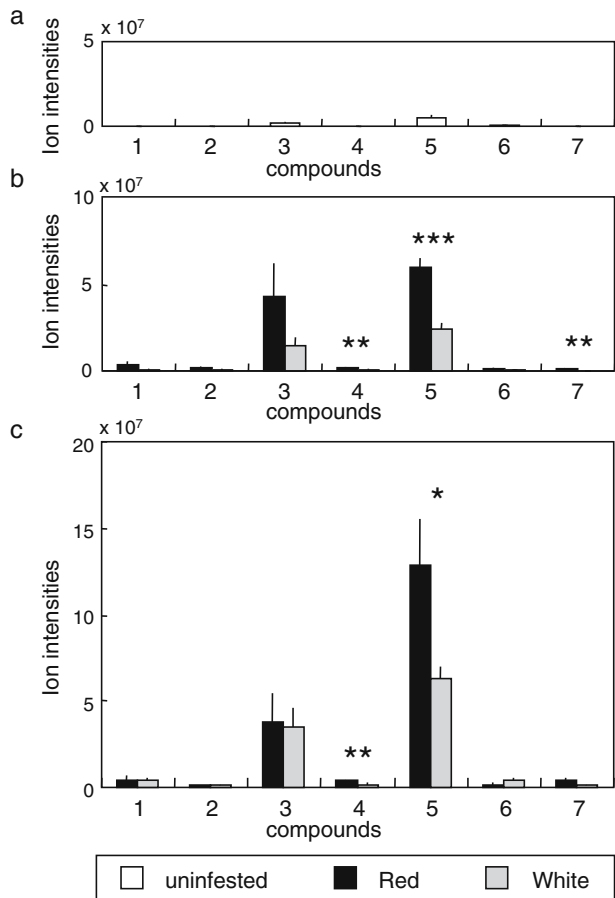

Fig. 5 Levels of endogenous salicylic acid (a) and salicylic glycoside (b) in lima bean leaves infested with Red and White strain mites. Different letters on the top of the bar in each treatment are significantly different ($P = 0.05$, Tukey–Kramer’s HSD)

Fig. 6 Ion intensities of head-space volatile compounds emitted from two lima bean leaves that were uninfested (a), or infested with Red/White strain mites: leaves infested with 5 females per leaf (b) and leaves infested with 20 females per leaf (c). Head-space volatiles were collected 72 hr after treatment. Error bars represent standard errors ($N = 4-8$); $***P < 0.001$, $**P < 0.01$, $*P < 0.05$ (t -test). Compounds: **1**, (Z)-3-hexenyl acetate; **2**, (Z)- β -ocimene; **3**, (E)- β -ocimene; **4**, (Z)-4,8-dimethyl-1,3,7-nonatriene; **5**, (E)-4,8-dimethyl-1,3,7-nonatriene; **6**, methyl salicylate; **7**, (E,E)-4,8,12-trimethyl-1,3,7,11-tridecatetraene

these volatiles (Fig. 6A). When the leaves were infested with five females, significantly higher amounts of (Z)-4,8-dimethyl-3,7,11-nonatriene (Z -DMNT), (E)-4,8-dimethyl-3,7,11-nonatriene (E -DMNT), and (E,E)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT) were emitted from leaves infested with Red females than in leaves with White females ($P < 0.05$, t -test; Fig. 6B). Also, the leaves infested with 20 Red females emitted higher amounts of Z -DMNT and E -DMNT than those from the leaves with 20 White females ($P < 0.05$, t -test; Fig. 6C).

Discussion

In this paper, we have shown that intraspecific variation in the Kanzawa spider mite, *T. kanzawai*, differentially affects induced defensive response in lima bean plants. From our cross experiments, we found that the color of scars induced by *T. kanzawai* was determined by mite genotype, and that the genotype of the Red strain was dominant over the White strain. Yano et al. (2003) reported the same results using kidney bean leaves as a food plant

for the mites. The performance of the Red strain mites on a lima bean leaf was slightly better than that of the White strain, and that difference was detectable at least after 7 d of damage made by newly emerged mites (Fig. 2). Interestingly, the number of eggs laid by randomly selected Red strain mites by both days 3 and 7 was significantly higher than that by White strain mites (Fig. 2), probably because average age of the randomly selected mates was higher than that of newly emerged mites. We found characteristic differences in acidic chitinase inductions between the two strains, which were randomly selected, even 1 d after infestation. Such difference in the gene induction would be the result of differences between factors injected in the leaves by the two strains, and the different response in lima bean plants against two strains would affect the performance of the mites.

It has been reported that the expression of defensive genes, such as genes for PR proteins, are induced by herbivory (Koiwa et al., 1997; Ozawa et al., 2000). Our results of gene expression analysis suggest that the damages made by Red strain mites resulted in an increased expression of both basic chitinase (*PR-3*) and acidic chitinase (*PR-4*), whereas the induction by White strain mites mainly affected the expression of basic chitinase (Fig. 4). To examine the mode of inheritance responsible for acidic chitinase induction, reciprocal crosses between the two strains were conducted (Fig. 4). Cross experiments indicate that the Red genotype was dominant over the White for the induction of acidic chitinase, suggesting that the Red strain has factors to induce acidic chitinase gene expression.

Damage made by the Red strain induced the expression of genes for both basic chitinase, which was downstream of the JA signaling pathway, and for acidic chitinase, which was downstream of the SA signaling pathway (Thomma et al., 1998; Ozawa et al., 2000). The induction of acidic chitinase and the higher accumulation of salicylate in leaves infested by the Red than the White (Fig. 5) indicate the specific activation of the SA signaling pathway in leaves infested by Red strain mites. Conversely, the JA signaling pathway would be induced by both strains, as a gene encoding basic chitinase was induced by both strains. Ozawa et al. (2000) showed that both the JA and SA signaling pathways are activated in lima bean leaves infested by *T. urticae*, and that both pathways were involved in the production of *T. urticae*-induced lima bean leaf volatiles. The major volatile compounds induced by methyl salicylate treatment in lima bean leaves are E-DMNT and TMTT (Ozawa et al., 2000). E-DMNT is also induced by the application of JA in lima bean and corn leaves (Hopke et al., 1994; Koch et al., 1999; Ozawa et al., 2000). By contrast, TMTT is not induced by JA treatment in lima bean leaves (Hopke et al., 1994; Koch et al., 1999; Ozawa et al., 2000). In this study, the emission of Z-DMNT, E-DMNT, and TMTT was higher in leaves infested with Red strain mites than those infested with White strain mites. Such differences could be partly explained by the differences between the strains in the activation of the JA and SA signaling pathways.

HIPVs have been attracting considerable attention among chemical ecologists and plant physiologists (Takabayashi and Dicke, 1996; Dicke and Vet, 1999; Kessler and Baldwin, 2002). One of the most intriguing features of HIPV production is the herbivore-species specificity: HIPVs emitted from infested plants qualitatively and/or quantitatively differ according to herbivore species, and such differences could result in the attraction of carnivorous natural enemies specific to the infesting herbivore (Takabayashi and Dicke, 1996; De Moraes et al., 1998; Dicke, 2000; Ozawa et al., 2000). Here, we show that even within the same herbivore species different strains induce strain-specific blends of volatiles. One of the mechanisms creating such strain specificity in lima bean plants would be the difference in their induction of the SA signaling pathway.

The Kanzawa spider mite is highly polyphagous, and we have found that Red strain mites made white scars on leaves of other plant species and *vice versa* (Matsushima and

Takabayashi, unpublished data). These data suggest that the response of plants against the damage made by two strains is expected to differ with the host plant species. Thus, a study is needed to clarify whether differences in the induction of the JA and SA signaling pathways, and in the production of herbivore-induced volatiles by the Red and White strains, can be observed in plants belonging to the same and different families.

Acknowledgments We thank Syuichi Yano for the helpful discussion to RM. This study was supported by CREST of JST (Japan Science and Technology Corporation) and by a postdoctoral fellowship to R.M. from Japan Society for the Promotion of Science (16000439-00).

2001), which may reflect the presence of particular attractants. One preferred plant is the tropical or Indian almond, *Terminalia catappa* L. Both leaf and fruit extracts of *T. catappa* attracted mainly female flies in laboratory arena bioassays (Chien and Yaw, 2000; Siderhurst and Jang, 2006).

Female-specific attractants are a promising, if illusive, goal of fruit fly control programs because a lure for females removes both females and potential offspring (Jang and Light, 1996). Currently, food-type attractants, such as fermenting sugars, hydrolyzed protein, and yeast, provide the best attractants for *B. dorsalis* females. However, these liquid lures lack potency, have limited field life, are difficult to handle, and attract nontarget species. Plant materials such as fruits and leaves that attract female fruit flies are regarded as promising sources of attractants. Host fruits are of particular interest because some tephritid females are known to be attracted by host volatiles while searching for oviposition sites (Jang et al., 1998, 1999; Jang, 2003). However, isolation and identification of attractants from fruits is often difficult because the fruit odors are a complex blend of volatiles, which change in composition during ripening. Rapid screening of multiple compounds of interest and/or analysis of complex blends has been facilitated by coupled gas chromatography-electroantennogram detection (GC-EAD), which has been successfully used to identify fruit fly attractants from several plant sources (Cosse et al., 1995; Zhang et al., 1999; Nojima et al., 2003a,b). In particular, identification of fruit volatiles that elicited responses from antennae of *Rhagoletis pomonella* led to the development of useful lures for control of this insect (Zhang et al., 1999; Stenliski and Liburd, 2002).

The objective of the present study was to employ GC-EAD analysis to screen for volatiles of *T. catappa* that are detected by the antennae of female oriental fruit flies, and which may serve as host plant attractants. Behavioral responses to several synthetic blends of compounds that elicited antennal responses were recorded in wind tunnel, outdoor olfactometer, and field cage bioassays, with particular attention given to attraction of female flies.

Methods and Materials

Insects

Adult flies were obtained as pupae from the mass-rearing unit at the USDA-ARS Pacific Basin Agricultural Research Center, Mass-Rearing Facility in Honolulu, HI, USA. Larvae were reared on a standard wheat, sugar, and yeast diet (Tanaka et al., 1969). Pupae were shipped by air to Hilo, HI, where they were placed into 30×30×30 cm cubical aluminum screen cages containing sugar, water, and hydrolyzed protein. Flies were held at 24°C, 60–80% relative humidity, and 12L:12D photoperiod until use. Prior to testing, flies were immobilized by chilling at 5°C and separated into groups of either 50 males or females and were then held at room temperature (24°C) for at least 1 hr before use. Flies were approximately 9 to 11 d old when tested and presumed to be mated (ca. >95% of females from mixed cages are mated by day 7) (Jang et al., 1997).

Fruits

Newly ripened fruits of *T. catappa* were collected from two locations, Onekahakaha Beach Park, Hilo, HI, and Anini Beach Park, Kauai Island, HI, from October to December 2004. Fruits from Kauai were shipped by air to Hilo. Fruits were extracted fresh, or frozen at –80°C

until use. Ripening fruit in the laboratory was also attempted, but once green fruit are removed/fall from the tree they do not continue to ripen.

Sampling of Volatiles

Three different solid-phase microextraction (SPME) fibers were used for sampling of volatiles: polydimethylsiloxane (PDMS; film thickness 100 μm ; Supelco Inc., Bellefonte, PA, USA), polyacrylate (PA; film thickness 85 μm) and Carbowax/divinylbenzene (CW/DVB; film thickness 70 μm). SPME fibers were conditioned before use in a GC injector (250°C) for 30 min. Three ripe *T. catappa* fruits were placed in a 500-ml clear straight-sided jar with a screw-top lid fitted with a Teflon liner. The SPME needle was inserted through a small hole in the lid, and the fiber was exposed for 1 hr to absorb volatiles. The fiber was then removed from the collection jar and immediately inserted into the GC injection port to desorb volatiles.

Headspace sampling was also conducted by using Porapak Q (50/80 mesh; Alltech, Deerfield, IL, USA). Absorbent (1 g) was packed between glass wool plugs in a Pasteur pipette, preconditioned at 70°C for 16 hr, washed with dichloromethane, and dried under charcoal-purified nitrogen. Ripe *T. catappa* fruits (2 kg) were placed in a 4-l round-bottomed aeration chamber. Charcoal-purified nitrogen (1 l/min) was used to sweep volatiles from the chamber for 16 hr. Volatiles were eluted from the adsorbents with 1 ml CH_2Cl_2 and stored at -80°C .

Analyses

Electroantennographic responses to fruit volatiles were recorded by using an Agilent Technologies (Palo Alto, CA, USA) 6890 gas chromatograph coupled to a Syntech (Hilversum, The Netherlands) electroantennogram detector system. The GC was equipped with an HP-5 column (30 m \times 0.32 mm ID, 0.25 μm film thickness; Agilent) with helium as carrier gas at 2.3 ml/min and makeup gas at 10 ml/min, which was added before the splitter. A Graphpack-3D/2 flow splitter (Gerstel Inc., Baltimore, MD, USA) was attached to the end of the column, and the effluent was split 1:1 between the flame ionization detector (FID) and the EAD via a heated transfer line (250°C). The injector, in splitless mode, and FID were held at 250°C and 275°C, respectively. The oven was programmed from 45°C/1 min, 10°C/min to 240°C, hold 13 min. Whole fly heads were removed with forceps and secured with electrode gel (Spectra 360; Parker Laboratories, Inc., Fairfield, NJ, USA) between the electrodes of a Syntech EAG probe antenna holder. During initial runs, 1-hexanol was puffed over the antennal preparation to check sensitivity. However, this was found to be unnecessary because the majority of antennal preparations showed usable responses to *T. catappa* volatiles and immediate use increased signal strength. Antennal preparations were used only once. Humidified air (350 ml/min) was used as a carrier for effluent from the EAD transfer line to the antennal preparation. The signals generated by the EAD and FID were passed through a Syntech NL 1200 high-impedance amplifier and analyzed using Syntech GC-EAD2000 software version 2.5. Twenty runs with SPME collections (10 PDMS, 5 PA, 5 CW/DVB) and 10 with Porapak Q collections were used to determine which peaks gave consistent EAD responses. Peaks eliciting EAD responses in at least three runs were marked for identification by GC-mass spectrometry (GC-MS).

GC-MS analysis was performed on an Agilent Technologies 6890N gas chromatograph interfaced with a Hewlett-Packard 5973 Mass Selective Detector equipped with an HP-5MS column (30 m \times 0.25 mm ID, 0.25 μm film thickness). The temperature program used was

45–300°C at 10°C/min with a 1-min start delay, with the injector temperature set at 250°C using helium carrier gas (1.1 ml/min). Compounds from *T. catappa* were tentatively identified on the basis of matches with literature mass spectra (NIST98 mass spectral database), and confirmed by comparison with spectra of authentic standards.

Chemicals

(*Z,E*)- α -Farnesene was prepared as part of a mixture of farnesenes by dehydration of *trans*-nerolidol according to Yarden et al. (1996). Separation of reaction products by column chromatography provided a mixture of farnesene isomers that were used for bioassays. A small amount of (*E,E*)- α -farnesene (<50 μ g, reference standard only) and (*E*)- β -farnesene (~100 mg, used for bioassays and reference standard) were available from previous work (Jang et al., 1989) (samples from R. Buttery, USDA-ARS-WRCC). All other synthetic compounds and solvents were purchased from Sigma-Aldrich (St. Louis, MO, USA) or Acros Organics (Geel, Belgium). Compound purities were >98% by GC (FID). Linalyl

acetate, citronellyl acetate, and menthone were mixtures of their respective isomers. All solvents were HPLC grade. Blends of compounds that elicited antennal responses tested in bioassays were: (1) a reconstructed blend of the compounds collected by SPME that elicited EAD responses (using farnesene isomer mixture) (EAD SPME blend; Table 1); (2) (EAD major blend) isopentyl acetate, isopentenyl acetate, 2-phenylethyl acetate, citronellyl acetate, and geranyl acetate; and (3) (EAD minor blend) ethanol, ethyl acetate, ethyl hexanoate, hexyl acetate, linalyl acetate, ethyl nonanoate, nonyl acetate, (*E*)-ethyl cinnamate, and (*E*)- β -farnesene. All blends contained equal amounts of all components at 2 μ g/ml water (60 μ g/trap). These concentrations roughly reflect the concentration of methyl eugenol found in pressed *T. catappa* juice (Siderhurst and Jang, 2006).

Bioassays

Three behavioral bioassays were used to evaluate the attractiveness of blends. The first bioassays tested attraction in a more controlled, smaller-scale, short duration assay, whereas the latter bioassays were more natural, larger, and encompassed most of the day.

- (1) A laboratory glass/metal flight tunnel, consisting of a 0.9 \times 0.9 \times 2.8 m rectangular glass tunnel equipped with inlet and exit fans that produced a laminar flow of air (Jang et al., 1997) was used to compare synthetic blends against a neutral control (water). Treatments were prepared by dissolving synthetic compounds in 30 ml of water, with two drops of the nonionic surfactant Igepal CO-630 (Sigma-Aldrich), in small, invaginated glass McPhail traps. For each assay, 50 males and 50 females were released from the downwind end of the flight tunnel and allowed to respond freely for 2 hr. At the end of each test, trapped flies were sexed and counted, and the remaining flies removed. The flight tunnel was then cleaned with window cleaner and a squeegee, and allowed to dry with the fans operating. All assays were run between 13:00 and 16:00 at a temperature of 26–28°C, under fluorescent lights (2,000 lux) (Jang et al., 1994).
- (2) An outdoor multiple rotating trap olfactometer was used to evaluate attractancy on an intermediate scale, over a longer period and under seminatural conditions. This outdoor olfactometer, consisting of a 3 \times 3 \times 2.5 m rectangular wood-framed screen cage (Jang et al., 1997), was used to compare different treatments in competitive tests. A rotating hub with 62-cm-long arms was hung from the center of the cage 1.8 m from the floor. The outer arms of the motorized hub unit revolved at 1.5 rpm. Treatments were prepared in small glass McPhail traps as previously described, and all tests included a neutral control (30 ml water). In addition, some tests included torula yeast/borax (1 pellet/100 ml water), an attractant known to attract females, as a positive control. Approximately 500 flies of each sex were placed in the outdoor cage. The duration of the tests was approximately 19 hr (initiated 13:00; terminated 08:00 following day). Tests were conducted under ambient outdoor conditions (usually 23–28°C) and only natural (indirect) light was used. At the end of the test, flies were removed from the traps, counted, and sexed.
- (3) A field cage was used to evaluate attractancy in a still larger scale arena, over a longer period and under more natural conditions. This screen field cage, 2.5 \times 6 \times 15 m, containing mixed fruit trees, was used to compare treatments in competitive tests. The fruit trees, which included mango, lemon, tangerine, and guava, were stripped of fruit and blossoms before each experiment. Treatments were prepared in small glass McPhail traps as previously described and were hung in mango trees at the corners of

the cage. Some tests included a neutral control (30 ml water) and some included torula yeast/borax (1 pellet/100 ml water,) as a positive control. Trap placements was randomized within each experiment. Approximately 500 flies of each sex were placed in the outdoor cage. Tests were initiated at 10:00 and terminated at 08:00 the following day (ca. 22 hr) when flies were removed from the traps, counted, and sexed.

Data Analysis

Results of the two-choice flight tunnel tests were compared using *t*-tests (Proc TTEST) (SAS, 2000). Multiple-choice test results were analyzed by using analysis of variance (ANOVA), and means were compared using Tukey's HSD studentized range test (Proc GLM) (SAS, 2000). All analyses of significance were made at the $P < 0.05$ level of significance.

Results

GC-EAD analyses of headspace volatiles from whole *T. catappa* fruit revealed 22 compounds that consistently elicited electrophysiological responses from antennae of *B. dorsalis* females (Fig. 1). The relative amounts and percentages of compounds varied substantially with collection type, with Porapak Q showing a higher proportion of smaller, more volatile compounds such as isopentyl acetate, 4-pentenyl acetate, and isopentenyl acetate, compared to SPME fibers (Table 1). However, collections with SPME fibers induced more and stronger EAD responses. Geranyl acetate and methyl eugenol produced the largest responses, and were also the most abundant compounds in SPME collections. Slight variations in compound abundances were seen with different types of SPME fibers, but did not substantially change the profile of EAD responses observed. The largest source of variation in the volatiles was between fruits collected at different locations (Kauai and Hilo) and times. SPME collections of Kauai fruit showed higher concentrations of isopentyl acetate, 4-pentenyl acetate, and isopentenyl acetate similar to Porapak Q collections. In addition to the compounds listed in Table 1, several others were observed to stimulate intermittent, weak responses and were not analyzed further.

Compounds eliciting EAD responses were identified by GC-MS with assignment made by mass spectral database matching and subsequent comparison with authentic standards. These standards were also run on GC-EAD to confirm their electrophysiological activity. This was particularly important in the case of linalyl acetate and 2-phenylethyl acetate because these peaks overlapped. Injections of each compound alone showed that both elicited responses from female antennae. (*Z,E*)- α -Farnesene was assigned by mass spectral data, relative retention index (RI of *Z,E* isomer higher than the *E,E* isomer) and comparison

Fig. 1 GC/EAD analyses of volatiles from *Terminalia catappa* using female *Bactrocera dorsalis*. Within each experiment different letters indicate significant differences at $P < 0.05$; Tukey's HSD (SAS, 2000).

with a mixture of synthetic farnesene isomers. Farnesene synthesis produced three isomers: (*E,E*)- α -farnesene and (*E*)- β -farnesene, which were identified by comparison with authentic standards, and a third isomer was assumed to be (*Z,E*)- α -farnesene. No attempts were made to assign the absolute configurations of compounds containing stereocenters. One consistently EAD stimulatory compound remained unidentified (MS and RI suggest terpinen-4-ol).

Individual compounds that elicited EAD responses were tested in the outdoor rotating olfactometer. There was no appreciable attraction of females to single component traps, and males were only attracted to the known sex attractants eugenol and methyl eugenol (data not shown). In wind tunnel bioassays, traps containing the EAD SPME blend showed female-biased attraction ($P < 0.05$) (Fig. 2a). In contrast, outdoor olfactometer tests with the EAD SPME blend did not show female-biased trap captures (Fig. 2b). Removal of methyl eugenol and eugenol from the blend reduced attraction of both sexes to the level of controls

in one assay (Fig. 2b) but did not restore the female-based attraction observed in the wind tunnel (Fig. 2b & c). In field cage tests, the EAD minor blend attracted more females than the EAD major blend ($P < 0.05$) (Fig. 2d). In addition, the EAD major blend attracted more male and female flies than the control, while the EAD minor blend was not significantly attractive to males ($P < 0.05$; Fig. 2d). Tests with the EAD minor blend vs. torula yeast in field cage (Fig. 2e) and outdoor olfactometer (Fig. 2f) bioassays again showed the selective attraction of females with the synthetic blend. In the field cage tests (Fig. 2e), there were no significant differences ($P < 0.05$) between the number of female flies caught in traps baited with the EAD minor blend, and males and females caught in traps baited with torula yeast. However, in the outdoor olfactometer tests (Fig. 2d), torula yeast-baited traps caught significantly ($P < 0.05$) more males and females than the respective male and female catches for the EAD minor blend. Similar to field cage results, the EAD minor blend female trap capture means were greater than male captures ($P < 0.05$), which did not differ from males captured in the control ($P < 0.05$).

Discussion

Coupled GC-EAD analysis of volatiles collected from *T. catappa* revealed consent female electroantennographic activity to 22 compounds. Identified compounds included acetates, ethyl esters, terpenoids, and phenylpropanoids—all widely found in odors of a variety of fruits and flowers. A number of the EAD stimulatory compounds identified are known to elicit electroantennographic responses from other fruit fly species. *Ceratitis capitata* (Light et al., 1988, 1992; Jang et al., 1989), *R. pomonella* (Nojima et al., 2003a,b), and *B. Tryoni* (Hull and Cribb, 2001) have shown electrophysiological activity to at least one of the following compounds identified in this study: ethanol, ethyl acetate, (*E*)-2-hexenal, isopentyl acetate, isopentenyl acetate, ethyl hexanoate, hexyl acetate, linalyl acetate, 2-phenylethyl acetate, geranyl acetate, nonyl acetate, and the isomers of farnesene (Table 1). Although the limited number of studies on these three species make comparisons difficult, it is interesting to note that *B. dorsalis* has the greatest compound overlap with *C. capitata*, a similarity which may be based in the polyphagous feeding habits of both species (Diaz-Fleischer et al., 1999).

Among the compounds previously known to elicit EAG responses from *B. dorsalis* antennae, methyl eugenol (Lee et al., 1997) and ethanol (Light and Jang, 1987) were found in odors of *T. catappa* fruit. Few electrophysiological studies have been conducted with *B. dorsalis*, and those have focused on limited classes of compounds (Lee et al., 1997, 1998; Light and Jang, 1987). The presence of methyl eugenol in *T. catappa* has been reported previously, and may partly explain why this tree is a preferred host for oriental fruit fly (Siderhurst and Jang, 2006). Because methyl eugenol is widely thought to only attract males, the observed EAD responses from antennae of females was surprising and may be supportive of a behavioral role for methyl eugenol in females of *Bactrocera* species, as suggested by Raghu (2004).

The aim of the blend formulations was to develop mixtures of compounds that would exhibit strong, female-biased attraction. Because of the variation in compound abundances observed in volatile collection, and to reduce testing complexity, all blends contained components at 2 $\mu\text{g/ml}$, roughly reflecting the concentration of methyl eugenol found in pressed *T. catappa* juice (Siderhurst and Jang, 2006). SPME collections have been used in previous research into fruit-based attractants for tephritids by (Zhang et al., 1999; Nojima et al., 2003a, b), and SPME results were the primary source for the formulation of the initial

blend (EAD SPME blend, Table 1) tested in the wind tunnel. 4-Pentenyl acetate and an unidentified compound (tentatively terpinen-4-ol) were commercially unavailable at the time of blend formulations. The female-biased attraction in wind tunnel bioassays, even with the presence of eugenol and methyl eugenol, is again somewhat surprising. However, these results are consistent with previous experiments conducted in the same arena. These previous experiments showed an ~8:1 female/male trap capture ratio with ethanol extracts of *T. catappa*, which contain methyl eugenol (Siderhurst and Jang, 2006). The meaning of these results is unclear but may suggest a female bias associated with this bioassay. All further tests were conducted in larger screen cages with fruit trees, under more natural conditions.

Tests with the EAD SPME blend in the outdoor olfactometer showed no sex-biased trap captures, presumably due to the presence of the eugenol and methyl eugenol in the lure formation, so these compounds were excluded from all further experiments. However, this blend failed to show female-biased attraction when eugenol and methyl eugenol (contained in EAD SPME blend) were removed from the lures (Fig. 2c). Two additional subset blends formulated roughly on the relative strength of EAD responses (EAD major and EAD minor) were tested in field cage trials. The blend of compounds with minor EAD responses had strongly female-biased attraction. Ethyl acetate, ethanol, ethyl hexanoate, and hexyl acetate, four of the nine EAD minor blend components, have been previously reported as components of attractive blends for females (Hwang et al., 2002). Further testing of this EAD minor blend against torula yeast in outdoor experiments showed comparable female attraction to this blend and to yeast, and much lower male attraction.

Similar analytical methodology, utilizing SPME and GC-EAD, has been applied to hosts of another tephritid, *R. pomonella*, including apple (Zhang et al., 1999), flowering dogwood (Nojima et al., 2003a), and hawthorn (Nojima et al., 2003b), and has resulted in successful identification of attractant blends. Although *T. catappa* is strongly attractive to *B. dorsalis* and since compounds that elicited EAD responses were readily identified, the formulation of a fruit odor-based lure from *T. catappa* has proven more difficult than initially expected, largely due to the number of compounds that stimulate the antennae. This difficulty may be reflective of the fundamental differences between monophagous spp., such as *R. pomonella*, and polyphagous spp., such as *B. dorsalis*. Diaz-Fleischer et al. (1999) has suggested that fruit flies with a large host range may respond to a broader range of host odors than monophagous or oligophagous species. This hypothesis is consistent with the relatively high number of compounds that elicit EAD responses from the polyphagous species *B. dorsalis* (this study) and *C. capitata* (Light et al., 1988, 1992; Jang et al., 1989), whereas *R. pomonella* showed responses to a more limited set of compounds (Zhang et al., 1999; Nojima et al., 2003a,b). With *R. pomonella*, a tight fly–host relationship would be expected to lead to olfactory/attraction mechanisms well tuned to the signature compounds/blend of the host. In contrast, *B. dorsalis* may be expected to detect and discriminate between the odors of many hosts, with receptors for a wider range of compounds and not respond as strongly to any single blend. This difference need not preclude the development of fruit odor attractants for generalist fruit fly species, as partly demonstrated in this study, but the formulation of blends may not be as straightforward as it is with specialists.

Acknowledgments We thank Lori Carvalho and Janice Nagata for their assistance in conducting behavioral bioassays and electrophysiological recordings and Charlie Rodd for providing fruit from Kauai. We also thank Dr. J. C. Dickens, Dr. C. Linn Jr., and Dr. D. M. Light for their helpful comments on an early version of this manuscript.

(EAG) recordings to the (2*S*,3*R*,7*R*)-isomers of the propionates of 3,7-dimethyl-2-tridecanol, 3,7-dimethyl-2-tetradecanol, and 3,7-dimethyl-2-pentadecanol, as well as to the acetates of the tri- and pentadecanols (the acetate of the tetradecanol was not tested). The propionate of (2*S*,3*R*,7*R*)-3,7-dimethyl-2-tetradecanol caught more males in the field than the corresponding isomer of tri- or pentadecanol. We suggest that the (2*S*,3*R*,7*R*)-isomer of 3,7-dimethyl-2-tetradecanol is likely the main sex pheromone precursor in *G. pallida*, with a subsidiary role for the (2*S*,3*R*,7*R*)-isomer of the tridecanol. Preparation of highly pure (2*R*,3*R*,7*R*)- and (2*S*,3*R*,7*R*)-stereoisomers of 3,7-dimethyl-2-tetradecanol, including the biologically active esters, was performed via chemoenzymatic methods and is described in detail.

Key words 3,7-Dimethyl-2-tetradecanol · sex pheromone · electrophysiology · gas chromatography · mass spectrometry · synthesis · stereoisomer · lipase · field activity · *Gilpinia pallida*

Introduction

Many species of the sawfly family Diprionidae (Hymenoptera: Symphyta) are important defoliators of northern coniferous forests (Smith, 1993). In 1976, the acetate and the propionate of the alcohol 3,7-dimethyl-2-pentadecanol (diprionol) were identified from *Neodiprion lecontei* (Fitch) and *Diprion similis* (Hartig) (Jewett et al., 1976), constituting the first examples of diprionid sex pheromones. Several other species within the family Diprionidae have been found to use these esters of diprionol or similar alcohols as sex pheromones (see reviews by Anderbrant, 1993, 1999). Usually, only the alcohol precursor is found in the females, whereas males are attracted by the corresponding acetate or propionate. Regarding chemical communication or pheromone biology, most species investigated so far belong to the large genera *Diprion* and *Neodiprion*, although *Macrodiprion* and *Microdiprion* species have also been studied (Bergström et al., 1998; Wassgren et al., 2000; Östrand et al., 2003).

Within the genus *Gilpinia*, only *G. frutetorum* F., a species introduced from Europe to North America, has been investigated. Kikukawa et al. (1982) reported a weak attraction to the acetate of a two-isomer diprionol mixture containing the (2*S*,3*R*,7*S*)- and (2*S*,3*R*,7*R*)-stereoisomers. This and several other species within this genus occur in Europe and Asia and sometimes cause severe damage to pine forests (Pschorn-Walcher, 1982). One of these is *G. pallida* (Klug), with documented outbreaks in northern, central, and eastern Europe. It has one, or in more southern areas, two generations per year and can cause considerable damage (Pschorn-Walcher, 1982). During outbreaks, it sometimes occurs with other diprionids, notably *Diprion pini* (L.) (A. Sierpinski, personal observation). Because *G. pallida* males were often caught in monitoring traps intended for *D. pini*, i.e., baited with the propionate of (2*R**3*S**)-3,7-dimethyl-2-tridecanol (Herz et al., 2000), we suspected that the *G. pallida* sex pheromone was similar to that of *D. pini*. We present here results from the investigations aimed to identify the pheromone, including analysis of female pheromone content, male antennal response and attraction in the field, and synthesis of the main pheromone component.

Methods and Materials

Insects

Females extracted for chemical analyses and males used for electrophysiological recordings came from laboratory cultures at TU-Munich and INRA, Orleans, both originating from

cocoons collected near Eching, Bavaria, Germany (Herz and Heitland, 2002). Additional insects came from cocoons collected at several locations in central and southern Finland.

Extraction

Whole bodies of 50–100 adult females were extracted in pure ethyl acetate for 72 hr at room temperature. Several extracts of females were prepared between 1996 and 2000. Females of different ages were used, from newly eclosed to about 3-d-old. Extracts were purified and fractionated by liquid chromatography (LC) (for details, see Bergström et al., 1995). Fractions 7 and 8, which contained dipironol and related precursor alcohols, were used to identify the structures and to determine the configuration of the stereoisomers.

Chemical Analysis

Purified extracts were analyzed by combined gas chromatography-mass spectrometry. A Hewlett-Packard 5890 gas chromatograph (GC) equipped with a Finnigan TSQ mass spectrometer (MS) (quadrupole) in the electron impact (EI) mode was used for the analyses. The analytical fused silica column (25 m × 0.25 mm i.d.) was a CP-WAX-58 (ChromPack, Middelburg, The Netherlands), coated with a nitroterephthalic acid-modified, chemically bonded polyethylene glycol as stationary phase (film thickness, 0.20 μm). The oven temperature program was kept isothermal at 50°C for 5 min, and then programmed to 220°C at 10°C/min. Alcohols were quantified by adding a known amount (100 ng) of 3,11-dimethyl-2-tetradecanol to the extracts as an internal standard before evaporation and LC.

Stereochemical Analysis

Two gas chromatographic methods were used to determine the configuration of the stereoisomers. In both cases, the alcohols were first derivatized for detection by specific detectors. One method was separation of isopropyl carbamate derivatives (König et al., 1982) on a XE-60-(*S*)-valine-(*S*)-2-phenylethylamide fused silica column (ChromPack; 50 m × 0.23 mm i.d., film thickness 0.12 μm) on a GC equipped with a nitrogen/phosphorous sensitive detector. Analytical conditions were as follows: isothermal at 120°C for 5 min and then programmed to 185°C at 2°C/min. Nitrogen was used as carrier gas at a pressure of 97 kPa. In this case, a Hewlett Packard 5880 GC was used. In the second method, the analysis was carried out on a Hewlett Packard 6890 GC supplied with Chemstation software and coupled to an electron capture detector ⁶³Ni. The stereoisomers were separated as pentafluorobenzoates (Wassgren and Bergström, 1995), by using a CP-Sil-88 fused silica column (ChromPack; 50 m × 0.25 mm i.d., film thickness 0.20 μm). Oven conditions were as follows: isothermal at 60°C for 3 min after injection and then raised at a rate of 5°C/min to 195°C, isothermal 40 min; carrier gas was N₂ (15 psi) and the injection technique was pulsed splitless mode with electronic pneumatic control (EPC).

Electrophysiology

One antenna was excised from each male and placed between two electrodes, consisting of thin glass capillaries filled with Ringer solution. The antennal base was in contact with one grounded platinum electrode. The signal from the electrode holding the antennal tip was connected to a high-impedance amplifier. The antenna was continuously flushed with a charcoal-filtered, moistened airstream of 0.5 m/sec. The outlet of the tube was 1 cm from

the antenna. The stimulus was injected into the airstream through an opening in the glass tube 20 cm upstream of the antenna. A stimulus was created by a stimulation device (Murphy Developments, Hilversum, The Netherlands), which delivered the stimulus in a 0.5-sec puff at a flow rate of 5 ml/sec. The stimulus originated from a Pasteur pipette containing a 5 × 20 mm piece of filter paper. The appropriate amount of synthetic sample, diluted in cyclohexane, was added to the filter paper and the solvent allowed to evaporate. During the recordings, a standard stimulus was delivered every third time, including the first and the last one. Electroantennograph (EAG) recordings were analyzed using “EAG version 2.2a” (Syntech, Hilversum, The Netherlands 1993). The EAG response to a stimulus was standardized by dividing the recorded response by the average of the responses of the standard puffed before and after. Mean responses were analyzed by ANOVA followed by Tukey’s *post-hoc* test at $P < 0.05$ using SPSS 11.0.4 for Macintosh. Data were log-transformed before analysis if necessary to obtain homogeneity among variances.

EAG recordings were performed at different times with different series of synthetic compounds. First, before the extraction and chemical analysis of the females had been completed, a number of known diprionid pheromone isomers were tested. Later, esters of several identified and available alkanol isomers were added (Table 1).

Field Tests

We were fortunate to encounter two outbreaks of this sporadic pest insect (Poland and Sweden) that provided sites for field behavioral assays. Another experiment was conducted in France at a site where *G. pallida* had been observed during previous years. Field trapping experiments were conducted in 1998 and 1999, using Lund-I cardboard sticky traps (Anderbrant et al., 1989). Traps were placed in pine trees 1–2 m above the forest floor and at least 30 m apart. Within tests, traps with baits were repositioned according to a Latin square design when at least 10 males were caught in a trap. Test compounds were weighed and diluted with a known amount of hexane or cyclohexane. An appropriate aliquot was applied to 1 × 4 cm dental cotton rolls (Celluron[®] No. 2, Paul Hartmann AG, Heidenheim, Germany) used as dispensers. The cotton roll was placed under the roof of the trap and released the substances at a logarithmically decreasing rate. The release from the 100 µg bait was approximately 3 µg/d after 5 d and 0.3 µg/d after 1 mo (Anderbrant et al., 1992).

In 1998, 100 µg of (2*S*,3*R*,7*R*)-propionates of 3,7-dimethyl-2-tridecanol, 3,7-dimethyl-2-tetradecanol, and 3,7-dimethyl-2-pentadecanol were tested. Two replicates were placed in the forest district Bielice of forest inspectorate Bydgoszcz, Poland, with Scots pine (*Pinus sylvestris* L.) stands of different ages. Trapping started on July 16 and ended on August 16. In France, one replicate was placed in a plantation of *P. sylvestris* and *P. uncinata* Miller ex Mirbel in the Hautes-Alpes near Bois du Villard (Granon) at 1990 m elevation from June 16 to July 9.

In 1999, the same experiment was repeated, but 50-µg baits were used in a young *P. sylvestris* plantation, near Arjeplog, in northern Sweden, where an outbreak had been recorded the year before. One trap baited with a mixture of all eight stereoisomers of the propionate of 3,7,11-trimethyl-2-tridecanol (800 µg, i.e., 50 µg per isomer) was added to the test. One of the isomers of this substance is the sex pheromone of the diprionid *Microdiprion pallipes*, often occurring in these northern areas (Bergström et al., 1998; Östrand et al., 2003). The traps were repositioned once. In Poland, in the same area where the test was performed in 1998, an experiment was conducted that included propionates of isomers of 3,7-dimethyl-2-tridecanol occurring in the female extracts.

Table 1 Purity and Reference to Description of Synthesis of Chemicals Used in EAG Recordings and in Field Tests with *Gilpinia pallida*

Chemicals

Commercially available chemicals were used without further purification unless otherwise stated. *Candida rugosa* lipase was purchased from Sigma Aldrich (Buchs, Switzerland) and stored at 4°C over blue gel. Dry diethyl ether was distilled from LiAlH₄. The alkyl halides were distilled prior to use and kept under argon. When preparing and using alkyllithium, the solvent was degassed by argon for about 1 hr prior to use. Li (s) was washed with

heptane and was made thin by using a hammer and cut in very thin pieces prior to use. The (3*R*,4*R*)-(-)-*cis*-dimethyl- γ -butyrolactone used was from the same batch as that prepared by Bergström et al. (1995), i.e., *RR*: >99.7% ee and <0.03% *trans*.

Purification and Analysis of Synthetic Materials

Preparative LC was performed on straight phase silica gel (Merck 60, 230–400 mesh, 0.040–0.063 mm; Merck, Darmstadt, Germany) by employing a gradient technique that used an increasing concentration of distilled diethyl ether in distilled pentane or of distilled ethyl acetate in distilled cyclohexane (0→100%), as eluent. Thin-layer chromatography (TLC) was performed on silica gel plates (Merck 60 F₂₅₄, precoated aluminum foil) eluted with ethyl acetate (20–40%) in cyclohexane and developed by spraying with vanillin in sulfuric acid and heated at 120°C. Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker DMX 230 (250 MHz ¹H and 62.9 MHz ¹³C) spectrometer using CDCl₃ as solvent and TMS as internal reference. Optical rotations were measured on a Perkin Elmer 241 polarimeter using a 1 dm cell. Mass spectra were recorded on a Varian Saturn 2000 instrument, operated in EI mode, and coupled to a Varian 3800 GC. Infrared (IR) spectra were recorded from compounds applied neat between NaCl plates by using a Perkin Elmer 782 infrared spectrometer. Unless otherwise stated, conversions and purity (Table 1) were monitored by GC (Varian 3300 or 3400 CX) with a 30 m × 0.25 mm i.d., 0.25 μm film thickness capillary column coated with VA-1 (Varian, Walnut Creek, CA, USA). Carrier gas was nitrogen (12 psi) with a split ratio of 1:50. The (2*R**3*R**):(2*R**3*S**) ratio of the individual isomers of (2*R**3*R**)-OH and (2*R**3*S**)-OH were determined by GC (Varian 3300 or 3400 CX) with a 30 m × 0.25 mm i.d., 0.25 μm film thickness capillary column coated with DB-WAX 52 CB (ChromPack). Carrier gas was helium (16 psi) with a split ratio of 1:30. Boiling points are uncorrected and given as air-bath temperatures (bath temperature/mbar) in a bulb-to-bulb (Büchi-GKR-51) apparatus.

Synthesis

2-Methylnonanoic acid **rac-2** (Figure 1)

Racemic 2-methylnonanoic acid was prepared as previously described (Hedenström and Andersson, 2002) via a malonic ester sequence. The analytical and spectroscopic data were identical with those in Hedenström and Andersson (2002).

C. rugosa Lipase Catalyzed Kinetic Resolution of 2-Methylnonanoic Acid **rac-2**

A cyclohexane solution (775 ml) containing the acid **rac-2** (20 g, 116 mmol), eicosanol (26 g, 87 mmol), tetracosane (internal standard, 6.1 mg/ml), Na₂SO₄/Na₂SO₄·10 H₂O [2 eqv./1 eqv. to maintain a water activity (*a_w*) of 0.8] was stirred for 15 min in a sealed flask at room temperature (Figure 1). The reaction was started by addition of immobilized *C. rugosa* lipase (7.4 mg/ml) into the flask. The reaction was stopped at 42.5% conversion by separating the enzyme by filtration and washing of the solid with cyclohexane (350 ml) and *n*-pentane (350 ml). The combined organic phases were extracted with aqueous sodium carbonate (10%, 5 × 150 ml) and the solvent was evaporated. The (*S*)-ester **S-3**, eicosanol, and the internal standard were present in the remainder, and after LC the (*S*)-ester (22.0 g, 48.6 mmol) was obtained chemically pure with >98% ee. The combined aqueous phase, containing the remaining substrate (*R*)-acid **R-2**, was washed with cyclohexane (300 ml)

Fig. 1 (a) *Candida rugosa* lipase (CRL), HO(CH₂)₁₉CH₃, cyclohexane, water activity $a_w = 0.8$, $c = 42.5\%$. (b) LiAlH₄, Et₂O. (c) CRL, HO(CH₂)₁₉CH₃, cyclohexane, water activity $a_w = 0.8$, $c = 13\%$

and cooled to 0°C and then acidified to pH 1 with 6 M HCl followed by extraction with diethyl ether (5 × 200 ml). The combined organic phase was washed with saturated sodium chloride and dried (MgSO₄). Evaporation to dryness yielded (58%) the (*R*)-2-methylnonanoic acid **R-2** (11.5 g, 67.5 mmol) in 76.5% ee as an oil. The obtained nonanoic acid was once more esterified, as described above, but now to a conversion of 12%. The ee was continuously analyzed and found at this conversion to be >99.8%, and the reaction was interrupted, followed by the workup procedure as described above resulting in 9.4 g (55.2 mmol) of (*R*)-2-methylnonanoic acid **R-2** with >98.7% chemical purity. The analytical and spectroscopic data were similar to those reported in the literature (Levene and

Marker, 1932; Nikishin et al., 1974; Hedenström and Andersson, 2002). The ee of the (*R*)-acid **R-2** and the (*S*)-ester **S-3** were determined as described for other acids and esters (Hedenström et al., 2003) after derivatization to the corresponding phenylethyl amides obtained from enantiomerically pure (*S*)- or (*R*)- α -phenylethylamine (Hedenström et al., 2003). The diastereomeric purity of the phenylethyl amides was determined by GC by using a 30 m \times 0.32 mm i.d., 0.25 μ m film thickness capillary column coated with EC-1 (Alltech, Deerfield, IL, USA). Carrier gas was nitrogen (12 psi) with a split ratio of 1:50. The GC oven was 180°C isothermal, and retention times (min) were *SS/RR* amides-16.7 and *SR/RS* amides-18.0.

(*R*)-2-methyl-1-nonanol **R-4**

The (*R*)-2-methylnonanoic acid from above (4.0 g, 23 mmol) was reduced with LiAlH₄ as described in Hedenström and Andersson (2002) for racemic alcohol and yielded (96%) the pure alcohol **R-4** as an oil (3.5 g, 22 mmol) with >99.8% ee (Figure 2). The enantiomeric purity of the (*R*)-2-methyl-1-nonanol was determined by using a 30 m \times 0.25 mm i.d., 0.25 mm film thickness capillary column coated with β -dex 225 (Supelco Inc., Bellefonte, PA, USA). Carrier gas was helium (13 psi) with a split ratio of 1:60. The GC was temperature-programmed at 70°C for 30 min, then 0.5°C/min up to 90°C. Retention time (min) for *S*-2-methyl-1-nonanol (**S-4**): 81.6 and *R*-2-methyl-1-nonanol (**R-4**): 80.9. The analytical and spectroscopic data were similar to those reported in the literature (Högberg et al., 1992; Hedenström and Andersson, 2002).

Fig. 2 (a) 1. TsCl, diethyl ether, -10°C ; 2. LiBr, acetone, Δ , 16 hr. (b) 1. Li(s), diethyl ether, -10°C ; 2. -100°C added to (*3R,4R*)-dimethyl- γ -butyrolactone (**RR-6**) and stirred for 10 hr. (c) (NH_2)₂·H₂O, KOH, diethylene glycol, 170°C 1 hr, 210°C 4 hr. (d) 1. P(Ph)₃, PhCO₂H, N₂(CO₂Et)₂; 2. LiAlH₄, Et₂O (C₂H₅OC)₂O, Pyridine

(*S*)-2-methyl-1-nonanol **S-4**

This was prepared from (*S*)-ester **S-3** in a manner similar to that described for other esters (Hedenström et al., 2003) (Figure 2). A solution of the eicosyl (*S*)-2-methylnonanoate in dry diethyl ether (22 g, 49 mmol) was added dropwise from above to LiAlH₄ (1.1 g, 29 mmol), and stirred in dry diethyl ether (32 ml) at room temperature. After 1 hr, the mixture was quenched with water (0.5 ml), 15% NaOH (0.5 ml), and 1.0 ml H₂O. After refluxing for 1 hr, the mixture was filtered and dried (MgSO₄). After evaporation of the diethyl ether, tetradecane was added to the remaining oil and fractional distillation (100–101°C/1 kPa) furnished after LC the pure title *S*-alcohol **S-4** (7.1 g, 45 mmol) with no loss in ee (>98.1% ee). The enantiomeric purity of the (*S*)-2-methyl-1-nonanol was determined by GC by using a 30 m × 0.25 mm i.d., 0.25 mm film thickness capillary column coated with β-dex 225 (Supelco Inc.). Carrier gas was helium (13 psi), with a split ratio of 1:60. The GC was temperature-programmed at 70°C for 30 min then 0.5°C/min up to 90°C. Retention time for *S*-2-methyl-1-nonanol (**S-4**): 81.6 and *R*-2-methyl-1-nonanol (**R-4**) was 80.9 min. $[\alpha]_D^{25} = -13.1^\circ$ ($c = 1.0$, MeOH). The analytical and spectroscopic data were similar to those reported in the literature (Högberg et al., 1992).

(*R*)-1-Bromo-2-methylnonane **R-5**

The *R*-alcohol **R-4** from above (3.4 g, 22 mmol) was dissolved in dry chloroform (22 ml) and stirred at –5°C (Figure 2). *p*-Toluenesulfonyl chloride (6.8 g, 36 mmol) was added in one portion and the mixture was stirred for 2.5 hr at –5°C. The mixture was poured into 25 ml H₂O and 65 ml diethyl ether. The organic phase was separated and then washed with 2M HCl (2 × 25 ml), saturated NaHCO₃ (20 ml), brine (20 ml), and dried (MgSO₄). The organic solvent was evaporated off at room temperature, leaving the tosylate as an oil. This was dissolved in dry acetone (40 ml) and added to a solution of dried (at 135°C) lithium bromide (9.8 g, 113 mmol) in dry acetone (16 ml). The mixture was refluxed for 4 hr. After dilution with water (200 ml), extraction with *n*-pentane (4 × 100 ml), washing with brine (100 ml), and drying (MgSO₄), the solvent was evaporated leaving an oil, which—after LC and bulb-to-bulb distillation (90°C/1 mm Hg)—gave the title bromide **R-5** (3.4 g, 15 mmol) with >97% chemical purity (with about 3% of the corresponding chloride) as measured by GC. The enantiomeric purity of the (*R*)-1-bromo-2-methylnonane was also determined by GC by using a 30 m × 0.25 mm i.d., 0.25 mm film thickness capillary column coated with β-dex 225 (Supelco Inc.). Carrier gas was helium (13 psi), with a split ratio of 1:60. The GC was temperature-programmed at 80°C for 1 min then 0.5°C/min up to 170°C. Retention time was 61.5 min for *S*-1-bromo-2-methylnonane (**S-5**) and was 62.1 min for *R*-1-bromo-2-methylnonane (**R-5**). The analytical and spectroscopic data were similar to those described by Hedenström and Andersson (2002) for racemic 1-bromo-2-methylnonane.

(2*R*,3*R*,7*R*)-3,7-Dimethyl-2-tetradecanol **RRR**

The title compound was prepared in the same way as the other structurally similar compounds in Hedenström and Andersson (2002) (Figure 2). Lithium (0.3 g, 40 mmol) was cut into small pieces and added to dry diethyl ether (15 ml, degassed of oxygen by argon) under stirring at –8°C. Into the reaction flask, 1.19 g (5.4 mmol) of distilled (*R*)-1-bromo-2-methylnonane in dry diethyl ether (15 ml, degassed of oxygen by argon) was added slowly (1 hr) *via* a syringe at –15°C. The mixture was stirred for 1.5 hr, then cooled to –78°C, and slowly added (0.4 hr) *via* a syringe into a solution of freshly distilled (3*R*,4*R*)-*cis*-dimethyl-

γ -butyrolactone **RR** (0.39 g, 3.4 mmol) in dry diethyl ether (15 ml, degassed of oxygen by argon) at -78°C . The reaction was allowed to slowly reach room temperature during 60 hr and then quenched with 5 ml THF. Water (100 ml) was added to the resulting mixture, followed by extraction with diethyl ether (3×100 ml), washing with brine (2×100 ml), by drying with MgSO_4 , and concentration. This crude ketoalcohol was purified by LC to give 0.20 g (0.78 mmol), which was immediately reduced as follows: The oil was dissolved in distilled diethylene glycol (2.5 ml) containing KOH (0.28 g) and hydrazine monohydrate (0.138 g, 2.7 mmol), and the solution was heated to 170°C for 3 hr then for 1 hr at 210°C . After cooling to room temperature, the mixture was poured into H_2O (50 ml), followed by extraction with Et_2O (4×25 ml), washing with H_2O (25 ml) and drying with MgSO_4 . Concentration furnished the title compound **RRR** as a yellow oil, which was chromatographed and distilled bulb to bulb to give 130 mg (0.54 mmol) with $>98.7\%$ chemical purity. The analytical and spectroscopic data were identical with those in Hedenström et al. (1992).

(2*S*,3*R*,7*R*)-3,7-Dimethyl-2-tetradecanol **SRR-1H**

The title compound was prepared by using a similar procedure described in Karlsson and Hedenström (1999), but from (2*R*,3*R*,7*R*)-3,7-dimethyltetradecan-2-ol (0.11 g, 0.45 mmol), which gave 0.13 g (0.38 mmol) of a pure benzoate after LC (Figure 2). This ester was reduced (LiAlH_4) to the corresponding alcohol and 45 mg of **SRR-1H** with $>99.3\%$ purity was obtained after LC and bulb-to-bulb distillation. The analytical and spectroscopic data were similar to those in Hedenström et al. (1992).

(2*R*,3*S*,7*S*)-3,7-Dimethyl-2-tetradecanol **RSS-1H**

The title compound was prepared as above, but from (2*S*,3*S*,7*S*)-3,7-dimethyl-2-tetradecanol (Hedenström et al., 2002a,b) (Figure 2). The analytical and spectroscopic data were identical (except for the optical rotation value) with those of **SRR-1H**.

Propionates of (2*R*,3*R*,7*R*)- and (2*S*,3*R*,7*R*)-3,7-dimethyl-2-tetradecanol

The esters were prepared with a minor modification of the method used for other alcohols (Karlsson and Hedenström, 1999) (Figure 2). To the alcohol, **RRR** or **SRR-1H** (40 mg, 0.17 mmol), in dry distilled pyridine (1 ml) propionic acid anhydride (0.4 ml) was added, and the mixture was heated to boiling point. After cooling to room temperature, the reaction mixture was poured into 2 M HCL (10 ml), followed by extraction with diethyl ether (3×20 ml), drying (MgSO_4), and concentration. The esters were furnished in near quantitative yield as yellow oils after LC and distillation with $>98.9\%$ (**RRR**) and $>99.5\%$ (**SRR-1Pr**) chemical purities, respectively.

Results and Discussion

Chemical Identification

Previously described pheromone precursors, (2*R**3*R**)-(2*R**3*S**)-isomers of 3,7-dimethyl-2-pentadecanol (diprionol), occurring in several diprionid species, were identified through GC-MS analyses of extracts from *G. pallida*. Furthermore, both (2*R**3*R**)- and (2*R**3*S**)-

3,7-dimethyl-2-tridecanol were detected. One of the ($2R^*3S^*$)-isomers (i.e., $2S,3R,7R$) of the tridecanol is previously known as a pheromone precursor in *D. pini*. The homologue 3,7-dimethyl-2-tetradecanol was also identified, and this alcohol has been reported in trace amounts in some sawfly species, e.g., in *Neodiprion sertifer* (Wassgren et al., 1992) and *D. pini* (Bergström et al., 1995). In *G. pallida*, we identified this compound as a ($2R^*3S^*$)-isomer; it was present in 50–260 pg/female, whereas only a trace of the ($2R^*3R^*$)-isomer was detected. The ($2R^*3R^*$)- and ($2R^*3S^*$)-isomers of the three homologues were present in different amounts, from traces to 750 pg/female (Table 2). Variation in amount was also observed in extracts of individuals of different ages (Table 2). Freshly eclosed German females from the 1996 collection contained only ($2R^*3R^*$)-3,7-dimethyl-2-pentadecanol. In contrast, 24–72 hr females contained other homologues. A mixture of extracts containing about 480 females from the years 1996–1999 contained the ($2R^*3R^*$)- and ($2R^*3S^*$)-isomers of the three homologues. Analysis of the exact configuration of the sex pheromone precursors showed that some of the observed ($2R^*3R^*$)- and ($2R^*3S^*$)-isomers were separated into more than one stereoisomer (Table 3). For example, ($2R^*3S^*$)-3,7-dimethyl-2-tridecanol was separated into both ($2R,3S,7R$)- and ($2S,3R,7R$)-3,7-dimethyl-2-tridecanol, with approximately 70 pg/female of each isomer.

Differences in composition between German and Finnish females were also observed, perhaps confounded by differences in ages of females from each population (German, 24–72 hr; Finnish, 24–30 hr). The main compound in Finnish females was ($2R^*3S^*$)-3,7-dimethyl-2-pentadecanol with $2R,3S,7S$ configuration, whereas stereoisomers of the other homologues were present in smaller quantities. In German females, ($2R,3S,7R$)-3,7-dimethyl-2-tetradecanol was identified, whereas in Finnish females, the $2S,3R,7R$ configuration was found. Furthermore, in German females, stereoisomers of the precursor 3,7-dimethyl-2-tridecanol, occurring as both the ($2R^*3R^*$) and ($2R^*3S^*$) forms, have a different composition. $2R,3R,7R$ or $2R,3R,7S$ configurations were identified in both materials, but we could not determine if it is the $2R,3R,7R$ - or $2R,3R,7S$ -stereoisomer, or

a mixture of both. The (2*R**3*S**)-isomer of 3,7-dimethyl-2-tridecanol was present in equal amounts in each as 2*R*,3*S*,7*R*- and 2*S*,3*R*,7*R*-stereoisomers, but the Finnish females contained only traces of the 2*S*,3*R*,7*R*-stereoisomer. German females usually contained more stereoisomers of each homologue. One of the German extracts did not contain detectable amounts of (2*R**3*R**)- or (2*R**3*S**)-3,7-dimethyl-2-pentadecanol. Our study reports the first observation of compounds with 2*R* configuration in a pine sawfly species.

trans-Perillenal, known from other diprionids (e.g., Wassgren et al., 1992), was found in all extracts at a concentration of 5–20 ng per female. The concentration of perillenal decreased with female age; freshly eclosed females contained about 20 ng/female, and the amount decreased to 4 ng/female for 24–72 hr insects.

Synthesis

The main procedure (Figures 1 and 2) was similar to that used earlier for preparation of sex pheromones from other pine sawfly species (Karlsson and Hedenström, 1999; Hedenström and Andersson, 2002). Thus, racemic 2-methylnonanoic acid (*rac*-**2**) was synthesized in good yield by using a published malonic ester sequence (Hedenström and Andersson, 2002). The racemate was resolved in two successive esterifications using eicosanol in cyclohexane at a specific water activity ($a_w = 0.8$; Figure 1). After LiAlH₄ reduction of the *S*-ester (**S-3**) and *R*-acid (**R-4**), the respective **R-4** and **S-4** alcohols were recovered in high enantiomeric purity (>99.8% and >98.1% ee, respectively). The alcohol **R-4** was converted to the bromide **R-5** via the tosylate by using a standard method (Figure 2). The bromide **R-5** was reacted with an excess of lithium metal in diethyl ether to yield the corresponding alkyl lithium, which was used to alkylate (3*R*,4*R*)-(-)-*cis*-dimethyl- γ -butyrolactone. This resulted in a ketoalcohol, which was reduced to the alcohol **RRR-1H**. Mitsunobu conditions (see Figure 2 for the reaction conditions) were used to invert the configuration at carbon 2 in compound **RRR-1H** and to form the diastereomeric compound **SRR-1H**. **RSS-1H** was similarly prepared but from **SSS-1H** (Figure 2). For electrophysiological and

behavioral tests, the propionates of **RRR-1H** and **SRR-1H** were prepared in quantitative yield by stirring with propionic anhydride in pyridine.

Electrophysiology

During the first EAG experiment, antennae from male *G. pallida* responded strongly and consistently to the two higher doses of both the acetate and propionate of (2*S*,3*R*,7*R*)-3,7-dimethyl-2-pentadecanol, as well as to the acetate of (2*S*,3*R*,7*R*)-3,7-dimethyl-2-tridecanol (Figure 3). Also, when the highest dose of the propionates of (2*S*,3*R*,7*R*)-3,7-dimethyl-2-tridecanol and of (2*S*,3*R*,7*S*)-3,7-dimethyl-2-pentadecanol was tested, the responses were significantly higher than to the blank control (Figure 3). In addition, a significant response was obtained when antennae were stimulated with the intermediate dose of the propionate of (2*S*,3*S*,7*S*)-3,7-dimethyl-2-pentadecanol, but as the response to the highest dose returned to levels not different from the blank, we consider this result as less relevant. Taken together, the results from these first recordings support the hypothesis of the stereoisomeric identity (2*S*,3*R*,7*R*) of the pheromone, based on catches in traps for *D. pini* (Herz et al., 2000).

A large number of compounds, as pure stereoisomers or as mixtures (Table 1), were screened in EAG recordings using one dose, 1 µg. None of the propionate stereoisomers with a 2*R* configuration elicited responses stronger than the solvent control, irrespective of alkanol chain length. This was true for males both from Finland and from Germany. The same weak activity was shown by the (2*R**3*R**) isomers tested and by the 2*S*,3*R*,7*S*-isomer.

Fig. 3 Mean electroantennographic response of antennae from male *Gilpinia pallida* (German origin) expressed as percentage of standard stimulus (STD), which was the propionate of (2*S*,3*S*,7*S*)-3,7-dimethyl-2-pentadecanol in a dose of 0.01 µg. Standard error (SE) is not shown because of the large number of data points ($N=9$, except for 0.1 µg SSS Penta ac, where $N=8$). SRR Tri ac: acetate of (2*S*,3*R*,7*R*)-3,7-dimethyl-2-tridecanol; pr: propionate; *: response to the solvent control. Because of the large number of substances tested, only mean values different from the solvent control are shown by letters. Different letters indicate significant differences among mean responses and between the mean and the solvent control ($P=0.05$, Tukey's test on log-transformed values)

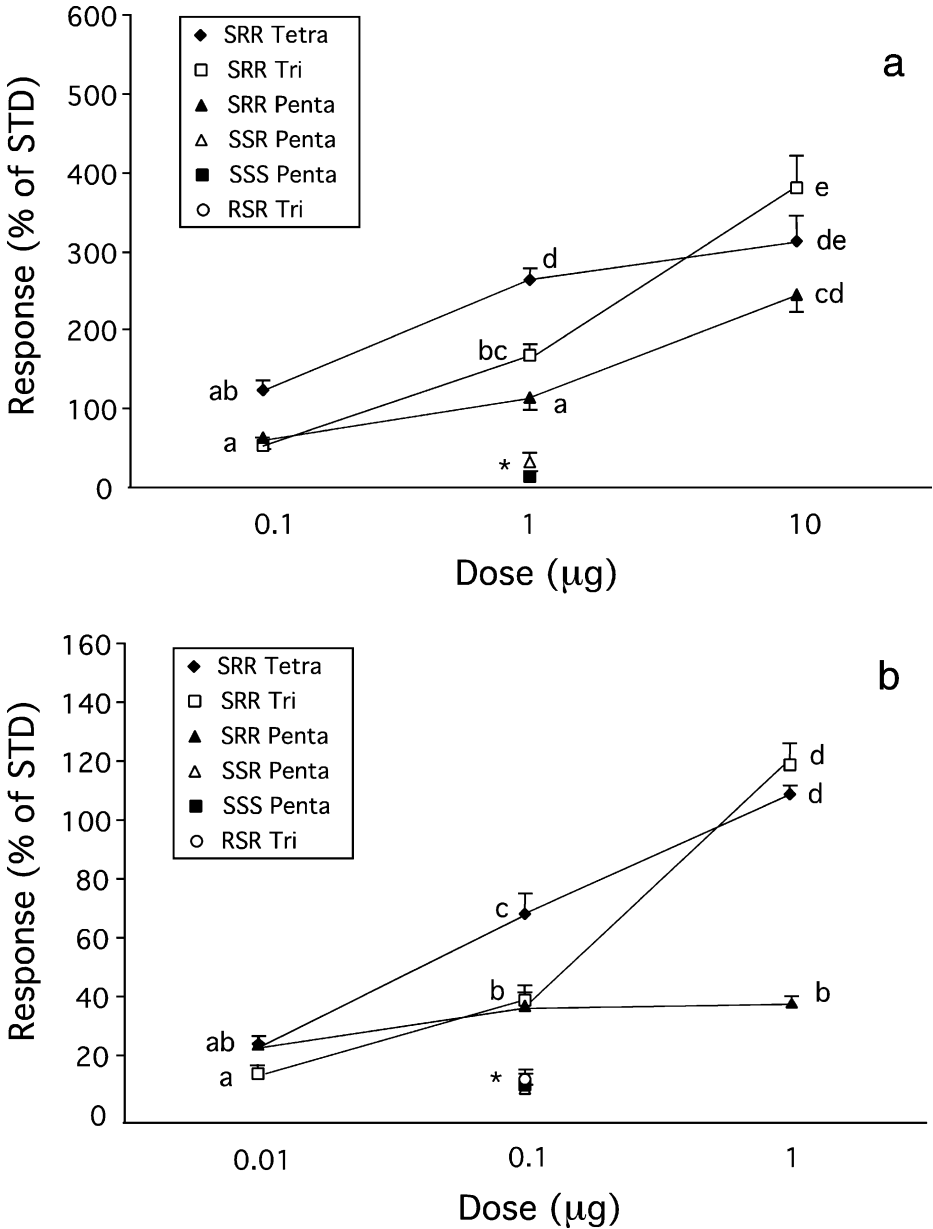

Fig. 4 Mean (+ or – SE) electroantennographic response of antennae from male *Gilpinia pallida* from (a) Germany ($N=8$) and (b) Finland ($N=5$) to some isomers of the propionates of 3,7-dimethyl-2-tridecanol, 3,7-dimethyl-2-tetradecanol, and 3,7-dimethyl-2-pentadecanol expressed as percentage of standard stimulus (STD), which was (a) 1 µg SRR Tri pr and (b) 0.1 µg SRR Tri pr. For abbreviations, see Figure 3 legend. *: Response to the solvent control. Different letters indicate significant differences among mean responses and between the mean and the solvent control ($P=0.05$, Tukey’s test on log-transformed values)

Table 4 Response of Male *Gilpinia pallida* to Traps Baited With (2*S*,3*R*,7*R*)-Propionates of 3,7-dimethyl-2-tri-, tetra- and pentadecanol (50 µg Bait), and of 3,7,11-trimethyl-2-tridecanol (800 µg Bait=50 µg per isomer), Sweden 1999^a

Bait	Total Catch	
	June 18, 1999	July 2, 1999
Blank	221	0
Propionate of 3,7,11-trimethyl-2-tridecanol	73	0
Propionate of (2 <i>S</i> ,3 <i>R</i> ,7 <i>R</i>)-3,7-dimethyl-2-tridecanol	603	1
Propionate of (2 <i>S</i> ,3 <i>R</i> ,7 <i>R</i>)-3,7-dimethyl-2-tetradecanol	1188	61
Propionate of (2 <i>S</i> ,3 <i>R</i> ,7 <i>R</i>)-3,7-dimethyl-2-pentadecanol	115	0

^a Seven *G. pallida* females were also trapped.

