Biparental Endowment of Endogenous Defensive Alkaloids in *Epilachna paenulata*

Soledad Camarano · Andrés González · Carmen Rossini

Received: 2 October 2008 / Revised: 17 October 2008 / Accepted: 7 November 2008 / Published online: 4 December 2008

Abstract Coccinellid beetles contain a variety of defensive alkaloids that render them unpalatable to predators. *Epilachna paenulata* (Coleoptera: Coccinellidae) is a South American ladybird beetle that feeds on plants of the Cucurbitaceae family. The defensive chemistry of *E. paenulata* has been characterized as a mixture of systemic piperidine, homotropane, and pyrrolidine alkaloids. Whole body extracts of adult beetles contain four major alkaloids: 2-(2′-oxopropyl)-6-methylpiperidine (**1**); 1-(6-methyl-2,3,4,5-tetrahydro-pyridin-2-yl)-propan-2-one (**2**); 1-methyl-9-azabicyclo[3.3.1]nonan-3-one (**3**); and 1-(2″-hydroxyethyl)-2-(12′-aminotridecyl)-pyrrolidine (**4**). Comparative studies of the defensive chemistry of eggs, larvae, pupae, and adults showed differences in alkaloid composition and concentration among life stages. While adults contained mainly the homotropane 1-methyl-9-azabicyclo[3.3.1]nonan-3-one (**3**), eggs showed the highest concentration of the piperidine 2-(2′-oxopropyl)-6-methylpiperidine (**1**). We studied the origin of this alkaloid in the eggs by feeding newly emerged, virgin adult beetles with [2-^{13}C]-labeled acetate, and by performing crosses between ^{13}C-fed and unlabeled males and females. GC-MS analysis of alkaloids from ^{13}C-fed males and females showed high incorporation of ^{13}C into the alkaloids, as evidenced from a 20–30% increase of isotopic peaks in diagnostic fragment ions, confirming the expected endogenous origin of these alkaloids. In addition, analyses of eggs from different crosses showed that labeled alkaloids from both parents are incorporated into eggs, indicating that *E. paenulata* males transfer alkaloids to the females at mating. Biparental endowment of chemical defenses into eggs has been shown previously in insects that acquire defensive compounds from dietary sources. To our knowledge, this is the first report of biparental egg endowment of endogenous defenses.

Keywords *Epilachna paenulata* · Nuptial gift · Biparental endowment · Egg defense · Coleoptera · Coccinellidae

Introduction

Ladybirds have been a remarkable source of novel structures, mainly alkaloids (Glisan King and Meinwald 1996) and polymeric nitrogen-containing substances (Schroeder et al. 1998a, b). Such compounds, which may have a clear defensive purpose (Eisner et al. 1986, 2002; Attygalle et al. 1993a, b; Glisan King and Meinwald 1996), include azaphenalenes, azabicyclo nonanes (homotropane), aliphatic and aromatic amines, pyrrolidine and piperidine alkaloids, azamacrolides and macrocyclic polyamines. In most cases, coccinellid alkaloids are of endogenous origin (Attygalle et al. 1994; Laurent et al. 2001, 2002), although a few studies have reported ladybird species that sequester alkaloids from their food source (Witte et al. 1990; Pasteels 2007).

Epilachna paenulata Germar 1824 (Coleoptera: Coccinellidae) is a phytophagous South American ladybird beetle that feeds on the leaves of cucurbits. The adults exhibit defensive capacity against generalist predators, due to the presence of systemic alkaloids that have been characterized

as a mixture of piperidine, homotropane, and pyrrolidine alkaloids (Scheme 1). Specifically, adult beetles contain four major alkaloids: 2-(2′-oxopropyl)-6-methylpiperidine (**1**); 1-(6-Methyl-2,3,4,5-tetrahydro-pyridin-2-yl)-propan-2-one (**2**); 1-methyl-9-azabicyclo[3.3.1]nonan-3-one (**3**); and 1-(2″-hydroxyethyl)-2-(12′-aminotridecyl)-pyrrolidine (**4**) (Camarano et al. 2006). These alkaloids are present in all life stages of the insect, albeit showing qualitative and quantitative variations among developmental stages (Camarano et al. 2006).

We have shown previously that the highest alkaloid concentration in *E. paenulata* is found in the eggs. Indeed, the concentration of the main egg alkaloid, piperidine **1**, is higher in the eggs than in the females that laid those eggs (Camarano et al. 2006), thus suggesting some mechanism of preferential endowment of alkaloid from females to eggs, or an additional source of alkaloid that finds its way into the eggs. We investigated the latter hypothesis. Specifically, we asked whether males transfer part of their alkaloids to the female, and if so, whether these alkaloids are found in the eggs.

Methods and Materials

Insects E. paenulata adults were obtained from a laboratory colony regularly maintained on squash plants (*Cucurbita* sp.), under controlled conditions of temperature (23±2°C) and a photoperiod L:D 16:8 h. For the initial settlement of the colony, individuals were collected on squash plants at organic farms near Montevideo, and new field-collected individuals were added every year. The different life stages were maintained separately in screened cages (30×30×30 cm), and 9 to 12 food plants (3-wk-old) were replaced every 3–4 days (Camarano et al. 2006).

Alkaloid Labeling Incorporation of ^{13}C labels to the alkaloids was done by feeding the adult beetles with squash leaves treated topically with [2-^{13}C]-sodium acetate (40 mg/ml in MeOH).

To analyze a pool of individuals (N=25), complete squash leaves were treated with 3.2 μg of labeled acetate/beetle/day. Beetles were allowed to feed for 5 days and then frozen for alkaloid analysis.

For hemolymph analyses, 80 μl of the same solution were applied on squash leaf disks (2.5 cm diam), and the disks were offered to newly emerged adults (N=8) caged in individual containers (4 cm diameter×8 cm height). Leaf disks were placed on agar (2%) to avoid dehydration and replaced daily. On day 5, the beetles were gently disturbed with forceps to trigger the reflex bleeding reaction that is typical of insects with systemic defenses, and the hemolymph was collected in glass capillaries (5 μl, Drummond Sci. Co.) for alkaloid analysis (González et al. 1999a; Camarano et al. 2006; Camarano 2008). The same protocol was followed to label the alkaloids in male or female beetles used for mating experiments and egg collection.

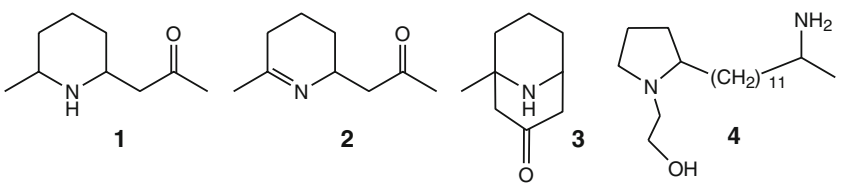
Control experiments were run under identical conditions for both labeling procedures, treating the leaves or leaf discs with methanol. Control and ^{13}C-fed beetles were all kept under the same environmental conditions described above.

Mating and Egg Collection Horizontal (male to female) and vertical (female to egg) alkaloid flow were studied by setting different mating pairs, in which one of the parent beetles had been fed with ^{13}C acetate (hereafter indicated with an asterisk: ♀* or ♂*).

To study male alkaloid transfer, eight virgin control females (♀) were placed individually with virgin ^{13}C-fed males (♂*). To determine if copula had taken place, the position of the beetles was recorded on video (Panasonic AG-DP200E Camera, recording 1 s every 10 min). After mating, the male was removed, and hemolymph was collected from the female 24 h later. Females were then allowed to lay eggs in the same containers (see next paragraph).

The vertical flow of alkaloids was studied similarly by collecting eggs from three groups of mating pairs: ♀* × ♂ (N=4), ♀ × ♂* (N=4), and ♀ × ♂ (N=2, control).

Alkaloid Extraction Three procedures for alkaloid extraction were carried out, depending on the matrix and sample size: (1) 25 pooled adults were killed by freezing and extracted under stirring with methanol (3 h); the extract was filtered, dried under vacuum, re-suspended in HCl (0.2 M), and washed with hexane (3×15 ml). The pH of the remaining aqueous phase was increased to 10 (NaOH, 1 M), and the alkaloids were extracted with methylene



Scheme 1 Systemic alkaloids identified in *E. paenulata*

chloride (3×15 ml). This final extract was concentrated under vacuum, at room temperature; (2) alkaloids from the hemolymph were extracted by suspending freshly collected hemolymph in 200 µl of ammonium hydroxide (pH 8) and extracting the alkaloids with methylene chloride (3× 150 µl); (3) alkaloids from the eggs were extracted with methanol (1 ml) at room temperature (24 h). Eggs were crushed to facilitate the extraction, and the solid remains were separated by centrifugation (14,000 rpm, 10 min). The supernatant solution was taken to pH 8 (NaOH), and extracted with methylene chloride (3×150 µl). In the two latter procedures, the joined methylene chloride extractions were concentrated to ca. 100 µl under N_2.

Analytical Procedures To determine ^{13}C incorporation into *E. paenulata* alkaloids, the extracts were analyzed by GC-MS as follows: extracts from pooled adults were analyzed by using an HP 5791 instrument equipped with an Elite-5 column (30 m; 0,32 mm), splitless injection in CH_2Cl_2, and a temperature program starting at 60°C (4 min) to 300°C (8 min) at 10°C/min. Injector and interphase temperature were 300°C, and total ion current detection mode was used. In the case of egg and haemolymph extracts, GC-MS analyses were performed on a Shimadzu QP 5050 or a Shimadzu QP 2010 [Carbowax 20M, 25 m, 0.32 mm; splitless injection in CH_2CI_2, 60ºC (6 min) - 204ºC (20 min) at 10ºC/min. Injector and interphase temperature: 250ºC]. Alkaloids (**1**, **2**, and **3**), where incorporation was studied, were identified previously on the basis of NMR and/or mass spectral data (Camarano et al. 2006). MS data are included in Table 1, Supplementary material. To enhance sensitivity, detection of alkaloids in the egg extracts was done by single ion monitoring (SIM) of the characteristic ions, specifically choosing the following peak clusters: 98-99-100-101-102-103 (characteristic of alkaloid **1**), 110-111-112-113-114-115-116 (characteristic of alkaloids **2** and **3**), 153-154-155-156-157-158-159-160 [cluster including M+ of **1** (*m/z*=155) and **2** and **3** (*m/z*=153)] (Camarano 2008). A validation process comparing mass spectra acquisition by two modes, total ion current and single ion monitoring, was carried out to ensure that acquisition by SIM had no effect on the data (Supplementary material Figs. 1 and 2).

Calculations of ^{13}C-enrichment of alkaloids were performed with freeware developed by the National Institutes of Health, US (available on line at http://sx102a.niddk.nih.gov/iso.html, last accessed in 2007, Hess et al. 2002). The program compares the relative intensities of all ion peaks within an ion cluster, for enriched and control samples, and calculates the enrichment as percent MPE (mole percentage excess) of the stable isotope related to its natural abundance, as well as the maximum number of labels incorporated.

Results

[2-^{13}C]-Acetate Incorporation into E. paenulata Alkaloids The analysis of alkaloid extracts from pooled adults (*N*=25) showed only the homotropane **3**. Analysis of the corresponding peak clusters (*m/z* 110 and 153) showed an incorporation of ^{13}C from acetate into this alkaloid, with a MPE of 22%.

In hemolymph samples, despite their low concentration, alkaloids **1**, **2**, and **3** were detected by GC-MS analyses in all the samples (e.g., alkaloid **3**, Fig. 1). The relative intensities within different ion clusters showed that *E. paenulata* incorporated labeled acetate into the three defensive alkaloids, with MPE of 20% to 30% (Table 1, Fig. 1). Noteworthy, this methodology allows the follow-up of ^{13}C incorporation within an individual through time, since hemolymph extraction does not injure the insect.

Alkaloid Egg Endowment (Vertical Flow) GC-MS analyses of egg samples showed detectable amounts of alkaloids **1** and **3** (SIM detection). Extracts of eggs laid by females from ♀* × ♂ mating pairs evidenced ^{13}C incorporation (Table 2) with up to five labels in alkaloid **3**, indicating that females transfer their own alkaloids to the eggs. Interestingly, the analyses of eggs laid by control females mated to ^{13}C-fed males (♀ × ♂*) also showed labeled alkaloids, indicating that male alkaloids are also transferred to the eggs they sire (Table 2, Fig. 2).

Male Nuptial Gift (Horizontal Flow) The existence of an alkaloidal nuptial gift from males to females at mating can be inferred from the fact that male alkaloid finds its way into the eggs. We also studied the fate of the male alkaloids in the females, by analyzing the hemolymph of mated females from ♀ × ♂* mating pairs. The main alkaloids in these hemolymph samples were **2** and **3**, but no evidence of ^{13}C labeling was found, suggesting that the male alkaloids do not pass the systemic circulation in the female, but rather remain confined to the female reproductive tract.

Discussion

The three major alkaloids (**1-3**) in *E. paenulata* showed incorporation of [2-^{13}C]-acetate when fed with squash leaves treated with the labeled precursor. These results confirm the notion that defensive alkaloids in this beetle are endogenous, as it is the case in other coccinellid species (Attygalle et al. 1993b, 1994, 1999; Glisan King and Meinwald 1996; Farmer et al. 1997; Radford et al. 1997; Schroeder et al. 1998a, b; Braekman et al. 1999; Laurent et

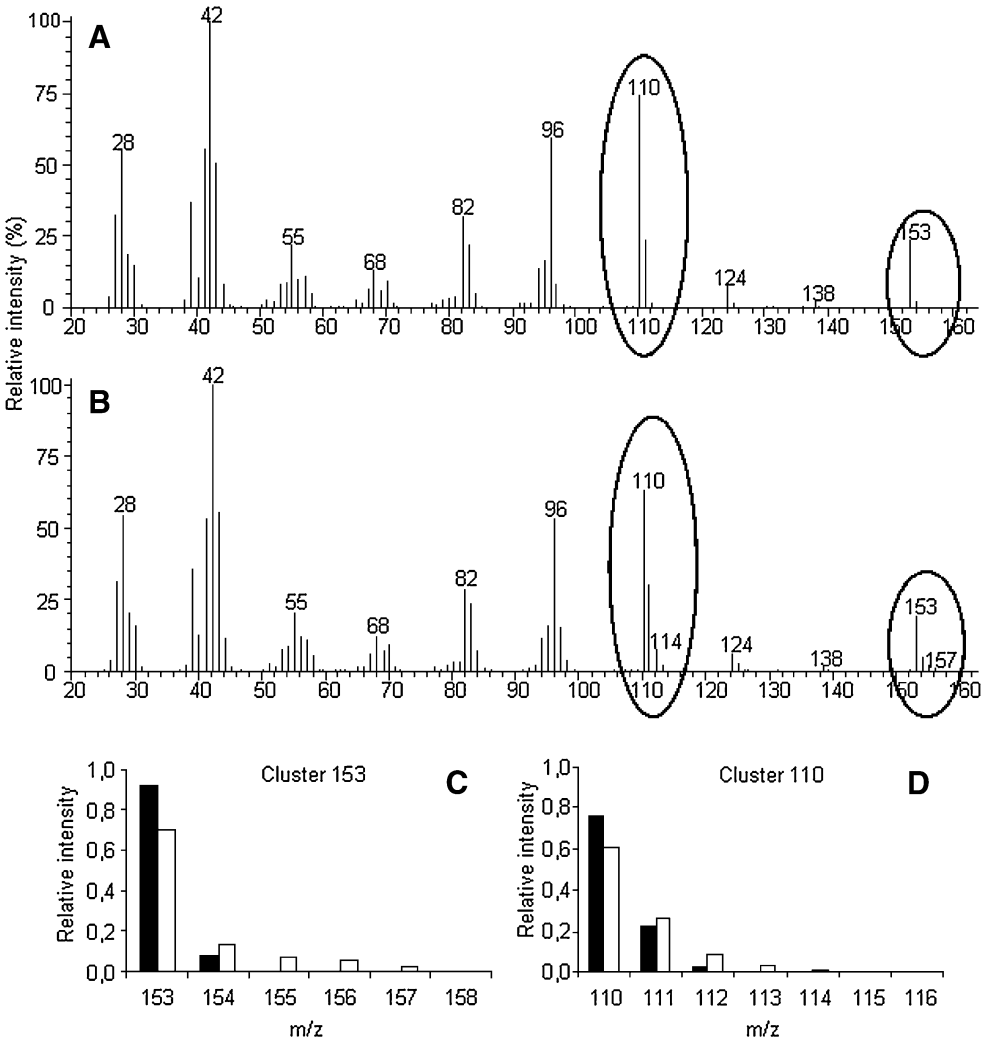


Fig. 1 MS trace of alkaloid **3** from hemolymph samples of *E. paenulata* individuals fed on normal diet (**a**) and on [2-^{13}C]-sodium acetate enriched diet (**b**). Two characteristic ion clusters show evidence for ^{13}C incorporation, given the relative increase of ions up to *M*+4. The relative intensities are presented in normalized form in **c** (*m/z* 153 cluster) and **d** *m/z* 110 cluster (*filled squares* control; *empty squares* ^{13}C-enriched samples) (TIC detection)

al. 2001, 2002). When using SIM detection, our data show that the alkaloids incorporated up to five acetate units (Table 2), which is in accordance with the polyacetate biosynthetic pathway that has been proposed for coccinellid alkaloids (Laurent et al. 2001). Preliminary experiments also showed weak incorporation of [18-D_3]-stearic acid into *E. paenulata*'s piperidine **2** (data not shown), suggesting a fatty acid-derived pathway. This is in agreement with earlier findings by Laurent et al. (2002), who demonstrated a fatty-acid biosynthetic pathway for the alkaloids adaline and coccinelline in *Adalia 2-punctata* and *Coccinella 7-punctata*, respectively. In plants, pyrrolidine and piperidine alkaloids are derived from amino acids such as ornithine and lysine, which cannot be ruled out from our data (Dewick 1997).

The incorporation of ^{13}C into the alkaloids allowed us to study the horizontal and vertical flow of chemical defenses in this beetle, since it made it possible to differentiate alkaloids from males and females. Eggs coming from one "labeled" parent, either female or male, showed alkaloid **1** and **3** labeled with ^{13}C (Table 2). Although egg protection by female defensive compounds is expected, our data show that males also can protect the eggs that they sire, by transferring part of their alkaloidal load to the females at mating. Since the males were removed from the mating container several days before the eggs were laid, the male must transfer the alkaloids to the female, and she then transfers the male's and her own alkaloids to the eggs.

Table 1 Enrichment of *E. paenulata* alkaloids in hemolymph samples from adults fed with [2-^{13}C]-sodium acetate

Alkaloid	*m/z*	Max. number of labels	Percent MPE[a] (mole percentage excess)
1[b]	98	1	26±5
2	110	2	26±9
	153	2	24±10
3	110	3	23±7
	153	4	24±7

[a] Data are shown as mean±SD (*N*=8) of the % MPE
[b] For alkaloid **1**, results are presented for ion cluster *m/z* 98, due to the low intensity of the M^+ cluster (*m/z* 155)

Table 2 Enrichment and maximum number of labels incorporated to alkaloids **1** and **3** in *E. paenulata* egg samples from different mating pairs

Alkaloid	*m/z* cluster	Origin of egg sample			
		♀* x ♂		♀ x ♂*	
		Max. number of labels	Percent MPE	Max. number of labels	Percent MPE
1	98	3	16±4	3	18±7
3	110	3	28±5	3	23±6
	153	5	23±5	3	20±5

Results are shown as mean±SD (N=4 for both mating types)
* Denotes individuals fed on [2-^{13}C]-sodium acetate enriched diet

Insect eggs often contain chemical defenses, and these toxins are provided either by the female, the male, or both sires (Hinton 1981; Hilker 1994). Males of several insect species pass a nuptial gift to the female at mating (Vahed 1998, 2007), and it is not uncommon that part of this gift is allocated to the eggs (Vahed 1998; Eisner et al. 2002). Biparental endowment of egg defenses has been demonstrated in a number of systems in which the defensive chemicals are acquired from the diet (Ferguson et al. 1985; Dussourd et al. 1988; Nishida and Fukami 1989; Blum 1992; González et al. 1999a; Hartmann 1999; Eisner et al. 2002). To our knowledge, however, biparental egg endowment of endogenous defenses, as shown here, has not been demonstrated before. In the case of cantharidin, a terpene anhydride produced de novo by some oedemerid and meloid beetles, the situation varies among species. In *Oedemera femorata* (Coleoptera: Oedemeridae), both sexes produce cantharidin, but females produce higher amounts than males. Transfer of cantharidin from males to females at mating was not found in this species, and hence, cantharidin in the eggs appears to originate solely from females (Carrel et al. 1986; Holz et al. 1994). In members of Meloidae, such as *Lytta vesicatoria*, the females are unable to produce their own cantharidin, and they receive it as a nuptial gift from males at mating. Females then bestow part of this cantharidin gift into the eggs (Meyer et al. 1968; Schlatter et al. 1968; Sierra et al. 1976; Eisner et al. 2002). Conversely, in the case of *Epicauta funebris*, only adult males keep the larval capability of biosynthesizing cantharidin, and although there is seminal transmission of cantharidin, it is not transferred into eggs, but rather kept by the females, likely for self-protection (McCormick and Carrel 1987; Carrel et al. 1993).