However, the propionate of the 2*S*,3*R*,7*R*-isomer of all three alkanols, 3,7-dimethyl-2-tridecanol, 3,7-dimethyl-2-tetradecanol, and 3,7-dimethyl-2-pentadecanol, and the acetate of the tri- and pentadecanol (acetate of tetradecanol not available) elicited antennal responses, with a clear dose–response relationship (Figure 4). This response pattern is analogous to that of *N. sertifer*, which showed strong EAG response to the acetate of the 2*S*,3*S*,7*S*-isomer of a homologous series of alkanols, i.e., 3,7-dimethyl-2-tridecanol to 3,7-dimethyl-2-hexadecanol (Wassgren et al., 1992).

Field Tests

We only trapped three male *G. pallida* during the 1998 experiment in France, but all were caught in the trap baited with the (2*S*,3*R*,7*R*)-propionate of 3,7-dimethyl-2-tetradecanol. This was also the only compound that attracted *G. pallida* in 1998 in Poland. In one replicate, 42 males were caught; whereas in the other, 30 males were trapped. The peak flight occurred at the end of July.

More than 2000 males were trapped during the 1999 experiment in northern Sweden (Table 4). Again, the (2*S*,3*R*,7*R*)-propionate of 3,7-dimethyl-2-tetradecanol was the most active homologue, although all other baits, including the blank, caught a considerable number of sawflies during the first trapping period (Table 4). Due to the short and intensive flight period and the remote location of the outbreak, the treatments were only rerandomized once, so statistical analysis of the data was not feasible. During the second trapping period, 61 of 62 males were caught in the trap baited with (2*S*,3*R*,7*R*)-propionate of 3,7-dimethyl-2-tetradecanol (Table 4).

Only 11 males were trapped during the 1999 experiment in Poland. Five responded to the trap baited with the (2*S*,3*R*,7*R*)-propionate of 3,7-dimethyl-2-tetradecanol, whereas three each responded to two traps baited with combinations of (2*R**3*S**)-isomers of propionates of 3,7-dimethyl-2-tridecanol. Taken together, the results of the field trapping indicate that the (2*S*,3*R*,7*R*)-isomer of 3,7-dimethyl-2-tetradecanol is likely the main component of the pheromone precursor in *G. pallida*, with lower, but substantial, response to the propionate of the *SRR* isomer of the tridecanol. The propionate of the pentadecanol homologue was even less active. With *N. sertifer*, only one of the 2*S*,3*S*,7*S* homologues (the acetate of 3,7-dimethyl-2-pentadecanol) caught a significant number of males, despite a strong electrophysiological response to all homologues (Wassgren et al., 1992).

We have no explanation as to why the precursor of the most electrophysiologically and behaviorally active stereoisomer was only detected in one of the samples (Tables 2 and 3).

Future studies of the actual release from females of different ages and geographical origins might shed light on this issue. It is possible that one or more of the other electrophysiologically active substances found in female *G. pallida* may also be pheromone precursors, and may function in blends with the esters of the tridecanol and tetradecanol. However, it was not possible to examine the effect of the other components because the populations had collapsed. It is also possible that male *G. pallida* respond to several esters of the main component, as was recently reported for *D. pini* (Anderbrant et al., 2005). However, the propionate of (2*S*,3*R*,7*R*)-3,7-dimethyl-2-tetradecanol is a potent attractant of *G. pallida* and might serve as lure in monitoring traps.

Acknowledgments We thank Johan Kristoffersson for help with the field test in Arjeplog, Sweden. The research was supported by the Swedish Natural Science Research Council (NFR), Swedish Council for Forestry and Agricultural Research (SJFR), Carl Trygger's Foundation for Scientific Research and the Commission of the European Communities, Agriculture and Fisheries (FAIR), specific RTD program, contract no. FAIR1-CT95-0339, "Pine sawfly pheromones for sustainable management of European forests" (PHERODIP). This study does not necessarily reflect the Commission's view and in no way anticipates its future policies in this area. Financial support to the group in Göteborg from The Royal Society of Arts and Sciences in Göteborg (KVVVS) and the Ebba and Sven Schwartz Foundation is gratefully acknowledged.

Introduction

The eggplant flea beetle, *Epitrix fuscula* Crotch (Coleoptera: Chrysomelidae), is an important pest of eggplants. Found throughout most of the United States, *E. fuscula* is most common in the south. It is the most prominent insect pest of eggplant in Arkansas, requiring multiple insecticide applications after transplanting for beetle control (McLeod et al., 2002). Adult beetles can be especially damaging in the spring and are capable of defoliating young eggplant transplants in as little as 12 hr (Sorensen and Baker, 1994; Andersen, 2000). Flea beetle feeding, including from *E. fuscula*, is an important cause of crop failure in eggplants grown by organic methods (Patton et al., 2003). A number of cultural practices recommended for flea beetle control include trap crops, row covers, removal of crop residues, sticky traps, and careful timing of plantings (Sorensen and Baker, 1994; Delahaut, 2001; Kuepper, 2003). An effective detection and monitoring tool, such as a pheromone, could assist in the control of *E. fuscula*.

The life history of *E. fuscula* was reported by Sorensen and Baker (1994). Briefly, adults overwinter in soil or ground debris and emerge and mate in early spring. Females lay eggs near the base of host plants. Larvae feed on roots or tubers and pupate in the soil when mature. Adult beetles emerge in about 7 to 10 days and begin to feed on foliage. In the southern U.S., the eggplant flea beetle is thought to have at least two generations per year (Sorensen and Baker, 1994; Capinera, 2001). This species has a limited host range, feeding primarily on solanaceous plants (Capinera, 2001). It causes damage to potatoes and sugar beets, and will feed on some weed species such as horse nettle and pokeweed (Sorensen and Baker, 1994). Adults cause the same type of characteristic, leaf-feeding damage associated with other flea beetles, consisting of numerous, small, irregular “shot holes” (Kuepper, 2003).

Previously, pheromones have been reported from both male and female flea beetles. Males of *Longitarsus jacobaeae* Waterhouse were reported to be attracted to cues associated with conspecific females, although no chemical compounds were identified (Zhang and McEvoy, 1994). The first report of a male-produced pheromone in a flea beetle was for *Phyllotreta cruciferae* (Peng and Weiss, 1992; Peng et al., 1999), detected from feeding beetles by laboratory and field bioassays. Subsequently, six male-specific sesquiterpenes were found in this species and fully characterized, and four of the six were synthesized (Bartelt et al., 2001; Muto et al., 2004; Mori, 2005). Soroka et al. (2005) found that a blend of these compounds was attractive in the field to both male and female *P. cruciferae* and that even greater attraction was possible when the blend was combined with allyl isothiocyanate (AITC), a previously known, host-related attractant for *P. cruciferae* (Vincent and Stewart, 1984; Pivnick et al., 1992). Tóth et al. (2005) performed a similar field trial in Hungary by using pure enantiomers of *P. cruciferae* pheromone components in combination with AITC and achieved similar results, attracting *P. cruciferae* as well as some other, congeneric species. The same male-specific compounds emitted by *P. cruciferae*, plus two additional sesquiterpene alcohols, have also been found in the volatiles emitted from males of three *Aphthona* flea beetle species, *A. flava*, *A. czwalinae*, and *A. cyparissiae* (Bartelt et al., 2001), but field bioassays have not yet been performed.

By using techniques that were employed with *P. cruciferae* and *Aphthona* spp., a male-produced pheromone was demonstrated in *E. fuscula*. The identification of six male-specific compounds and the synthesis and field activity of the two major components are reported.

Methods and Materials

Insects

In early May of 2004, overwintered *E. fuscata* adults were collected from eggplants on an organic farm located in Farmington, IL, USA. In 2005, beetles were again collected from the same site and from an eggplant research plot at National Center for Agricultural Utilization Research (NCAUR), in Peoria, Illinois. The sex was determined under a microscope, by using the abdominal characteristics described for *Phyllotreta* (Smith, 1983). The fifth abdominal sternum of females appears as a simple, smooth surface, but in males contains an apical median lobe. The beetles were used for collection of volatiles in the laboratory.

Collection of Volatiles

Volatiles were collected from groups of males, females, or mixed-sex beetles feeding on eggplant leaves, and from eggplant leaves alone, as described previously for another species and host (Bartelt et al., 2006). Briefly, beetles and foliage were placed in 45×3 cm (ID), horizontal glass tubes, equipped with Super-Q (Alltech, Deerfield, IL, USA) filters on both ends and through which air was drawn (300 ml/min) by vacuum. The inlet filter cleaned incoming air, and the second filter trapped the volatiles emitted within the tube. Typically, 10 beetles were used per tube, but numbers ranged from 3–20. A single eggplant leaf, about 9 cm in length and 5 cm at its greatest width, served as a food source and was replaced every time volatiles were collected. To keep the leaf fresh, the petiole was placed in a 5-ml glass vial containing water. A Teflon[®] seal, held in place with a ring-shaped screw cap, kept water from spilling. Collection duration was 1 to 4 d, and collected volatiles were recovered by rinsing the outlet Super Q filter with 400 µl of hexane into a vial. Collectors were kept in an incubator at 27°C with a relative humidity of about 50%. Light was provided by eight 40-W fluorescent tubes set about 0.5 m above and behind the collection tubes, and the daily light cycle was 16:8 hr light/dark.

Gas Chromatographic/Mass Spectrometric and Gas Chromatographic Analysis

All volatile collections were analyzed by coupled gas chromatography/mass spectrometry (GC–MS), and comparisons were made among collections from feeding males, females, and mixed sexes and from host plants only. The analyses were conducted on a Hewlett Packard 5973 mass selective detector, interfaced to a Hewlett Packard 6890 GC. For most analyses, a 30-m DB-5MS capillary column (0.25 mm ID, 1.0 µm film thickness, J&W Scientific, Folsom, CA, USA) was used. The temperature program was 50°C for 1 min, then rising to 280°C at 10°C per min and holding for 5 min at 280°C. The temperature of the splitless inlet was 200°C, and the transfer line temperature was 285°C. The Wiley MS library (Wiley, 1995) was installed on the data system.

Chiral GC–MS analysis was conducted for some samples (see below) by using a 30-m Cyclodex-B column (0.25 mm ID, 0.25 µm film thickness, J&W Scientific). Temperature program was 50°C for 1 min, then rising at 30°C/min to a final temperature of either 120°C or 130°C.

A Hewlett Packard 5890 GC was used for quantitation and was equipped with a DB-1 column (as above), splitless and cool-on-column inlets, and flame-ionization detector. Estimation of amounts of selected compounds in samples was by the external standard method, relative to nonadecane, by using the splitless inlet (200°C). Septum release rates

were measured using the internal standard method (nonadecane, 4.09 μg per sample) and cool-on-column injections (with inlet temperature tracking the oven temperature).

Electrophysiology

Coupled GC–electroantennographic (GC–EAD) analyses were carried out on a Hewlett Packard 6890 GC, interfaced to antennal preparations. Amplified EAD and GC profiles were obtained simultaneously and analyzed by Syntech GC–EAD software. General methods and equipment have been previously described by Cossé and Bartelt (2000).

Liquid Chromatography

Fractionation of collected volatiles on open columns of silica gel (6×0.5 cm ID, in Pasteur pipettes), followed by GC–MS analysis of fractions, gave information on compound polarity and served as an initial purification step. Elution was with hexane, then 10% ether in hexane, and finally with 25% ether in hexane (3 column volumes per solvent).

High-performance liquid chromatography (HPLC) and other techniques were applied to these silica gel fractions to gain further information about compounds **1–6** (Fig. 1). For HPLC, a Waters 515 pump (flow rate=1 ml/min) and a Waters R401 differential refractometer detector were employed. A Supelcosil LC-SI silica column (25 cm, 0.46 cm ID, 5 μm particle size, Supelco, Bellefonte, PA, USA) was used for purifying aldehydes **1** and **2** before hydrogenation and nuclear magnetic resonance (NMR), and the solvent was 10% ethyl ether (redistilled) in hexane. A silica column (Adsorbosphere Silica 5 μ , a 25×4.6 -mm ID silica column; Alltech) that had been treated with silver nitrate

Fig. 1 Compounds **1–6**, detected during the analysis of volatiles from male *E. fuscula* feeding on eggplant leaf. Compound **7**, *ar*-himachalene, derived from *E. fuscula* **3**, to determine absolute configuration (see text). Chemical Abstracts index names: **1**, (2*E*,4*E*,6*Z*)-2,4,6-nonatrienal; **2**, (2*E*,4*E*,6*E*)-2,4,6-nonatrienal; **3**, (9*R*,9*aS*)-5,6,7,8,9,9*a*-hexahydro-3,5,5,9-tetramethyl-1*H*-benzocycloheptene; **4**, (9*R*,9*aS*)-2,3,5,6,7,8,9,9*a*-octahydro-5,5,9-trimethyl-3-methylene-1*H*-benzocycloheptene; **5**, (3*R*,9*R*,9*aS*)-2,3,5,6,7,8,9,9*a*-octahydro-3,5,5,9-tetramethyl-1*H*-benzocyclohept-3-ol; **6**, (3*S*,9*R*,9*aS*)-2,3,5,6,7,8,9,9*a*-octahydro-3,5,5,9-tetramethyl-1*H*-benzocyclohept-3-ol; **7**, (5*R*)-6,7,8,9-tetrahydro-2,5,9,9-tetramethyl-5*H*-benzocycloheptene

(Heath and Sonnet, 1980) was used for separating hydrocarbons **3** and **4**, with 0.5% 1-hexene in hexane as solvent. All effluent was collected in consecutive 1-ml fractions.

Hydrogenation

Microscale hydrogenation of HPLC-purified **1** and **2** (combined) was conducted over 10% palladium on carbon. A sample of **1** and **2** (ca. 100 ng) in a tapered vial was taken to dryness under a stream of argon and immediately redissolved in CH_2Cl_2 (100 μl). A small amount of catalyst (<1 mg, barely visible in the solution) was added. By using a fine needle, hydrogen was bubbled through the solution for 5 min at room temperature. Then, the solution was concentrated about 10-fold under argon and analyzed by GC–MS.

NMR Spectroscopy

NMR spectra were acquired on a Bruker Avance 500 instrument with a 5-mm inverse broadband probe with a Z-gradient. Proton and COSY spectra were obtained for beetle-derived **1** and **2** in CDCl_3 and for synthetic **1** and **2** in both CDCl_3 and deuterobenzene, as described below.

Chiral Analysis of Compounds **3**, **4**, **5**, and **6**

The enantiomers of **4** are known to separate on a Cyclodex-B capillary column (Bartelt et al., 2001), and the hydrocarbon silica gel fraction of the natural sample, which contained **4**, was compared with racemic synthetic **4** on that column (final temperature 130°C). The enantiomers of **3** do not separate on Cyclodex-B (Bartelt et al., 2001), but an alternative analysis was possible: Compound **3** in the hydrocarbon silica fraction was separated from **4** by HPLC on the silver nitrate column (**3** eluting 3–4 ml after injection, and **4**, at 6–7 ml), and then **3** was converted to *ar*-himachalene (**7**; Fig. 1) by treatment with 2,3,5,6-tetrachlorohydroquinone (Mehta and Singh, 1977; Bartelt et al., 2001), and the product compared with racemic **7** on Cyclodex-B (final temperature 120°C). The 25% ether hexane silica gel fraction from *E. fuscula*, which contained alcohols **5** and **6** but was free of **3** and **4**, was treated with a

Fig. 2 Synthesis of aldehydes **2** and **1** (see text). Reagents and details for steps: (a) triethyl 2-phosphonoacetate, either in tetrahydrofuran with BuLi as base or in hexane with Li *t*-OBu as base, 0°C, warming to room temperature (RT), 1 hr, 88% yield; (b) diisobutylaluminum hydride in hexane/ether (1:1), 0°C, 1 hr, 90% yield; (c) MnO_2 in methylene chloride, RT, 16 hr, 85%. Aldehyde **1** was prepared in the same way except that (2*E*,4*Z*)-2,4-heptadienal was the starting material instead of **8**

strong cation exchanger (acidic form) to dehydrate **5** and **6** (Bartelt et al., 2001). The resulting compound **4** was analyzed on the Cyclodex-B column as above.

Chemicals

Aldehydes **1** and **2** were synthesized, and sesquiterpenes **3** to **7** were available from previous research (Bartelt et al., 2003; Muto et al., 2004).

Synthesis of **2** (Fig. 2) used commercial (2*E*,4*E*)-2,4-heptadienal (**8**) (Sigma-Aldrich, St. Louis, MO, USA) as the starting material. The chain was extended by a Wittig–Horner reaction with triethyl 2-phosphonoacetate (Boutagy and Thomas, 1974) to form the triene ester (**9**); both lithium *t*-butoxide in hexane (Petroski and Weisleder, 2001) and *n*-butyllithium in tetrahydrofuran (Bartelt et al., 1990) were satisfactory base/solvent combinations. The ester was reduced to alcohol **10**. In an initial trial, reduction was performed with LiAlH₄ (Bartelt et al., 1990), but this reagent also gave some reduction of the olefin system. Subsequent reductions were performed with diisobutylaluminum hydride (Miller et al., 1959; Kreft, 1977), and the unwanted overreduction did not occur. In either case, the resulting alcohol was oxidized to aldehyde **2** with MnO₂ (Petroski, 2003).

Aldehyde **1** was prepared by the same route (Fig. 2), but the starting material, (2*E*,4*Z*)-2,4-heptadienal (**11**), was not commercially available. Instead, this was prepared by the method of Petroski (2003). By GC–MS analysis, synthetic **1** contained 12% of **2** as an impurity immediately after synthesis. The product was diluted to a concentration of 27 µg/µl in CH₂Cl₂ and stored at –70°C until needed for field tests.

Instability of **1** was a concern, and to evaluate its lability a solution was kept at ambient laboratory conditions and periodically analyzed. Synthetic **1** (100 µg in 1.8 ml of hexane) was added to a 2-ml glass autosampler vial with crimp-top septum cap, along with undecanol (22.7 µg) as internal standard. GC analysis was performed immediately after preparing the sample (1-µl injection through the cool-on-column inlet), and subsequent injections were made every 24 hr for 3 d (the Teflon[®] lined septum top was not replaced during the test).

Field Lures

Red rubber septa (Sigma-Aldrich) were cleaned by Soxhlet extraction for 6 hr with CH₂Cl₂ and allowed to air dry overnight. To prepare septa, a solution of synthetic **1** was applied (500 µg in 20 µl), followed by CH₂Cl₂ (300 µl). After the solvent soaked in, the septa were aired 1 hr in a fume hood and then kept in a tightly capped glass jar. Septa were always used in the field the same day they were prepared and discarded after 24 hr.

The emissions of compounds **1** and **2** from freshly prepared septa were analyzed in the laboratory. Three septa were placed individually in volatile collectors, and collections of approximately 1-d duration were made for 3 consecutive days and quantitated by GC.

Field Tests

Field tests were conducted during three periods and in two areas. The three periods were late spring (7 d, May 26 to June 1, 2005), mid summer (5 d, July 11 to July 15, 2005), and late summer (10 d, August 2 to August 19, 2005). The first test area was a commercial organic vegetable farm in Farmington, IL, that contained both eggplant (var. Black Bell, Rosa Bianca, and Pingtung Long) and potatoes (var. Kennebec, Pontiac, Red Norland, All

Blue, Cranberry Red, and Onaway). The second area was a research plot located at the NCAUR that was planted only in eggplant (var. Black Beauty and Salangana hybrid).

Traps used in the field trials were yellow sticky cards, coated with adhesive on both sides (“Sticky Strips,” Olson Products, Medina, OH); these were cut in half (final size, 15×15 cm). Holes were punched on opposite sides, and the traps were secured to bamboo stakes (1 m high) with twist ties. Traps were situated so that their bottom edges were about 5–10 cm above the tops of the plants. Lures were attached with wire to the tops of traps.

A paired experimental design was used. Each pair consisted of a baited and unbaited trap, separated by about 5 m. Within the pairs, assignment of treatments to traps was by coin flip and, thereafter, was alternated each day. Traps were replaced with new ones each day, and the used ones were taken to the laboratory for examination. All flea beetles were removed from the traps (by using hexane to help dissolve the glue) and examined under a microscope to confirm identity, and the numbers of *E. fuscula* were recorded. Analysis of variance was conducted, as described with results. Sex ratios were determined from 5 subsamples of 10 beetles, each chosen randomly from both the treatment and control trap catches. Sex was confirmed by dissection (whether aedeagus was present).

Results

Volatile Collections

Comparisons of volatile collections from adult *E. fuscula* males and females revealed six male-specific peaks (1–6 in Fig. 3). The most abundant (1) was detected in 82 out of the 93 male volatile collections made in 2004 and 2005. In the 25 collections from 2005, the mean amount of 1 was 5.5 ± 4.2 (SD) ng per male per day, and the maximum was 16 ng per male per day. The minor compounds were also detected consistently whenever 1 was prominent. Typical ratios are summarized in Table 1. Compounds 1–6 were not found in the 50 volatile collections from females or in the 9 collections from eggplant leaves only. In GC traces for females or eggplant only, peaks sometimes occurred at the same, or similar, retention times as the numbered compounds from males (e.g., Fig. 3), but in these cases the mass spectra did not agree with the male compounds. Nine of 10 mixed-sex collections contained compounds 1–6 in amounts and proportions consistent with the collections from males.

Fig. 3 Comparisons of volatiles collected from male (top) and female (bottom, mirror view) *E. fuscula* beetles feeding on eggplant leaf. Compounds 1–6 are detectable only from the male volatiles. Some peaks in female collections had similar retention times to male-specific compounds (e.g., peaks 3 and 5) but differed in mass spectra. Peaks marked with asterisks are probably geometrical isomers of 1 and 2 (see text)

Table 1 Mean Percentage of each Male-specific Compound in the Volatile Collections Relative to Compound **1** based on GC–MS Peak Area

Male-specific compound	Mean (%) to 1±SD
1	100 ^a

^b *N*=12

Electrophysiological (GC–EAD) Analysis

Gas chromatographic-electroantennographic analysis of collected volatiles of male beetles feeding on eggplant foliage showed that the natural **1** and **2** were readily detected by the antennae of males (*N*=3) and females (*N*=4; Fig. 4, male example shown). Similar results were obtained for the synthetic aldehydes. Male and female antennae did not respond to **3**–**6** in volatile collections from males feeding on eggplant foliage, perhaps because of the relatively small amounts (<1 ng/compound). However, when synthetic **3**–**6** were injected at 10 ng/compound, compounds **3** and **5** did elicit antennal responses in five out of five tests. Compound **6** produced responses in two of the five tests, but no response was seen to compound **4**. Male and female antennae also responded to some foliage-specific compounds, but these were not addressed further.

Identification of Compound **1**

Compound **1** eluted from silica gel with 10% ether in hexane, a polarity consistent with an aldehyde, ketone, or ester. Silica HPLC of volatile collections rich in **1** (10 of these, combined) afforded a sample suitable for NMR spectroscopy and microhydrogenation; compound **1** (and also **2**) eluted between 8 and 9 min after injection.

The mass spectrum of **1** (Fig. 5, top) suggested a molecular weight of 136 but did not match any library spectra. An aldehyde or ketone with molecular weight 136 (C₉H₁₂O) would have four degrees of unsaturation, and an ester of the same weight (C₈H₈O₂) would have five. Hydrogenation over palladium increased the molecular weight to 142 (Fig. 5, bottom), indicating the uptake of six hydrogen atoms and, therefore, the presence of three

Fig. 4 Positive GC–EAD response (male antennae) to compounds **1** and **2** in a volatile collection from male beetles feeding on eggplants

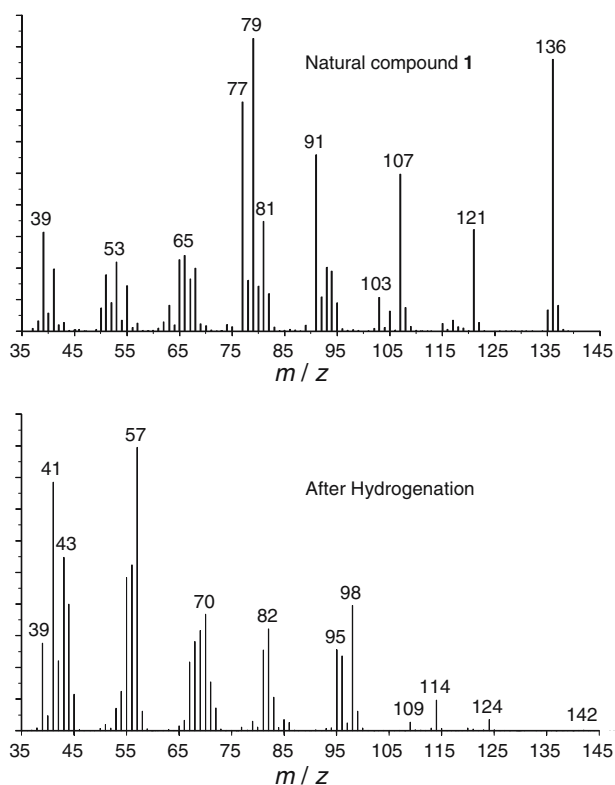

Fig. 5 Positive EI mass spectrum of compound **1** after HPLC isolation (top). Nonanal the resulting product after hydrogenation (bottom)

carbon–carbon double bonds in the original compound. The mass spectrum of the hydrogenation product gave a good library match to nonanal, and authentic nonanal had the same mass spectrum and GC retention time as the hydrogenation product. Because hydrogenation over palladium was not expected to affect an aldehyde group or the carbon skeleton, compound **1** was concluded to be a nonatrienal (the fourth degree of unsaturation required by the molecular weight being accounted for by the aldehyde carbonyl).

The ^1H and COSY NMR spectra of HPLC-purified **1** (Fig. 6; Table 2) defined the locations and configurations of the double bonds. The ^1H spectrum in CDCl_3 indicated six olefinic protons (δ 5.79–7.18), an aldehydic proton (δ 9.57), and an ethyl group (terminal methyl group at δ 1.09, split into a triplet by the methylene group at δ 2.30). The olefinic protons had to be on six consecutive carbons in the middle of the nine-carbon chain because the one-carbon aldehyde and two-carbon ethyl groups occupied the ends. Thus, compound **1** was a 2,4,6-nonatrienal. As shown in Fig. 6, the coupling involving olefinic protons was readily followed in the COSY spectrum from the aldehyde end to the alkyl end of the structure, and the olefinic proton resonances were thus assigned to specific chain positions. The key coupling constants $J_{2,3}$, $J_{4,5}$, and $J_{6,7}$ were read from the assigned ^1H spectrum as 15.2, 15.4, and 10.7 Hz, indicating configurations of *E*, *E*, and *Z*, respectively (Williams and Fleming, 1980). Thus, compound **1** was (2*E*,4*E*,6*Z*)-2,4,6-nonatrienal. Synthetic **1** matched the natural compound by mass and NMR spectra and by GC retention time.

Table 2 Proton NMR Data for Aldehydes **1** and **2**

NMR property	Compound 1		Compound 2	
	CDCl ₃	C ₆ D ₆	CDCl ₃	C ₆ D ₆

^b Evidence for a *Z* double bond ($J < 12$ Hz).

Identification of **2**

Compound **2** had a mass spectrum that was nearly identical to **1** and was believed to be a geometrical isomer. The beetle-derived NMR sample (Fig. 6) contained a small amount of **2**, and most of its resonances were visible, being somewhat offset from those of **1**. Assignment of resonances was performed from the COSY spectrum as with **1**. Coupling constants $J_{2,3}$ and $J_{4,5}$ were 15.2 and 14.6 Hz, indicating *E* double bonds, but resonances for the olefinic protons at positions 6 and 7 were obscured, so that $J_{6,7}$ could not be observed. However, given that **2** is not identical to **1**, it was concluded that the 6 double bond of **2** must be *E* and, therefore, that compound **2** was (2*E*,4*E*,6*E*)-2,4,6-nonatrienal. The mass spectrum and GC retention time of synthetic **2** were identical to the natural product, and so was the NMR spectrum, to the extent that resonances could be compared. When deuterobenzene was used as the NMR solvent instead of CDCl₃, shifts of the olefinic protons changed, but overlap of signals in **1** and **2** was not completely avoided (Table 2). Minor amounts of compounds, believed to be geometrical isomers of **1** and **2** based on mass spectra, were sometimes found in the male-produced volatiles (peaks identified with asterisks, Fig. 3), but these did not elicit antennal responses.

Fig. 6 The ¹H (top) and COSY (bottom) NMR spectra of natural sample from *E. fuscula* that contained compounds **1** and **2**. Assignment of resonances to compound position numbers are shown in upper panel; data for compound **2** are indicated with (')

Compounds 3–6

Compounds **3** and **4** eluted from silica gel with hexane (polarity consistent with hydrocarbons), whereas **5** and **6** eluted with 25% ether in hexane (polarity consistent with alcohols). Mass spectra of compounds **3**, **4**, **5**, and **6** (Fig. 1) were recognized from previous flea beetle research (compounds A, C, F, and G, respectively, in Bartelt et al., 2001). The GC retention times of the *E. fuscula* compounds also matched those of authentic standards on the achiral column.

Analysis of **4** and of derivatives of **3**, **5**, and **6** from *E. fuscula* on the Cyclodex-B GC column allowed assignment of the absolute configurations. Compound **4** from *E. fuscula* had a retention time of 20.50 min, the earlier of the enantiomers of **4** (racemic **4** gave peaks at 20.51 and 20.75 min). *P. cruciferae* and *A. flava* also have the earlier eluting enantiomer of **4** (Bartelt et al., 2001), which was shown by chiral synthesis (Muto et al., 2004) to have the (9*R*,9*aS*) configuration (see Fig. 1). *ar*-Himachalene (**7**) derived from *E. fuscula* **3** had a GC retention of 39.70 min, the latter of the enantiomers (racemic **7** gave GC peaks at 39.17 and 39.70 min). Mori (2005) established that the later-eluting enantiomer has the (5*R*) configuration (Fig. 1), and therefore the **3** from which it was derived had to have the (9*R*,9*aS*) configuration. Finally, alcohols **5** and **6** from *E. fuscula* dehydrated to give just one enantiomer of **4**, which eluted at 20.50 min, corresponding to the (9*R*,9*aS*) configuration. Thus, **5** and **6** must have been (3*R*,9*R*,9*aS*) and (3*S*,9*R*,9*aS*), respectively.

Labile Compounds

Lability of compounds **1**, **5**, and **6** made it difficult to accurately characterize the chemical blend of **1–6** at the instant it was emitted from the beetles. Isomerization of **1** into thermodynamically more stable **2** occurs over time if **1** is not carefully protected (e.g., kept in solution in a dark freezer at -70°C). For example, immediately after the sample of synthetic **1** was placed in the autosampler vial, the amount of **2** was 18% of the amount of **1**, by GC analysis. When the vial was left at ambient conditions in the laboratory, the amount of **2** as a percentage of **1** increased to 31%, 66%, and 93% after 24, 48, and 72 hr, respectively. However, the total amount of sample in the vial (**1** plus **2**) decreased by less than 3% after 72 hr (measured with internal standard), indicating most of the relative decrease in **1** must have been due to isomerization to **2**.

Isomerization of **1** was also likely in the Super Q collections from live beetles because the measured relative amounts of **2** increased as durations of volatile collections increased. For collections of 1-d duration, the amount of **2** as a percentage of **1** (mean \pm SD) was $26\pm$

Table 3 Mean Number of *E. fuscula* Adults Caught on Baited and Unbaited Sticky Traps during Three Trial Periods in 2005

Time period	Mean trap catch (<i>E. fuscula</i> /trap/d)			
	Baited	Control	N	Ratio baited:control
May 26–June 10	26.9 ^a	5.8	35	4.6:1.0
July 11–15	7.6 ^a	2.3	25	3.3:1.0
August 2–18	10.6 ^b	6.5	50	1.6:1.0

^a Significant difference between treatment and control at the 0.001 level.

^b Significant difference between treatment and control at the 0.01 level.

13 ($N=23$). For collections of 2-, 3-, and 4-d duration, the corresponding amounts of **2** were 33 ± 10 ($N=23$), 40 ± 19 ($N=29$), and 43 ± 12 ($N=13$), respectively. From linear regression analysis, the amount of **2** relative to **1** increased by 5.1 ± 1.7 (SE) percentage points per day ($t=4.38$, $P<0.001$). The predicted fitted value of **2** for time=0 d (i.e., time of emission from beetles) was $21.4\pm 3.0\%$ (SE), a value that was significantly different from zero ($t=7.12$, $P<0.001$). Thus, the apparent rate of isomerization of **1** was not high enough to account totally for the presence of **2**. It was concluded that **2** was, in fact, being emitted by the beetles.

It has been reported that compounds **5** and **6** both decompose in a heated GC inlet into compounds **3** and **4** (Bartelt et al., 2001); 50% degradation was typical, and the resulting ratio of the **3** and **4** that were formed was about 1:1. Thus, it is likely that the amounts of **3** and **4** actually in beetle emissions are considerably lower than the measured values in Table 1, and correspondingly, the real amounts of **5** and **6** from the beetles are higher than the values in Table 1.

Field Lures

Aldehydes **1** and **2** were readily released from the rubber septa, but isomerization of **1** was a problem. In 17-hr collections of emitted volatiles in the laboratory, mean amounts of compounds **1** and **2** were as follows: $27\ \mu\text{g}\pm 8.0$ (SD) and $28\ \mu\text{g}\pm 9.2$ SD, respectively, ($N=3$). Although the solution applied to the septa contained only 18% of **2**, relative to **1**, this percentage increased to 104% in the 17-hr collection, and by 72-hr collection, the amount of **2** relative to **1** was 257%.

Field Experiments

Traps baited with synthetic **1** (also emitting **2** at a level that was at least 18% as high as **1**) performed significantly better than control traps in all three trial periods (Table 3). In a three-way ANOVA (factors being treatment, seasonal period, and trap pair), the overall treatment effect was highly significant ($F=98.3$, $df=1,107$, $P<0.001$), but there was also a significant interaction between treatment and seasonal period ($F=11.5$, $df=2,107$, $P<0.001$). Thus, the relationship between the treatment and control catches changed with time of year. As shown in Table 3, the ratio between treatment and control (by using newly prepared septa each day) was 4.6:1 in late spring, but decreased to 3.3:1 in early summer and, further, to 1.6:1 in late summer. The effect of **1** and **2** was strongest in late spring, although it was significant ($P<0.01$) in all three periods. In the subsamples from treatment and control traps, captured beetles were 64% and 48% females, respectively ($N=50$ for each treatment).

Discussion

Volatile collections of male *E. fuscula* feeding on eggplant foliage showed six compounds that were not present in volatile collection from feeding females or from foliage alone. The two major male-specific compounds, (2*E*,4*E*,6*Z*)-2,4,6-nonatrienal (**1**) and (2*E*,4*E*,6*E*)-2,4,6-nonatrienal (**2**), were identified by GC-MS, NMR, and microscale hydrogenation. Both compounds were synthesized and matched natural **1** and **2** by all available criteria. The true amount of **2** emitted from the beetles, relative to **1**, is not yet known because of the tendency for **1** to isomerize into **2**, but it was concluded that at least some **2** is naturally

present. The beetle antennae respond to both compounds in GC–EAD tests. Field tests of baits containing synthetic **1** and **2** were attractive to both male and female *E. fuscula*, compared with unbaited traps. Although the blend of **1** and **2** was attractive in all three time periods, it performed best early in the season, shortly after the emergence of overwintered adults.

Aldehyde **1** has been reported previously in the volatiles from blended endive leaves (Götz-Schmidt and Schreier, 1986), and has recently been identified from oat flakes and Darjeeling black tea (Schuh and Schieberle, 2005, 2006). Aldehyde **1** has also been reported as being among the most odor-active compounds found in food, detectable to humans at an odor threshold of 0.0002 ng/l in air and with an oat-flake-like aroma (Schuh and Schieberle, 2005). In our research, it was not uncommon to detect an odor similar to bread baking when volatile collections from males were processed. Aldehyde **2** was first identified from the volatile oil of blended dry beans (Buttery, 1975), and has also been reported in the volatile constituents of endive leaves (Götz-Schmidt and Schreier, 1986) and cooked spinach (Näf and Velluz, 2000). Interestingly, the human nose is 20,000 times less sensitive to **2** than it is to **1** (Schuh and Schieberle, 2005).

Schuh and Schieberle (2005) provided proton NMR data for both **1** and **2** that generally agree with ours. One difference for **1** is that they reported the resonance for the proton at position 7 to be within a multiplet at 6.05 to 6.25 ppm, whereas we found its shift to be 5.79 ppm. Another difference is that the aldehydic proton of **1** was reported to be slightly upfield of that for **2** (9.55 vs. 9.58 ppm, respectively), whereas the reverse was true in our spectra (9.57 and 9.56 ppm, respectively). The Schuh and Schieberle (2005) synthesis of **1** resulted in a mixture of isomers, in which **1** was not the major product. This situation, along with the absence of COSY data, may have made peak assignment difficult.

Compounds **1** and **2** have not been previously reported from other flea beetle species or from any other insect species. However, it is interesting to note that males of another chrysomelid beetle, *Diorhabda elongata* Brullé, emit a homologous compound, (2*E*,4*Z*)-2,4-heptadienal, as part of their aggregation pheromone (Cossé et al., 2005).

Small amounts of other isomers of **1** and **2** were detected in the male-produced volatile collections, although their origin, exact configuration, and attractiveness are unknown. Considering the instability of compound **1**, the presence of these other isomers is not unexpected. Schuh and Schieberle (2005) also encountered additional isomeric compounds of 2,4,6-nonatrienals during synthesis of (2*E*,4*E*,6*Z*)- and (2*E*,4*Z*,6*Z*)-2,4,6-nonatrienal.

The additional four minor male-specific compounds (**3**, **4**, **5**, and **6**) matched synthetic and natural male-specific sesquiterpenes previously identified from *Phyllotreta* and *Aphthona* spp. flea beetles in GC retention times, mass spectra, and chirality (Bartelt et al., 2001; Tóth et al., 2005). The configurations of all four compounds are identical at ring positions 9 and 9a (Fig. 1), suggesting a common biosynthetic origin. The GC–EAD activity of **3**, **5**, and **6** in *E. fuscula* is consistent with, but does not prove, a pheromonal function. Field tests were attempted with racemic **3–6** during the late summer period (when results for **1** and **2** were weakest) but were inconclusive.

Pheromonal activity has been demonstrated at least for compound **3** in *P. cruciferae* (Soroka et al., 2005; Tóth et al., 2005); the males of this species emit both **3** and **4**. Males of *Aphthona flava*, *A. czwalinae*, and *A. cyparissiae* also produce **3** and **4** as well as **5** and **6**, with the proportions of each being species specific (Bartelt et al., 2001). Such a situation might be expected if the species share a common habitat and if the suites of compounds serves as pheromones, but field bioassays with synthetic compounds have not yet been conducted for the *Aphthona* species.

Further enhancement of field attractant lures may be possible once true emission rates of **1–6** from *E. fuscula* males are determined, taking into account distortions in ratios caused by chemical changes occurring before analysis (i.e., **1** isomerizing into **2**) or during analysis (i.e., **5** and **6** dehydrating into **3** and **4**). Additional compounds (i.e., other 2,4,6-nonatrienal isomers, or plant volatiles) may also increase attraction. Finally, finding a delivery system that will avoid or minimize the isomerization of **1** into **2** is also needed. In spite of these unresolved issues, a new pheromone attractant has been demonstrated to be effective in capturing *E. fuscula*, and adds to the growing list of pheromone systems identified in the flea beetle family.

Acknowledgments We are grateful to Anne Patterson of Living Earth Farm for assistance and to Richard Stessman and Nathan Deppe for growing and tending eggplants at the NCAUR garden plots. David Weisleder and Karl Vermillion of NCAUR acquired the NMR spectra. Dr. Alexander S. Konstantinov (Chrysomelidae), Systematic Entomology Laboratory, Agriculture Research Service, US Department of Agriculture, provided insect identification.

significance of avian odors has received relatively little attention. Weldon and Rappole (1997) suggested that avian odors may be indicative of chemical defense or unpalatability. Few endogenous chemical defenses have been documented, but exogenous defenses, applied to plumage and nests, may be widespread (Simmons, 1966; Clark and Mason, 1985, 1988; Ehrlich et al., 1986; Clayton and Vernon, 1993; Gwinner et al., 2000; Lafuma et al., 2001; Parkes et al., 2003; Weldon, 2004). The best known examples of endogenous chemical defense among birds are the Pitohuis and *Ifrita kowaldi* of New Guinea (Dumbacher et al., 1992, 2000). These species apparently sequester batrachotoxins, a potent class of neurotoxins, from dietary sources such as Choresine beetles (Family Melyridae; Dumbacher et al., 2005). The concentrations can be sufficient in skin and plumage to act as a deterrent against parasites and predators (Dumbacher et al., 1992, 2000; Dumbacher, 1999). However, chemical characteristics of these neurotoxins vary widely within and among species, consistent with evidence that they are acquired from an environmental source (Dumbacher et al., 2000). Two species of pitohuis (“hooded” *Polyporous dichrous* and “variable” *P. kirhocephalus*) emit a sour odor that is hypothesized to serve as an olfactory warning of the birds’ poisonous characteristics (Dumbacher et al., 1992). The chemical odors of pitohuis have not yet been characterized qualitatively or quantitatively.

Crested auklets (*Aethia cristatella*) produce a citruslike odorant dominated by even-numbered aldehydes (6–12 carbons) that may function as an ectoparasite repellent and signal of mate quality (Douglas et al., 2001, 2004; Hagelin et al., 2003). Two of the primary constituents are potent invertebrate repellents, and synthetic analogues of the crested auklet odorant repel, paralyze, and kill ectoparasites in a dose-dependent fashion (Douglas et al., 2001, 2004, 2005b). The efficacy of synthetic analogues is comparable to that of commercial arthropod repellents (Douglas et al., 2005b). Brief exposure of auklet lice to *in situ* concentrations of the odorant in tissues caused paralysis and mortality; however, suspension of pigeon lice above crested auklet feathers had no effect on survivorship compared to controls (Douglas et al., 2005a).

This report presents a method for comparison of odor production in live crested auklets that can also be applied to other vertebrates. In this method wild birds were captured and confined in a purified and regulated airstream, and the birds’ emissions were captured onto polymer traps. This method offers several advantages. First, it is not necessary to harvest tissues. Chemical concentrations vary considerably within an individual crested auklet’s plumage, and a large sample of feathers is probably necessary to obtain an accurate mean quantitative value (Douglas, 2006). This would compromise the bird’s thermal insulation and its fitness. Second, the method isolates measurements of the birds’ chemical emissions from potential environmental contamination. Third, the method yields accurate and precise duplicate measurements of specific compounds, and these measurements can be calibrated against known standards. Portable industrial instruments designed for detection of volatile organics are not sufficiently specific or accurate for this type of research application. The method described here provides a quantitative comparison of chemical emissions in live birds that does not compromise their fitness in any way.

Methods and Materials

Field Methods Research on the chemical odor of crested auklets was conducted at a colony on Big Koniuji Island, Alaska, from June 4 to July 16, 2002. In terms of phenology, this period corresponded with the onset of egg-laying to early chick rearing. The colony is situated in an ancient glacial cirque at 243 m elevation on a mountain overlooking Yukon

Harbor. The crested auklet nests in rock talus, high on the steep slopes of this cirque. It is the only seabird species that nests in the cirque. Breeding adults synchronized visitations each morning during the incubation period, gathering in a large flock in Yukon Harbor prior to visiting the colony. Birds arrived on the colony surface in a large flock and were captured in noose carpets strung over landing rocks. Each bird was measured, banded with a USFWS metal band, color bands, sampled, sexed by bill characteristics (according to Jones, 1993a), and inspected for ectoparasites.

Each bird was then placed into a glass reaction kettle, and volatile emissions were collected in a purified airstream. The flow rate of 1.0 l/min delivered oxygen at a rate of 0.2 l/min (dry atmospheric air = 20.95% oxygen; Schmidt-Nielsen, 1997), which was more than sufficient to supply the oxygen consumption needs of a 300-g nonpasserine bird (0.25 l/h at rest; Lasiewski and Dawson, 1967). Air temperature during volatile collections was 6–10°C. Duration of sampling was measured with a stopwatch. Volatile emissions were collected for 50 min on all except six birds. The period of collection for those six was reduced to 30 min. Gas chromatography (GC) peak areas for octanal were adjusted to account for the difference in collection times. The adjusted values for those six individuals lay within the range of other values in the sample. After GC-mass spectrometry (MS) analysis, peak values for all samples were normalized to a 50-min collection time (CT) with the following equation: $50 \text{ min}/\text{CT} * \text{peak area} = \text{adjusted peak area}$. Collection traps were eluted with 2.0 ml of methanol, and the elution was collected in borosilicate glass vials (3/8 oz; Fisher Scientific), sealed with Teflon-lined caps and a vapor seal (DuraSeal

Fig. 1 Volatile collection system for measuring chemical emissions. Regulated and purified air is pulled by battery-operated vacuum pump into glass reaction kettle containing live crested auklet. Volatile emissions are captured onto polymer traps that are placed in the exiting air stream.

stretch film). The chambers were scrubbed with baking soda, rinsed with freshwater, and dried with a clean cotton towel between each sampling.

Design of Volatile Collection System The design of this system benefited from the study of similar methods used to collect plant volatiles (e.g., Turlings et al., 1991). The collection chamber (Figure 1) consisted of a 4000-ml Pyrex reaction kettle (Corning # 6947-4 L) and kettle lid (VWR 36393-051) clamped securely with a kettle clamp (VWR Cat. No. 36393-051). All tubing and fittings were glass or Teflon. The incoming airstream was filtered through a glass dispersion tube (Lab Glass UA-71801-11950, extra coarse porosity 170–220) and then an in-line charcoal filter (Whatman Carbon Cap). This purified airstream entered the chamber through a 24/40 glass elbow (LabGlass LG-1980-100). The outgoing airstream was split, exiting through two 24/40 glass elbows into two glass collection traps. The collection traps were custom manufactured by Lab Glass (Vineland, NJ, USA) and adapted from a design described in Turlings et al. (1991). Each trap was 6 cm long by 9 mm outer diam (6 mm ID). The tube was fitted with a 325-mesh stainless steel frit sealed across the diameter of the tube, 20 mm from the downstream end. Glass collection traps were packed with Super Q (80–100 mesh; Alltech, Deerfield, IL, USA) or Tenax (35/60 mesh; Alltech). These traps were conditioned under vacuum in a Bullet Dryer at 225°C for 14 hr prior to shipping to the field site. The polymer (50.0 mg) was placed on top of the frit and held in place with a small plug of glass wool. Air exiting from these collection tubes was passed through Gilmont flow meters hooked up to a battery operated vacuum source (Cole Parmer Model # 7530-25). Flow rate was regulated at 500 ml/min through each trap. Flow meters were factory calibrated prior to the field season, and calibration of the flow meters was checked again after fieldwork. This calibration was performed with Sierra 820 Mass Flowmeter, and SE was ± 0.41 ml/min. The volatile collection system was calibrated in the field by passing 3.0 ml of synthetic octanal through a bubbler, placed in line (Ace Midget Bubbler with 145–175 μm filter; Ace Glass Inc., Vineland, NJ, USA). This calibration was run exactly as performed with crested auklets, with the volatile collection system operating for 50 min. The calibration was performed once at the end of the field season to avoid contamination of equipment and samples with standards.

Chemical Analysis GC-MS was carried out in the SIM mode (selective ion monitoring) with an HP5890 Series II Gas Chromatograph equipped with a 20 m \times 0.25 mm, 5% phenyl siloxane column (Alltech), and an HP5972 Series Mass Selective Detector. The injector and detector temperatures were maintained at 250°C throughout, and the column flow was 1.0 ml/min. The instrument was programmed from 60°C to 250°C in two stages. The first stage increased at a rate of 4°C/min to a final temperature of 120°C, and remained at that temperature for 4 min. The second stage increased at a rate of 8°C/min to a final temperature of 250°C, and remained at that temperature for 2 min. Octanal was selected as an index of chemical potency because it is consistently the most abundant constituent in the crested auklet odorant (40%; Douglas et al., 2001), and it is also strongly repellent to ticks (Douglas et al., 2004). Retention time and ion abundances were obtained in EI mode from standard (99% Octanal, ACROS Organics, C.A.S. 124-13-0), and results were consistent across five replicates at different concentrations. The most abundant ions were chosen for monitoring, and dwell times (ms) were set for each ion according to its relative abundance (ion/dwell time: 43.0/100, 41.0/80, 44.0/70, 57.0/30, 84.1/30). Subsequent analyses of standards in SIM mode showed that these parameters consistently discriminated octanal from background and obtained well-defined peaks.

Quality control was assured by the inclusion of blanks, duplicates, internal standards, augmented standards, and calibration standards run at intervals in sequences at the frequency of 5–10% of total samples. Standards were made by serial dilutions in methanol (ACROS Organics HPLC grade). Undecenal (97% Undecyclic Aldehyde, ACROS Organics, C.A.S. 112-45-8) was used as an internal standard, and was added to all samples. Blanks with the internal standard were also included in the sequence. Precise quantities of standards were measured with an Eppendorf Pipette (Model 4710). Accuracy and precision of the pipette were determined by replicate weighing of 10- μ l samples of distilled water with a Mettler AE163 analytical balance ($x = 9.94 \times 10^{-3}$ g; $SE = \pm 8.38 \times 10^{-5}$; $SD = 3.25 \times 10^{-4}$).

GC-MS variability was addressed by calibrating response factors of the target analyte and the internal standard. A series of calibrations was conducted at four concentrations of octanal and undecenal (3.8×10^{-3} , 4.8×10^{-3} , 6.0×10^{-3} , and 9.0×10^{-3} μ l/ml) to obtain the regression of relative response ($R^2 = 0.96$, $P < 0.001$, $N = 22$). The following regression equation was obtained:

$$\text{Octanal Peak Area} = 7.58 * (\text{Undecenal Peak Area}) + 14135$$

For each sample, the difference between the obtained and expected GC peak areas of the internal standard was calculated. This difference in undecenal peak area was applied in the regression equation above, and the value was added to the obtained value for octanal.

Duplicate samples were collected for all birds. However, the Big Koniuji colony is located in a rugged spot, and some samples were lost due to damage to the sample vials. Some samples were expended in the testing and calibration of analytical methods. I analyzed 103 samples from 57 individuals—46 individuals with duplicate split samples and 11 individuals with single split samples. Results obtained for Tenax and Super-Q volatile traps in the 46 duplicate split samples were similar. Standard error of splits, expressed as a percentage of peak area, was 8%. In the case of duplicate split samples, average octanal peak area was used as a relative index for chemical potency. In the cases where only single splits were available, the obtained value for octanal peak area ($\pm 8\%$) was used as the relative index. Quantitative measurements, obtained from field calibration with synthetic octanal and bubbler, were used to calculate emission rates for the birds.

Evaluating Ectoparasite Abundance A visual inspection method, similar to that described in Clayton and Walther (1997), was used as a relative measure of ectoparasite prevalence and abundance. A subsample of crested auklets ($N = 12$) was fumigated with carbon dioxide (as described in Visnak and Dumbacher, 1999), and dusted with pyrethrum (as described in Clayton and Walther, 1997) to evaluate the accuracy of the visual inspection method. Ticks were identified as *Ixodes uriae* by Lance Durden and were deposited in the U.S. National Tick Collection (curated at Georgia Southern University) under accession number RML 123386. Lice were identified by Dale Clayton as belonging to the genera *Austromenopon*, *Quadriceps*, and *Saemundssonina*, and these lice were deposited into the frozen collections of the Price Institute for Phthirapteran Research at University of Utah.

Results

Chemical emission rates differed among individuals, but not between the sexes. Measurements from the field calibration obtained a mean peak area of 277,424,557 ($SE = \pm 4,586,885$)

from 3.0 ml octanal passed into the volatile collection system. Applying this calibration, the average chemical emission for crested auklets was $5.7 \mu\text{l octanal}/50 \text{ min} \pm 0.42$ (peak area = 529,800; SE = $\pm 38,800$ or 7% sample mean). There was a sevenfold difference between the highest and lowest chemical emissions. A male had the highest chemical emission at $19.9 \mu\text{l}/50 \text{ min}$ (PA = 1,842,816), and the lowest chemical emission was also a male at $2.8 \mu\text{l}/50 \text{ min}$ (PA = 262,271). Male and female auklets did not differ in chemical emission rates, $t_{(0.05)\text{two-tailed}} = 0.44$, $P = 0.66$. The mean value for male auklets was $5.6 \mu\text{l}/50 \text{ min} \pm 0.52$ (PA = 518,900; SE = $\pm 48,500$, $N = 41$) vs. $6.0 \mu\text{l}/50 \text{ min} \pm 0.68$ (PA = 557,900; SE = $\pm 62,600$, $N = 16$) for females. Measurements were also obtained for one subadult male and female with well developed ornaments. The male emitted $4.4 \mu\text{l}/50 \text{ min}$ (PA = 405,974), and the female emitted $8.8 \mu\text{l}/50 \text{ min}$ (PA = 813,506).

Most birds had no ticks, despite a high abundance of *I. uriae* ticks on the colony surface. The individual with lowest octanal emission had 14 ticks attached between the rictal plate and eye on the left side of the face. All of these ticks were in the process of obtaining blood meals. Prevalence of tick parasitism was low. Only 2 out of 96 auklets examined by visual inspection methods had ticks (just 2% of the population sampled). The second auklet had 2 ticks attached to its face. Results for the visual inspection method were similar to results for the combined methods of fumigation and dust ruffling. Only one tick was found on 12 crested auklets by the combined methods of fumigation and dust ruffling. The low abundance of ticks on auklets was remarkable considering our own encounter rate with ticks in the colony. We noted 5–10 ticks on our pant legs per hour while sitting in the colony. We counted as many as 20 ticks questing (host-seeking behavior) within small areas ($0.37\text{--}0.91 \text{ m}^2$) on the surface of large landing rocks where auklets alighted.

Visual inspection suggested that the prevalence and abundance of lice were low. Lice were found on 4 of the 96 birds inspected, an infection rate of 4.2%. Comparison of the visual inspection method with fumigation and pyrethrum dusting was in agreement with results from visual inspection. Only one louse was found by fumigation, and only one louse was found by dust ruffling on 12 crested auklets. No more than four lice were found on any bird, including specimens that were collected for dissection.

Discussion

Differences in octanal emission rates may be related to the ability to produce odor. Higher emission rates probably represent a higher expenditure of lipid reserves since the aldehydes appear to be products of fatty acid synthesis (Douglas 2006). The male with the highest chemical “potency” in this study would have expended a minimum of 0.57 ml lipid per 24 h in order to consistently maintain the same level of emissions. The male with the lowest chemical potency would have expended approximately seven times less.

The prevalence of tick parasitism on adult crested auklets in this study (2.1%) was unexpectedly low considering the high abundance of ticks in the colony. Two species of Pitohui birds (New Guinea) known for chemical defenses also exhibited a lower than expected infection rate from ticks (3.1%, $N = 32$) compared to other genera of passerines (Mouritsen and Madsen, 1994). The tick infection rate reported here for crested auklets was much lower than what has been found in other subpolar seabird colonies where parasitism by *I. uriae* ticks has been studied. Infestations in subarctic colonial seabirds have been documented in as high as 70% of the adult population (Barton et al., 1996), and intensity of *I. uriae* infestations in some subantarctic seabird colonies may be sufficient to cause mortality in adult king penguins (*Aptenodytes patagonicus*; Gauthier-Clerc et al., 1998).

Higher rates of octanal emission in crested auklets may be associated with lower incidence of tick parasitism. Aldehydes could interfere with four stages of *Ixodes* tick parasitism—engagement, exploration, penetration, and attachment (described in Kebede, 2004). Crested auklets thrust their bills and faces into the scented nape feathers of conspecifics (“ruff-sniff” behavior) during courtship and social behavior (Jones, 1993b; Hunter and Jones, 1999; Hagelin et al., 2003; Jones et al., 2004). This behavior may provide crested auklets an opportunity to evaluate chemical potency of prospective mates (Douglas et al., 2001, 2004; Douglas, 2006). Crested auklets also engage in a mutual anointment behavior that helps to distribute aldehyde secretions to body regions where crested auklets cannot self-preen (Douglas, 2006). Anointment of facial skin and plumage around the head and neck could help to deter ticks and interfere with the intraspecific chemical signaling that ticks use to locate attachment sites on the host (Sonenshine, 1985). In fact, aldehyde concentrations in crested auklet plumage are sufficient to reduce tick locomotion (Douglas, 2006). Below some threshold of chemical defense, crested auklets are likely to be more vulnerable to tick parasitism. In this study, the crested auklet with the lowest chemical emission rate (half the population mean) was parasitized by 14 ticks clustered together between the eye and rectal plate. Ticks often attach around the eyes of birds because the skin is thin, and the area cannot be preened by the host (Reed et al., 2003). Chemical potency and associated repellence of ectoparasites may be a basis for mutual sexual selection in crested auklets (Douglas et al., 2001, 2004; Douglas, 2006).

The louse infection rate among crested auklets at Big Koniuji Island, as best could be determined, was 4.2%. Similarly, there was a very low infection rate at another mono-specific colony of crested auklets. No lice were found on 80 adults at Talan Island (see Douglas et al., 2004 for details). By contrast, the prevalence and abundance of lice were much higher in a mixed-species colony that included both crested auklets and least auklets (*A. pusilla*) at St. Lawrence Island, Alaska (Douglas et al., 2005a). Among these crested auklets, there was a 100% infection rate ($N = 21$), and the intensity of infection (adult + juvenile lice) ranged from 8 to 91 lice per bird (Douglas, unpublished data). Numerical results are not directly comparable because data for Douglas et al. (2005a) were obtained by body washing, which is a more accurate method than visual inspection (Clayton and Drown, 2001). Nevertheless, a qualitative difference can be inferred. To the extent that it has been evaluated, the prevalence of louse infections in crested auklets is higher at mixed-species colonies.

This study reports on a novel research application for estimating chemical emission rates in crested auklets. The method has several advantages. Accurate quantitative estimates of chemical production and emissions can be obtained for live vertebrates without harvesting tissues that might jeopardize the animal’s fitness. The live specimen is isolated in a leak proof chamber supplied with a purified airstream. This eliminates the possibility of contamination from plant volatiles, insects, and naturally occurring materials. Flow rate is regulated, and this is critical for determining rates. The quantitative measurements can be calibrated to known standards. The methods reported here could be applied to other vertebrates to study the relationship of chemical emissions to a range of studies including hormones, mate selection, reproductive behavior, or parasitism.

Acknowledgments Laboratory analyses were made possible by the support of the Dept. of Chemistry and Biochemistry, Univ. of Alaska Fairbanks. Professors R. Stolzberg and T. Clausen offered suggestions and assistance. Research was supported with grants from the Eppley Foundation for Research, Inc., and the

Angus Gavin Memorial Bird Research Fund, Univ. of Alaska Foundation. Logistical support was also provided in part by a grant from the Center for Global Change and Arctic System Research sponsored by the Alaska Sea Grant College Program. A. Springer helped support this research. A. Kelly and A. Maccormack assisted with fieldwork. J. Galvin and the Rita B F/V provided logistical support. The Alaska Maritime Natl. Wild. Refuge and the Aleut Corp. granted research permits. T. Jones, W. Conner, and W. Simpson offered suggestions on design of the volatile collection system. Ø. Tøien checked the calibration of flowmeters.

Introduction

Allelopathy is a direct or indirect effect of one plant on another through the production of chemical compounds that are released into the environment (Rice, 1984). Many allelochemicals are toxic to higher plant growth, even at low concentrations, and they can have effects on seed germination. As a consequence, allelopathy may be involved in regulating density and distribution of species in natural settings. Inhibition of seed germination and root growth in response to chemicals released by many species including sorghum (*Sorghum bicolor*), wheat (*Triticum aestivum*), and rye (*Secale cereale*) have been consistently reported in the literature (Inderjit and Callaway, 2003; Inderjit and Duke, 2003; Weston and Duke, 2003).

Sunflower (*Helianthus annuus* L.) can actively influence the growth of surrounding plants. Dried sunflower residues and leaf powder incorporated in the soil reduced the growth of sorghum, soybean, and sunflower itself (Irons and Burnside, 1982; Schon and Einhellig, 1982). Leather (1987) demonstrated selective phytotoxicity of sunflower residues towards weeds. Batish et al. (2002) observed the reduced growth of *Cyamopsis tetragonoloba*, *Pennisetum americanum*, *Zea mays*, and *S. bicolor* in fields with sunflower residues, and attributed this to phenolics released from decomposing tissue of sunflower. Macias and coworkers have isolated more than 240 natural compounds from different cultivars of sunflower (Macias et al., 2002). In commercial crops of *H. annuus*, many terpenoids including monoterpenes, sesquiterpenes lactones, diterpenes, triterpenes, and two new families of sesquiterpenoids, heliannanes and helispiranes, have been identified (Macias et al., 2000, 2002 and references therein). Most of those compounds inhibited germination of *Lactuca sativa* at concentrations lower than 10^{-8} M (Macias et al., 2001). Although the inhibitory effect of phytotoxins in sunflower leaves extracts or crop residues on germination of various seeds has been reported previously (Azania et al., 2003), their mode of action has not yet been demonstrated.

Maturing seeds of white mustard accumulate food reserves as storage oils (60%) and insoluble proteins (40%) (Bewley and Black, 1994). During seed germination, proteins are first hydrolyzed by endopeptidase to soluble peptides that are subsequently degraded to oligopeptides and aminoacids (Bewley and Black, 1994). In mobilization of triacylglycerides in seeds, the glyoxylate cycle plays a key role to effect net gluconeogenesis from the acetyl-CoA derived by oxidation. The enzymes of the glyoxylate cycle such as isocitrate lyase (ICL, EC 4.1.3.1) increase their activity during maximum fat metabolism in specialized fat microbodies (glyoxysomes) located in the storage tissue of germinating seeds. Seed germination requires a fine balance between glycolysis and the oxidative pentose phosphate pathway reject, to ensure a sufficient supply of reducing power, ATP, and carbon skeletons for further biosynthesis. High mitochondrial respiration rates occurring in catabolic phases of germination, just after imbibition, support energy supply for growth processes and result in radicle protrusion.

Since undisturbed reserve mobilization is an important requirements for germination as well as subsequent plant growth and development, we investigated the influence of water extracts of sunflower leaves on catabolic processes taking place during mustard seed germination. We measured also O₂ uptake by intact seeds and energy metabolism by determining adenylate (ATP, ADP, AMP) concentrations in tissues of germinating seeds. Additionally, changes in ultrastructure of germinating seeds provoked by the presence of sunflower phytotoxins were observed.

Methods and Materials

Plant Material and Growth Conditions Leaves from field grown sunflower cv. Ogradowy were harvested at the beginning of the flowering stage. Tissue was air-dried, and ground to obtain

a fine powder. A 10% (w/v) water extract was formulated and used as a source of phytotoxic compounds as described by Bogatek et al. (2006). Cation exchange capacity (CEC) of the resultant extract was measured with a Wescor Dew Point Microvoltmeter, model HR-33T.

Mustard seeds (*Sinapis alba* L.) were germinated in 9-cm Petri dishes (50 seeds per dish) on filter paper moistened with distilled water (control) or with a 10% (w/v) water extract from sunflower leaves at 20° C in darkness. Additional experiments were performed with seeds allowed to imbibe an aqueous PEG (polyethylene glycol) 8000 solution (28.5% w/v), characterized by CEC equal to that of the sunflower foliar extracts. Treatments were arranged in a completely randomized design with four replications. Germination percentages were determined after 18 hr (0.75 d) and then every day for 8 d. Seeds were considered germinated when the radicle visibly protruded from the seed coat.

Seed viability was estimated by using a standard tetrazolium test. Seeds were incubated in 1% (w/v) solution of 2,3,5-triphenyl tetrazolium chloride for 8 hr at 30°C in darkness. Seeds with nonstained embryos were scored as nonviable. The experiments were repeated 3–4 times.

Adenosine Phosphate Assay Adenosine phosphates were extracted from seeds according to Olempska-Beer and Bautz-Freeze (1984). ATP, ADP, and AMP contents within the extracts were measured with the bioluminescence method with a pico-ATP biophotometer (Jobin et Yvon, France), as described by Saglio et al. (1979). The results are expressed as pmol mg⁻¹ DW, and values were obtained from five independently prepared extracts. The energy charge (EC) was calculated by the ratio (ATP+0.5 ADP)/(ATP + ADP + AMP).

Gas Exchange Oxygen consumption was measured with a Hansatech gas-phase oxygen electrode unit type LD1/2 supported by the Oxygraph Plus system at room temperature in darkness. Intact seeds (50–100) rinsed with distilled water were put into a 20-ml container with an oxygen electrode, and changes in O₂ concentration were determined over the course of 30 or 60 min for dry seeds. Results are expressed as μmol O₂ g⁻¹ DW min⁻¹ and represent values obtained from at least five independent experiments.

Enzyme Extraction and Determination Seeds (1 g) were rinsed with distilled water and homogenized in 10 ml extraction medium containing: 0.05 M phosphate buffer pH 7.6, 10 mM MgCl₂, 1 mM ethylenediaminetetraacetic acid (EDTA), and 1 mM dithiothreitol (DTT) in an ice bath. The homogenate was centrifuged for 20 min at 15,000 g at 4°C. The resulting supernatant was filtered through a column Pharmacia 10 PD equilibrated with 0.05 M phosphate buffer pH 7.6. The resulting enzymatic extract was used immediately for the ICL assay and a protein content determination.

ICL activity (threo-D₅-isocitrate glyoxylate lyase, EC 4.1.3.1, ICL) was determined according to the procedure described by Bogatek et al. (1989). The reaction mixture contained the following: 0.05 M phosphate buffer pH 7.6, 10 mM MgCl₂, 1 mM EDTA, 5 mM DTT, 3.3 mM phenylhydrazine hydrochloride, 4 mM, D-isocitric acid (Sigma, 49.4% from threo-D₅-isocitrate), and the enzyme extract. Enzyme activity was expressed in nmol of glyoxylate released within 1 hr per mg protein.

Proteins were determined according to the procedure described by Bradford (1976) with bovine serum albumin (BSA) as a standard.

Microcalorimetric Measurements Analyses of thermal energy (μW) released from seeds were conducted in an isothermal microcalorimeter (BioActivity Monitor 2277) at 20°C for 40 hr. Twenty ml ampoules equipped with lids that enabled air exchange were used. Five seeds were put into an ampoule, heated for 25 min, and placed into the measurement

chamber. Seeds were germinated for 40 hr on filter paper moistened with sunflower foliar extract. The reference treatment consisted of an ampoule where only filter paper was moistened with extract. Seeds germinating on filter paper moistened with water only were utilized as a control. Heat emission was recalculated per 0.1 g DW. Measurements were performed with five replications.

Microscopic Observations Small blocks of tissues from cotyledons, radicles, and basal parts of the hypocotyl were fixed according to the procedure described by Karnovsky (1965) after 0, 0.75, 1.5, and 2 d of imbibition in water or in aqueous extracts of sunflower foliage. Samples were also collected from seeds that had imbibed sunflower extract for a period of 8 d. After 24 hr of postfixation in 1% osmium tetroxide, samples were dehydrated through a graded ethanol series and embedded in Epon 812. Ultrathin sections were stained with uranyl acetate and lead citrate (Reynolds, 1963) and viewed with a JEOL 1200X electron microscope.

Data Analyses Data are presented as means \pm standard errors of the means (SEM). ANOVA with Duncan's multiple range test was used to evaluate the data. Statistical analysis was performed by means of the StatSoft Statistical program.

Results

Germination Almost all (96%) untreated (control) mustard seeds germinated within 4 d (Table 1), and their prolonged culture resulted in the formation of etiolated seedlings. Aqueous extracts of sunflower leaves resulted in nearly complete reduction in germination of mustard seeds. After 8 d of treatment, only 4% of the seed population germinated, but no visible growth was observed. They continued throughout the course of the experiment to remain at a stage comparable to control seeds after 18 hr. Therefore, seeds after 18 hr (0.75 d) of imbibition in water were regarded as a potential control for comparative purposes to treated seeds due to their similar morphological and physiological growth stage. Moreover, water uptake by mustard seeds during the first 18 hr of imbibition of sunflower extracts was not statistically different from seeds germinated in water (data not shown). The CEC of sunflower extract was observed to be -1.1 MPa.

To check the influence of water potential upon germination, we used a 28.5% (w/o) PEG solution characterized by equal $\Psi = -1.1$ MPa. Reduced water potentials resulted in delayed seed germination, but more than 50% of seeds that imbibed in PEG germinated within 8 d (Table 1). At the end of second week of culture, 75% of PEG-treated seeds germinated. Moreover, almost all of them (90%) remained viable, indicating that alterations in seed germination were more likely attributable to toxicity of sunflower extracts than to water stress. The low germination of seeds in the presence of sunflower extracts was not correlated with seed viability. Only a slight decrease in seed viability was detected during the first 5 d of incubation in sunflower extracts (Table 1). Treatment longer than 2 wk was lethal, and tetrazolium evaluation showed that all seeds were dead (Table 1).

Microscopic Observations There are three types of organelles containing storage materials in white mustard embryos: (1) protein bodies with small, angular-shaped globoids embedded in densely stained, amorphous matrix; (2) myrosin grains; and (3) spherical oil bodies, with well-defined boundaries, closely packed together but never coalescing.

Fig. 1 Morphology of storage materials prior to imbibition. Radicle cell filled with numerous oil bodies and large protein bodies (pb)

Fig. 2 (a, b) Control, 18 h incubation. After protein body (pb) digestion, arrowhead indicates cisterna of rough ER. (c) Control, 36 h incubation. Fusion of protein bodies (pb) during proteolysis

At the start of imbibition, only a few densely stained cells were observed, and indications were that cells were filled with storage materials, especially with oil bodies. Plastids and mitochondria were not distinguishable (Fig. 1). During the first 48 hr of incubation, protein and oil bodies remained undigested in the cotyledons. Mobilization of storage reserves was evident only in the axis of the embryo, both in the control and in treated seeds. Structural changes accompanying this process were visible first in the region of the root–hypocotyl boundary, and progressed acropetally towards both apices. Differences in degree of storage material digestion were also observed across the axis. Degradation of protein bodies was first initiated in the protoderm, then in the cortex, and finally in the stele.

After 18 hr of aqueous incubation, in the protoderm cells, protein bodies appeared to undergo structural changes during proteolysis. Irregular, light areas first appeared near the membrane, and then progressively increased toward the center of each protein body. The only densely stained, amorphous matrix lost its electron opacity. Remnants of storage proteins were later visible as clumps of fibrous material, which gradually disappeared. Finally, vacuoles developed as a result of proteolysis (Fig. 2). Autophagy was likely another means for vacuolar system development, which was manifested by circular cisterns of ER with sequestered cytoplasm, as the first step of autophagic vacuole formation (Fig. 4a). Protein bodies were not degraded in the embryos treated for 18 hr with the sunflower extracts. Numerous rod-shaped structures with tripartite profiles appeared near the oil bodies, and some of them were visible as connections between two oil bodies (Fig. 3a, b).

Fig. 3 (a, b, d) Sunflower allelopathic extract, (c) control, 36 h incubation. Partially depleted oil bodies (ob) so-called saccules; arrowheads indicate ring or rod-shaped membranous appendages

Fig. 4 (a) Control, 18 h incubation. Initial step of autophagic vacuole formation: part of cytoplasm with mitochondrion (m) and small vacuole sequestered by ER cistern. (b) Control, 48 h incubation. Large vacuoles (v) formed as the result of storage protein digestion

Morphology of mitochondria and increased amounts of rough ER cisterns, proplastids, and dictyosomes indicated an increase in metabolic activity of the cells in both the control and treated embryos during the first hours of imbibition.

As imbibition progressed, digested protein bodies also were visible in the cortex and stele cells of control embryos. Vacuoles formed from protein bodies increased in

numbers and fused to form large centralized vacuoles. These vacuoles were often connected with nearly initiated autophagic vacuoles (Fig. 4b). At the same time, various stages of partly depleted oil bodies were visible in the embryos of the controls as well as in treated seeds. Lipid body membranes formed interesting local invaginations leading finally to concave “sacculles”. In two dimension views, sacculles appear as ring-shaped structures (Fig. 3c, d).

Number of oil bodies, as well as connecting structures, significantly decreased in control embryos, and eventually in the protoderm cells later in all layers of the radicle (Fig. 5a). In embryos of seeds germinating in sunflower extracts, protein bodies remained unaltered and numerous. A considerable number of oil bodies were also visible in the cells of radicles and hypocotyls (Fig. 5b).

After 8 d imbibition of sunflower phytotoxins, seed coats of nearly all seeds remained unbroken, indicating complete inhibition of radicle growth. The protein bodies matrices were divided into dense lumps accumulating closely to surrounding membranes. Abnormally dense cytoplasm with weakly discernible organelles (Fig. 5c) indicated that embryos were significantly injured over time.

Isocitrate Lyase Activity Transformation of lipids to sugars, expressed as the activity of ICL, was markedly inhibited in seeds imbibing sunflower extracts. After 18 hr of germination in the presence of sunflower extracts, ICL activity in mustard seed was reduced twofold in comparison to the control. Activity decreased progressively during the experimental period, being almost undetectable after 8 d (Fig. 6).

Gas Exchange and Energy Metabolism Oxygen uptake by intact dry seeds was low and increased during the first 18 hr of imbibition (Table 2). In treated seeds, oxygen uptake was 50% that of the control, and remained constant till the end of culture (Table 2).

Changes in ATP, ADP, and AMP concentration and the adenylate pool ($\Sigma = \text{ATP} + \text{ADP} + \text{AMP}$) during germination of mustard seeds are shown in Table 3. In dry seeds, ATP, ADP, and AMP concentrations were 8.2, 27.0, and 83.0 pmol mg⁻¹ DW, respectively, representing 7%, 23%, and 70% of the total adenylate pool. ATP concentration increased sharply during the first 18 hr of imbibition; however, in treated seeds, concentration was twofold lower than in the control, reaching 197 and 398 pmol mg⁻¹ DW, respectively, and remained about 200 pmol mg⁻¹ DW until the end of experiment. ADP concentration in both control and treated seeds increased similarly during the first 18 hr of germination, while a slight decrease in AMP concentration was detected (Table 3). As a consequence, the energy charge, which was low in dry seeds (0.18), sharply increased in seeds of both conditions of culture (Table 3). It remained about 0.67–0.70 during the 8 d of culture, although seed viability decreased (Table 1).

Metabolic Heat Production The heat efflux from seeds germinating in water was expressed as a continuous increase from 53 $\mu\text{W } 0.1 \text{ g}^{-1} \text{ DW}$ at the start to 250 $\mu\text{W } 0.1 \text{ g}^{-1} \text{ DW}$ at the

Fig. 7 Metabolic heat emission by white mustard seeds germinating in water or foliar extracts of sunflowers

40th hr of the culture (Fig. 7). Sunflower phytotoxins altered the typical heat emission pattern observed in control seeds. During first 12 hr, sharp increases in metabolic heat emission were detected, being twofold higher than in the control and reaching values of 165 and 80 $\mu\text{W } 0.1 \text{ g}^{-1} \text{ DW}$, respectively. After 12 hr, heat production decreased and stabilized at about 110 $\mu\text{W } 0.1 \text{ g}^{-1} \text{ DW}$, remaining constant until the end of experiment.

Discussion

One common effect of phytotoxic compounds is the inhibition of seed germination and the resulting abnormalities in seedling development. Standard germination processes consist of several key phases that include imbibition, catabolism, anabolism, and finally radicle protrusion. Therefore, radicle emergence is considered the culmination of the germination process and the starting point for seedling growth. Until this point, growth of the radicle is a result of cell expansion, which is a turgor-driven process (Cosgrove, 1997). It was demonstrated that mustard seed germination and viability were more depressed by sunflower foliar extracts than by the osmotic stress induced by treatment with PEG 8000 solution, characterized by equal CEC ($\Psi = -1.1 \text{ MPa}$) (Table 1). Although the germination process was delayed by low Ψ , almost all seeds remained viable. Thus, the lack of seed germination, observed in the presence of sunflower extracts, appeared to be a consequence of extract phytotoxicity rather than water availability.

During the catabolic phase, storage materials are hydrolyzed and provide substrates for biosynthetic processes and respiration. Phytotoxins produced by different plants are known to lower the total respiration rate in higher plants (Cruz-Ortega et al., 1988; Abraham et al., 2000). In our experiments, O_2 uptake increased sharply in control seeds, representing typical dynamics encountered during catabolic phases of germination, whereas in treated seeds, oxygen uptake was only 40% higher than in dry seeds. The biochemical reactions taking place in living cells are the source of heat emission. Heat is produced particularly during these processes of energy metabolism such as respiration. The microcalorimetric measurements of heat efflux from cells are useful in the estimation of their metabolic activity as well as in the analysis of response to stress conditions (Smith et al., 2000, 2001). The amount of heat emitted by germinating seeds reflects their viability and their reactions to stressors such as toxins or cold temperatures (Edelstein et al., 2001). In control seeds, heat emission was correlated with an increased respiration rate, whereas in seeds imbibing sunflower extracts this correlation was not detected. Maximum heat emission after 12 hr was neither accompanied by high oxygen uptake nor by any increase in ATP concentration. In our previous experiments, increased ROS (H_2O_2) production was detected in mustard seeds after 18 hr of imbibition of sunflower leaves extract (Bogatek et al., 2005). Therefore, we can not exclude the possibility that the transient increase in heat production may be a result of oxidative reactions taking place in seeds exposed to sunflower phytotoxins.

ATP is used in anabolic processes such as RNA and protein synthesis. In dry seeds, the adenylate pool is mainly composed of AMP and ADP (Bewley and Black, 1994). The increased respiration rate during early phases of germination generally results in increased ATP production. Earlier attempts to show a correlation between seed ATP content and germination have yielded conflicting results (Spoelstra et al., 2002), suggesting that the absolute level of ATP observed does not necessarily correlate well with germination. Moreover, ATP concentration is the result of both ATP synthesis and utilization, and depends on turnover of ATP pool. Monoterpenes and quinones present in sunflower extract may act as uncouplers of oxidative phosphorylation leading to a decrease in ATP synthesis. Moreover, inhibition of

cytochrome oxidase and the activation of an alternative respiration pathway has been induced in the past by other allelochemicals (Peñuelas et al., 1996; Abraham et al., 2000).

Reduced respiration rates in treated seeds and the likely inhibition of oxidative phosphorylation resulted in the observed reductions of the adenylate pools. In our experiments, although ATP concentration in seeds treated with sunflower extracts remained lower than in the control (Table 3), concentrations were sufficient to support germination, but perhaps not enough to maintain postgermination root growth. In addition, root growth in the postgermination phase is dependent on the supply of substrates for synthesis derived from reserve mobilization. Sugar content in mustard seeds was relatively low, and it appears that carbohydrates do not play a major role during mustard seed germination. Sucrose concentration in dry seed was also low (11 mg g⁻¹ DW) and decreased rapidly during the first 18 hr of germination to undetectable levels in both control and treated seeds (data not shown).

The initiation of protein mobilization is mediated by proteases, stored in the embryonic axes (Schlereth et al., 2001), so protein reserves are generally degraded early during the germination processes. An increase in total endopeptidase activity was observed in winter *Triticale* grains (Bielawski et al., 1994) and *Vigna mungo* (Hosokawa et al., 1999) seeds during 48–72 hr of germination. In seeds of Brassicaceae, breakdown of storage proteins starts earlier and proceeds faster than mobilization of storage oils. Digestion of proteins in *Brassica napus* is detectable after 24 hr, and is completed by 5 d after initiation. At this time, only 50% of the oil bodies appear broken (Murphy et al., 1989). Our results are consistent with these findings. A significant increase in total endopeptidase activity was detected after 48 hr of germination (data not shown), whereas activity of ICL increased 48 hr after this time. Digestion of protein storage material also was detected at an ultrastructural level. The first signs of proteolysis were visible in protein bodies after 18 hr of imbibition. Similar time courses of protein mobilization have been previously noted in germinating seeds of white mustard (Werker and Vaughan, 1974), where structural changes in protein bodies were visible between 12 and 36 hr. During undisturbed germination, hydrolysis of storage reserves, followed by accumulation of solutes, lowers the osmotic potential of the radicle cells, leading to a marked increase in water uptake and vacuolar volumetric growth (Bewley and Black, 1994). Inhibition of storage protein mobilization results in the lack of a vacuolar system, ensuring that the radicle cells remain in a state unable to support expansive growth.

Inhibition in storage lipid mobilization due to the presence of phytotoxins has been observed in germinating canola (*B. napus*) seeds (Baleroni et al., 2000). Although lipid content decreased slowly in seeds treated with ferulic and *p*-coumaric acids, it was always 50–80% higher than in control seeds. Baleroni et al. suggested that inhibition of seed germination and primary root elongation observed in the presence of these allelochemicals might be attributable to a reduction in lipid mobilization, probably caused by decreased activity of lipolytic enzymes and ICL. Both phenolic allelochemicals strongly inhibited radicle growth during germination of weed species (Reigosa et al., 1999). Data obtained by Maffei et al. (1999) suggest that benzoic acids affect not only ICL enzyme activity but also act at its transcriptional/translational level. The treatment of cucumber (*Cucumis sativus*) seedlings with 3,4-dimethoxybenzoic and vanillic acids resulted in lower ICL activity accompanied by the disappearance of ICL protein in seedlings extracts.

It has also been reported that the appearance of membranous so-called “sacculles” or “lipid-rich membranes” is typical in germinating seeds of Brassicaceae (Wanner and Theimer, 1978). They were originally thought to arise due to removal of the lipid contents faster than reduction of the surface area. Hence, the lipid body coat forms local invaginations, leading finally to collapsed rod-shaped structures with tripartite profiles (Huang, 1992). Localization of activity of alkaline lipase, the enzyme involved in TGA hydrolysis within these structures (Rosnitschek and Theimer, 1980; Lin and Huang, 1983) additionally confirmed their origin.

It has also been demonstrated that in developing *B. napus* seeds TAGs are synthesized within specialized subdomains of the ER and accumulated in the membrane's phospholipid bilayer. Then, nascent oil bodies are released by budding from terminal ends of tubular ER (Lacey and Hills, 1996). Similar models of biogenesis have been proposed for barley, supported by observation that oil bodies remain attached to the ER by long extensions of the outer leaflet of the ER membrane (Bethke et al., 1998). Considering that empty oleosomes "ghosts" were not observed after lipid mobilization, it seems that the rod-shaped structures were rather connections between oil bodies and ER than remnants of oil body coats. The fact that membranous extensions were visible in treated radicle cells after 8 d of extract exposure, when the activity of ICL was inhibited, confirms this interpretation. It seems likely therefore, that only cup-shaped oil bodies might be recognized as a result of partial digestion of storage oils. Both structural changes in oil bodies and initial activity of ICL indicate that breakdown of storage oils started in the embryos treated with sunflower phytotoxins. However, the total number of oil bodies did not decrease significantly, indicating that degradation of storage lipids was stopped. Similar results were described by Lewitt et al. (1984) with alkaloids from *Datura stramonium* in sunflower seedlings. Electron microscopy showed that treated cells contained greater amounts of lipid bodies than control cells.

Our data suggest that the inhibitory effect of phytotoxins in extracts of sunflower leaves on seed germination is mediated through the disruption of normal cellular metabolic processes rather than through direct organelle damage. Metabolism of seed storage reserves in germinating seeds is a process that usually takes place rapidly during early phases of germination. In the presence of sunflower aqueous extracts, metabolic processes are markedly reduced or even stopped in germinating seeds, providing evidence for the rapid impact of certain allelochemicals upon seed germination and ultimately the successful seedling growth of neighboring species.

of both plants and insects, with the resulting induced plant volatiles and/or insect pheromones serving as important infochemicals (Turlings et al., 1990; Vet and Dicke, 1992; Landolt and Phillips, 1997; Reinecke et al., 2002). For example, some chrysomelid beetles are attracted to host plants that are infested or wounded by conspecifics (Bolter et al., 1997; Landolt et al., 1999; Kalberer et al., 2001; Tansey et al., 2005), and increase pheromone production when feeding on the host plant (Smyth and Hoffman, 2003). Once identified, semiochemicals can have useful pest management applications, such as improved monitoring and sampling of natural enemies (Burkholder and Ma, 1985; Howse 1998; Tinzaara et al., 2002).

The cottonwood leaf beetle, *Chrysomela scripta* (Fabricius) (Coleoptera: Chrysomelidae), is the most important arthropod pest affecting *Populus* plantations in North America (Coyle et al., 2005). Both larval and adult feeding can cause growth loss and destruction of leaders and shoots (Caldbeck et al., 1978; Bassman et al., 1982; Coyle et al., 2002). Current management strategies rely primarily on synthetic pesticides, largely because no simple and reliable sampling schemes are available. An ability to attract beetles to traps would greatly enhance development of sampling schemes for integrated pest management. To date, responses to volatiles have not been demonstrated for this insect. However, adult *C. scripta* have been observed to form feeding and mating aggregations on trees, suggesting the potential use of semiochemicals for location of conspecifics.

The first objective of this study was to identify the sources of attraction to *C. scripta*, with particular emphasis on whether these sources are likely to be a pheromone, host plant volatiles, induced plant volatiles, or a combination of herbivore and plant volatiles. The second objective was to evaluate the effectiveness of attractive odor sources in field trials.

Materials and Methods

Plants and Insects

Two-yr-old potted trees of clone DN34 (*Populus deltoides* × *nigra*) were obtained from KF Evergreens (Osseo, WI, USA). Clone NM6 (*P. nigra* × *maximowiczii*) was obtained as dormant cuttings from the USDA Forest Service in Rhinelander, WI, USA, and International Paper Company (Alexandria, MN, USA). Trees were maintained in a greenhouse (18L:6D photoperiod) with an average temperature of 20°C in the winter and 30°C in the summer, and were cultured for a period of 9 mo before being replaced by fresh material from the same sources. Plants were potted in commercial potting mix (Metro-Mix 300; Sungro, Bellvue, WA, USA), watered daily, and supplied with fertilizer via slow release pellets (Osmocote Plus; Scotts-Sierra Horticultural Products Company, Marysville, OH, USA). An additional aqueous fertilizer solution was delivered weekly at 300 ppm (Sunshine Technigro; Sungro, Bellvue, WA, USA). Foliage used for experiments and feeding was collected from actively growing branch terminals, washed in a mild dish-soap solution, rinsed with cold water, and placed in 22 -ml plastic water vials (#53–77; Syndicate Sales, Inc., Kokomo, IN, USA). Processed foliage was housed upright in an ice chest lined with a large plastic bag and stored in a walk-in cooler at 6°C.

A colony was established in the fall of 2004 from *C. scripta* collected in a hybrid poplar plantation near Carlos, MN, USA (45°N 59' 30"W, 95°W 06' 00"W). Beetles were housed in plastic boxes lined with a paper towel, and fed foliage from both DN34 and NM6 trees.

Foliage was supported above the box floor by metal screening. Beetle diet was occasionally supplemented with washed, field-collected foliage during the summer. Rearing boxes were housed in a growth chamber at 23°C and an 18L:6D photoperiod.

Bioassays

Behavioral choice tests were conducted in an olfactometer (122×62×62 cm) housed in a climate controlled room at approximately 23°C with no outside light (Fig. 1). The frame was constructed with wood, the floor was made of fiberboard, and the walls and ceiling consisted of fiberglass window screening. A release port consisting of a hole (7.6 cm diam) fitted with a wide-mouth jar ring was located in the center of the floor, allowing attachment of a 0.24 -l glass jar (Ball Corporation, Bloomfield, CO, USA). Two lucite plates (each 12.7 cm²) were mounted at either end of the ceiling, each having a 7.6 -cm diam. hole fitted with a wide-mouth jar ring. These two plates served as external attachment points for the 0.95 -l glass odor source jars (Ball Corporation), which were inverted above the ceiling.

The plates were roughened with a 40 -grit electric sander to facilitate beetle traction. Each odor source jar was fitted with a cone of aluminum window screening with an entrance hole (1 cm diam.) at the apex that allowed movement into the jar. A second aluminum screen prevented access to the odor source, and the space between the two screens functioned as a trap. Two PVC tubes (1.3 cm inner diam) eter) mounted on lucite bases (15 cm²) on each side of the release chamber facilitated climbing from floor to ceiling. Lighting consisted of two 34-W fluorescent tubes suspended 40 cm above the olfactometer. The ceiling of the olfactometer was hinged to provide access for cleaning.

For each replicate, twenty 1- to -4-wk-old beetles of mixed sex were placed in the release jar. Release and odor source jars containing living specimens contained a folded

Fig. 1 Olfactometer arena used for behavioral choice tests. The floor is solid; all other sides are screened. Insects are released from a central chamber in the floor and allowed to respond to odor sources in jars attached to the ceiling. Each odor source jar is fitted with a conical screen with a 1-cm hole serving as an insect entry. A second screen prevents access to the odor source and functions as a trap. Two vertically spanning posts focus insect activity in the center of the arena between the odor sources. (a) Odor source jars with trap screens, (b) release chamber, (c) beetle ladders, (d) light source

tissue (Kimwipe EX-L; Kimberly-Clark Corp., Roswell, GA, USA) to absorb extra moisture. Clone DN34 was used for all odor sources involving a plant, with sprigs trimmed as needed to standardize them to the meristematic tip through the first eight leaves, or through leaf plastochron index (LPI) 7 (Larson and Isebrands, 1971). Water-filled plastic vials preserved plants during experiments.

The location of odor sources was determined randomly. After 24 hr, non responding beetles were removed, and the response of trapped beetles was recorded. The arena was wiped down with ethanol and then hexane between trials. Odor source jars, release chamber jars, and screen traps were cleaned with a noninterfering cleansing solution (Powdered Precision Cleaner; Alconox, Inc., New York, NY, USA), air-dried, rinsed with ethanol, and then rinsed with hexane between trials. Each test consisted of 10 replicates unless otherwise noted. Insects and plants were used only once.

Test of Odor Source Components

In the first series of experiments, the full complement of odors emanating from plants, beetles, and the plant–beetle interaction was tested against a blank. After this, several putatively attractive components were tested vs. a blank to identify active components. The odor sources were prepared as follows.

- 1) Plant–*C. scripta* complex (beetles feeding on foliage): one sprig of foliage with 20 beetles of mixed sex. The blank control consisted of a water vial and a tissue.
- 2) Unwounded foliage: one sprig of foliage. The blank control consisted of a water vial and a tissue. $N=16$.
- 3) Beetles: 20 beetles of mixed sex. The blank control consisted of a tissue. All responding beetles were dissected to determine sex.
- 4) Frass: frass from 20 beetles that had been feeding on one sprig of foliage for 24 hr. Frass was collected from the wax paper lining of a rearing chamber using a moistened tissue. The blank control consisted of a moistened tissue that had been rubbed across clean wax paper.
- 5) Visual stimulus (green or yellow paper): two colors of laminated paper rectangles (8×14 cm) were tested. The blank control consisted of laminate with no paper inside.

Comparison of Attractiveness of Odor Source Components to the Full Complement of Odors

To determine if any single attractive component was as attractive as the full complement of odors from beetles feeding on foliage, we conducted direct comparisons between sources that proved attractive in the first series of assays. Each component was tested against the plant–*C. scripta* complex as described above and was prepared as follows.

- 1) Unwounded foliage: prepared as described above.
- 2) Beetles: prepared as described above with the addition of a water vial control.
- 3) Frass: prepared as described above with the addition of a water vial control and a tissue. A moistened tissue that had been rubbed over clean wax paper was added to the comparison odor source jar (plant–*C. scripta* complex) as a control.
- 4) Beetle-wounded foliage: one sprig of foliage was placed into a small plastic box and exposed to 20 beetles for 24 hr before being placed in the odor source jar.

Effect of Plant Wounding

To determine whether wounding must be done specifically by feeding, or whether mechanical wounds alter attraction, two comparisons were made to unwounded foliage.

- 1) Beetle-wounded foliage: prepared as described above. $N=11$.
- 2) Artificially wounded foliage: immediately preceding the choice test, one sprig of foliage was treated with a 6 -mm diam hole-punch to simulate a level of defoliation comparable to 20 beetles feeding for 24 hr (100 punches).
- 3) Washed-beetle-wounded foliage: foliage was prepared as for “beetle-wounded,” then hand-washed, and rinsed $\times 3$ in water. The unwounded comparison foliage was also hand-washed and rinsed $\times 3$ in water.

Comparison of Attractiveness of Volatiles Released from Starved vs. Fed Beetles

To discern whether frass plays a role in the attractiveness of volatiles from *C. scripta*, we made a direct comparison between the attractiveness of volatiles released from adults that had been starved for a period of 24 hr and volatiles from adults that had recently been fed.

Field Trapping

We tested the effects of two odors and two colors on trap catches of adult beetles in the field. This study was located in a heavily infested 28.1 -ha plantation in the location reported above. The planting was 4 yrs old and composed of clone NM6. A 1 -ha plot was established and 120 standard boll weevil traps (Nebeker et al., 2002) were deployed on a 10×12 grid with 10 m spacing. Traps were placed between rows on wooden posts at a height of 1 m from the ground.

There were two odor treatments: a blank control and three sprigs of NM6 foliage+20 beetles; and two color treatments: black and yellow. Bait treatments were prepared using washed greenhouse-grown NM6 foliage trimmed to include the meristematic tip through the first five leaves (LPI 4) and placed in plastic water vials as described above. The sprigs were then placed in a 12 -oz paper coffee cup with 20 beetles collected from a hybrid poplar nursery near Arlington, WI, USA ($43^{\circ} 17' 30''\text{N}$, $89^{\circ} 23' 00''\text{W}$) and then covered with mesh netting held in place with a rubber band. Controls consisted of a paper coffee cup containing three water vials covered with mesh netting. Bait cups were clipped to the inside of boll weevil traps using 0.95-cm metal binder clips.

Color treatments were prepared by spray painting traps with yellow or black plastic-bonding spray paint (Krylon Fusion Sunbeam and Black Gloss; Sherwin-Williams Co., Cleveland, OH, USA). The treatments were deployed in a completely randomized, 2×2 two factorial design. Due to loss of data from the first four rows of traps, the final replication is as follows: black control, $N=16$; black baited, $N=26$; yellow control, $N=18$; yellow baited, $N=20$. Trap catches were tallied and removed daily between 6 and 7 P.M. for the duration of the 4-d trial to prevent the build-up of potentially attractive adult *C. scripta* within traps.

Statistics

Statistical analyses were performed using SAS for Unix (v.8, SAS Institute Inc., Cary, NC, USA). Beetle responses to the two different odor sources were subjected to an ANOVA

with beetle response in a given trial as the experimental unit. ANOVA was chosen for the analysis instead of chi square in order to allow for a more conservative approach that included blocking factors of odor source location, arena used, and trial period. The sex ratio of beetles responding to beetle volatiles was subjected to chi square analysis to determine if it deviated from the expected 1:1 ratio.

Statistical analysis of trap data was performed using SAS software as described above. Trap catch totals were $\log(y+1)$ transformed and subjected to ANOVA for color, bait, and interaction effects. The least significant difference (LSD) method was used to determine mean separations between the four treatment combinations, with $\alpha=0.01$ to insure a conservative interpretation.

Results

Laboratory Assays

None of the blocking factors of odor source location, arena used, or trial period were significant except in one instance noted below. Odors released from the plant–*C. scripta* complex ($F_{1,8}=34.85$, $P<0.001$) as well as those from unwounded foliage ($F_{1,21}=10.59$, $P=0.004$), beetles ($F_{1,12}=47.15$, $P<0.001$), and frass ($F_{1,12}=9.91$, $P=0.008$), were more attractive than a blank control (Fig. 2). Responses to green ($F_{1,12}=2.69$, $P=0.127$) or yellow ($F_{1,12}=1.44$, $P=0.253$) visual stimuli did not differ from those to a blank. The sex ratio of responders to volatiles from beetles alone was 32:35 (M/F) and was not statistically different from 1:1 ($\chi^2_1, P=0.8$).

Fig. 2 Number of adult *C. scripta* responding to potentially attractive odor sources and visual cues vs. blank controls in two-way behavioral choice tests. Beetles feeding on foliage = plant–*C. scripta* complex; Unwounded foliage = plant alone; Beetles = *C. scripta* alone; Frass = frass alone; Green paper = green visual cue; Yellow paper = yellow visual cue; NS = not significant. An asterisk indicates significant attraction to a given odor source (* $P<0.05$, ** $P<0.01$, *** $P<0.001$)

In direct comparisons, only volatiles from beetle-wounded foliage were as attractive as the full complement of odor from the plant–*C. scripta* complex ($F_{1,12}=1.62, P=0.228$) (Fig. 3). Although attractive when compared to a blank, the odor sources of unwounded foliage ($F_{1,11}=17.79, P=0.001$), beetles ($F_{1,12}=122.93, P<0.001$), and frass ($F_{1,12}=7.11, P=0.020$) were not as attractive as the plant–*C. scripta* complex in a direct comparison.

Beetle-wounded foliage was more attractive than unwounded foliage ($F_{1,13}=13.97, P=0.002$) (Fig. 4). In contrast, attraction to artificially wounded foliage was not different from attraction to unwounded foliage ($F_{1,12}=0.01, P=0.922$). Even with frass removed by washing, beetle-wounded foliage remained more attractive than unwounded foliage ($F_{1,18}=8.17, P=0.010$). In this comparison only, the blocking factor of odor source location was also significant ($F_{1,18}=6.44, P=0.021$).

Attraction to adult beetles appears to exist independently of frass, with no difference in response to starved vs. fed beetles ($F_{1,12}=0.02, P<0.891$).

Field Trapping

Both color ($F_{1,76}=9.00, P=0.004$) and bait ($F_{1,76}=23.47, P<0.001$) affected trap catch (Fig. 5). There was no significant interaction between color and bait ($F_{1,76}=0.63, P=0.429$). Baited yellow traps caught more than any other trap. Unbaited yellow trap catches did not differ from either of the black treatments, but among black traps, baited traps caught more beetles than unbaited ones (LSD, $\alpha=0.01$).

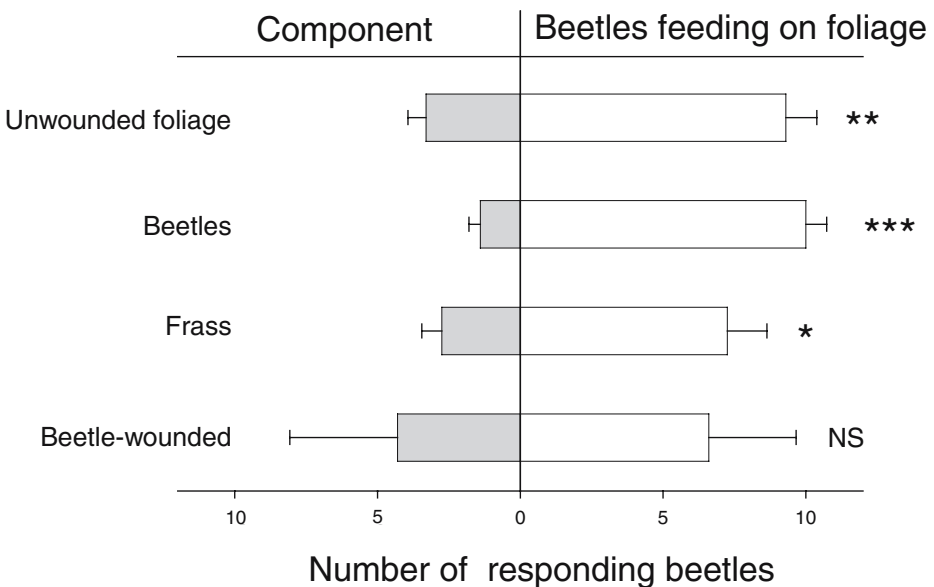

Fig. 3 Number of adult *C. scripta* responding to attractive odor source components when compared to the full complement of odors. Unwounded foliage = plant alone; Beetles = *C. scripta* alone; Frass = frass alone; Beetle-wounded = wounded plant with *C. scripta* by-products; Beetles feeding on foliage = plant–*C. scripta* complex; NS = not significant. An asterisk indicates significant attraction to a given odor source (* $P<0.05$, ** $P<0.01$, *** $P<0.001$)

Fig. 4 Effect of wounding by beetle feeding and artificial means on attraction of *C. scripta* to foliage. Beetle-wounded = wounded plant with *C. scripta* by-products; artificially wounded = hole-punched plant; unwounded foliage = plant alone. Washed beetle-wounded = wounded plant with visible *C. scripta* by-products removed; NS = not significant. An asterisk indicates significant attraction to a given odor source (* $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$)

Discussion

These results suggest that aggregation by *C. scripta* is mediated by the presence of beetles and their feeding on host plants. Similar results have been found for other chrysomelid beetles, such as the Colorado potato beetle, *Leptinotarsa decemlineata* (Say), and two flea beetles, *Phyllotreta cruciferae* (Goeze) and *Aphthona nigricutis* (Foudras), each of which are attracted to volatiles from feeding conspecifics (Peng and Weiss, 1992; Landolt et al., 1999; Tansey et al., 2005). Moreover, attraction by other beetle species to wound-induced foliage has been demonstrated (Loughrin et al., 1995; Bolter et al., 1997; Kalberer et al., 2001).

The data indicate that both *C. scripta* and their host plants, especially wounded plants, emit attractive signals. The behavioral responses of *C. scripta* are consistent with the presence of a pheromone for two reasons: 1) beetles are attracted either to conspecifics that have recently fed or to conspecifics that had been starved for 24 hr; and 2) frass alone is attractive (Fig. 2). The release of pheromones through frass is common in other Coleoptera (Wood 1982). One or both sexes may produce a pheromone, and examples of each are known in the Coleoptera (Landolt and Phillips, 1997). In this study, the odor source beetles were of both sexes, so it is not yet known if the attractive compound functions primarily as a sex pheromone. However, both sexes respond equally to odors emitted by conspecifics.

Although beetle-produced volatiles are attractive by themselves, the host plant, particularly a wounded host plant, is critical in eliciting the strongest response by *C. scripta*. Because wounding of the plant by *C. scripta* but not by artificial means increases the attractiveness of the foliage, and beetle-wounded foliage remains more attractive than unwounded foliage even after removal of insect by-products (Fig. 4), our results suggest

Fig. 5 Total number of adult *C. scripta* trapped in response to various odor and visual stimuli. Standard boll weevil traps were deployed for 4 d and assigned one of two color treatments: black or yellow; and one of two odor treatments: control or baited. Sampling was for 4 d. Letters A–C above the bars indicate significant differences in trap catches between treatments, with means sharing the same letter not significantly different (LSD, $\alpha=0.01$). An asterisk indicates a significant treatment effect (* $P<0.05$, ** $P<0.01$, *** $P<0.001$). NS = not significant

wound induction plays an important role in attraction. This is consistent with reports on the more widely-studied *L. decemlineata* (Landolt et al., 1999). Attraction to beetle-wounded foliage is not mutually exclusive with the presence of a pheromone, as pheromone production may be stimulated by feeding or require the co-occurrence of host volatiles to elicit a full response (Wood 1982; Landolt and Philips, 1997; Reinecke et al., 2002). Although we have demonstrated that beetle-wounded foliage from which frass has been removed retains its attractiveness when compared to unwounded foliage, we did not directly compare this treatment with beetles feeding on foliage. Thus, it remains to be determined whether the attractiveness of beetles feeding on plants is due solely to the emission of damage-induced volatiles, or also includes compounds of beetle origin.

Field evaluations confirmed attraction to volatiles from beetles feeding on foliage. Although laboratory assays did not provide evidence for attraction to color alone, visual cues influenced beetle responses to attractive volatiles in the field. Color-based differences in trap catches have been previously documented for other chrysomelid adults, such as *L. decemlineata* and two *Diabrotica* species (Zehnder and Speese, 1987; Hesler and Sutter, 1993). The order in which *C. scripta* responds to cues is not known, but based on these results, it seems likely that initial landings are based on visual (Fig. 5, A and AB) and olfactory (Fig. 2, Unwounded foliage) attraction to the host plant, with volatile cues from conspecifics subsequently increasing arrestment by *C. scripta* in a particular location (Figs. 3, 4, and 5).

With more knowledge of the chemical ecology of *C. scripta*, efficient sampling schemes could be developed for improved monitoring. A close correlation between trap catch and population density would aid plantation managers in making threshold-based pesticide applications, which are the cornerstone of integrated pest management. In summary, our results demonstrate orientation by *C. scripta* adults to volatile cues, and indicate that these interactions are of sufficient strength to function in commercial plantations.

Acknowledgments This research was supported by funds from the USDA Forest Service North Central Research Station and International Paper Company, and we express our gratitude to Don Riemenschneider, Mike Young, and Scott Cameron. Olfactometer design was improved based on the recommendations of Alonso Suazo and Yasmin Cardoza, and Mark Allington was instrumental in their construction. Brian Aukema provided statistics consultation. Thanks to Lynn Hummel and Isaac Kabera for greenhouse support. We also thank Wynnee Lou, Megan Hyslop, and Jason Jones for technical assistance with insects and plants. Rick Lindroth, Claudio Gratton, and David Coyle (UW-Madison Dept. of Entomology), Jun Zhu (UW-Madison Dept. of Statistics), and two anonymous reviewers provided valuable critiques of this manuscript.

Introduction

Bark residue from tree debarking is a byproduct of wood production. In Quebec, Canada, about 1.2 million tons of residues are produced each year (Anonymous, 2000) and left to degrade for decades. In northern Quebec, away from potential users, approximately 10% of bark residues are piled up as landfill in industrial bark wastelands. Bark contains many chemical constituents in varying concentrations (USDA, 1971); most residues are rich in cellulose and lignin, but also contain waxes, cutin, suberin, resins, and tannins. They have a low pH, and hydrolyzable phenolics are often released during degradation from the C6–C3 phenylpropanoid acid subunit of lignin (USDA, 1971), cutin, suberin, and tannins (Marchand et al., 2005).

Bark residue wastelands have increased in volume (i.e., to a height of several meters spread over several ha) and are aesthetically unpleasant. There is limited research on how to revegetate this industrial wasteland. Some residue sites have been covered with mineral soil and seeded; this has had some success, but in general it is unsustainable and not environmentally sound because it requires tons of soil to be transported.

The characteristics of industrial bark residue change over time with environmental exposure. Fresh bark wastelands are light brown and woody without vegetation. This inhibitory effect on the surrounding vegetation is identified as allelopathic and patterning vegetation effects have been noted (Rice, 1984). The oldest wastelands resemble black soil, and rhizobium–legume (*Vicia cracca* and *Trifolium* spp.) symbioses have been found growing on them. This phenomenon raises the possibility of a new organic soil cover being developed with bark residues so that these sites can be revegetated by legume species. To explore the potential for this approach, we needed to identify the soluble phytotoxic compounds from barks of various ages and to evaluate their potential toxicity.

Phenolic compounds are the most widely distributed allelopathic compounds, followed by terpenoids, flavonoids, alkaloids, and cyanogenic glycosides (Rice, 1984). One hypothesis for the absence of plant growth on fresh bark is the presence of phenolics that are soluble and known to affect biodiversity and the growth, development, and nutrition of plant species (Rice, 1984; Siqueira et al., 1991). Water extracts from bark have been reported to inhibit plant growth mainly due to their phenolic compounds (Rice, 1984).

The objectives of this study were to: (1) identify and quantify the phenolic compounds from bark of different ages; and (2) determine which barks could be used to develop a novel organic soil cover. We used simulated solutions (mixtures of standard phenolic compounds) to evaluate the potential toxic effects of phenolic compounds on rhizobial growth, the germination index, plant growth, nodule number, and the nitrogen fixation activity of two legume species under laboratory conditions.

Methods and Materials

Bark Materials

White spruce bark, provided by Tembec Inc. (Taschereau, QC, Canada), was collected from an 18-ha, 10-m high bark wasteland that was established in 1950. Samples were taken from

Table 1 Selected physicochemical characteristics of bark residues of five ages

Bark age (years)	Moisture (%)	Bulk density (gm/cm ³)		pH
		Fresh	Dry	
Fresh	60.2	0.33	0.12	4.1
<1	59.8	0.42	0.17	4.7
1–5	70.1	0.37	0.16	4.5
5–10	70.1	0.51	0.22	5.0
10–20	67.0	0.48	0.24	5.5

several locations within the top 30 cm of the pile. Bark was divided into five categories based on age: fresh bark coming directly from the industry, <1-yr-old bark, light brown 1- to 5-yr-old bark, brown 5- to 10-yr-old bark, and black 10- to 20-yr-old bark. Bark from these five categories had different physicochemical characteristics (Table 1). After collection, barks were transported on ice to the laboratory and analyzed as soon as possible.

Phenolic Compounds Extraction

Four extractant solutions were used: cold water (Whitehead et al., 1983; Blum et al., 1991), considered a weak extractant; hot water at 85°C (Chantigny et al., 2000) and 0.1 M NaOH (Whitehead et al., 1981), both considered to be mild extractants; and 2 M NaOH (Whitehead et al., 1983), considered to be a strong extractant. Unless stated otherwise, extractions were performed at room temperature. Each treatment combination (bark residue and extractant solution) was replicated $\times 3$.

The extraction method was a modification of Whitehead et al. (1981). Briefly, for the cold water, 0.1 M NaOH, and 2 M NaOH solutions, 20 g of bark (wet weight; w.w.) were added to 100 ml of extractant solution and agitated for 16 hr with a reciprocal shaker (Eberbach Corp., Ann Arbor, MI, USA). The hot water solution was agitated in a water bath set at 85°C. Each suspension was centrifuged at $23,435 \times g$ for 15 min (rotor Sorvall GSA, Sorvall RC-5B centrifuge). Supernatants were recovered and filtered through 5 layers of cheesecloth and then through filter paper (Whatman no. 1). Filtrates were adjusted to pH 2.5 by using HCl 1 N and maintained at 4°C overnight. The acidification of bark extracts resulted in the precipitation of humic acids (Charest et al., 2005) that were separated by centrifugation ($23,435 \times g$) and filtrated through Whatman no. 42 filter paper. Supernatants were washed $\times 3$ with 10 ml ethyl acetate. The resulting 30-ml pooled solution was evaporated to dryness under N₂ atmosphere at 40°C, and the solids were dissolved in 2 ml of 50% methanol and kept in darkness at -4°C before undergoing chromatography.

Table 2 Mobile-phase gradient program used to separate phenolic compounds in bark extracts^a

Time (min)	Mobile phase A (%)	Mobile phase B (%)
Initial	100	0
0	100	0
0.01	100	0
15	70	30
50	22	78
60	100	0

^a Flow rate was 0.7 mL/min. All changes were asymptotically done over time (small initial change followed by more rapid change) by using curve shape 5 except for the change from 0.01 to 15 min, which was asymptotically changed by using curve shape 7. (Peaknet software release 4.30 Dionex, Sunnyvale, Ca, USA)

Liquid Chromatography

Methanol-dissolved samples were filtered through 0.45- μm nylon filters (Supelco, Bellefonte, PA, USA). Phenolics were identified by injecting a 10- μl aliquot into a Dionex DX 500 chromatograph (Dionex Corp., Sunnyvale, CA, USA) equipped with an AS40 Automated Sampler and a 10- μl valve loop injector, a Dionex GP40 Gradient Pump, and an AD20 absorbance detector. Chromatography was performed with a DuPont Zorbax ODS (4.6 mm \times 25 cm) column and a Zorbax guard column. Peaknet software release 4.30 (Dionex) was used for data acquisition and processing.

Chromatographic Conditions

The eluting solvents used were as follows: mobile phase A, water–methanol–acetic acid–ethyl acetate (93+2+4+1, v/v/v/v); mobile phase B, water–methanol–acetic acid–ethyl acetate (35+60+4+1, v/v/v/v) with a variable gradient at a flow rate of 0.7 ml/min (Table 2; adapted from Kelley et al., 1994). Phenolic compounds were characterized by their UV absorbance at 254 nm. Peaks were identified by comparing retention times with pure standards.

Standards

Preliminary analyses by gas chromatography-mass spectrometry identified 14 phenolic compounds in the bark residue samples. These compounds were gallic acid, protocatechuic acid, catechol, caffeic acid, vanillic acid, vanillin, (*P*)-coumaric acid, (*P*)-hydroxy-benzoic acid, ferulic acid, 3-hydroxy-4-metoxycinnamic acid, (*O*)-hydroxy-phenylacetic acid, benzoic acid, salicylic acid, and *trans*-cinnamic acid. Samples were obtained from Sigma (St. Louis, MO, USA). Standards were of a high-purity grade. Each was dissolved in high-performance liquid chromatography (HPLC)-grade methanol/deionized water (1:1 v/v) and injected, without prepurification, alone or in mixture, to calibrate the chromatograph.

Quantification was based on peak areas as determined by Peaknet software release 4.30 (Dionex) using external standards. These values (in $\mu\text{g/g}$) were transformed by using the following formula: Value ($\mu\text{mol/l}$)=(Value ($\mu\text{g/g}$) \times Bark dry bulk density (g/cm^3) $\times 10^3$)/Molecular weight.

The mean and standard deviation of each phenolic compound was determined (Table 3). The total phenolic content represents the sum of the mean quantities of the phenolic compounds detected.

Solutions for Toxicity Tests

Pure phenolic compounds were used for the toxicity tests to avoid possible interactions with other chemicals during extraction. First, concentrated solutions in 50% methanol were prepared for each compound. Second, dilutions from 150- to 4500-fold were made (in water) to obtain a mean for each compound (Table 3). These high dilutions allowed us to minimize the amount of methanol in our simulated solutions. A total of 20 solutions was made, i.e., five for each bark age category for the four extractants. These solutions contained, on average, 12 phenolics in mixture. They were kept at 4°C, in darkness, and used within 24 hr. Since bark pH varies with bark age, no pH adjustments were made to reflect the natural conditions of bark wastelands.

Toxicity Test on Rhizobial Growth

Four rhizobial species were selected (known as the microsymbionts of legume species that are used in plant toxicity evaluations and described below): *Mesorhizobium loti* for birdsfoot trefoil (*Lotus corniculatus*) and *Rhizobium leguminosarum* bv. *viciae* for nodulation of common vetch (*Vicia sativa*). Three strains of *M. loti* were used: NZP 2213 (also designated USDA 3471 or ATCC 33669), NZP 2234, and L3 (Agriculture and Agri-Food Canada, Sainte-Foy, Quebec, Canada). The three strains of *R. leguminosarum* bv. *viciae* were: USDA 2370 (also designated ATCC 10004), USDA 2489, and 175P1 (Nitragin, Milwaukee, WI, USA). *Mesorhizobium* sp., strain N28, and *Rhizobium* sp., strain SM2, respectively, sensitive and resistant to sainfoin seed diffusates (phenolics), were also used (Prévost et al., 1990). Each strain was grown in 50 ml of yeast mannitol broth (YMB; Vincent, 1970) contained in 125-ml Erlenmeyer flasks placed on a rotary shaker at 28°C. This medium was buffered with CaCO₃ and had a pH of about 7. As soon as the optical density reached 0.6–0.7 (630 nm), 20 ml of the rhizobial culture were incorporated per liter of sterile YMA, maintained as a liquid at 45°C. Then, 10 ml of inoculated YMA were distributed on Petri plates. After cooling, 4 disks of sterile paper (10 mm diam) were placed on the surface of the YMA for each plate. Each disk was impregnated with 100 µl of one of 20 different phenolic solutions. Petri plates were kept at 4°C for 18 hr to allow the compounds to diffuse, and then were incubated at 28°C for 4 d. Finally, the diameters of the zones of inhibition were recorded. This test was repeated ×3. A factorial experiment, using the microbial strains as the main factor and the solvents and bark ages as subfactors, was set up according to a split-plot design (Snedecor and Cochran, 1967; Steel and Torrie, 1980).

Phytotoxicity Test on Seed Germination

We determined the effects of phenolic compounds on seed germination and rootlet growth in combination with a germination index (Zucconi et al., 1981). Cress (*Lepidium sativum*) was used as a reference (Zucconi et al., 1981); it is an acid-tolerant species and its root growth is not affected by pH (Bonanomi et al., 2006). Vetch (*V. sativa*), a close relative of the weed *V. cracca* that has been observed under pioneer vegetation conditions, was also selected because this species prefers sandy soils and has a pH ranging from 5.5 to 8.5. The third species was birdsfoot trefoil (*L. corniculatus*). This species is tolerant of acidic pH (about 4.5) and is often used for revegetation (Hardy BBT Ltd., 1989). Preliminary tests with water, adjusted to pH levels of 3.5–5.5 to correspond to the pH of the barks and the simulated solutions (4.1±0.4), yielded 100% germination after 24 hr (data not shown). These tests indicate that germination could be evaluated with 15 seeds per Petri plate for cress and birdsfoot trefoil and with eight seeds for vetch.

Three sterile filter papers were placed at the bottom of a Petri plate and impregnated with 4 ml of a phenol acid solution or acidic water (control). Petri plates were placed in darkness at 27°C; the cress seeds were kept for 36 hr and the vetch and birdsfoot trefoil seeds for 3 d. Percentage of seed germinated and the rootlet lengths were recorded. The germination index was calculated by multiplying the % of germination by the average length of the rootlets (Zucconi et al., 1981). All tests included a water control, and each was repeated ×4. A factorial experiment, using the bark ages and extractant solutions as the main factors, was set up in a completely randomized block design (Snedecor and Cochran, 1967; Steel and Torrie, 1980). Analyses of variance included a least significant difference (LSD) treatment comparison. Pearson correlation coefficients between the germination index and the total

phenolic compounds, and between the germination index and each single compound, were calculated.

Phytotoxicity Test on Plant Growth, Nodulation, and Nitrogen Fixation Activity

Plants were grown in transparent plastic growth pouches to allow visualization of nodulation according to a standard method for testing legume inoculants (Anonymous, 2005). Two nitrogen forms were studied: nitrogen obtained through dinitrogen fixation (i.e., in the presence of rhizobia) and mineral nitrogen (in the presence of mineral nitrogen in the nutrient solution). A split-plot design with four blocks was set up with the two forms of nitrogen as the main factor and the 20 phenolics solution as the subfactor. The analyses of variance included an LSD treatment comparison (Snedecor and Cochran, 1967; Steel and Torrie, 1980).

Seeds were surface sterilized for 10 min in a 20-ml solution of Javex (5%), 4 ml of Tween 20 (50% V/V), and a 4-ml buffer [8 ml concentrated HCl mixed with 32 ml KH_2PO_4 (1 M)]. Seeds were washed several times in sterile distilled water and dried under sterile conditions. Plant nutrient solutions contained 0 or 15 mol m^{-3} NO_3^- -N as KNO_3 and Ca $(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ (Chalifour and Nelson, 1988), and solutions were balanced for their K and Ca concentrations. Eight seeds were placed in each growth pouch (Anonymous, 2005) that was filled with the appropriate nutrient solution (pH 4.2 ± 0.1) without the phenolic compounds. Pouches containing the N-free nutrient solution were inoculated with about 10^9 cells of the appropriate rhizobial strain, i.e., 175P1 for vetch and NZP 2234 for birdsfoot trefoil. These growth pouches were wrapped in aluminum foil and kept in the dark for 3 d. Thereafter, growth pouches containing 8 seedlings were selected, and the nutrient solution was removed and replaced with 30 ml of nutrient solution containing the phenolic compounds or the control. These solutions had pH values of 4.1 ± 0.4 .

Plants were kept under light for 16 hr at a temperature of 20°C, and then placed in the dark for 8 hr at 15°C. They were watered with bidistilled water every second day. After 10 d, nutrient solutions containing the phenolics were removed and replaced with fresh solutions. At 40 d of age, the dry weight of the aerial and root parts was measured for each growth pouch. All results are expressed on a dry weight basis relative to the control, where % biomass = [(treatment (d.w.)/control (d.w.))] \times 100. The number of nodules per root was also determined and is expressed as: % nodule number = (nodule number per root system for one treatment/nodule number per root system for the control) \times 100. The aerial parts and the nodules were ground and their total N content was determined by dry combustion (CNS-1000 Analyser, Leco Co., St. Joseph, MI, USA).

Results

To identify and quantify the phenolic compounds from bark of different ages, several extractants were compared. For most extractants, the highest yield of total phenolic compounds was obtained from the youngest bark (Table 3). With the exception of young bark residues, more phenolics tended to be extracted by hot water, 0.1 M NaOH, and 2 M NaOH than with cold water (Table 3). However, certain compounds, such as salicylic acid, were better extracted with cold water than with 2 M NaOH. Also, others, such as proto-catechuic acid, catechol, caffeic acid, vanillin, and ferulic acid, were better extracted with hot water than with 0.1 M NaOH. These results were used to reproduce solutions of various concentrations to simulate the different phenolic concentrations of the bark residues so as to avoid possible interactions from other bark compounds.

Fig. 1 Germination index of cress, birdsfoot trefoil, and vetch in the presence of phenolic simulated solutions of bark of various ages extracted with cold water, hot water, NaOH 0.1 N, or NaOH 2.0 N

Growth inhibition of *Mesorhizobium* sp. and *Rhizobium* sp. strains was not detected from treatments involving the 20 solutions that simulated extracts from bark of different ages from the four solvents.

To determine phytotoxic effects on seed germination, we used the 20 simulated bark extract solutions. Cress and vetch did not germinate in the solution that simulated the 2 M NaOH extract; this treatment was excluded from the statistical analyses. In general, stronger extractants, and younger bark residues, lowered the germination index for all species (Fig. 1). However, the germination index differed among species according to extractant strength and age of the bark residue; the highest germination index was with cress, followed by birdsfoot trefoil, and then vetch. However, only birdsfoot trefoil germinated in the solutions that simulated the 2 M NaOH solvent and resulted in a germination index higher than that in vetch.

For cress, on average, the germination index decreased from the cold to the hot water extract, but increased from the hot water extract to the 0.1 M NaOH extract of the fresh bark, 1- to 5-yr-old bark, and 5- to 10-yr-old bark (Fig. 1). Correlation analyses shows a negative relationship between the germination index and the total phenolic content, and the 11 phenolic compounds, i.e., the germination index decreased with concentration of phenolics (Tables 3 and 4).

For birdsfoot trefoil, seeds germinated even in the simulated solution of 2 M NaOH solvent (Fig. 1). The germination index decreased from the cold to the hot water extract, and from the 0.1 M NaOH to the 2 M NaOH extract of most barks, but increased with the ages of bark extracted with 0.1 M NaOH. Finally, the total phenolic content and 10 individual phenolics were correlated with the germination index of birdsfoot trefoil all, except for phenylacetic acid (Table 4).

For vetch, the germination index decreased from the cold to the hot water extract or 0.1 M NaOH, but increased with the age of the bark (Fig. 1). The total phenolic content and all individual phenolic were correlated with the germination index, except for vanillic acid (Table 4).

To determine the phytotoxicity of the 20 simulated bark extracts, we tested their effects on the rhizobium–legume symbiosis. For birdsfoot trefoil, the control had a mean aerial biomass of 22 ± 3 mg in the presence of rhizobia, but 16 ± 4 mg in the presence of mineral nitrogen. Its mean root biomass was 9 ± 1 mg in the presence of rhizobia and 13 ± 2 mg in the presence of mineral N. For vetch, the control had a mean aerial biomass of 87 ± 2 mg in the presence of rhizobium and 69 ± 4 mg in the presence of the mineral N. Its mean root biomass was 24 ± 3 mg in the presence of rhizobium and 31 ± 1 mg in the presence of mineral N.

For the aerial and root biomasses of birdsfoot trefoil and for the aerial biomass of vetch, there were significant interactions between the nitrogen source and the simulated phenolic solutions; the LSD test was applied to the 40 treatments. For the root biomass of vetch, the nitrogen source and simulated phenolic solutions factors were significant but their interaction

was not. However, for the purposes of data presentation, the LSD test was performed over the 40 treatments. For birdsfoot trefoil and vetch, in the presence of rhizobia, the least growth (aerial and root biomasses) was with the fresh bark regardless of the strength of the extractants and with the 2 M NaOH extractant regardless of bark age (Figs. 2 and 3). Often, plant growth decreased with an increase in total phenolic content and with some specific phenolic compounds (Tables 5 and 6). The greatest growth was generally measured in the cold water extracts of <1-yr-old bark. In the presence of mineral N, the least growth followed the same trends as that in the presence of rhizobia for both plant species. For birdsfoot trefoil, the greatest growth was measured from the solution that simulated bark older than 1 to 5 yr extracted with hot water or 0.1 M NaOH. For vetch, the greatest aerial biomass accrued from the solution that simulated the 10- to 20-yr-old bark extracted with hot water; the greatest root biomass accrued with solutions that simulated bark older than 1 to 5 yr extracted with hot water.

For birdsfoot trefoil, the control had a shoot N content of $1.00 \pm 0.18\%$ in the presence of rhizobia, and $2.00 \pm 0.11\%$ in the presence of mineral N. Also, in the presence of rhizobia, the number of nodules per control plant was 25 ± 1 with a nodule N content of 8.64%. For vetch, the control had a shoot N content of $3.00 \pm 0.26\%$ in the presence of rhizobia, but $2.4 \pm 0.18\%$ in the presence of N in the nutrient solution. Also, in the presence of rhizobia, the number of nodules per control plant was 16 ± 1 with a nodule N content of $6.43 \pm 0.94\%$.

For both plant species, the interaction between the nitrogen source and the extractant solutions was significant for shoot N content; again, the LSD test was applied to the 40 treatments. For the number of nodules and the nodule N content, only the rhizobia treatments were further analyzed. For the nodule N contents of birdsfoot trefoil, nodule weights were too low to perform the N analyses. In the presence of rhizobia for vetch, the shoot N contents increased with the solutions that simulated the oldest barks (Fig. 4a); these

increases were generally greater when plants were grown in the presence of mineral N with strong extractants. For birdsfoot trefoil in the presence of rhizobia, shoot N content was greatest in the fresh or 5- to 10-yr-old barks extracted with cold water or 0.1 M NaOH, the <1-yr-old barks extracted with hot water, the 1- to 5-yr-old bark extracted with hot water or 0.1 M NaOH, and the 10- to 20-yr-old bark extracted with 0.1 M NaOH (Fig. 4b). However, in the presence of mineral N, the shoot N content was greater for <1-yr-old barks or 5- to 10-yr-old barks extracted with hot water. The correlation analyses showed a decrease in aerial biomass N content with vanillin and ferulic acids in the presence of rhizobium, but in the absence of rhizobium there was a decrease for most phenolic compounds and for the total phenolic content (Tables 5 and 6).

For birdsfoot trefoil, the number of nodules tended to increase when the solutions simulated 1- to 5-yr-old bark extracted with cold water, 5- to 10-yr-old bark extracted with 0.1 M NaOH, and the 10- to 20-yr-old bark extracted with hot water as compared with the other extracted bark residues (Fig. 5a). However, for vetch, the number of nodules tended to increase when the solutions simulated 1- to 5-yr-old bark extracted with cold water compared with the other extracted bark residues (Fig. 5b). Vetch nodule N content was higher when the solutions simulated barks older than 1 yr extracted with cold and hot water compared with the other extracted bark residues (Fig. 6). Again, the analyses of correlation showed a decrease in nodule N content with an increase in the (*P*)-hydroxybenzoic acid and *trans*-cinnamic acids (Table 5).

Discussion

Detection of water-soluble phenolics has been reported from several plants, debris, and litter (Dalton, 1999), and now from bark residues. Various methods have been used to extract phenolic compounds, including water (Whitehead et al., 1983; Blum et al., 1991), chelating agents, methyl alcohol, and NaOH (Rice, 1984; Dalton et al., 1987; Blum et al., 1997; Dalton, 1999). A link between the concentration of the compound extracted and biological activity has not previously been established; this information will be important for developing a soil cover medium using bark residues.

This study showed that the total content of phenolics and the content of most individual compounds increased with extractant strength; cold water = hot water = 0.1 N NaOH < 2 M NaOH for fresh bark, and cold water < hot water = 0.1 N NaOH < 2 M NaOH for bark less than 1 yr old. In general, these results agree with those of Dalton (1999) in the ability of various extractants to recover ferulic acid from soil, i.e., water = methanol < sodium acetate < EDTA = DTPA < NaOH. However, fresh bark appears to carry substantial amounts of soluble phenolics and, in this particular case, the extracting abilities of cold water, hot water, or 0.1 N NaOH were similar. Under our conditions, extensive sorptive and complex reactions, and degradation of phenolics by abiotic or biotic factors, such as microbes (Inderjit et al., 1999; Schmidt and Ley, 1999), were possible but unlikely. Fresh bark results using cold and hot water and 0.1 N NaOH were often similar in the extraction of individual phenolics, even though pH, hydrolysis, and oxidative conditions differed. Also, the hot temperature (85°C) and alkaline pH (NaOH) conditions inhibited microbial growth. For the cold water extractant, there was probably no growth of microorganisms because a N source was not available and the conditions were acidic. These results are in contrast with those of a cold water soil incubation, where the addition of ferulic acid, a carbon source, created an environment that was favorable for the growth of microbes (Dalton, 1999).