In *E. paenulata*, the presence of male alkaloid in the eggs indicates a nuptial gift, but the pathway by which this gift reaches the eggs remains unknown, since we did not detect male-labeled alkaloid in the hemolymph of the females they mated with. This result suggests that most of the male alkaloid remains confined within the female reproductive tract, from where it is allocated into the eggs, probably as they are laid. Careful dissections of the female reproductive tract and analysis of its parts, in particular the spermatheca (Rossini et al. 2001; Nikbakhtzadeh et al. 2007), should provide insight about the fate of male alkaloids after seminal transfer. In other insects, defensive male nuptial gifts become systemic within the female body. In *Utetheisa ornatrix* (Lepidoptera: Tortricidae), for exam-

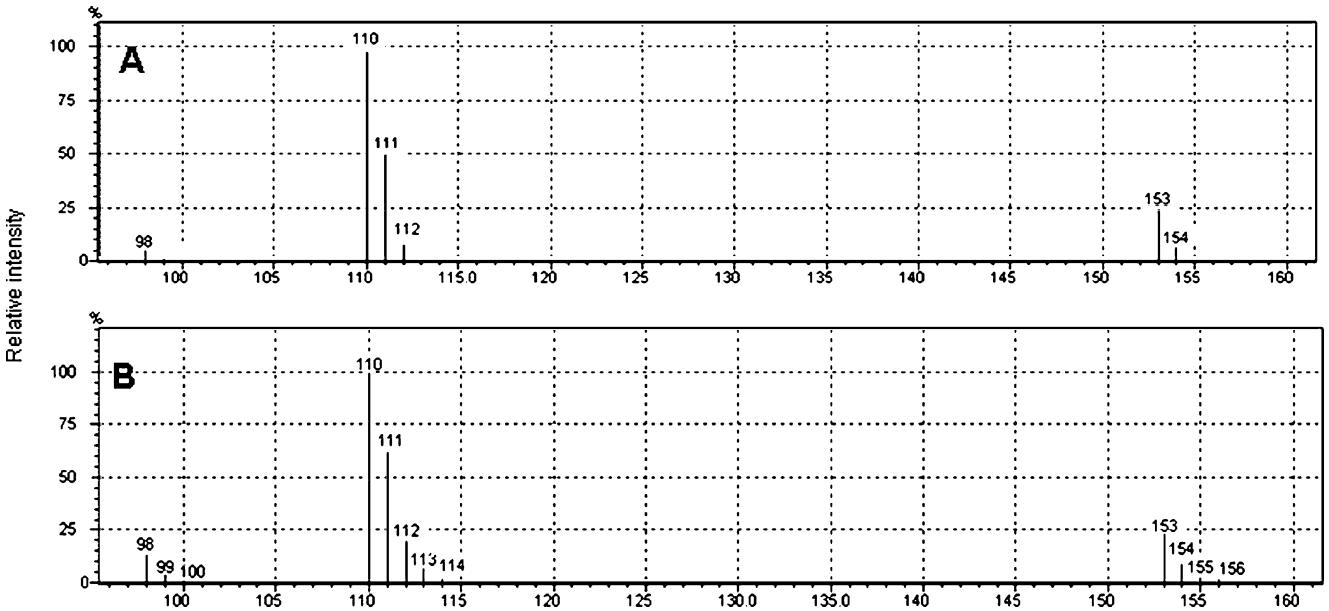

Fig. 2 MS traces of homotropane **3** from eggs laid by control *E. paenulata* females (**a**) and control *E. paenulata* females mated to ^{13}C-fed males (**b**) (SIM detection)

ple, females can use the pyrrolizidine alkaloids transferred by males both for their own defense and for the protection of the eggs (González et al. 1999b), since the alkaloids become systemic even before the mating pair uncouples.

The adaptive value of male egg protection in *E. paenulata* is open to question. The female load may be insufficient to properly protect the eggs against predators and/or microorganisms. Obtaining and testing eggs with different alkaloidal loads, below and above female levels, would be useful to test this hypothesis. If male defenses do make a difference for the fitness of the female, it opens the possibility for some overt or cryptic process of sexual selection that may favor males with larger alkaloid loads.

Abstract We tested the hypotheses that host-searching behavior of the egg parasitoids *Telenomus podisi* and *Trissolcus basalis* may be differentially influenced by the different blends of volatiles released from the metathoracic glands of adult stink bug host species. We further studied whether such a differential response is due to different individual components of these glands and whether these responses reflect host preferences. Y-tube olfactometer bioassays were carried out with crude extracts of metathoracic glands of five different host species of neotropical stink bugs. Additionally, we tested the parasitoids' responses to synthetic standards of individual compounds identified in these stink bug glands. Results showed that females of *T. basalis* and *T. podisi* responded differentially to crude gland extracts of the different species of host stink bugs and to the compounds tested. The parasitoid *T. basalis* showed a positive taxic behavior to *Nezara viridula* methathoracxic gland extracts of a host species preferred in the field, i.e., *N. viridula.* Furthermore, *T. basalis* responded positively to 4-oxo-(*E*)-2-hexenal and (*E*)-2-decenal, two components of *N. viridula* glandular secretion. Higher residence time, reduced linear velocity, and higher tortuosity in the arm of the olfactometer supplied with 4-oxo-(*E*)-2-hexenal showed that this compound modifies the kinetics of some traits of *T. basalis* walking pattern and suggests that it might stimulate the searching behavior of this parasitoid. The parasitoid *T. podisi* was attracted to crude gland extracts of the preferred host (*Euschistus heros*) and also to 4-oxo-(*E*)-2-hexenal. Additionally, this parasitoid responded positively to (*E*)-2-hexenal and to the hydrocarbon tridecane, both of which are defensive compounds released from the metathoracic glands by several stink bugs. The results indicate some degree of specialization in the response of two generalist parasitoid species toward defensive secretions of stink bugs.

Introduction

Parasitoids are known for using semiochemicals as medium- and long-range cues when searching for hosts (Vinson 1985, 1998; Vet and Dicke 1992; Steidle and van Loon 2002; Fatouros et al. 2008). Semiochemicals that originate from the host habitat, the hosts themselves, or indirectly from stages associated to the host can be used by parasitoids during a hierarchical sequence of steps for host location and selection (Vinson 1985).

Egg parasitoids face the challenge of finding hosts that are not, or are barely apparent (eggs). Therefore, they must

rely on semiochemical cues that are more detectable than those from the eggs, such as those from stages of the host that are not suitable for parasitism (adults or immature stages) or from host plants (Vet et al. 1991, 1995; Vet and Dicke 1992; Vinson 1998; Fatouros et al. 2008).

Scelionidae that parasitize eggs from stink bugs can use several types of semiochemicals for long-range localization of habitat, microhabitat, and hosts: volatiles from plants damaged by stink bug oviposition or feeding (Colazza et al. 2004; Moraes et al. 2005a, 2008); sex pheromones (Aldrich 1985, 1995; Borges et al. 1998, 2003; Bruni et al. 2000; Silva et al. 2006); volatile defensive secretions from the metathoracic (adults), or dorsal abdominal (nymphs) glands of stink bugs (Aldrich 1985, 1995; Mattiaci et al. 1993; Borges and Aldrich 1994); or crude whole body extracts of stink bugs (Colazza et al. 1999; Salerno et al. 2006). Volatiles from nonhost stages of stink bugs, such as pheromones or defensive compounds, as well as contact chemicals (traces left by walking insects) also can be used for host location, recognition, and acceptance, thus leading to successful oviposition (Bin et al. 1993; Borges et al. 1999, 2003; Colazza et al. 1999; Conti et al. 2003). Physical stimuli such as visual and resonance cues also may be involved in successful host search (Borges et al. 1999). Laumann et al. (2007) demonstrated that foraging *Telenomus podisi* Ashmead, 1881 can orientate toward hosts by using substrate-borne vibratory signals produced during sexual communication of host stink bugs.

The Scelionidae comprise a large family with about 3,000 described species (Masner 1993) that primarily attack eggs of Heteroptera and Lepidoptera and less frequently are reported as egg parasitoids of Diptera, Orthoptera, Coleoptera, and Araneae (Arias-Penna 2002; Austin et al. 2005). In central Brazil, *Trissolcus basalis* (Wollaston 1958) and *T. podisi* are common parasitoids of stink bug eggs. In soybean agroecosystems in Brazil, *T. basalis* shows high parasitism in eggs of the pentatomid stink bug *Nezara viridula* (L., 1758) and *T. podisi* in eggs of the pentatomid *Euschistus heros* (Fabricius 1794) (Corrêa-Ferreira and Moscardi 1995; Medeiros et al. 1997, 1998; Pacheco and Correa-Ferreira 2000). These field observations were confirmed by Sujii et al. (2002) in a laboratory study, who reported that *T. podisi* showed high parasitism indices in *E. heros* eggs both in no choice and multiple-host choice experiments. In the same set of experiments, *T. basalis* showed high parasitism indices on eggs of *N. viridula* and *Piezodorus guildinii* (Westwood. 1837) in no choice experiments and showed a clear preference for eggs of *N. viridula* in multiple-host choice experiments (Sujii et al. 2002).

Aldrich (1995) pointed out that preferences observed in scelionid wasps may be based on differential long-range attraction to stink bugs allomones. There is evidence that *T. basalis* uses (*E*)-2-decenal, a defensive compound of *N. viridula*, as a kairomone (Mattiaci et al. 1993).

In this study, we tested the following hypotheses by using *T. podisi* and *T. basalis* and five different stink bug species as hosts: (1) Host-searching behavior of the egg parasitoids is differentially influenced by blends from metathoracic glands of the different host stink bug species; (2) Individual components of these blends may be responsible for such a differential response; (3) A differential response to odor from metathoracic glands of hosts is related to the preference for these host species.

We recorded the parasitoids' behavioral responses in a Y-tube olfactometer to crude metathoracic gland extracts of five neotropical stink bugs species and to synthetic standards of individual compounds of the metathoracic glands of different species.

Methods and Materials

Insects Parasitoids used in this work were obtained from a laboratory colony that started from parasitized stink bug egg masses collected near the Embrapa Genetic Resources and Biotechnology Laboratory in Brasilia, DF, Brazil (15°47′ S and 47°55′ W). Insects were maintained in an environmental chamber in plastic cages (25-cm^2-angled-neck tissue culture flasks, ICN Biomedicals) under a 14-h photophase at 26.0± 0.5°C and 65±10% relative humidity. Droplets of pure bee honey were supplied as a food source. Both parasitoid species (*T. basalis* and *T. podisi*) were reared on *E. heros* eggs. Host eggs were exposed to parasitoid females for 24 h and then removed and placed in glass tubes (7.5×1.3 cm) for incubation. Adult parasitoids obtained with these procedures were kept for 24–48 h in the plastic cages described above for mating. Later, the females were separated individually into glass tubes (4×0.5 cm) for use in bioassays. In this way, all females used in the bioassays were similarly experienced.

Gland Extracts To test the influence of the defensive compounds from different host species on the response of the parasitoids, bioassays were performed with the natural blends of metathoracic glands obtained by dissecting adults of different species. Adults of *E. heros*, *N. viridula*, *P. guildinii*, *Chinavia impicticornis* (Stål 1872), and *Edessa meditabunda* (Fabricius 1794) were dissected under a stereoscopic microscope, and the metathoracic glands were extracted with microdissecting forceps. The contents of the dissected glands were extracted in *n*-hexane for 2 h. Then, the tissues were removed, and the volume was adjusted to four glands per milliliter. With this procedure, we obtained metathoracic gland extracts having the defensive compounds in similar concentrations to the range of the solutions of individual compounds used in the bioassays

(next section; M.C.B. Moraes, unpublished data). Before the bioassays, the qualitative compositions of the extracts were checked by gas chromatography (data not shown). Four to five extracts of each species were obtained with this procedure and used in the bioassays.

Chemicals For the bioassays that used individual compounds, solutions of the synthetic standards of (*E*)-2-hexenal, 4-oxo-(*E*)-2-hexenal, tridecane, (*E*)-2-decenal, and undecane were prepared at two concentrations (0.01 and 0.1 mg/ml hexane). These compounds were selected based on the following criteria: (1) compounds commonly found in defensive secretions of neotropical stink bugs and the cosmopolitan, *N. viridula*, i.e., (*E*)-2-hexenal, 4-oxo-(*E*)-2-hexenal, and tridecane (Borges and Aldrich 1992; Aldrich 1995; Zarbin et al. 2000; Moraes et al. 2005b; Borges et al. 2007; Pareja et al. 2007); (2) a compound found as a major component in glands of *N. viridula* and *Chinavia* spp. and as a minor component in *E. heros* and *Thyanta perditor* (Fabricius 1794), i.e., (*E*)-2-decenal (Borges and Aldrich 1992; Moraes et al. 2005b; Pareja et al. 2007); and (3) undecane, a compound found as a major component exclusively in *Edessa meditabunda* (Borges and Aldrich 1992) and *E. rufomarginata* (Howard and Wiemer 1983) and in low amounts (near trace quantities) in *Chinavia ubica* (Rolston 1983), *T. perditor*, *E. heros*, and *P. guildinii* (Borges and Aldrich 1992; Moraes et al. 2005b; Pareja et al. 2007).

All authentic standards were purchased from Sigma-Aldrich (St Louis, MO, USA), Fluka (Buchs., Switzerland), Bedoukian (Danbury, CT, USA), or TCI (Tokyo, Japan). Synthetic 4-oxo-(*E*)-2-hexenal was provided by J.R. Aldrich (USDA, Beltsville, MD, USA).

General Procedures for Olfactometer Bioassays A Y-tube olfactometer constructed with an acrylic block with a Y-shaped cavity (27.5×21.0 cm), placed on top of a translucent glass plate and covered with transparent glass, was used to test the influence of the chemical compounds on the behavior of the parasitoids. The trunk of the apparatus measured 8 cm, plus a 1-cm circular area at the base of the trunk for insect liberation, and each arm measured 7 cm (at an angle of 130°, id 1.5 cm). Charcoal-filtered, humidified air was passed through each arm at 800 ml/min in a push–pull system. The air flow was maintained with two aquarium pumps. The olfactometer was illuminated from above by two fluorescent lamps (40 W) and from below by two infrared lamps (homogenous emission of wavelengths at 950 nm provided by 108 LEDs). The behavior of the insects was recorded by a CCD Sony SPT M324CE camera (fitted with a 4- to 50-mm/F1:1.6 zoom lens with an infrared filter) coupled to the Xbug software (Colazza et al., unpublished). Filter papers (1.5-cm long, 0.5-cm wide) treated with 5 µl of the test solution [gland extract or synthetic compound (25 ml), see above] were introduced into a glass chamber located close to the air entrance in one of the arms. In the other arm, a glass chamber with a filter paper treated with 5 µl *n*-hexane was used as control. To avoid any bias in the parasitoid responses, the arms through which control and treatment odors were presented were inverted every two to three bioassays. The apparatus was cleaned after two to three bioassays with fragrance-free liquid soap, rinsed thoroughly with water, and dried in convector ovens (at 160°C for the glass material and 60°C for the acrylic box).

For each bioassay, a single naïve *T. podisi* or *T. basalis* female (24–48 h adult stage) was introduced at the base of the Y-tube, and its behavior was monitored for 10 min. Insects that had not made a choice after 5 min were considered as nonresponders, and they were not included in the statistical analyses. To test for any bias between the two olfactometer arms, blank tests were carried out, in each set of bioassays, presenting *n*-hexane in both arms (N=30 for each parasitoid species). All bioassays were performed between 1000 to 1600 hours in a room at 26.0±1.0°C. During each bioassay, two parameters were recorded: first choice, measured as the arm of the olfactometer into which the insect entered first for at least 1 cm and remained for at least 20 s; and residence time, measured as the percentage of total bioassay time spent in each arm of the olfactometer.

Bioassays with Defensive Gland Extracts These bioassays were performed to test the response of the parasitoids toward the natural blend of defensive glands of different stink bugs species. Gland extracts that were obtained as described above were used. As a first step, extracts of each species were contrasted with *n*-hexane to test whether the parasitoid showed a significant response to the natural blend of each species. In a second step, the gland extracts of the host species for which a parasitoid showed a positive response were contrasted to investigate in a dual choice test whether the parasitoid showed a preference for one or another host species. For each parasitoid species, 40–50 insects were tested toward each defensive blend extract against *n*-hexane and toward each relevant host species—species pair recording the same parameters as described above.

Bioassays with Synthetic Compounds To test the effect of individual components present in the defensive gland blends, bioassays were performed with authentic standards of the compounds. Compounds tested in bioassays were used in solutions at two concentrations (0.1 and 0.01 mg/ml *n*-hexane). These concentrations were chosen based on previous bioassays described by Mattiaci et al. (1993) and Pires et al. (2001). Each compound was tested using *n*-

hexane as control; 30–55 replicates were performed for each compound at each concentration. The parameters computed during the monitoring were first choice and residence time. Additionally, we investigated the effect of individual compounds on specific parameters of the parasitoids' searching behavior, i.e., linear velocity (mm/s), turning rate (°/cm), and tortuosity. Turning rate is the number of times that the insect changes its route in the olfactometer, and the tortuosity index quantifies insect kinetic movement by the calculation $T=1-mp/tl$, in which mp represents the projection of the track in general straight line of the plain and tl the total length of the track (Borges et al. 2003). The index varies between 0 (zero) for minimal and 1 (one) for maximal tortuosity. Slow linear velocity, high turning rate, and tortuosity may be indicative of searching behavior stimulated by a cue.

Bioassays with Defensive Blends vs. Individual Compounds To test whether individual compounds that elicit positive response in parasitoids have the same effect as complete natural blends from defensive glands, bioassays were performed that contrasted the complete defensive gland blends against individual compounds for which each parasitoid showed a positive response; 40–50 bioassays were performed, and first choice and residence time were recorded.

Statistical Analyses The choices made by the parasitoids in the bioassays were analyzed by logistic regression and estimation of the probability of choosing the test odor. The model fitted contained a factor for the side (left or right) on which the test odor was presented to control for this variability. The hypothesis of no preference (50% first choice to each odor) was tested by means of a χ^2 Wald test. The percentages of the total bioassay time spent in each odor field and in blank tests (residence time) were analyzed by Wilcoxon's matched-pairs test after arcsine transformation of the data. Mean average linear velocity, turning rate, and tortuosity in treatment and control arms for each compound were compared with Student's t test or Mann–Whitney test when the data were not normally distributed. Insects that made a choice but remained immobile for more than 300 s were excluded from the residence time, linear velocity, turning rate, and tortuosity analyses.

Results

Y-tube olfactometer bioassays with metathoracic gland extracts of the five adult stink bug species showed that each parasitoid species responded selectively to the gland extract of its preferred stink bug host species. The egg parasitoid *T. basalis* preferred odor from extracts of *N. viridula* when compared to the control ($\chi^2_1=5.33$, $P=0.021$, $N=46$; Fig. 1a). Residence time in this treatment was higher than in the control ($W=395.0$, $P=0.014$, $N=43$; Fig. 1b). Odors of metathoracic glands of the other stink bug species did not elicit significant preference nor did they affect residence time (Fig. 1a and b). Since *T. basalis* showed a response only to extracts of *N. viridula*, no comparisons were necessary with extracts of other species.