In general, the concentration of each phenolic decreased with bark age. For fresh bark, the phenolic content varied from 789 to 1279 $\mu\text{g/g}$ (d.w.) (9 to 12×10^{-4} M), regardless of the strength of the extractant. Other bark ages had a phenolic acid content ranging from 5 to 19 $\mu\text{g/g}$ (d.w.) (5 to 26×10^{-6} M) when extracted with cold water, 145 to 236 $\mu\text{g/g}$ (d.w.) (21 to 29×10^{-5} M) when extracted with hot water and 0.1 M NaOH, and 843 to 1231 $\mu\text{g/g}$ (d.w.) (13×10^{-4} to 16×10^{-4} M) when extracted with 2 M NaOH. These results show that more than 60% of the total phenolic contents in fresh bark were soluble in cold water, and thus, they would inhibit biological activity more than older residues.

The lower yield of cold water extraction for bark less than 1 yr old, and older residues, was probably attributable to the water failing to penetrate the bark, washing only its surface where phenolic compounds exist in a free state. Also, during the first year of exposure in the bark wasteland, there would have been substantial water leaching as a result of environmental conditions (rain and snow), and the microbes would have biodegraded over time. When the strength of the solvent increased, from hot water or 0.1 M NaOH to 2 M NaOH, more internal tissues were probably reached, resulting in a more complete hydrolysis. Also, the bound forms of phenolics are normally released by 2 M NaOH (Rice, 1984; Dalton et al., 1987).

The predominant phenolics identified in bark residues are phenylacetic, vanillin, ferulic, catechol, and coumaric and protocatechuic acids. The C6–C2 phenylacetic acid is a deaminated product of phenylalanine, the precursor of cinnamic acid, coumaric acid, coniferaldehyde, ferulic acid, or conyferyl alcohol in the lignin biosynthetic pathway (Sibout et al., 2005). The chromatographic peak for phenylacetic acid has to be optimized to be detected by UV. Its presence in bark could be linked to the lignin biosynthetic or degradation

pathway, involving at least the decarboxylation of 3-phenyl-propionic acid or the oxidation under acidic conditions of the etherified coniferylaldehyde to phenylacetic acid (Pan et al., 2000). In addition, the presence of phenylacetic acid could originate from plant material during degradation (Rice, 1984). Some of the other compounds belong to the vanillyl phenols (vanillin and vanillic acids) that are typical of the gymnosperm lignin signature (Hedges and Mann, 1979). The cinnamyl phenols (coumaric and ferulic acids) were present in our bark residue extracts. These compounds have been reported in the lignocellulose complex, and ferulic acid can be derived from holly tree bark (Hedges and Mann, 1979), suberin-associated waxes, and cutin (Otto et al., 2005). The bark residues may also have contained needles that would explain the presence of the cinnamyl phenols. The coumaryl and synapyl alcohol-derived units have been reported in minor amounts in spruce lignin (Kögel, 1986). The origin of the cinnamyl phenols may also be related to the degradation of the coumaryl and synapyl alcohol-derived units present in the lignocellulose complex, suberin, or cutin.

The decrease in concentration of phenolics over time, under prevailing environmental conditions, could be attributable to abiotic factors (such as rain and melting snow), photo-oxidation (Siqueira et al., 1991; Chaves et al., 2002), or to biotic phenomena that occur during the decomposition of organic matter (An et al., 2000), mainly the progressive degradation by microorganisms (Siqueira et al., 1991; Blum, 2004). For example, we found that the content of phenylacetic and ferulic acids decreased with bark age. The catabolism of ferulic acid by microorganisms produces vanillin, vanillic acid, protocatechuic acids (Peng et al., 2003), and catechol (Bocks, 1967), and they increased in older barks, especially the latter compounds. The dominance of vanillyl phenols over time in our study agrees with the results of the incubated needle litter experiment of Sjöberg et al. (2004), whereas the decrease in cinnamyl phenols agrees with results of Hedges and Weliky (1989), cited in Sjöberg et al. (2004).

The biological activities of the bark extracts were determined with biological tests, especially from fresh bark residues. The phenolic solutions were made by simulating bark composition over various ages and extractants in order to minimize the interference from other compounds that might be present in bark residues. No pH correction was made, and the effects of hydrogen ion concentration and the phenolic mixtures are combined, but they are still within the range occurring in the bark residues. Use of these simulated phenolic solutions increased the relevance of our results for the development of a new soil cover, in agreement with Blum's (1999) reflections on bioassays.

Based on biological activity, we made the following conclusions. First, simulated phenolic solutions did not inhibit rhizobial growth on YMA, even though total phenolics were between 5×10^{-6} and 1.6×10^{-3} M. Inhibition of rhizobial growth was expected because concentrations above 10^{-4} (Rice et al., 1981) to 10^{-5} M have been reported to inhibit growth (Gauv and Pareek, 1976). Rice (1964), using a YMA medium at pH 8.2, demonstrated the inhibitory activity of plant extracts on *Rhizobium*. The synergistic effects of a 10^{-3} M mixture of (*P*)-coumaric and ferulic acids, (*P*)-hydroxybenzoic and (*O*)-hydroxyphenylacetic acids, or ferulic and vanillic acids, were found to inhibit rhizobial growth on YMA (Rice et al., 1981). Gauv and Pareek (1976) attributed the decreased growth of *Rhizobium* to (*P*)-hydroxybenzoic and salicylic acids at concentrations of 10^{-3} M. In our study, these phenolics were present in all bark extracts, but possibly in combinations and concentrations too low to inhibit rhizobia. Also, the presence of mannitol and CaCO_3 , which buffered the pH to about 7 in the culturing media, have been shown to prevent toxicity effects of phenolics on *Rhizobium* growth (Blum et al., 2000; Seneviratne and Jayasinghearachchi, 2003). Under our experimental conditions, mixtures were not toxic to rhizobial growth on

YMA; therefore, this test was not useful in relating the rhizobial growth to phenolic toxicity.

Second, the simulated phenolic solutions had inconsistent effects on germination and root elongation of cress, vetch, and birdsfoot trefoil. Cress had the highest germination index, followed by birdsfoot trefoil; both are acidic-resistant species. Vetch, a species that prefers a soil pH above 5.5, had the lowest germination index. There was an improvement in index and plant growth with the aging of the residues, and with the decreasing strength of the extractant solutions. Allison et al. (1963) and Rice (1984) report that phytotoxic compounds are usually present in large quantities in bark. The germination of cress and vetch was completely inhibited with the 2 M NaOH simulated solution, with a total phenolic content of about 1.2 to 1.6×10^{-3} M, whereas the germination of birdsfoot trefoil was inhibited by 90%. These results are similar to those of Siqueira et al. (1991), i.e., a concentration of 1 to 7×10^{-3} M was the minimal concentration needed to inhibit germination by 50%. Our germination test was useful in linking the biological activity to the phenolic toxicity of fresh barks with that of barks older than <1 year for all plant species. Three major toxicity groups were detected for vetch: fresh bark, <1- to 10-yr-old bark, and 10- to 20-yr-old bark.

Third, the phenolic extracts had inconsistent effects on vetch and birdsfoot trefoil growth, nodule number, and N_2 fixation activity. In the presence of rhizobia or mineral N, the simulated solutions at 8.8×10^{-4} to 1.6×10^{-3} M of total phenolics decreased the aerial and root dry weights and the nodule number. For vetch and birdsfoot trefoil, N content decreased at the highest concentration of phenolics. The shoot and root weights of birdsfoot trefoil were more affected than those of vetch, especially with fresh bark residues and 2 N NaOH extracts. High phenolic concentrations have been reported to decrease plant growth, to be phytotoxic, and to alter N_2 fixation activity (Rice et al., 1981; Rice, 1984; An et al., 2000; Seneviratne and Jayasinghearachchi, 2003). Our results support this concept of phytotoxicity on rhizobium–legume symbioses for high concentrations of total phenolics. In addition, the presence of various phenolics in a mixture could have antagonistic, neutral, or synergistic effects on seed germination, plant growth and N fixation. For example, Li et al. (1993) suggests that mixtures of phenolics, including caffeic, ferulic, and *trans*-cinnamic acids, enhance their inhibitory effects. In our simulated solutions, the analyses of correlation shows a negative relationship with six other phenolic compounds and with the germination index for cress, vetch, and birdsfoot trefoil, i.e., protocatechuic acid, catechol, (*P*)-hydroxybenzoic acid, vanillin, (*P*)-coumaric, and 3-hydroxy-4-methoxycinnamic acids. Also, the shoot and root dry weights, N content of the aerial part, nodule number and nodule N content were negatively correlated with the total phenolics content, and catechol, (*P*)-hydroxybenzoic acid, vanillic acid, caffeic acid, vanillin, (*P*)-coumaric, ferulic acid, 3-hydroxy-4-methoxycinnamic acid, benzoic acid, and *trans*-cinnamic acid. (*P*)-Coumaric, ferulic, (*P*)-hydroxybenzoic, and vanillic acids at 10^{-3} M have been reported to reduce the number of nodules, and ferulic and (*O*)-hydroxyphenylacetic acids have been shown to reduce the N_2 fixation on bush black beans (Rice et al., 1981).

On the other hand, in the presence of rhizobia, when the simulated phenolic solutions content was between 5×10^{-6} and 1.3×10^{-5} M of total phenolics, then the aerial and root dry weights of birdsfoot trefoil and the root dry weight of vetch increased, generally resulting in a greater shoot N content, nodule number, and nodule N content than in the presence of mineral N. Rice et al. (1981) and Seneviratne and Jayasinghearachchi (2003) also report that low concentrations of phenolic compounds stimulated nodule formation or N_2 fixation activity. Rice et al. (1981) reports that (*P*)-coumaric, (*P*)-hydroxybenzoic, and vanillic acids could stimulate N_2 fixation. At low concentrations, our results suggest that phenolics modified the rhizobium–legume symbiosis positively. In the case of the cold

water extraction of the 1- to 5-yr-old bark, 5- to 10-yr-old bark, and 10- to 20-yr-old bark, only three phenolics were present, namely, vanillin, benzoic and salicylic acids; their effects alone or in mixture could be investigated further. For the other simulated solutions that improved the symbioses, the presence of more than 14 compounds in the mixture does not allow us to identify any individual phenolic that was beneficial to the symbiosis. More attention should be given to understanding the beneficial effects of older bark residues on legume symbiosis.

Plant growth and shoot N content were greater in the presence of rhizobia than in the presence of mineral N at $15 \text{ mol m}^{-3} \text{ NO}_3^- \text{-N}$. This suggests that N_2 fixation was providing more nitrogen to the plants than the added mineral N or that the rhizobia could detoxify the phenolic compounds.

The effect of the extracts on vetch and birdsfoot trefoil is of interest because such decreases in biological activity can be related to the toxicity of the phenolics extracted from fresh bark and 2 N NaOH 2N extractant, particularly in terms of plant growth, N_2 fixation, and nodule number for both plant species in the presence of *Rhizobium*. For both plant species, the solutions simulating the cold water extract from bark residues older than <1 year and the hot water extractant for the 10- to 20-yr-old bark residues increased the nodule number. From a practical point of view, the <1-yr-old bark residues should be selected in combination with legume species for revegetation purposes. Finally, the inoculated birdsfoot trefoil seems to be more sensitive to fresh bark and to the 2 N NaOH extractant that decreased the nodule number. Thus, again, from a practical point of view, fresh bark should not be used as an organic soil cover.

In summary, rhizobial growth on YMA was not affected by solutions that simulate the composition of the phenolic compounds of bark residues. On the other hand, the germination index of cress, birdsfoot trefoil, and vetch, and the growth, nodule number, and N_2 fixation activity of birdsfoot trefoil and vetch, were strongly inhibited by the simulated solutions from the young bark and the 2 N NaOH extractant. Germination inhibition varied with the species; vetch appears to be the most sensitive, and cress and birdsfoot trefoil the most resistant, which is related to the pH sensitivity of these species. However, plant growth, nodule number, and the N_2 fixation activity of vetch were less negatively affected by the high concentration of phenolics than birdsfoot trefoil, whereas a low concentration of phenolics affected birdsfoot trefoil more than vetch. In this case the pH sensitivity of these species was not related to the plant response. Vetch and birdsfoot trefoil need to be further investigated under greenhouse or field conditions. For revegetation purposes involving a novel organic soil cover, <1-year-old bark and older bark residues should be used in combination with legume species.

Acknowledgments The authors thank Tembec Inc. for their financial support and for supplying the bark residues. We thank Dr. F.-P. Chalifour and two anonymous reviewers for constructive suggestions. We also thank J. Tremblay for assistance in various aspects of this study.

Stapley, 2003; Labra and Niemeyer, 2004; Amo et al., 2004; reviewed in Kats and Dill, 1998; Apfelbach et al., 2005). Since prey species also respond to unknown predator odors, some have suggested that recognition of predator odors as a sign of potential danger is innate (Epple et al., 1993; Apfelbach et al., 2005). Such an innate recognition of predator odor would be an enormous advantage. After perceiving a predator odor, the prey animal can avoid the encounter with the predator. This is a highly critical advantage because the very first encounter with a predator usually ends fatally for the prey (Edut and Eilam, 2003). However, another possible explanation for the observed effects of unknown predator odors is that they contain components of a known predator. This would mean that recognition of the unknown predator odor is not innate but is rather based on previous experience with other predators.

A better way to test for innate recognition of predator odors is to use prey animals that have had no previous experience of predator odors, i.e., laboratory-reared animals, and to observe their behavior during exposure to different predator and nonpredator odors. A number of studies have shown that the odors of certain predators (usually cats or foxes) induce autonomic and behavioral signs of fear in laboratory animals (reviewed in Blanchard et al., 1990a; Dielenberg and McGregor, 2001; Apfelbach et al., 2005; Fendt et al., 2005; Takahashi et al., 2005). Since these laboratory animals (rats, mice) were totally naive to predators and predator odors, this is evidence that rats and mice innately recognize predator odors as signs of potential danger. Major drawbacks to these studies, however, are that in each case they have invariably used only one particular predator odor and that they have carried out control experiments either with synthetic odors instead of nonpredator odors or simply by eliminating all odors. As a result, the responses observed in these studies were perhaps general responses to unfamiliar animal odors.

The aim of the present study was to collect further data supporting the hypothesis that predator odor recognition is innate. To this end, the behavioral effects of different rodent odors were tested on male laboratory rats that were all naive to the odors used in the study. Urine samples from different canids and felids (wolf, coyote, bobcat, fox, and cat) were used as test stimuli, and urine samples of herbivore nonpredators (cow and horse) or of female rats were used as control stimuli, along with saline (i.e., no odor). Each rat was exposed in a test arena to all odors in a randomized order, and the behavior of the rat was observed. If laboratory rats are innately able to recognize predator odors, defensive behavior is expected during exposure to predator urine, but not during exposure to the control stimuli. The following defensive behaviors of rats are described in laboratory but also in field studies (Blanchard and Blanchard, 1971, 1990; Dielenberg and McGregor, 2001; Carobrez et al., 2001; McNaughton and Corr, 2004; Apfelbach et al., 2005): flight, hide and avoidance behavior, freezing behavior, potentiation of defensive reflexes, and “risk assessment behavior” such as flat back approaches, prolonged approach to and short direct contacts with the potentially dangerous stimuli.

Methods and Materials

Animals

Fourteen male Sprague–Dawley rats (Charles River GmbH, Sulzfeld, Germany) weighing 220–260 g (age, 3–4 mo) at the beginning of the experiments were used. Animals were maintained on a 12:12 hr light/dark cycle, and food and water were available *ad libitum*.

All experiments were performed in accordance with ethical guidelines for the use of animals in experiments and were approved by the local animal care committee (Regierungspräsidium Tübingen, ZP 4/02).

Odor Probes

Urine probes of bobcats, cougars, foxes, coyotes, and wolves were purchased from PredatorPee Inc. (Bangor, ME, USA). Urine probes of female cows and horses (females, males, geldings) were self-collected at two ecological farms in Waldhausen, a village close to Tübingen. Urine probes of female rats ($N=6$) were self-collected by using a metabolic cage at the animal facility of the Department of Animal Physiology of the University of Tübingen. Lastly, urine probes of healthy female and male cats were drawn by a local veterinarian by means of bladder catheterization. All samples were collected in the week before the experiments and were stored in a refrigerator at -18°C until they were used.

Samples were presented as follows: 3 ml of predator or nonpredator urine or saline (control) were administered in a Petri dish (5 cm diam.). The Petri dish was put in one corner of the arena (see below) at a distance of 5 cm from each wall of the arena.

Apparatus

All behavioral tests were conducted in a square arena with walls and a cover made from transparent Plexiglass (92×92 cm; ActiMot, TSE Systems, Bad Homburg, Germany). Illumination of the arena was between 200 and 250 lx. There was no ventilation of the arena during the tests. Rat movements were monitored by infrared detectors (distance between two detectors: 2.5 cm, height: 2.5 cm), and rearings were detected by a second arrangement of infrared detectors (height: 12.5 cm). The ActiMot software automatically calculated the motor activity [distance traveled (m)], the number of rearings, the duration of “resting behavior” (activity <1 cm/sec), the total time spent in the middle of the arena (size of the middle: 46×46 cm), and the total time spent in the corner with the urine probe (size of the “corner”: 23×23 cm).

In addition, the behavior of the animal was videotaped. The videotapes were analyzed by an observer who was unaware of the test conditions. The duration and frequency of the following types of behavior were recorded: flat back approach, contact with the sample, grooming, and freezing. The time elapsed before first contact with the sample and the number of fecal boli were recorded.

Behavioral Procedures

To familiarize the rats with the arena, each animal was placed together with odorless saline solution in a Petri dish (3 ml saline) into the arena for 10 min once per day on 3 consecutive d. On the following 10 d, a urine sample or saline control solution was put in one corner of the arena, and the rat was put in the opposite corner. The rat’s behavior was monitored for the next 10 min by the infrared detectors and videotaped as described above.

Each rat was tested daily between 8:00 AM and 4:00 PM with one of the samples. Samples were presented in a pseudorandomized order, and the corner with the urine samples (and thereby also the animal’s “start” corner) was changed in pseudorandomized order. The arena was cleaned with soapy water and 70% ethanol after each test, and then ventilated with clean air for 45 min (ca. 15 l/min). Control studies in our laboratory with

trimethylthiazoline, an intensive synthetic predator odor inducing strong fear behavior, showed that the cleaning procedure removed all odors that might affect the animal's behavior.

Statistical Analysis

Data are presented as mean values with standard error of the mean. The data were also grouped for each animal according to sample type (i.e., predator urine, nonpredator urine, female rat urine, and saline controls). All data were normally distributed except for the number of rearings. Normally distributed data were analyzed by repeated-measures analyses of variance (ANOVAs) with odor or odor group as a within-subject factor. Student's *t*-test (with Bonferroni correction) was used for pairwise comparisons with the saline control. Nonnormally distributed data were analyzed by a Kruskal–Wallis test; pairwise comparisons were done by the nonparametric multiple comparison according to Zar (1999, p. 224).

Results

The type of urine used strongly affected the time the animals spent in the corner with the urine probe (ANOVA: $F_{9,108}=11.59$, $P<0.001$; Figure 1a). Pairwise comparisons with the saline control showed that animals spent less time in the sample corner in the case of urine from wolves ($t=5.01$, $P<0.001$), coyotes ($t=4.7$, $P=0.001$), bobcats ($t=3.75$, $P=0.003$), cougars ($t=3.79$, $P=0.003$), and foxes ($t=2.42$, $P=0.03$), but more time in this corner in the case of urine from female rats ($t=2.66$, $P=0.02$). The urine of cows, horses, and cats did not affect the time spent in the sample corner ($t<1.09$, $P>0.30$). After the data had been grouped according to sample type, ANOVA revealed significant effects of the different sample types ($F_{3,39}=14.78$, $P<0.001$). Pairwise comparison with the saline controls showed significant effects for predator urine ($t=2.6$, $P=0.02$) and female rat urine ($t=3.04$, $P=0.009$), but not for nonpredator urine ($t=1.21$, $P=0.25$). Furthermore, the effects of exposure to predator urine and nonpredator urine differed ($t=5.26$, $P<0.001$). Typical traces of an individual rat during exposure to different urine samples illustrate avoidance behavior indicated by reduced time spent in the corner with the predator urine samples (Figure 2).

Flat back approaches are not direct and fast approaches to the samples; rather, they are more of a hesitant, sneaking approach to the threatening stimulus, with many stops. Nonparametric analysis with the Kruskal–Wallis test revealed an effect of urine samples on the number of flat back approaches ($H=29.87$, $P<0.001$; Figure 1b). *Post-hoc* pairwise comparisons showed an increase in the number of flat back approaches during exposure to the urine of coyotes, bobcats, cougars, foxes, and wolves ($Q>10.56$, $P<0.001$), but not during exposure to the urine of cats, cows, horses, and female rats ($Q=0$). The results were confirmed by an analysis of the grouped data ($H=19.72$, $P<0.001$): compared with the saline controls, predator urine led to an increase in the number of flat back approaches ($Q=6.35$, $P<0.001$), whereas the urine of nonpredators or female rats did not ($Q=0$). In addition, a difference was found between the effects of predator urine and nonpredator urine ($Q=56$, $P=0.007$).

The type of urine used influenced the time elapsed before the animal's initial contact with the samples (ANOVA: $F_{9,108}=2.41$, $P<0.02$; Figure 1c). On the other hand, pairwise comparisons showed no significant differences in this elapsed time before contact with the saline sample and other samples ($t<2.1$). However, after the data were grouped (ANOVA:

Fig. 1 Behavioral effects of exposure to different urine samples. (a) Time spent in the corner with the sample; (b) numbers of flat back approaches to the sample; (c) time elapsed before contact with the sample; (d) duration of the contact with the sample; (e) numbers of rearing during exposure to the different samples. Left panel illustrates the mean behavioral effects to each urine sample (\pm SE); right panel illustrates the mean behavioral effects to the different odor groups (\pm SE). *** P <0.001, ** P <0.01, * P <0.05, comparison with the saline control (after an ANOVA). +++ P <0.001, ++ P <0.01, comparison with exposure to nonpredator urine (after an ANOVA)

Fig. 2 Typical examples of traces of one rat during exposure to the saline control (a), to urine of a female rat (b), to urine of the nonpredator cow (c) and horse (d), and to urine of the predator cougar (e) and coyote (f). Dark ring represents the placement of the urine sample

$F_{3,39}=8.34$, $P<0.001$), an increase was found in the time elapsed before contact with predator urine samples compared with that before contact with the saline controls ($t=3.60$, $P=0.003$) and the nonpredator urine samples ($t=3.29$, $P=0.006$).

For contact duration, ANOVA showed an influence of the urine samples ($F_{9,108}=11.41$, $P<0.001$; Figure 1d). Pairwise comparison with the saline controls revealed an increase in the duration of contact with the urine of female rats ($t=3.65$, $P=0.004$) and a reduced duration of contact with the urines of coyotes, wolves, and cougars ($t>3.07$, $P<0.01$). However, after grouping the data (ANOVA: $F_{3,39}=14.45$, $P<0.001$), the effects of female rat urine were still found ($t=4.21$, $P=0.001$), but longer contact with nonpredator urine was found ($t=2.59$, $P=0.02$). No effect of predator urine was found on contact duration relative to the saline control ($t=0.88$, $P=0.38$), but there was a difference with nonpredator urine ($t=3.42$, $P=0.005$).

There were no effects of individual urine samples on the rat's rearing behavior (ANOVA: $F_{9,108}=1.63$, $P=0.12$; Figure 1e). However, after grouping the data (ANOVA:

$F_{3,39}=3.01$, $P<0.041$), a significant increase was found in rearing during exposure to predator urine ($t=3.32$, $P=0.006$). There was also a trend to increased rearing behavior with nonpredator urine ($t=1.99$, $P=0.07$). No significant difference was found in rearing behavior during exposure to predator urine and exposure to nonpredator urine ($t=1.44$, $P=0.17$).

Analysis of the data on urine samples both singly and as group showed no statistical effects of the predator urine samples on resting behavior, time spent in the middle of the arena, general motor activity (distance traveled), freezing, grooming, and numbers of fecal boli (data not shown).

Discussion

Our expectation was that defensive behavior is only observable during exposure to predator urine, but not during exposure to other samples. It should be noted that the rats used in the study were totally naive to all odors tested, i.e., that observed differences cannot be a consequence of some odors being unknown, with others being known. Exposure to urine samples of canid and feline predators induced different defensive behaviors in the animals. Behavioral responses to the different predator urine samples, with exception of cat urine samples, were similar. Possible reasons for this exception are discussed below.

Animals spent less time in corners with urine samples of canid and feline predators than in corners with saline controls and nonpredator urine, indicating avoidance behavior. Furthermore, flat back approaches, a form of risk assessment (Blanchard et al., 1990b), were only observed only in the presence of predator urine samples. In addition, there was a longer delay in making contact with predator urine samples, and the duration of contact with some of the predator odors (coyote, cougar, and wolf) was significantly decreased. Interestingly, rearing behavior—an indicator of exploratory behavior and vigilance—was increased in frequency during exposure to both predator and nonpredator urine. Other behavior indicators such as resting behavior, freezing, general motor activity (distance traveled), and grooming were not affected by exposure to predator urine. The first two indicators often increase and the latter two often decrease in frequency during exposure to aversive stimuli (Yamada and Nabeshima, 1995; Blanchard et al., 2003a; Misslin, 2003; Apfelbach et al., 2005). Female rat urine increased both the time spent in the sample corner and the duration of contact with the sample (cf. Markham et al., 2004), clearly showing that our experiment was sensitive not only to aversive, but also to attractive odors.

All types of behaviors analyzed in the present study are potentially modulated by danger. Freezing behavior is a species-specific defensive response in rats and is often used to measure fear (Fendt and Fanselow, 1999; Wiltgen and Fanselow, 2003; Sullivan et al., 2004). Surprisingly, freezing behavior was infrequent in the present study and was not exclusive to predator urine, ostensibly indicating that the canid and feline predator odors used here were unable to induce defensive behavior. However, this conclusion must be rejected for several reasons. Freezing behavior is observed only when the threatening stimulus is very intense, i.e., danger is acute (e.g., Blanchard and Blanchard, 1990; McNaughton and Corr, 2004). Indeed, intense stimuli such as foot shocks or high concentrations of trimethylthiazoline (a component of the fox odor) were able to induce freezing behavior in the experimental setup used in the present study (Fendt, unpublished observations). Results of the present study, therefore, indicate that the canid and feline predator urine samples used in this study are not a strong indicator of acute danger and do not induce freezing behavior. It is also questionable whether freezing would be an adequate

response to predator odor. While predator odor indicates the presence of a predator in the area, it is not implicitly an indicator of acute and direct predatory threat. Therefore, it is more expedient for the prey animal to intensify its risk assessment behavior or to avoid an area with predator odor in order to prevent an encounter with the predator (cf., McNaughton and Corr, 2004). On the other hand, freezing responses and flight or fight behavior are more relevant when there is acute and direct danger of encountering a predator. Another possible explanation for the lack of freezing behavior in experiments involving the presence of predator odors is that the occurrence of freezing behavior depends upon the test context. It has been shown repeatedly that a threatened animal responds by freezing only if it has no way to avoid the threatening stimulus (e.g., Blanchard and Blanchard, 1971). Otherwise, it responds with flight or avoidance behavior rather than freezing behavior.

Consequently, either the quality or intensity of the stimuli in the present study or the testing context itself was such that freezing behavior and the related inhibition of spontaneous activity and of grooming were not an appropriate response for our test animals during exposure to the samples of predator urine. As discussed above, a more appropriate response when the threatening stimulus is lower in intensity might be risk assessment behavior (cf., McNaughton and Corr, 2004) such as flat back approaches (or “stretch approaches”; e.g., Markham et al., 2004). In the present study, flat back approaches were observed only in response to the urine probes of canid and feline predators and were much more frequent as the animals approached these samples.

Direct exploration of stimuli occurs much faster when the stimuli are potentially dangerous (cf., Markham et al., 2004). For example, I found that the duration of contact with the urine probes of canid and feline predators was much shorter than with other stimuli. In contrast, the urine of female rats, which is highly attractive to male rats, was explored much longer (cf., Markham et al., 2004).

Potentially dangerous stimuli are approached not only more slowly and for a shorter period of time, but they are also avoided more thereafter (reviewed in McGregor et al., 2002; Apfelbach et al., 2005; Takahashi et al., 2005). In the present study, animals spent less time in corners with urine samples of canid and feline predators than those containing urine of nonpredators and female rats or a saline control solution. Quantitatively, in fact, this type of behavior, i.e., time spent in the urine sample corner or avoidance of that corner, was the most pronounced of all the behavioral responses assessed.

In summary, different defensive behaviors were induced by urine samples of canid and feline predators, but not by the other nonpredator samples. Although the behavioral effects of the predator urine were by and large similar, there was one major exception: the cat urine did not induce defensive behavior. This has also been demonstrated by Blanchard et al. (2003b). In that study, avoidance behavior, decreased duration of contact, and increased frequency of risk assessment behavior and freezing were induced by exposure to cat feces and cat fur/skin, but not by exposure to cat urine. This may be explained as follows. First, predator urine in general appears to be less fear-inducing than the odor of feces or skin/fur (cf., Blanchard et al., 2003b; only cat odor was tested in this study). Second, cat odor may change during domestication so that its fear-inducing properties are weakened or lost altogether. Third, cat urine was acquired in the present study by bladder catheterization. Urine acquired in this way is likely to induce less fear, as the urine used for scent marking is usually enriched by secretions of the anal gland. Fourth, domesticated cats may have a vegetarian or mixed diet changing the properties of the cat odor especially of the urine odor (cf., Berton et al., 1998).

In contrast to cat urine, urine of the other canid and feline predators used in the present study induced defensive behavior. Similar effects have been shown in a number of studies

with other prey species: beavers, black-tailed deer, snowshoe hares, deer mice, guinea pigs, house mice, gray squirrels, meadow voles, and mountain voles during exposure to coyote, wolf, fox, and bobcat urine (Sullivan et al., 1985a,b, 1988; Epple et al., 1993; Nolte et al., 1994; Swihart et al., 1999; Rosell, 2001), and, most relevantly, in rats during exposure to fox urine (Burwash et al., 1998; Campbell et al., 2003; Farmer-Dougan et al., 2005). The results of all these studies were confirmed here. In contrast to the previous work, however, the present study used (1) both predator and nonpredator urine samples and (2) laboratory animals with no experience whatever of predators or their odors. In other words, this present experiment is the first to conclusively demonstrate that several predator odors (here: canid and feline urine), but not other natural odors (here: urine of conspecifics and herbivores) induce innate defensive behavior in inexperienced rats.

Taken as a whole, the study showed that exposure to canid and feline predator urine induces defensive behaviors, particularly avoidance and risk assessment behavior, in predator-odor naive rats. It should be mentioned that this study is limited in that only canid and feline urine was used as predator odors and only herbivore urine was used as nonpredator odor. However, it is the first to test *different* predator and nonpredator probes in laboratory-reared animals. The results support the hypothesis that the effect of predator odors on the behavior of many species observed in numerous studies (reviewed in Kats and Dill, 1998; Apfelbach et al., 2005) is based on an innate recognition of predator odors. Such an innate “recognition” of predator odor is a survival advantage. In parallel, an innate recognition of visual and acoustic predator cues has also been discussed in other studies (e.g., Hirsch and Bolles, 1980; Hendrie, 1991; Hendrie et al., 1996; Eilam et al., 1999).

Acknowledgments The author thanks Daniel Endler, Daniela Schmieder, and Verena Koller for assistance with these experiments, as well as Dr. Björn Siemers for comments on the manuscript.

Introduction

Acoustic and chemical signals can play important roles during mate choice in many insects, including *Drosophila* species (Gerhardt and Huber, 2002). Pheromonal signaling systems can influence both reproductive isolation and speciation, in addition to influencing proximate decisions during courtship (Greenfield, 2002). It is of considerable interest to identify particular mate–mate signals that influence mating success in local populations and those that may determine isolation between populations or species. In some cases, mate recognition systems can influence both sexual selection and sexual isolation (Boake et al., 1997; Carson, 2000). Understanding both the genetic and environmental influences on expression of these signaling systems should help to reveal the nature of genetic differences in mate recognition systems and their evolution (Etges, 2002).

In many *Drosophila* species, epicuticular hydrocarbons (EHC) are thought to serve as contact pheromones as well as to enhance desiccation resistance (Blomquist et al., 1987). Although the genetic basis of some hydrocarbon components is partially understood in some drosophilids (reviewed in Gleason et al., 2005), genetic and environmental influences on production and deposition (Wigglesworth, 1988) are poorly known for most species. Once revealed, the structure and function of individual hydrocarbon genes alone will be insufficient without knowledge of how EHCs are expressed in natural or experimental populations subject to potential environmental modification. We seek to gain a further understanding of the role of lifetime environmental influences on genetic variation in EHC production in insects and how this EHC variation influences behavior, mate choice, sexual selection, and sexual isolation in nature (e.g., Toolson and Kuper-Simbron, 1989; Howard et al., 1995; Howard, 1998; Liang and Silverman, 2000; Woodrow et al., 2000; Savarit and Ferveur, 2002; Buczkowski et al., 2005).

Here, we investigate the role of dietary triacylglycerols in larval *Drosophila mojavensis* on subsequent adult EHC profiles. Differences in natural larval feeding substrates vs. synthetic laboratory media influence EHC abundance in this species (Stennett and Etges, 1997). These differences also influence adult mating preferences (Etges, 1992, 1998; Brazner and Etges, 1993). In *D. mojavensis*, the function of cuticular lipids seems unrelated to desiccation resistance by reducing water loss (Gibbs et al., 1998), underscoring their role, and probable maintenance, as contact pheromones (Etges and Ahrens, 2001). We hypothesize that identifying substrate-specific precursors that influence adult EHC profiles will help to resolve host plant influences on mating behavior, as well as identify ecological sources of variation on patterns of reproductive isolation in nature.

Fatty acid metabolism and EHC biosynthesis have been well studied in *D. melanogaster* and should help in understanding lipid metabolism in *D. mojavensis*. Adult EHC production involves modification of fatty acid precursors, but little is known about the influences of fatty acids in larval diets on adult EHCs. Production of adult *D. melanogaster* sex pheromone (*Z,Z*)-7,11-heptacosadiene starts from either acetate or from medium-sized fatty acids (Chan Yong and Jallon, 1986; Jallon et al., 1986). From preformed fatty acids produced by fatty acid synthetase (de Renobales and Blomquist, 1984), palmitate is a better substrate than stearate and is desaturated into palmitoleate (ω -7) (Ferveur et al., 1989) by the *desat1* gene product (Wicker-Thomas et al., 1997; Dallerac et al., 2000; Labeur et al., 2002). From palmitoleate there is elongation to *cis*-vaccenate and subsequently several elongations, a second desaturation (the substrate of which has not yet been characterized) by another desaturase (Wicker-Thomas and Jallon, 2001; Jallon and Wicker-Thomas, 2003), and a subsequent decarboxylation (Jallon, 1984; Pennanec'h et al., 1997). Fatty acid

analysis of sexually mature *D. melanogaster* indicates high percentages of palmitoleate, but lesser quantities of oleate and *cis*-vaccenate, with oleate and linoleate decreasing as (*Z,Z*)-7,11-heptacosadiene synthesis occurs (Pennanec'h et al., 1997). Very long chain (C_{20} , C_{22} , C_{24} , and C_{26}) fatty acids with apparent ω -7 unsaturation and female dienoic acids with 22 and 24 carbons have also been detected (Pennanec'h et al., 1997). Together, these experiments and those of other groups (Keith, 1967a,b; Pennanec'h et al., 1991) suggest that fatty acids, either from biosynthesis or the diet, impact the biosynthesis of pheromones and other dipteran EHCs.

We hypothesize that different fatty acids in the cactus diets of *D. mojavensis* can change pheromone and other adult EHC profiles. A number of different hosts are used by *D. mojavensis*, including agria cactus, *Stenocereus gummosus*, in Baja California and organ pipe cactus, *S. thurberi*, in mainland Mexico and Arizona (Heed and Mangan, 1986). Fatty acid profiles of both agria and organ pipe cactus are mainly characterized by caproic (C_{10}) and lauric (C_{12}) acids in concentrations of 34–45%, with much lower concentrations of caprylic acid (C_8) and others in sizes up to C_{18} (Fogleman and Kircher, 1986). There are no overall significant differences between cactus species with respect to fatty acid composition (Fogleman and Kircher, 1986). However, cactus fatty acid analysis shows greater quantities of unsaturated fatty acids (12:1, 12:2, and 18:1) in agria vs. organ pipe cactus, but the location of double bonds has not been determined. It may be that minor quantities of unsaturated fatty acids in the diet of *D. mojavensis* influence biosynthesis of unsaturated EHCs, so we employed both saturated and unsaturated triacylglycerols to determine whether they influence EHC profiles of adult *D. mojavensis*.

EHCs of adult *D. mojavensis* are composed of C_{28} to C_{40} alkanes, 2-methylalkanes, alkenes, methyl-branched alkenes, and multimethylene interrupted alkadienes, with the largest fraction of adult hydrocarbons composed of C_{35} alkadienes (Toolson et al., 1990; Stennett and Etges, 1997; Etges and Jackson, 2001). We hypothesize that the EHCs of *D. mojavensis* are derived from three fatty acid pools: ω -9, ω -7, and saturated fatty acids. The ω -9 fatty acids are precursors of the 9-alkenes and the 8, *X*-alkadienes (e.g., $C_8=C_{16}=C_9$, $C_8=C_{18}=C_9$, $C_8=C_{20}=C_9$, etc.) since they are really 9, *X*-alkadienes counting from the other end. The ω -7 fatty acids are precursors to the 7-alkenes and the 7, *X*-alkadienes (e.g., $C_7=C_{16}=C_{10}$, $C_7=C_{18}=C_{10}$, $C_7=C_{20}=C_{10}$, etc.). The saturated fatty acids are precursors to the alkanes, and the 10-, 12-, and 8-alkenes also result from saturated fatty acids when desaturation occurs late in the biosynthetic pathway.

Given the previously described fatty acid profiles in agria and organ pipe cactus, and the substrates known to be involved in EHC biosynthesis, we used tripalmitolein ($C_{16}:1$, ω -7), tristearin (C_{18}), and triolein ($C_{18}:1$, ω -9) in differing concentrations in larval diets to assess their influences on egg to adult viability and on adult EHC composition in two populations of *D. mojavensis*.

Methods and Materials

Fly Stocks

Populations of *D. mojavensis* were collected in 1996 from south of Santa Rosalia, Baja California Sur (stock no. A975, 15 adults), and El Fuerte, Sinaloa (stock no. A991, 185 adults), over baits or by collecting adults emerging from fermenting cactus tissues, “rots,” returned to the laboratory. All flies were maintained on banana–malt–yeast–agar food at room temperature in mass cultures (Brazner and Etges, 1993). Several hundred adults from

each population were placed in separate oviposition chambers and kept in an incubator programmed for a 14:10 L/D photoperiod and a temperature cycle of 27:17°C. Eggs were collected daily on oviposition media from 8:00 AM to 6:00 PM in removable Petri dishes attached to each chamber. Eggs were washed with deionized water, 70% ethanol, and surface sterilized for 10 min in 70% ethanol. Eggs were then counted in sterile, deionized water in groups of 100 onto 1-cm² pieces of sterile filter paper and placed into vials containing *Drosophila* medium (see below). Filter paper was removed after 24–48 hr, and numbers of unhatched eggs were counted in order to calculate egg to adult viability.

Food vials were prepared with standard Instant *Drosophila* Medium[®] formula 4–24 (Carolina Biological Supply Co., Burlington, NC, USA); or with “defatted” medium (both controls), as well as by adding different concentrations of triacylglycerols (TAGS) to the dry, homogeneous defatted diet. For the defatted medium, lipids were removed from the standard medium by Soxhlet extraction with hexane. We prepared 9% stock solutions of each triacylglycerol. Triolein (ω -9), tripalmitolein (ω -7), and tristearin in pentane were added to 2 g of dry defatted diet in final concentrations of 1%, 3%, and 9%. Each 2-g aliquot of food was completely dried under a fume hood, added to a sterile 8 dram shell vial, and rehydrated with an equal volume of sterile, deionized water. Combinations of equal amounts of all three TAGs were also prepared so that the final concentrations of the three combined would be 1%, 3%, and 9%. These latter treatments were prepared to test the hypothesis that all three TAGS should produce EHC profiles more like the standard or defatted diets, but at comparable concentrations to the single TAG treatments. Two replicate cultures of each TAG concentration were created for each population of *D. mojavensis*, and six replicates were included for both the standard and defatted diets. Live baker’s yeast was added to each vial *ad libitum* to insure larval survivorship.

Epicuticular Hydrocarbon Analyses

All eclosed adults were aspirated from each culture vial daily, sexed under light CO₂, and placed into separate vials containing banana–yeast–malt–agar food for at least 14 d and then frozen in hexane-rinsed glass vials at –20°C. EHCs were extracted from groups of males and females in Biosil minicolumns. Each column consisted of a Pasteur pipette containing packed glass wool and Biosil (silica gel, Sigma[™] S-4133, Sigma-Aldrich, St. Louis, MO, USA) flushed several times with HPLC-grade hexane. Flies were added to the top of the column, washed in 8 ml of hexane, and the hydrocarbons were collected in hexane-rinsed vials. After the hexane was evaporated with nitrogen, each sample was sealed and stored at –20°C. When only one or two flies were available from some replicates, we used hydrocarbon extraction procedures described by Savarit et al. (1999). Flies were placed in conical glass microvials and immersed in 50 μ l hexane per fly. The vials were agitated, and after 20 min, flies were removed, the hexane was evaporated off, and each vial was frozen.

Each hydrocarbon sample was redissolved in hexane (2 μ l/fly) containing 382 ng of docosane (C₂₂) per μ l as an internal standard with the exception of samples containing only one or two flies, which were redissolved in 5 μ l hexane with the same concentration of internal standard. One μ l of each sample was analyzed by capillary gas–liquid chromatography using a Shimadzu GC14 (Shimadzu Scientific Instruments, Columbia, MD, USA) fitted with a 30 m DB-1 fused silica column (Agilent Technologies, Palo Alto, CA, USA). Injector and detector temperatures were set at 345°C with the injector port in split mode (split ratio=100:1) and the column was heated from 200°C to 345°C at 10°C/min holding at 345°C for 5 min (Stennett and Etges, 1997).

Statistical Analyses

Egg to adult viability was calculated as the number of eclosed adults divided by the number of hatched eggs. Variation in viability due to substrate and TAG concentration was assessed with analysis of variance (ANOVA; SAS Institute, 2004). Viability data were arcsin transformed prior to analysis.

EHC amounts were estimated by analysis of peak integrations using EZCHROM software (ver. 2.1) provided by Shimadzu. Each sample amount was normalized by the amount of internal standard. Replicate groups of flies were analyzed together. All data were expressed as ng/fly of EHCs and were analyzed by ANOVA and multivariate analysis of variance (MANOVA) using PROC GLM in SAS (SAS Institute, 2004) with population, TAG, TAG concentration, and sex as main effects and all interactions between main effects. Population and all interactions with population were considered random effects.

Post-hoc multiple comparisons were evaluated, and canonical correlation analysis in PROC GLM and CANDISC was employed to reveal EHC responses to different TAGs. Contrasts among diet treatments were also carried out using EHCs grouped by chemical structure according to Etges and Jackson (2001).

Results

Effects of Triacylglycerols on Egg to Adult Viability

Type of TAG, concentration of TAG, and their interactions had significant effects on egg to adult viability in these two populations of *D. mojavensis* (Fig. 1, Table 1). Overall, flies reared on standard medium, defatted medium, or defatted medium with tristearin had equivalent viabilities that were significantly higher than those from flies reared on defatted medium with triolein, tripalmitolein, or combinations of all three TAGs (Tukey's multiple range test, $P < 0.05$). Except for tristearin, concentrations of TAGs exceeding 1% drastically reduced viability: egg to adult viability of controls (mean \pm 1 SD on standard diet = 0.47 ± 0.21 ; on defatted diet = 0.57 ± 0.30) and of defatted diet with all three TAGs at 1% (0.24 ± 0.10) were higher than viabilities for diets with TAGs at 3% and 9% (both 0.18; Tukey's multiple range test, $P < 0.05$). Egg to adult viability of laboratory populations of *D. mojavensis* reared on fermenting cactus or banana food tend to be much higher (> 0.80 , see Etges and Ahrens, 2001) than on standard diet, suggesting that the latter medium reduced preadult fitness in these experiments. Similar viabilities of flies reared on standard and defatted diets were surprising given the removal of lipids in the latter (Fig. 1), but may have been mediated by the addition of live baker's yeast.

At triolein and tripalmitolein concentrations of 3% and 9%, very few flies survived to eclosion (Fig. 1), with many never making it to the pupal stage. At these higher concentrations, flies that did eclose seemed to be unable to initiate cuticle hardening and died before wing expansion.

Effects of Triacylglycerols on Adult Epicuticular Hydrocarbons

Differences in EHC amounts due to TAG type were apparent for all but six of the 25 EHC components assayed (Table 2 for quantities and Appendix for ANOVA of the 20 most abundant EHCs). The ANOVA results were based on all TAGs employed, plus combinations of them at each concentration for which flies eclosed. The two control media were not included in these ANOVAs so we could focus on TAG differences. In most cases,

Fig. 1 Egg to adult viability (± 1 SD) of two populations of *Drosophila mojavensis* cultured on defatted media with 1%, 3%, and 9% triacylglycerols alone and in combination. Live Baker's yeast was added to all cultures when initiated. See the text for details

EHC amounts were lowest for flies reared on defatted media, but similar among flies reared on standard medium and defatted media supplemented with TAGs (Table 2). Missing data due to high or total egg to adult mortality, particularly in the 3% and 9% tripalmitolein-containing cultures, meant that TAG type and concentration were somewhat confounded in the ANOVAs. This may partially explain the lack of a concentration effect in these analyses, except in a few cases.

EHC differences due to TAG type were overlaid on the known population differences that in some cases resulted in Population \times TAG interactions (Appendix). Consistent with most previous studies, 13 of the EHC components differed between the Baja California and Sinaloa (mainland) populations, especially 2-methyloctacosane ($C_{28.65}$), 8,24-tricontadiene ($C_{33.63}$), 9,25-pentatricosadiene ($C_{34.59}$), and 9,27-heptatricosadiene ($C_{36.5}$). The latter three alkenes showed characteristic regional differentiation in amounts, where mainland populations all expressed much greater amounts of these EHCs than Baja California populations (Stennett and Etges, 1997; Etges and Ahrens, 2001). Two of these EHCs, $C_{33.63}$ and $C_{34.59}$, exhibited Population \times TAG interactions suggesting that even though amounts

^a See Toolson et al. (1990) and Erges and Jackson (2001) for details of the GC-MS analyses and determination of the double bond locations.

^b Diet refers to the two control diet treatments in this study and the three triacylglycerols (concentrations combined) added to the defatted diet. Combination refers to the combination of all three triacylglycerols. *N*=number of replicate cultures.

^c ECL is the equivalent chain length of each hydrocarbon component, if known.

^d Group definitions are M fem=mainland females; M mal=mainland males; B fem=Baja females; B mal=Baja males.

differed between populations, Sinaloa EHCs responded to the three TAGs far differently than Baja California EHCs (Fig. 2a). In both cases, combinations of the three TAGs increased EHC amounts in the Sinaloa population far more than in the Baja population. For the large $C_{34.59}$ diene component, 9% TAG concentrations vastly reduced the amounts of this EHC as compared to 1% and 3% concentrations (Tukey's multiple range test, $P < 0.05$).

Multivariate ANOVA of EHC differences revealed significant variation due to all treatments except for the Population \times Sex interaction (Table 3). Here, Roy's Greatest Root is the largest characteristic root or eigenvalue that explains the greatest proportion of variation (percent) in each factor of the MANOVA. The largest eigenvalues for population and sex accounted for 100% of the total variation in EHC abundance, with more complex sources of variation explaining TAG differences given that the first eigenvalue accounted for approximately half of the variation (Table 3). Males had more EHCs than females (likelihood ratio = 0.3331, $F = 4.76$, $df = 24/57$, $P < 0.001$). Because the data were unbalanced by the absence of flies in the 3% and 9% triolein and tripalmitolein treatments (Fig. 1), concentration effects were confounded with TAG type, and may have spuriously resulted in a significant TAG \times concentration interaction term.

The overall pattern of EHC variation due to control and TAG treatments was assessed by calculating Mahalanobis distances between groups in PROC CANDISC (Table 4). Significance of these differences indicated that these dietary treatments almost always caused significantly different EHC profiles, except for a number of comparisons involving control diets (overall variation indicated by Roy's Greatest Root = 3.33, $F = 7.91$, $df = 24/57$, $P < 0.001$). EHC profiles were different between triolein and tripalmitolein treatments, and among these two diets and all others. Both control diets produced similar EHC profiles, but only the defatted control diet resulted in similar EHC profiles as the combination treatment ($P = 0.159$, Table 4).

Loadings for each diet on the first three canonical variables, accounting for 89.8% of TAG variation, showed clearer similarities between tristearin and control diet treatments (Fig. 2b). The overall effects of tripalmitolein and triolein strongly influenced the effects of the combination diets, i.e., EHC differences due to the three TAGs in combination were more "similar" to the tripalmitolein and triolein centroids than to the tristearin centroid (Fig. 2b). Removing the control diets from this analysis made this tripalmitolein-combination comparison somewhat more apparent (Fig. 2a). Here, population differences were included, revealing some overlap between EHC differences from tristearin-treated Baja California files and those due to the combination diet. Qualitatively, these results suggest that there may have been a greater influence of this unsaturated TAG in the combination diets for this Baja California population than for the Sinaloa population. However, replicate numbers were limited for the Sinaloa population.

Pairwise *post-hoc* comparisons revealed the effects of dietary treatments on EHC profiles (Table 5). Missing data due to the absence of flies in the 3% and 9% triolein and tripalmitolein treatments did not permit the use of the CONTRAST option in the MANOVA for all EHCs together except for one case, so pairwise contrasts between treatments were performed, despite a loss of power (Scheiner, 1993). Only one *post-hoc* comparison was possible, tristearin vs. TAG combination, revealing the nature of this unsaturated TAG on EHC profiles ($F = 3.62$, $df = 24/7$, $P = 0.035$). Least square means were greater for a majority of the EHCs assayed due to the TAG combination diets than tristearin, including $C_{28.65}$, $C_{30.78}$, $C_{32.63}$, $C_{32.70}$, $C_{32.79}$, all C_{34} components, $C_{34.59}$, $C_{34.66}$, and $C_{36.5}$. Thus, although not toxic even at higher concentrations (Fig. 1), tristearin is insufficient alone as a substrate for EHC biosynthesis vs. the combination of the unsaturated and saturated TAGs used here.

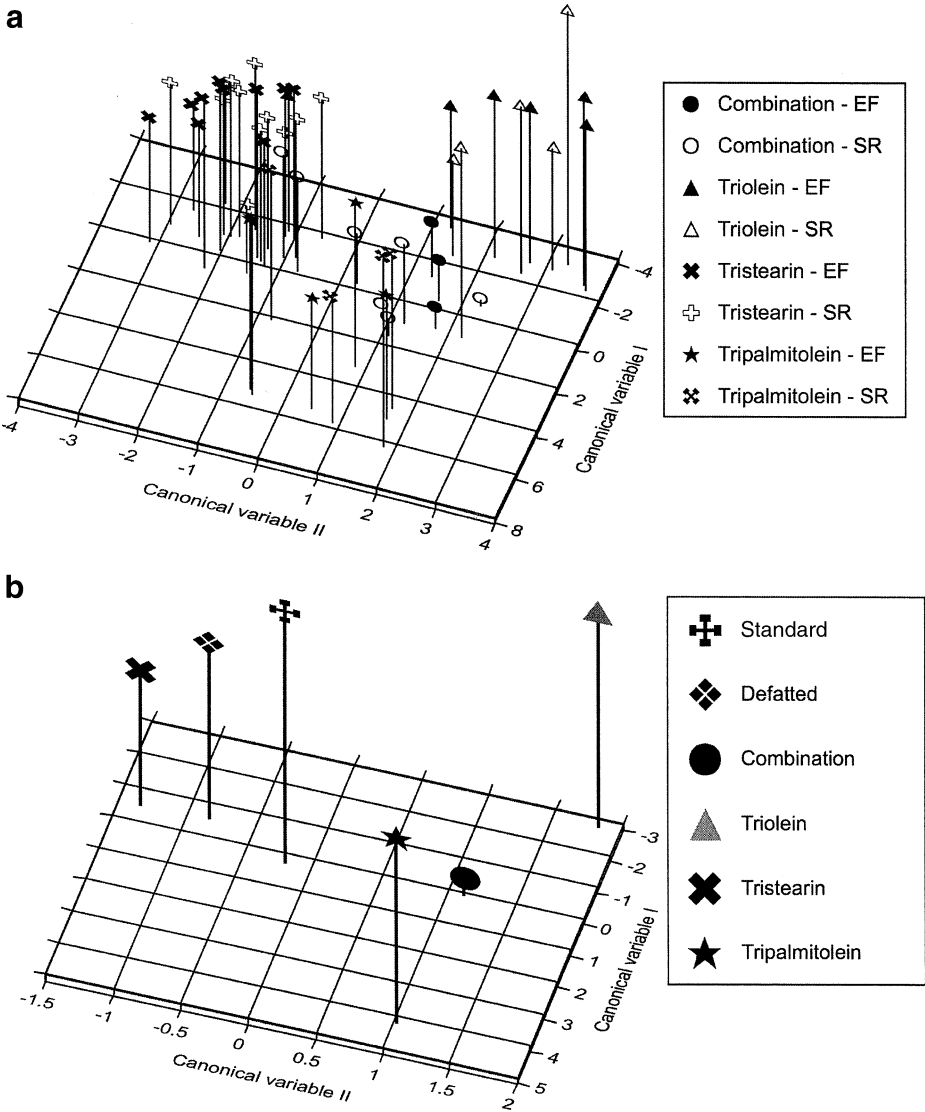

Fig. 2 Canonical discriminant function plot (a) showing the effects of triacylglycerols for each population (EF: El Fuerte, Sinaloa, mainland; SR: Santa Rosalia, Baja California) with the control diet data excluded to better illustrate the effects of the three triacylglycerols on epicuticular hydrocarbon variation. Canonical discriminant function plot (b) showing the effects of the three triacylglycerols alone and in combination, plus the two control diets on variation in epicuticular hydrocarbon profiles for all *Drosophila mojavensis* in this study grouped by population, sex, and triacylglycerol concentration

The remaining pairwise TAG comparisons for EHC profiles caused a reduction in the degrees of freedom for the error term required for significance testing, and this resulted in undefined eigenvalues. To increase degrees of freedom, EHC components were combined into hydrocarbon classes, i.e., alkanes, methylalkanes, alkenes, methylalkenes, and alkadienes (Etges and Jackson, 2001). Grouping the EHCs together by chemical structure

^a Combinations of all three triacylglycerols (TAGs) were included, but control diets were not, in order to assess TAG effects in combination with the other factors.

reduced the dimensionality and perhaps some of the variation in the data (Table 5). Several of the comparisons were not significantly different despite the significance of the Mahalanobis' distances (Table 4). Pairwise *post-hoc* comparisons again showed that most EHC differences were caused by tristearin vs. the unsaturated TAGs (Fig. 2b), suggesting that TAG substrate-induced shifts in adult EHCs may not have necessarily influenced specific classes of hydrocarbons, but caused overall shifts in most types of hydrocarbons (Table 5). Triolein caused greater amounts of all EHCs than tristearin, particularly in 2-methyloctacosane (C_{28.65}), 2-methyltricontane (C_{30.65}), 7- and 9-hentricontene (C_{30.78}), 8,24-tricontadiene (C_{32.63}), 9,25-pentatricontadiene (C_{34.59}), 8,26- and 7,27-pentatricontadiene (C_{34.66}), and all three major C₃₇ components (Table 2 and Tukey's multiple range tests, all *P*<0.05 based on ANOVAs in Appendix). Similarly, tripalmitolein caused greater amounts of all EHCs than tristearin in many of the same EHCs including 2-methyloctacosane (C_{28.65}), 2-methyltricontane (C_{30.65}), 7, 25-tricontadiene (C_{32.70}), 10-, 12-, and 14-tritricontene (C_{32.79}), 10-, 12-, and 14 tetratricontene (C_{34.ene}), 9,25-pentatricontadiene (C_{34.59}), 8,26- and 7,27-pentatricontadiene (C_{34.66}), 9,27-heptatricontadiene (C_{36.5}), and 8,28-heptatricontadiene (C_{36.6}) (Table 2 and Appendix, Tukey's multiple range tests, *P*<

0.05). Thus, we tentatively rejected the hypothesis that particular unsaturated or saturated TAGs in larval diets induced variation in specific saturated or unsaturated EHCs in the adults. Both unsaturated TAGs caused higher levels of all adult EHCs, suggesting they are more easily incorporated into EHC biosynthesis than tristearin despite the higher toxicity of the unsaturated TAGs during larval development (Fig. 1).

Discussion

Low larval diet concentrations of some triacylglycerols present in the fermenting cactus tissues used by *D. mojavensis* as breeding sites caused significant shifts in amounts of EHCs expressed in mature adults. The hypothesis that different fatty acid pools from larval diets would be preferentially used as substrates for different saturated and unsaturated adult EHCs was rejected. Unsaturated triacylglycerols caused increases in a wide range of adult EHCs in *D. mojavensis* (Tables 1, 2, and 5), and although not toxic at higher concentrations, tristearin diets were consistently associated with lower quantities of most adult EHCs. Thus, tristearin is not likely a suitable substrate for lipid biosynthesis in *D. mojavensis*, consistent with Pennac'h et al. (1997), who found that stearic acid was not a preferred precursor for hydrocarbon production in adult *D. melanogaster*, yet palmitic acid was readily incorporated. The chemical cues that determine mate recognition and sexual isolation in *D. mojavensis* are therefore sensitive to some of the triacylglycerols present in natural rearing substrates.

The observed variation in TAG response shown by the Population \times TAG interactions (Appendix) in EHC abundance suggests these genetically differentiated populations differ in ability to synthesize adult EHCs from fatty acid precursors. The large geographic differences in EHC profiles, particularly due to differences between Baja California and mainland Mexico and Arizona populations (Stennett and Etges, 1997; Etges and Ahrens, 2001) in amounts of 8,24-tricontadiene ($C_{32.63}$), 9,25-pentatricontadiene ($C_{34.59}$), and 9,27-heptatricontadiene ($C_{36.5}$) are thus sensitive to TAG variation. Overall, variation in amounts of EHCs was more influenced by population differences than by the types of TAGs used in this study (Fig. 2a, Table 1), but the mainland population here (Sinaloa) was more sensitive to TAG amounts than the Baja California population. Such geographical variation is consistent with previous observations that mainland populations of *D. mojavensis* are more

sensitive to available nutrients in rearing substrates than Baja populations (Etges and Heed, 1987). At higher larval densities in cactus cultures where competition for food is increased, mainland populations express reduced viability and longer development times than Baja California populations, suggesting lower genetic homeostasis in mainland populations for these components of fitness (Etges, 1989).

Even though all larval cultures were supplemented with live baker's yeast and adults were aged to maturity on banana media, EHC profiles from triolein- and tripalmitolein-treated flies were significantly different among other treatment groups, with few differences due to the control diets (Table 4). Flies were aged at least 12–14 d on lab food in order to ensure that they were sexually mature (ca. 8–10 d for males at 25°C; Markow, 1982). This may have influenced adult EHC profiles despite the effects of these TAGs during larval stages, along with the effects of including live yeast to insure survivorship on the diet. Supplemental yeast provides larvae with nucleic acids, sterols, and essential vitamins and nutrients, including fatty acids. However, cultures from all treatment groups included the yeast, so if the additional yeast affected fatty acid metabolism in the flies, all treatment groups should have been influenced to the same degree. Because EHC amounts increase in abundance from eclosion to sexual maturity in *D. mojavensis* (Toolson et al., 1990), we wanted to be sure that our assays were performed with adults that had been reared in the same way as in previous experiments that had shown the consequences of preadult rearing environments on adult mating behavior.

EHC production has been intensively studied in adult insects (reviewed in Blomquist, 2003), but the influence of metabolism of lipids during larval stages on adult EHC profiles is not well understood. Biosynthesis of adult EHCs has been intensively studied, particularly in immature males and females in *D. melanogaster*, *D. simulans*, and *D. erecta*. EHC sexual dimorphism increases with age until sexual maturity is attained (Jallon and Wicker-Thomas, 2003). In *D. mojavensis*, rearing larvae on fermenting cactus lowers pre-mating isolation compared to laboratory media (Etges, 1992; Brazner and Etges, 1993) despite a maturation period of up to 2 wk on banana food. We used this protocol to directly compare the effects of preadult rearing conditions without changing adult rearing procedures used in previous experiments. Thus, the rearing substrates experienced by preadult *D. mojavensis* cause a “carryover” effect that influences adult EHC composition and mating behavior past the age of sexual maturity.

The effects of tristearin in larval diets on adult *D. mojavensis* EHCs were consistent with earlier observations of its role as a lesser used substrate for adult EHC biosynthesis (Pennanec'h et al., 1997). Tristearin's effects on larval viability suggest it is either not metabolized effectively in larvae, or once assimilated, it has negligible effects even at higher concentrations (Fig. 1). Since the effects of tristearin on EHC profiles were not significantly different from either of the control diets, but very different from both triolein and tripalmitolein (Table 4), it may not be assimilated into adult hydrocarbons. More data will be needed to confirm this. Tripalmitolein, tristearin, and triolein are present in much lower concentrations (0–2.3%) in agria and organ pipe cacti than the most abundant saturated fatty acids, capric (C₁₀) and lauric (C₁₂) acid, which together account for 30–45% of total fatty acids (Fogleman and Kircher, 1986). Capric and lauric acids have been shown to have negligible effects on larval viability in *D. mojavensis* at 0.5% concentrations, but lauric acid significantly depressed viability at 1%. Thus, saturated fatty acids *per se* are not poor substrates for lipid and hydrocarbon metabolism: some are assimilated during larval growth and development and have variable effects depending on concentration.

Direct chemical links between host substrates and the resulting pheromonal cues used as both mate recognition signals and part of species recognition systems have broad

significance to studies on ecological speciation (Funk, 1998; Nosil et al., 2002; Sandoval and Nosil, 2005). In general, host plant adaptation typically involves host chemistry to some degree (Harborne, 1982; Bernays and Chapman, 1994; Thompson, 1994; Becerra, 1997; Funk et al., 2002), so host plant fatty acid or TAG determinants of EHC abundance in adult *D. mojavensis* provide direct evidence for how differential host use might determine reproductive isolation among insects. Although future studies will be necessary to show that TAG-induced shifts in adult EHC abundance directly influence patterns of mate choice, these diet-induced phenomonal shifts need to be considered in studies on reproductive isolation, particularly in *Drosophila* species. Enough is known about cactus stem chemistry that we can now design further experiments to examine the effects of these secondary compounds on the behavior and physiology of the insects that use these host plants.

Perhaps half of the species in the large *D. repleta* group (ca. 100 species) use cacti to carry out their life cycles. Along with a few other drosophilids that are cactus specialists, e.g., species in the *nannoptera* group (Heed, 1982), there are likely other species in which adult physiology and behavior has been shaped by the host plants used for feeding and breeding. In the Sonoran Desert, cactophilic *Drosophila* use different species of columnar cacti as breeding sites (Heed and Mangan, 1986). Host chemistry has been studied in detail in order to understand why certain host cacti are used preferentially by particular *Drosophila* species (Fogleman and Abril, 1990; Fogleman and Danielson, 2001). For *D. mojavensis*, crude lipid extracts from its major host plants, agria and organ pipe cactus, are not toxic because fatty acids and sterol diols are esterified to either neutral triterpenes, betulin and calenduladiol, or di-hydroxysterols (Fogleman et al., 1986). These neutral triterpenes are not toxic, but low concentrations of medium chain fatty acids and sterol diols can significantly depress larval viability. However, *D. mojavensis* is more tolerant of free fatty acids during larval growth and development than other desert drosophilids (Fogleman and Kircher, 1986). Agria and organ pipe cacti contain higher concentration of these fatty acids than other host cacti, so this may help to explain why *D. mojavensis*, but not other *Drosophila* species, tend to specialize on these cacti.