The egg parasitoid *T. podisi* significantly preferred the odor from gland extracts of *E. heros* ($\chi^2_1=13.88$, $P<0.001$, $N=40$; Fig. 2a). When extracts of *N. viridula* were tested,

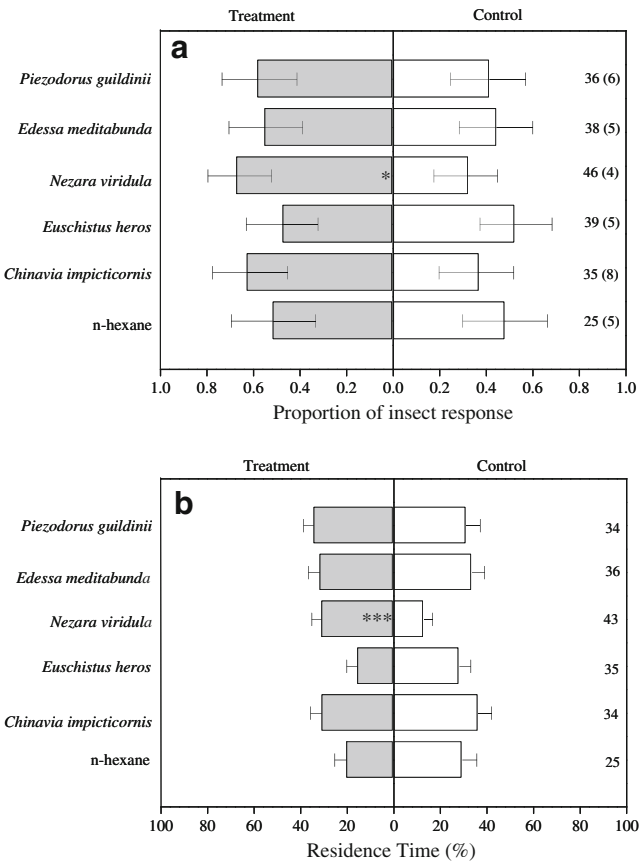

Fig. 1 First choice (**a**) and residence time (**b**) of the parasitoid *T. basalis* in Y-tube olfactometer bioassays with blends of metathoracic glands of different species (four glands per milliliter *n*-hexane) and *n*-hexane as control. Analyses of first choices were carried out by logistic regression and a Wald χ^2 statistic to assess significance. Mean residence time in treatment and control arms was analyzed by Wilcoxon's matched-pairs test. *$0.05>P>0.01$, ***$P<0.001$. *Bars* indicate the mean values of the parameters, and *lines* are the 95% confidence interval for first choice and SE for residence time. *Numbers on the right side of the figures* are the total number of insects tested. *Numbers in brackets in figure* (**a**) represent the number of insects that did not respond to the treatment tested

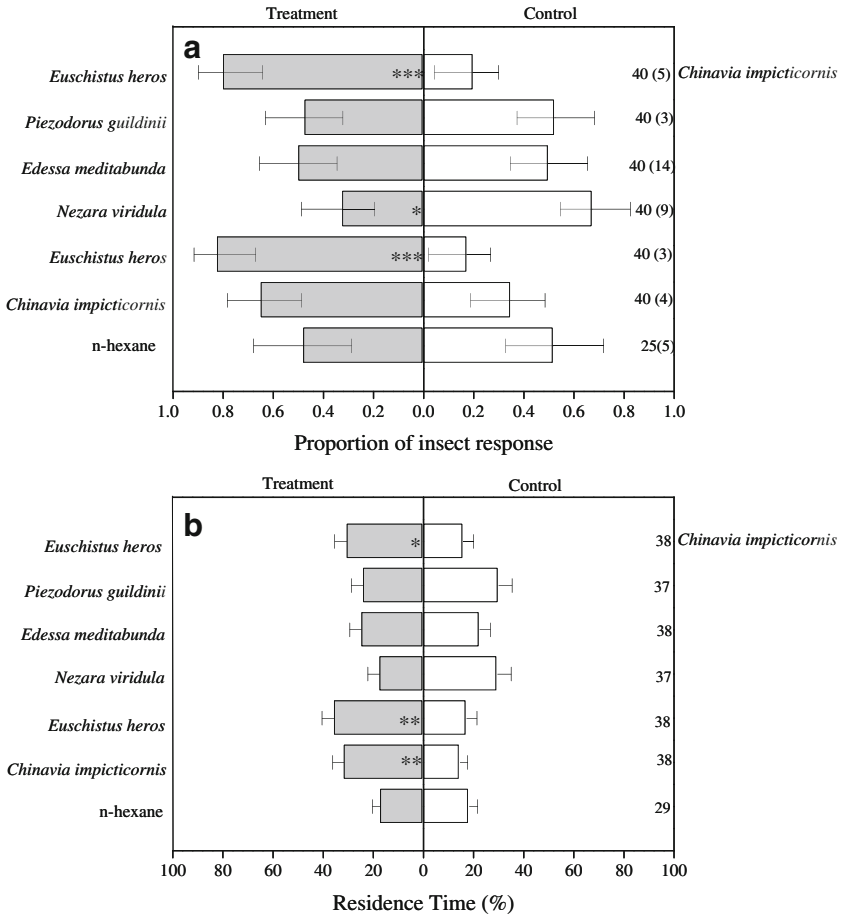

Fig. 2 First choice (**a**) and residence time (**b**) of the parasitoid *T. podisi* in Y-tube olfactometer bioassays with blends of metathoracic glands of different species (four glands per milliliter *n*-hexane) and *n*-hexane as control. Analyses of first choices were carried out by logistic regression and a Wald χ^2 statistic to assess significance. Mean residence time in treatment and control arms was analyzed by Wilcoxon's matched-pairs test. *0.05>*P*>0.01, **0.01>*P*>0.001, and ***$P<0.001$. *Bars* indicate the mean values of the parameters, and *lines* are the 95% confidence intervals for first choice and SE for residence time. *Numbers on the right side of the figures* are the total number of insects tested. *Numbers in brackets in figure* (**a**) represent the number of insects that did not respond to the treatment tested

the parasitoid preferred the control arm of the olfactometer (χ^2_1=4.69, *P*=0.030, *N*=40; Fig. 2a). Parasitoids spent more time in the olfactometer arm supplied with extract of *E. heros* glands than in the control arm (*W*=352.0, *P*=0.011, *N*=38). Odor from extracts of *C. impicticornis* glands (Fig. 2b) also elicited a longer residence time (*W*=349.0, *P*=0.012, *N*=38), whereas the first choice for this odor was not significant (χ^2_1=3.49, *P*=0.062, *N*=40). When the metathoracic gland extracts of *E. heros* were tested against those of *C. impicticornis*, female *T. podisi* showed a clear preference for *E. heros* extracts (χ^2_1=12.30, $P<0.001$, *N*=40 for initial choice and *W*=307.0, *P*=0.026, *N*=38 for residence time; Fig. 2a and b).

The parasitoids showed clear differential responses to the different synthetic compounds tested. *T. basalis* preferred 4-oxo-(*E*)-2-hexenal (χ^2_1=7.68, *P*=0.005, *N*=30) and (*E*)-2-decenal (χ^2=4.53, *P*=0.033, *N*=30) at the higher concentration tested (0.1 mg/ml) against the control (80 and 70% choosing the arm with treatments, respectively; Fig. 3a). This positive response to 4-oxo-(*E*)-2-hexenal was confirmed when the percentage residence time was analyzed. Residence time in the treatment arm supplied with 4-oxo-(*E*)-2-hexenal was higher when compared to the residence time spent in the control arm for the two concentrations tested (*W*=178.0, *P*=0.007, *N*=23 and *W*=271.0, $P<0.001$, *N*=26 for 0.01 and 0.1 mg/ml, respectively; Fig. 3b). (*E*)-2-Hexenal, tridecane, and (*E*)-2-decenal did not show significant effects on *T. basalis* behavior, whereas undecane at the higher concentration tested (0.1 mg/l) caused the parasitoid to spend more time in the control arm (*W*=151.0, *P*=0.015, *N*=22; Fig. 3).

T. podisi showed a positive response to (*E*)-2-hexenal (χ^2_1=4.50, *P*=0.034, *N*=25) and tridecane (χ^2_1=4.61, *P*=0.032, *N*=47) at 0.01 mg/ml and to 4-oxo-(*E*)-2-hexenal at 0.1 mg/ml (χ^2_1=9.22, *N*=0.002, *N*=25). On the other hand, (*E*)-2-decenal and undecane did not elicit a significant response by this species (Fig. 4a). Accordingly, *T. podisi* females showed a higher proportion of residence time in arms of the olfactometer with (*E*)-2-hexenal (0.01 mg/ml) (*W*=211.0, $P<0.001$, *N*=22) and 4-oxo-(*E*)-2-hexenal at the two concentrations (*W*=114.0, *P*=0.03, *N*=20 and *W*=116.0, *P*=0.035, *N*=22 for 0.01 and 0.1 mg/ml, respectively; Fig. 4b). *T. podisi* females did not show higher residence time in the olfactometer arms supplied with

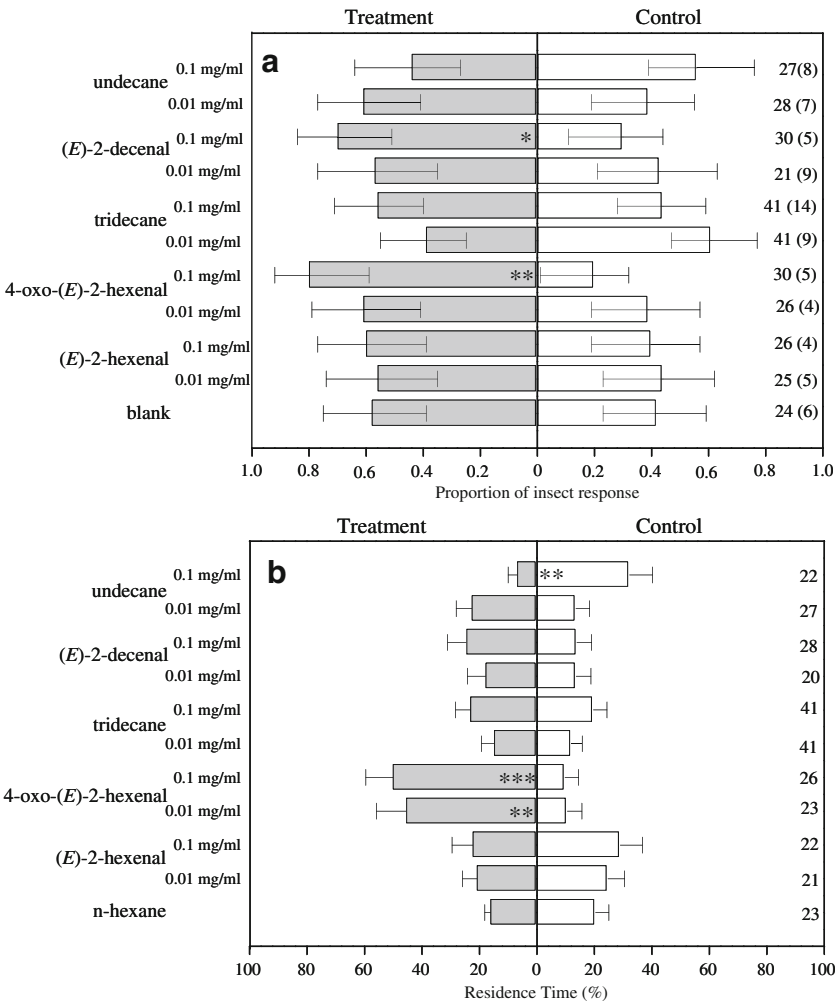

Fig. 3 First choice (**a**) and residence time (**b**) of the parasitoid *T. basalis* in Y-tube olfactometer bioassays with different stink bug defensive compounds as treatments in two dosages (5 µl of 0.01 and 0.1 mg/ml *n*-hexane) and *n*-hexane as control. Analyses of first choices were carried out by logistic regression and a Wald χ^2 statistic to assess significance. Mean residence time in treatment and control arms was analyzed by Wilcoxon's matched-pairs test. *0.05>*P*>0.01, **0.01>*P*>0.001, and *** indicate *P*<0.001. *Bars* indicate the mean values of the parameters, and *lines* are the 95% confidence intervals for first choice and SE for residence time. *Numbers on the right side of the figures* are the total number of insects tested. *Numbers in brackets in figure* (**a**) represent the number of insects that did not respond to the treatment tested

(*E*)-2-decenal, tridecane, or undecane compared to controls (Fig. 4b).

T. basalis showed slower linear velocity (t=2.81, df=22, P=0.01) and a higher tortuosity index (t=2.16 df=23 P=0.04) in olfactometer arms with 4-oxo-(*E*)-2-hexenal (0.1 mg/ml) when compared to hexane (control; Fig. 5). Linear velocity was slower when exposed to tridecane at 0.01 mg/ml compared to the control (Mann–Whitney test U=819.0, N=32, 326, P<0.001), and (*E*)-2-decenal reduced the turning rate of the parasitoid in the control arm (Mann–Whitney test U=318.0, N=15, 17, P=0.008). The other compounds did not show significant effects on *T. basalis* walking patterns parameters (Fig. 5).

T. podisi showed slower linear velocity when exposed to (*E*)-2-hexenal at both 0.1 and 0.01 mg/ml (Mann–Whitney test U=149, N=10, 12, P=0.027, and t test t=2.41, df=20, P=0.021 for 0.01 and 0.1 mg/ml, respectively) and to 4-oxo-(*E*)-2-hexenal at 0.1 mg/ml (Student t test t=2.71, df=20, P=0.013; Fig. 6). Tortuosity was higher when the parasitoid was exposed to (*E*)-2-hexenal (0.01 mg/ml; Student's t test t=2.20, df=24, P=0.037) and 4-oxo-(*E*)-2-hexenal (0.1 mg/ml; Student's t test t=2.97, df=24, P=0.007). Exposure to 4-oxo-(*E*)-2-hexenal led to an increase of the turning rate of *T. podisi* females (Student's t test t=2.14, df=28, P=0.04). Tridecane, (*E*)-2-decenal, and undecane did not show significant effects on *T. podisi* walking pattern parameters (Fig. 6).

When the compounds to which the parasitoids showed significant positive responses were tested against the crude metathoracic gland extract preferred when tested singly, *T. basalis* did not show a preference for the *N. viridula* gland extracts when tested against 4-oxo-(*E*)-2-hexenal at 0.01 mg/ml, but preferred the arm with gland extracts when it was contrasted against 4-oxo-(*E*)-2-hexenal at 0.1 mg/ml (χ^2_1=4.59, P=0.032, N=36). In contrast, when *N. viridula* gland extracts were tested against (*E*)-2-decenal (at 0.1 mg/ml), the parasitoid preferred the arms treated with the aldehyde (χ^2_1=4.59, P=0.032, N=35; Fig. 7 a). In

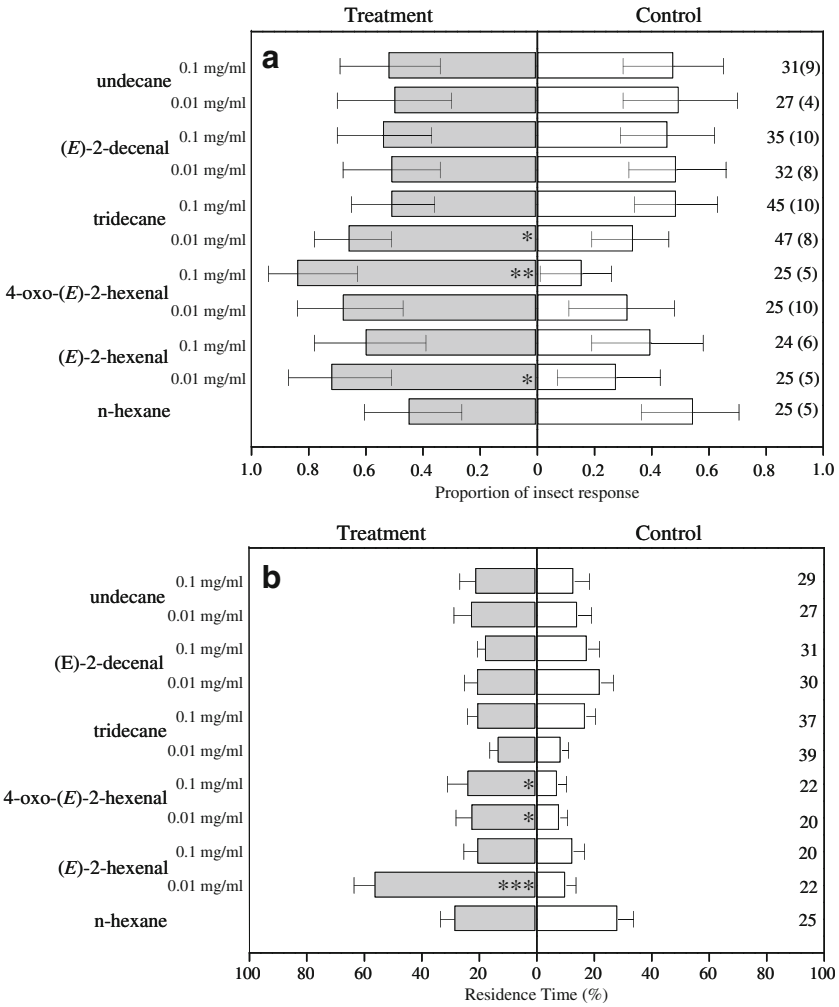

Fig. 4 First choice (**a**) and residence time (**b**) of the parasitoid *T. podisi* in Y-tube olfactometer bioassays with different stink bug defensive compounds as treatments in two dosages (5 µl of 0.01 and 0.1 mg/ml *n*-hexane) and *n*-hexane as control. Analyses of first choices were carried out by logistic regression and a Wald χ^2 statistic to assess significance. Mean residence time in treatment and control arms was analyzed by Wilcoxon's matched-pairs test. *0.05>*P*>0.01, **0.01>*P*>0.001, and *** indicate *P*< 0.001. *Bars* indicate the mean values of the parameters, and *lines* are the 95% confidence intervals for first choice and SE for residence time. *Numbers on the right side of the figures* are the total number of insects tested. *Numbers in brackets in figure* (**a**) represent the number of insects that did not respond to the treatment tested

contrast, the residence time in arms of the olfactometer with the stink bug gland extract or with individual defensive compounds was the same for all combinations tested (Fig. 7b).

The parasitoid *T. podisi* did not prefer odor of *E. heros* glands when this was tested against individual compounds (Fig. 8a, b).

Discussion

Scelionid parasitoids show clear host preferences (Sujii et al. 2002) for stink bug eggs that maximize their biological performance (Pacheco and Corrêa-Ferreira 1998; Kivan and Kilic 2002, 2004; Laumann et al. 2008). Egg parasitoids that search for nonapparent hosts may rely especially on easily detectable cues such as host pheromones or host allomones (Vet and Dicke 1992). Aldrich (1995) postulated that the differential use of adult stink bug host allomones by egg parasitoids should reflect the host preference observed in different species of Scelionidae.

Our results confirm the hypothesis that females of *T. basalis* and *T. podisi* respond differentially to metathoracic gland extracts of different species of stink bugs. Furthermore, the data support the hypothesis that this differential response is related to the preference of hosts reported by Corrêa-Ferreira and Moscardi (1995), Medeiros et al. (1997, 1998), and Pacheco and Correa-Ferreira (2000) from field data, and Sujii et al. (2002) from laboratory experiments. Even when considering that the response of *T. podisi* to *E. heros* gland extracts may be influenced by preimaginal or emergence experience of the parasitoids that were reared on *E. heros* eggs, the response of *T. basalis*, reared on the same host, to gland extracts of *N. viridula* clearly indicates an innate response of this parasitoid to blends of their favorite host. The relevance of individual components of the attractive odor of host metathoracic glands for the parasitoids' host-searching behavior is discussed below.