Throughout its evolutionary history, *D. mojavensis* has expanded its range by switching to different host cacti. Originating in Baja California, *D. mojavensis* colonized mainland Mexico, Arizona, and southern California by switching host plants. Use of agria cactus in Baja California is considered ancestral, with derived mainland populations using organ pipe cactus in Sonora and Sinaloa, Mexico, as well as southern Arizona (Etges et al., 1999). Sina cactus, *S. alamosensis*, is occasionally used in Sonora and northern Sinaloa, and in southern California, California barrel cactus, *Ferocactus cylindraceous*, is a major host. The colonization of mainland Mexico from Baja California by switching to organ pipe cactus has caused widespread genetic differences in life history traits, chromosome and genic frequency shifts, and physiological adaptation to these secondary hosts that has also resulted in the evolution of altered mating preferences in mainland populations (Etges, 1998; Etges and Ahrens, 2001, 2002). The evolutionary relationships between *D. mojavensis* and its host cacti suggest that this is an ideal system with which to pursue the molecular and chemical causes of ecological speciation, particularly if the mechanisms underlying these evolutionary shifts are related to host plant chemistry. These host plants have shaped the development and physiology of the insects that use them, causing not only adaptive responses in terms of host use and specialization, but also potential reproductive isolation among species that use different hosts.

Acknowledgments We thank J. C. Fogleman for information about host cactus chemistry, B. Durham for access to the GC, and S.J. Seybold and two anonymous reviewers for constructive comments. This work was

different herbivores) and specificity of effect (the range of organisms affected by a given induced response) (Karban and Baldwin, 1997; Stout et al., 1998; Agrawal, 2000). Specificity of elicitation, the focus of our study, occurs when the induced response varies among herbivores, across chemical types, or if it varies in magnitude or location within the plant. For example, mechanical wounding can differ from herbivory (Hartley and Lawton, 1987; Turlings et al., 1990; Mattiacci et al., 1995; Alborn et al., 1997; McCloud and Baldwin, 1997), and different herbivores, species and/or developmental stages, can generate distinct responses (Stout et al., 1994; Takabayashi and Dicke, 1996; Inbar et al., 1999; Schittko et al., 2000). Furthermore, certain compounds within a class may be induced and not others (Clausen et al., 1989; Bodnaryk, 1994; Stout et al., 1994, 1998; Doughty et al., 1995; Ruuhola et al., 2001), or the response may only occur in certain tissues (Jones et al., 1993; Stout et al., 1996). Whereas these studies document specificity of induction, no single study simultaneously examines how contrasting herbivores differentially induce closely related chemicals and how these induced responses vary both locally (in the damaged tissue) and systemically (but see combined studies of Stout et al., 1994, 1996, 1998). This study focused on the specificity of phytochemical induction in *Salix sericea*.

Like many members of the Salicaceae, *S. sericea* is attacked by a diversity of herbivores and produces phenolic glycosides, a group of chemicals that deter feeding of many generalist herbivores (Tahvanainen et al., 1985; Lindroth et al., 1988). The two most common phenolic glycosides in *S. sericea* are salicortin and 2'-cinnamoylsalicortin, which can account for 11.6 and 1.5% of the dry leaf mass, respectively (Orians et al., 1996). Induction of phenolic glycosides has been previously reported in cuttings from adult plants of *S. myrsinifolia* but not *S. pentandra* (Julkunen-Tiitto et al., 1995; Ruuhola et al., 2001). More specifically, Ruuhola et al. (2001) only found significant induction of certain phenolic glycosides in undamaged immature leaves, but not in damaged mature leaves of *S. myrsinifolia*. Mature damaged leaves only showed increases in degradation products. Stevens and Lindroth (2005), using 2-yr-old *Populus tremuloides* obtained from root micropropagation, did not observe rapid induction of phenolic glycosides immediately after manual damage but found that levels were elevated later in the season (termed within-season-delayed systemic induction). Although these studies show that induction can occur, it is not known whether different herbivores have contrasting effects or if seedlings can be induced, locally or systemically.

Here, we examined whether *Plagioderia versicolora* adults, *P. versicolora* larvae, and *Calligrapha multipunctata bigsbyana* adults (Chrysomelidae, Coleoptera) induce phenolic glycosides both locally (damaged leaves) and systemically (in undamaged leaves above and below the damaged leaves). We hypothesized that the induction of phenolic glycosides would be pronounced in response to both species, as high concentrations of phenolic glycosides are known to inhibit their feeding and growth rates (Tahvanainen et al., 1985; Orians et al., 1997). We also expected induction to be greatest in the young damaged leaves, intermediate in the younger undamaged leaves, and minimal in mature undamaged leaves.

Methods and Materials

Plants and Insects

Salix sericea (Marshall), silky willow, is a 0.5- to 4-m high shrub that occurs in riparian and swampy areas in eastern Canada and northeastern United States. In New York, *S. sericea* produces leaves continuously from May until September. Plants flower in late April, and

the female plants set seed at the end of May. Seed germination occurs immediately. *S. sericea* is attacked by numerous specialist and generalist herbivores, including several species of coleopteran leaf chewers (Orians and Fritz, 1996; Orians et al., 1997).

S. sericea full-sibling progeny (S47×S16) was generated from a wild population of willows in Milford, NY. Crosses were made by transferring pollen from S47 male to catkins of S16 female. We used a single full-sib family to minimize possible genetic variation in constitutive chemistry and induced responses (Stevens and Lindroth, 2005). Catkins had been covered with mesh pollination bags to prevent visitation by insect pollinators, and, once pollinated, bags were replaced and left until seed maturation. On June 3, 2002, seeds were sown in separate trays, and the resulting seedlings were grown in a shaded open-end greenhouse (30% of full sun) located at our field station in Milford, NY. Following germination, each seedling was transferred to a 0.75-dl pot. Seedlings were watered daily and received a weekly standard solution of fertilizer (6 g/l of Peters Professional NPK 20:20:20). The experiments were initiated on July 28, when the seedlings were between 6 and 13 cm tall and had 5–11 fully expanded leaves.

Beetles (Coleoptera: Chrysomelidae) were collected from the immediate area surrounding the field station on the day before the experiments were initiated. *C. multipunctata bigsbyana* (Kirby) adults and *P. versicolora* (Laicharting) adults and larvae, hereafter referred to as *Calligrapha* adults and *Plagioder*a adults and larvae, respectively, were collected while feeding on *S. sericea* and *S. sericea* × *S. eriocephala* hybrids. While both species are generalist feeders on *Salix*, *Calligrapha* is native, whereas *Plagioder*a is not. It is, therefore, conceivable that the response to the native *Calligrapha* could be greater. Adults were held without food prior to induction assays; larvae were caged along with the leaf they were feeding on at the time of collection.

Plant Treatments

Treatments were initiated on July 28, 2002 (d 0). Each seedling was randomly assigned to one of four treatments: *Plagioder*a larvae (PVL; $N=28$), *Plagioder*a adults (PVA; $N=29$), *Calligrapha* adults (CMA; $N=30$), and control (CON; $N=26$). Each seedling was randomly placed within the greenhouse on d 0 and again on d 2.

For each plant, a clip cage (5.0-cm diameter, consisting of two plastic petri plate tops hinged together with a metal hair clip and ventilated with eight 1-mm holes) was attached to the third youngest fully expanded leaf on d 0, ensuring that the entire leaf was inside the cage. Preliminary experiments on *S. sericea* found that the clip cages had no effect on salicylate concentrations after 4 d of being attached to the plant (unpublished data). Plants in the PVL group received a clip cage containing two *Plagioder*a larvae, plants in the PVA group received a clip cage containing two *Plagioder*a adults, plants in the CMA group received a clip cage containing one *Calligrapha* adult, and plants in the CON group received an empty clip cage. Two *Plagioder*a were used because a single *Calligrapha* adult consumes more leaf material per unit time. On d 1, clip cages were transferred to the next youngest, fully expanded leaf. On d 2, all clip cages and herbivores were removed from the plants.

Based on previous experiments looking at induction strength over time, plants were harvested on d 4, the time of maximal induction (unpublished data). Foliage was divided three ways: local, systemic young (SY), and systemic mature (SM) leaves. The local sample consisted of the two leaves enclosed within the clip cage, the SY sample consisted of all leaves above (younger than) the locally damaged leaves, and the SM sample consisted of all the leaves below (older than) the local leaves. All leaves from each location (SY, local, and

SM) were vacuum-dried at room temperature for 2 d, weighed, and stored at -20°C until high-performance liquid chromatography (HPLC) analysis.

Chemical Analysis

Salicortin and 2'-cinnamoylsalicortin were analyzed with standard techniques (Orians 1995). Briefly, leaf samples were ground to a fine powder and mixed thoroughly using a ball-mill grinder (Kleco). For each sample, 10.0 ± 0.3 mg leaf powder, or as much tissue that was available, were added to a microcentrifuge tube. Each tube received 1.0 ml of 6.4 mM 1,3-dimethoxybenzene in methanol as an internal standard. Following 5 sec of vortexing, the samples were sonicated at $1-2^{\circ}\text{C}$ for 13 min, and centrifuged at 7,000 rpm/min for 3 min. The extract was poured off and filtered using 0.45- μm pore Acrodiscs. Samples were analyzed at 277 nm on an HPLC (Hewlett Packard Model 1100) equipped with a 3.9×150 mm Nova-Pak C18 column (Waters) and an UV detector, using a gradient of methanol and dH_2O . Peaks representing phenolic glycosides were quantified using purified laboratory standards.

Measurement of Leaf Damage

Because the amount of leaf area consumed varied among herbivory treatments, we tested whether the amount of leaf area consumed had an effect on chemical concentrations. To estimate leaf area, leaves were photocopied and their images scanned by using NIH Imaging Software version 1.62 (<http://rsb.info.nih.gov/nih-image/>). For those plants that received herbivory, this was a measurement of the postherbivory area. To estimate preherbivory leaf area, leaves were photocopied and the missing portions of the chewed leaves were filled in. The manipulated image was scanned and analyzed as before to estimate preherbivory leaf area. The amount of leaf area consumed was calculated as: (preherbivory area) – (postherbivory area). If a leaf was consumed entirely, its area was assumed to be equal to the area of the plant's other local leaf.

Data Evaluation and Statistics

The amount of leaf area consumed was compared among the treatments using one-way ANOVA, and correlations were performed to determine if the amount of leaf area consumed was related to phenolic glycoside concentrations. Because larger seedlings (as measured by total above-ground biomass) had higher concentrations of phenolic glycosides (data not shown), we also examined the correlation between the total mass of the leaves at each location (local, SY, or SM leaves) and 2'-cinnamoylsalicortin and salicortin concentrations. There was a strong positive correlation for all samples (see [Results](#)), further indicating that larger plants produced higher concentrations of phenolic glycosides. Total leaf mass at each location was, therefore, included as a covariate in subsequent analyses to control for the effects of seedling size.

To examine the effects of leaf age on baseline phenolic glycoside concentration, we compared the concentration of the two phenolic glycosides across the three leaf locations (SY, local, and SM) in CON plants using a one-way analysis of covariance (ANCOVA; with location as the main effect and total leaf mass as the covariate). To test for induction at each leaf location, the effect of herbivore treatment was analyzed by using a one-way ANCOVA (with herbivore treatment as the main effect and leaf tissue mass as the covariate). Significance of differences among leaf locations and treatments were determined

with a LSMeans Student's *t*-test (JMP statistical software version 5.0.1.2, SAS Institute Inc., Cary, NC, USA, 1989–2003).

Results

2'-Cinnamoylsalicortin and salicortin were detected in all samples and accounted for 1.30 ± 0.09 and $11.59 \pm 0.30\%$ (mean \pm SE), respectively, of the mean dry leaf mass of CON plants (similar to previous reports on this species [Orians et al., 1996]). There was a strong positive relationship between 2'-cinnamoylsalicortin and salicortin concentrations within SY, local, and SM leaves for all treatments ($r^2=0.366$, 0.414 , and 0.153 , respectively; $P < 0.001$). There were also strong positive relationships between total leaf mass and salicylate concentrations within the SY, local, and SM leaves for all treatments (for 2'-cinnamoylsalicortin, $r^2=0.249$, 0.260 , and 0.322 , respectively, and for salicortin, $r^2=0.283$, 0.264 , and 0.146 , respectively; $P < 0.001$). The same trend was observed in the local leaves of the CON treatment when analyzed separately, indicating that larger plants (more leaf biomass at each location) were capable of producing higher concentrations of phenolic glycosides.

In CON plants, 2'-cinnamoylsalicortin concentrations were highest in the SY leaves, whereas salicortin concentrations were highest in the local leaves (Fig. 1). Specifically, 2'-cinnamoylsalicortin concentrations were significantly higher in SY leaves compared to local leaves and in the local leaves compared to the SM leaves (Fig. 1a–c; $F=26.01$; $P < 0.001$). Salicortin concentrations were significantly higher in local leaves compared to SY and SM leaves, whereas SY and SM leaves had similar concentrations (Fig. 1d–f; $F=12.03$; $P < 0.001$).

Plants in the CMA treatment lost the greatest amount of leaf area to herbivory (2.490 ± 0.230 cm²), whereas plants in the PVL treatment lost the least amount of leaf area to herbivory (1.370 ± 0.200 cm²), significantly less than the plants in the CMA treatment ($P < 0.001$). The amount of leaf area lost to herbivory in the PVA plants (2.110 ± 0.200 cm²) was not significantly different from either of the other two treatments ($P > 0.05$). Leaf area removed by PVL, PVA, or CMA was not positively correlated with phenolic glycoside concentration. In fact, leaf area removed was correlated with lower phenolic glycoside concentration in three cases: for both 2'-cinnamoylsalicortin and salicortin concentration in the local leaves in response to *Plagioder*a larvae, and for salicortin concentration in the SY leaves (Table 1).

Of the two phenolic glycosides, only 2'-cinnamoylsalicortin was induced. There was a significant overall treatment effect of herbivory on 2'-cinnamoylsalicortin concentration in the SY leaves ($F=2.71$; $P=0.049$). Mean 2'-cinnamoylsalicortin concentration was higher in SY leaves of the three herbivore treatments than in CON treatment (Fig. 1a), whereas 2'-cinnamoylsalicortin concentration in local and SM leaves were similar among the treatments (Fig. 1b, c). Mean salicortin concentrations in SY and SM leaves were similar among all treatments (Fig. 1d, f). Mean salicortin concentrations were significantly lower in local leaves of the PVL plants than in CON plants (Fig. 1e).

Discussion

Overall, we found evidence for specificity of induction. All herbivores tested caused 2'-cinnamoylsalicortin concentrations to increase systemically, but only in the youngest,

Fig. 1 The effects of treatments on least square mean (\pm SE) 2'-cinnamoylsalicycortin (a, b, c) and salicycortin (d, e, f) concentrations in SY, local, and SM *Salix sericea* leaves. Treatments were compared by one-way ANCOVA with leaf tissue mass as a covariate. Different letters above bars indicate significant differences between treatments ($P=0.05$). ANCOVA results are presented above the graph. SY = systemic young leaves, local = local leaves, SM = systemic mature leaves, CON = clip cage controls ($N=26$), PVL = *Plagioderma versicolora* larvae ($N=28$), PVA = *P. versicolora* adults ($N=29$), CMB = *Calligrapha multipunctata bigsbyana* adults ($N=30$)

undamaged upper leaves. In contrast, there was no increase in salicycortin concentration. Thus, young *S. sericea* seedlings are capable of increasing the concentration of 2'-cinnamoylsalicycortin in young leaves in response to beetle herbivory. Whereas the three herbivore treatments caused similar patterns of induction in young undamaged leaves, *P. versicolora* larvae actually caused a significant drop in salicycortin levels within damaged leaves.

Table 1 Pearson's correlation coefficients (r) representing the relationship between leaf area consumed by herbivores and the concentrations of 2'-cinnamoylsalicortin and salicortin in SY, local, and SM *Salix sericea* leaves

Herbivore treatment	2'-Cinnamoylsalicortin			Salicortin		
	SY	Local	SM	SY	Local	SM
PVL	-0.293	-0.479**	-0.277	-0.443*	-0.592***	-0.253
PVA	-0.118	-0.134	-0.167	0.261	0.214	0.089
CMA	0.263	-0.155	-0.008	0.110	-0.063	-0.045

SY = Systemic young leaves, SM = systemic mature leaves, PVL = *Plagioderia versicolora* larvae, PVA = *P. versicolora* adults, CMA = *Calligrapha multipunctata bigsbyana* adults.

* $P < 0.05$.

** $P < 0.01$.

*** $P < 0.001$.

Patterns of induction are best examined in context of baseline levels of phenolic glycosides. The distribution of phenolic glycosides within the control seedlings varied according to the compound. The distribution of 2'-cinnamoylsalicortin showed a clear negative relationship with leaf age (e.g., the young sink leaves had the highest concentrations, whereas the oldest mature leaves had the lowest). The spatial distribution of salicortin, however, revealed a different pattern: local leaves had significantly higher salicortin concentrations than both systemic young and systemic mature leaves. This result is consistent with previous work on *S. sericea* seedlings (Orians, unpublished data). Similarly, Julkunen-Tiitto et al. (1995) found that whereas the concentrations of many phenolic glycosides are highest in the young shoot tips of *S. myrsinifolia*, the concentration of others (e.g., salicortin-2) are highest in the mature leaves. These results indicate that phenolic glycoside biosynthesis can continue after leaf transition from sink to source leaves (see also Kleiner et al., 1999).

Not only were 2'-cinnamoylsalicortin concentrations highest in youngest leaves, but the three beetle treatments induced significant increases in the concentration of 2'-cinnamoylsalicortin, but not salicortin, in these younger leaves. Ruuhola et al. (2001) also found phenolic glycoside induction to be greatest in leaves with constitutively higher concentrations and suggest that induction of phenolic glycosides was probably a result of increased biosynthesis. It is interesting that 2'-cinnamoylsalicortin, which rarely exceeds 2% dry leaf mass, was induced but that salicortin, which often exceeds 10% dry leaf mass, was not. This could be due to the fact that 2'-cinnamoylsalicortin is most likely synthesized by adding a 2'-cinnamoyl group to salicortin, and, thus, the observed increase may be a result of enhanced conversion of preexisting salicortin to 2'-cinnamoylsalicortin. Because salicortin levels decreased in the locally damaged leaves, it is tempting to speculate that this was the source of salicortin. There is, however, no evidence to date that phenolic glycosides are transported within the vascular system from leaf to leaf. Rather, we suggest that any decrease in salicortin concentrations in SY leaves went undetected because salicortin concentrations were so much higher than 2'-cinnamoylsalicortin concentrations.

We had expected the damaged leaves to exhibit the greatest induction, but none was observed. As expected, induction was absent in the SM leaves. Whereas SY leaves exhibited induction, the lack of 2'-cinnamoylsalicortin induction in damaged leaves suggests that this compound is not inducible in source leaves (see also Ruuhola et al., 2001). Compared to control plants, all three herbivore treatments exhibited lower mean

salicortin concentrations in locally damaged leaves, although the PVL treatment was the only treatment that showed a significant difference. This decrease probably represents chemical degradation (Clausen et al., 1989; Julkunen-Tiitto et al., 1995) and would suggest that 2'-cinnamoylsalicortin is less prone to degradation. Clausen et al. (1989) reported that crushing *P. tremuloides* leaves induced a rapid (within seconds to minutes) enzymatic conversion of salicortin to salicin and 6-HCH. Although few of the samples in this study contained detectable quantities of salicin (personal observation), it is possible that salicin degraded even further in the days following wounding. Differences in local salicortin concentrations between the *Plagioder*a adults and larvae treatments may reflect different feeding strategies. Adult beetles feed by chewing on leaves, from the outer edges inward, whereas larvae feed by skeletonizing the leaves from the inner leaf outward, thereby causing damage to more leaf area per amount consumed and possibly causing more degradation. Alternatively, the lower concentrations found in larva-consumed tissues may reflect the fact that remaining vein tissue does not contain as much salicortin as mesophyll tissue.

Despite differences in the amount of leaf area removed, this did not have an effect on the amount of induction observed, as there were no significant positive relationships between phenolic glycoside concentration and the amount of leaf area consumed by herbivores. These data suggest that induction of 2'-cinnamoylsalicortin in *S. sericea* may be an “all- or none” response triggered by even small amounts of herbivory by these beetles. In previous experiments, mechanical damage designed to mimic herbivory did not produce an induced response (Fields, unpublished data), indicating that 2'-cinnamoylsalicortin induction in *S. sericea* occurs in response to a specific cue presented by the beetles. Would the same pattern of induction be observed following herbivory by a highly specialized beetle such as *Chrysomela* spp., which use phenolic glycosides as both feeding stimulants and as a source of defensive metabolites? We suggest that such herbivores would not elicit a strong induction of phenolic glycosides in willow because this could result in substantial costs to the plant. Although preliminary results in 2001 with *Chrysomela knabi* support this prediction (personal observation), we were unable to test this in 2002 because *C. knabi* were absent that year.

The ecological consequences of these induced changes are unknown. We suggest that induction could reduce subsequent feeding by herbivores such as *Plagioder*a, which are known to be sensitive to changes in phenolic glycoside concentration (Tahvanainen et al., 1985; Orians et al., 1997). Our data suggest a possible negative effect on beetle feeding: leaves with constitutively higher phenolic glycoside concentrations received significantly less larval *P. versicolor*a herbivory. Interestingly, there was no clear pattern or significant differences for adult *P. versicolor*a, suggesting that feeding preference may be a function of developmental stage. Although *C. multipunctata bigsbyana* also prefers foliage with moderate to low concentrations of phenolic glycosides (Orians et al., 1997), we found no association between leaf chemistry and leaf area consumed for this species.

One of the main questions raised by this study asks why 2'-cinnamoylsalicortin is inducible but salicortin is not. We suggest three possibilities that merit further investigation. First, salicortin production may be hindered during leaf expansion. Second, salicortin is known to be an oviposition/feeding stimulant for a number of beetles (Tahvanainen et al., 1985; Orians et al., 1997). If 2'-cinnamoylsalicortin is not increasing its concentrations, holding salicortin concentrations steady might represent a strategy to minimize future herbivory and oviposition. Third, plants may induce 2'-cinnamoylsalicortin because it is more bioactive. Although we favor the first explanation, we cannot reject the other two.

Experiments examining the effects of 2'-cinnamoylsalicortin and salicortin on beetle behavior and performance would be useful in assessing the plausibility of the second and third explanations.

In summary, there is accumulating evidence for specificity of induction in terms of which chemicals are induced, the developmental stage of the leaves that are induced, and the agent of damage (Stout et al., 1996; Agrawal, 2000; Ruuhola et al., 2001). For *S. sericea* seedlings, we observed induction of one of two phenolic glycosides but only in young sink leaves. Although all herbivores tested caused similar patterns of induction, the question whether more specialist beetles that can easily detoxify phenolic glycosides cause similar effects requires further study. Interestingly, the magnitude of induction was not influenced by the amount of leaf area consumed or the species/stage of herbivore feeding, indicating an all-or-none response triggered by even small amounts of damage by these beetles.

Acknowledgments We thank Robert Fritz (Vassar College) for facilitating our experiments at the willow research station and L. and E. Sosnowski for letting us work on and collect from their property. We thank Cris Hochwender, Benedicte Albrechtsen, and Mary-Ellen Czesak for seedlings, use of equipment, greenhouse space, and support. We appreciate the suggestions and encouragement offered by Frances Chew, Sara Lewis, George Ellmore, and the members of the Orians lab group. Brian Brannigan and Steven Lower provided assistance in the lab. We thank Hartwick College Biology Department for providing laboratory space. This research was supported by a National Science Foundation grant (DEB 9981568) to Colin Orians.

spongy-fruited *Clistocarpa*, fleshy-fruited *Sarcocarpa*, and capsular-fruited *Chaenocarpa*. Whereas *Clistocarpa* consists of a single species, *Yucca brevifolia* Engelmann, the other two sections consist of some 20 species each. Plants produce up to several hundreds of flowers on single or multiple inflorescence stalks, and individual flowers are open and fragrant only after sunset. All reproductive behaviors of yucca moths, i.e., mating within host flowers, oviposition into ovaries, and active pollination, take place at night in all but one species (Powell and Mackie, 1966), and floral volatiles are thus suggested to be important sensory cues for these insects during host and mate search.

In contrast to the fig–fig wasp pollination mutualism, where the floral scents of many *Ficus* species have been chemically identified (Grison et al., 1999; Grison-Pigé et al., 2002a; Song et al., 2001) and where there is behavioral evidence for fig pollinator attraction to host volatiles (Grison-Pigé et al., 2002b; Hossaert-McKey et al., 1994; Song et al., 2001), data on the chemical ecology of the yucca–yucca moth mutualism are scarce. Recently, however, a research program was initiated to elucidate the role of floral scent in this classic insect–plant interaction and to analyze how the floral fragrance chemistry has evolved within the yucca lineage. So far, a detailed chemical analysis of the floral odor has only been conducted on the capsular-fruited *Yucca filamentosa* L. (Svensson et al., 2005). This species is native to southeastern USA, but has been spread by European settlers across eastern USA in modern times (Pammel, 1925). It relies on two distantly related *Tegeticula* species for pollination in different parts of its range: *Tegeticula cassandra* Pellmyr on the Florida peninsula and *Tegeticula yuccasella* Riley elsewhere (Pellmyr, 1999; Althoff et al., 2006). Gas chromatography and mass spectrometry (GC-MS) analyses of the floral headspace of *Y. filamentosa* revealed a complex blend of homoterpenes and long-chain aliphatic hydrocarbons, but also two dioxygenated compounds previously not reported as floral compounds in angiosperms (Svensson et al., 2005).

In this study, we report on the chemical characterization of the floral fragrance of a second species within *Chaenocarpa*. *Yucca elata* Engelmann occurs in southwestern USA and adjacent Mexico and appears to rely solely on *Tegeticula elatella* Pellmyr for pollination (Pellmyr, 1999). A recent amplified fragment length polymorphism (AFLP) based phylogeny of a subset of closely related *Tegeticula* pollinators has confirmed close relationship between *T. elatella* and *T. cassandra*, whereas *T. yuccasella*, the most abundant pollinator of *Y. filamentosa*, is nested within another species cluster of moths (Althoff et al., 2006). As no robust phylogeny is available for *Chaenocarpa*, the precise phylogenetic relationship between *Y. elata* and *Y. filamentosa* is not known. However, a phylogeographic analysis of the widely distributed, nonmutualistic *Tegeticula intermedia* Riley, which utilizes both yuccas as hosts, has revealed indirect evidence that these plants have probably been allopatric for several million years (Segraves and Pellmyr, 2004). This is also supported by paleoecological data showing an emergent barrier between eastern and western yuccas (Graham, 1999). The combination of a long history of isolation and dependence on distantly related pollinators in most parts of their ranges suggests that these yuccas may have diverged in their floral odor blends, and this hypothesis was tested here.

Methods and Materials

The Plants

Yucca elata inhabits semidesert grasslands in Arizona, New Mexico, northwestern Texas, and adjacent Mexico (Fig. 1). This 3- to 4-m-tall species produces single or multiple

rosettes on trunks, each with one or several paniculate inflorescence stalks. It flowers from early May to early June. In contrast, *Y. filamentosa* grows in sandy and rocky habitats in eastern USA. From a basal rosette, a single paniculate inflorescence stalk is produced. Plants flower from late April to mid July. Both yuccas produce up to several hundreds of white, bell-shaped flowers per inflorescence.

Floral Scent Collection

The floral fragrance of *Y. elata* was collected from four populations in 2004 and 2006: Benson (Cochise, Arizona; 31°58'04N, 110°17'40W), Portal (Cochise; 31°52'17N, 109°02'59W), Rock Hound State Park (Luna, New Mexico; 32°11'13N, 107°36'36W), and Big Bend National Park (Brewster, Texas; 29°15'00N, 103°15'00W; Fig. 1). The number of young flowers on each plant was counted before odor sampling to estimate release rates of volatile compounds on a per flower basis. The inflorescence was enclosed with a polyvinylacetate bag (406×444 mm), and a glass cartridge (7 mm i.d.) filled with 100 mg of Super Q absorbent (Alltech Associates, State College, PA, USA) was connected to the bag. Air passed through the filter at a rate of 200 ml/min using a PAS-500 personal air sampler (Supelco, Bellefonte, PA, USA). Odor collection was performed from 2000 to 2400 hours, corresponding to the maximum release of floral scent of *Y. elata* and peak activity of associated yucca moths, and after collection filters were eluted with 3 ml of hexane and extracts were stored at -18°C until analysis. Empty bags were used as ambient controls to check for possible contaminants emitted from a bag itself. Before GC-MS analysis, extracts were concentrated to 75 µl under N₂, and 5 µl of 0.03% toluene were added as an internal standard to each sample to enable crude estimation of release rates of compounds.

GC-MS Analysis of Floral Scent

Floral volatiles of *Y. elata* were analyzed using a Shimadzu GC-17A gas chromatograph, equipped with a DB-5 column (30 m×0.32 mm i.d., and 1-mm film thickness), and linked to a Shimadzu QP5000 mass spectrometer (EI: ionization energy=0.70 kV). Helium was used as carrier gas at a velocity of 43 cm/sec, and injector temperature was 270°C. Oven temperature was programmed for 50°C for 2 min after injection and then increased at 10°C/

Fig. 1 Distribution of *Y. elata*. Dots indicate sites of odor collection: (1) Benson, (2) Portal, (3) Rock Hound State Park, and (4) Big Bend National Park

Fig. 2 Gas chromatogram of the floral headspace of *Y. elata*. Peak numbers correspond to compounds in Table 1

min to 275°C. Compounds in extracts were identified by comparing mass spectra and retention times with those of available reference compounds and by mass spectral matches to library spectra.

Analysis of Geographic Variation in Floral Scent

For each population, the relative abundance of individual compounds in the fragrance blend was calculated. Also, the coefficient of variation ($CV = \text{standard deviation} \times 100 / \text{mean}$) for each compound was calculated, using arcsine square-root-transformed ratios to better approximate a normal distribution. Two principal components analyses (PCA) were performed on arcsine square-root-transformed proportions of scent compounds. The first analysis included scent data from the four populations of *Y. elata* to screen for geographic variation in the odor blend. The second analysis also incorporated scent data from 10 populations of *Y. filamentosa* (Svensson et al., 2005) to test whether the floral odor blends of these two species differ. Before analysis, each variable was scaled to unit variance. The total release of floral compounds from *Y. elata* was quantified by the formula:

$$\text{Emission rate} = \frac{\left(\sum \frac{\text{peak area of compound}_x}{\text{peak area of IS}} \right) \times \text{amount of IS}}{\frac{\# \text{ flowers on plant}}{\text{h of sampling}}}$$

× extract volume after addition of IS

Total release rates of compounds were compared between populations using one-way analysis of variance. All statistics were performed using JMP 3.2.1 (SAS Institute, 1998). Leaves and flowers of *Y. elata* from each population were kept as vouchers and deposited at the A. C. Moore Herbarium at University of South Carolina.

Results

Analyses of floral headspace extracts of *Y. elata* revealed that this species produces a blend of homoterpenes and aliphatic hydrocarbons virtually identical to that of *Y. filamentosa* (Fig. 2). The same 21 compounds recently identified from *Y. filamentosa* were also found in all *Y. elata* individuals, with the exception of the six plants from Big Bend NP, which lacked β -myrcene. The same two dioxygenated compounds with a prominent peak at m/z 66 in the mass spectrum found in *Y. filamentosa* were also present in all *Y. elata* extracts (Fig. 2). Additional compounds, like β -pinene and *trans*- β -ocimene (not found in *Y. filamentosa*), were detected only in trace amounts in a few samples. Few compounds in small amounts were found in ambient controls.

Compound numbers are the same as in Fig. 2. Trace (tr.) indicates amounts less than 0.1% of total.

^aCompounds in which mass spectra and retention times were compared with that of reference compounds.

The relative ratios of 21 floral volatiles identified for *Y. filamentosa*, and also present in *Y. elata*, are shown in Table 1. Because of the absence of β -myrcene in Big Bend samples, this compound was excluded from the PCA. In the first PCA, four principal components with eigenvalues >1 explained 85.2% of the total variation found in floral fragrance data. On PC1, (*E*)-4,8-dimethyl-1,3,7-nonatriene was the only compound with strong negative loading, whereas all aliphatic hydrocarbons had similar positive loadings (Table 2). On PC2, the C_{11} -alcohol and the first eluting dioxygenated compound loaded positively, whereas (*E*)-4,8-dimethyl-1,3,7-nonatriene and a majority of the aliphatic hydrocarbons loaded negatively.

A score plot of the first two principal components in the initial PCA revealed little geographic variation of the odor blend in *Y. elata*. Considerable overlap in the fragrance blend was observed across populations, with the exception of samples from Big Bend, which formed a distinct cluster in odor space. However, in a second PCA including fragrance data also from *Y. filamentosa* (Svensson et al., 2005), the floral odor blends of the two yuccas largely overlapped (Fig. 3), and *Y. elata* from Big Bend was nested within *Y. filamentosa*. The total emission of floral volatiles in *Y. elata* did not differ between populations (Benson: $1.08 \pm 0.20 \mu\text{l flower}^{-1} \text{hr}^{-1}$; Portal: $1.16 \pm 0.21 \mu\text{l flower}^{-1} \text{hr}^{-1}$; Rock Hound: $1.03 \pm 0.17 \mu\text{l flower}^{-1} \text{hr}^{-1}$; Big Bend: $1.56 \pm 0.23 \mu\text{l flower}^{-1} \text{hr}^{-1}$; $F=1.12$, $df=3$, $P>0.10$).

Compound numbers are the same as in Fig. 2.

Fig. 3 Score plot of the first two principal components based on 20 compounds found in the floral headspace from four populations of *Y. elata* (■: Benson, $N=8$; ◆: Portal, $N=11$; ●: Rock Hound, $N=9$; ▲: Big Bend NP, $N=6$) and 10 populations of *Y. filamentosa* (from Svensson et al., 2005; ○, $N=87$)

Discussion

Contrary to our prediction of divergent scent composition with different pollinators, GC-MS analyses of the floral headspace of *Y. elata* revealed that this yucca produces a blend of floral volatiles virtually identical to the related, allopatric species, *Y. filamentosa*. The same 21 compounds identified in the floral scent of *Y. filamentosa* (Svensson et al., 2005) were also found in *Y. elata*. Furthermore, the relative ratios of these compounds within the odor blends of the two yuccas are very similar, as shown in the score plot in Fig. 3. Low variation in the fragrance blend was observed both within and among populations of *Y. elata*, similar to the pattern observed in *Y. filamentosa*, where no difference in the floral scent composition was observed between populations with different pollinators (Svensson et al., 2005). Whether low variation in the fragrance blend and the use of unique compounds reflect mechanisms for selective attraction of exclusive pollinators to host

flowers has yet to be tested. In fact, little is known about the adaptive significance of low variation in the floral odor blends in plants. Few studies have analyzed how this trait varies between populations (e.g., Azuma et al., 2001; Knudsen, 2002; Dötterl et al., 2005), and direct comparisons of the variation of floral compounds that are electrophysiologically active in pollinators with that of nonactive ones have only been conducted in sexually deceptive *Ophrys* orchids (Ayasse et al., 2000; Mant et al., 2005).

Although earlier studies suggested monophyly for the section *Chaenocarpa* (McKelvey, 1947), the phylogenetic relationships among capsular-fruited taxa have not been fully resolved. Available AFLP data support rapid diversification of this group (Pellmyr et al., unpublished data), and at this point, the hypothesis of a close relationship, or even sister species status, of *Y. elata* and *Y. filamentosa* cannot be tested. On the other hand, the phylogeographic work on *T. intermedia* by Segraves and Pellmyr (2004) indicates that the two yuccas may have been allopatric for a long time. Western populations of this yucca moth feed on several capsular-fruited yuccas, including *Y. elata* (Pellmyr, 1999; Segraves and Pellmyr, 2004), whereas eastern populations only use *Y. filamentosa* as host (Pellmyr, 1999). Both mtDNA and AFLP data suggest that this moth arose in the west and later spread eastward. There was a deep genetic split between populations east and west of the Mississippi River basin, corresponding to a divergence time of about three million years (Segraves and Pellmyr, 2004). Although their ancestral ranges are unknown, it is reasonable to assume that *Y. elata* and *Y. filamentosa* have been allopatric for a similar period of time. Still, their fragrance blends are similar, and such lack of divergence in a potential key trait mediating attraction of exclusive pollinators may indicate that strong stabilizing or purifying selection has been imposed on the fragrance blend. Floral traits under strong selection (e.g., tube length in hummingbird-pollinated flowers) are expected to show relatively little variation (Fenster, 1991). If scent is irrelevant to the obligate interactions between yuccas and yucca moths, we would expect measurable divergence in chemistry between isolated populations of *Y. filamentosa* and *Y. elata* simply because of genetic drift. The identification and synthesis of floral scent compounds and their attractiveness to obligate pollinators in the field will be critical steps toward a better understanding of how selection acts on both emitters and receivers in this pollination mutualism.

Acknowledgements Permission to collect floral scent was kindly provided by Big Bend National Park. We thank Michael Hickman for providing technical assistance. We also thank Jette Knudsen, Lina Kristoffersen, Wen Qi Rosén, Christian Olsson, Maria Strandh, and two anonymous reviewers who gave valuable comments on the manuscript. This project was supported by a grant from the Wenner-Gren Foundations in Sweden (postdoctoral fellowship) to GPS; NSF grant DEB-0317217 to RAR; and NSF grants DEB-0075944, DEB-0075803, and DEB-0516841 to OP.

Introduction

The pistachio twig borer, *Kermania pistaciella* (Lepidoptera: Oinophilidae), is one of the most important insect pests in plantations of pistachio, *Pistacia vera*, in Turkey and Iran. Females lay eggs close to shoot tips and fruit clusters. Larvae bore into and feed on terminal buds and in twigs and shoots formed the previous year. Larval feeding causes abscission of fruit buds and die-back of twigs (Küçükarslan 1966) and may directly damage fruit clusters (Mart et al., 1995). Pupation takes place in cocoons attached to the branch surface near larval exit holes. After 20–25 days, adults eclose, and females lay up to 60 eggs. The 1-month flight period of first-generation adults occurs in April–May (Küçükarslan 1966).

Many pistachio plantations in Turkey and Iran are treated annually with insecticides to reduce damage caused by *K. pistaciella* larvae. For example, in southeast Turkey in 2005, 548,600 trees were sprayed with insecticides to suppress *K. pistaciella* populations (Anonymous 2005). Identification of the *K. pistaciella* sex pheromone might be a first step toward pheromone-based control tactics (e.g., attract and kill) of *K. pistaciella* populations. We report the identification, synthesis, and field testing of (2*S*,12*Z*)-2-acetoxy-12-heptadecene as the major component of the sex pheromone of *K. pistaciella*.

Methods and Materials

Experimental Insects In early March 2001, in several locations of the Nizip province of Gaziantep (Turkey), sections of pistachio tree branches bearing pupal cocoons were cut off and sent under import permit from Agriculture and Agri-Food Canada (Food Production and Inspection Branch) to Simon Fraser University. Insects were kept at 24°C in mesh cages under a photoperiod of 13-hr light/11-hr dark. Eclosed males were transferred to and kept individually in filter paper-lined Petri dishes. The abdominal tip with pheromone gland of 1- to 2-d-old females was removed and extracted with hexane for 15 min.

Analyses of Extracts Aliquots of 1 female equivalent (FE) of such extracts were analyzed by coupled gas chromatographic-electroantennographic detection (GC-EAD; Arn et al., 1975; Gries et al., 2002), employing a Hewlett-Packard (HP) 5890 gas chromatograph fitted with a column (30 m×0.25 or 0.32 mm ID) coated with DB-5, DB-23, or DB-210 (J&W Scientific, Folsom, CA, USA). Helium was used as carrier gas (35 cm/sec), with temperature programs described in the captions of Figs. 2 and 4. GC-mass spectrometry (MS) of compounds eliciting responses from antennae and of synthetic standards employed a Saturn 2000 Ion trap GC-MS (Varian Instruments) fitted with the DB-5 column referred to above.

Instrumentation Nuclear magnetic resonance (NMR) spectra of synthetic compounds were taken on a Varian AS500 spectrometer at 499.77 MHz for ¹H and 125.68 MHz for ¹³C spectra with chemical shifts reported in parts per million relative to tetramethylsilane (¹H, δ 0.00) and CDCl₃ (¹³C, δ 77.00). Elemental analyses were performed using a Carlo-Erba model 1106 elemental analyzer. Optical rotations were measured with a Perkin-Elmer 341 polarimeter.

The major candidate pheromone component in gland extracts was isolated by high-performance liquid chromatography (HPLC), employing a Waters LC 625 HPLC equipped with a Waters 486 variable wavelength UV–visible detector set at 210 nm, HP Chemstation

software (Rev.A.07.01), and a reverse phase Nova Pak[®] C₁₈ (3.9×300 mm) column (Waters) eluted with acetonitrile (1 ml/min).

The absolute configuration of the HPLC-isolated natural pheromone component **B** and the enantiomeric excess of synthetic standards were determined by analyses of samples on a custom-made chiral GC column coated with a 1:1 mixture of heptakis-(2,6-di-*O*-methyl-3-*O*-pentyl)- β -cyclodextrin and OV-1701 (König et al., 1992; Pietruszka et al., 1992).

Syntheses

(*Z*)-12-Heptadecen-2-ol (compound **2** in scheme 1, Fig. 1). Racemic (*Z*)-12-heptadecen-2-ol was synthesized starting with (*Z*)-11-hexadecenal (**1**, scheme 1, Fig. 1; Bedoukian Research, Danbury, CT, USA). Compound **1** (225 g, 0.915 mol) in 400 ml of ether was added dropwise under argon at 0–10°C in 3 hr to a stirred solution of methylmagnesium chloride (3 M in ether; 333 ml, 1 mol). The mixture was allowed to warm to room temperature, quenched with 200 ml of saturated aqueous NH₄Cl, and extracted with ether (3×200 ml). Extracts were combined, washed with brine, dried (anhydrous MgSO₄), filtered, and evaporated *in vacuo*, affording 233 g of (*Z*)-12-heptadecen-2-ol (**2**, 99% pure by GC, 0.906 mol, 99% yield) as a slightly yellowish oil. ¹H NMR (CDCl₃) δ : 0.89 (t, 3H, *J*=7.1 Hz), 1.18 (d, 3H, *J*=6.3 Hz), 1.21–1.49 (m, 24H), 2.05 (m, 1H), 3.78 (m, 1H), 5.34 (m, 2H). ¹³C NMR (CDCl₃) δ : 129.84, 129.82, 68.15, 39.34, 31.94, 29.74, 29.63, 29.59, 29.55, 29.51, 29.27, 27.16, 26.88, 25.76, 23.45, 22.32, 13.98. Anal. calcd. for C₁₇H₃₄O (%): C, 80.24; H, 13.47; found C, 79.96; H, 13.24.

(*Z*)-2-Acetoxy-12-heptadecene (compound **3** in scheme 1, Fig. 1). Racemic (*Z*)-2-acetoxy-12-heptadecene was synthesized by adding 94 ml (0.99 mol) of acetic anhydride dropwise at room temperature to a stirred solution of 233 g (0.906 mol) of alcohol **2** in 100 ml (1.23 mol) of pyridine. After stirring for 6 hr, the reaction was quenched with water, and the product was extracted with ether/hexane (1:1) (3×250 ml). Combined extracts were washed successively with saturated aqueous NaHCO₃, HCl (10%), water, and brine, then dried (anhydrous MgSO₄). Filtration and removal of solvents afforded 270 g of (*Z*)-2-acetoxy-12-heptadecene (**3**, 99.5% pure by GC, quantitative yield). ¹H NMR (CDCl₃) δ : 0.87 (t, 3 H, *J*=7.0 Hz), 1.18 (d, 3 H, *J*=6.3 Hz), 1.21–1.35 (m, 22 H), 1.50 (m, 2 H), 2.00 (s, 3 H), 4.86 (m, 1 H), 5.33 (m, 2 H). ¹³C NMR (CDCl₃) δ : 170.68, 129.79, 129.77, 70.99, 35.88, 31.92, 29.72, 29.50, 29.49, 29.47, 29.42, 29.24, 27.14, 26.87, 25.37, 22.30, 21.31, 19.90, 13.94. Anal. calcd. for C₁₉H₃₆O₂ (%): C, 80.24; H, 13.47; found C, 79.96; H, 13.24.

(2*S*,12*Z*)-12-Heptadecen-2-ol, (2*R*,12*Z*)- and (2*S*,12*Z*)-2-acetoxy-12-heptadecene (compounds **4**, **5**, and **6** in scheme 2, Fig. 1). Enantioselective syntheses of these compounds were initiated by adding 70 mg of immobilized lipase Novozym 435 (10,000 units per gram, Sigma Chemical, St. Louis, MO, USA; Xiao and Kitazume, 1997) to a stirred solution of 0.600 g of racemic alcohol **2** (2.36 mmol; scheme 2, Fig. 1) and 0.53 ml of vinyl acetate (5.75 mmol, Aldrich Chemical, Milwaukee, WI, USA) in 3 ml of hexane. After stirring for 4 hr at 40°C, the Novozym-containing resin was filtered off, solvents were evaporated *in vacuo*, and alcohol **4** (0.280 g) and acetate **5** (0.340 g) were separated by flash chromatography [10 g of SiO₂, ether/hexane (1:20) as eluent]. Subsequent acetylation of alcohol **4** with acetic anhydride in pyridine and usual work-up (see above) afforded 0.320 g (1.08 mmol) of (2*S*,12*Z*)-2-acetoxy-12-heptadecene [**6**, 99.5% pure, 45.8% yield (theory: 50%)], [α]_D²⁰ = +0.83° (c 4.5; CHCl₃). The NMR spectrum of acetate **6** was consistent with that of racemic acetate **3**. The enantiomeric excesses (ee) of **4**, **5**, and **6** were

SCHEME 3

Fig. 1 Synthesis of racemic (*Z*)-12-heptadecen-2-ol (**2**) and (*Z*)-2-acetoxy-12-heptadecene (**3**) (scheme 1); enantioselective syntheses of (*2S*,*12Z*)-heptadecen-2-ol (**4**), (*2R*,*12Z*)-2-acetoxy-12-heptadecene (**5**) and (*2S*,*12Z*)-2-acetoxy-12-heptadecene (**6**) (scheme 2); and synthesis of (*2S*,*12Z*)-2-acetoxy-12-heptadecene (**6**) from (*2R*,*12Z*)-2-acetoxy-12-heptadecene (**5**) (scheme 3)

99, 95, and 99%, respectively, as determined by gas chromatography that separated enantiomers with baseline resolution (Fig. 2).

Additional quantities of **6** were obtained by a three-step synthesis (scheme 3, Fig. 1), based on inversion of the absolute configuration of **5**. A mixture of **5** (0.280 g) and K_2CO_3 (1.0 g) in methanol (10 ml) was stirred for 18 hr at room temperature. After removal of 9 ml of methanol *in vacuo*, ether (20 ml) and water (5 ml) were added to the reaction mixture. The organic layer was washed with water and brine, dried (anhydrous $MgSO_4$) and solvents were removed *in vacuo* to afford (2*R*,12*Z*)-12-heptadecen-2-ol (**7**, 95% pure by GC). Without further purification, alcohol **7** was mesylated at 0°C with methanesulfonyl chloride (1.5 ml) in the presence of triethylamine (2 ml) in dichloromethane (10 ml). After 1 hr, the reaction was quenched with aq. $NaHCO_3$. Extraction with ether (50 ml), washing of the extract with 10% HCl, water, and brine, and drying and evaporation of solvent afforded the (*R*)-mesylate **8**. Without further purification, mesylate **8** was stirred for 96 hr at 60–70°C in dry dimethylformamide (10 ml) with 3 g of sodium acetate. Usual work-up of the reaction mixture and purification of the product by flash chromatography yielded 0.180 g of pure **6** with 90% ee. Overall yield based on **5** was 64%.

Assignment of the absolute configuration of **6** was confirmed by an alternative synthesis, which comprised converting (*Z*)-1-bromo-9-tetradecene to the Grignard reagent and then to the monocuprate, adding (*S*)-propylene oxide and acetylating the resulting alcohol **4**. This

Fig. 2 Representative recording of flame ionization detector (FID) and electroantennographic detector (EAD: male *Kermania pistaciella* antenna) responses to one female equivalent of female *K. pistaciella* pheromone extract. Chromatography: DB-5 column; splitless injection, temperature of injection port and FID: 240°C; temperature program: 1 min at 50°C, then 20°C/min to 280°C

approach also proved conducive to large-scale synthesis of **6** (Britton and Khaskin, unpublished data).

Acetoxyheptadecanes (Table 1) were produced from the corresponding alcohols synthesized by Grignard reactions of suitable aldehydes with *n*-alkylmagnesium bromides. 2-Acetoxyheptadecenes with various (*E*)- and (*Z*)-double bond positions (Table 1) were synthesized from the corresponding hexadecenals according to scheme 1.

Field Experiments Field experiments were conducted in a pistachio orchard of the Gaziantep Pistachio Research Institute in Gaziantep, Turkey. Experiments employed a randomized complete block design with 8–10 replicates each. Delta-like traps were made from 2-L milk carton (Gray et al., 1984), coated with Tanglefoot (The Tanglefoot, Grand Rapids, MI, USA) and suspended from trees ~1.5 m above ground with ~16-m spacing. Traps were baited with a gray sleeve stopper (West Pharmaceutical Services, Lionville, PA, USA) impregnated with candidate pheromone components in HPLC-grade hexane.

Experiment 1 tested whether racemic (*Z*)-2-acetoxy-12-heptadecene was effective in attracting male *K. pistaciella*. Experiment 2 tested whether the corresponding alcohol, (*Z*)-12-heptadecen-2-ol, enhanced attractiveness of the acetate or was attractive by itself. Experiment 3 explored which enantiomer of (*Z*)-2-acetoxy-12-heptadecene was attractive and whether there were synergistic or inhibitory interactions between enantiomers. Considering the inhibitory nature of the *R*-enantiomer in experiment 3, experiment 4 retested the *S*-enantiomer by itself and in combination with either one or both enantiomer(s) of (*Z*)-12-heptadecen-2-ol. Doses used in field experiments are shown in Fig. 5.

Trap catch data were subjected to nonparametric analysis of variance by ranks (Friedman's test) followed by comparison of means (Scheffé test; Zar 1984; SAS/STAT 1988).

Results and Discussion

GC-EAD analyses of pheromone gland extracts from female *K. pistaciella* revealed two components (**A** and **B**) that elicited strong responses from male *K. pistaciella* antennae (Fig. 2). The mass spectrum of compound **B** (Fig. 3) with diagnostic fragment ion m/z 61 indicated an acetate functionality. Moreover, fragment ion m/z 236 [MW of $C_{19}H_{36}O_2$ (296)–60], instead of m/z 238 [MW (298)–60] expected for a saturated compound (Table 1), suggested that compound **B** had one double bond.

Hydrogenation (Millar and Haynes, 1998 and references cited therein) of pheromone gland extract, followed by repeated GC-EAD and GC-MS analyses, revealed a new EAD-active compound (**B1**) with different retention characteristics (Table 1). **B1** did not co-chromatograph with synthetic heptadec-1-yl acetate, suggesting that it might be a saturated secondary or tertiary acetate. It was determined to be 2-acetoxyheptadecane by GC-MS analyses and comparison of its GC retention indices (Table 1) with those of seven synthetic acetoxyheptadecanes (acetoxy group at C1, C2, C3, C4, C5, C6, and C7, respectively).

To determine the position of the double bond in 2-acetoxyheptadecene (**B**), HPLC-isolated **B** was treated with dimethyl disulfide (DMDS; Dunkelblum et al., 1985). The mass spectrum of the DMDS-derivative (MW=390) had adduct fragment ions [m/z 117 (26%) ($CH_3-S=CH-(CH_2)_3-CH_3$)⁺; m/z 213 (100%) ($273-HOAc$)⁺; m/z 273 (15%) ($CH_3-CHOAc-(CH_2)_9-CH=S-CH_3$)⁺; and m/z 390 (M^+ , 16%)] that revealed a double bond at C12. Synthetic (*Z*)-2-acetoxy-12-heptadecene, but not the (*E*)-isomer, and none of (*Z*)-2-acetoxy-10-heptadecene, (*Z*)-2-acetoxy-11-heptadecene, and (*Z*)- or (*E*)-2-acetoxy-13-heptadecene co-chromatographed with female-produced **B** (Table 1).

Comparative GC analyses of synthetic racemic (*Z*)-2-acetoxy-12-heptadecene, the synthetic *S*-enantiomer, and insect-produced **B** revealed that female *K. pistaciella* produces the *S*-enantiomer of **B** (Fig. 4). Component **A** (Fig. 2) had retention indices (Table 1)

Fig. 3 Ion trap mass spectrum of compound **B** in Fig. 2 (compound **6** in Fig. 1)

Fig. 4 Flame ionization detector (FID) chromatograms of racemic (*Z*)-2-acetoxy-12-heptadecene (**3** in scheme 1, Fig. 1), (*2S,12Z*)-2-acetoxy-12-heptadecene (**6** in schemes 2, 3; Fig. 1); and HPLC-isolated, insect-produced **B** (Fig. 2); chromatography: custom-made GC column coated with a 1:1 mixture of heptakis-(2,6-di-*O*-methyl-3-*O*-pentyl)- β -cyclodextrin and OV-1701 (König et al., 1992; Pietruszka et al., 1992); splitless injection; temperature of injection port and FID, respectively: 240 and 250°C; temperature program: 1 min at 100°C, then 10°C/min to 180°C (20 min)

indicative of an alcohol functionality. It was shown to be (*Z*)-12-heptadecen-2-ol by comparison of its GC and GC-MS data with those of authentic **2**.

In field experiment 1, traps baited with racemic (*Z*)-2-acetoxy-12-heptadecene (**3**) captured large numbers of male *K. pistaciella* (Fig. 5). The corresponding alcohol, (*Z*)-12-heptadecen-2-ol (**2**), was not attractive, and a 1:1 (w/w) mixture of **2** and **3** (as found in pheromone gland extracts) was significantly less attractive than **3** alone (Fig. 5, experiment 2). However, the addition of different ratios of alcohol **2** to the acetate **3** may have enhanced, instead of reduced, the attractiveness of the lure. This remains to be determined by further field tests. (*2S,12Z*)-2-Acetoxy-12-heptadecene attracted many males, whereas the *R*-enantiomer was not attractive and, when added to the *S*-enantiomer, significantly reduced its attractiveness (Fig. 5, experiment 3). Attractiveness of the *S*-acetate was reduced by either or both enantiomers of the corresponding alcohol (Fig. 5, experiment 4).

(*2S,12Z*)-2-Acetoxy-12-heptadecene is the first secondary acetate reported as a sex pheromone component in the Lepidoptera. In contrast, secondary alcohols have been identified in several species of the Lepidoptera, including *Stigmella malella* [(*S*)-(*E*)-6,8-nonadien-2-ol and (*S*)-(*Z*)-6,8-nonadien-2-ol (Tóth et al., 1995)], *Eriocrania cicatricella* [(*2R*)-heptan-2-ol (Zhu et al., 1995)], *Eriocrania sangii* [(*2S,6Z*)-nonen-2-ol (Kozlov et al., 1996)], *Eriocrania semipurpurella* [(*2S,6Z*)-nonen-2-ol and (*2R,6Z*)-nonen-2-ol (Kozlov et al., 1996)], and *Orgyia detrita* [(*11S,6Z,9Z*)- and (*11R,6Z,9Z*)-6,9-heneicosadien-11-ol (Gries et al., 2003)].

Straight-chain secondary acetate sex pheromones also commonly occur in cecidomyiid midges, including the Hessian fly *Mayetiola destructor* [(*2S,10E*)-2-acetoxy-10-tridecene; Foster et al., 1991; Harris and Foster, 1991; Millar et al., 1991], pea midge *Contarinia pisi* [(*S,S*)-2,11-diacetoxytridecane, (*S,S*)-2,12-diacetoxytridecane and 2-acetoxytridecane;

Fig. 5 Mean numbers (+SE) of male *Kermania pistaciella* captured per experimental period in experiments 1–4 in sticky traps baited with various candidate pheromone components, placed in pistachio orchards of the Gaziantep Pistachio Research Institute in Gaziantep, Turkey. In each experiment, bars with different letter superscripts are significantly different; nonparametric analysis of variance by ranks (Friedman’s test) followed by comparison of means (Scheffé test), $P < 0.05$ (Zar 1984; SAS/STAT 1988)

Hillbur et al., 1999, 2000, 2001], Douglas fir cone gall midge *Contarinia oregonensis* [(2*S*,4*Z*,7*Z*)-2-acetoxy-4,7-tridecadiene; Gries et al., 2002], *Aphidoletes aphidimyza* [(*R*,*S*)-2,7-diacetoxytridecane; Choi et al., 2004], swede midge *Contarinia nasturdii* [(*S*,*S*)-2,9-diacetoxyundecane, (*S*,*S*)-2,10-diacetoxyundecane, (*S*)-2-acetoxyundecane; Hilbur et al., 2005], and western red cedar cone midge *Mayetiola thujae* [(*S*,*S*)-2,12-diacetoxyheptadecane, (*S*,*S*)-2,13-diacetoxyheptadecane, (*S*,*S*)-2,14-diacetoxyheptadecane; Gries et al., 2005]. Cecidomyiid midges and *K. pistaciella* belong to discrete taxonomic orders (Diptera and Lepidoptera, respectively) of the Insecta. However, these two orders are related, which might explain the similarity of some of their sex pheromone structures.

With the *K. pistaciella* pheromone identified and shown to attract large numbers of male moths, it may be possible to develop pheromone-based tactics for control of *K. pistaciella*. In a 75-ha experiment in commercial pistachio orchards in Iran in 2005, plots treated with a proprietary attract-and-kill formulation containing chiral pheromone had significantly fewer larvae-infested fruit bunches (>120,000 assessed) than insecticide-treated plots or control plots (unpublished data; two PCT patent applications filed in 2006).

Acknowledgements We thank Wittko Francke for lending us a custom-made chiral column and for review of the manuscript, Eberhard Kiehlmann and one anonymous reviewer for constructive comments, Micky Yang for elemental analyses, Sharon Oliver and Renée Picard for word processing, and Bob Birch for graphical illustrations. The research was supported by a Discovery grant from the Natural Sciences and Engineering Research Council of Canada (NSERC) and by an NSERC-Industrial Research Chair to G.G. with Phero Tech Int., SC Johnson Canada, and Global Forest Science as industrial sponsors.

Fig. 1 Structures and spectra of abietanes. A 1-mM mixture of five common abietanes (20 μ l injections) was analyzed by HPLC (see “Methods and Materials”) and spectra obtained at the apex of each peak. Retention times for the abietanes are given in Fig. 2

conifers (Wagner et al., 1983; Larsson et al., 1986). The activity of individual plant defense compounds commonly varies with the presence of other compounds, with interactive effects such as synergism frequently yielding results not predictable from analysis of individual components (Berenbaum, 1985). Moreover, concentrations of phytochemicals are typically highly variable in nature, due to both environmental and genetic differences. Thus, it is commonly necessary to analyze large numbers of samples to determine ecological significance. Based on these considerations, it is desirable to have an easy, quantitatively reliable method for separating resin acids from plant tissues. A significant analytical challenge arises from the similarity of their structures (Fig. 1).

The most common method used for resin acid analysis is gas chromatography (GC) of the methyl esters (Zinkel and Engler, 1977) with detection by flame ionization or mass spectrometry. However, this method has disadvantages, including instability of the derivatized samples (Latorre et al., 2003) and hazards of methylating reagents (potentially explosive and carcinogenic). Furthermore, considerable sample preparation is typically required with crude biological samples, in addition to derivatization. This may include extraction, partitioning of acid components into liquid or solid phase, solvent evaporation, redissolving sample in GC-compatible solvent, and removing moisture from the sample prior to injection.

There have been recent attempts to provide simple and robust analytical methods for resin acid analysis by high-performance liquid chromatography (HPLC). Reversed-phase HPLC of underivatized resin acids in river water does not resolve the structural isomers studied (abietic, isopimaric, and pimaric), and detection by negative ion electrospray mass spectrometry does not provide isomeric speciation (McMartin et al., 2002). Determination of dehydroabietic and abietic acids in Chinese medications (Lee et al., 1997) and adhesive (Lee et al., 1994) with UV detection is reported but without analysis for other abietanes.

Likewise, coumarin ester derivatives of nonaromatic resin acids are not resolved (Volkman et al., 1993).

Here, we report a simple method for the analysis of abietanes by reversed-phase HPLC. Advantages include: (1) no sample derivatization is required and therefore related expenditures and hazards are avoided; (2) extraction and chromatographic conditions are mild, and therefore, the sample components, and consequently their biological activities, should be unchanged; and (3) all components of the HPLC mobile (methanol, acetic acid, and water) phase are volatile and therefore recovery of compounds from fractionated sample is simplified. These benefits are particularly advantageous in biological studies that require rapid analysis of plant materials and screenings for biological activities.

Methods and Materials

Chemicals Abietic (90–95%), neoabietic (99+%), palustric (90–95%), levopimaric (95+%), and dehydroabietic (99+%) acids were purchased from Helix Biotech (British Columbia, Canada).

Sample Preparation Stock solutions of standard resin acids were prepared in 95% ethanol at approximately 2 mg/ml. These solutions were diluted using positive displacement syringes to prepare solutions of defined concentrations according to absorbance at λ_{\max} and literature (Joye and Lawrence, 1967) molar absorption coefficients: abietic at 241 nm ($24,150 \text{ M}^{-1} \text{ cm}^{-1}$), neoabietic at 252 nm ($24,540 \text{ M}^{-1} \text{ cm}^{-1}$), palustric at 266 nm ($9,060 \text{ M}^{-1} \text{ cm}^{-1}$), levopimaric at 272 nm ($5,800 \text{ M}^{-1} \text{ cm}^{-1}$), and dehydroabietic at 268 nm ($698 \text{ M}^{-1} \text{ cm}^{-1}$) and 276 nm ($774 \text{ M}^{-1} \text{ cm}^{-1}$).

White spruce (*Picea glauca*) samples were collected from 10 mature trees in a planted stand in Dane County, WI, USA, in August. For the preparation of extracts, approximately 500 mg of phloem were cut into 2-mm pieces, extracted with 4 ml methanol, filtered through glass wool, and the extracts stored at -20°C . Extracts were filtered through 0.45- μm Teflon syringe filters prior to HPLC.

Instrumentation and Software A Hewlett-Packard (Palo Alto, CA, USA) series 1050 HPLC, fitted with an Alltech (Deerfield, IL, USA) Alltima C18 column (5 μm , $250 \times 4.6 \text{ mm}$) and a Hewlett-Packard diode array detector was used. An isocratic mobile phase with a ternary solvent system (85%, 5%, and 10%; methanol, 5% acetic acid, water, respectively) was run at a flow rate of 1 ml/min. Data were analyzed with Agilent ChemStation (Santa Clara, CA, USA) for LC 3D software.

Results and Discussion

Method Development Abietanes have distinctive spectra that we used here, together with chromatographic separation, to distinguish and quantify the resin acids by HPLC. The spectra of the individual components (Fig. 1), chromatographically separated from a 1-mM mixture of standards, show λ_{\max} values of 240 nm (abietic), 250 nm (neoabietic), 266 nm (palustric), 272 nm (levopimaric), and 266 nm (dehydroabietic). This is in excellent agreement with spectra obtained with the standards run separately, indicating little or no

Fig. 2 Multiwavelength analysis. HPLC chromatographs obtained from a 1-mM mixture of abietanes (Fig. 1) are shown at wavelengths to optimize detection and differentiation between components. Dehydroabietic acid ($rt=15.5$ min) is well resolved from the other four abietanes and detected at 268 nm

interference in the mixture. Neoabietic and abietic acids have the greatest response factors in the diagnostic wavelength region, followed by palustric, levopimaric, and dehydroabietic acids. These response factors are also in reasonable agreement with literature values of the relative molar absorption coefficients at the corresponding λ_{\max} values (see “Methods and Materials”).

Although detection of analytes at λ_{\max} provides the greatest sensitivity (absorbance units), it may not allow the determination of component concentrations if peaks are not chromatographically resolved. However, the overlay spectra of the abietanes (Fig. 1) indicated that it might be possible to distinguish the abietanes in a mixture and minimize interferences by careful choice of detection wavelengths. Also, detection at an isosbestic point provides summation of component concentrations at a wavelength of equal response. The purpose is to allow quantification in terms of absolute concentration, instead of arbitrary absorbance units, even in cases where chromatographic separation is not complete. Specifically, at 282 nm, palustric and levopimaric acid give equal response; at 240 nm, abietic and neoabietic acid give equal response; at 268 nm, neoabietic acid is detected without interference from abietic acid; and at 300 nm, levopimaric acid is preferentially detected over palustric acid.

Chromatograms of a 1-mM mixture at these four wavelengths are presented in Fig. 2 and provide a test to determine whether a multiwavelength approach can provide quantitative results. Detection at 268 nm allows baseline resolution for neoabietic acid ($rt=25.6$ m) without interference from other components, even its nearest neighbor abietic acid ($rt=24.8$ m), because it does not absorb at this wavelength. Both abietic and neoabietic acids are detected with essentially the same response at 240 nm with little interference from levopimaric and palustric acids. Similarly, palustric and levopimaric acid give the same response at 282 nm with no interference from neoabietic acid (chromatographically resolved) or abietic acid (no absorbance at 282 nm). Levopimaric and pimaric acids can be further distinguished at 300 nm, and concentrations determined without interference from the other abietanes. Dehydroabietic acid ($rt=15.5$ min) is well resolved from the other four abietanes and detected at 268 nm. For

Fig. 3 Abietanes in *P. glauca*. HPLC analysis of methanol extract (20 μ l injection) from *P. glauca* is shown with detection at 240 and 268 nm

convenience, response factors for the abietanes can be normalized to that of abietic acid at 240 nm by using standards determined individually: 240 nm: abietic (100%), neoabietic (102%), levopimaric (7.3%), palustric (19%); 268 nm: abietic (0%), neoabietic (40%), levopimaric (26%), palustric (40%); 282 nm: abietic (0%), neoabietic (1.1%), levopimaric (24%), palustric (22%); 300 nm: abietic (0%), neoabietic (0%), levopimaric (5.5%), palustric (1%).

Accordingly, the concentrations of abietanes in the 1-mM mixture were in close agreement with predicted levels (from simple dilution of stocks to prepare the mixture). For illustration, Fig. 2 chromatograms results are: abietic (1.08 mM at 240 nm), neoabietic (1.0 mM at 268 nm; 1.1 mM at 240 nm), levopimaric (1.08 mM at 282 nm; 1.02 mM at 300 nm), palustric (1.21 mM at 282 nm, 1.14 mM at 268 nm), and levopimaric–palustric sum (2.06 mM at 282 nm peak area). Peak heights are used for response factors to minimize the contribution of neighboring analytes, except in the case of levopimaric–palustric acid summation where peak areas can be used without interferences. This may allow in principle a more accurate determination of palustric by subtracting levopimaric acid concentration (1.02 mM at 300 nm) from levopimaric–palustric sum (2.06 mM at 282 nm).

The basis for the analytical technique described here relies on both the optimal combination of wavelengths for detection and the chromatographic resolution of the peaks. The degree of resolution we observe (Fig. 2) is similar to that reported previously with a Hypersil C8 column and a mobile phase of methanol–water–propanol (Rigol et al., 2003). However, the order of elution of the abietanes in their case is different (levopimaric–neoabietic < abietic < palustric). It is noteworthy that the coelution of levopimaric and neoabietic was problematic with detection by negative ionization/mass spectrometry because no fragmentation was observed (Rigol et al., 2003). The analytes of identical m/z 301 were not distinguished from each other, in contrast to the multiwavelength UV detection method presented here. We have included acetic acid in the mobile phase to stabilize pH conditions for the acid components, thus improving reproducibility and peak shape.

Detection of Abietanes in *P. glauca* The HPLC of methanol extract from *P. glauca* phloem is shown in Fig. 3. Spectral analyses of the analytes at peak apices correspond to standards using automated spectral library search. As illustrated before with standards, the following is observed: abietic (1.83 mM at 240 nm), neoabietic (1.39 mM at 268 nm and 1.44 mM at 240 nm), levopimaric (0.54 mM at 282 nm, 0.49 mM at 300 nm, and 0.56 mM at 268 nm), palustric (0.46 mM at 282 nm and 0.42 mM at 268 nm), and levopimaric–palustric sum (1.04 mM at 282 nm peak area). This corresponds to 4.0 mg abietic, 3.1 mg neoabietic, 1.2 mg levopimaric, and 0.95 mg palustric acids per gram of dry extracted phloem. The averages \pm standard deviations for 10 samples are 3.1 ± 1.6 mg abietic, 3.1 ± 2.2 mg neoabietic, 2.4 ± 2.6 mg levopimaric, and 2.2 ± 2.2 mg palustric acids per gram dry extracted phloem. The concentration of dehydroabietic acid was too low, or the interferences in the oleoresin too high, for reliable detection. A major peak at 23 min (observed at 240 nm) has a spectrum similar to that of abietic acid. This unknown was observed in all *P. glauca* samples tested.

In summary, the analytical method presented here for common abietanes has advantages particularly useful in ecological studies where large numbers of samples are required for statistical validation, and where it is important to retain the biological activities of the plant constituents. This is demonstrated with complete methanol extracts of conifer phloem with no prior fractionation. Therefore, all components are available from the chromatographic separation for subsequent chemical or biological characterizations. Samples are not derivatized (in contrast to typical GC methods), and therefore biological activities of fractionated components are retained. Components include not only the diterpenes but also monoterpenes, sesquiterpenes, and phenolics in oleoresin. The method is simple and rapid, employing robust reversed-phase HPLC. Detection at four wavelengths and spectral analysis provides confirmation and/or refinement for quantitative determination of abietic, neoabietic, levopimaric, and palustric acids.

recognition of host plants by larvae of *M. sexta*. To answer this question, we examined various solanaceous species by standard methods and isolated fractions that were eluted in a standard chromatographic program. Fractions that showed activity in feeding bioassays were analyzed for the presence of indioside D and/or other active components.

In this work we report the isolation and identification of a new compound, a different furostan glycoside, from *S. surattenses*, which appears to account for stimulation of feeding by *M. sexta* larvae on this plant.

Methods and Materials

Plants

Solanum surattenses was grown from seeds (personal seed collection of MH) in a greenhouse under 16:8 L/D, RH=75%, and temperature=28°C until plants reached a height of approx. 0.75 cm (3–4 months).

Extraction and Isolation

The foliage that was about 0.75 cm high was extracted with hot water (approximately 5 ml g), and the solid debris was filtered off. The resulting extract was concentrated under reduced pressure to a small volume. The extract was applied to a C₁₈ reverse-phase preparative column and eluted under medium pressure with increasing concentrations of MeOH (0%, 25%, 50%, 75%, and 100%) in water, and five fractions were collected (1–5). Fractions 2–4 were combined and rechromatographed on a second C₁₈ column by eluting with increasing concentrations of MeOH (0%, 25%, 35%, 45%, 55%, 75%, and 100%) in water. Seven fractions (A–G) were collected, and fraction F was further separated by HPLC using a Discovery RP Amide C₁₆ semiprep column (Supelco, 25 cm×10 mm, 5 μm) using a water/acetonitrile gradient system (0% acetonitrile at 0 min; 30% at 5 min; 63% at 30 min and 100% at 50 min; flow rate 2.2 ml/min) and monitored at 254 nm by a diode array detector (Program I). The active fraction, between 20.7 and 25.5 min, as identified by bioassay experiments, was collected and rechromatographed on an amide C₁₆ analytical column (Discovery, Supelco, 15 cm×4.6 mm, 5 μm) using a slightly different water-acetonitrile gradient system (0% acetonitrile at 0 min; 23% at 10 min, 30% at 40 min, and 100% at 50 min; flow rate 1.0 ml/min) (Program II), and an active fraction (compound **1**) was isolated (yield ~0.5 mg/gm leaf material).

Instrumentation

CID mass spectra were recorded using a Waters-Micromass (Manchester, UK) Quattro I triple quadrupole mass spectrometer equipped with an electrospray ion source. The source temperature was held at 85°C. The argon gas pressure in the collision cell was adjusted to attenuate precursor ion transmission by 50%, and laboratory-frame collision energy was optimized for each experiment. Samples were infused into the ESI source as acetonitrile–water solutions at a rate of 5 μl min⁻¹ via a syringe pump. Solutions were prepared by dissolving samples in 80:20 (v/v) of acetonitrile/deionized water mixture (LC-MS grade acetonitrile; Riedel-de Haën, Seelze, Germany) and 0.1 ml of 1.0% (v/v) formic acid in water (~25% in H₂O, Fluka, Buchs SG, Switzerland). Accurate mass measurements were obtained by electrospray ionization mass spectrometry (ESIMS) using an Autospec high-

resolution mass spectrometer (Micromass) with PEG as the reference material. All nuclear magnetic resonance (NMR) experiments were performed on a Bruker AVANCE 600, with a 5 mm TXI probe at 30°. All 2D NMR spectra were acquired in CD₃OD using standard Bruker pulse sequence. Signal at 3.3 ppm for MeOH was used as an internal reference to calibrate the spectra. Spectra were analyzed using Bruker XWINNMR version 3.5 software. Chemical shifts are presented as ppm.

Bioassays

Choice assays were conducted using 1.4 cm diam discs cut from fresh cowpea (nonhost) leaves as the substrate. Four discs were presented to each larva. Two of the discs were treated with 20 μ l (10 μ l on each side) of the test solution diluted in methanol, and the two control discs were treated with same amount of methanol. Treated and control discs were pinned alternately in a 15 cm Petri dish lined with moist filter paper. One 3rd- or 4th-instar *M. sexta*, reared on potato foliage, was randomly selected and placed at the center of each dish. After a period of 30–120 min, we recorded whether a treated or control disc was eaten. Distinct biting was also recorded as stimulatory activity. In general, if the sample was active, insects fed on one of the treated discs within the first 15 min.

Statistical Analyses

2 \times 2 Tables were prepared for the number of treatments and controls that were eaten or not, and Fisher's exact tests were conducted to determine whether the extracts were active or not.

Results and Discussion

Bioassay-guided fractionation of methanolic extracts led to the isolation of a single compound (**1**), which showed significant feeding stimulant activity (Table 1). Forty-two g leaf equivalents (gle) of extract yielded 19.9 mg of compound **1**. Throughout the isolation process, most of the fractions were active at a concentration of 0.1 gle, but higher

concentrations were necessary to demonstrate activity of the highly purified material. Some loss of activity occurred with repeated fractionations, and compound **1** eluted as a broad peak with a long trailing edge.

Compound **1** was isolated as white amorphous powder. A positive-ion ESIMS showed a signal at m/z 1071 for $(M+Na)^+$, and additional accurate ESIMS provided a molecular formula of $C_{51}H_{84}O_{22}$ [1049.189 Da was observed for $(M+H)^+$ ($C_{51}H_{85}O_{22}$), (1049.553 Da calculated)]. 1D 1H NMR spectral data provided conclusive evidence of a steroidal glycoside structure. Under positive-ion ESI conditions, MS–MS of the quasimolecular ion peak, m/z 1071, peaks for product ions were observed at m/z 1031 (loss of water), 885 (loss of a deoxyhexose), 869 $[(M+H) - 162]^+$ (loss of a hexose), 723 $[(M+H) - 162 - 146]^+$ (loss of a hexose and a deoxyhexoses), 577 $[(M+H) - 162 - 146 - 146]^+$ (loss of two deoxyhexose and a hexose) and 415 $[(M+H) - 162 - 146 - 146 - 162]^+$ (loss of two hexoses and two deoxyhexose), 397 $[(415+H) - 18]^+$. The results suggested the presence of four sugar molecules, two of which are deoxyhexoses and the other two hexoses. The fragmentation pattern also suggested branched substitutions of sugars since fragmentation could result in a loss of either a hexose moiety or a rhamnose moiety. The presence of four sugars was confirmed by the presence of four NMR peaks at δ 5.14, 4.83, 4.49, and 4.22 for the anomeric protons. Moreover, the COSY, HSQC- TOCSY, and 1HNMR spectra suggested the two deoxyhexoses to be rhamnose and the two hexoses to be glucose based on the coupling constants observed for protons of each hexose moiety (Table 2). Also, the anomeric protons of two rhamnose moieties showed a small coupling constant of 1.3 Hz, indicating that they were β -substituted at C-1. Similarly, the large coupling constants of around 8 Hz indicated the glucose moieties were α -substituted. Furthermore, 1H NMR showed the presence of six methyl groups, four as doublets at δ 1.24, 1.24, 0.99, and 0.94, and two as singlets at δ 1.04 and 0.82, respectively. The signals at δ 1.24 and 1.24 correlated to sugar moieties in COSY and HSQC-TOCSY and were assigned to two rhamnoses. The multiplicity of methyl group signals suggested that the aglycone is a steroidal molecule. The signal at δ 3.58 suggested the presence of a 3-*O*-substituted OH group, which was correlated to the protons at δ 2.44 (dd, $J=12, 2.33$ Hz) and 2.28 (dd, $J=12, 12$ Hz) of C-4, and confirmed the α -orientation of the hydroxyl group. The downfield shift of H-4ab and a broad signal at δ 5.39 suggested presence of $C_5:C_6$ unsaturation. This was further confirmed by ^{13}C NMR and HMBC correlations. Peaks at δ 3.71, and 3.38 showed a correlation to signals at δ 1.73 and 0.94. Also in TOCSY, they correlated to a quaternary carbon signal at δ 110.0 ppm. The signal at δ 4.56 and its correlation to the doublet at δ 0.99 in TOCSY, along with COSY data established the presence of a furan ring. Thus, we concluded that compound **1** was a furostan derivative. The reported NMR values for the steroidal part compared well with some of the literature values reported for furostan derivatives, and the configuration at carbon 25 matched with 25*R* (Table 2) (Aquino et al., 1986; Yahara et al., 1996). Linkages between sugar moieties were ascertained by chemical shifts of ^{13}C of sugars and by HMBC and ROESY correlations. The anomeric proton at δ 4.49 showed a correlation with the proton at δ 3.58 and 2.44 in ROESY, thus indicating that the glucose is attached to C-3, and all these protons are on the same side of the molecule. Similarly, the signal at δ 5.15 correlated to 4.49 and 3.58. The signal at δ 3.39 correlated to the signal at 100.91 in HMBC, and thus established that one of the rhamnose molecules is attached to glucose at the C-2' position. The anomeric proton at δ 4.29 showed a correlation to the proton at δ 3.51 of C-4 in ROESY. The anomeric carbon at δ 101.8 showed a correlation to the proton at δ 3.58 in HMBC, thus establishing the substitution on C-3'' of rhamnose molecule. This was further substantiated by the shift to a higher value (78.0 ppm) for the carbon attached to it. The fourth anomeric proton at δ 4.22 of the second glucose

moiety showed a correlation to the signal at δ 3.71 and 3.37 of C-26 protons in ROESY and HMBC. Furthermore, the ^{13}C NMR shift of C-26 was similar to that of compounds in which C-26 is substituted with a glycoside (Yahara et al., 1996). Therefore, we could establish that compound **1** is 26-*O*- β -D-glucopyranosyl-(25*R*)-furosta-5-ene-3- β -yl-*O*- α -L-rhamnopyranosyl-(1''-2')-*O*- α -L-rhamnopyranosyl-(1'''-3'')-*O*- β -D-glucopyranoside (Fig. 1). To the best of our knowledge, this compound has not been previously reported.

Acceptance of *S. surattenses* as a host plant by *M. sexta* larvae can be explained by the stimulatory effect of compound **1**. Compound **1** has the same steroidal structure as indioside D, which was reported as a feeding stimulant for *M. sexta* from potato foliage (del Campo

Fig. 1 Chemical structures of compound **1** and indioside-D

et al., 2001), but it differs in the types of sugars and in their attachment. Indioside D has branched sugar substitution, whereas the sugars in compound **1** are not branched.

Solanaceous plants are rich in steroidal and triterpenoid glycosides, and many of these, alone or in combination, may be capable of serving as recognition factors for this insect. Other fractions of *S. surattenses* extracts showed varying amounts of feeding stimulatory activity at different concentrations, suggesting that more than one compound is involved in recognition of this plant. Furthermore, recent studies with potato foliage have indicated that other compounds may also be involved in stimulating feeding by *M sexta* larvae (Müller and Renwick, 2001). Additional chromatographic fractions in potato extract were active in bioassays, but the active compounds were not isolated and identified. These results suggest that *M. sexta* may become “tuned” to any one of several related steroidal glycosides.

M. sexta is one of about 800 species of hawkmoths (Family: Sphingidae) worldwide that develop on a variety of host plants (Oehlke, 2005). The genus *Manduca* (tribe: Sphingini), consisting of approximately 70 species, is widely distributed throughout North and South America and in the Caribbean Islands. The main hosts are in the Solanaceae, Verbenaceae, Boraginaceae, Bignoniaceae, Oleaceae, and Annonaceae, although a few of them feed on some other families (Mechaber and Hildebrand, 2000; Oehlke, 2005). All of these plant families are rich in biologically important chemical constituents that include terpenoids, iridoids, lignans, flavonoids, quinones, alkaloids, etc., and their glycosides.

Larval food is selected by adult *M. sexta* females during oviposition, and the female's choice of plant for oviposition is based on stimulants that may include visual, volatile, and contact cues (De Boer and Hanson, 1984; Fraser et al., 2003). Furthermore, oviposition stimulants and feeding stimulants may not be the same compounds or even the same type of compounds. Several researchers have studied the role of host volatiles that are involved in attracting the moth to the plant (Fraser et al., 2003), but little is known about the contact oviposition stimulants. It is likely that the different host plant families are related in having similar oviposition stimulants that attract the females to lay eggs on them. del Campo et al. (2001) have shown that the presence of indioside D alone was sufficient to stimulate feeding by *M. sexta* larvae. However, after their experience with this compound in their diet, larvae became dependent on it for continued feeding. This dependency has been related to development of receptor sensitivity to the compound. This would suggest that larvae have the plasticity to develop receptor sensitivity to a compound and thus may be capable of developing sensitivity to different chemicals in different host families, based on their first experience (De Boer and Hanson, 1984). In addition, acceptance of a plant for oviposition or feeding is dependent on the presence of other components in the host, either stimulants or deterrents that may contribute to a balance of positive and negative stimuli that results in acceptance or rejection of a plant.

Introduction

The leaf beetle *Diorhabda elongata* Brullé (Coleoptera: Chrysomelidae) has been successfully introduced into the United States from China as a biocontrol agent for saltcedar (*Tamarix* spp., Tamaricaceae) (DeLoach et al., 2003, 2004). Saltcedars were originally imported from Eurasia as ornamentals and for erosion control of streambanks and river channels. However, these fast-growing shrubs or small trees are invasive and have become a major component of western riparian ecosystems (Friedman et al., 2005), causing serious environmental and economic damages (Zavaleta, 2000; Shafroth et al., 2005).

In an earlier study (Cossé et al., 2005), we identified the male-produced aggregation pheromone of *D. elongata* as a 1:1 blend of two seven-carbon compounds, (2*E*,4*Z*)-2,4-heptadienal (2*E*, 4*Z*-7:Ald) and (2*E*,4*Z*)-2,4-heptadien-1-ol (2*E*, 4*Z*-7:OH) and demonstrated attraction to the synthetic compounds in the field. The pheromone was identified in collections of volatiles from beetle-infested saltcedar by using electrophysiological analysis of these collections as a key tool. We noted that the antennae of male and female beetles responded to a number of compounds from the host foliage in addition to the pheromone components. Here, we report the identification and quantification of several saltcedar-emitted compounds and their electrophysiological and field activity for *D. elongata* adults.

Methods and Materials

Insects

Adult *D. elongata* used in this study were collected from a field population at Lovelock, NV, USA, or obtained from a colony maintained by one of us (DWB) at the United States Department of Agriculture Agricultural Research Service (USDA-ARS) Exotic and Invasive Weed Research Unit, Albany, CA, USA. The beetles originated from sites near Fukang, in the Xinjiang province of northwestern China (DeLoach et al., 2003; Lewis et al., 2003). Upon arrival at the USDA-ARS National Center for Agriculture Utilization Research (NCAUR) in Peoria, IL, USA, adult beetles were kept at 25°C under a 17-hr light/7-hr dark photoperiod. *Tamarix ramosissima* Ledebour was grown year-round in a greenhouse facility at NCAUR to provide food for the beetles. The beetles were used for electrophysiological tests and also to create feeding damage on saltcedar foliage.

Collections of Volatiles

Two types of collection techniques for volatiles were used: solid-phase microextraction (SPME) and Super-Q/activated charcoal filters. The SPME collections allowed for rapid

detection of changes in saltcedar volatile profiles, whereas the Super-Q/charcoal collections served as the source of saltcedar volatiles for compound quantification and gas chromatographic–electroantennogram detection (GC-EAD) analysis.

Volatile saltcedar compounds, emitted during the first 30 min of experiments and directly after beetles were placed on the saltcedar foliage, were collected simultaneously on polydimethylsiloxane/divinylbenzene (65 μm) fibers of SPME needles (Supelco, Bellefonte, PA, USA) and on collection filters (Cossé et al., 2002) containing a mixture (40 mg, 1:1) of Super-Q porous polymer (80–100 mesh, Alltech, Deerfield, IL, USA) and activated charcoal (Darco G-60, EM Science, Cherry Hill, NJ, USA).

Collections of volatiles were made from saltcedar foliage (branch approximately 75 cm long), either infested with beetles (about 200, both sexes but predominately males) or without beetles. In either case, the foliage was placed in a vertical glass tube (5 cm inside diameter [i.d.] \times 65 cm) with the freshly cut end protruding from the lower opening into a beaker of water. A piece of fine mesh nylon cloth with a small central hole for the saltcedar stem was secured around the lower end of the tube to keep the beetles contained. In some cases, collections of volatiles were made specifically from the flowering parts on the foliage. The collections were made at 25°C under a 17-hr light/7-hr dark photoperiod.

Using several reducing glass adapters, the top of the tube (female 55/50 ground glass joint) was fitted with an adapter with a male 24/40 joint on one end and a threaded fitting with an air-tight “O” ring seal on the other (Ace Glass, Vineland, NJ, USA, #5028-30). The threaded airtight fitting held one leg of a T-shaped glass tube (0.5 cm outside diameter). A second leg received the SPME needle through a rubber septum, and the last leg was connected to the Super-Q/charcoal filter assembly, which was, in turn, connected to a vacuum line (for diagram, see Bartelt and Zilkowski, 1999).

With the vacuum line, air was drawn through the collection tube and past the SPME fiber at 25 ml/min during the SPME sampling. After 30 min, the SPME needle was removed and the flow rate adjusted to 1 l/min for the remainder of the 24-hr collection period. Foliage was replaced on a daily basis and any dead beetles in the collector were replaced with fresh ones. Collected volatiles were rinsed from the filters into vials using methylene chloride (400 μl) after every 24 hr. 1-Octanol (10 μl of a methylene chloride solution containing 250 ng/ μl) was added to each vial as a quantitative internal standard.

It was confirmed that the 6-carbon and larger compounds did not break through the Super-Q/charcoal filters by placing a second filter in series and analyzing both separately. However, collection filters of Super-Q or 60–80 mesh-activated charcoal (GraphTrap-GB, Alltech) alone did not trap 6-carbon compounds quantitatively, and the very fine powdered Darco G-60 charcoal created excessive airflow resistance in the filters. The mixture of Super-Q and Darco G-60 charcoal resolved both problems.

Quantification

The amounts of (*E*)-2-hexenal (2*E*-6:Ald), (*Z*)-3-hexenal (3*Z*-6:Ald), (*Z*)-3-hexen-1-ol (3*Z*-6:OH), and (*Z*)-3-hexenyl acetate (3*Z*-6:OAc) in the collections of volatiles were quantified by coupled GC–mass spectrometry (GC-MS) using selected ion monitoring (SIM) mode. Two ions were monitored for each compound, *m/z* 83 and 98 for 2*E*-6:Ald, *m/z* 82 and 100 for 3*Z*-6:OH, *m/z* 69 and 98 for 3*Z*-6:Ald, and *m/z* 67 and 82 for 3*Z*-6:OAc. The selected ions for the internal standard, 1-octanol, were *m/z* 70 and 84. Quantification was based on the italicized ions of the above-mentioned ion pairs, whereas the second ions served as qualifiers (proper ion ratios would support compound identity and purity in the GC peaks).

Serially diluted solutions of all the synthetic compounds and internal standard (0.01–30 ng/ μ l) were first analyzed by GC with flame-ionization detection (GC-FID) to verify proper concentrations and further analyzed by GC-MS in SIM mode to obtain linear calibration curves (log dose vs. log abundance). The linear calibration curves (average of three replicate injections for each concentration) served as the basis of the quantification. In SIM mode, compounds were still easily detectable at concentrations as low as 10 pg/ μ l.

Electrophysiology

GC-EAD analyses were made by methods and equipment generally described by Cossé and Bartelt (2000). GC-EAD connections were made by inserting a glass-pipette silver-grounding electrode into the back of an excised beetle head. A second glass-pipette silver-recording probe was placed in contact with the distal end of one antenna. Both pipettes were filled with Beadle–Ephrussi (Ephrussi and Beadle, 1936) saline.

Instrumentation

Volatile collections were analyzed by GC-FID and GC-MS. Samples were injected in splitless mode using Hewlett Packard 6890 (Palo Alto, CA, USA) instruments fitted with 30-m DB-1, DB-5, or DB-Wax capillary columns (0.25 mm i.d., with 1.0-, 0.25-, and 0.5- μ m film thickness, respectively, J&W Scientific, Folsom, CA, USA). Temperature programs were from 40 to 280°C at 10°C per minute. Inlet temperatures were maintained at 280°C, and GC-EAD effluent interface from postcolumn splitter was kept at 280°C. For SPME analysis, the GC inlet port was fitted with an SPME-optimized glass liner (Supelco). Mass spectrometry was performed using a Hewlett Packard 5973 instrument (electron impact, 70 eV). The Wiley mass spectral library, with 275,821 spectra, was available on the MS data system (Wiley, 1995).

Chemicals

The two pheromone components, 2*E*,4*Z*-7:Ald and 2*E*,4*Z*-7:OH, were synthesized according to Petroski (2003). The purities of the compounds were >95% by GC-FID; by GC-MS, impurities were other geometrical isomers. 3*Z*-6:Ald (50% in triacetin, Bedoukian, Danbury, CT, USA) was obtained in pure form by Kugelrohr distillation (room temperature, 40 mm Hg) and stored (–70°C) as a dilute solution in methylene chloride. *E,E*-Farnesene was obtained by gentle reflux (4 hr) of *E,E*-farnesol (1 g) with Dowex 50W-X4 cation exchange resin (2 g) in hexane (50 ml), followed by open column chromatography on silver nitrate-coated silica (25% AgNO₃, elution solvent 15% 1-hexene in hexane). All other compounds were purchased (Aldrich, Milwaukee, WI, USA) with purities >97%.

Field Lures

Two types of host odor lures were prepared for field testing. The first lure type consisted of four green leaf volatiles (GLV), 3*Z*-6:Ald (4 mg), 2*E*-6:Ald (4 mg), 3*Z*-6:OH (0.8 mg), and 3*Z*-6:OAc (0.6 mg), in mineral oil. The second lure type consisted of seven compounds, heptanal (0.1 mg), octanal (0.25 mg), nonanal (1 mg), *E,E*-2,4-heptadienal (0.2 mg), *E,E*-2,6-nonadienal, indole (2 mg), and *E,E*-farnesene (2 mg), in mineral oil. A bulk solution of the compounds needed for each lure type was prepared in mineral oil (enough of each for

50 lures, in a total volume of 25 ml). Then, aliquots (0.5 ml) of this mixture were placed in 1.5 ml polypropylene micro centrifuge tubes (Bio Plas Inc., San Rafael, CA, USA) together with a piece (1 cm long) of braided cotton roll (Richmond Dental, Charlotte, NC, USA). The emission rates of freshly prepared GLV lures were measured in an incubator, using the general reported methods and equipment reported earlier (Cossé et al., 2005). Specifically, volatiles were collected from lures at 25°C with a 150-ml/min airflow. Volatiles were collected periodically over 2 d, and the release rates of individual compounds were measured by GC-FID using 1-octanol as the quantitative internal standard.

Lures were stored at -20°C until needed. Prior to field deployment, the caps of the tubes were pierced with a single pinhole (1 mm) to allow compound release from the headspace.

Pheromone lures (Cossé et al., 2005) consisted of a 1:1 mixture of 2*E*,4*Z*-7:Ald and 2*E*,4*Z*-7:OH (500 µg of each component), released in a nearly 1:1 ratio at 7 µg component⁻¹ d⁻¹.

Field Study

Experiments were carried out between May and September 2004 in saltcedar stands along the Humboldt River (40°01'N, 118°31'W) 17 km southwest of Lovelock, NV, USA, where a population of *D. elongata* had been established (DeLoach et al., 2004).

Yellow sticky traps (15.5×30.5 cm, AgriSense, Pontypridd, UK) were attached to branches (oriented vertically) in the upper half of the trees, typically at a height of 2–4 m, and were placed in trees that were at least 10 m apart and were similar in size, foliage density, and in accessibility to beetles flying from downwind. There were always other saltcedar trees near the treatment trees and usually between them as well. The protective paper was removed only from one side of the trap, so that the sticky side was oriented downwind. The traps were set out in midafternoon, when flight activity usually began to intensify, and trap counts were made the following morning. Thus, each replicate lasted 1 d. A wire, wrapped around the bait tube, was used to secure the lure to a trap.

The field experiments were carried out in two types of saltcedar stands. Defoliated saltcedar consisted of saltcedar that had previously experienced complete defoliation and had little or no foliage present during the experiment. For the experiment beginning on May 6, 2004, the stand had experienced defoliation the previous season, and adult beetles had overwintered in the leaf litter beneath the stand. They were newly emerged from overwintering when the experiment was performed. Later in the season, newly defoliated saltcedar stands were the result primarily of heavy infestation with *D. elongata* larvae. The second stand type had little or no previous defoliation; adults were just beginning to move into these stands, whose trees had relatively lush green foliage during the tests.

Three sets of experiments were deployed. The first set was a preliminary assessment of the host odor lures. The two types of host odor lures (four-component and seven-component) were first combined on traps and compared to unbaited control traps in a paired design ($N=12$), followed by the pairwise comparison of only the four-component GLV lures and unbaited controls ($N=6$). In addition, there was one comparison of the seven-component lure vs. unbaited control.

The second experiment, deployed in both saltcedar stand types, was a more systematic pairwise comparison of the GLV lures and unbaited controls, throughout the 2004 season, starting on May 6, when the overwintered beetles were becoming active, and finishing on September 14, when all of the beetles had entered reproductive diapause (DeLoach et al., 2004). The first trapping day in both types of saltcedar stands had 18 replications per

treatment followed by six replications per treatment for all other days. Trapped beetles were sexed periodically (Cossé et al., 2005). Sweep net samples were taken on June 28 in both types of saltcedar stands and included both flying beetles and those present on foliage. Captured beetles were counted and sexed.

The third experiment measured the effects of combining pheromone and GLV lures and was set up on August 11, 2004, at least 200 m away from the nearest saltcedar trees. Traps used in this experiment were two-sided yellow sticky panel traps (15.2×30.5 cm, both sides exposed, Seabright Laboratories, Emeryville, CA, USA). Treatments were pheromone lure, GLV lure, pheromone and GLV lures combined, and unbaited control. A randomized complete block design was used (four traps per block), and there were four replicates of each treatment.

Statistical Analyses

Counts of *D. elongata* adults on traps were transformed using $\log(X+1)$ to stabilize variance. The data from the pairwise experiments were analyzed by paired *t*-tests, whereas data from the randomized complete block design were submitted to analysis of variance and means were compared using the least significant difference test.

Results

GC-EAD Analysis of Saltcedar Volatiles

GC-EAD comparisons of volatiles collected by Super-Q/charcoal from beetle-infested saltcedar foliage and foliage alone showed that male and female antennae responded to a variety of compounds (Fig. 1). Compounds that triggered male and female antennal responses were identified as 3Z-6:Ald, 2E-6:Ald, 3Z-6:OH, 2E-6:OH, 1-hexanol, heptanal, 3Z-6:OAc, octanal, (2E,4E)-2,4-heptadienal, benzyl alcohol, nonanal, (2E,6Z)-2,6-nonadienal, indole, and (E,E)-farnesene. By GC-MS, only trace amounts of the same compounds could be detected in collections of volatiles from uninfested saltcedar, and the antennal activity to these was in most cases inconclusive. More consistent GC-EAD activity from uninfested saltcedar could be obtained from collections of volatiles of crushed saltcedar foliage followed by sample concentration. Additional collections of volatiles from the flowering parts of saltcedar showed a relative abundance of benzyl alcohol, which was easily detected by the antennae of both sexes. Male and female antennae responded also to the two pheromone compounds, 2E,4Z-7:Ald and 2E,4Z-7:OH, which were present in beetle-infested foliage collections. Identities of GC-EAD-active compounds were verified by GC-MS and GC-EAD analysis of authentic standards.

Collections of Volatiles by SPME

Thirty minutes after placing the beetles on saltcedar foliage, several GLV compounds were already easily collected by SPME and detected by GC-MS (Fig. 2A), whereas these compounds were almost absent in the SPME collections from uninfested saltcedar foliage (Fig. 2B). Compounds that were consistently more abundant in the beetle-infested SPME collections were 3Z-6:Ald, 2E-6:Ald, 3Z-6:OH, 3Z-6:OAc (coeluting with compound d in Fig. 2A), nonanal, and decanal. SPME collections from uninfested saltcedar showed only

Fig. 1 Simultaneously recorded gas chromatogram with FID and EAD of female *D. elongata* antenna to volatiles collected from male and female *D. elongata* adults feeding on saltcedar. Letters denote antennal activity by: (Z)-3-hexenal (a), (E)-2-hexenal (b), (Z)-3-hexen-1-ol (c), (E)-2-hexen-1-ol (d), 1-hexanol (e), (Z)-3-hexenyl acetate (f), octanal (g), (2E,4E)-2,4-heptadienal (h), benzyl alcohol (i), nonanal (j), (2E,6Z)-2,6-nonadienal (k), indole (l), and (E,E)-farnesene (m)

trace amounts of 3Z-6:Ald, 2E-6:Ald, nonanal, and decanal. In addition, SPME collections from beetle-infested saltcedar also showed the presence of the two male-produced pheromone components, 2E,4Z-7:Ald and 2E,4Z-7:OH. The most abundant and earliest detectable GC-EAD-active compounds in collections of volatiles from beetle-infested saltcedar were selected for further analysis.

Quantification of GLVs from Saltcedar

Quantification of four GLVs, 3Z-6:Ald, 2E-6:Ald, 3Z-6:OH, and 3Z-6:OAc, collected from saltcedar, with and without the feeding beetles, revealed that beetle-infested saltcedar foliage emitted about 50 times more of the four compounds than did uninfested foliage (Table 1). Nearly equivalent amounts of each of the four compounds were released by uninfested foliage, whereas proportionally greater amounts of 2E-6:Ald and lesser amounts

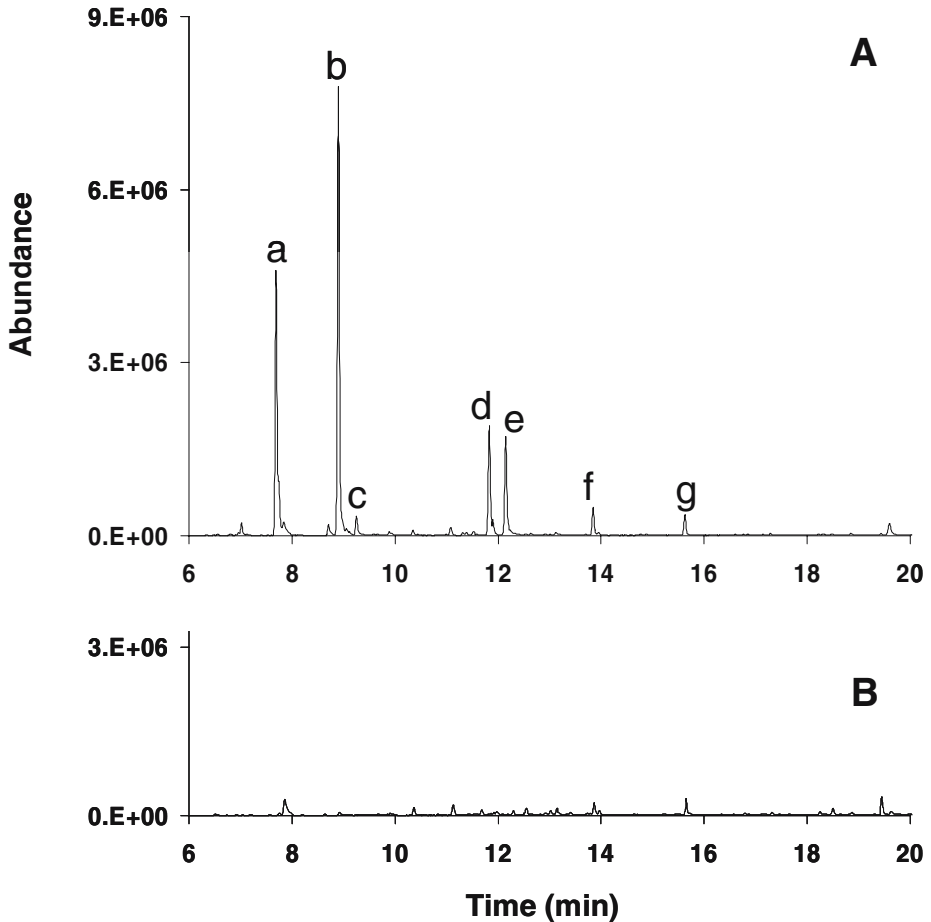

Fig. 2 GC-MS profiles of SPME-collected volatiles during the first 30 min of a 24-hr collection of volatiles from (A) saltcedar foliage infested with feeding adult *D. elongata* and (B) saltcedar foliage alone. Letters above the GC-MS peaks denote the presence of (*Z*)-3-hexenal (a), (*E*)-2-hexenal (b), (*Z*)-3-hexen-1-ol (c), (2*E*,4*Z*)-2,4-heptadienal (d), (2*E*,4*Z*)-2,4-heptadien-1-ol (e), nonanal (f), and decanal (g)

of 3*Z*-6:Ald and 3*Z*-6:OAc were released by infested foliage. Preliminary analysis of Super Q/charcoal collected saltcedar emissions (Cossé et al., 2005) showed that some of the less volatile compounds (2,6-nonadienal, indole, and *E,E*-farnesene) could only be detected towards the end of the 24-hr collection period.

Field Lures and Field Study

After 24 hr, the GLV field lures released approximately 30 µg/hr and in a ratio of nearly 32:3:1:1 (2*E*-6:Ald/3*Z*-6:OH/3*Z*-6:Ald/3*Z*-6:OAc; Table 2). Preliminary field trapping experiments captured 314±152 (Mean ± SD, *N*=12) beetles per trap per day in response to the two host odor baits combined, whereas the unbaited traps caught 32±60 (Mean ± SD, *N*=12) beetles per trap per day. The GLV lure alone caught 254±94 (Mean ± SD, *N*=6)

beetles per trap per day, whereas the unbaited traps caught 12±24 (Mean ± SD, N=6) beetles per trap per day. A single pair of traps comparing the trap catch of the seven-compound host odor lure (16 beetles per trap per day) with that of the unbaited control (five beetles per trap per day) elicited a much lower response. Therefore, the GLV lure was selected for further field testing.

The second set of field trapping experiments demonstrated the attractiveness of the GLV lures to male and female *D. elongata* throughout the season and in the two types of saltcedar stands (Table 3). Significantly more adults were attracted to traps baited with GLV compared to the control traps during seven different periods in defoliated saltcedar stands. Similar results were obtained in saltcedar stands with abundant foliage during four trapping periods. In both types of saltcedar stands, the response ratio between GLV and control treatments was higher early in the season and slowly declined throughout the season (Table 3). Relatively high numbers of beetles were trapped on May 6 and August 12 in the defoliated saltcedar stands.

Trap counts showed a strong bias towards males in both baited and unbaited traps (Table 3). Similar male bias was found in aerial sweep net samples, collecting 38 males and nine females in areas with foliage and seven males and three females in defoliated areas. The observed sex ratio was consistent between the two saltcedar foliage categories (2×2 contingency table, $X^2=0.58$, 1 *df*, $P=0.44$; overall, 79% males). Sweep net samples of beetles from saltcedar trees showed a considerably more balanced sex ratio, with 43 males and 26 females from defoliated saltcedars (from 30 plants) and 29 males and 24 females from saltcedars with foliage (from 15 plants). Again, the sex ratio was not significantly different between the two saltcedar stand types (2×2 contingency table, $X^2=0.72$, 1 *df*, $P=0.40$; overall, 59% males). However, the proportion of males in the aerial sample was significantly higher than in the sample from the trees (after summing over stand type in the

above data sets, a 2×2 contingency table for sex vs. aerial/tree sampling gave $X^2 = 6.82$, 1 *df*, $P < 0.01$).

In the third field experiment, adult *D. elongata* were attracted to traps baited with pheromone, GLV, or both, in numbers that were significantly higher than those found on the unbaited control traps (Table 4). There was no significant difference between the numbers of *D. elongata* attracted to traps baited with GLV lures compared to those attracted to traps baited with pheromone lures. The combination of GLV and pheromone lures attracted the highest number of beetles, with approximately six times more *D. elongata* than to GLV lures alone, and approximately four times more *D. elongata* than to pheromone lures alone (Table 4).

Discussion

In this study, we focused on possible biologically active saltcedar volatiles released during feeding by *D. elongata*. The experimental results demonstrated that at least 15 volatile compounds were antennally active to male and female *D. elongata*. Collections of volatiles from uninfested saltcedar showed relatively small amounts of GC-EAD-active material, but collections from beetle-infested foliage showed that the feeding activity of the beetles significantly increases the amounts of GC-EAD-active saltcedar volatiles released into the air. GLVs (Visser and Avé, 1978; Visser, 1986) especially were released in relative abundance and could be easily detected during the first 30 min after feeding began, whereas relatively lesser amounts could only be detected in the samples collected over a 24-hr period. Numerous studies have demonstrated the quantitative and qualitative differences between volatiles emitted by herbivore-infested plants compared to the volatiles emitted by uninfested plants (for reviews, see Dicke et al., 1998; Dicke and Vet, 1999; Dicke and van Loon, 2000), and several of these studies have shown the role of the identified GC-EAD-active compounds in tritrophic interactions (for reviews, see above). In this study, we focused only on GC-EAD-active material. Qualitative differences in these compounds were not noted between beetle-infested and noninfested plants, but the quantitative differences were dramatic.

The behavioral significance of the identified GLVs was demonstrated in the field. A blend of four of the most abundant, antennally active GLVs, released at compound ratios mimicking the beetle-infested plant release ratios, was highly attractive to male and female *D. elongata* in areas where most of the saltcedar stands were completely defoliated. Furthermore, this synthetic blend was still highly attractive to male (and, to a lesser extent, female) *D. elongata* in areas with an abundance of beetles and saltcedar foliage.

Further evidence for the importance of the GLV blend was demonstrated with the observed synergistic effect when pheromone and GLVs were combined (Table 4). It should be noted that this synergistic effect was demonstrated in previously uninfested saltcedar stands. As such, the combination of the pheromone and the green leaf odor blend could be a useful attractant in detecting the presence of *D. elongata* in newly colonized areas. This would be a useful tool in the saltcedar biocontrol program.

In beetle taxa with aggregation pheromones, pheromone emission occurs at the feeding/breeding site, and host-derived volatiles are potent synergists of the pheromones for some taxa (Borden, 1985; Bartelt, 1999). Only recently has the synergistic interaction of host compounds and pheromones been shown for chrysomelid beetles (Soroka et al., 2005; Tóth et al., 2005).

Field observation of *D. elongata* showed that the population density is not uniformly distributed among the saltcedar bushes. Especially in newly colonized stands of saltcedar, the presence of adult beetles is highly aggregated with, for example, a single plant containing hundreds of feeding beetles being surrounded by many other similar-looking plants without any beetles. In those instances where a small number of beetles landed and started feeding on a previously uninfested saltcedar bush, it was quickly (<30 min) followed by the arrival of numerous other beetles on the same saltcedar branch (personal observations by authors Cossé, Bartelt, and Bean). If the original group of pioneer beetles contained males, one could envision that the arrival of the additional beetles was caused by the release of the male-specific aggregation pheromone, the release of attractive host volatiles as a result of the feeding action, or both stimuli.

Our earlier study dealing with the identification of the male-specific aggregation pheromone of *D. elongata* showed that males feeding on saltcedar foliage released a 1:1 mixture of 2E,4Z-7:Ald and 2E,4Z-7:OH, and that this mixture attracted significant numbers of males and females to traps placed in saltcedar stands in various stages of

defoliation (Cossé et al., 2005). In this study, the pheromone could be detected within the first 30 min after placing the beetles on the saltcedar foliage in the collector.

Certain chrysomelid beetles, such as *Diabrotica* spp. (for review, see Metcalf and Metcalf, 1992) and *Leptinotarsa decemlineata* (Dickens, 1999, 2000, 2006), are attracted to blends of some of the same GC-EAD-active compounds found in this study. For example, benzyl alcohol and indole, two volatile components associated with the blossoms of *Cucurbita* spp., were both antennally active and attractive to adult *Diabrotica undecimpunctata howardi* and *Diabrotica virgifera virgifera* in field studies (Andersen and Metcalf, 1986; Lampman et al., 1987). Antennae of *L. decemlineata* responded to several volatile potato foliage compounds, including 3Z-6:OH, 2E-6:OH, 3Z-6:OAc, nonanal, decanal, and indole (Dickens, 1999). However, Dickens (2000) showed that some blends containing the GLVs 3Z-6:OH and 2E-6:OH can also be unattractive or repellent for *L. decemlineata*. Also, cereal leaf beetles, *Oulema melanopus*, did not respond to a GC-EAD-active oat volatile, 3Z-6:OAc, in field tests (Rao et al., 2003). Behavioral activity to GLVs has also been demonstrated with other Coleoptera; for example, scarab beetles, *Melolontha melolontha* (Reinecke et al., 2005) and *Phyllopertha horticola* (Ruther and Mayer, 2005), are strongly attracted to single or blends of specific GLV compounds. In addition, GLVs significantly enhanced the responses of the smaller European elm bark beetle, *Scolytus multistriatus*, and boll weevil, *Anthonomus grandis*, to their respective pheromones (Dickens et al., 1990).

Future field tests with *D. elongata* will be necessary, using single components and different blends and blend ratios of saltcedar volatiles, to fully investigate the behavioral significance of all of the EAD-active compounds.

The field bioassays showed a male-biased sex ratio that was surprisingly strong on some of the trapping dates. It is possible that males were more attracted to the host plant odors, but with similar male sex ratios in unbaited control traps and aerial sweeps, a more likely explanation is that males are simply the more active fliers, especially because the beetle sex ratio on the foliage was far less male-biased. In previous field tests of the aggregation pheromone blend, only a slight male bias was noted in the captured beetles (Cossé et al., 2005). Again, it is possible that males are more strongly attracted to host plant odors than females and that this differential attraction is not as pronounced with aggregation pheromones. A more likely explanation is that the behavioral, physiological, and ecological context of these experiments is critical in the outcome, both in terms of attraction to the baits and the sex ratio of captured beetles. For instance, placement of traps outside of the areas where beetles are mating and ovipositing might bias the sex ratio toward males, if they are the primary colonizers. The physiological status of the beetles, whether it be reproductive, diapause, hungry, or fed, will also undoubtedly have a strong influence on response to behaviorally active compounds.

Future field studies might further investigate the hypothesis that male *D. elongata* are pioneers in the colonization of saltcedar and that successful establishment of new populations is being guided by both the release of the male-produced aggregation pheromone and some of the volatile compounds released by the host plants.

Tannins can form stable complexes with proteins and can also act as metal chelators (e.g., Laks, 1989; Slabbert, 1992; Hättenschwiler and Vitousek, 2000). As a consequence, they play multiple roles in biogeochemical processes such as organic matter decomposition, nutrient dynamics, soil formation, and (heavy) metal transport (Kraus et al., 2003a). Through tannin–proteins complexes, N mineralization is affected, and organic matter decomposition and nutrient dynamics decrease or increase (Handley, 1961; Schimel et al., 1998; Fierer et al., 2001; Kraus et al., 2003a, 2004; Nierop et al., 2006). In the mineral soil compartment, tannins release metals from soil particles and can promote podzolization (Bloomfield, 1953, 1957; Coulson et al., 1960; Kaal et al., 2005), a soil-forming process that involves the release, translocation, and precipitation of Al, Fe, and organic matter.

Despite the many roles tannins play in soil processes and litter decomposition, they are difficult to detect in the same litter and soils (Tiarks et al., 1989; Schofield et al., 2001; Lorenz and Preston, 2002; Lorenz et al., 2004). Often, tannin concentrations are measured with colorimetric methods including the Folin–Ciocalteu and the Prussian Blue assays for total phenolics, the HCl–butanol and the vanillin assays for CT, and the potassium iodide assay for hydrolyzable tannins (Waterman and Mole, 1994; Yu and Dahlgren, 2000; Schofield et al., 2001; Hartzfeld et al., 2002). These methods require extraction prior to quantification, and indicate decreasing amounts of tannins upon litter decay (e.g., Schofield et al., 1998; Bradley et al., 2000; Lorenz et al., 2000; Maie et al., 2003; Nierop et al., 2006), suggesting that tannins have been decomposed or leached away. ^{13}C nuclear magnetic resonance (NMR) spectroscopy, however, suggests that a portion of tannins are inextricable and, therefore, escape the analytical windows of the assays developed for quantification (Benner et al., 1990; Lorenz et al., 2000; Yu and Dahlgren, 2000; Maie et al., 2003). Although NMR is a suitable method for detecting tannins in solid plant and soil material, tannin resonances interfere with those of lignin and polysaccharides, which may hamper obtaining detailed information on tannin amounts, structures, and possible transformations (Wilson and Hatcher, 1988; Preston et al., 1997; Parfitt and Newman, 2000; Lorenz and Preston, 2002; Maie et al., 2003). Along with an acid-catalyzed depolymerization method (Hernes and Hedges, 2000) and MALDITOF-MS (Behrens et al., 2003), thermally assisted hydrolysis and methylation (THM) offers an alternative to study both HTs and CTs in plants, litter, and soils (Garnier et al., 2003; Nierop et al., 2005). Although most products obtained by THM from tannins have also been found from lignin, the 1,3,5-trimethoxybenzenes derived from the A ring of CTs have never been identified from lignin, and are thus good markers of CTs in environmental samples (Nierop et al., 2005).

In this paper, we used THM to assess the fate of HTs and CTs after addition to Corsican pine litter and subsequent incubation. Knowledge of the amounts of tannins added, comparison between Folin–Ciocalteu and HCl–butanol assays that quantify extractable tannins and those present in litter, will provide clues to the fate of tannins in coniferous litter.

Methods and Materials

Litter collection, pretreatment, and general composition. Litter, i.e., material from the F1 horizon, was collected from a pine forest named Luizenberg, which is situated in the Amsterdamse Waterleiding Duinen, a coastal dune area with a partly decalcified sandy soil at the south of Zandvoort, west of Amsterdam (the Netherlands). The trees, Corsican pine (*Pinus nigra* var. *maritima*), were planted in 1935. Collected litter was air-dried at 30°C for 24 hr and subsequently sieved over 2 cm to remove coarse fragments and to obtain a rather homogenous substrate, which was stored at 2°C before experiments and analysis.

Condensed tannin collection. Needles from Corsican pine were collected by cutting branches from the trees in May 2003. Needles were dried under vacuum on the same day and subsequently ground to pass a 2-mm sieve and stored at 2°C before further treatment. Tannins were obtained by following the method described Preston (1999). Ground needles were extracted with hexane with a Soxhlet device to remove lipids. Residual needles were subsequently extracted by a mixture of acetone/water (7:3, v/v) for 24 hr. After centrifugation, the dark green solution was stored at 2°C, and the extraction/centrifugation sequence was repeated twice with the solid residue. All three solutions were combined, and the acetone was removed under vacuum. The resulting aqueous solution was subsequently extracted by dichloromethane 3–5 times to remove remaining lipids until the organic phase was colorless, followed by extraction with ethyl acetate to obtain an orange to brown solution. After freeze-drying, the crude tannins obtained were loaded on a Sephadex LH-20 column and eluted by methanol/water (1:1, v/v) to remove low molecular weight phenolics and tannin monomers. After switching the eluate to acetone/water (7:3, v/v), tannins were obtained from the Sephadex LH-20 column. The collected and combined water/acetone solution was rotary evaporated to give an aqueous solution that was freeze-dried to yield purified CTs. Tannins were characterized by solution ^{13}C NMR, having a procyanidin/prodelphinidin ratio of content of 37:63, an average chain length of 6.6%, and 85% *cis* configuration (Nierop et al., 2005).

Hydrolyzable tannins. Tannic acid (TA), a commercially available tannin, is often used as hydrolyzable tannin. Although TA is a rather reactive compared with other tannins and as such not a very representative HT (Kraus et al., 2003b), it is used by many researchers and serves as a useful tannin for comparison. TA of Merck was used, which has an average molecular weight of 1700 (=10 gallic acid units linked to the sugar core), and based on ^{13}C NMR, was pure (Kaal et al., 2005).

Incubation experiment. Five g (on absolute dry basis) of air-dried litter were weighed into Petri dishes, after which 5 ml water were added to give a moisture content of 100% (w/w). All filled Petri dishes were stored in an isothermal room (20°C) for 4 d to acclimate. Next, a series of control, TA-containing and CT-containing samples were prepared as follows.

To control samples, another 5 ml of water were added to obtain litter material with a moisture content of 200% (w/w). To the TA series, 5 ml of a solution of 20 g/l TA were added, which yielded litter material with the same moisture content as the control samples, and in addition 100 mg of TA per 5 g litter (on a dry weight basis). For the CT series, the same procedure as for the TA samples was followed, but using 5 ml of a solution of 20 g/l CT. Per time step ($t=1, 2, 4, 7, 14, 21, 28, 35, 42, 56, 70,$ and 84 d) during the incubation series, four replicates were used for each experiment (control, TA, and CT). Consequently, apart from the initial situation ($t=0$ d, only control samples), for each time step, 12 dishes were prepared as described, which accounted for 148 dishes in total. All preparations were incubated at a constant room temperature of 20°C.

Extraction and tannin assays. Total phenolics and CTs were determined with the Folin–Ciocalteu assay and the HCl–butanol assay, respectively (Waterman and Mole, 1994; Yu and Dahlgren, 2000), using 0.7 g of litter (DW basis), that was extracted by 40 ml of acetone/water (7:3, v/v) for 24 hr in the dark at 20°C. Total phenolics in the extracts obtained were determined with TA as the standard for all samples. Although it is preferable to use CT as a standard in case of the CT-amended series (Kraus et al., 2003b), control samples appeared to have certain levels of total phenolics as determined by Folin–

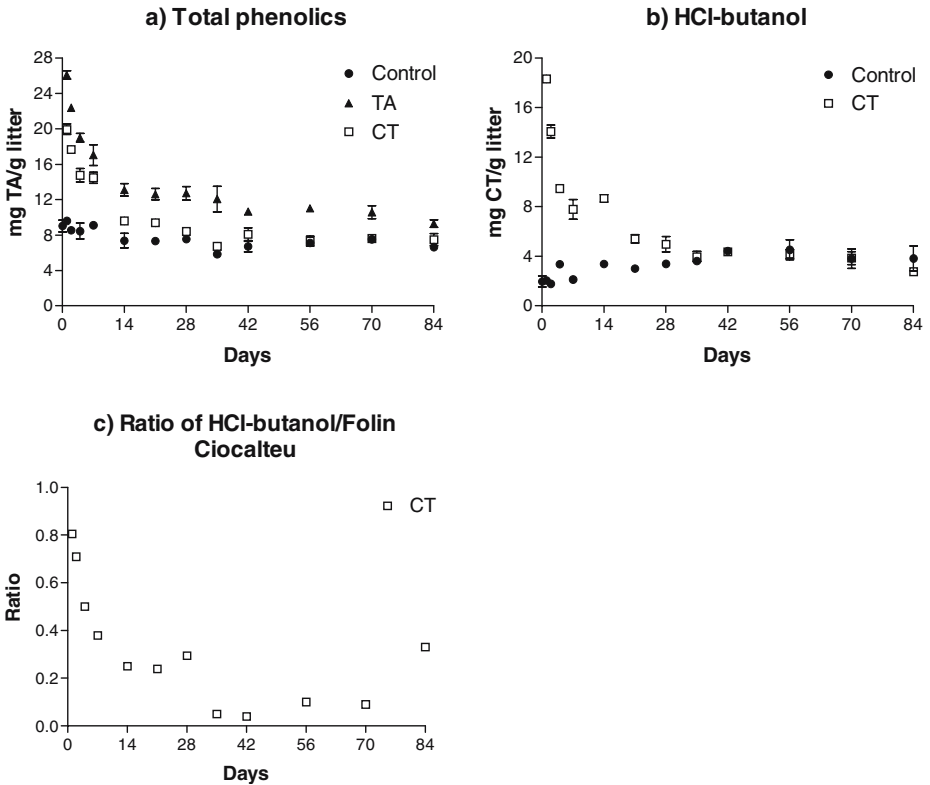

Fig. 1 (a) Total phenolic concentrations (Folin–Ciocalteu assay) in acetone/water (70:30, v/v) extracts from litter during the incubation experiment, (b) CT concentrations (HCl–butanol assay) in the same acetone/water extracts, and (c) the ratio of CTs measured by HCl–butanol assay divided by total phenolics measured by Folin–Ciocalteu assay in acetone/water extracts for the CT series (corrected for levels in control series). Errors bars indicate SEM ($n=4$)

Ciocalteu, whereas no response was found using HCl–butanol. Therefore, to allow comparison with control samples, TA was also used as the standard for the Folin–Ciocalteu assay for the CT-amended series. For the HCl–butanol assay, CT derived from Corsican pine was used as the standard.

Thermally assisted hydrolysis and methylation-gas chromatography/mass spectrometry. Litter samples were freeze-dried and milled. Prior to THM, they were pressed onto Curie-point wires, after which a droplet of a 25% solution of tetramethylammonium hydroxide (TMAH) in water was added. Samples were subsequently dried by a 100-W halogen lamp. THM was performed by heating the sample for 5 sec at 600°C. The Horizon Instruments Curie-Point pyrolyzer was connected to a ThermoQuest Trace GC 2000 gas chromatograph, and the products were separated by a fused silica column (J&W, 30 m, 0.32 mm i.d.) coated with DB-1 (film thickness 0.50 μm). Helium was used as carrier gas. The oven was initially kept at 40°C for 1 min; then it was heated at a rate of 7°C/min to 320°C, and maintained at that temperature for 10 min. The column was coupled to a Finnigan Trace MS quadrupole mass spectrometer (Electron Ionization; ionization energy 70 eV, mass range m/z 45–600,

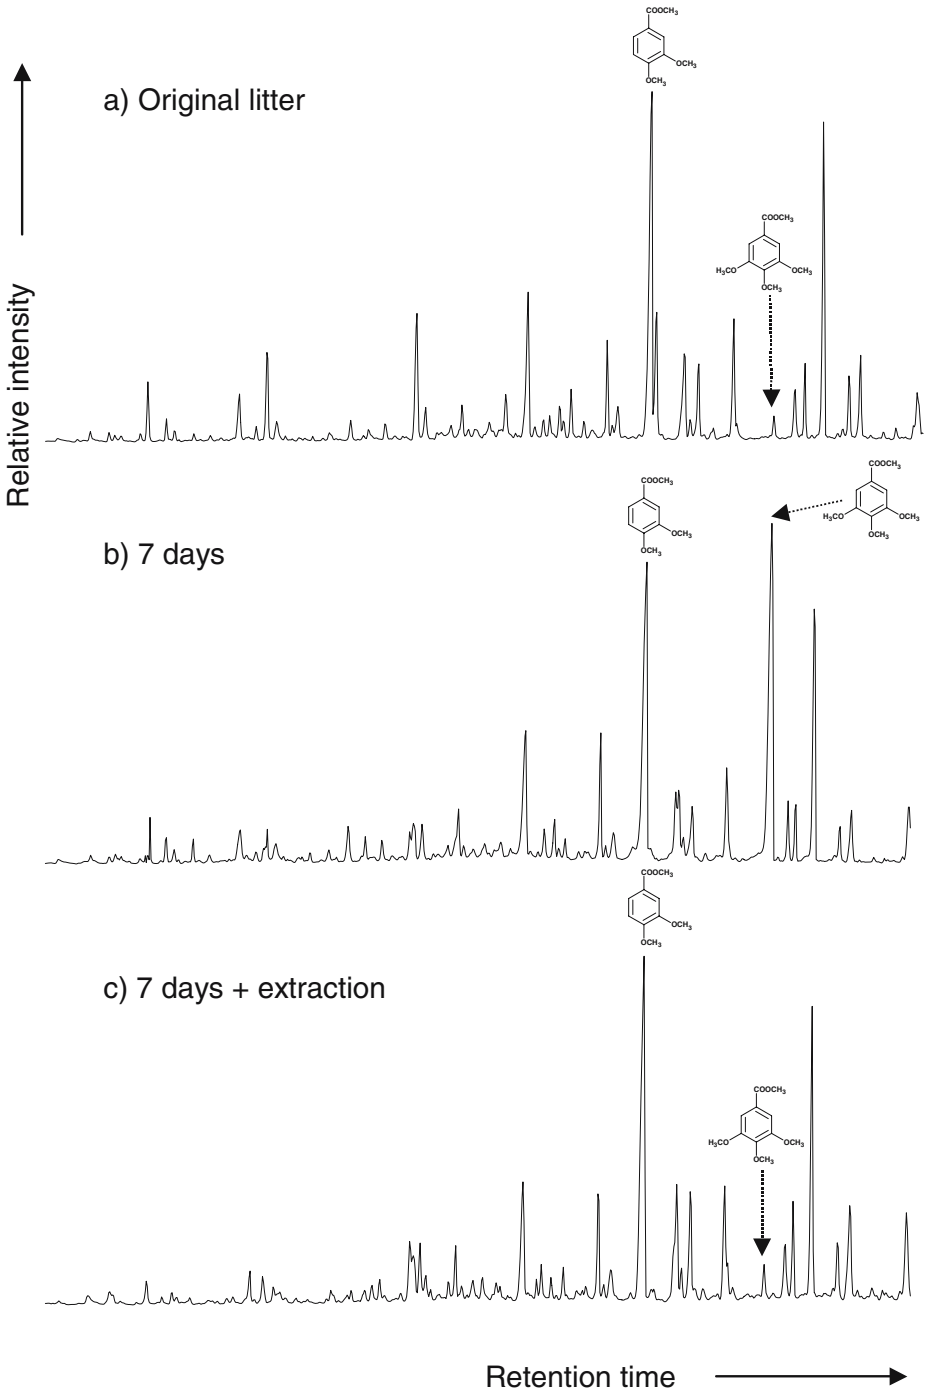

Fig. 2 Gas chromatograms of products from thermally assisted hydrolysis and methylation (THM) for (a) original litter, (b) TA-amended litter after 7 d incubation, (c) TA-amended litter after 7 d incubation and followed by acetone/water extraction. Methylated gallic acid and methylated vanillic acid are marked to emphasize the relative differences

cycle time 1 sec). Identification of the compounds was carried out by interpretation of their EI spectra with a NIST library, by their GC retention times, and by comparison with literature data.

Results

Total phenolics and condensed tannins. Total phenolics expressed as TA equivalents for the control litter decreased from 9.0 mg TA/g litter initially to 6.6 mg TA/g litter after 84 d incubation (Fig. 1a). For TA, the first day after addition, TA contents represented 26.1 mg TA/g litter and declined rapidly to 9.3 mg TA/g litter finally, while CT after 1 d started with 20.0 mg TA equivalents/g litter and ended at 7.5 mg TA equivalents/g litter. Using the HCl–butanol assay to measure CTs specifically, the control litter contained small amounts of CTs (2–4 mg CT/g litter), and the CT-amended litter exhibited a decline similar to that obtained by Folin–Ciocalteu (Fig. 1b). Only a few TA-amended samples were analyzed with the HCl–butanol assay, and yielded the same amounts of CTs as the control samples. For clarity, they were not included in the graph. The amount of CTs, as measured by the HCl–butanol assay, divided by the amount of total phenolics, as measured for the CT series (and corrected for the total phenolics present in control litter), decreased with time (Fig. 1c)

Thermally assisted hydrolysis and methylation To elucidate whether decreasing amounts of TA and CT, as determined by the Folin–Ciocalteu and HCl–butanol assays, were due to decomposition or whether they remained in the litter as inextricable compounds, THM was applied to litter samples to assess the appearance of TA and CT added through the subsequent incubation period followed by acetone/water extractions.

TA produces only methylated gallic acid (3,4,5-trimethoxybenzoic acid, methyl ester, or methyl trimethoxy benzoate) upon THM (Nierop et al., 2005). The initial litter revealed a small peak of 3,4,5-trimethoxybenzoic acid, methyl ester. Figure 2 shows the THM chromatogram of the TA-amended samples. After acetone/water extraction, the methylated gallic acid peak reduced to a height similar to control litter. For comparison, the peak representing (methylated) vanillic acid was marked as well. To show the resemblance between TA as measured by Folin–Ciocalteu and the relative amounts of TA detected by THM, Fig. 3 displays the decline as observed by both methods.