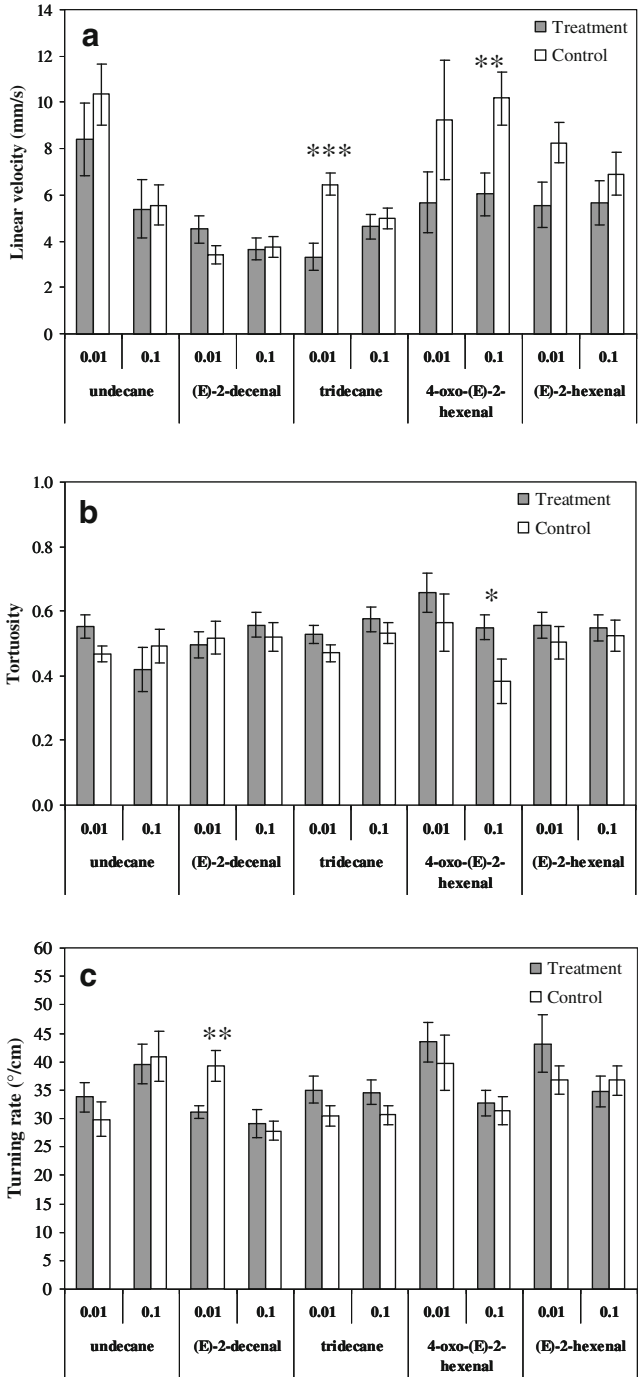

Fig. 5 Walking patterns (mean±SE) of *T. basalis.* **a** Linear velocity, **b** tortuosity, and **c** turning rate. Bioassays were performed in a Y-tube olfactometer with different stink bug defensive compounds as treatments in two dosages (5 µl of 0.01 and 0.1 mg/ml *n*-hexane) and *n*-hexane as control. Means of each treatment and control were compared with Student's *t* test or Mann–Whitney test. *0.05>*P*>0.01, **0.01>*P*>0.001, and ***$P<0.001$

T. basalis showed taxic behavior to two individual compounds tested: 4-oxo-(*E*)-2-hexenal and (*E*)-2-decenal. These findings corroborate the results reported by Mattiaci et al. (1993) who showed that (*E*)-2-decenal is used as a long-range kairomone by *T. basalis*. When testing *T. basalis,* the higher values of residence time, tortuosity, and reduced linear velocity in olfactometer arms supplied with 4-oxo-(*E*)-2-hexenal suggest that this compound can

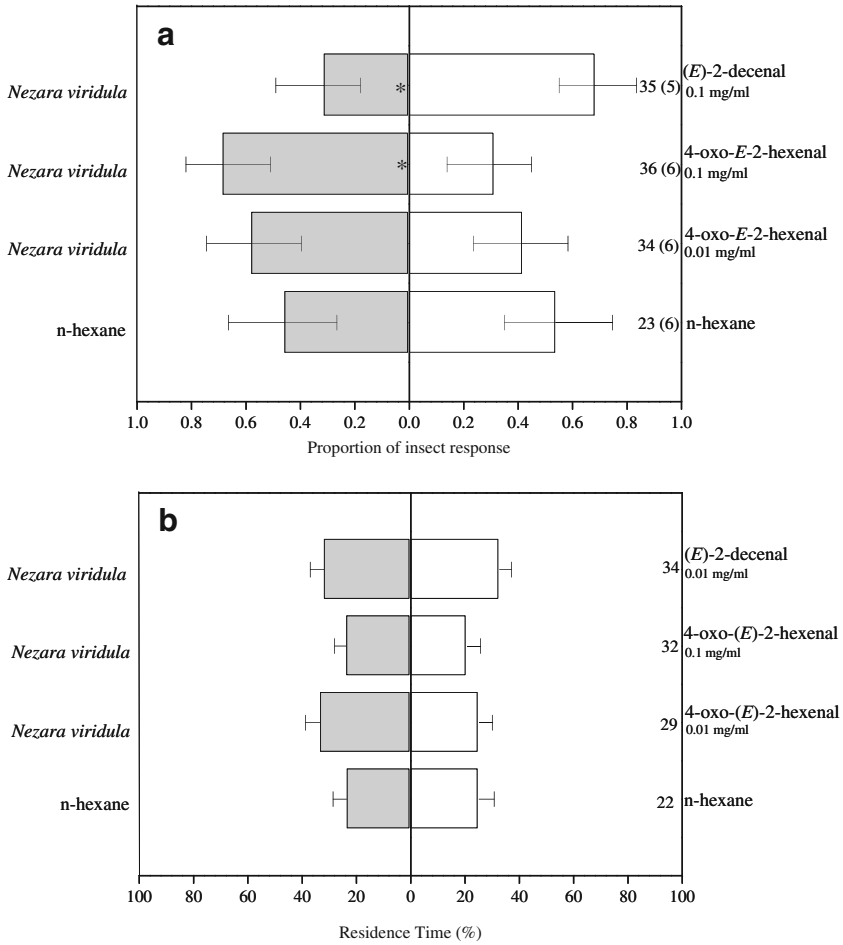

Fig. 7 First choice (**a**) and residence time (**b**) of the parasitoid *T. basalis* in Y-tube olfactometer bioassays contrasting the blends of metathoracic glands of *N. viridula* with different stink bug defensive compounds. Analyses of first choices were carried out by logistic regression and a Wald χ^2 statistic to assess significance. Mean residence time in treatment and control arms was analyzed by Wilcoxon's matched-pairs test. *0.05>*P*> 0.01. *Bars* indicate the mean values of the parameters, and *lines* are the 95% confidence intervals for first choice and SE for residence time. *Numbers on the right side of the figures* are the total number of insects tested. *Numbers in brackets in figure* (**a**) represent the number of insects that did not respond to the treatment tested

stimulate searching behavior of the parasitoid and modify kinetic components of the walking pattern.

T. podisi showed significantly positive response to (*E*)-2-hexenal and 4-oxo-(*E*)-2-hexenal, and these compounds also modified the kinetic search pattern. In contrast, tridecane affected only the initial choice of the parasitoid. The individual responses of *T. podisi* to these compounds are in concordance with those reported by Pires et al. (2001) by using olfactometer bioassays with groups of ten *T. podisi* females.

When both individual compounds and crude blends of metathoracic gland extracts that elicited positive taxic responses by the parasitoids were contrasted, the individual compounds had similar attraction power, suggesting that they can be used by the parasitoid during foraging behavior with the same efficiency as the whole blend released from glands. The only exceptions were 4-oxo-(*E*)-2-hexenal and (*E*)-2-decenal for *T. basalis.* The first compound showed lower attraction than extracts of *N. viridula* glands, and the second was more attractive than the extracts, confirming the strong kairomonal effect previously reported by Mattiaci et al. (1992) for this compound.

Long-range host location and selectivity mediated by semiochemicals has been previously reported for *Trissolcus* spp. responding to volatiles from stink bug nymphs and/or adults in bioassays with living insects (Colazza et al. 1999; Conti et al. 2003, 2004; Salerno et al. 2006; Silva et al. 2006). These previous studies showed that the parasitoids have stronger preference to cues from host stink bug females in a preovipositional state (Colazza et al. 1999). In concordance with the observations here, the parasitoids' response to volatiles from living host insects during host location behavior are related to cues derived from their preferred host or from hosts with old association history (Conti et al. 2004; Salerno et al. 2006).

The response of *T. podisi* and *T. basalis* to 4-oxo-(*E*)-2-hexenal may indicate a general response toward a characteristic compound of Heteroptera (Borges and Aldrich 1992; Aldrich 1995; Pareja et al. 2007). The response to (*E*)-2-decenal (*T. basalis*) and tridecane (*T. podisi*) indicates that even parasitoids with broad host spectra (Orr 1988; Austin et al. 2005) show a certain degree of specialization in the use of cues during searching behavior. The preference of *N. viridula* by *T. basalis* is reflected by its

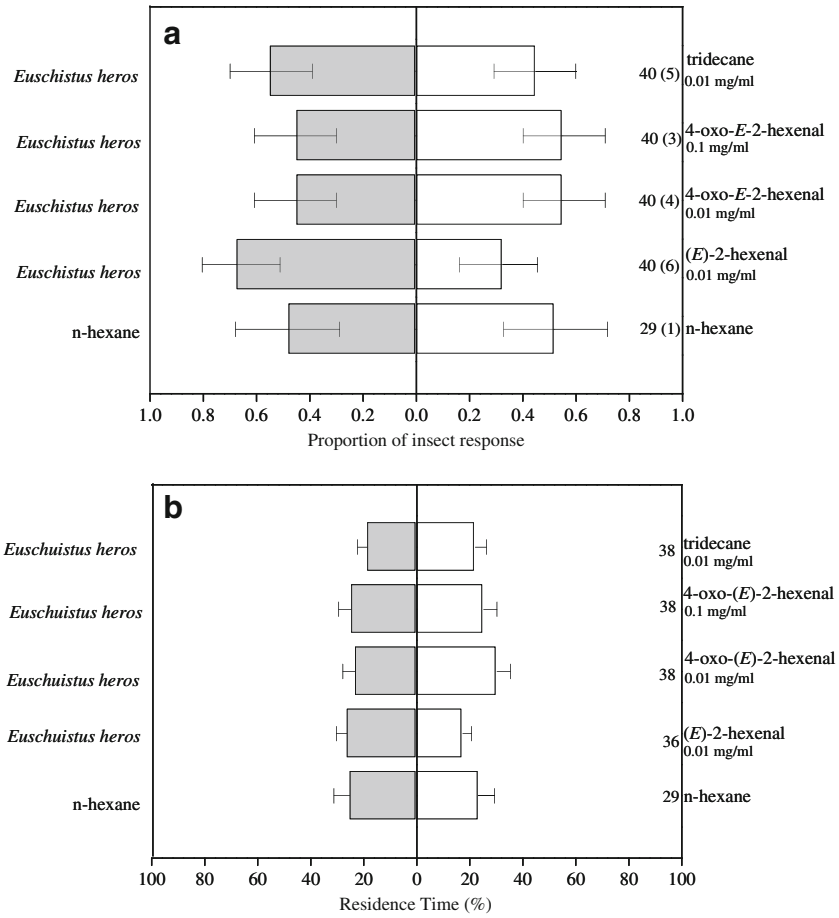

Fig. 8 First choice (**a**) and residence time (**b**) of the parasitoid *T. podisi* in Y-tube olfactometer bioassays contrasting the blends of metathoracic glands of *E. heros* with different stink bug defensive compounds. Analyses of first choices were carried out by logistic regression, and a Wald χ^2 statistic to assess significance. Mean residence time in treatment and control arms was analyzed by Wilcoxon's matched-pairs test. *Bars* indicate the mean values of the parameters, and *lines* are the 95% confidence intervals for first choice and SE for residence time. *Numbers on the right side of the figures* are the total number of insects tested. *Numbers in brackets in figure* (**a**) represent the number of insects that did not respond to the treatment tested

preference to (*E*)-2-decenal, a major component of defensive glands of the host *N. viridula* (Borges and Aldrich 1992). In addition, *Edessa* spp. release undecane as a major compound from their metathoracic glands (Howard and Wiemer 1983; Borges and Aldrich 1992), and they are not known as hosts of *T. basalis* and *T. podisi* in Brazil (Côrrea-Ferreira and Moscardi 1995; Medeiros et al. 1998). Neither parasitoid species showed a significant response toward undecane, suggesting that these parasitoids may use defensive compounds to discriminate unsuitable hosts.

The response of *T. podisi* to (*E*)-2-hexenal may characterize a general response to cues from the habitat where hosts can be found because this compound is usually found in glands of stink bugs: (*E*)-2-hexenal is also a common green leaf volatile present in volatile blends from plants (Hatanaka 1993) and has been reported as a component of soybean headspace (Moraes et al. 2008), which is the major host plant of stink bugs in Central Brazil. This general cue may be replaced, in more advanced steps of host-searching behavior, by specific cues from the host, such as 4-oxo-(*E*)-2-hexenal or tridecane.

A paradigm of host search in parasitic insects predicts that generalist parasitoids use nonspecific cues, while specialists use specific ones (Vet and Dicke 1992; Meiners et al. 2000, Steidle and van Loon 2003). Phoretic scelionids and many other egg parasitoid species with reduced host spectra are known to use species-specific host sex pheromones (Nordlund et al. 1983; Aldrich 1985; Arakaki et al. 1996, 1997; Colazza et al. 1997; Bruni et al. 2000). *T. podisi* uses the sex pheromone of its preferred host, *E. heros* (Sujii et al. 2002; Borges et al. 1998, 1999; Silva et al. 2006). The results presented here indicate that, in addition to this specific response to host sex pheromones, a specific response to host allomones may help the parasitoid find hosts where the performance of their progeny will be high. Thus, even though the scelionid species studied here have quite a broad host spectrum, host species-specific cues might help parasitoids orientate to the most preferred host species.

The use of semiochemicals for behavioral manipulation of parasitoids has been proposed and discussed extensively. In recent years, semiochemicals have also been discussed as a tool to improve biological control (Vet and Dicke 1992; Lewis and Martin 2000; Powell and Pickett 2003). Specific knowledge about host–parasitoid relationships mediated by semiochemicals is important for improving the effectiveness of applications of semiochemicals in integrated pest control.

Acknowledgment We thank H. Santos and D. Tiburcio, for helping with field collection and laboratory rearing of the insects used. We are grateful to Monika Hilker for assistance with editorial corrections and suggestions that helped us improve the work, and to two anonymous reviewers for comments on the first version of this work. This work received financial support from the Brazilian Council for Scientific and Technological Development (CNPq), Distrito Federal Research Foundation (FAPDF), Catholic University (scientific initiation studentship to MFSA), and EMBRAPA.

Caterpillar Footprints as Host Location Kairomones for *Cotesia marginiventris*: Persistence and Chemical Nature

Michael Rostás · Mirko Wölfling

Received: 15 October 2008 / Revised: 22 December 2008 / Accepted: 31 December 2008 / Published online: 20 January 2009

Abstract Herbivores walking over the epicuticular wax layer of a plant may leave tracks that disclose their presence to hunting predators or parasitoids. The braconid wasp *Cotesia marginiventris* is a solitary parasitoid of young noctuid caterpillars. It can locate potential hosts from a distance by orienting toward the scent of herbivore-damaged plants. Upon landing on the caterpillars' food plant, the female parasitoid searches for further cues (kairomones) that confirm the presence of a suitable host. In a previous study, we showed that *C. marginiventris* recognizes the chemical footprints of absent *Spodoptera frugiperda* caterpillars on a leaf. Here, we report on the persistence and chemical nature of this host location kairomone. In a series of behavioral assays, we confirmed that caterpillars of *S. frugiperda* leave chemical tracks that elicit characteristic antennation behavior in *C. marginiventris* for up to 2 days. Both hexane extracts of caterpillar footprints and of the larvae's ventral cuticle induced antennation and contained almost identical long-chain hydrocarbons, thus suggesting the prolegs and claspers as the kairomones' main source. A series of linear C_{21} to C_{32} alkanes accounted for ca 90% of all identified compounds. Female wasps showed significant antennation responses on leaves treated with a reconstructed blend of these *n*-alkanes. However, wasp responses were relatively weak. Therefore, we presume that minor compounds, such as monomethyl-branched alkanes, which were also found, may contribute additionally to host recognition.

Introduction

For parasitoids, semiochemicals play an important role in each stage of locating, recognizing, and accepting a potential host (Vinson 1998; Steidle and Van Loon 2002). Finding a host's microhabitat, e.g., its food plant, is often accomplished by orienting toward herbivore-induced volatile plant compounds (Turlings et al. 1995; Dicke et al. 2003; Heil 2008). Upon landing on a plant, chemical cues of lower volatility that are more closely associated with a host become important. Such chemicals (kairomones) may emanate directly from the host or from host by-products like feces or moth scales (Godfray 1994).

In recent years, it has become clear that small amounts of chemicals remain on the substrate when insects walk over a plant surface. These chemical footprints can be exploited as host location cues by foraging natural enemies, or they may serve other purposes in inter- and intraspecific interactions such as oviposition deterrence or the marking of previously visited flowers in the case of bumblebees (Klomp 1981; Hemptinne et al. 2001; Borges et al. 2003; Conti et al. 2003; Eltz 2006; Colazza et al. 2007; Collatz and Steidle 2008; Rutledge et al. 2008).

The parasitoid *Cotesia marginiventris* Cresson (Hymenoptera: Braconidae) is distributed from North to South America and has been considered for use in augmentative biological control of vegetable pests. As a solitary koinobiont endoparasitoid, it parasitizes early instar lepidopteran larvae belonging to the Noctuidae family (Riddick 2006). Its host location behavior has been investigated intensively, mainly in studies that address the parasitoids' long-range

attraction to host plants by using herbivore-induced volatiles and in the context of how these signals may be influenced by biotic and abiotic factors (Turlings et al. 1995; Cardoza et al. 2002; Gouinguené and Turlings 2002; Rostás et al. 2006; Winter and Rostás 2008). Earlier research also has assessed the parasitoids' responses to contact kairomones. By-products of the host such as feces, larval and pupal cutical material, scales, silk, or oral secretion elicit increased klinokinesis, antennal palpation, or ovipositor probing (Loke and Ashley 1984a, b; Dmoch et al. 1985).

In addition to these cues, Rostás et al. (2008) found that naïve *C. marginiventris* can recognize chemical footprints on the wax surface of leaves produced by walking second-instar caterpillars of *Spodoptera frugiperda* Smith (Lepidoptera: Noctuidae). In the current study, we addressed the question of how long such caterpillar footprints can be detected by the female parasitoid, and we investigated their chemistry.

Materials and Methods

Insects Eggs of *S. frugiperda* (Smith) were provided by Bayer CropScience AG (Monheim, Germany) on a weekly basis. After hatching, larvae were reared in plastic boxes (19×9×5.5 cm) and provided with kidney bean-based artificial diet for noctuids (modified from King and Leppla 1984). Insects were kept in a climate chamber with a 15: 9-h L/D photoperiod at 28/25°C (L/D) and 75% humidity. After 5 to 6 days, caterpillars were used either for parasitoid rearing or for experiments. All caterpillars were in their second larval stage in which they are still small and feed gregariously.

A colony of *Cotesia marginiventris* (Cresson) was maintained in the laboratory. For rearing, about 45 *S. frugiperda* larvae were offered to three mated *C. marginiventris* females in a plastic box (20×20×5.5 cm). Wasps were allowed to oviposit for 24 h and were then removed. Herbivore larvae were kept in the boxes until the emergence of the wasp cocoons. Cocoons were removed from the herbivore boxes and transferred to rearing cages (Bugdorm I, Megaview Science Education Services, Taichung, Taiwan). Cages were checked daily for eclosed imagines. Adult parasitoids were provided with water and honey.

Barley (*Hordeum vulgare* cv. Bonus) was cultivated in pots (9-cm diameter). Plants were kept in growth chambers at 300–400 µmol photons m^{-2} s^{-1} light intensity with a day/night cycle of 16:8 h (24:18°C) and 70% relative humidity.

Behavioral Assays A 5.5-cm diameter glass Petri dish covered by a glass plate was used as a test arena for observing the wasps' host location behavior. The Petri dish was surrounded by a 25-cm-high white cardboard cylinder and illuminated by a 25-W light bulb from above. The antennation behavior of single wasps, which had no previous experience with caterpillars, was observed for 10 min using the software Noldus Observer 5.0 (Noldus Information Technologies, Wageningen, Netherlands). Only insects that spent more than 50% of the time in motion were used for analyses. Wasps that showed no antennation behavior throughout the experiment were subjected to a motivation test in which they were provided second-instar host larvae for oviposition. Wasps that laid an egg into at least one caterpillar were included in the analyses as we assumed that they were in oviposition mood even though they did not display antennation behavior. Antennation on the cut edges of the leaves was observed occasionally but not recorded, as *C. marginiventris* is known to respond to green leaf volatiles released by damaged plant tissue (Hoballah and Turlings 2005). Fifteen wasps were observed in each experiment if not stated otherwise. All dual-choice assays were analyzed by using nonparametric Wilcoxon matched pairs test. Wasp responses to hexane and methylene chloride extracts of caterpillars were compared with Bonferroni-corrected Mann–Whitney *U* test.

Persistence of Caterpillar Tracks A clip cage (diameter 20 mm, height 26 mm) covered with gauze on the top and bottom end for ventilation was attached to the upper part of the second leaf of a potted barley plant (*H. vulgare* cv. Bonus). Clip cages contained four caterpillars, which were left to walk over the leaf surface for 15 min. Clip cages were then removed, and the leaf was examined carefully. Only leaves without bite marks, feces, or silk were used in the experiments. Leaves with any kind of residue were discarded. As controls, leaves were used onto which empty clip cages had been attached. The upper part of the leaf (5 cm length) was cut off at different time points (0, 24, 48, and 72 h after clip cage removal). A test and a control leaf section were placed into the arena for observation of parasitoid antennation behavior (see above). Leaf material and wasps were exchanged after each observation.

Chemistry of Caterpillar Tracks In a first bioassay, we tested total body extracts of second-instar *S. frugiperda* assuming that footprint components should be a fragment thereof. Groups of ten caterpillars were shock-frozen in −80°C and then extracted with 1 ml methanol, methylene chloride, and *n*-hexane (Carl Roth GmbH KG, Karlsruhe, Germany), respectively. After 1 min, extracts were filtered (Schleicher and Schüll 595, Dassel, Germany) and evaporated to dryness under a stream of nitrogen. Residues were dissolved in 100 µl of the appropriate solvent and stored at −80°C until used. Pure solvents were used as controls.

Extracts of chemical footprints were prepared by keeping second-instar *S. frugiperda* without food overnight to allow for defecation. Thirty-three to 34 larvae were then left to walk on two microscopic glass slides placed side-by-side, since glass has been shown to provide a good surface for isolating and collecting insect footprints. The slides were covered with a small glass Petri dish (diameter 25 mm, height: 11 mm) to prevent larvae from escaping. All glassware was cleaned thoroughly with distilled water, ethanol, acetone, and *n*-hexane before use. After 1 h, caterpillars were removed, and both glass slides and Petri dish were rinsed with 1 ml *n*-hexane. This procedure was repeated 9×. Three of the extracts were pooled to obtain the footprints of 100 caterpillars. Each of the three pooled extracts was then concentrated to 80 µl under a gentle flow of nitrogen. Glassware without caterpillars was rinsed with *n*-hexane as a control. All extracts were kept at −80°C until used for bioassays or GC-MS analyses.