Fig. 3 (a) Total phenolics for TA-amended litter after 1, 7, and 28 d incubation, and (b) the methylated gallic acid/methylated vanillic acid ratio to indicate the relative abundance of TA in the same samples. Both total phenolics ($n=4$) and methylated gallic acid/methylated vanillic acid ratios ($n=3$) are corrected for untreated litter; errors bars indicate SEM

Fig. 4 Ratio of relative abundance of A ring products of CTs (1,3,5-trimethoxybenzene + 2-methyl-1,3,5-trimethoxybenzene) to G14 [*threo* 1-(3,4-dimethoxyphenyl)-1,2,3-trimethoxy propane] derived from lignin as a measure of CT concentrations for both extracted and nonextracted CT-amended litter. Errors bars indicate SEM ($n=3$)

With THM, CTs decompose into many products, of which the 1,3,5-trimethoxybenzenes are the most abundant. They are derived from the A rings, and are the only ones typical of CTs (Nierop et al., 2005). Applying THM to the initial litter yielded very small peaks of 1,3,5-trimethoxybenzene and 2-methyl-1,3,5-trimethoxybenzene. The most abundant peaks in the chromatograms were from methylated vanillic acid, most of which is derived from lignin rather than B ring products of CTs. To enable (semi-)quantification, the peak areas of 1,3,5-trimethoxybenzene and 2-methyl-1,3,5-trimethoxybenzene were integrated and related to that of G14 (*threo* 1-(3,4-dimethoxyphenyl)-1,2,3-trimethoxy propane), which is an aromatic product typical of lignin (Clifford et al., 1995) but not of tannins (Nierop et al., 2005). Figure 4 shows that without extraction the amounts of CTs remained at a constant level. As the peaks were very small and did not really increase upon CT addition, we also incubated samples with 5 times as much CTs (100 mg/g), and this was incubated for 28 d. Peaks of A ring products clearly increased, and after 28 d, peaks with and without extraction remained relatively high (Fig. 5).

Discussion

For TA, the behavior can be explained rather easily. TAs are degraded and used as a carbon source (Kraus et al., 2004; Nierop et al., 2006). The decline in TA concentrations on Folin–Ciocalteu shows this, and since TAs were not present in the litter after acetone/water extractions as determined by THM, the Folin–Ciocalteu assay reflects the actual concentration of TA in litter samples. Based on these data, TA does not seem to exist in strong complexes with proteins or other organic matter components. In addition, THM is a sensitive method to detect and quantify the TA (HT) in environmental samples. However, this approach works only well when CT concentrations are low, as THM produces methyl esters of 3,4,5-trimethoxybenzenes from prodelphinidin B rings (Nierop et al., 2005). Moreover, HTs occur only in dicots that also contain syringyl-lignin, which in turn yields a.o. methylated syringic acid upon THM (Clifford et al., 1995). Because methylation of syringic acid gives the same product as when gallic acid is methylated, there are limitations to the use of THM in identifying HTs unambiguously (Filley et al., 2006).

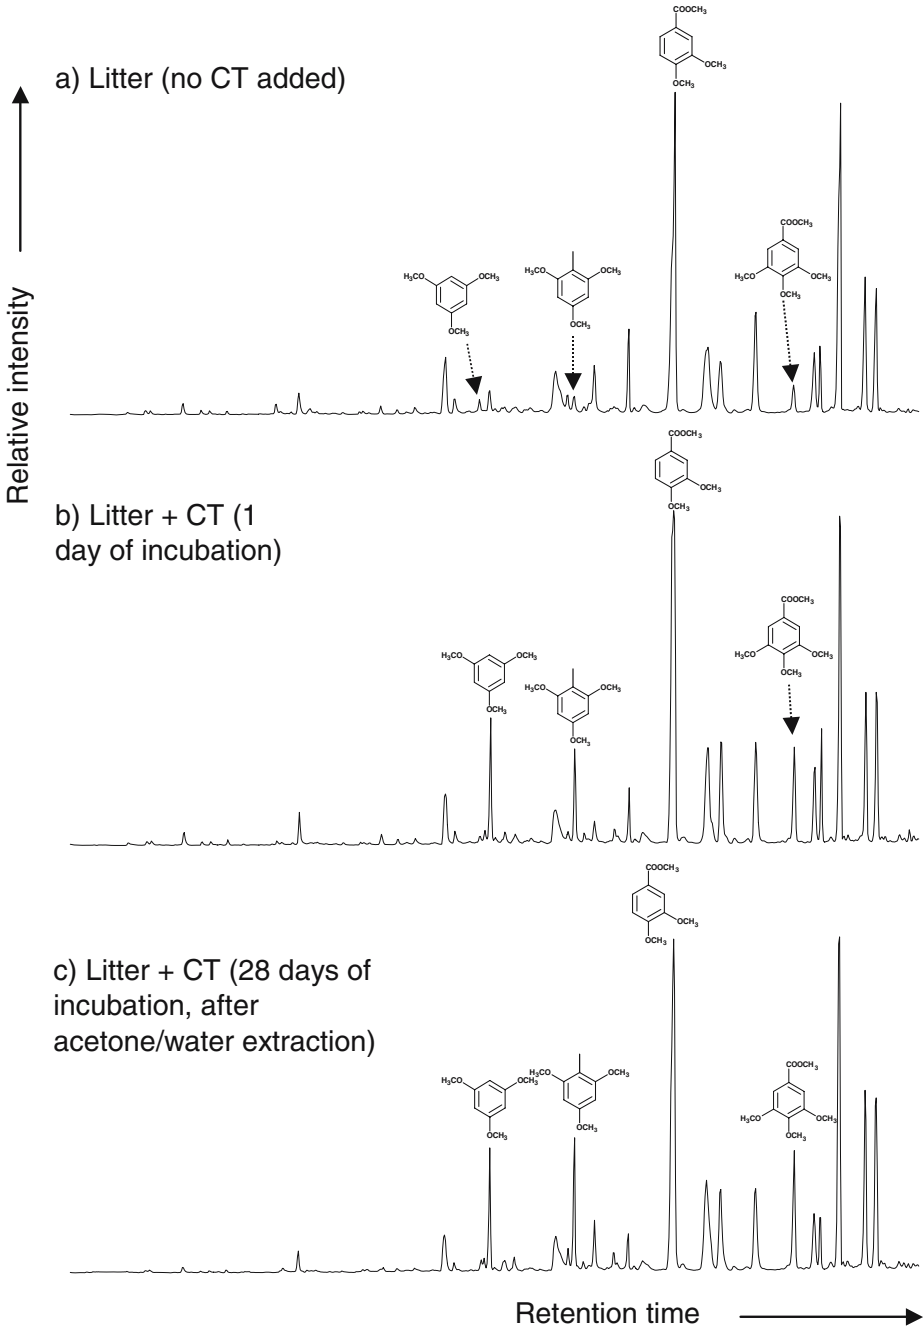

Fig. 5 Gas chromatograms of products from thermally assisted hydrolysis and methylation (THM) for (a) original litter, (b) CT-amended litter after 1 d incubation, and (c) CT-amended litter after 28 d incubation followed by acetone/water extraction

By contrast, CTs are more difficult to extract from litter samples. With increasing incubation time, extractable amounts of CTs decrease, and the ratio of extractable CTs (using HCl–butanol)-to-extractable phenolics (using Folin–Ciocalteu) declines as well (Fig. 1c). The latter suggests that the fraction of total extractable phenolics recognized as CTs becomes smaller in the course of the incubation. As HCl–butanol oxidatively cleaves the interflavanoid bonds (Porter et al., 1986; Waterman and Mole, 1994), longer CTs produce more colored products than shorter ones, because they contain more such linkages (Kraus et al., 2003b). The possible decrease in the average chain length of extractable CTs may be attributable to either increasing inextricability of longer chain CTs, or degradation in the form of depolymerization of CTs resulting into smaller and “simpler” phenolics. A similar behavior was found for sorption of CTs to quartz particles coated with iron oxides (Kaal et al., 2005). THM of CTs produces many compounds that are also identified upon THM of lignin (e.g., Clifford et al., 1995). B rings bearing two hydroxyl groups yield the same THM products as found for guaiacyl lignin; similarly, B rings containing three hydroxyl groups give products encountered for syringyl lignin. However, A ring products, i.e., 1,3,5-trimethoxybenzenes, are not identified after THM of lignin, and these products serve as excellent markers for CTs in any kind of litter.

The fate of CTs in soils has long been an unsolved problem (Lorenz and Preston, 2002). The low degree of extractability or yield may be attributable to CT decomposition, leaching through the soil profile, sorption to mineral phases, or the formation of strong tannin–protein/organic matter complexes (Hättenschwiler and Vitousek, 2000). In addition, chemical transformations such as oxidation and (de)polymerization may impose difficulties in identifying and quantifying tannins (Tiarks et al., 1989). There appears to be no single mechanism that applies to any soil system. From the incubation experiment using Corsican pine litter, the extent of CT decomposition is small (Nierop et al., 2006), and leaching and interactions with mineral soil particles are absent, so that the main reason for the inextricability (Fig. 4) must be the formation of (strong) tannin–organic N complexes (Benner et al., 1990; Hernes et al., 2001; Maie et al., 2003). This is supported by prolonged effects of CTs seen for net N mineralization in particular (Nierop et al., 2006), and the chemical modifications observed for CTs in decaying mangrove leaves (Hernes et al., 2001).

Introduction

Generalist phytophagous insects feed on a wide variety of plant species. However, their host choice is of ecological importance, and the host species on which females oviposit affects the development and fitness of offspring (Jaenike, 1978; Singer, 1983; Courtney et al., 1989). In many herbivorous species, young instars are more vulnerable to natural enemies and are less efficient at escaping natural enemies than imagoes (Nomikou et al., 2003). It would be advantageous for adult herbivores to discriminate among risky and safe host plant species, and thus to select high-quality host plants whatever the risk is when the threat of natural enemies is low (Freitas and Oliveira, 1996). Moreover, natural enemies may exert selection pressure on the host plants used by phytophagous insects (Ohsaki and Sato, 1999; Stireman and Singer, 2003; Singer and Stireman, 2003). For example, a plant that contains defensive allelochemicals or precursors can be chosen by a phytophagous insect for the protection it provides against natural enemies (Stamp, 2001; Shiojiri et al., 2002). Plants can also change phytophagous aspects so that the attractiveness of their by-products (e.g., frass) to the parasitoids is modified (Mondor and Roland, 1997).

Grape berry moths, *Lobesia botrana* (Lepidoptera: Tortricidae) and *Eupoecilia ambiguella* (Lepidoptera: Tortricidae), are among the most serious insect pests in European viticulture. Both are polyphagous and may occur sympatrically in vineyards, but their relative frequency depends on climatic factors (Thiéry, 2005). The larval host plant, including the grape cultivar, modifies several patterns involved in the reproductive output of *L. botrana*, for example, the development time of the larvae (Savopoulou-Soultani et al., 1994; Thiéry and Moreau, 2005; Moreau et al., 2006a) and larval metabolism. As a result, infochemicals produced by larvae may be modified as in other species (Lill and Marquis, 2001; Thorpe and Day, 2002). The host plant ingested by *L. botrana* larvae during its development may also modify parasitism of eggs by the generalist egg parasitoid *Trichogramma cacoeciae* (Thiéry, Pizzol, and Wajnberg, unpublished data).

Female *L. botrana* exhibit preferences among the different grape cultivars (Maher et al., 2001), and larvae feed on the plant on which the eggs are laid, most of the larvae developing close to the oviposition site. Therefore, the chemical cues related to frass are always located close to the larvae themselves, and thus provide pertinent local information for a larval parasitoid. Frass is often a relevant cue for natural enemies during the host location process (Auger et al., 1990; Reddy et al., 2002; Steidle and Van Loon, 2003), and it can be expected to be relevant also to our model/system.

Several studies have shown that parasitoids and predators can be efficient biological control agents against the different grape berry moths. As much as 50–60% of the moth larvae can be naturally controlled (Luciano et al., 1988; Coscolla, 1997; Thiéry et al., 2001; Bagnoli and Lucchi, 2005; Thiéry et al., 2006). The main parasitoids reported in most European vineyards belong either to Hymenoptera (Trichogrammatidae, Ichneumonidae, Braconidae or Pteromalidae) or to Diptera (Tachinidae; Thiéry et al., 2001, 2006). The pteromalid wasp *Dibrachys cavus* is a generalist, gregarious ectoparasitoid of more than 200 species belonging to different families (Peck, 1963, Universal Chalcidoidea Database, 2003). It has been found on overwintering pupae of *L. botrana* in France (Causse et al., 1984), Italy (Marchesini and Della Monta, 1994), and Spain (Coscolla, 1997). This parasitoid is a multivoltine species that can attack each generation of *L. botrana* (Faure and Zolstarewsky, 1925). *D. cavus* parasitizes fifth instars of *L. botrana* just before pupation and not pupae (Faure and Zolstarewsky, 1925; Chuche, Xuéreb and Thiéry, unpublished observations).

The goal of our study is to determine which components of the host odor attract *D. cavus* from a distance. Thus, we tested the specificity of such an attraction and whether it varied

according to the larval food plant. First, we tested the response of *D. cavus* females to host larvae without frass, to silk, and to frass alone, and whether it discriminated among different host species on the basis of their odor. Second, we tested the influence of host larval food and frass for attractiveness.

Methods and Materials

Insects

Our *D. cavus* strain originates from grapes harvested in an experimental vineyard (INRA Bordeaux, La Ferrade). Insects were reared in the laboratory for successive generations on *L. botrana* larvae under a 16:8 (light–dark) photoperiod, at $23 \pm 1^\circ\text{C}$, and 45–50% relative humidity. Under these conditions, adults *D. cavus* emerged ca. 20 days after oviposition on the larval cuticle. Emerging adults were collected daily, except during the weekends, transferred into new boxes containing fifth instars *L. botrana*, and supplied with a 20% honey–water solution. We used a strain of *L. botrana* reared without diapause under the conditions described above on a semisynthetic diet (control medium) as described in Thiéry and Moreau (2005), and a strain of *E. ambiguella* reared in our laboratory (same conditions as for *L. botrana* except 60–70% relative humidity). All experiments were performed in a climate chamber under controlled conditions as described above. *D. cavus* were all 48-hr-old, mated, fed females with no previous oviposition experience. They were tested only once. The frass of four phytophagous insect species was tested: three Lepidoptera—*L. botrana*, *E. ambiguella*, and *Sphinx ligustri* (Sphingidae)—and an Orthoptera selected as a control: *Chorthippus brunneus* (Acrididae). The Sphingidae and the Orthoptera used have never been described as *D. cavus* hosts.

Plants, Insect Diets, Frass Collection, and General Procedure

Grape cultivars supplied as larval food were compared using a standardized procedure adapted from that described by Thiéry and Moreau (2005) and Moreau et al. (2006a). *L. botrana* larvae were reared in enclosed plastic cups (diam: 3 cm on base and 4 cm on top; height: 3 cm) with five larvae per cup, filled with 15 ml of artificial diet. This medium was identical to the two references quoted above. Plant material was freeze dried, and a fine powder was made using a blender as described in Moreau et al. (2006a). A limited range of host plants was tested, two grape cultivars: *Vitis vinifera* (Vitaceae) cv. Pinot noir and Riesling, the presumed ancestral host of *L. botrana*: *Daphne gnidium* (Thymelaeaceae; Maher and Thiéry, 2006), another possible host plant of *L. botrana*: *Rosemary officinalis* (Lamiaceae; Katerinopoulos et al., 2005), and tansy: *Tanacetum vulgare* (Asteraceae) used as a possible repellent source for *D. cavus*. We used bunches of *V. vinifera* harvested in mid-July, *T. vulgare* flowers (β -thujone chemotype, cf. Gabel and Thiéry, 1994), leaves of *R. officinalis*, and flowers, and berry of *D. gnidium*. Plants were all collected on the INRA Bordeaux site.

Box lids were pierced to allow air circulation. Using a fine brush, five newly hatched larvae (age < 24 hr) were transferred into each box: 15 boxes for *R. officinalis* and *D. gnidium* diet, 30 for Pinot noir and *T. vulgare*, 45 for Riesling, and control.

The two grape moths were fed on the control medium and their frass was collected. *Sphinx* frass was harvested from a natural population of larvae collected from *Catalpa*

bignonioides (Bignoniaceae) leaves. Larvae of *C. brunneus*, a specialist of Poacea, were harvested from a natural population in the Limoges area, and their frass were collected.

Bioassays

Experiments were conducted by using a T-tube olfactometer made of transparent glass (0.4 cm ID; stem 10 cm, arms 5 cm). Each arm was connected to a small plastic chamber holding the odor source (Fig. 1). To avoid contact with the odor source and to hide the source, small pieces of black glass fiber tissue were placed at the ends of each arm of the olfactometer. Filtered air (0.3 l min^{-1}) was sucked through the olfactometer by a pump connected to a flowmeter. Females were individually introduced into the olfactometer and observed for at least 2 min. Females that did not express a choice after 2 min were discarded. A female that settled at least 10 sec near one of the container was scored.

To avoid a bias due to possible chemical marking of the walking tracks, the glass tube and the glass fiber tissue were changed after each test. The position of the T-tube was turned 180° after each test to avoid effects of any directional bias. The T tubes were washed in hot water (ca. 70°C), rinsed in purified high-performance liquid chromatography (HPLC) quality water, and dried in an oven at 60°C before each experiment. All tests were performed between 09:00 and 18:00. All experiments were conducted under artificial light at $24 \pm 1^\circ\text{C}$. A white circular paperboard arena (diam: 35 cm; height: 21 cm) surrounded the olfactometer to prevent visual perturbations and to create a homogeneous light. *D. cavus* females were offered different dual choices.

Fig. 1 T-tube olfactometer and set-up used in this study. Details are provided in the text

Responses to Larvae, Silk, and Frass

Attractiveness of fifth instar *L. botrana* or of their by-products (silk and frass) was tested. In this experiment, parasitoids were given the choice between one larva or 0.07 mg of silk, which corresponds to the average mass of a *L. botrana* cocoon, or 0.02 g of frass (i.e., the average production of two to three larvae in 24 hr or the larval production in 2–3 d) and a blank (no odor). Twelve cocoons of larvae reared on control medium were weighed to calculate the average amount of silk produced per larva. The average amount of frass produced per *L. botrana* larva was calculated from 19 fourth instars (L4) reared on control medium and by collecting their frass produced during 24 hr. The average amount collected in this condition was 9.96 ± 4.78 mg. Because of the small number of *E. ambiguella* and *S. ligustri* larvae, their attractiveness could not be tested.

Preferences for *L. botrana* Larvae Reared on Different Foods

The attractiveness of larvae fed on different plants (Pinot noir, Riesling, or *T. vulgare*) was compared with larvae fed on control medium.

Preferences for Frass Produced by Different Species

Frass produced by the three Lepidoptera species was compared at the identical mass mentioned above. To test the influence of the rearing host on the olfactory response of parasitoid females, some *D. cavus* were reared on *E. ambiguella*, as described for *L. botrana*. These parasitoids had the choice between frass produced by the two tortricids.

Preferences for *L. botrana* Frass from Different Larval Foods

Frass collected from larvae fed with different plants (Pinot noir, Riesling, *T. vulgare*, *D. gnidium*, or *R. officinalis*) was compared with those of larvae fed on control medium or on another plant supplemented medium.

Responses to Solvent Extracts

To isolate attractive cues, *L. botrana* frass was extracted by using solvents with different polarities. Three ml of solvent were added to 172.5 mg of dry frass (the production of ca. 300 L4). After 15 min at room temperature, frass was removed. Five different solvents were used: acetone, dichloromethane, hexane, methanol (99–99.80% purity, SDS, Peypin, France), or purified HPLC quality water. Each solvent was tested in the olfactometer, and none was found repellent or attractive. *D. cavus* females were given the choice between an extract and its respective solvent. Extracts and solvents were presented on a piece of Whatman paper (1 cm²). Different volumes were tested: 10, 30, and 60 µl, corresponding to 1, 3, and 6 larval equivalents, respectively.

Statistical Analysis

Statistical tests were performed using [Statistica Software \(Version 6.0, Stat Soft, Inc.\)](#). Attraction scores were analyzed using the Cochran *Q* test.

Results

Responses to Larval Silk and Frass

Female parasitoids were not attracted to larvae ($N=100$; $Q=0.1$; $P>0.05$) nor to silk ($N=99$; $Q=2.13$; $P>0.05$; Fig. 2). However, *D. cavus* females were attracted to the frass of the three Lepidoptera tested: *L. botrana* ($N=100$; $Q=20.60$; $P<0.001$), *E. ambiguella* ($N=100$; $Q=5.07$; $P=0.02$), and *S. ligustri* ($N=100$; $Q=4.06$; $P=0.04$). The frass produced by the grasshopper, *C. brunneus*, was not attractive ($N=100$; $Q=0.41$; $P>0.05$; Fig. 2).

Preferences for *L. botrana* Larvae Reared on Different Foods

There was no significant difference in the choice of *D. cavus* for larvae fed on control medium or on media supplemented with Pinot, Riesling, or tansy ($N=50$; respectively, $Q=0.53$; $Q=0$ and $Q=0$).

Preferences for Frass Produced by Different Species

The parasitoid was more attracted to the odor of from *S. ligustri* than from *L. botrana* ($N=100$; $Q=25.82$; $P<0.001$), or *E. ambiguella* ($N=100$; $Q=9.04$; $P=0.003$; Fig. 3). *D. cavus* was also more attracted to the frass from *L. botrana* than from *E. ambiguella* ($N=100$; $Q=4.74$; $P=0.03$). This preference was independent of the species on which *D. cavus* had been reared; *D. cavus* females reared from *E. ambiguella* also preferred *L. botrana* frass ($N=100$; $Q=7.04$; $P=0.008$).

Preferences for *L. botrana* Frass from Different Larval Foods

There was no significant difference in choice of *D. cavus* for frass from *L. botrana* fed on control medium or fed on supplemented medium ($N=50$; Pinot, $Q=0.35$; Riesling, $Q=3.13$; tansy, $Q=0.82$ and rosemary, $Q=1.39$). There was also no significant difference in choice of *D. cavus* for frass from *L. botrana* fed on different supplemented medium: Riesling vs. Pinot ($Q=1.26$), Pinot vs. tansy ($Q=0.20$), Riesling vs. tansy ($Q=3.27$), Riesling vs. daphne ($Q=1.09$), and Riesling vs. rosemary ($Q=0.09$). For all, $N=50$.

Fig. 2 Responses of *D. cavus* females to larvae, silk of *L. botrana*, or frass of different insect species. Lb: *Lobesia botrana*; Ea: *Eupoecilia ambiguella*; Sl: *Sphinx ligustri*; Cb: *Chorthippus brunneus*. White bars = no odor. * $P<0.05$ and ** $P<0.01$

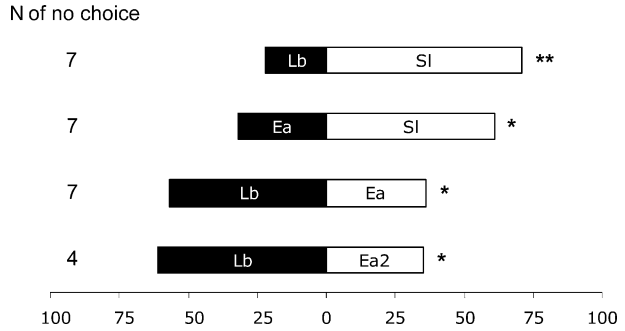

Fig. 3 Choice of *D. cavus* females between the odor of frass produced by caterpillars from different species. Lb: *Lobesia botrana*; SI: *Sphinx ligustri*; Ea: *Eupoecilia ambiguella*. Ea2: choice of females reared on *E. ambiguella*. All results: $N=100$. $*P<0.05$ and $**P<0.01$

Responses to the Solvent Extracts

D. cavus females responded in a dose-related way to extracts. None of the solvent extracts were attractive at the dose of 1 larval equivalent (Fig. 4). However, significant attraction was observed with water, dichloromethane, and methanol extracts applied at 3 larval equivalents ($N=50$; respectively $Q=12.8$; $P<0.001$; $Q=8$; $P=0.005$; $Q=4$; $P=0.045$). At the higher dose of 6 larval equivalents, only dichloromethane and water extracts elicited attractive responses as compared with solvent alone ($N=50$; respectively $Q=8.07$; $P=0.004$ and $Q=6.25$; $P=0.012$). Acetone and hexane extracts were not found to be attractive. Methanol elicited a similar percentage of females attracted, but because of a higher proportion of nonchoosing females, this result was not significant ($Q=3.2$; NS).

Fig. 4 Choice of *D. cavus* females between extracts of frass of *L. botrana* larvae and the correspondent solvent. All results: $N=50$. $*P<0.05$; *a), concerns the two treatments dichloromethane and water (see Results for details)

Thus, 3 larvae equivalents represented the optimally attractive dose, which corresponds to the amount of frass tested in the other experiments.

Discussion

The experiments demonstrate that *D. cavus* was attracted to frass produced by three species of Lepidoptera, but not by larvae alone. Moreover, *D. cavus* was not attracted to the silk produced by *L. botrana* larvae. Results revealed that larval food did not modify frass attractiveness, but that the moth species did.

Frass is a digestion residue containing nonabsorbed solids, water, scraps, diverse secretions, and microorganisms. Defecation is an essential physiologic process that also plays an important role in the ecology of host–parasitoid interactions (Weiss, 2003, 2006). Defecation behavior can partly be the result of natural selection, including predator/prey interactions, toxins or pathogens exposure, feeding, and social signalization (Weiss, 2003, 2006). For animals living near their feeding site, like *L. botrana*, presence and accumulation of frass can be disadvantageous because this can make prey more obvious to natural enemies. Hence, egestion products like frass can be perceived as an indicator of host presence (Bouchard and Cloutier, 1985; Reddy et al., 2002; Rogers and Potter, 2002).

D. cavus females were not attracted at distance to the different larvae tested or to their silk, but their frass represented an orientation cue. This could be extracted by different solvents, and *D. cavus* responded to these extracts in a dose-dependent way. Thus, frass bears chemical information able to attract this parasitoid. The volatiles extracted by water, dichloromethane, and methanol were attractive; thus, one may expect that a complex volatile signal made from intermediate to polar volatiles is needed to mimic the complete frass odor. Analytical comparisons of the different extracts were not performed in this work. However, such comparisons would be needed to confirm this point.

Although *D. cavus* is a generalist species, it was attracted in varying degree to the frass of the three Lepidoptera tested, and not at all to that of *C. brunneus*, which has not been described as a host. Generalist insects do exhibit preferences among their different hosts (Vinson, 1976; Janz, 2003; Maher and Thiéry, 2006). There is increasing evidence that natal or prenatal experience influences the preferences of the adult insect (Corbet, 1985; Vet et al., 1990; Rojas and Wyatt, 1999; Davis and Stamps, 2004). There are several examples of parasitoids responding to chemicals encountered during their larval or preimaginal instars (Corbet, 1985; Vet et al., 1990; Vet and Groenewold, 1990). The parasitoid *Nemeritis canescens* (Hymenoptera: Ichneumonoidea) reared on the nonhost insect *Meliphora grisella* (Lepidoptera: Pyralidae) develops an olfactory attraction for its rearing host (Alloway, 1972). In *D. cavus*, females reared on *L. botrana* were more attracted to *L. botrana* frass, but those reared on *E. ambiguella* were not specifically attracted to their developmental host frass. Therefore, we conclude that preimaginal conditioning to the rearing species did not occur in *D. cavus*.

Host alimentation can strongly influence parasitoid choices (Sauls et al., 1979; Benrey et al., 1997). Gandolfi et al. (2003) showed that rearing *Hyssopus pallidus* (Hymenoptera: Eulophidae) on *Cydia pomonella* (Lepidoptera: Tortricidae), fed on a medium supplemented with apple, enhances the attractiveness of the parasitoid to caterpillar frass. *D. cavus* has been found on numerous phytophagous species that feed on a wide range of host plants. However, none of the plants used in our experiment modified the attractiveness of the frass. Therefore, the plant on which the host feeds may be of minor importance to this parasitoid.

The experiments demonstrate that there is likely a general signal that makes Lepidoptera frass attractive to *D. cavus*. Actually, *D. cavus* is an extreme generalist, and generalists often use nonspecific chemical cues for host location rather than specific ones (Vet and Dicke, 1992; Thiéry and Gabel, 1993; Godfray, 1994; Steidle and van Loon, 2003). The olfactory signal used by this species may include general molecules indicating the occurrence of a wide range of possible hosts (e.g., Lepidoptera) and additional ones giving more specific information to discern among hosts.

This work is a first step toward understanding the relationships between *D. cavus* and two grape moths. We only focused on the responses of the wasp to odors, not considering the complete set of cues used by the wasp in its host recognition and acceptance. Indeed, the larval host plant influences the growth and survival of larvae of several generalist herbivores (Lazarević et al., 1998; Tikkanen et al., 1999; Serrano and Lapointe, 2002). In *L. botrana*, previous work showed that larval food modifies the larval development time (Savopoulou-Soultani et al., 1994; Moreau et al., 2006a,b; Thiéry and Moreau, 2005) and also their size with consequences on adult fitness. *L. botrana* larvae fed on different host plants may offer different food quality for their parasitoids, but *D. cavus* seems not to discriminate between the volatile information corresponding to such larvae.

Acknowledgments We thank Pr. D. Petit (University of Limoges) for supplying Orthoptera frass and M. E. Toulouse for regular production of insects. The first author was supported by a grant from our laboratory. We thank L. Bordenave UREFV (INRA Bordeaux) for the free use of the grape cultivars used in this study, and Dr. G. Wegner-Kiss (Freiburg, Germany) who supplied adults of *E. ambiguella* used to initiate our laboratory strain. We thank two anonymous referees of the journal for their improvement suggestions.

Zea mays · Parasitoids · Volatile Organic Compounds (VOCs) · Herbivore-Induced Plant Volatiles (HIPVs) · Host location · Associative learning · Tritrophic interactions · Indole · Shikimic acid · Glyphosate · Induced defenses

Introduction

Plants that are attacked by herbivorous arthropods are known to release a complex blend of volatile organic compounds (VOCs). These herbivore-induced plant volatiles (HIPVs) are exploited by predators and parasitoids as foraging signals that help them locate their herbivorous prey or hosts (Turlings and Wäckers, 2004; Arimura et al., 2005). At present, more than 1000 low-molecular-weight organic compounds have been reported to be emitted from plants, including alkanes, alkenes, alcohols, ketones, aldehydes, ethers, esters, and carboxylic acids (Dudareva et al., 2004; Niinemets et al., 2004). Although some of these compounds are constitutively emitted by undamaged, healthy plants, considerably higher amounts are emitted after herbivore damage and various HIPVs may even be synthesized *de novo* in response to damage (Turlings et al., 1990, 1998; Paré and Tumlinson, 1997). Some HIPVs are specific to certain plant taxa, for example, sulfur containing compounds in *Allium* plants (Dugravot et al., 2004) or glucosinolate breakdown products in Brassicaceae species (Scascighini et al., 2005), but others are common to many species (Fritzsche Hoballah et al., 2002; van den Boom et al., 2004). Common compounds include “green-leaf volatiles” (C₆ aldehydes, alcohols, and derivatives), cyclic and acyclic terpenoids, phenolic compounds, and nitrogenous compounds (Dicke, 1999; Paré and Tumlinson, 1997). These derive from at least three pathways. Green leaf volatiles are products of the enzymatic activity of hydroperoxide lyase (HPL), a component of the lipoxygenase (LOX) pathway, which results in multiple rearrangement of (*Z*)-3-hexenal (Bate and Rothstein, 1998; Blee, 1998). Terpenoids are synthesized via the isopentenyl pyrophosphate (IPP) intermediate following the classical mevalonate pathway or via an alternative IPP pathway with glyceraldehyde-3-phosphate and pyruvate identified as the direct precursors of IPP (Lichtenthaler et al., 1997). Finally, aromatic compounds, such as methyl salicylate (MeSA) and indole, are formed via the shikimic acid pathway (Bennett and Wallsgrove, 1994; Paré and Tumlinson, 1997).

In maize plants, the mechanisms of biosynthesis, induction, and release of HIPVs are well characterized (Turlings et al., 1998; Frey et al., 2000; Shen et al., 2000; Schnee et al., 2002; Gouinguéné et al., 2003; Schmelz et al., 2003a,b,c; Köllner et al., 2004; Lawrence and Novak, 2004; Ruther and Kleier, 2005), and the ecological significance of these compounds in tritrophic signaling has been demonstrated in laboratory and field experiments (Turlings et al., 1990; Bernasconi et al., 1998; Hoballah and Turlings, 2001; Fritzsche Hoballah et al., 2002; Rasmann et al., 2005). In particular, the role of green leaf volatiles and terpenoids in attracting natural enemies of the herbivores has been investigated in various experiments (D’Alessandro and Turlings, 2005; Hoballah and Turlings, 2005). Yet, it remains unclear which compounds are essential for attraction (D’Alessandro and Turlings, 2006). One group of compounds that has hardly been studied in the context of parasitoid attraction are the shikimic acid derived VOCs.

The main shikimic acid derived VOC released by maize seedlings after infestation with larvae of *Spodoptera* moths is indole (Turlings et al., 1998; D’Alessandro and Turlings, 2005). This compound is induced after treatment of maize seedlings with volicitin [*N*-(17-hydroxylinolenoyl)-L-glutamine], a fatty acid-amino acid conjugate found in the regurgitate of *Spodoptera* larvae (Alborn et al., 1997; Turlings et al., 2000). Indeed, jasmonic acid, which is involved in the induction of HIPVs in maize (Schmelz et al., 2003a), also appears

to be an integral part of volicitin-mediated induction of indole (Frey et al., 2000). Frey et al. (2004) identified an enzyme in maize, indole-3-glycerol phosphate lyase (Igl), which converts indole-3-glycerol phosphate to free indole. This differs from the enzyme BX1, which catalyzes the conversion of indole-3-glycerol phosphate to indole to form the direct defense compounds 2,4-dihydroxy-2*H*-1,4-benzoxazin-3(4*H*)-one (DIBOA) and 2,4-dihydroxy-7-methoxy-2*H*-1,4-benzoxazin-3(4*H*)-one (DIMBOA), or tryptophane synthase, which produces the amino acid tryptophane (Frey et al., 1997). The selective activation of the evolutionarily similar genes *igl* and *bx1* suggests that the plants are capable of selecting direct or indirect defense mechanisms depending on the type of stress they are exposed to. Therefore, volatile indole was expected to be a key compound in the attraction of natural enemies of the herbivores.

Here we studied the importance of shikimic acid derived HIPVs, in particular indole, in attracting females of two parasitoid species, *Cotesia marginiventris* (Cresson) (Hymenoptera: Braconidae) and *Microplitis rufiventris* (Kokujev) (Hymenoptera: Braconidae). Both attack early instars of numerous lepidopteran moths, including many pests, and are known to use plant-provided VOCs in host location (Gouinguéné et al., 2003; Hoballah and Turlings, 2005). We manipulated the volatile blend emitted by maize seedlings (*Zea mays* var. Delprim) that had been fed upon by larvae of *Spodoptera littoralis* (Boisduval) (Lepidoptera: Noctuidae) by incubating the plants in glyphosate [*N*-(phosphonomethyl)glycine]. This compound inhibits the enzyme 5-enolpyruvylshikimate-3-phosphate (EPSP) synthase (Haslam, 1993; Schönbrunn et al., 2001) and strongly reduces the amounts of shikimic acid derived VOCs. Attraction of the odor from these inhibited plants was compared to that of the natural blends emitted by control plants. Subsequently, we tested an inhibited blend against an inhibited blend to which we added back a natural amount of synthetic indole, the major shikimic acid derived HIPVs.

C. marginiventris females, like many other female parasitoids, are able to learn and associate plant VOCs with the presence of suitable hosts during oviposition experiences (Turlings et al., 1993; D'Alessandro and Turlings, 2005). We therefore compared the responses of naïve and experienced female parasitoids, and in a series of learning experiments with *C. marginiventris* females, we estimated how well the wasps can learn to associate indole with host presence.

Methods and Materials

Insects and Insect Treatments The caterpillar *S. littoralis* (Boisduval) (Lepidoptera: Noctuidae) and the solitary endoparasitoids, *C. marginiventris* (Cresson) (Hymenoptera: Braconidae) and *M. rufiventris* (Kokujev) (Hymenoptera: Braconidae) were reared as previously described (Turlings et al., 2004). Adult parasitoids were kept in plastic cages at a male/female ratio of approximately 1:2 and were provided with moist cotton wool and honey as food source. Cages were kept in incubators (*C. marginiventris*, 25±1°C; *M. rufiventris*, 23±1°C; 16:8 hr L/D) and transferred to the laboratory 30 min before the experiments. We tested mated 2- to 4-d-old naïve and experienced females. The latter were given experiences by allowing them to oviposit 3–5 times into second instar *S. littoralis*. A metal screen was attached to the top opening (2 cm diam) of an odor source vessel of the same type as used in the olfactometer (see below). Approximately 20 larvae were placed on the screen, and individual wasps were allowed to oviposit in one or two larvae, while they were exposed to the odor of the source that was placed inside the vessel. This source was either an infested control plant, an infested inhibited plant, or synthetic indole only. Airflow and concentrations of volatiles

were the same as during the olfactometer bioassays (see below). Naïve females were neither exposed to the volatiles nor given any oviposition experience before testing. The different groups of wasps were kept separately in small plastic boxes with moist cotton wool and honey and released into the olfactometer 1–3 hr after the oviposition experiences.

Plants and Odor Sources Maize (*Z. mays*, var. Delprim) was sown in plastic pots (10 cm high, 4 cm diam) with commercial potting soil (Ricoter Aussaaterde, Aarberg, Switzerland) and placed in a climate chamber ($23 \pm 2^\circ\text{C}$, 60% r.h., 16:8 hr L/D, and $50,000 \text{ lm/m}^2$). Plants used for the experiments were 10–12 d old and had 3 fully developed leaves. The evening before the experiments, plants were cut with a razor blade at soil level, while the stem was held under water to prevent air entering the vascular system. Subsequently, they were placed in a vial (8 ml) filled with either deionized water (control plant) or in a 1 mM glyphosate [*N*-(phosphonomethyl)-glycine; Fluka, Buchs, Switzerland] solution (inhibited plant). Vials were wrapped in aluminum foil, and one vial containing a single plant was placed in an open odor source vessel of the olfactometer (described by Turlings et al., 2004). Two hr after incubation, plants were infested with 20 second instar *Spodoptera*, which were released in the whorl of the youngest leaf. After infestation, plants were kept under laboratory conditions ($25 \pm 2^\circ\text{C}$, $40 \pm 10\%$ r.h., 16:8 hr L/D, and 8000 lm/m^2) and were used for the experiments the following day, between 10 A.M. and 4 P.M.

To check whether the treatment of the plants with the inhibitor affected the larval feeding behavior, plants were collected after the bioassays, and the leaves were scanned into Adobe Photoshop 6.0. The total leaf area removed during the 24-hr feeding period was compared for the different treatments based on differences in pixels that indicated tissue removal.

Indole (purity $\geq 99\%$; Fluka) was released from a device consisting of a 2-ml glass vial that contained 500 mg synthetic indole (Fig. 1), which was connected, via a glass capillary,

Fig. 1 Schematic representation of the odor delivery system for synthetic VOCs

to a Teflon tube placed between two glass tubes connecting the top of an odor source vessel to an olfactometer arm. Preliminary experiments with various synthetic volatile compounds (e.g., MeSA, linalool, indole) showed that at room temperature this device allowed the constant release of pure compounds, and that their release rates could be controlled by adjusting the length and the diameter of the capillary tube (Duran, Hirschmann EM). The release rate was calibrated to the lower range of amounts of indole that was found for infested maize plants. Vials were prepared freshly the evening before the experiments and connected the following morning to the odor source vessels used for training or testing.

Olfactometer Bioassays All odor sources were tested for attractiveness to parasitoids in a four-arm olfactometer (described by D'Alessandro and Turlings, 2005) as indicated in Table 1. Cleaned and humidified air entered the odor source vessel at 1.2 l/min (adjusted by a manifold with four flowmeters; Analytical Research System, Gainesville, FL, USA) via Teflon tubing and carried the VOCs through to the olfactometer compartment. Half of the air (0.6 l/min/olfactometer arm) was pulled out via a volatile collection trap that was attached to the system above the odor source vessels (see "Collection and analyses of VOCs"). Incoming and outgoing air were balanced by a Tygon tube connected to a vacuum pump via another flow meter and a pressure gauge. Empty arms were connected to empty vessels and carried clean, humidified air only.

Wasps were released in groups of six into the central part of the olfactometer, and after 30 min the wasps that had entered an arm of the olfactometer were counted and removed. Wasps that did not enter an arm after this time were removed from the central part of the olfactometer and considered as "no choice." Experiments were replicated on eight different days, and for each replicate a total of six groups of six wasps were tested during a 3-hr sampling period, alternating between groups of naive and experienced wasps in experiments where three different groups were tested (total of 96 wasps/group), or only naive wasps in the other experiments (total 288 wasps). Ten neon tubes attached to a metal frame above the olfactometer provided approximately 7000 lm/m² at the height of the odor source vessels. All bioassays were carried out between 10 A.M. and 4 P.M.

Collection and Analyses of VOCs VOCs of each odor source were collected during the olfactometer bioassay on a Super-Q trap (25 mg, 80–100 mesh; Alltech Associates, Deerfield, IL, USA, described by Heath and Manukian, 1992). Each trap was attached horizontally to the elbow of the olfactometer and connected via Tygon tubing to a flowmeter (Analytical Research System) and a vacuum pump. Air carrying the volatiles was pulled through each trap for 3 hr at a rate of 0.6 l/min during each behavioral bioassay. Afterwards, the traps were extracted with 150 μ l dichloromethane (Suprasolv; Merck, Dietikon, Switzerland), and 200 ng of *n*-octane and *n*-nonyl acetate (Sigma, Buchs, Switzerland) in 10 μ l dichloromethane were added to the samples as internal standards. All extracts were stored at -76°C until analyses. Traps were washed with 3 ml dichloromethane before they were reused for a next collection.

VOCs of the experiments with control and inhibited plants were analyzed with a gas chromatograph (Agilent 6890 Series GC system G1530A) coupled to a mass spectrometer that operated in electron impact mode (Agilent 5973 Network Mass Selective Detector; transfer line 230°C, source 230°C, ionization potential 70 eV, scan range 33–280 amu). A 2- μ l aliquot of each sample was injected in the pulsed splitless mode onto an apolar capillary column (HP-1, 30 m, 0.25 mm ID, 0.25 μ m film thickness; Alltech Associates). Helium at constant flow (0.9 ml/min) was used as carrier gas. After injection, the column temperature was maintained at 40°C for 3 min and then increased to 100°C at 8°C/min and

Table 1 Odor sources and experimental design

Further details on odor sources, number, and treatment of wasps are described in the text and in the figures. Treatments of the plants are given in parentheses.

subsequently to 200°C at 5°C/min followed by a post-run of 5 min at 250°C. The detected volatiles were identified by comparison of their mass spectra with those of the NIST 02 library, by comparison of their spectra and retention times with those of authentic standards, and by comparison of retention times with those in previous analyses (D'Alessandro and Turlings, 2005). Compounds that were not identified by comparing retention times and spectra with those of pure standards are indicated in Fig. 2 with superscript N, and their identity should be considered tentative. Twelve samples per treatment were analyzed in the SIM mode (ion 117, qualifier 95), and indole was quantified based on a calibration curve with known amounts of synthetic indole. All other compounds were only quantified in the full scan range based on comparison of their peak area with those of the internal standards (*n*-octane for compounds 1–14, *n*-nonyl acetate for compounds 14–27). A total of 18 samples were injected per treatment.

Statistical Analyses The functional relationship between parasitoids' behavioral responses and the different odor sources offered in the four-arm olfactometer was examined with a log-linear model (a generalized linear model, GLM). As the data did not conform to simple variance assumptions implied in using the multinomial distribution, we used quasi-likelihood functions to compensate for the overdispersion of wasps within the olfactometer (Turlings et al., 2004). The model was fitted by maximum quasi-likelihood estimation in the software package R (R: A language and Environment for Statistical Computing, Version 1.9.1, Vienna, Austria, 2006, ISBN 3-900051-07-0 <http://www.R-project.org>), and its adequacy was assessed through likelihood ratio statistics and examination of residuals. We

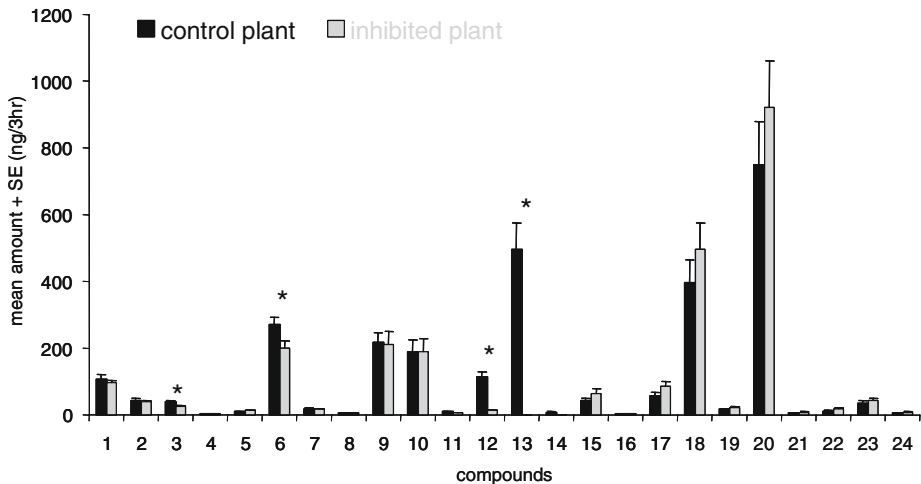

Fig. 2 Mean amount (\pm SE) (ng) of major VOCs recollected from cut *Spodoptera*-induced maize seedlings during 3 hr. Control plants were incubated in water, inhibited plants were incubated in a 1 mM glyphosate solution. Asterisks above bars indicate significant differences (*t*-test on $\log(x+1)$ transformed data, $P < 0.05$) in the amount of a specific compound. $N = 18$ per treatment. The compounds are as follows: **1**, (Z)-3-hexenal; **2**, (*E*)-2-hexenal; **3**, (Z)-3-hexen-1-ol; **4**, (Z)-2-penten-1-ol acetate; **5**, β -myrcene; **6**, (Z)-3-hexenyl acetate; **7**, (*E*)-2-hexenyl acetate; **8**, (Z)- β -ocimene^N; **9**, linalool; **10**, (3*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT); **11**, benzyl acetate; **12**, phenethyl acetate; **13**, indole; **14**, methyl anthranilate; **15**, geranyl acetate; **16**, unknown sesquiterpenoid; **17**, (*E*)- β -caryophyllene; **18**, (*E*)- α -bergamotene; **19**, unknown sesquiterpenoid; **20**, (*E*)- β -farnesene; **21**, unknown sesquiterpenoid; **22**, unknown sesquiterpenoid; **23**, β -sesquiphellandrene^N; **24**, (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT). The compounds are ordered in accordance with their retention on a nonpolar capillary column

tested “treatment” effects (=odor sources) for naive and experienced wasps separately, and we included “release” as an explanatory variable to avoid “pseudo-replications.” In addition, we tested if there was a significant effect of “experience” and an interaction between “treatment \times experience.”

The amounts of VOCs were analyzed by using *t*-tests. Amounts of VOCs that were not normally distributed were $\log(x+1)$ transformed prior to analysis. The amounts of indole quantified in the single ion mode were analyzed with a Kruskal–Wallis test. Differences between the treatments were analyzed with the Tukey’s test. Differences between the removed leaf areas after caterpillar feeding were analyzed with a *t*-test. All analyses were run on SigmaStat (Version 2.03).

Results

VOCs of Control and Inhibited Plants Herbivore-infested maize seedlings that were incubated with their cut stem in water (control plants) released a volatile blend consisting of 24 detectable VOCs, including green leaf volatiles, terpenoids, and shikimic acid derivatives (Fig. 2). Seedlings that were incubated in a 1 mM glyphosate solution released only trace amounts of indole and methyl anthranilate and had strongly reduced amounts of other shikimic acid derived VOCs (*t*-test: benzyl acetate, $t_{34}=1.741$, $P=0.092$; phenethyl acetate, $t_{34}=11.218$, $P<0.001$). The amounts of VOCs derived from other biochemical pathways were similar to those of the control plants, except for the somewhat reduced amounts of (*Z*)-3-hexen-1-ol ($t_{34}=2.306$, $P=0.027$) and 3-*Z*-hexen-1-ol acetate ($t_{34}=2.577$, $P=0.014$). In addition to the compounds quantified in Fig. 2, we also detected trace amounts of (*E*)-nerolidol, (*Z*)-jasmone, and some minor, unidentified compounds. These VOCs were not included in quantification analyses.

The single ion mode analyses of indole revealed that during the 3-hr bioassay periods we collected 835.44 ± 135.91 ng from control plants and only 0.55 ± 0.17 ng from inhibited plants. In bioassays where synthetic indole was added to the air stream with the odor of an inhibited plant, we detected 192.77 ± 11.46 ng. There was a significant difference between the amounts released by these three treatments (Kruskal–Wallis followed by Tukey test, $H_2=30.294$, $P<0.001$).

Inhibitor treatment did not affect the larvae’s feeding rate; the leaf areas removed by the larvae during a 24-hr feeding period were similar for control plants (4.73 ± 0.40 cm²) and for inhibited plants (4.81 ± 0.38 cm²) (*t*-test: $t_{20}=-0.15$, $P=0.882$).

Attractiveness of Inhibited vs. Control Plants Neither naïve nor experienced *C. marginiventris* females significantly distinguished between VOC blends emitted by *Spodoptera*-induced maize seedlings with strongly reduced amounts of shikimic acid derived VOCs (see above) and VOCs emitted by control plants (Fig. 3a, GLM, naive: $F_{1,15}=0.78$, $P=0.39$; experienced on inhibited blend: $F_{1,15}=3.91$, $P=0.067$; experienced on control blend: $F_{1,15}=0.43$, $P=0.52$). Yet, the type of experience had a significant effect on the choice of the wasps ($F_{1,60}=4.566$, $P=0.037$), implying that *C. marginiventris* females were able to detect the difference between the two odor sources. The responsiveness (the proportion of wasps entering an arm with one of the two treatments) was high and similar for all treatments, and only few wasps entered an empty arm (Fig. 3a).

Naive and experienced females of *M. rufiventris* significantly preferred the inhibited blend (Fig. 3b, GLM, naive: $F_{1,15}=11.04$, $P=0.005$; experienced on inhibited blend: $F_{1,15}=$

Fig. 3 Importance of shikimic acid derived VOC for the attraction of two parasitoid species. (a) Choice of *C. marginiventris* females and (b) *M. rufiventris* females between arms carrying VOCs of *Spodoptera*-induced maize seedlings that were either incubated in water (control plants) or in a 1 mM glyphosate solution (inhibited plants). Pretreatment of the wasps (=type of experience) is indicated on the left. Pie charts indicate overall responsiveness (=number of wasps entering the different types of arms). GLMs were performed in order to test for differences between the two odor arms within one group of wasps as well as to compare the types of experiences. *** $P < 0.001$, ** $P < 0.01$, * $P < 0.05$, n.s. = no significant difference, $P > 0.05$

26.19, $P < 0.001$; experienced on control blend: $F_{1,15} = 6.19$, $P = 0.025$). As with *C. marginiventris*, the type of experience had an effect on the choice of the wasps ($F_{1,60} = 7.073$, $P = 0.010$). The responsiveness was high, and none of the *M. rufiventris* wasps entered an empty arm.

Role of Indole Indole was the major shikimic acid derived VOC released by *Spodoptera*-induced maize seedlings (Fig. 2). We tested its role in the attraction of the two parasitoid

species by comparing the attractiveness of HIPV blends released by two inhibited plants, whereby we added synthetic indole back to one of the blends. The amounts of indole added (192.77 ± 11.46 ng/3 hr) fell within the lower ranges of indole detected in a natural induced maize blend (see above). *C. marginiventris* did not distinguish between the two blends (Fig. 4a, GLM: $F_{1,47}=0.87$, $P=0.36$). In contrast, *M. rufiventris* significantly preferred the inhibited blend without synthetic indole (Fig. 4b, $F_{1,47}=43.16$, $P<0.001$). Results for both wasps are consistent with those from the previous experiment, showing an insignificant role of shikimate-derived compounds for *C. marginiventris* attraction, whereas they have a repellent effect on *M. rufiventris*.

Learning of Indole When *C. marginiventris* females were given a choice between one arm with synthetic indole (192.77 ± 11.46 ng/3 hr) and three arms with clean air only, they neither showed an innate (naive wasps) attraction towards indole (Fig. 5a, GLM: $F_{1,47}=0.60$, $P=0.44$), nor were they attracted to indole after having experienced a natural blend that contained similar amounts of indole ($F_{1,47}=0.29$, $P=0.60$). However, if they were exposed to pure indole during oviposition experiences they preferred an arm carrying indole over arms with clean air ($F_{1,47}=11.62$, $P=0.001$), although the type of experience had only a marginal effect on their choices ($F_{1,124}=2.919$, $P=0.090$) and the overall responsiveness was rather low (Fig. 5a).

In an additional experiment, we tested whether exposing the wasps to indole during ovipositions increases the attraction towards an induced maize blend containing indole (control plant) compared to a blend with only trace amounts of indole (inhibited plant). As

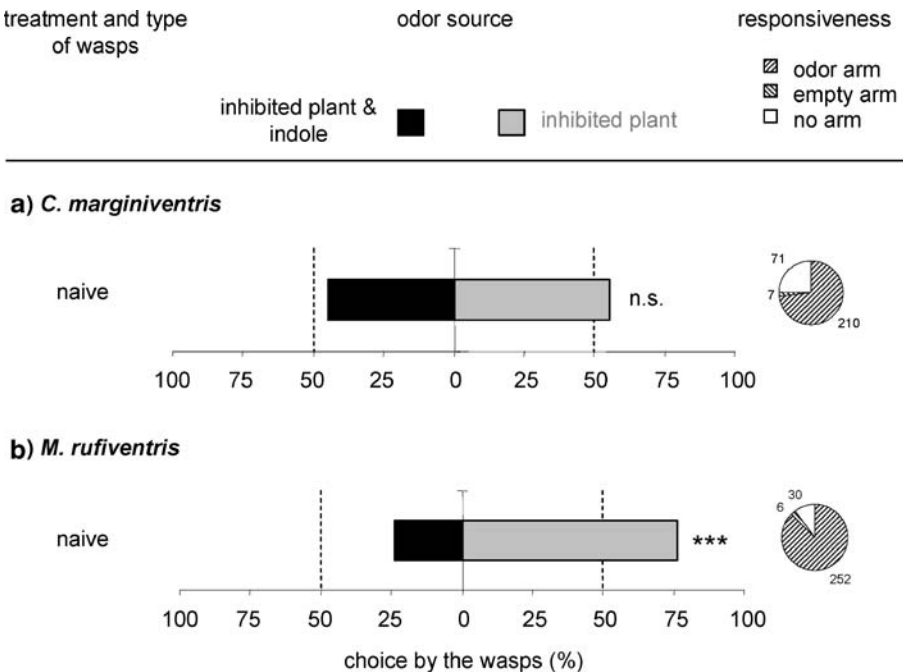

Fig. 4 Importance of indole for the attraction of two parasitoid species. (a) Choice of naïve *C. marginiventris* females and (b) naïve *M. rufiventris* females between arms carrying *Spodoptera*-induced maize VOCs of inhibited plants and of inhibited plants to which synthetic indole was added. See Fig. 3 for further explanations

Fig. 5 Importance of indole in learning experiments by *C. marginiventris*. (a) Choice of females with different learning experiences between arms carrying synthetic indole and empty arms with clean air only. (b) Choice of females with different learning experiences between arms carrying *Spodoptera*-induced maize VOCs of control and inhibited plants. See Fig. 3 for further explanations

in the experiments above, naive wasps and wasps that had experienced the control blend did not distinguish between the two blends (Fig. 5b, GLM: $F_{1,15}=0.062$, $P=0.81$; $F_{1,15}=1.92$, $P=0.19$, respectively). Interestingly, even an experience with pure synthetic indole did not result in a change in preference ($F_{1,15}=3.70$, $P=0.074$), and the type of experience did not have a significant effect on the wasps’ choice ($F_{1,60}=0.214$, $P=0.646$).

Discussion

One way of studying the importance of individual VOCs for the attraction of natural enemies is to compare the attractiveness of an incomplete with a normal blend of HIPVs (D’Alessandro and Turlings, 2005). By restoring the incomplete blend with synthetic

compounds that are missing, the importance of the added compounds can be confirmed (de Boer and Dicke, 2004). Here, we used glyphosate, an inhibitor of the enzyme EPSP synthase (Haslam, 1993; Schönbrunn et al., 2001), to inhibit the production of shikimic acid derived HIPVs. As expected, this inhibitor treatment resulted in a strong reduction of the emission of indole, methyl anthranilate, phenethyl acetate, and benzyl acetate, whereas the amounts of most other compounds, except two green-leaf volatiles, were not affected by the inhibitor treatment (Fig. 2). Treating plants with glyphosate normally results in lower amounts of chorismate, a precursor for the production of salicylic acid (SA) (Shah, 2003). SA has been shown to synergistically or antagonistically interact with jasmonic acid (Thaler et al., 2002; Bostock, 2005), an important hormone involved in the induction of maize VOCs (Schmelz et al., 2003c). We speculate that SA does not play a major role in induced volatile emissions in this maize variety. Indeed, MeSA, the volatile form of SA, was only occasionally detected in trace amounts in our control plants.

Glyphosate-treated plants are also expected to contain lower levels of phenolic compounds, which should have a positive effect on herbivores. However, we did not observe any difference in the amount of leaf damage inflicted by *Spodoptera* larvae between glyphosate-treated and glyphosate-untreated plants. A possible negative effect of glyphosate through direct toxicity has been ruled out in ecotoxicological risk assessment studies with arthropods (Giesy et al., 2000). Furthermore, glyphosate is not readily volatilized and is primarily degraded by microbial metabolism in the soil (Tu et al., 2001). Indeed, we did not detect additional VOCs from glyphosate-treated seedlings, making glyphosate a suitable inhibitor to study the attractiveness of shikimic acid derived VOCs.

Attractiveness of Shikimic Acid Derived VOCs It is generally assumed that HIPVs are exploited by natural enemies of the herbivores in order to locate their host or prey (Dicke, 1999; Turlings and Wäckers, 2004), but which compounds of a volatile blend are actually important in the foraging behavior of natural enemies is not yet known for most tritrophic systems (Dicke and van Loon, 2000). Previous studies on caterpillar-induced maize volatiles showed that qualitative differences in the odor blend may be more important for the attraction of parasitic wasps than quantitative differences (Fritzsche Hoballah et al., 2002). Indeed, a blend of induced maize volatiles with reduced amounts of the three major sesquiterpenoids, (*E*)- β -caryophyllene, (*E*)- α -bergamotene, and (*E*)- β -farnesene, was equally attractive to naive *C. marginiventris* as control blends with high amounts of these compounds, whereas removing some minor, polar compounds from the blend rendered it completely unattractive to *C. marginiventris* (D'Alessandro and Turlings, 2005). Here, we provide another example showing that some common HIPVs, i.e., shikimic acid derived volatiles, are not involved in the initial attraction of two parasitoids to host infested plants (Figs. 3 and 4). Indole, which is one of the dominating compounds in *Spodoptera*-induced maize volatiles (Turlings et al., 1998; D'Alessandro and Turlings, 2005), might even be repellent or might mask the attractiveness of compounds used for host location. Interestingly, several studies on maize volatiles indicate specific induction of volatile indole by herbivore-derived elicitors and not by excision stress or mechanical damage (Frey et al., 2000; Schmelz et al., 2003b). However, in other studies, many of the common herbivore-induced VOCs, including indole and several terpenoids, have been detected in analyses of VOCs released by plants exposed to other forms of stresses, as for example mechanical wounding (van den Boom et al., 2004), exposure to other VOCs (Ruther and Fürstenau, 2005), or infection by microorganism (Huang et al., 2003). Hence, the emission of various volatiles can be induced by a number of enemies and stresses, yet natural enemies are able to discriminate between different forms of stresses (Takabayashi et al.,

1995; De Moraes et al., 1998; de Boer et al., 2004; Vuorinen et al., 2004). Selection must have favored parasitoids with an ability to distinguish between host- and nonhost-related compounds and an innate response to compounds that are specifically correlated with host presence is the most likely mechanism that allows them to make such distinctions (Vet and Dicke, 1992). We hypothesize that naïve females of generalist parasitic wasps are attracted only to a few key compounds within a complex blend of volatiles, and that most other compounds within such a blend contribute little to its initial attractiveness. They may mask the attractive compounds, or may even be repellent. Still, these compounds may become attractants when the wasps have associated them with host presence.

Importance of Learning One way for parasitoids to deal with highly complex and variable blends is their ability to learn by association (Turlings et al., 1993; Vet et al., 1995). It is assumed that such learning processes are specifically important for generalist wasps such as *C. marginiventris* and *M. rufiventris*, parasitizing various host, feeding on different plant species (Vet and Dicke, 1992; Steidle and van Loon, 2003). Indeed, *C. marginiventris* shows a keen ability for associative learning, whereas this form of learning is less clear for *M. rufiventris* (D'Alessandro and Turlings, 2005; Hoballah and Turlings, 2005; Tamò et al., 2006). Here again, *C. marginiventris* showed a significant shift in its preference in favor of the blend that it had experienced during multiple ovipositions (Fig. 3a). The response of *M. rufiventris* also changed significantly after experience, but it maintained a significant preference for the odor of inhibited plants even after having experienced the odor of control plants (Fig. 3b).

The predatory mites (*Phytoseiulus persimilis*) have been found to strongly associate MeSA with the presence of their prey if they are reared in the presence of a complex blend of herbivore-induced VOCs that includes MeSA (de Boer et al., 2004). Similarly, Vet et al. (1998) found that the *Drosophila* parasitoid *Leptopilina heterotoma* learned to discriminate between odors from substrates that were qualitatively different, but failed to discriminate when differences were small, unless unrewarding experiences provided evidence of the absence of hosts in one of the substrates. That some compounds are more important than others for associative learning was found for the parasitoid *M. croceipes*. After conditioning to a complex mixture, females of this species established a hierarchy among various components, with some of them accounting for a major part of the behavioral activity evoked by the mixture (Meiners et al., 2003). In our study, *C. marginiventris* was able to learn and subsequently respond to pure synthetic indole; however, this learning of indole had no effect on the females' responses to natural, complex blends with or without indole (Fig. 5). Apparently, indole is not a compound that is strongly associated during learning processes, especially if it is not offered in a complex volatile environment. Although indole is strongly induced after *Spodoptera* infestation on maize plants, it is also found in a variety of other stress-induced plant volatile blends (see above), and may not provide foraging parasitic wasps with specific information on the presence or absence of hosts.

In summary, we studied the role of shikimic acid derived VOCs, in particular indole, in the host searching behavior of two parasitoid species, *C. marginiventris* and *M. rufiventris*. This group of VOCs forms a substantial part of the volatile blend released by maize seedlings in response to feeding by lepidopteran larvae, but the results show that they are not important for the attraction of the two wasp species tested here. Attraction of *C. marginiventris* was not affected by the presence or absence of indole, the major shikimic acid derived VOC, whereas this compound was repellent rather than attractive to *M. rufiventris*. Learning of indole during oviposition experiences did not greatly alter these

responses. Hence, this study suggests that parasitoids do not use all herbivore-induced VOCs for habitat and host location to a similar degree, but rather pay selective attention to a few compounds. Identifying these key compounds seems crucial for a good understanding of the host searching process in parasitoids and for the development of strategies to increase the efficiency of natural enemies for the control of pest insects (Turlings and Ton, 2006).

Acknowledgment We thank the members of the Evolutionary Entomology laboratory at the University of Neuchâtel for their continuous support and stimulating discussions on behavioral and chemical aspects of this study. We also thank Yves Borcard for parasitoid rearing and Syngenta (Stein, Switzerland) for the weekly shipments of *S. littoralis* eggs and artificial diet. We are grateful to Ingrid Ricard and Anthony Davison for statistical advice. This project was funded by the Swiss National Science Foundation (grant 31-058865.99) and the Swiss National Centre of Competence in Research “Plant Survival.”

Introduction

The rice stalk stink bug, *Tibraca limbativentris* Stal, 1860 (Hemiptera: Pentatomidae), is a neotropical pest of paddy rice in Brazil, Argentina, and Uruguay (Panizzi et al., 2000). Recently, it was reported in the Dominican Republic (Jorge, 1999) and also in Colombia, Ecuador, Panama, Costa Rica, and Suriname, and is a potential threat to the United States. Introduction into North America may result in serious losses to U.S. and Mexican rice production. Other economically important crops may serve as host plants as well (North American Plant Protection Organization-Phytosanitary Alert System; <http://nappo.org/>).

Tibraca limbativentris is a damaging insect to rice in Brazil. Feeding of the insects at the base of the plants in the vegetative stage causes the phenomenon known as “dead heart”, and feeding during the reproductive stage causes the plants to exhibit damage known as “white panicle” (Ferreira et al., 1997). Bug populations have been high for several consecutive years (up to 200 individuals/m²), causing production losses varying from 5% to 80% (Ferreira et al., 1997 and references therein). This species occurs in almost all states of Brazil and is sometimes found on alternative hosts such as soybean, tomato, wheat, and native Gramineae (Panizzi et al., 2000 and references therein).