For comparison of cuticular hydrocarbons, the ventral side of the caterpillar body was extracted with *n*-hexane. Twenty caterpillars were frozen in liquid nitrogen. Then, a 1-µl droplet of *n*-hexane was placed onto a microscopic glass slide with a gas-tight syringe (Hamilton-Bonadaz, Bonaduz, Switzerland). The drop spread over the glass slide covering it as a thin film. By using soft forceps, a caterpillar was placed quickly into the *n*-hexane film before the solvent had evaporated completely. By this procedure, the surfaces of the ventral side including legs, pseudopods, and claspers were extracted. Due to the small size of the second instar, it was not feasible to extract only the extremities.

Observations of wasp antennation responses to the total body and chemical footprint extracts were performed as described above. Single *C. marginiventris* were offered two segments of barley leaves. Each segment was treated with test or control extract (total body 10 µl/leaf, chemical footprints 30 µl/leaf). The solvent was left to evaporate completely before observation started. Wasps were exchanged after each observation. Treated leaves were replaced after five observations (total body) or after each observation (chemical footprints). Fifteen replications were carried out for each treatment.

In another bioassay, wasp antennation responses to the main compounds of the footprint extract were tested. This was accomplished by partially reconstructing the footprint extract with a mixture of standard *n*-alkanes (nC_{21}–nC_{32}, all Sigma-Aldrich, Taufkirchen, Germany). GC analyses of the reconstructed blend were carried out to verify that quantities and ratios of the alkanes were the same as in the original footprint extract that was previously offered to *C. marginiventris*.

Gas Chromatography Hexane extracts were analyzed by gas chromatography and mass spectrometry (Agilent Technologies 6890N Network GC System coupled with a 5973 Network Mass Selective Detector). Three microliters of each sample were injected with an automated injection system in pulsed splitless mode. The column was an Agilent 19091-s933 HP-1 capillary column (length 30 m, diameter 0.25 mm, film thickness 0.25 µm). The oven was held at 150°C for 2 min, and then increased at 5°C min^{-1} to a final temperature of 320°C, which was held for 20 min. Helium (1.5 ml min^{-1}) was used as carrier gas. Linear alkanes were identified by their characteristic EI-MS fragmentation pattern and in addition by using MSD ChemStation (Agilent Technologies) software with the Wiley 275 and NIST 98 mass spectrum libraries. Identities were confirmed further by comparing retention indices and mass spectra with those of authentic *n*-alkane standards (nC_{21}–C_{32}, Sigma-Aldrich, Taufkirchen, Germany). In the case of the monomethyl-alkanes, tentative identification was based on the characteristic fragmentation pattern that indicated the position of the methyl-branch and on the retention indices of the closest *n*-alkanes. Quantities of hydrocarbons were assessed by the external standard method. Calibration curves to determine linearity were obtained from each identified *n*-alkane at four concentrations (1, 5, 10, 25 ng/µl) with three replications per concentration. Linearity was assumed when the regression coefficient R^2 was >0.998. Quantities of monomethyl-alkanes and unidentified compounds were estimated by comparing

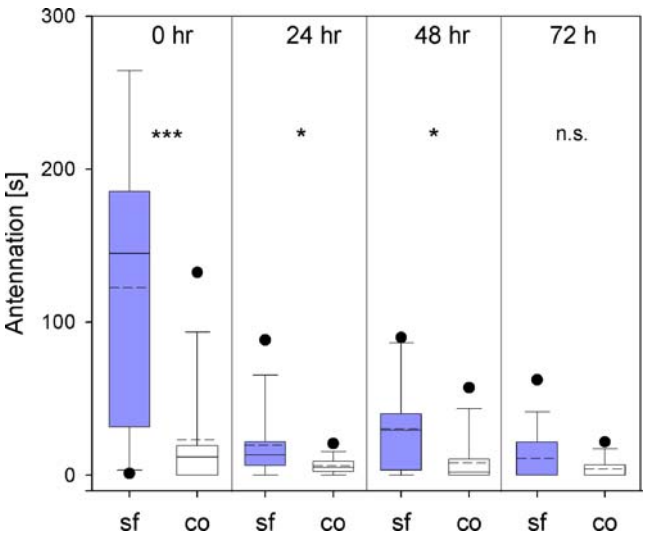

Fig. 1 Antennal drumming of *C. marginiventris* on caterpillar footprints. *Dark boxes* represent barley leaves on which caterpillars of *S. frugiperda* had walked upon for 15 min. *White boxes* represent controls. *Times (0–72 h) above boxes* indicate lag time between removal of caterpillars and observation of wasp behavior. *Boxes* show median (*solid line*) and mean (*dashed line*), 25th and 75th percentiles. *Whiskers* are 5th and 95th percentiles. *Dots* indicate outliers. *Asterisks* denote significant differences: ***$P<0.001$, *$P<0.05$, *n.s.* not significant

peak areas with those of the closest standard *n*-alkane and, thus, were not as absolute as in the case of *n*-alkanes.

Results

Bioassays Assessing Kairomone Persistence The duration of high frequency antennation behavior of *C. marginiventris* observed at various time points after removal of larvae is summarized in Fig. 1. Choice tests showed that female wasps responded most strongly to leaf segments on which caterpillars had been removed right before the experiment started. All parasitoids responded and displayed prolonged antennal drumming on treated leaves (0 h $Z = 3.408$, $P < 0.001$). Significantly longer sequences of antennation on caterpillar-treated leaves were also observed after a time lag of 24 and 48 h, respectively, following the brief exposure to second-instar *S. frugiperda* (24 h $Z = 2{,}981$, $P = 0.003$; 48 h $Z = 2.293$, $P = 0.022$). However, 93% of the observed wasps responded in the 24-h test, while 80% displayed antennal palpation in the 48-h test. After a period of 72 h, wasps still showed a tendency for caterpillar-treated leaf segments, but the difference in antennation time compared to control leaves was no longer significant (72 h $Z = 1.820$, $P = 0.069$). Antennal drumming was observed in 53% of tested wasps.

Chemical Analyses Twenty-one out of 26 detected compounds were identified in the hexane extracts of *S. frugiperda* footprints (Table 1, Fig. 2). All major compounds were odd and even numbered linear alkanes with chain lengths ranging from 21 to 32 carbon atoms (>90% of total). The three most abundant compounds were nC_{25} (13.5%), nC_{26} (10.4%), and nC_{27} (10.3%), representing 34% of the total hydrocarbon extract. Apart from linear alkanes, only monomethyl-branched compounds ($4MeC_{24}$–$4MeC_{28}$ and $3MeC_{25}$–$3MeC_{28}$) could be identified. Comparison with hexane extracts of the ventral side of second-instar cater-

pillars showed that the footprint compounds were present in the same ratios in the body extract, as well.

Bioassays that Assessed Kairomone Chemistry Female *C. marginiventris* responded equally well to hexane and methylene chloride extracts of whole caterpillars (hexane vs. control, $Z=2.52$, $P=0.012$, methylene chloride, $Z=2.52$, $P=0.012$; hexane vs. methylene chloride, Mann–Whitney U test, $U=112.5$, $P=0.999$; Response: 53% of wasps in both treatments). Virtually, no response was observed when leaves were treated with methanol extracts of the herbivore. One parasitoid showed brief antennal drumming on the test leaf, another individual responded to the control.

In a bioassay that tested hexane extracts of caterpillar footprints, 67% of the observed wasps elicited characteristic antennation behavior (Fig. 3a). The footprint extract was more attractive than the control extract ($Z=2.803$, $P=0.005$). The mix of *n*-alkanes (C_{21-32}) applied to the barley surface elicited a weaker but still significant response in *C. marginiventris* ($Z=1.991$, $P=0.046$). Forty percent of the tested individuals responded in the experiment (Fig. 3b).

Discussion

The parasitoid *C. marginiventris* responds to chemical residues (footprints) of its lepidopteran host *S. frugiperda* with characteristic host recognition behavior, displayed as antennal drumming on the substrate (Rostás et al. 2008). However, the persistence and chemistry of these footprints had not yet been investigated.

Our experiments showed that the host location kairomone was persistent for a relevant period of time. Only 15 min of walking by four small caterpillars left sufficient amounts of infochemicals on the plant surface to induce a clear antennation response 48 h after caterpillars had been removed. Following a lag time of 72 h, antennation time on the treated area was no longer significant. These results suggest that host-derived chemicals are uncharged lipophilic compounds of low volatility, as only such chemicals can be sorbed onto the leaf surface and stay there for some time due to the lipophilic properties of the plant cuticle (Müller and Riederer 2005). Little is known about the persistence of insect walking tracks. Hemptinne et al. (2001) reported that females of the ladybird *Adalia bipunctata* avoid laying eggs on filter paper contaminated with conspecific larval tracks for at least 10 days. Tracks produced by ladybird larvae were predominantly straight-chain and methyl-branched alkanes in the C_{21} to C_{33} range. The bioactivity of footprints is expected to vary with the nature and concentration of deposited chemicals, the substrate, and the perceiving insect species. Most insect tracks reported, so far, consist of long-chain alkanes and alkenes (Kosaki and Yamaoka 1996; Hemptinne et al. 2001; Votsch et al. 2002; Nakashima et al. 2004; Eltz 2006; Colazza et al. 2007). Thus, their persistence can be expected to be in the range of days rather than hours. An exception, however, was found in the tracks of the grain beetle *Oryzaephilus surinamensis* that can be detected by the parasitoid *Cephalonomia tarsalis* for only 30 min (Collatz and Steidle 2008). Aldehydes rapidly oxidizing to fatty acids were the active components in the footprints of the beetle (Collatz, personal communication).

Extracts with methylene chloride and hexane, but not methanol, of entire *S. frugiperda* caterpillars elicited clear antennal drumming responses in female *C. marginiventris* to equal extents. This shows that wasps use apolar cuticular components for host recognition and suggests that caterpillar footprints should be lipophilic, as well. Further bioassays with hexane extracts of *S. frugiperda* footprints have confirmed this notion, as wasps responded positively to the offered residue chemicals. The major compounds that account for more than 90% of the footprint extract are a homologous series of saturated alkanes ranging from heneicosane (nC_{21}) to dotriacontane (nC_{32}) with pentacosane (nC_{25}) being the most abundant. Monomethyl-branched alkanes and five unidentified compounds also were present,

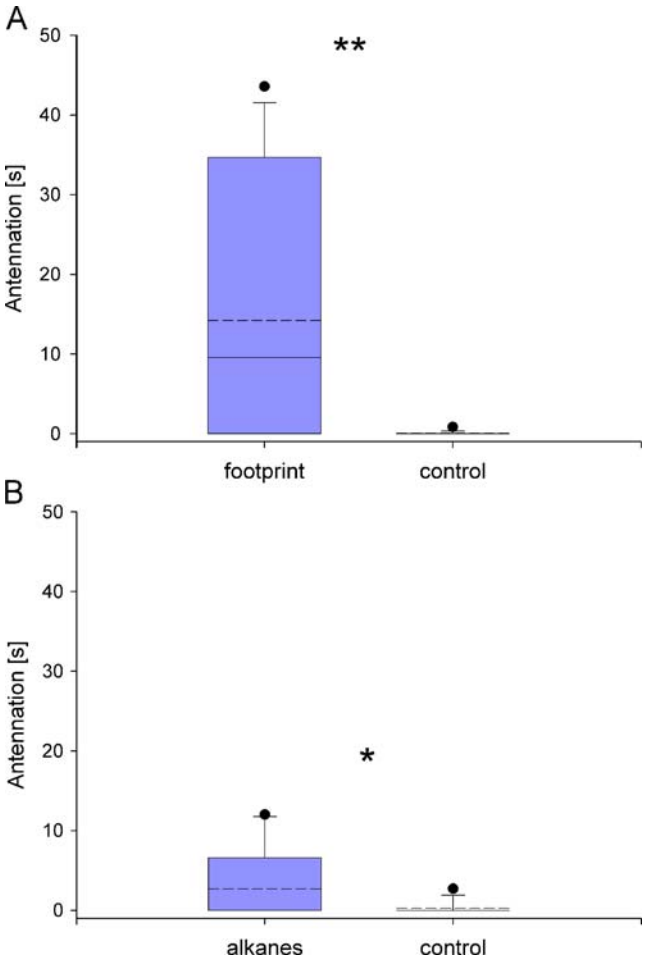

Fig. 3 Antennal drumming of *Cotesia marginiventris* on **a** hexane extracts of caterpillar footprints and **b** *n*-alkanes found in footprint extract. *Dark box* represents leaves treated with footprint extract or *n*-alkanes, respectively. *White box* represents hexane control. *Boxes* show median (*solid line*) and mean (*dashed line*), 25th and 75th percentiles. Whiskers are 5th and 95th percentiles. *Dots* indicate outliers. *Asterisks* denote significant differences: $*P<0.05$, $**P<0.01$

but occurred only as minor compounds. An almost identical pattern of chemicals was found in the hexane extract of the caterpillar's ventral cuticle. Thus, we suggest that footprint compounds may be of cuticular origin. Thoracical legs, prolegs, and claspers were observed to be in contact with the substrate (Fig. 4), and it seems that the most likely source for the kairomone should be the caterpillar's prolegs and claspers. These extremities are covered by a cuticle and represent a larger surface in contact with the leaf than the claws of thoracical legs.

With regard to compositions and ratios of cuticular and footprint alkanes, remarkably similar findings have been reported from the pentatomid bug *Nezara viridula* (Colazza et al. 2007). *Trissolcus basalis*, a parasitoid of this bug, uses the deposited hydrocarbons to locate host eggs and may even distinguish between male and female residues by the presence or absence of *n*-nonadecane. In two other species of the genus *Cotesia* (*C. kariyai* and *C. plutellae*), linear, monomethyl- and dimethyl-branched alkanes (C_{20}–C_{40}) from the cuticula of lepidopteran hosts also are known to serve as host recognition cues upon contact with the host (Ohara et al. 1996; Roux et al. 2007). Whether some of these compounds are deposited on the substrate, where they can be exploited as host location kairomones, remains to be investigated.

In a final experiment, we tested the wasps' response to the main compounds of the footprint extract. Commercially available $n\mathrm{C}_{21}$–$n\mathrm{C}_{32}$ alkanes were used to partially reconstruct the chemical footprint extract in the same amounts and ratios as had been tested in the preceding bioassay. *C. marginiventris* females showed significant antennal drumming on leaves treated with this *n*-alkane blend. However, the response was considerably weaker, suggesting that some minor components, such as the methyl-branched alkanes or other unidentified chemicals are important for host recognition, as well. Our observation is consistent with studies on *N. viridula* and its egg parasitoid *T. basalis* where a reconstructed blend of straight-chain hydrocarbons extracted from the host also induced only weak arrestment responses in *T. basalis* females (Colazza et al. 2007). Methyl-branched alkanes and alkenes often occur in insect hydrocarbons, and sometimes, they have behavioral activity as contact pheromones (Ginzel et al. 2003). In plant waxes, however, they can be detected only in trace amounts, if at all. This and the fact that *n*-alkanes are common plant wax compounds suggests that minor constituents may enable wasps to detect insect hydrocarbons against a background of similar plant hydrocarbons. In the experiments described here, barley leaves were used as a surface for caterpillars to walk on. The epicuticular wax of this plant contains very small proportions of *n*-alkanes with heptacosane ($n\mathrm{C}_{27}$) as the only overlapping compounds that are also present in the chemical footprint extract (Rostás et al. 2008). At least in this case, it can be assumed that linear alkanes derived from the caterpillars can be recognized as host-specific kairomones. Future research will need to assess whether the degree of overlap between plant and insect hydrocarbons plays a role in the perception of chemical footprints on

Fig. 4 *Spodoptera frugiperda* walking on a barley leaf. Note that only thoracical legs, prolegs, and claspers touch the substrate

different waxy surfaces. Depending on the specific wax composition, the detection of chemical footprints on different plant surfaces may be easier or more difficult for hunting parasitoids and predators.

In summary, we confirmed that parasitoids use footprint chemicals deposited on the epicuticular wax layer of plants as low-volatile cues to find their host in its microhabitat. Tracks produced by caterpillars consist mostly of linear alkanes and minor amounts of branched alkanes that presumably originate from the cuticle of prolegs and claspers. On barley leaves, these footprints can be detected by *C. marginiventris* for a maximum of 2 days. Our findings add to the growing body of literature demonstrating the importance of insect-derived chemicals deposited on plants. These serve as a bridge in time and thus mediate numerous interactions. We expect that future research will establish the significance of residual chemicals in regulating behavior—an aspect of insect ecology that awaits full appreciation.

Acknowledgements The authors are grateful to G. Trautmann (Bayer CropScience) for weekly supplies of *Spodoptera frugiperda* and to V. Uhl for technical assistance. We also thank M. Riedel for assistance with compound identifications, M. Riederer for making lab space available, and J. Winkler-Steinbeck for cultivating barley. Two anonymous reviewers provided helpful comments. Financial support was provided by the Deutsche Forschungsgemeinschaft (SFB 567, TP B9).

Received: 25 January 2008 / Revised: 8 August 2008 / Accepted: 13 November 2008 / Published online: 3 December 2008

Abstract Tomato (*Solanum lycopersicum*) polyphenol oxidases (PPOs), enzymes that oxidize phenolics to quinones, have been implicated in plant resistance to insects. The role of PPO in resistance to cotton bollworm [*Helicoverpa armigera* (Hübner)] and beet armyworm [*Spodoptera exigua* (Hübner)] (Lepidoptera: Noctuidae) was evaluated. Consumption, weight gains, and mortality of larvae feeding on foliage of transgenic tomato lines overexpressing PPO (OP lines) and of larvae feeding on foliage of transgenic tomato lines with suppressed PPO (SP lines) were compared with consumption, weight gains, and mortality of larvae feeding on non-transformed (NT) plants. Increases in foliage consumption and weight gains were observed for cotton bollworms feeding on leaves of SP plants compared to NT and OP plants. PPO activity was negatively correlated with both weight gains and foliar consumption of cotton bollworm, substantiating the defensive role of PPO against this insect. Similarly, beet armyworm consumed less foliage (both young and old leaves) from OP plants than SP plants. Larvae feeding on OP leaves generally exhibited lower weight gains than those feeding on SP leaves. These results indicate that tomato PPO plays a role in resistance to both cotton bollworm and beet armyworm.

Introduction

Beet armyworm [*Spodoptera exigua* (Hűbner)] and cotton bollworm [*Helicoverpa armigera* (Hűbner)] are two of the most destructive and widely distributed Lepidopteran pests of many important crops, including tomato, sugar beet, legumes, cotton, maize, soybean, tobacco, pepper, alfalfa, potato, onion, sunflower, and citrus, as well as many weeds (Center for Integrated Pest Management 1982). Control measures for beet armyworm and cotton bollworm are both expensive and unsuccessful because both pests are fecund and polyphagous and because both have developed resistance against insecticides. The most successful crop protection recommendations include monitoring of pest populations, implementation of integrated pest management with conservation and augmentation of parasites and predators, the use of sex pheromone traps and hormone inhibitors, and the use of transgenic Bt crops (Haffman et al. 1996; Summers et al. 1996, 2004; Sikora 2000; Godfrey and Kaffka 2003; Manjunath 2004; Mellet and Schoeman 2004; Tillman and Bell 2006). However, a recent study confirmed the development of seven to 50-fold resistance to Bt toxins (Cry1Ac) from *Bacillus thuringiensis* in cotton bollworm within 17 to 21 generations (Akhurst et al. 2006). Therefore, development of other effective control methods must be further investigated for future use.

Polyphenol oxidases (PPOs) are copper metalloenzymes that catalyze two distinct reactions: the *o*-hydroxylation of monophenols to *o*-diphenols (EC 1.14.18.1) and the

oxidation of *o*-dihydroxyphenols to *o*-diquinones (EC 1.10.3.2; Steffens et al. 1994). Quinones are highly reactive intermediates that rapidly polymerize, leading to the formation of black or brown pigments that affect the quality and nutritional value of many fresh and processed products (Mayer and Harel 1991; Friedman 1997). In most plant species, PPO and its mono and/or *o*-diphenolic substrates are stored separately (PPO in plastids, phenolics in the vacuole) and come into contact only after cellular decompartmentalization occurs as a consequence of wounding, senescence, or attack by insects or pathogens. Under acidic conditions (pH<4), quinones undergo a reversed disproportionation reaction to form semiquinone radicals, leading to the generation of reactive oxygen species (ROS). At higher pHs, black or brown pigments are produced from nucleophilic Michael addition reactions of quinones, and the covalent 1,4-addition of quinones to cellular nucleophiles may also occur (Guyot et al. 1995, 1996). These secondary reactions may lead to damage of DNA, protein, and/or lipid (Steffens et al. 1994).

PPOs, which are ubiquitous in angiosperms, may have evolved to the point of now fulfilling diverse functions in different plant species. Several physiological roles for PPO have been suggested that include biosynthesis of pigments (aurones or betalains) and 8 to 8′ lignans, production of phenolic signaling molecules, regulation of plastidic oxygen levels, and plant defense (Mayer and Harel 1979; Vaughn et al. 1988; Goldman et al. 1998; Nakayama et al. 2000; Li and Steffens 2002; Cho et al. 2003; Thipyapong et al. 2004a; Wang and Constabel 2004; Gandía-Herrero et al. 2005). In tomato, the PPO gene family is clustered on chromosome eight and consists of seven members including PPO A, A′, B, C, D, E, and F (Newman et al. 1993). PPOs are accumulated in leaves, roots, stems, and flowers of tomato with particularly high levels in young tissues that are vulnerable to diseases and insect pests. These PPO gene members are expressed differentially in various vegetative and reproductive tissues and in response to abiotic and biotic stresses (Thipyapong et al. 1997, 2004a, b; Thipyapong and Steffens 1997). The constitutive and induced expression patterns of PPOs suggest the possible involvement of PPOs in plant defense. In particular, a variety of evidence has implicated PPO in defense against diverse diseases and insect pests. PPO activity levels are associated with disease resistance or are induced in response to pathogen infection in several plant–pathogen interactions (Tyagi et al. 2000; Banga et al. 2004; Campos et al. 2004; Krishnamoorthy et al. 2004; Raj et al. 2006). In addition, a role for PPO in resistance to *Pseudomonas syringae* pv. *tomato* has been demonstrated unequivocally using transgenic tomato plants with modified PPO expression; overexpression of PPO led to increased resistance, while PPO suppression led to hypersusceptibility (Li and Steffens 2002; Thipyapong et al. 2004a). Recently, these transgenic tomato plants also were used as a platform to establish the defensive role of PPO against common cutworm [*Spodoptera litura* (F.)] (Thipyapong et al. 2006; Mahanil et al. 2008). We report the effect of PPO on foliar consumption, larval weight gains, and mortality of two additional Lepidopteran insects, cotton bollworm and beet armyworm, using genetically modified tomato plants with altered PPO expression in an otherwise identical genetic background.

Methods and Materials

Plant Material and Growth Conditions Five tomato (*Solanum lycopersicum* cv. Money Maker) genotypes varying in PPO activity levels were used for this study: a non-transformed (NT) line, two independent antisense PPO transgenic lines, A14-6 and A19-3, with suppressed PPO activity (SP lines), and two independent sense PPO transgenic lines, S-18 and S-28, overexpressing PPO activity (OP lines). These SP and OP transgenic plants have been described in detail previously (Li and Steffens 2002; Thipyapong et al. 2004a) and were from the F_8–F_9 generations. Briefly, transformation constructs used for generating these SP and OP tomatoes were made by ligating a 2-kb potato PPO complementary DNA (Hunt et al. 1993), exhibiting 68–91% DNA sequence similarity to the seven tomato PPO genes (Newman et al. 1993), into transformation vector pBI 121 (Clontech) in the antisense orientation relative to the CaMV 35S promoter or by ligating the same gene in the sense orientation relative to the CaMV 35S promoter within cloning vector pART 7 (Gleave 1992). The constructs were introduced into *Agrobacterium tumefaciens* that was then used to transform cotyledons and hypocotyls of tomato. The SP lines A14-6 and A19-3 have approximately two to 40-fold reduced PPO activity and lack or have low levels of immunologically detectable PPO in leaf homogenates. Neither endogenous nor antisense PPO messenger RNA is detectable in leaves or flowers of A14-6 (Thipyapong et al. 2004a). The OP lines S-18 and S-28 contain two to tenfold increased PPO activity and immunodetectable PPO and show up to 30-fold increases in PPO transcripts (Li and Steffens 2002). No effect on plant growth and development was observed from PPO modification. The transgenic plants exhibited morphology and plant vigor similar to NT plants and flowered and set seeds normally (Steffens et al. 1994; Li and Steffens 2002; Thipyapong et al. 2004a, b; Mahanil et al. 2008). In addition, the total foliar protein contents of these transgenic plants were not significantly different from those of NT plants (Mahanil et al. 2008). All tomato genotypes were grown in 1:1 peat moss/soil mix in a laboratory culture room with a 13-h photoperiod at a

photosynthetic photon flux density of 200–300 μmol m^{-2} s^{-1} at plant height and 26–30°C day/night temperature.

Cotton Bollworm [Helicoverpa armigera (Hübner)] Feeding Assays Cotton bollworm larvae were collected from the Suranaree University of Technology Farm and from cotton fields in Lop Buri province, Thailand and reared on artificial diet until pupation. The performance of cotton bollworm larvae when feeding on detached leaves of tomato genotypes varying in PPO activity levels was evaluated. Leaf position was counted from the top of the plants with the topmost (youngest) leaf node as node 1. Male and female adults were randomly mated, and the resulting eggs were allowed to eclose. Neonates were reared on artificial diet for 4 days. The 4-day-old larvae were then weighed and divided equally onto detached leaves taken from nodes 4 and 8 of four tomato genotypes, NT, A14-6, A19-3, and S-18. Each larva was placed onto detached leaves in an individual plastic container (6-cm diameter) and allowed to feed for 7 days. The initial areas of leaves were measured with a leaf area meter. The petioles of leaves were wrapped in wet cotton, and leaf material was changed every 2 days, or sooner if they were almost completely eaten, so that larvae were never food limited. After 7 days of feeding, weight gains of larvae (assuming that larvae in all treatments contained similar amounts of food in their guts at the end of the experiment), larval mortality, and remaining leaf areas were recorded.

Five replications were used for each treatment (genotype). Each replication consisted of three larvae, each in its own plastic container, fed leaves from five to ten plants grown near each other in the plant culture room for the entire experiment. Thus, a total of 15 larvae were used per treatment per experiment. For statistical analysis, mean weights and leaf areas consumed were calculated for the three larvae in each replication, and these mean weights and areas were used in the analyses. Leaf areas were measured when leaves were changed, and after the 7 days of feeding, the leaf areas consumed were calculated from the original leaf areas minus the leaf areas remaining after feeding. Percent mortality was calculated by the following formula: Percent mortality = (number of dead larvae/number of total larvae) × 100. The effects of plant genotype and leaf age (node) on larval weight gains and leaf areas consumed were evaluated using analysis of covariance (ANCOVA) with initial larval weight as the covariate (Raubenheimer and Simpson 1992; Horton and Redak 1993). Relative growth rates (RGRs) were calculated by dividing weight gains by the product of mean larval weight and feeding duration in days, as appropriate for assays in which larvae molted one or more times (Farrar et al. 1989). A two-way analysis of variance (ANOVA) of larval RGRs was conducted. All analyses were conducted using PROC MIXED in SAS (SAS Institute 2003).

In addition, the relative importance of pre-ingestive effects (e.g., feeding deterrence) vs. post-ingestive effects (e.g., antibiosis) of PPO on larval weight gains was investigated by ANCOVA using weight gain as the response variable and leaf consumption as the covariate. This analysis was conducted using PROC MIXED in SAS (Horton and Redak 1993).

In a separate experiment to further evaluate the defensive role of PPO, correlations between PPO activity levels and cotton bollworm weight gains and between PPO activity levels and leaf areas consumed were estimated using a population of 22 A19-3 and S-18 transgenic plants segregating for the PPO transgenes and, hence, for PPO activities. PPO activities in these plants ranged from 1.00 to 18.95 μmol quinone formed per minute per milligram protein. At the beginning of the experiment, a leaflet from node 4 of each plant was used to measure PPO activity, and separate leaflets from the same leaf were used for the feeding assay. Neonate larvae were allowed to feed on detached node 4 leaves of individual plants (ten neonates per leaf) for 2 days. Then, five larvae were randomly selected, weighed, and divided onto detached node 4 leaflets of the same plant, the leaf areas of which had been measured. One larva was placed onto each leaflet in an individual plastic container (6-cm diameter). Larvae were allowed to feed on leaves for 7 days. Leaves whose petioles were wrapped in wet cotton were changed every 2 days, or sooner if they were almost completely eaten, so that larvae were never food limited. After 7 days, the weight gains and remaining leaf areas were recorded. Correlation between PPO activity levels and cotton bollworm weight gains and between PPO activity levels and leaf areas consumed were analyzed by SAS (SAS Institute 2003).

Beet Armyworm [Spodoptera exigua (Hübner)] Feeding Assays Beet armyworm larvae were collected from vegetable farms in Nakhon Ratchasima province, Thailand and reared on artificial diet until pupation. Male and female adults were allowed to randomly mate and lay eggs. Five genotypes of tomato, A14-6, A19-3, NT, S-18, and S-28, were used to evaluate the effect of PPO on larval performance of beet armyworm when their plant-derived diets varied in PPO activity levels. The experiments were conducted three times at different times of the year (experiment 1 in March, experiment 2 in October, and experiment 3 in June). After hatching, the neonates were equally divided and placed onto detached leaves of each genotype that were placed in plastic boxes (16×22 cm^2), one genotype per box. After 5 days (experiments 1 and 2) or 7 d (experiment 3), larvae were weighed and transferred to individual plastic containers (6-cm diameter; one larva

per container) containing one or more detached leaves, the leaf areas of which had been measured with a leaf area meter. Larvae were allowed to feed for 5 days (experiment 1) or 7 days (experiments 2 and 3). Leaves were changed every 2 days, or sooner if they were almost completely eaten, so that larvae were never food-limited. After 5 or 7 days of feeding, the mortality and weights of larvae and remaining leaf areas were recorded, and weight gains, RGRs, percent mortality, and leaf areas consumed were calculated as described for the cotton bollworm feeding assay. Weight gains were calculated at two stages of larval growth; the first stage at 0–5 days old (experiments 1 and 2) and 0–7 days old (experiment 3) and the second stage at 5–10 days old (experiment 1), 5–12 days old (experiment 2) and 7–12 days old (experiment 3). Leaf areas consumed were calculated only from the second stage in all three experiments. In experiments 1 and 2, larvae were continuously fed on foliage of the five tomato genotypes until pupation. Pupal weight was measured 24 h after pupation. Larval lifespan was calculated as the time from egg eclosion to pupation.

Fifteen replications (three larvae per replication), seven replications (two larvae per replication), and ten replications (three larvae per replication) were used in experiments 1, 2, and 3, respectively. Each larva was maintained in its own plastic container and fed leaves from three to five plants grown near each other for the entire experiment. For statistical analysis, mean weights, leaf areas consumed, and larval life spans were calculated for the two or three larvae in each replication. The mean weights, areas, and life spans for all replications were used in the analyses. For experiments 1 and 2, the effects of plant genotype on first stage weight gains, pupal weight, and larval life span were analyzed by one-way ANOVA. The effects of plant genotype on second-stage weight gains and leaf areas consumed were analyzed by ANCOVA with initial larval weight as a covariate. ANCOVA could not be used for the analysis of first-stage weight gains because neonate larvae were too small to obtain an initial weight (i.e., initial weights for neonate larvae were assumed to be zero). For experiment 3, the effects of plant genotype and leaf node on first stage weight gains were analyzed by two-way ANOVA, while two-way ANCOVA with initial larval weight as a covariate was used to analyze the effects of plant genotype and leaf node on second-stage larval weight gains and leaf areas consumed. In addition, an ANCOVA was conducted with weight gain as the response variable and leaf consumption as the covariate as described for the cotton bollworm feeding assay.

Protein Extraction, Quantification, and PPO Activity Assay Tomato leaflets (from node 4 and/or node 8) were collected at the beginning of insect feeding assays and homogenized at a ratio of 200-mg fresh weight to 1-ml homogenization buffer [0.1 M Tris–HCl, pH 7.0, 0.1 M KCl, 1 mM PMSF, 1 μg ml^{-1} leupeptin, 1% (*v*/*v*) Triton X-100, 3% (*w*/*v*) PVPP, and 1 mM Na_2EDTA). The homogenate was centrifuged at 10,000×*g* at 4°C for 20 min, and the supernatant was used for protein quantification and PPO activity assay. Total protein was quantified by the Bradford method (Bradford 1976) using bovine serum albumin as standard. PPO activity was measured spectrophotometrically following Thipyapong et al. (1995) using 2 mM 4-methylcatechol as a substrate. Catalase (280 U) was added to each sample 15 min prior to measurement for elimination of peroxidase-mediated phenolic oxidation. Specific activity was expressed as micromole quinone formed per minute per milligram protein. Seven replicates were used for each treatment. One-way ANOVA was used to evaluate the effect of plant genotype on PPO activity using SAS (SAS Institute 2003).

Results

Overexpression of PPO Increases Resistance to Cotton Bollworm The role of PPO in resistance to cotton bollworm was evaluated with a transgenic tomato line that overexpresses PPO (S-18) and two independent transgenic lines with suppressed PPO levels (A14-6, A19-3). Growth on these transgenic lines was compared to growth on the NT control with intermediate PPO level. At the time when the cotton bollworm performance was evaluated, foliage of OP plants showed 2.6-fold higher PPO activity levels than NT plants, while SP plants had 1.5- to 2.9-fold lower PPO activity levels than NT plants (Table 1). Four-day-old larvae were placed on nodes 4 and 8 leaves of tomato genotypes with varied PPO activity levels and allowed to feed for 7 days. Larval weight gains were significantly affected by plant genotype ($F_{3,29}$=6.35, P=0.002), leaf node ($F_{1,29}$=4.32, P=0.05) and by the interaction of plant genotype and leaf node ($F_{3,29}$=13.6, P<0.001). The covariate (initial weight) effect was not significant ($F_{1,29}$= 0.03, P=0.87). Weight gains were higher on node 8 leaves than on node 4 leaves, and the effects of plant genotype on weight gains were much more pronounced on node 8 leaves than on node 4 leaves. On node 8 leaves, weight gains were highest on plants with suppressed PPO activities, intermediate on wild-type plants, and lowest on lines with overexpressed PPO. The weight gains of cotton bollworm larvae feeding on node 8 A14-6 and A19-3 leaves were 3.0- and 1.9-fold higher than those feeding on NT leaves, respectively. The ANOVA of larval RGRs yielded results that were very similar to the ANCOVA analysis (data not shown).

Leaf areas consumed were significantly affected by plant genotype ($F_{3,29}$=5.85, P=0.003), leaf node ($F_{1,29}$=34.44,

Table 1 Leaf area consumption, percent mortality, and weight gains of *H. armigera* feeding on tomato leaves from genotypes differing in PPO activity levels

Leaf node	Genotype	PPO activity (μmol quinone formed per minute per milligram protein)	Leaf area consumption (cm^2)	Weight gain (mg)	RGR ($mg\ mg^{-1}\ day^{-1}$)	Percent mortality

RGR relative growth rate
[a] A14-6, A19-3: transgenic lines with suppressed PPO activity; NT: non-transformed control; S-18: a transgenic line overexpressing PPO activity
[b] Data are presented as means±SE

$P<0.001$), and by the interaction of plant genotype and leaf node ($F_{3,29}=17.74$, $P<0.001$). The covariate effect was not significant ($F_{1,29}=0.25$, $P=0.62$). At node 4, leaf areas consumed by cotton bollworm were not markedly different among genotypes. However, at node 8, the amount of foliage consumed by cotton bollworm differed greatly among genotypes. Cotton bollworm larvae feeding on A14-6 and A19-3 leaves consumed 2.2 to 2.8 and 1.7 to 2.1 times more foliage than those feeding on NT and S-18 leaves, respectively.

When the effects of plant genotype on weight gains of larvae were further analyzed using leaf consumption as a covariate, the covariate effect was significant ($F_{1,27}=16.34$, $P<0.001$), but the effects of plant genotype, leaf node, and leaf node by genotype were not (genotype, $F_{3,27}=1.92$, $P=0.15$; node, $F_{1,27}=1.82$, $P=0.19$; genotype by node, $F_{3,27}=1.59$, $P=0.21$).

Finally, when cotton bollworm neonates were fed, in a separate experiment, on node 4 leaves of a population of transgenic tomato plants segregating for PPO activities (activities ranged from 1.00 to 18.95 μmol quinone formed per minute per milligram protein), a negative correlation was found between PPO activity levels and weight gains ($r=-0.598$, $P<0.001$; $y = 3.0764x + 55.421$). Similarly, PPO activity levels were negatively correlated with foliar consumption ($r=-0.540$, $P<0.001$; $y = -0.4859x + 11.618$; Fig. 1).

Overexpression of PPO Increases Resistance to Beet Armyworm PPO-mediated resistance to another tomato Lepidopteran insect pest, *S. exigua*, was also evaluated in three experiments with five tomato genotypes [two independent SP lines (A14-6 and A19-3), 2 independent OP lines (S-18 and S-28), and NT control] in a manner similar to that used with *H. armigera*. In experiments 1 and 3 (PPO activities were not determined in experiment 2), differences in PPO activity levels were found among NT, OP, and SP plants. The lines S-18 and S-28 had the highest PPO activity (1.7- to 4.5-fold higher than NT), NT had intermediate PPO activity, and A14-6 and A19-3 had the lowest PPO activity (1.3- to 3.1-fold lower than NT;

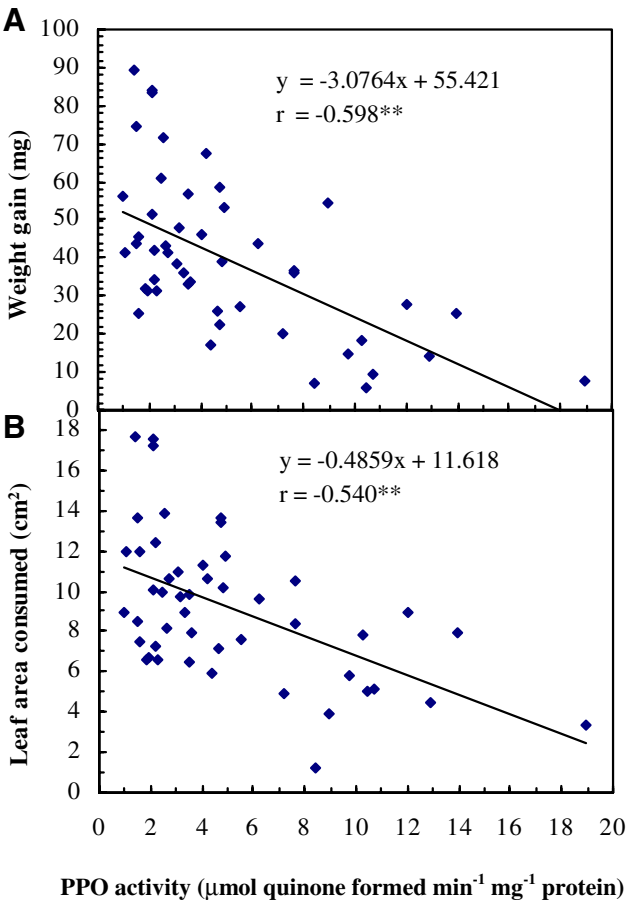

Fig. 1 Correlation between PPO activity and (**a**) weight gain or (**b**) leaf area consumption of cotton bollworm larvae (*H. armigera*) feeding on node 4 leaflets of transgenic tomato plants segregating for PPO activity levels

Table 2). Similar variation in immunologically detectable PPO levels among tomato genotypes also was observed in experiment 2 (data not shown). In agreement with previous reports (Thipyapong et al. 2004a, b; Mahanil et al. 2008), basipetal declines in PPO activities from younger (node 4) to older (node 8) leaves were observed in all five tomato genotypes (Table 2).

The effects of PPO over- and underexpression on *S. exigua* feeding and growth were similar to those observed for cotton bollworm. Consumption of foliage by beet armyworm larvae significantly differed when feeding on different tomato genotypes in both experiment 1 (leaf node 8) and experiment 2 (leaf node 4; experiment 1, main effect of genotype, $F_{4,66}=8.66$, $P<0.001$; effect of covariate, $F_{1,66}=6.80$, $P=0.01$; experiment 2 main effect of genotype, $F_{4,24}=3.33$, $P=0.03$; effect of covariate, $F_{1,24}=0.34$, $P=0.57$). In experiment 3, leaf areas consumed by larvae were significantly affected by leaf node ($F_{1,76}=3.84$, $P=0.05$), but the effect of plant genotype was only marginally significant ($F_{4,76}=2.39$, $P=0.06$), and the genotype by node effect was not significant ($F_{4,76}=0.76$, $P=0.55$). The effect of initial weight (covariate) in experiment 3 was significant ($F_{1,76}=27.99$, $P<0.001$). OP plants with the highest PPO activity levels had the lowest leaf areas consumed in all three experiments at both young (node 4) and old (node 8) leaves. In contrast, consumption of foliage on SP plants with the lowest PPO activity levels was significantly higher than consumption of foliage on NT and OP plants in most experiments. In experiment 1, leaf areas consumed by beet armyworm were the lowest on OP plants (2.1 to 3.5 times lower than SP and 1.5 to 2.2 times lower than NT plants, respectively). In experiment 2, larvae on A19-3 consumed more leaf area than larvae on NT (1.4 times) and OP (2.3 to 2.4 times) plants. In experiment 3, foliar consumption at node 4 of OP plants were 1.6 to 2.6 and 1.8 to 3.1 times lower than foliar consumption on NT and SP plants, respectively. At node 8, the consumption of OP foliage was 1.9 to 2.2 times lower than consumption of A14-6 foliage (Table 2).