The control of *T. limbativentris* is heavily based on chemical pesticides (Usta et al., 1994; Ferreira et al., 1997; Costa and Link, 1998/99; Panizzi et al., 2000). For example, in Colombia, stink bugs in rice require up to three insecticide applications per season (Pantoja et al., 1995).

Because of the habit of *T. limbativentris* feeding in the upside-down position at the base of the plants, when the damage is perceived by growers, the economic threshold has already been reached. Thus, pheromone-baited traps might be a useful tool for monitoring these pests. The objectives of the research described herein were to determine whether *T. limbativentris* produces a male-specific sex pheromone, as reported for other phytophagous stink bug species, and, if so, to identify the chemical structure(s) of the biologically active compound(s).

Methods and Materials

Insects

Tibraca limbativentris adults were from a colony started with adults collected near Embrapa Rice and Beans, Goiania-Goiás (16°4'S and 49°14'W). Insects were reared on rice plants, *Oryza sativa*, potted in a large (5 kg) pot in a green house and kept as a stock colony. In the laboratory, where the knowledge of sexual maturity (age) was necessary for bioassays and collection of volatiles (aeration experiments), bugs were reared in 5-l plastic containers with the food supply being renewed 3 times per wk (Cavalcante et al., 2004), at 26 ± 1°C and 65 ± 10% relative humidity under 14:10 light/dark photoperiod (from 06:00 to 20:00 hr).

Most of the egg masses were laid on the rice plants, and 3 times a week these plants were transferred to new plastic containers where the nymphs were reared as above.

To prevent interactions between the sexes, males were separated from females after their imaginal molt and cuticular hardening (ca. 24 hr). For all experiments, sexually mature adults (>15-d-old) were used (Cavalcante et al., 2004).

Collection of Volatiles

Volatiles were collected from individual groups of 15 male or female *T. limbativentris* ($N=50$). The insects were gently introduced into 1-l glass containers (Zhang et al., 2003) to minimize emission of defensive secretions. Air was drawn into the container through 4–12 mesh-activated charcoal (Fisher Scientific, Pittsburgh, PA, USA), and out of the container through two traps (15×1.5 cm OD) containing Super Q (200 mg each; Alltech Associates, Inc., Deerfield, IL, USA) by vacuum pump (~ 1 l/min). The adsorbent traps were eluted with hexane (4×0.5 ml per sample) and each sample was concentrated to approximately 100 μ l under a gentle flow of nitrogen for further analysis. Insects were fed with fresh green beans (*Phaseolus vulgaris*; replaced three times a week) and aerated continuously for 15 d, changing the adsorbent traps daily, to get enough material for bioassays and chemical analysis. To check the emanation of any volatiles from the green beans that would contaminate the airborne collection from the above experiment, the same procedure was carried out with three green beans inside the glass chambers and the volatiles were collected for 24 hr for 4 d ($N=12$).

Olfactometer Bioassays

A two-choice olfactometer modified from Borges and Aldrich (1994) was used to test the biological activity of live insects, insect aeration extracts of *T. limbativentris*, and synthetic compounds. The olfactometer release chamber was a 500-ml, three-neck, round-bottomed flask (all 24/40 joints, Kontes, Vineland, NJ, USA). Two 250-ml rotary evaporator trap adapters (24/40 joints) were attached to each side arm of the release flask (the treatment and control arms). A charcoal (20/40 mesh) filter (130×10 mm ID) was attached to the side arms using two 40-cm-long pieces of a Silastic tubing (3/16 inch ID \times 5/16 inch OD; VWR Scientific Corporation, Darmstadt, Germany), inserted in a “Y” connector of the same diameter and connected to adapters (24/40 joint) on each side arm of the olfactometer. The air was humidified by passage through a container of distilled water between the charcoal filter and the arms of the olfactometer. The middle neck of the flask was connected to the vacuum pump with an adapter and the air flow was adjusted with a “Clear Flow Rotameter” (Accura Flow Products, Warminster, PA, USA) to a flow of 0.8 l/min. The apparatus was positioned horizontally on a countertop in a room with bright fluorescent lights (4×40 W) during daytime conditions, and lighted with red lamps (4×60 W) during scotophase. The temperature in the bioassay room was maintained at $26.0 \pm 1.0^\circ\text{C}$. The positions of the olfactometer arms were inverted between control and treatments after each three repetitions to avoid any positional bias. The apparatus was cleaned with fragrance-free liquid soap, rinsed thoroughly with water, and dried at 80°C , after each five replicates. The insects were placed in the round-bottom flask (release chamber), and the treatments were placed at the end of the reducing adapter chamber (treatment arms).

A single *T. limbativentris* adult was gently introduced into the release chamber of the Y-tube olfactometer with the aid of an artist’s paint brush (Camel Hair, number 1), and its pattern of behavior (response) was recorded for 15 min/replicate. The duration of each

bioassay replicate was monitored using a stopwatch. Before testing, the insects were allowed to acclimatize for a short period (ca. 3 min) in the release chamber while assembling the treatment chambers. The first choice of the insect was recorded, i.e., the first arm of the olfactometer that the insect chose and remained in for at least 100 sec. The test insects were used only once during the bioassays.

Determination of Period of Maximum Activity

To test if *T. limbativentris* had a daily cycle of sexual activity, bioassays were carried out to determine the cycle of maximum response by testing insect responses to volatiles from live bugs used as the pheromone source. For this experiment, the following periods were designated: morning (M=06:00–12:00), afternoon (A=12:00–18:00), and night (N=18:00–24:00). Fifty replicates were carried out for each time period and the number of insects attracted to the pheromone source was recorded.

Bioassays with Living Insects

Experiments were carried out to determine whether males were the pheromone-producing sex, analogous to other phytophagous stink bug species (Borges et al., 1987; Aldrich et al., 1987, 1994; Borges and Aldrich, 1994; Borges, 1995; McBrien and Millar, 1999; Millar, 2005; Moraes et al., 2005). The attraction of insects of both sexes to odors from males or females was tested, respectively, by offering test individuals a choice between odors from live insects and a clean air control ($N=50$ for each combination). Because observations during rearing indicated peak mating activity occurred at night, bioassays were performed in the evening and scotophase.

Bioassays with Insect Extracts and Synthetic Compounds

The same bioassay procedures described above were used to compare the biological activity of aeration extracts and authentic synthetic standards. The solution of test stimulus was one individual equivalent (IE) of aeration extract spotted on a strip of filter paper (1.5 cm long and 0.5 cm wide). Controls consisted of filter papers treated with hexane. Because females were attracted to male odor, and all other combinations with live insects did not show a positive response, only females were used as responders in all subsequent bioassays. Bioassays ($N=15–31$) with an aeration extract from males or females were carried out using an extract obtained from a 24-hr aeration of 15 bugs.

Based on experimental findings with 0.01, 0.1, and 1 mg/ml, bioassays were conducted with 10 μ l of 0.1 mg/ml, (i.e., 1000 ng of the synthetic compound) loaded on a strip of filter paper (1.5 cm long and 0.5 cm wide). The responses of *T. limbativentris* females to two sets of zingiberenol isomers (zingiberenol I comprising the four stereoisomers of the group (1*RS*, 4*RS*, 1'*R*)-4-(1',5'-dimethylhex-4'-enyl)-1-methylcyclohex-2-en-1-ol ($N=56$) and zingiberenol II comprising the four stereoisomers of the group (1*RS*, 4*RS*, 1'*S*)-4-(1',5'-dimethylhex-4'-enyl)-1-methylcyclohex-2-en-1-ol ($N=71$) were compared to a hexane control. In addition, zingiberenol I was compared against zingiberenol II ($N=41$).

Chemical Analysis

Extracts were analyzed by gas chromatography (GC; HP-6890, HP-1 column, 50 m \times 0.25 mm ID, 0.25 μ m film, J&W Scientific, Folsom, CA, USA), by using a

temperature program of 30°C for 1 min, 5°C/min to 150°C for 0.1 min, 10°C/min to 250°C for 20 min. Samples (1 µl) were injected in cool on-column mode with hydrogen carrier gas, and a flame ionization detector (FID) at 270°C.

Extracts were analyzed by coupled GC–mass spectrometry (GC–MS) by using a Thermo-Finnigan MAT95XP magnetic sector mass spectrometer, which was directly coupled to a TRACE 2000 GC. The GC was equipped with a DB-1 column (50 m × 0.25 mm ID, 0.25 µm film, J&W Scientific) and a cool on-column injector. The carrier gas was helium. Ionization was by electron impact (70 eV, source temperature 200°C). Data were collected and analyzed with Xcalibur software.

The components of aeration extracts from both sexes of *T. limbativentris* were tentatively identified by comparison of GC retention times with those of synthetic standards using polar and nonpolar columns (HP-Wax column, 30 m × 0.3 mm ID, 0.45 µm film or HP-1 column, 50 m × 0.25 mm ID, 0.25 µm film, both from J&W Scientific) with the temperature programs described above. Chemical identifications were confirmed by comparison of retention time and MS data with authentic standards and with MS library data (NIST, Saturn library 2000).

To confirm the presence of an alcohol group in the putative pheromone components, microsilylation was carried out using *N*-methyl-(trimethylsilyl)-trifluoroacetamide (MSTFA) in a 1-ml glass vial. An aliquot of 50 µl was taken from an extract of volatiles of 20 males of *T. limbativentris*, concentrated under a stream of nitrogen flow almost to dryness, and redissolved in 100 µl of MSTFA. The sample was heated in a water bath at 60°C for 1 hr, and analyzed directly by GC–MS using the conditions described above. The same reaction was conducted with a standard solution of zingiberenol (2 µl of 100 mg/ml), prepared as described below.

Synthesis of 4-[(1'*R*)-1,5-Dimethylhex-4-enyl]-1-Methylcyclohex-2-en-1-ol

Zingiberenol mixtures were prepared by Fuji Flavor Co., Ltd. (Tokyo, Japan), with the help of Dr. Tatsuji Chuman. The eight stereoisomers of zingiberenol were prepared in two samples, with each of the samples containing four diastereoisomers. The zingiberenol I mixture contained the (1*R*,4*R*,1'*R*), (1*S*,4*R*,1'*R*) (1*R*,4*S*,1'*R*) and (1*S*,4*S*,1'*R*) stereoisomers, whereas Zingiberenol II contained the (1*R*,4*R*,1'*S*), (1*S*,4*R*,1'*S*), (1*R*,4*S*,1'*S*), and (1*S*,4*S*,1'*S*) stereoisomers (Figure 1). The syntheses of zingiberenols I and II were conducted following method II from Hagiwara et al. (2002). In brief, the 4-[(1'*R*)-1,5-dimethylhex-4-enyl]-1-methylcyclohex-2-en-1-ols were synthesized from (*R*)-citronellal. GC–MS *m/z* 222, 207, 204, 189, 179, 161, 151, 137, 123, 119, 109, 95, 77, 69, 55. IR (KBr): 3352, 2927, 2858, 1450, 1377, 1122, 980 cm⁻¹. ¹H-NMR (300 MHz, CDCl₃), δ: 0.81 (d, 1.2 H, *J*=6.9 Hz), 0.84 (d, 0.3 H, *J*=7.5 Hz), 0.86 (d, 1.2 H, *J*=6.9 Hz), 0.88 (d, 0.3 H, *J*=7.5 Hz), 1.10–2.14 (m, 11 H), 1.27 (s, 3 H), 1.60 (s, 3 H), 1.69 (broad s, 3 H), 5.06–5.12 (m, 1 H), 5.50–5.65 (m, 2 H). The compounds 4-[(1'*S*)-1,5-dimethylhex-4-enyl]-1-methylcyclohex-2-en-1-ol were synthesized using the same procedure starting from *S*-citronellal, and gave analogous spectra.

Chemicals

Decanal, nonanal, limonene, 6-methyl-5-hepten-2-one, decane, (*E*)-2-octenal, tridecane, tetradecane, and pentadecane were purchased from Sigma Aldrich (Gillingham, Dorset, UK). α-Copaene, α-pinene, β-pinene, and *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (MSTFA) were purchased from Fluka (Steinheim, Germany).

Fig. 1 (a) Zingiberenol I, containing the four isomers, (1*RS*,4*RS*,1*R*)-4-(1',5'-dimethylhex-4'-enyl)-1-methylcyclohex-2-en-1-ol. (b) Zingiberenol II, containing the four isomers (1*RS*,4*RS*,1'*S*)-4-(1',5'-dimethylhex-4'-enyl)-1-methylcyclohex-2-en-1-ol

Statistical Analysis

Data on the responses of males and females to different treatments (live insects, aeration extracts, and synthetic compounds vs. control) were analyzed using χ^2 tests, for first choice. Only the insects that left the release chambers of the olfactometer were considered for the analyses. Treatments in which the “nonresponders” (insects that fail to respond in each of the treatments) were >70% were not statistically analyzed.

Results

Determination of Period of Maximum Activity

Bioassays with virgin sexually mature females showed that the attraction to males was strongest during the night period (18:00–24:00 hr). During the morning and afternoon period, >90% of the insects tested did not leave the release chamber of the olfactometer,

Fig. 2 Number of female *T. limbativentris* responding to live males during different periods of the day and night in laboratory bioassays. Morning; 8:00–12:00 hr; afternoon, 12:00–18:00 hr; and night, 18:00–24:00 hr ($\chi^2 = 14.44$, $P < 0.001$, $N = 50$). Left-hand side: Number of insects that failed to respond in each of the treatments. $**P < 0.01$

Fig. 3 Response of *T. limbativentris* (first choice) males and females in olfactometer arms responding to different treatments: females attracted by males ($\chi^2 = 19.70$, $P < 0.001$, $N = 50$), females attracted by females, males attracted by females, and males attracted by males, recorded during evening and scotophase under laboratory conditions $***P < 0.001$

indicating that this species has a crepuscular/nocturnal sexual activity cycle (Figure 2). Therefore, all subsequent bioassays were performed during this period.

Bioassays with Live Insects

In the Y-tube olfactometer bioassays, female bugs were attracted to odors of live males, but not to odors of live females (Figure 3). Males were not attracted to odors of either sex (Figure 3). These results, in concordance with the analyses of insect extracts, show that males produce a sex pheromone.

Bioassays with Insect Extracts and Synthesized Compounds

Tibraca limbativentris females were more attracted to male extract (treatment arm) than to the hexane control (Figure 4). Male extract did not attract males, and extracts of females were not attractive to either sex (Figure 4). Following results with live insects and extracts, and chemical analyses, the responses of *T. limbativentris* females to zingiberenol I comprising the four stereoisomers, (1*RS*, 4*RS*, 1'*R*)-4-(1',5'-dimethylhex-4'-enyl)-1-methylcyclohex-2-en-1-ol, and to zingiberenol II comprising the four stereoisomers, (1*RS*, 4*RS*, 1'*S*)-4-(1',5'-dimethylhex-4'-enyl)-1-methylcyclohex-2-en-1-ol, were tested in olfactometer bioassays. First, zingiberenols I and II were tested against male extract and in both bioassays the synthetic compounds were as attractive as extracts from males (Figure 5). When zingiberenols I and II were compared against each other, the two were equally

Fig. 4 Number of *T. limbativentris* (first choice) males and females in olfactometer arms responding to different treatments: females attracted by extracts from males ($\chi^2 = 13.37$, $P < 0.001$, $N = 27$), females attracted by extracts from females, males attracted extracts from males, and males attracted by extracts from females $***P < 0.001$

Fig. 5 Number of *T. limbativentris* (first choice) females in olfactometer arms responding to different treatments: females tested to extracts from males (1 IE) and zingiberenol I (Z I; 1000 ng), and females tested to extracts from males (1 IE) and zingiberenol II (Z II; 1000 ng). ns: not significant

attractive (Figure 6). However, when zingiberenols I and II were compared against neutral controls, only zingiberenol II was attractive (Figure 6). These results suggest that at least one of the stereoisomers in the zingiberenol II blend is a sex pheromone component for this species.

Chemical Analysis

Comparison of aeration extracts collected from both sexes of *T. limbativentris* by GC and coupled GC–MS showed that aeration extracts from males contained at least two male-specific compounds, in addition to several compounds that were common to both sexes (Figure 7). Compounds found in both sexes were identified by comparison with authentic standards as α -pinene (1), β -pinene (2), 6-methyl-5-hepten-2-one (3), decane (4), limonene (5), (*E*)-2-octenal (6), nonanal (7), dodecane (8), decanal (9), tridecane (10), α -copaene (11), tetradecane (12), pentadecane (13), and hexadecane (14), by using both polar and apolar columns. The GC analysis of control extracts obtained from aerations of green beans for 4 d did not show any compound detectable by FID.

Fig. 8 Mass spectral data of compounds 15 (top) and 16 (center) obtained from volatiles collected from live males, and mass spectra from synthetic zingiberenol (bottom)

Fig. 9 Gas chromatogram of volatile chemicals collected from live male *T. limbativentris* and of a standard solution of synthetic zingiberenol containing the four diastereoisomers. (a) Polar column, DB-WAX. (b) Nonpolar column, HP-1. Numbers 1 and 2 indicate isomers of zingiberenol. Two diastereoisomers were resolved on the HP-1 column and three diastereoisomers were resolved on the DB-WAX column

The fragmentation patterns for compounds 15 and 16 suggested a sesquiterpene-type structure with an alcohol group, with a possible molecular ion at m/z 222, and an ion at m/z 204 (M-18), arising from loss of water (Figure 8). The NIST library matched the fragmentation pattern of compounds 15 and 16 with the fragmentation pattern of sesquisabinene hydrate or zingiberenol (Figure 8). Comparison of the GC retention times of compounds 15 and 16, by using polar and nonpolar columns, with synthetic zingiberenol isomers (I and II) containing the four diastereoisomers, was carried out (Figure 9a and b). Compounds 15 and 16 coeluted with the two isomers of zingiberenol solution II that were resolved on the HP-1 column. Because zingiberenol has three chiral centers (positions 1', 1, and 4), there are eight isomers (four enantiomeric pairs of diastereomers). Zingiberenols I and II contained four diastereoisomers each and are “enantiomers.” Although diastereoisomers frequently can be separated on an achiral column, the zingiberenol I and II mixtures separated into only two peaks on the HP-1 column. Therefore, zingiberenols I and II were silylated to obtain a better separation of the four diastereoisomers on an achiral column. The derivatization was carried out using *N*-methyl-(trimethylsilyl) trifluoroacetamide (MSFTA) with the male aeration extract and the zingiberenol (I and II) mixtures. The four derivatized diastereoisomers in zingiberenols I and II were indeed separated on the HP-1 column (Figure 10a). For the derivatized aeration extract of male *T. limbativentris*, compounds 15 and 16 disappeared and three new compounds were generated, which

Fig. 10 Gas chromatogram showing four isomers of silylated zingiberenol ($C_{15}H_{28}O-TMS$) (top) and the three peaks obtained from derivatization of the sample obtained from airborne collection of volatiles of male *T. limbativentris* (bottom)

Fig. 11 Mass spectral data showing the pattern of fragmentation. (a) Compound 2: silanized zingiberenol (from Fig. 5a) ($C_{15}H_{28}O-TMS$). (b) Compound 2 (from Fig. 5b), obtained from derivatization of samples obtained from collection of volatiles of male *T. limbativentris*

matched the retention times of three of the four derivatized isomers in zingiberenols I and II (Figure 10b). Coinjection of MSFTA-derivatized zingiberenols I and II confirmed that each solution contained only the four diastereoisomers and all peaks matched each other. GC–MS analysis of the derivatized zingiberenol I and II mixtures and the male *T. limbativentris* aeration extract showed that the four derivatized compounds in zingiberenols I and II closely matched fragmentation patterns to the three derivatized compounds in the male extract. Figure 11 shows the fragmentation pattern of compound 2 of zingiberenol II mixture, identical to compound 2 of the male extract.

Discussion

Some of the compounds identified in the aeration extracts from *T. limbativentris* are common in stink bugs, such as (*E*)-2-octenal, (*E*)-2-decenal, nonanal, tridecane, and dodecane (Borges and Aldrich, 1992; Aldrich et al., 1993, 1995; Ho and Millar, 2001; McBrien et al., 2002; Moraes et al., 2005). In addition, males produced at least three isomers of zingiberenol, one or more of which appear to be sex pheromone components for this species.

In a direct comparison, female *T. limbativentris* were equally attracted by the zingiberenol I and II blends. However, fewer insects responded to zingiberenol I than to zingiberenol II when each blend was tested versus a control. This suggests that one or more of the isomers in zingiberenol II constitute the natural pheromone. Although the stereoisomeric mixture of zingiberenol II was attractive to females in this study, further electrophysiological and behavioral bioassays with individual isomers and specific blends need to be carried out to determine the precise configurations of the male-produced *T. limbativentris* sex pheromone component(s). There are several examples known of stink bug species that use different proportions of stereoisomers to produce a unique signal, such as *Acrosternum hilare* (McBrien et al., 2001) and *Nezara viridula* (Brézot et al., 1994).

When tested during different times of the day, females responded best during the period between 18:00 and 24:00 hr. This is similar to the behavior patterns found for other pentatomid species, such as *Euschistus heros* and *Thyanta perditor*, where the strongest responses were recorded during the afternoon to evening (Borges et al., 1998a,b; Moraes et al., 2005). However, this pattern differs from that found in other pentatomids such as

Nezara viridula (Borges et al., 1987) and *E. obscurus* (Borges and Aldrich, 1994), which show no variation in the level of responsiveness of females to males throughout the day.

In this study, both genders released some compounds that are seldom found or reported from stink bug airborne collections, such as α -pinene, β -pinene, and 6-methyl-5-hepten-2-one. The specific functions of these compounds, as well as the impact of factors such as different rearing conditions and diets upon their production, remain to be studied. The compound 6-methyl-5-hepten-2-one is clearly insect-produced and not from diet, because extracts of the metathoracic glands of both sexes contain this compound. However, some of the other compounds, such as α -pinene, β -pinene, limonene, and α -copaene, were not found in metathoracic gland extracts. Additionally, the green bean control aerations did not show the presence of any of these compounds. Thus, all these compounds appear to be released by *T. limbativentris*.

In summary, this work demonstrated that female *T. limbativentris* were attracted to a pheromone blend released by conspecific males and that females were attracted to a blend of synthetic zingiberenol isomers. The biological role of zingiberenol in the *T. limbativentris* male-specific emissions still needs to be determined under natural conditions. Furthermore, the role and absolute configuration of each of the zingiberenol isomers produced by males remain to be determined.

Acknowledgments We thank H elio Moreira dos Santos and Diva Tiburcio for helping with field collecting and laboratory rearing the insects used in this study. This work received financial support from CNPq and Embrapa, and a Rothamsted International Fellowship to MCBM. Rothamsted Research receives grant-aided support from the Biotechnology and Biological Sciences Research Council of the United Kingdom. This research was, also, supported by the International Foundation for Science, Stockholm, Sweden, through a grant to Maria Carolina Blassioli Moraes.

Introduction

Hymenoptera are impressive with regard to the diversity of species and levels of social organization. According to their different lifestyles and ecological niches, they possess a huge variety of exocrine glands with diverse functions. In solitary Hymenoptera, these glands contain secretions that serve functions in the context of mate attraction, courtship, prey paralysis, and defense (e.g., Rathmayer, 1962; Wilson, 1972; Quicke, 1997; Gnatzy et al., 2004). Because of the increased requirements for communication and defense of social species, many of these glands have gained various new functions in bees, wasps, and ants (e.g., alarm, trail establishment, recruitment, or reproductive dominance; see Hölldobler and Wilson, 1990; Blum, 1992). One of these “social” glands, the postpharyngeal gland (PPG), has long been thought to be idiosyncratic to ants (Formicidae) and evolved in response to the requirements of the social life (e.g., Hölldobler and Wilson, 1990; Schoeters and Billen, 1997; Lenoir et al., 1999). The PPG of ants is a large cephalic reservoir that is involved in species (Oldham et al., 1999) and nestmate recognition (Soroker et al., 1994; Hefetz et al., 1996), as well as in task discrimination (Kaib et al., 2000). However, several other functions of the PPG such as digestion, caste determination, or a storage organ for nutrients for queens or larvae have been discussed. Not all of these roles have been well corroborated, but it can be assumed that in ants the PPG serves several functions depending on species, age, sex, caste, and mating status (Eelen et al., 2006).

Recently, a PPG was found in females of the European beewolf *Philanthus triangulum* (Hymenoptera, Crabronidae; formerly Sphecidae, Melo, 1999), a solitary hunting wasp (Strohm et al., *in press*). Based on its morphology and the chemistry of its contents, the gland is considered to be homologous to the PPG known in the Formicidae (Strohm et al., *in press*). The function of the PPG in beewolf females is different from that in ants. Beewolf females hunt honeybee workers as prey for their offspring and store the paralyzed bees as provisions for the larvae in brood cells in the soil (Strohm, 1995; Strohm and Linsenmair, 1999). Females apparently apply the secretion of their PPG to the surface of their honeybee prey and this delays fungal infestation in the warm and humid underground nests (Strohm and Linsenmair, 2001; Herzner et al., unpublished data).

Unexpectedly, *P. triangulum* males also possess PPGs that are even larger than those in females (Herzner et al., *in press*). Beewolf males establish and scent-mark territories with a marking pheromone that attracts conspecific females for mating (Simon Thomas and Poorter, 1972; Evans and O’Neill, 1988; Strohm, 1995; Strohm and Lechner, 2000; Schmitt et al., 2003). The marking pheromone of *P. triangulum* has been characterized for three different populations (Borg-Karlson and Tengö, 1980; Schmidt et al., 1990; Schmitt et al., 2003) and was thought to be produced and stored in the mandibular gland (Gwynne, 1978; Schmidt et al., 1985; Evans and O’Neill, 1988; Schmidt et al., 1990). However, because the mandibular gland does not have a large reservoir, we hypothesized that the marking pheromone might be stored in the large PPG. Therefore, we took direct samples from dissected PPG reservoirs and analyzed these by combined gas chromatography-mass spectrometry (GC-MS). We compared our findings with a previous description of the pheromone in the same population (Schmitt et al., 2003).

The PPG content of female beewolves shows a marked dimorphism. The main component of the hydrocarbon mixture is either (*Z*)-9-pentacosene or (*Z*)-9-heptacosene (Strohm et al., unpublished). Because these compounds also occur in the male marking pheromone and such a variation in the male pheromone might have important implications for mate choice (Herzner et al., 2006), we looked for such a dimorphism in males. Finally,

we examined whether total-head extracts are sufficiently similar to samples directly taken from the PPG to allow for analyses of the pheromone by extracting heads instead of dissecting individual glands.

Methods and Materials

Specimens

Adult male beeswolves were obtained from a laboratory population (see, e.g., Strohm and Linsenmair, 1997). Freshly eclosed males were individually marked and kept as previously described (Herzner et al., 2006). Because age has been shown to influence pheromone composition (Kaltenpoth and Strohm, 2006), all males used for the analyses were the same age. Twelve to 14 d after emergence, males were caught and stored individually in small polystyrene vials (35 mm diam, 82 mm length, filled with 2 cm of moist sand) with rubber foam plugs for 2 d, so that they could replenish the reservoirs of their marking pheromone. They were then anesthetized with CO₂ and individually frozen at -18°C until chemical analyses were conducted.

Extracts

For the analyses, males were thawed and decapitated, and the heads were dissected under a stereo microscope. The PPG was carefully uncovered by removing the frontal part of the head capsule by cutting the cuticle between the eyes, toruli, and lateral ocelli very shallowly with a razor blade. If the reservoir is not damaged, it bulges out. A sample of the PPG content was taken by inserting the tip of a fine glass pipette directly into the gland reservoir. The sample was then dissolved in redistilled hexane.

For the complete inventory and characterization of the contents of the PPG, samples of three males were combined and reduced in volume to approximately 100 µl via a stream of nitrogen at ambient temperature. An aliquot of 1 µl was analyzed by combined GC-MS (setup 1, manual injection). To check for any nonpolar substances hidden under the peaks of polar pheromone compounds, the extract was fractionated on a conditioned SiOH glass column (Chromabond, 500 mg; Macherey-Nagel, Düren, Germany) according to the manufacturer's instructions, and 1 µl of both the hexane and the dichloromethane fraction were analyzed by combined GC-MS (setup 1, manual injection).

Some components that were detected and characterized in the pooled samples could not be satisfactorily identified in samples of individual males because of the smaller amounts of secretion. Therefore, the number of peaks included in the respective analyses varies somewhat.

To compare samples directly taken from the PPG with those obtained from total head extracts, 15 males were dissected as described above. After a sample of the PPG content had been taken, the remaining head capsule still containing the PPG and most of its contents was extracted in redistilled hexane for 3 hr. The samples were reduced in volume to approximately 100 µl, and 1 µl of each solution was analyzed by GC-MS (setup 1, automatic injection).

To investigate possible dimorphism in the composition of the PPG content, we analyzed a large sample of 45 males in order to be able to detect a low frequency of one morph. Males were obtained and treated as described above. For this second analysis, we extracted whole heads that were incised to open the glands. The heads were individually extracted in

redistilled hexane for 3 hr, the sample volume was reduced to approximately 100 μl , and 1 μl of each sample was analyzed by GC-MS (setup 2, automatic injection).

Capillary Gas Chromatography-Mass Spectrometry. Setup 1

GC-MS analysis was performed with an Agilent 6890N Series gas chromatograph (Agilent Technologies, Böblingen, Germany) coupled to an Agilent 5973 inert mass selective detector. The GC was equipped with an RH-5ms+ column (30 m \times 0.25 mm ID; $df=0.25\ \mu\text{m}$), and the temperature program ramped from 60°C for 1 min to 300°C at 5°C/min, hold 10 min. Helium was used as carrier gas (constant flow 1 ml/min). A split/splitless injector was used (250°C) with the purge valve opened after 1 min. Electron impact mass spectra (EI-MS) were recorded with an ionization voltage of 70 eV, a source temperature of 230°C, and an interface temperature of 315°C. MSD ChemStation Software (Agilent Technologies, Palo Alto, CA, USA) for Windows was used for data acquisition.

Capillary Gas Chromatography-Mass Spectrometry. Setup 2

GC-MS analysis was performed with a Fisons Instruments (Fisons, Egelsbach, Germany) GC 8000 Series coupled to a Fisons Instruments MD800 quadrupole mass detector. The GC was equipped with a DB-5 column (30 m \times 0.25 mm ID; $df=0.25\ \mu\text{m}$; J&W, Folsom, CA, USA), and the temperature program ramped from 60°C to 310°C with 5°C/min, hold 10 min. Helium was used as carrier gas (constant pressure, 90 mbar). A split/splitless injector (240°C) was used with purge valve opened after 60 sec. Electron impact mass spectra were recorded with an ionization voltage of 70 eV, a source temperature of 220°C and an interface temperature of 315°C. Xcalibur software (ThermoFinnigan, Egelsbach, Germany) for Windows was used for data acquisition.

Chemicals and Pheromone Compound Identification

Solvents (Fluka, Deisendorf, Germany) were distilled and checked for purity by GC-MS prior to use. (*Z*)-9-Octadecen-1-ol and 1-eicosanol were identified by comparing retention times and mass spectra of the PPG extracts with those of synthetic standards [(*Z*)-9-octadecen-1-ol: Merck Schuchard OHG, Hohenbrunn, Germany; 1-eicosanol: Dr. Ehrens-dorfer GmbH, Augsburg, Germany]. *n*-Alkanes were identified by comparing retention times and mass spectra of beewolf gland extracts with data from earlier analyses (Schmitt et al., 2003; Strohm et al., *in press*) and with data from a commercial MS library (NIST, Gaithersburg, MD, USA). The corresponding alkenes were identified by their typical mass spectra and retention times. The positions and geometries of the double bonds were inferred by comparison with earlier analyses on the chemistry of the pheromone (Schmitt et al., 2003) and of the PPG content or cuticular hydrocarbons of conspecific females that had been characterized by Fourier transform infrared (FTIR) spectrometry and dimethyl disulfide (DMDS) derivatization (Strohm et al., *in press*); peaks with identical retention times were considered to be the same isomers. Some alkenes were present only in threshold amounts in all our earlier and the current analyses and could thus not be characterized completely. The alkadienes were characterized by their typical mass spectra and their retention times. Due to their very small amounts, the position and geometry of the double bonds could not be determined. Methyl alkanes were identified by diagnostic ions, standard MS databases (see above), and by determining Kovats indices by the method of Carlson et

al. (1998). The ketone Δ -16-pentacosen-8-one was identified by comparing the retention time and mass spectrum of the peak with Δ -16-pentacosen-8-one present in the female PPG (Strohm et al., *in press*).

Statistics. Head Extracts vs. PPG Content

Peak areas were obtained by manual integration (MSD ChemStation) and relative peak areas were transformed to logcontrasts (Aitchison, 1986; Reyment, 1989) before analysis. Mean values of individual peaks were normalized by log transformation. To test for a chemical congruency between the substances found in the PPGs and in the head extracts, we conducted a regression analysis between the proportions of components (Aitchison and log transformed) in the samples directly obtained from the PPG and in the head extracts [reduced major axis regression (RMA); Legendre and Legendre, 1998] using RMA Software for Reduced Major Axis Regression v.1.17 (A. J. Bohonak, San Diego University, USA; freely available at <http://bio.sdsu.edu/pub/andy/RMA.html>). To assess the chemical similarity between the PPG samples and the head extracts, we tested whether there was a direct proportionality, i.e., the slope of the resulting regression line should not deviate significantly from 1 and the y -intercept should not deviate significantly from 0.

Statistics. Chemical Dimorphism

Peak areas were obtained by automatic integration (Xcalibur). The relative peak areas were transformed to logcontrasts (Aitchison, 1986; Reyment, 1989). Since in females the dimorphism is most striking for the compounds (*Z*)-9-pentacosene and (*Z*)-9-heptacosene (Strohm et al., *in press*), we first focused on these peaks. The different isomers of the unsaturated hydrocarbons were not well separated in the chromatograms (see below). Therefore, in the following “pentacosene” and “heptacosene” refer to the mixture of isomers. However, in all cases the (*Z*)-9 isomers were dominant.

Inspection of the chromatograms revealed that based on the proportions of pentacosene and heptacosene in their pheromone blends, males could be classified into two distinct types: those with pentacosene as the dominant hydrocarbon (C_{25} -type males) and those with comparable proportions of pentacosene and heptacosene (C_{25}/C_{27} -type males). To test for a bimodal distribution, we analyzed the frequency distribution of the proportion of heptacosene via a histogram plot (see results). The histogram revealed that the males could be assigned to two groups according to their proportion of heptacosene. We compared the proportions (relative peak areas, Aitchison transformed) of all substances between these two groups with exact tests for two independent samples (using SPSS 13.0 for Windows, SPSS Inc., Chicago, IL, USA).

Results

PPG Content

The substances found in the samples taken directly from the PPGs of three males are shown in Table 1 (the assignment of numbers to the different compounds in Table 1 is consistent throughout the manuscript). Apart from the previously described 11 substances (Schmitt et al., 2003), we characterize another 42 compounds, 33 of which were hydrocarbons and nine of which contained functional groups. Two new peaks were not identified.

Table 1 Compounds detected in the postpharyngeal gland of male *P. triangulum* arranged in the order of elution on our gc-ms setup 1

Compound	Compound Name
1	Hexanoic acid
2	Nonanal
3	Octanoic acid
4	Nonanoic acid
5	Pentadecane
6	(<i>S</i>)-2,3-Dihydrofarnesoic acid
7	(<i>Z</i>)-9-Octadecen-1-ol
8	(<i>Z</i>)-10-Nonadecen-2-one
9	1-Octadecanol
10	Heneicosane
11	Unidentified substance 1
12	Docosane
13	(<i>Z</i>)-11-Eicosen-1-ol
14	$\Delta_{x,y}$ -Tricosadiene
15	(<i>Z</i>)-9-Tricosene
16	(<i>Z</i>)-7-Tricosene
17	1-Eicosanol
18	Δ_x -Tricosene
19	Tricosane
20	5-Methyl tricosane
21	7-Methyl tricosane
22	9-Methyl tricosane
23	$\Delta_{x,y}$ -Tetracosadiene
24	(<i>Z</i>)-9-Tetracosene
25	(<i>Z</i>)-7-Tetracosene
26	Tetracosane
27	Unidentified substance 2
28	$\Delta_{x,y}$ -Pentacosadiene
29	(<i>Z</i>)-9-Pentacosene
30	(<i>Z</i>)-7-Pentacosene
31	Δ_x -Pentacosene
32	Δ_x -Docosenol
33	Pentacosane
34	13-Methyl pentacosane
35	11-Methyl pentacosane
36	7-Methyl pentacosane
37	(<i>Z</i>)-9-Hexacosene
38	Hexacosane
39	Δ -16-Pentacosen-8-one

49	Nonacosane

Table 1 (continued)

Compound	Compound Name
50	15-Methyl nonacosane
51	13-Methyl nonacosane
52	Triacontane
53	(Z)-9-Hentriacontene
54	(Z)-7-Hentriacontene
55	Hentriacontane

Head Extracts vs. PPG Content

We detected 30 compounds in the samples directly taken from the PPG and in the head extracts of the 15 individual males. Several substances had to be combined for the analysis, because peaks were not always well separated (Fig. 1). A total of 20 peaks (Aitchison and log transformed) were subjected to the correlation and regression analyses. All substances found in the PPG samples were also present in the total-head extracts and *vice versa*. Furthermore, the relative amounts of substances in the heads showed a strong linear correlation with the corresponding substances in the PPG that did not deviate significantly from direct proportionality (Fig. 1) [slope of the RMA regression line: 0.960 (95% confidence intervals, 0.797–1.123), *y*-intercept -0.1247 (95% confidence intervals, -0.2391 to -0.0104)]. The only substance deviating conspicuously from the regression line was (*S*)-2,3-dihydrofarnesoic acid, which was always more abundant in the head extracts.

Chemical Dimorphism

Twenty-three peaks were reliably identified in all 45 samples and were included in this analysis. As noted above, several peaks had to be combined for the analysis (Fig. 4). The

Fig. 1 Correlation between the relative amount (relative peak area Aitchison- and logtransformed, see text) of a particular component in the postpharyngeal gland (PPG) and in head extracts of males of the European beewolf ($r^2=0.88$, $N=20$ compounds, $P<0.001$). The regression line was generated by using reduced major axis regression ($y = 0.9600x - 0.1247$). The data are based on extracts of 15 males. The numbers correspond to the numbers in the peak list (Table 1)

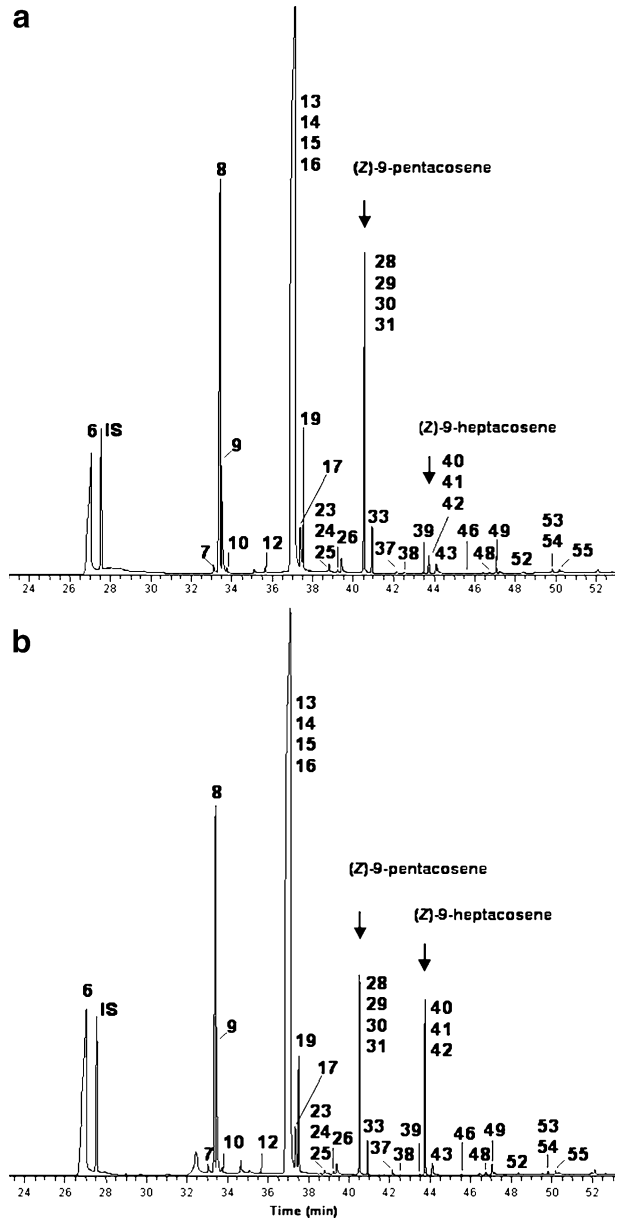

Fig. 2 Total ion chromatograms of the head extracts of an individual male with pentacosene as the predominant hydrocarbon peak (C_{25} -type, a) and an individual male with similar proportions of pentacosene and heptacosene (C_{25}/C_{27} -type, b). The numbers correspond to the numbers in the peak list (Table 1). IS: internal standard (octadecane)

chromatograms and the histogram revealed that among the 45 males analyzed, 39 individuals (87%) belonged to the C_{25} -type with pentacosene as the predominant hydrocarbon, whereas six individuals belonged to the C_{25}/C_{27} -type with pentacosene and heptacosene in approximately equal proportions (Figs. 2 and 3). Besides the differences in the proportions of pentacosene and heptacosene, the two types significantly differed in five other peaks (Fig. 4).

Fig. 3 Frequency distribution of the proportion of heptacosene (mixture of isomers, see text) in the head extracts of 45 males. The males can clearly be separated into two groups with no overlap

Discussion

Fifty-five compounds were identified from samples directly taken from the PPG of male *P. triangulum*, including 11 compounds previously described as components of the marking pheromone of *P. triangulum* males (Schmidt et al., 1990, 2003). These results, together with our observation that (as described for other *Philanthus* species; Schmidt et al., 1985) the compounds isolated from heads or PPGs of male *P. triangulum* can also be found on freshly marked territories of beewolf males (Herzner et al., unpublished data), support our hypothesis that the PPG of male European beewolves functions as the marking pheromone reservoir.

The 44 substances that had not been described by Schmitt et al. (2003) were included here for several reasons. In the earlier study, most of the minor hydrocarbons were omitted because they were also found in cuticle extracts and we concluded that they might not be part of the marking pheromone (see also Schmidt et al., 1990). Here, we show that the hydrocarbons are present in the PPG and therefore, we consider them to be part of the marking secretion. Most importantly, for the current study we pooled the gland extracts of three large males, concentrated the resulting sample and injected it manually, permitting the detection of trace components in the extracts.

One of the compounds that is new to the cephalic secretion of male European beewolves is (*Z*)-9-octadecen-1-ol. It had been previously isolated from glands and cuticle of several apid species (see, e.g., Andersen et al., 1988; Bergström, 1985) and from jojoba (*Simmondsia chinensis*) seeds (Tobares et al., 2003). 1-Eicosanol has been described as a component of the marking secretion of males of a cuckoo bumblebee (Kullenberg et al., 1970) and is present in the female sex pheromone gland of the European grapevine moth *Lobesia botrana* (Arn et al., 1988). It can also be found on cocoons and on the cuticles of different developmental stages of the honeybee *Apis mellifera* (Donzé et al., 1998). The

Fig. 4 Differences between the C₂₅-type and the C₂₅/C₂₇-type in the mean proportions of individual components of head extracts (Aitchison-transformed, $N=45$ males). Bars to the right of the line (positive values) indicate that the proportion of the given substance is higher in the C₂₅/C₂₇-type; bars to the left of the line (negative values) indicate that the proportion of the substance is higher in the C₂₅-type. Asterisks indicate significant differences (exact tests for independent samples; *** $P<0.0001$; ** $P<0.001$)

ketone Δ -16-pentacosen-8-one is also present in the PPG of *P. triangulum* females (Strohm et al., *in press*). Δ -18-Pentacosen-10-one has been found to be a contact pheromone component of the white-spotted longicorn beetle *Anoplophora malasiaca* (Yasui et al., 2003).

Based on descriptions in the literature (Gwynne, 1978; Borg-Karlson and Tengö, 1980; Schmidt et al., 1985, 1990; Evans and O'Neill, 1988; McDaniel et al., 1992), we had initially assumed that the marking pheromone in *P. triangulum* was secreted from the mandibular glands. Owing to its delicate structure (Herzner et al., *in press*), the PPG of male beeswolves is destroyed when dissecting heads to remove and extract the mandibular glands. When the PPG is damaged, its contents spill out and disperse in the head capsule contaminating the mandibular gland with the PPG contents. This was possibly the case in

previous studies on beewolf male pheromones (Borg-Karlson and Tengö, 1980; Schmidt et al., 1985, 1990, 2003).

When taking extreme care during dissection, it is possible to remove the mandibular glands without damaging the PPG. When we extracted mandibular glands that were not contaminated with the contents of the PPG, we detect only minor amounts of some of the PPG gland components (Herzner and Strohm, unpublished data). Therefore, in total head extracts, the vast majority of the compounds detected seem to originate from the PPG and not from the mandibular glands.

In our analyses, all components of the PPG were also present in total head extracts and *vice versa*. Furthermore, the proportions of all compounds were similar between the two types of extracts. The only component that showed a marked discrepancy in its relative abundance between the PPG and the head extracts was (*S*)-2,3-dihydrofarnesoic acid, which was always more abundant in the head extracts. The reason for this difference is not yet clear. Owing to the extraordinary size of the PPG (Herzner et al., *in press*), its contents dominate head extracts, and the contribution from other tissues or the cuticle to the extract is minimal. The high congruence between direct samples of the PPG and total head extracts of male European beewolves shows that the latter yield valid samples of the marking secretion. Therefore, it seems justified and far more practical to use total-head extracts for studies on the male beewolf marking pheromone. In particular, when doing quantitative analyses, the risk of losing some secretion due to improper dissection can be avoided.

The PPG has long been considered idiosyncratic to ants. In ant workers, it typically contains a blend of straight and methyl-branched hydrocarbons (Soroker et al., 1995; Cabrera et al., 2004; Lucas et al., 2004) that mainly play a role in nestmate recognition (Crozier and Dix, 1979; Soroker et al., 1998; Vienne et al., 1995; Lenoir et al., 1999). Female *P. triangulum* also possess large PPGs (Strohm et al., *in press*) that contain a blend of mainly straight-chain unsaturated and saturated hydrocarbons, as well as minor proportions of methyl-branched long-chain hydrocarbons and long-chain unsaturated ketones (Strohm et al., *in press*). Many of the hydrocarbons, as well as the ketones Δ -16-pentacosen-8-one and Δ -18-heptacosen-10-one, that were present in the male PPG are also found in the female PPG. The female PPG is morphologically different from the male gland and contains, besides the ketones, no substances with functional groups. The PPG secretion of female beewolves is used for prey preservation (Strohm and Linsenmair, 2001) and has a completely different function from the PPG content of beewolf males.

Thus, in beewolf females the PPG may be subject to natural selection to increase the protection against fungal infestation of their honeybee prey and larvae (Strohm and Linsenmair, 2001). In contrast, the PPG of males is subject to strong sexual selection (Herzner, 2004; Herzner et al., 2005, 2006; Kaltenpoth and Strohm, 2006). Such a change in function and sexual dimorphism regarding glands and their contents is not unusual (e.g., the methathoracic and dorsal abdominal glands in some Heteroptera (Aldrich, 1988; Aldrich et al., 1996; Ho et al., 2003; Zhang and Aldrich, 2003)). The significance of this sexual dimorphism remains mostly unclear, however. Even in ants, the morphology and function of the PPG seem to exhibit inter- and intraspecific variability (Schoeters and Billen, 1997; Eelen et al., 2006).

In addition to the morphological and chemical differences in PPG between the sexes, there is a dimorphism with regard to the composition of the gland content within each sex of *P. triangulum*. The majority of males (87%) had pentacosene as the dominant hydrocarbon (C_{25} -type). A minority of males (13%), however, possessed almost equal proportions of pentacosene and heptacosene (C_{25}/C_{27} -type) with a bimodal and non-

overlapping distribution of the two types with regard to the proportion of heptacosene. The chemical dimorphism in the PPG content of beewolf females is much more pronounced than in males. In females, the main compound, accounting for 70–80% of the blend, is either (*Z*)-9-pentacosene or (*Z*)-9-heptacosene, and there are no intermediate types with similar amounts of both compounds such as the C_{25}/C_{27} -type in males (Strohm et al., *in press*). The proportions of the pentacosene-morph and the heptacosene-morph in females are 80% and 20%, and similar to the proportions of the C_{25} -type and the C_{25}/C_{27} -type in males (87% vs. 13%). The meaning of this chemical dimorphism is not yet clear. The dimorphism is only exhibited by hydrocarbons without functional groups. Moreover, if the dimorphism had a genetic basis, recognition of relatives—in particular with regard to the avoidance of inbreeding (Herzner et al., 2006)—would be facilitated.

Our findings might have important implications for the evolution of the PPG within the Hymenoptera. If the PPG existed only in ants, it would be tempting to assume that it had evolved in response to the requirements of the social communication system (Hölldobler and Wilson, 1990; Lenoir et al., 1999; Eelen et al., 2006). The existence of a PPG in beewolf females suggested that this gland might have evolved in some early Aculeates for the purpose of prey preservation (Strohm and Linsenmair, 2001; Strohm et al., *in press*). We now know that the PPG in male beewolves is a marking pheromone reservoir. This beewolf marking pheromone probably represents the male sex pheromone, because females are attracted to males territories by the windborne pheromone, and most matings occur in the males' territories or in the nearby vegetation (Simon Thomas and Poorter, 1972; Alcock, 1975; Gwynne, 1978; O'Neill, 1979, 1983; Evans and O'Neill, 1988; Strohm, 1995; Strohm and Lechner, 2000; Schmitt et al., 2003; Herzner et al. 2005, 2006). Therefore, the pheromone should be subject to sexual selection with regard to both its composition and amount (Herzner, 2004, 2005, *in press*, 2006; Kaltenpoth and Strohm, 2006). Because sexual selection can be a strong evolutionary force (Kaneshiro and Boake, 1987; Lande, 1981; Higashi et al., 1999), the evolution of the gland might have been influenced by the requirements of males to store large amounts of pheromones to attract females. Regardless of the evolutionary origin of the PPG, our findings show that this gland, which was assumed to have a "social" function in ants, serves an entirely different function as a reservoir for a male sex pheromone in a solitary wasp.

Acknowledgement We thank Martin Kaltenpoth for maintaining GC-MS setup 1 and Frank Heckel for maintaining GC-MS setup 2. This study was supported by the German Science Foundation DFG (SFB 554 TP B3 and STR 532/ 1–2).

then sexuals at the end of the summer. In Central Europe, the first drones usually start emerging at the end of August, and gynes from the beginning of September. After several days, the sexuals leave the nest individually without orientation flights (Matsuura and Yamane, 1990) at which time most gynes mate only once, with double or triple mating occurring rarely (Foster et al., 1999; Takahashi et al., 2003, 2004). Details about the rendezvous sites of *Vespa* drones and gynes, as well as the male seeking strategy, are vague. Batra (1980) reported anecdotal observations of males entering nests or flying at specific places near the nests. She observed several matings on the nest envelope, and suggested that mating occurs mainly inside the nesting cavity, with colony feces acting as male attractant. In contrast, Matsuura and Yamane (1990) reported matings at the nest entrance only for *V. mandarinia*, and suggested that mating in other *Vespa* species occurs at locations other than the nest.

Chemical communication is widespread among social wasps (Landolt et al., 1998) and in *Vespa* species alarm (Veith et al., 1984; Ono et al., 2003), marking (Ono et al., 1995), and queen (Ikan et al., 1969) pheromones are known. Furthermore, cuticular lipids are involved in nestmate recognition (Ruther et al., 1998, 2002). The use of pheromones in male attraction is common in social Hymenoptera (reviewed by Ayasse et al., 2001; Keeling et al., 2004), and although there is evidence for sex pheromones in some species of the Vespidae, not a single one has been identified (Ayasse et al., 2001). Ono and Sasaki (1987) demonstrated the presence of copulation releasing pheromones in six *Vespa* species, including *V. crabro*. Cuticular extracts applied to dead drones elicited mating attempts by conspecific males, suggesting that cuticular lipids are involved. Males also attempted to copulate with immobilized gynes of other species, indicating that the chemical signals are not species-specific. However, the study was conducted in the laboratory with large groups of walking drones, and it is unknown whether extracts from gynes attract flying males over longer distances under natural conditions.

The aim of the present study was to obtain a more detailed description of the male seeking strategy in *V. crabro* in their natural habitat and to investigate whether sex pheromones or fecal volatiles are involved in mate finding. We also compared the composition of the cuticular lipids from gynes, workers, and drones.

Methods and Materials

Experimental Sites Field experiments were carried out at three different garden sites (A, B, and C with 1, 3, and 3 nests, respectively) in Berlin, in September and October 2002 and 2003. The nest at site A was a naturally founded one, whereas those at B and C had been relocated from their natural nest sites at the beginning of the colony cycle and established at their new sites for at least 6 wk prior to the emerging of drones and gynes. General observations on the male mate seeking tactics were carried out by observing the habitat around the nests on eight consecutive days, at the end of September and the beginning of October 2002 for sites B and A, respectively. The maximum number of drones seen simultaneously at any spot was determined once a day for 1 hr starting at 8.30 A.M. Additionally, the presence of patrolling drones was verified several times a day until dusk. Observations were never carried out when other experiments were taking place.

Response to Caged Gynes We investigated the response of patrolling drones to living gynes held in wooden cages (5 × 6 × 1.5 cm), with each end covered in metal screen (1.5 mm

mesh width). This arrangement allowed for the release of volatile cues but removed any visual cues. Pairs of cages (one containing a gyne and an empty control, $N=7$) were hung in bushes, 1.5–2 m above the ground, at patrol sites. Each trial lasted for 8 min, with the position of the cages being switched after 4 min. The number of drones landing on the cages was counted, and repeated landings by a drone in the same behavioral sequence were counted as one single event.

Response to Gyne and Worker Extracts Gynes and workers ($N=8$ for each caste) were frozen, washed for 1 min in 1.5 ml dichloromethane, and the extracts were stored at -18°C until used. For the bioassays, the extract of each gyne was slowly applied to the body of a worker, which had already been extracted and thus cleaned of its own cuticular lipids, using an Eppendorf pipette. The solvent was allowed to evaporate for at least 10 min. Each pair ($N=8$), consisting of one treated and one untreated worker, was hung about 20 cm apart on the outer leaves of a sun lit bush at the rendezvous sites in the two garden colonies (sites A and C). The number of drone landings, copulation attempts (protruded genitalia), and actual copulations were counted for 20 min, with the positions of treated and untreated workers being exchanged after 10 min. In a control experiment, 5 pairs of workers were tested, with one being treated with worker extract to exclude the possibility that the response of the drones was due to the extraction and reapplication procedure *per se*.

Response to Fecal Volatiles As hornets defecate under their nests, the feces may serve as an orientation cue for drones seeking gynes still inside the nests. Before placing nests inside the nesting boxes, their bottoms were covered with untreated wood chip pet litter to absorb the feces. The litter was removed from one colony after 2 mo and a 2-cm-deep layer was spread in the bottom of three open wooden boxes ($22 \times 12 \times 12$ cm). The boxes were placed at sites with drones for 1 hr on 2 d, and the number of drones inspecting the boxes was recorded.

Chemical Analyses Aliquots (1 μl) of gyne ($N=4$), worker ($N=5$), and drone ($N=6$) extracts were analyzed by coupled gas chromatography-mass spectrometry (GC-MS). Analytical separations were performed on a Fisons 8060 GC, mass spectra were obtained on a MD800 quadrupole mass spectrometer (Thermo Finnigan, Egelsbach, Germany). We used a $30 \text{ m} \times 0.32 \text{ mm}$ ID DB-5ms fused silica column, film thickness 0.25 μm (J&W Scientific), with helium (inlet pressure 10 kPa) as the carrier gas. The temperature started at 150°C , increased at $2^{\circ}\text{C}/\text{min}$ up to 300°C . Identification of the straight-chain hydrocarbons was done by comparisons of mass spectra and retention times with those of authentic reference compounds. Branched hydrocarbons were identified by diagnostic ions resulting from the favored fragmentation at the branching points (Lockey, 1988; Nelson, 1993) and by comparing retention indices with compiled data for nonpolar columns (Carlson et al., 1998). The position of the double bonds of unsaturated hydrocarbons was determined by iodine-catalyzed methylthiolation using dimethyl disulfide (Francis and Velant, 1981; Howard, 1993). Peak areas for each compound were calculated, and related to the total peak area for each run. In cases where more than one compound coeluted, detected by a scan-by-scan analysis of diagnostic ion chromatogram, only one area was calculated.

Statistical Analyses The maximum numbers of drones observed simultaneously at sites A and C were compared by using a *t*-test. The differences in the number of drones landing near and attempting to copulate with treated and untreated workers, as well as the number

of landings on caged gynes and control cages, were analyzed by using the Wilcoxon matched-pair test. The relative abundance of lipids in cuticular extracts from gynes, workers, and drones were compared via a Kruskal–Wallis ANOVA and Mann–Whitney U tests. All tests were run with Statistica 5.1 scientific software (StatSoft, Tulsa, OK, USA).

Results

Male Seeking Strategies Patrolling drones were observed at all three nesting sites, at different spots up to 185 m away from the actual nests. We found 10 different spots at site A and 6 at site B. Drones flew with their oriented heads towards vegetation such as bushes, trees, and hedges, which were only visited if they were in direct sunlight. After patrolling a spot for a few seconds, they flew to another one. No substrate marking behavior was observed, and there was no evidence that drones preferred to alight on specific parts of the vegetation. During the whole period, they only alighted five times and never at the same site. The maximum number of drones observed simultaneously at one spot was 4 ± 1.4 ($N=19$ observations) with no difference between sites A and C ($t=-1.39$, $df=17$, $P=0.183$), and there was no evidence of aggression (e.g., chasing) between individuals. Males started patrolling the early morning when it was sunny, even when temperatures were as low as 7°C , but they were never encountered after 4 P.M. ($N=5$ observations). On three occasions, drones were observed alighting on colony nesting boxes, but were chased away by workers before they could enter the hive.

Response to Caged Gynes Drones alighted more often on cages with gynes than on the control cages ($Z=2.201$; $P=0.028$; Table 1). During each trial, 2–7 drones were patrolling the bushes with cages.

Response to Gyne and Worker Extracts Drones alighted beside or on ($Z=2.37$, $P=0.018$; Table 2), and attempted to copulate ($Z=2.20$, $P=0.028$) more often with gyne extract-treated than control workers. In three cases, drones succeeded in copulating with the dead workers (Fig. 1). Workers treated with their own cuticle extract did not elicit significantly more landings ($N=4$) of drones than the controls ($N=3$; $Z=0.53$; $P=0.60$), and no copulation attempts were observed.

Response to Fecal Volatiles The litter containing nest fecal matter was completely ignored by the drones at all sites, and none ever alighted on a box.

Chemical Analyses The chemical analyses of cuticular extracts from gynes, workers, and drones by GC-MS revealed 65 chromatographic peaks but as some compounds co-eluted, 86 chemicals were identified (Table 3, Fig. 2). No components were detectable within the first 15 min. Apart from the two terpenoid esters citronellyl citronellate and citronellyl geranylate, all compounds were typical cuticular hydrocarbons (saturated, monounsaturated, monomethylalkanes, and dimethylalkanes) with chain lengths between 21 and 33 carbon units. Extracts from workers and drones were similar with only the relative abundance of 15 peaks being significantly different between the two. In contrast, the hydrocarbon profiles from queens were more diverse, and 50 out of the 65 peaks occurred in significantly higher relative abundances in gynes than in workers and drones. The most striking differences between extracts from gynes and those of workers and drones were that (a) citronellyl citronellate (peak 1) and citronellyl geranylate (peak 4) were not found in gynes; (b) whereas all three had monoenes with a double bond in position 9 (peaks 5, 16, 30, 46), gynes also had considerable amounts of other monoenes, particularly with double bonds in position 7 and 5

^a Numbers with different lowercase letters are significantly different at $P < 0.05$ (Mann–Whitney *U* test).

(peaks 6, 7, 17, 18, 31, 32, 47, 48); (c) 3-methyl derivatives (peaks 12, 23, 38) were common to all three morphs, but queens also had relative high amounts of alkanes with methyl branches at the more central positions 5, 7, 9, 11, 13, and 15 (peaks 9–11, 20–22, 34–36, 50, 51, 62); and (d) dimethylalkanes were generally more abundant in gyns (peaks 37, 39, 44, 52, 53, 55, 58, 63, 65).

Discussion

Our observations suggest that the mate finding strategy of *V. crabro* drones consists of nonaggressive patrolling behavior close to a nesting site, as reported for *V. maculifrons* (Post, 1980), without the establishment of substrate-based lek systems (Shelly and Whittier, 1997) seen in some paper wasps or hover wasps (Beani et al., 1992, 2002). This is supported by our observations, and those of Batra (1980) of drones patrolling at considerable distances from the nest. However, we rarely saw drones attempting to enter a nest, and when they tried, guard workers effectively drove them off. This is in contrast to the report of Batra (1980). However, one cannot rule out the possibility of the ability of *V. crabro* drones to enter nests under certain conditions, as intraspecific differences in mate seeking strategies have been reported for some bee species (Paxton, 2005). We did not observe marking behavior by *V. crabro* drones, as suggested by Batra (1980) or as been described in polistine wasps (Beani and Calloni, 1991). There are no examples of male marking behavior by vespine wasps in the literature (Downing, 1991).

The study demonstrates the involvement of a female sex pheromone in the mating system of *V. crabro*. The fact that drones alighted on cages containing gynes but never on control cages suggests that visual information is of minor importance. It is also unlikely that acoustic signals play a role in hornet mate finding, since they are neither able to detect airborne soundwaves nor able to produce sound with their folded wings. Hence, behavioral display by the gynes is not essential for male attraction. We found no evidence to support the hypothesis that volatiles of the feces from a hornet nest attract drones (Batra, 1980).

Summarizing these observations, the mating system of *V. crabro* fits into the conceptual framework about patterns in male-seeking tactics of Hymenoptera considering the rendezvous site, male sexual behavior, the use of sex pheromones, and the density and distribution of both sexes (Alcock et al., 1978; Ayasse et al., 2001). Since each nest produces several reproductives, this aggregation of gynes leads to a rendezvous site near the emerging site of the females, which are using sex pheromones to attract the males. Such a female-produced sex attractant is well known in ants (Hölldobler and Bartz, 1985) and other social wasps (Downing, 1991; Landolt et al., 1998), as well as in nonsocial parasitic wasps (Eller et al., 1984; Kaihno et al., 1991; Swedenborg and Jones, 1992; Swedenborg et al., 1993; McNeil and Brodeur, 1995).

Cuticular hydrocarbons are of importance for many social insect species (Howard and Blomquist, 2005), involved in nest (e.g., Singer and Espelie, 1992; Sumana et al., 2005) and nestmate (e.g., Ruther et al., 1998, 2002; Dani et al., 2001) recognition, as well as for marking trails between the actual nest and the entrance of the cavity housing a nest in a cavity breeding species (Steinmetz et al., 2002). In *Polistes dominulus* queens (Vespidae), there is a relationship between cuticular hydrocarbon profiles and the size of the corpora allata, the source of juvenile hormone that modulates ovarian development and sexual maturation (Sledge et al., 2001, 2004). A similar relationship could also exist in *V. crabro*, with males responding most to the cuticular profiles of sexually mature females. The active compounds in *V. crabro* gynes remain active, even when females are stored in separate glass vials at -18°C . This suggests that these bioactive hydrocarbons are stable and of low volatility, but clearly (as seen in this study) are sufficiently volatile to attract patrolling *V. crabro* males over some distance. A similar situation has been reported for

◀ **Fig. 2** Reconstructed total ion chromatograms of cuticle extracts from (a) gynes, (b) workers, and (c) drones of *V. crabro*. Peak numbers correspond to Table 3

deceptive orchids that mimic the sex pheromones of solitary bees, as flying *Andrena nigroaenea* males were attracted to dummies treated with a mixture of synthetic hydrocarbons with chain lengths between 21 and 29 carbon units (Schiestel et al., 1999, 2000).

Butts et al. (1995) reported that cuticular hydrocarbon profiles from *V. crabro* are colony-specific, with only quantitative differences between queens and workers. However, these authors identified only 13 compounds, possibly due to the use of suboptimal analytical techniques that could neither resolve the different monoenes nor detect numerous minor components. Another possible explanation for the difference between our results and those of the previous study is that the authors used old, mated queens from colonies rather than unmated gynes. As noted above, there is a relationship between cuticular profiles and ovarian development, and in addition the pheromone bouquet in some species of Hymenoptera can change after mating (Ayasse et al., 1990, 1999; Engels et al., 1993; Pankiw et al., 1996). Future studies are necessary to establish which of the gyne cuticular hydrocarbons are important in mate finding by *V. crabro* drones, probably by using GC-electroantennographic detection (EAD), as this approach has been successfully used for male hymenopterans (Schiestel et al., 1999).