Weight gains were measured at two stages. The first stage encompassed days 0 to 5 after initiation of feeding in experiments 1 and 2 and days 0 to 7 in experiment 3. The second stage encompassed days 5 to 10 after initiation of feeding in experiment 1, days 5 to 12 in experiment 2, and days 7 to 12 in experiment 3. First-stage weight gains differed significantly among tomato genotypes in experiment 1 (leaf node 8) and experiment 2 (leaf node 4; experiment 1: $F_{4,67}=109.23$, $P<0.001$; experiment 2: $F_{4,26}=17.86$, $P<0.001$). First-stage weight gains in experiment 3 were significantly affected by genotype and node, but not by the interaction of genotype and node (main effect of genotype, $F_{4,90}=21.45$, $P<0.001$; main effect of node, $F_{1,90}=4.88$, $P=0.03$; genotype by node, $F_{4,90}=2.34$, $P=0.06$). In all experiments, first-stage weight gains of beet armyworm larvae feeding on OP leaves were lower than those of larvae feeding on SP leaves. The differences were 1.4- to 3.3-fold. Also, beet armyworm larvae feeding on SP leaves possessed higher first-stage weight gains than those feeding on NT leaves (1.2- to 2.4-fold). In experiment 1, feeding on OP leaves resulted in 1.7- to 1.9-fold reduction in first-stage weight gains, while feeding on SP leaves enhanced first-stage weight gains by 1.2- to 1.8-fold relative to NT plants. In experiment 2, first stage weight gains were 1.4- to 2.4-fold higher on SP leaves than on NT and OP leaves. In experiment 3, larvae feeding on SP leaves had 1.8- to 2.8-fold and 1.5- to 2.5-fold higher first-stage weight gains than those feeding on OP leaves at nodes 4 and 8, respectively.

Second-stage weight gains were similarly affected by the suppression and overexpression of PPO; larval growth differed on different tomato genotypes at leaf node 8 (experiment 1: $F_{4,66}=21.01$, $P<0.001$; $F_{1,66}=5.01$, $P=0.03$ for the covariate effect), but not leaf node 4 (experiment 2: $F_{4,25}=0.47$, $P=0.76$; $F_{1,25}=5.77$, $P=0.02$ for the covariate effect). In experiment 3, weight gains were significantly affected by plant genotype ($F_{4,76}=4.43$, $P=0.003$), leaf node ($F_{1,76}=5.01$, $P=0.03$), and initial weight ($F_{1,76}=14.10$, $P<0.001$), but not by the interaction of node and genotype ($F_{4,76}=0.52$, $P=0.72$). Rearing the larvae on OP leaves again resulted in the lowest second-stage weight gains. When compared to weight gains of larvae feeding on SP lines, the second-stage weight gains of larvae feeding on OP leaves were 1.3- to 3.7-fold lower. In experiment 1, second-stage weight gains of larvae feeding on OP leaves were 1.2- to 2.3-fold and 1.8- to 2.9-fold lower than those feeding on NT and SP leaves, respectively. Figure 2 shows that sizes of beet armyworm larvae varied when fed on node 8 leaves of plants differing in PPO activity levels in this experiment. In experiment 2, consumption of A19-3 leaves led to the highest second-stage weight gains (1.5-fold and 1.7- to 1.9-fold higher than those feeding on NT and OP leaves, respectively). In experiment 3, beet armyworm feeding on OP leaves at node 4 exhibited 1.6- to 3.1-fold and 1.9- to 3.7-fold lower second-stage weight gains than those feeding on NT and SP leaves, respectively. At node 8, the second-stage weight gains of larvae feeding on OP leaves were 2.2- to 2.8-fold lower than those feeding on SP leaves.

In the two experiments (experiments 1 and 2) in which larvae were allowed to feed on different tomato genotypes until pupation, pupal weight and duration of the larval stage were recorded. No significant variation in pupal weight was found among beet armyworms fed the different genotypes. However, in experiment 1, beet armyworms feeding on SP leaves tended to have higher pupal weights than those feeding on NT and OP leaves (Table 2). For larval life

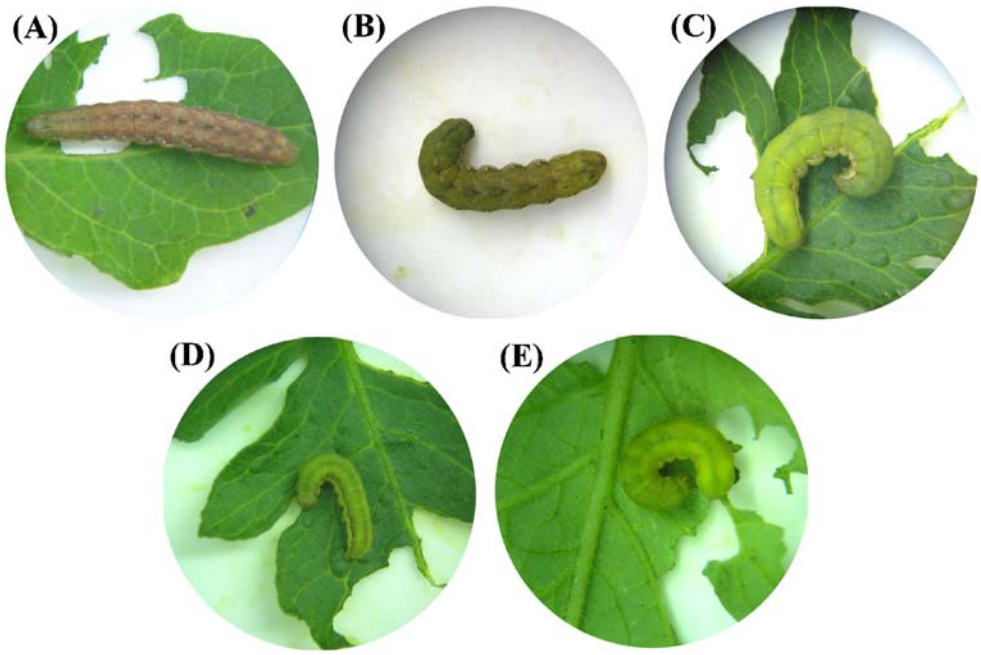

Fig. 2 Ten-day-old larvae of beet armyworm feeding on node 8 tomato leaves with differing PPO activity levels, A19-3 (**a**), A14-6 (**b**), NT (**c**), S-18 (**d**), and S-28 (**e**). *A14-6, A19-3* transgenic lines with suppressed PPO activity; *NT* non-transformed control; *S-18*, *S-28* transgenic lines overexpressing PPO activity

spans, significant differences were found among beet armyworm feeding on different genotypes in experiment 1 ($F_{4,23}$=56.99, P<0.001) when node 8 leaves were used. The larval life spans of insects feeding on OP leaves were significantly longer than those feeding on NT and SP leaves. However, life spans in the second experiment when node 4 leaves were used were not significantly different among genotypes (Table 2).

In some experiments, the percent mortality of beet armyworm feeding on S-18 plants tended to be higher than those feeding on other genotypes (Table 2), but these differences could not be evaluated statistically.

When ANCOVAs using weight gain as the response variable and leaf consumption as a covariate were used to analyze the results of experiments 1–3, the effect of plant genotype was significant in experiments 1 and 3 (experiment 1, $F_{4,66}$=20.57, P<0.001; experiment 3, $F_{4,76}$=4.29, P=0.004), but not experiment 2 ($F_{4,\ 24}$=0.54, P=0.71). The covariate effect was significant (P<0.01) in all three analyses.

Discussion

A role for PPO in resistance to arthropod herbivores frequently has been suggested due to the correlation of insect resistance with PPO activity levels and the inducibility of PPO by arthropod herbivory (Felton et al. 1989; Castañera et al. 1996; Stout et al. 1998; Cooper et al. 2004; Ramiro et al. 2006). Two mechanisms have been hypothesized for PPO-mediated insect resistance. The first is the entrapment of small soft-bodied insects by polymerized glandular trichome exudates from type A or type VI trichomes of *Solanum* species. Ruptured trichomes of these species release oxidatively polymerized exudates that limited feeding and mobility of white flies (*Bemisia tabaci*), spider mites [*Tetranychus cinnabarinus* (Boisduval)], aphids [*Myzus persicae* (Sulzer)], and potato leafhoppers [*Empoasca fabae* (Harris)], causing the death of these insects (Stoner et al. 1968; Kisha 1981; Tingey et al. 1982; Tingey and Sinden 1982; Ryan et al. 1983; Steffens and Walters 1991). Additionally, Simmons et al. (2004) found that high densities of type VI trichomes on tomato leaves could entrap *H. armigera* neonates, causing high mortality. The second putative mechanism is the PPO-mediated reduction in nutritive quality, digestibility, and palatability of plant tissues to insects. PPO-catalyzed quinones can alkylate nucleophilic amino acids, such as lysine, histidine, cysteine, and methionine of proteins, rendering them indigestible. Growth rates of *S. exigua* were reduced when fed on artificial diet supplemented with chlorogenic acid and PPO (Felton et al. 1989). Recent research, including the present study, has attempted to substantiate the role of PPO in resistance to insects using transgenic plants that overexpress PPO (see below). Use of transgenic PPO-expressing plants has partially eliminated the confounding effects of other factors (e.g., other inducible proteins and allelochemicals).

Our results using tomato plants over- and underexpressing PPO activity provide evidence (albeit not unequivocal) for PPO-mediated resistance to two Lepidopteran pests of tomato, cotton bollworm and beet armyworm. In all experiments with beet armyworm that used neonate larvae (first-stage weight gains), a significant effect of PPO (plant

genotype) was found on weight gains. Significant effects of plant genotype on larval weight gains and consumption were also found for older (second stage) beet armyworm larvae in two of three experiments. In addition, higher PPO levels were associated with longer larval development times, although no PPO effect was found on pupal weight. In general, the effects of plant genotype on beet armyworm consumption and growth were more evident when assays were conducted with older (node 8) rather than younger (node 4) leaves.

For cotton bollworm assays, which used 4-day-old larvae, suppression of PPO in node 8 leaves of SP plants allowed cotton bollworm larvae to grow 1.9 to 3.0 times faster and consume 2.1- to 2.8-fold more leaf material than larvae feeding on node 8 leaves of NT and OP plants. In contrast, significant differences in growth or consumption of bollworm larvae were not found when leaves from node 4 were used. However, when neonate bollworm larvae were used for a correlation analysis, PPO activity levels of node 4 leaves were negatively correlated with both weight gains and leaf consumption of cotton bollworm. Taken together, the results of these experiments with cotton bollworm and beet armyworm suggest that PPO exerts stronger effects on younger larvae than on older larvae and that the effects of PPO are stronger in older tomato leaves than in younger leaves.

The results presented here are in general agreement with those reported in other studies that used plants with altered PPO activities. Wang and Constabel (2004) found that forest tent caterpillar larvae feeding on leaves of transgenic poplar overexpressing PPO had reduced average weight gains and higher mortality rates than those feeding on control leaves, but only when larvae from older egg masses were used. In tomato, feeding common cutworm larvae with leaves of transgenic tomato plants overexpressing PPO also reduced their growth rates and increased their mortality compared to those feeding on leaves of NT and transgenic plants with suppressed PPO activity (Thipyapong et al. 2006; Mahanil et al. 2008). This previous work on common cutworm also showed an instar-dependent PPO effect and a lack of effect on pupal weight (Mahanil et al. 2008). Recently, the effect of induced PPO and proteinase inhibitor (PI) accumulation on growth reduction of *H. armigera* also was found in transgenic tobacco overexpressing *Tobpre-proHypSys-A*, which encodes a hydroxyproline-rich glycopeptide systemin precursor protein (Ren and Lu, 2006). However, elevated PPO levels do not always lead to reduction in the growth of insects; Barbehenn et al. (2007), for example, found only limited impact of elevated PPO activities on two lymantriid caterpillars, *Lymantria dispar* and *Orgyia leucostigma*, in transgenic poplar. Clearly, the effects of elevated PPO on insect growth and development vary according to both plant and herbivore species (Barbehenn et al. 2007; Mahanil et al. 2008).

These results implicate PPO as a component of constitutive and/or inducible defensive systems against Lepidopteran insect pests in tomato. The mechanisms through which PPO exerts its effects on insect growth are, however, still unclear. An ANCOVA of the effect of diet treatment on insect weight gains using consumption as a covariate can sometimes be used to help disentangle pre-ingestive effects (e.g., feeding deterrence) from post-ingestive effects (e.g., antibiosis; Horton and Redak 1993). The results of such an analysis of our experiments suggest that differences in the growth of beet armyworms and cotton bollworms on diets with elevated PPO activities were due at least in part to post-ingestive effects, since the use of consumption as a covariate in the analyses of weight gains failed to eliminate the treatment (plant genotype) effect on weight gains in two of three cases in which an effect of genotype was originally detected. Note also that the differences in consumption rates in our studies are not only consistent with a pre-ingestive effect (e.g., feeding deterrence) of PPO but are also with a compensation hypothesis—larvae feeding on OP leaves increased consumption of a presumably low-quality diet (stemming from the antinutritive effect of PPO) relative to that on more nutritious diets (SP and NT leaves). The latter hypothesis is supported by our previous work on dietary utilization by common cutworm larvae showing that larvae feeding on OP leaves possessed higher relative consumption rates compared to those feeding on NT and SP leaves (Mahanil et al. 2008).

For the post-ingestive effect of PPO, it is possible that the highly hydrophilic quinones generated as a result of cellular decompartmentalization by cotton bollworm and beet armyworm feeding undergo a variety of secondary reactions, forming ROS under the acidic conditions in plant tissues (Guyot et al. 1995, 1996). This reaction could be substantial in tomato where abundant PPO and phenolic compounds are stored in trichomes whose rupture could rapidly generate large amount of quinones before reaching, or while in, the low-oxygen-level midgut, as has been suggested by Barbehenn et al. (2007). Interestingly, it has been shown previously that OP tomatoes accumulated much more PPO in trichomes than NT tomatoes, whereas SP tomatoes had minimal PPO in their trichomes (Thipyapong et al. 2004b). The resulting ROS as well as quinones may be directly toxic to the arthropods. Quinones may also cross-link with nucleophilic groups of amino acids and proteins, especially the sulfhydryl, amine, and amide groups, thus leading to reduction in nutritive quality and digestibility of dietary proteins and palatability of leaf tissues (Felton et al. 1989). In particular, the alkaline pH conditions (7.5–10) of many Lepidopteran insect midguts may favor covalent bond formation and cross-linking between quinones and amino acids/proteins, rendering them unusable by digestive and absorption systems (Felton et al.

1989; Steffens et al. 1994). Moreover, quinones may damage DNA directly by covalent modification or lead to substantial alteration of DNA, lipid oxidation, and protein oxidation/fragmentation through ROS formation. ROS such as H_2O_2 could also act as a diffusible signaling molecule to induce other defense genes e.g., PIs, and genes for cellular protection and phytoalexin biosynthesis. In addition, the cross-linking of oxidized phenolics as well as oxidative cross-linking of cell wall proteins and enhanced lignin formation may contribute to additional line of defense in the form of a physical barrier that hampers nutritional acquisition by herbivores (Chamnongpol et al. 1998; Grant and Loake 2000; Orozco-Cárdenas et al. 2001). The reduction of insect growth, development, and leaf consumption observed here might result from any of these mechanisms acting alone or in combination.

It is evident that PPO-mediated resistance is effective against at least three Lepidopteran insect species in addition to a bacterial disease, *P. syringae*. However, additional field testing will be required to assess the practical usefulness of increased PPO activity levels in imparting durable, broad-spectrum resistance to tomatoes when used as a component of an integrated pest management program.

Received: 29 June 2008 / Revised: 19 October 2008 / Accepted: 3 December 2008 / Published online: 17 January 2009

Abstract The new bioactive sesquiterpenoid (3*R*,6*E*)-2,6,10-trimethyl-3-(3-*p*-hydroxyphenylpropanoyloxy)-dodeca-6,11-diene-2,10-diol, named megalanthine, was isolated from the resinous exudates of *Heliotropium megalanthum*. The degradation products of this compound were identified. Several plant-defensive properties (insecticidal, antifungal, and phytotoxic) were evaluated after obtaining positive results in a preliminary etiolated wheat coleoptile bioassay. This bioassay showed the need to have both the phenolic and sesquiterpene moieties of the natural product present to achieve a biological effect. This result was confirmed in phytotoxicity bioassays. Megalanthine was ruled out as a significant plant–plant defense agent because of its lack of stability. The positive results recorded in the antifungal and antifeedant tests suggest, however, that this chemical is relevant in several ecological interactions involving *H. megalanthum*.

Introduction

Species of *Heliotropium* of the *Cochranea* section (Heliotropiaceae) are endemic to the coastal hills of northern and central Chile and southern Peru. Like many plants of that area, they characteristically produce resinous exudates that cover the leaves and stems (Johnston 1928). These exudates are associated with a complex defense mechanism that includes the prevention of excessive water evaporation and protection against UV radiation (80–320 nm), phytopathogens, and phytophagous organisms (Johnson 1983; Kelsey et al. 1984; Torres et al. 1994; Reina et al. 1997; Villarroel et al. 1997, 2001; Urzúa et al. 1998; Modak et al. 2004).

In this study, we describe the isolation and structural elucidation of megalanthine (**1**), a major component of the resinous exudates of *Heliotropium megalanthum* J. M.

Johnston (Boraginaceae), the alkaloidal fraction of which previously afforded the pyrrolizidine alkaloids (PAs) megalanthonine and lycopsamine (Reina et al. 1998).

Megalanthine spontaneously degrades. Of special interest is the comparison of the bioactivity levels of the degradation products with those of the original natural compound, since this may allow possible plant–plant ecological relationships to be established (Macías et al. 2005).

To explore the activity of the compounds, we used the etiolated wheat coleoptile bioassay, (Cutler 1984) antifeedant test, and toxic bioassays of selected compounds, against the herbivorous insect models *Spodoptera littoralis* (Boisduval), *Leptinotarsa decemlineata* (Say), and the aphid *Myzus persicae* (Sulzer), as well as antifungal studies on three *Fusarium* species. In addition, we tested the selective cytotoxicity on insect Sf9 cells derived from *S. frugiperda* pupal ovarian tissue and mammalian Chinese hamster ovary (CHO) cells. We also tested the phytotoxicity against the dicotyledonous (*Lactuca sativa*, *Lepidium sativum*, and *Lycopersicon esculentum*) and monocotyledonous (*Allium cepa* and *Triticum aestivum*) species, which are denoted as standard target species (STS) (Macías et al. 2000).

Methods and Materials

General Experimental Procedures Optical rotations were measured on a Perkin-Elmer 137 polarimeter. Infrared (IR) spectra were obtained on KBr disks on a Bruker IFS66V FTIR spectrometer. Nuclear magnetic resonance (NMR) spectra were obtained on Bruker AMX2 500 MHz, Varian UNITY-400, and INOVA-600 spectrometers with $CDCl_3$ as solvent. Chemical shifts are given in parts per million with respect to residual ^1H signals of $CDCl_3$ (δ 7.25), and ^{13}C shifts are with respect to the solvent signal (δ 77.0). High-resolution mass spectrometry was carried out on a VG AUTOESPEC mass spectrometer (70 eV). Column chromatography was performed on silica gel (63–200 mesh), and thin layer chromatography (TLC) analysis by using aluminum-packed precoated silica gel plates. For high-performance liquid chromatography (HPLC), LiChrosorb silica 60 was used in the normal-phase mode and LiChrospher RP-18 in the reverse-phase mode with a refractive index detector on a Hitachi L-6020A HPLC instrument. All solvents were spectroscopic grade or distilled from glass prior to use. Fetal bovine serum (FBS), L-glutamine, and penicillin/streptomycin were supplied by GIBCO-BRL (UK). 3-[4,5-Dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) and *p*-nitrophenylphosphate were purchased from Sigma-Aldrich. All of these products were used as received.

Plant Material H. megalanthum J. M. Johnston was collected during the flowering season in October 1995 in the north of Chile (Atacama, III Region) and was identified by Dr. Sebastian Teiller from the Museo de Historia Natural de Santiago de Chile. A voucher specimen is deposited in the herbarium of this museum (number ST 2569).

Extraction and Isolation The resinous exudates of *H. megalanthum* were obtained by dipping 800 g of fresh plant in cold CH_2Cl_2 for 15 to 20 s. Extracts were concentrated to afford 8 g of residue. Resinous exudates were fractioned by flash column chromatography on silica gel, using CH_2Cl_2 with increasing amounts of MeOH as eluent. The major fraction was purified first by Sephadex LH-20 chromatography with *n*-hexane/$CHCl_3$/MeOH (2:1:1) as eluent and then by silica gel preparative TLC eluted with *n*-hexane/EtOAc (1:1) to give megalanthine (**1**) (300 mg, 0.0375% f.p.w.).

Megalanthine (**1**) was stored under dry conditions in the absence of light, at 4°C, but it underwent degradation under these conditions (about 20% in 1 month). Purification of the mixture with silica gel CC, eluted with a gradient of $CHCl_3$/Me_2CO, yielded a fraction with compounds of higher polarity. This fraction was found to be enriched with degradation products **2** and **3** after HPLC separation with MeOH/ACN/H_2O (2:1:2) on a RP-18 semipreparative column at a flow rate of 3 mL min^{-1} and with a refractive index detector.

Megalanthine (**1**): colorless oil; $[\alpha]^{25}_D$+28.6° (MeOH; c 0.77); IR (neat, KBr) ν_{max} cm^{-1}: 3,400 (OH), 2,973, 2,929, 1,710, 1,640, 1,614, 817; see Tables 1 and 2 for ^1H and ^{13}C NMR data; electron impact mass spectrometry (EIMS), *m/z* (rel. int.): 404 $[M]^+$ (0.5), 387 $[M–OH]^+$ (17), 386 $[M–H_2O]^+$ (14), 369 $[M–H_2O–OH]^+$ (35), 315 (2), 301 (12), 221 (20), 220 (22), 202 (32), 187 (10), 166 (20), 149 (30), 107 (100), 93 (15); high-resolution electron impact mass spectrometry (HREIMS) *m/z* calculated for $C_{24}H_{36}O_5$ 404.2563, found 404.2544.

Saponification of Megalanthine Megalanthine (**1**) (20 mg) was dissolved in MeOH (0.5 mL) and 5% NaOH (3 mL) and the mixture was stirred continuously at room temperature for 12 h. After the usual workup, the product was purified by using HPLC with a silica gel analytical column eluted with $CHCl_3/Me_2CO$ (4:1) at a flow rate of 1 mL min^{-1} to yield 7 mg of dihydro-*p*-coumaric acid (**5**) and 8 mg of (3*R*,6*E*,10*S*)-2,6,10-trimethyl-3-hydroxydodeca-6,11-diene-2,10-diol (**4**).

(R)- and (S)-Methoxyphenylacetic Acid Derivatives of Compound **4** Compound **4** (4 mg) was treated with CH_2Cl_2 solutions of *N*′-dicyclohexylcarbodiimide (25 mg in 1 mL), *N*,*N*-dimethylaminopyridine (3.5 mg in 0.5 mL), and (*R*)- or (*S*)-methoxyphenylacetic acid (MPA) (10 mg in 0.5 mL); the mixture was stirred at room temperature for 22 h. Evaporation of the solvent under reduced pressure yielded a residue that was purified by HPLC with a Si 60 analytical column, eluting with $CHCl_3/Me_2CO$ (89:11) at a flow rate of 1 mL min^{-1} and a RI detector to yield 4 mg of (*R*)-MPA ester **4R** and 3.5 mg of (*S*)-MPA ester **4S**, respectively.

Preparation of **2** *and* **3** A solution of megalanthine (**1**) (60 mg) in CH_2Cl_2 (10 mL) was stirred with 1.1 equivalents of metachloroperbenzoic acid (MCPBA) at room temperature for 6 h. The crude product was purified by column chromatography $CHCl_3/Me_2CO$ (9:1). Compounds **2** (21 mg) and **3** (19 mg) were obtained after purification by HPLC by using a silica gel analytical column and eluting with $CHCl_3/Me_2CO$ (4:1) at a flow rate 1 mL min^{-1}.

Wheat Coleoptile Bioassay Wheat seeds (*T. aestivum* L. cv. Cortex) were sown on 15 cm diameter Petri dishes filled with Whatman #1 filter paper moistened with water and were grown in the dark at 24°C for 4 days. The etiolated seedlings were removed from the dishes and selected by size uniformity. Selected seedlings were placed in a Van der Wij guillotine, and the apical meristems (2 mm) were cut off and discarded. The next 4 mm of the coleoptiles were removed for bioassay and kept in aqueous nutritive buffer for 1 h to synchronize growth. Pure compounds were dissolved in dimethyl sulfoxide (DMSO) and diluted to the appropriate concentration with a phosphate–citrate buffer containing 2% sucrose at pH 5.6 to give stock solutions with a final DMSO concentration of 0.5%. The buffer with 0.5% DMSO was used as a control. Assays were carried out in duplicate.

Test concentrations were obtained by dilution. The bioassay was performed in 10 mL test tubes: five

coleoptiles were added to each test tube containing 2 mL of the test solution. Three replicates were made for each test solution, and the experiments were run in duplicate. Test tubes were placed in a roller tube apparatus and rotated at 0.25 rpm for 24 h at 22°C in the dark. All manipulations were carried out under a green safelight. Coleoptiles were measured by digitalization of their photographic images.

Statistical Analysis Data were statistically analyzed by using Welch's test with significance fixed at 0.01 and 0.05. Results are expressed in bar charts in which the null value represents the control, negative values represent inhibition, and positive values represent stimulation of the studied parameter (Macías et al. 2000). Statistical significance is expressed by means of letters where "a" means significantly different from the control with 0.01 confidence and "b" means significantly different from the control with a confidence from 0.01 to 0.05. The absence of a letter indicates no significant difference from the control values.

Insect Bioassays *S. littoralis*, *L. decemlineata*, and *M. persicae* colonies were reared on an artificial diet (Poitout and Bues 1974), potato (*Solanum tuberosum* L), and bell pepper (*Capsicum annuum*) plants, respectively, and maintained at 22±1°C, >70% relative humidity with a photoperiod of 16:8 h (L/D) in a growth chamber.

Choice Feeding Assay These experiments were conducted with sixth instar *S. littoralis* larvae, *L. decemlineata* adults, and *M. persicae* apterous adults. Percentage feeding inhibition (%FI) indexes were calculated as described previously (Reina et al. 2001). For FI values >65%, compound **1** was tested in a dose–response experiment in order to calculate its effective antifeedant dose (EC_{50}, the effective dose for 50% feeding reduction), which was determined by linear regression analysis (%FI on log dose). The settling inhibition effect was calculated by the ratio $\%T/\%C$ where $\%T$ is the percentage of aphids settled on the treated disk and $\%C$ is the percentage of aphids settled on the control disk. Significant differences were tested by the Mann–Whitney test.

Oral Cannulation This experiment was performed with preweighed newly molted *S. littoralis* L6 larvae. A sixth instar was orally injected with 40 μg of the test compound in 4 μL of DMSO (treatment) or solvent alone (control) with a Rheodyne Hamilton syringe (50 μL) attached to a Hamilton microdispenser, as described by Reina et al. (2001). The syringe tip was inserted into the mouth of the larvae (maximum of 5 mm), and then larvae were forced to feed until no regurgitation was observed. In total, 20 larvae were "fed" this way per compound tested (Burgeno-Tapia et al. 2008). At the end of the experiments (72 h), larval consumption and growth were calculated on a dry weight basis. A covariance analysis (ANCOVA1) of food consumption (ΔI) and biomass gains (ΔB) with initial larval weight (BI) as covariate (covariate $P>0.05$) was performed to test for significant effects of the test compounds on these variables (Reina et al. 2001).

Cytotoxicity Sf9 cells derived from *S. frugiperda* pupal ovarian tissue (European Collection of Cell Cultures [ECCC]) and mammalian CHO cells (a gift from Dr. Pajares, I. C. Biomédicas, CSIC) were grown as described previously (González-Coloma et al. 2002). Briefly, Sf9 cells, derived from *S. frugiperda* pupal ovarian tissue (ECCC), were maintained in TC-100 insect cell medium supplemented with 10% FBS, 1% L-glutamine, and 1% penicillin/streptomycin at 26°C. Mammalian CHO cells were grown in RPMI 1640 medium supplemented as above at 37°C under a humified atmosphere of 5% CO_2/95% air. Cells seeded in 96-well flat-bottom plastic microplates with 100 μL of medium per well (initial densities of 5×10^4 and 10^4 cells per well for the insect and mammalian cultures, respectively, were exposed for 48 h to serial dilutions of the test compounds). Cell viability was analyzed according to the MTT (Sigma) colorimetric assay method (Mosmann 1983). A 10-μL aliquot of stock MTT solution (5 mg/mL in PBS) was added to all wells, and the cultures were further incubated for 4 h. The medium was then removed by aspiration, 100 μL of dimethyl sulfoxide was added to dissolve the purple formazan precipitate, and the absorbance at 570 nm (reference wavelength of 630 nm) was measured on a microplate reader (SLT Lab Instruments, Groedig, Austria). For each treatment, cell viability was calculated as the percent absorbance of the control (untreated cells). The relative potency of **1** (EC_{50} values, the effective dose to give 50% cell viability) was determined by linear regression analysis (percent cell viability on log dose) for the sensitive cell lines.

Antifungal Activity Assays *Fusarium moniliforme* (Sheldon), *F. oxysporum* fs. *lycopersici* (Scheldt), and *F. solani* (Mart) (Spanish Collection of Type Cultures CECT codes CECT 2152, CECT 2715, and CECT 2199, respectively) were grown in potato dextrose agar in Petri dishes and kept in the dark at 27°C. These cultures were frequently renovated in order to maintain the fungus in optimal conditions. The antifungal activity of **1** was tested at several doses (0.5, 0.1, 0.05, and 0.01 mg/mL) against the three species and estimated as mycelial growth inhibition. The relative potency of **1** (EC_{50} values, the effective dose to give 50% mycelial growth inhibition) was determined by linear regression analysis (percent inhibition on dose) for the sensitive species.

Standard Target Species Bioassays Seeds of lettuce (*L. sativa* L. cv. Roman), cress (*L. sativum* L.), tomato (*L. esculentum*), onion (*A. cepa* L. cv. Valenciana), and wheat

(*T. aestivum*) were obtained from FITÓ, S.L. (Barcelona, Spain). All undersized or damaged seeds were discarded, and the assay seeds were selected for uniformity. Bioassays were carried out in 9 cm diameter plastic Petri dishes with Whatman #1 filter paper as the support.

The general procedure for seedling bioassay was as follows: 25 seeds of each species per dish, except for *T. aestivum* (ten seeds per dish), were placed in 5 mL of the test solution and incubated in the dark at 25°C. Four replicates for each concentration were set up. Germination and growth time varied for each plant species: *L. sativum*, 3 days; *L. sativa*, *L. esculentum*, and *T. aestivum*, 5 days; and *A. cepa*, 7 days.

Test stock solutions (10^{-3} to 10^{-4} M) were prepared with DMSO and then diluted to 10^{-7} M with 10 mM 2-[*N*-morpholino]ethanesulphonic acid. The following solutions were obtained by dilution while maintaining the 1% DMSO percentage. Parallel blind (1% DMSO) and positive controls were performed. The positive controls used the commercial herbicide LOGRAN, a combination of *N*-(1,1-dimethylethyl)-*N*-ethyl-6-(methylthio)-1,3,5-triazine-2,4-diamine (terbutryn, 0.6%), and 2-(2-chloroethoxy)-*N*-{[(4-methoxy-6-methyl-1,3,5-triazin-2-yl)amino]carbonyl} benzenesulfonamide (triasulfuron, 59.4%), as an internal reference according to a previously reported study (Macías et al. 2000). LOGRAN stock solutions were prepared so that the major component (triasulfuron) was present at the same molarity as the materials to be tested.

Bioassay Data Acquisition The evaluated parameters (germination rate, root length, and shoot length) were recorded by using a Fitomed system (Castellano et al. 1999) that allowed automatic data acquisition and statistical analysis by its associated software.

Statistical Analysis Data were statistically analyzed with Welch's test with significance fixed at 0.01 and 0.05. Results are expressed in bar charts in which the null value represents the control, negative values represent inhibition, and positive values represent stimulation of the parameter under investigation (Macías et al. 2000). Statistical significance is expressed by letters with "a" meaning significantly different from the control with 0.01 confidence and "b" meaning significantly different from the control with a confidence from 0.01 to 0.05. The absence of a letter indicates no significant difference from the control values.

Results and Discussion

Megalanthine (**1**), the major compound of the resinous exudate (3.75%), showed a molecular ion at *m/z* 404.2544 in the HREIMS, and this is consistent with the molecular formula $C_{24}H_{36}O_5$. Additional peaks in the EIMS were observed at *m/z* 387 $[M–OH]^+$, *m/z* 369 $[M–OH–H_2O]^+$, and the base peak at *m/z* 107. A strong absorption was observed at 3,400 cm^{-1} in the IR spectrum, and this corresponds to the presence of two or more hydroxyl groups.

The ^{1}H NMR and COSY spectra (Table 1) showed signals for the protons of two subunits, a terpene and an aromatic moiety. The ^{13}C NMR spectrum (Table 2) confirmed the existence of a sesquiterpene unit with three oxygenated carbons [C-2 (δ 72.6), C-3 (δ 79.6), and C-10 (δ 73.9)] and two double bonds [C-6 (δ 134.3), C-7 (δ 125.1) and C-11 (δ 144.7), C-12 (δ111.9)]. The aromatic unit was identified as a dihydro-*p*-coumaric acid derivative. At this point, the number of unsaturations was justified and the sesquiterpene unit should be linear. Based on the structure of farnesyl sesquiterpene, the structure of **1** was proposed and this was subsequently confirmed by heteronuclear multiple bond correlations (HMBC). The position of the phenolic moiety was determined to be at C-3 because the ^{1}H NMR spectrum contained a signal at δ 4.74 *dd* for H-3, which is consistent with a vicinal acyloxy group, and a long-range correlation was observed between H-3 (δ 4.74) and C-9′ (δ 173.5) in the HMBC spectra. Compound **1** was saponified to obtain the dihydro-*p*-coumaric acid (**5**) and the sesquiterpene unit (**4**), which had the expected shielded signal for H-3 in the ^{1}H NMR spectrum (δ 3.33 *dd*). The

Fig. 1 Configurational correlation model for the (*R*)- and (*S*)-MPA derivatives. The MPA plane is shown; $H_{7,5,4a,4b}$ and $H_{1,13}$ are on the *right* and *left* sides of the plane, respectively. Model A, to determine the absolute configuration of C-3, is illustrated

spectroscopic data for the sesquiterpenic unit are in agreement with data previously described for 6*E*-2,6,10-trimethyl-3-hydroxydodeca-6,11-diene-2,10-diol (Miyase et al. 1987; Díaz et al. 1992; Miyazawa et al. 1996). Mosher's method was used to determine the absolute configuration of the chiral center (C-3) of compounds **1** and **4**. Compound **4**, which had a secondary alcohol at C-3, was esterified with the enantiomers of the chiral reagent, MPA (Latypov et al. 1996), and the resulting mixture was subjected to HPLC separation to afford compounds **4R** and **4S**.

The method requires the assignment of as many proton signals as possible of the (*R*)- and (*S*)-MPA esters, and this enables the $\Delta\delta$ (*R*–*S*) values to be determined for the protons. Protons with positive $\Delta\delta$ values should be placed on the right-hand side of model A while those with negative $\Delta\delta$ values are placed on the left (Ohtani et al. 1991) (Fig. 1). The application of the model confirmed that the absolute configuration of C-3 in compound **4** is *R*. The structure of the new sesquiterpene megalanthine (**1**) was thus determined to be (3*R*,6*E*)-2,6,10-trimethyl-3-(3-*p*-hydroxyphenylpropanoyloxy)-dodeca-6,11-diene-2,10-diol.

Compound **1** was stored under dry conditions in the absence of light at 4°C. About 20% was degraded to give two major compounds (**2** and **3**) within a month. Both compounds had very similar ^{1}H NMR spectra, and these corresponded to modifications at positions 6 and 7 of megalanthine (**1**). The H-7 signal at δ 3.77 (*dd*, *J*=7.1, 7.1 Hz) and the H-14 signal at δ 1.16/1.15 (*s*) for compounds **2** and **3** suggested oxygenation at C-6 and C-7. The ^{13}C NMR spectra of these compounds showed two signals at δ 72.5 and 85.1, which are assigned, respectively, to C-6 and C-7 by HMBC correlations. The

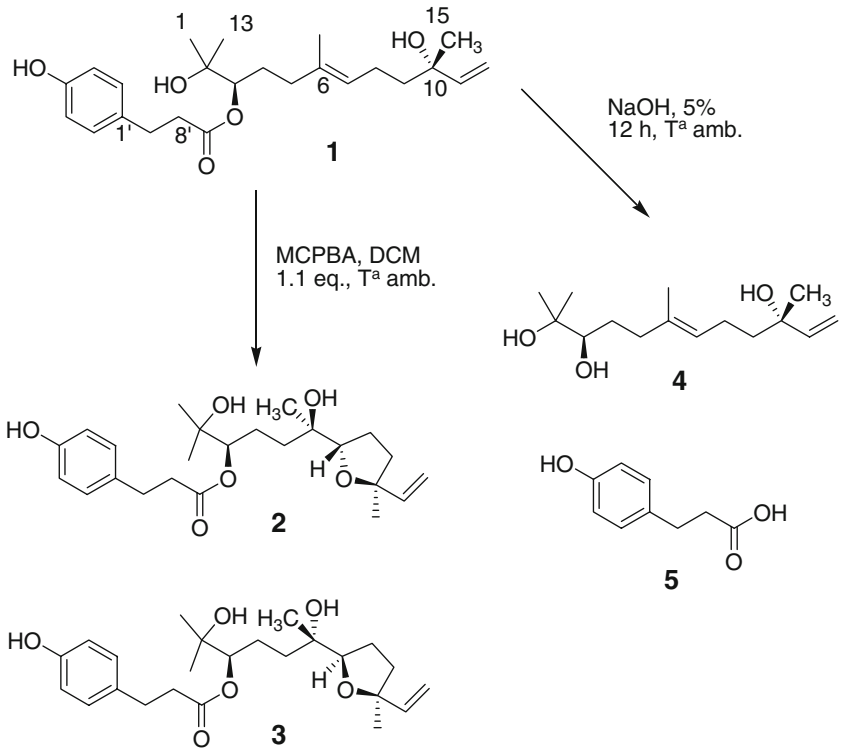

Fig. 2 Structures and chemical correlation of the new compound **1** (megalanthine), it degradation compounds **2** [(3*R*,6*R**,7*S**,10*S**)-7,10-epoxy-2,6,10-trimethyl-3-(3-*p*-hydroxyphenyl propanoyloxy)-dodec-11-ene-2,6-diol)] and **3** [(3*R*,6*S**,7*R**,10*S**)-7,10-epoxy-2,6,10-trimethyl-3-(3-p-hydroxyphenylpropanoyloxy)-dodec-11-ene-2,6-diol] and it saponification products **4** [(3*R*,6*E*,10*S**)-2,6,10-trimethyl-3-hydroxydodeca-6,11-diene-2,10-diol)] and **5** (dihydro-*p*-coumaric acid)

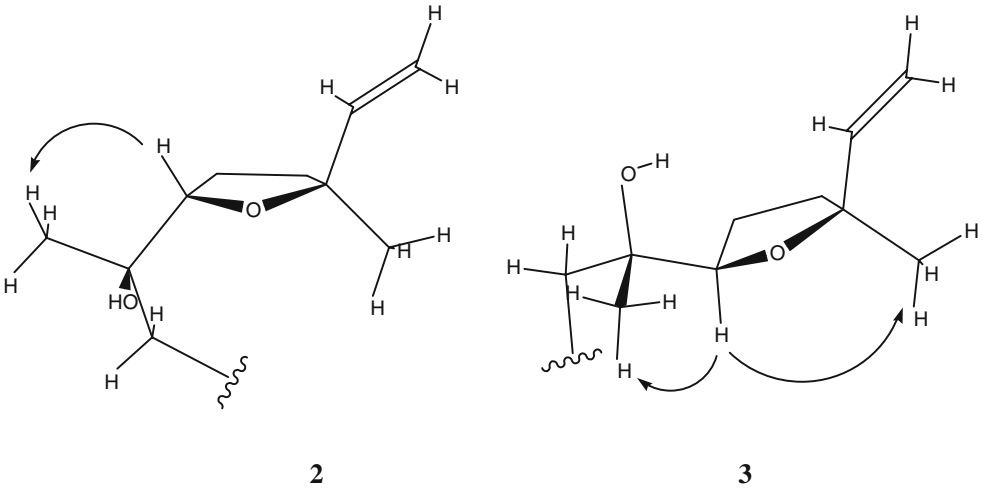

2 **3**

Fig. 3 NOE effects between H-7, H-14, and H-15 in the more stable conformers of compounds **2** and **3**, as identified by PM3 calculations

HREIMS data for the two compounds showed a molecular ion peak at *m*/*z* 420.2500 and 420.2529, respectively, which is consistent with a molecular formula $C_{24}H_{36}O_6$, and a base peak at *m*/*z* 107, corresponding to the *p*-hydroxyphenylmethyl radical, as in compound **1**. This molecular formula indicates the existence of an additional unsaturation in comparison to compound **1**, and this could be assigned to a cyclic ether. A study of the HMBC spectra (3 Hz) showed a correlation between C-7 and C-10, providing evidence for the presence of a tetrahydrofuranic cycle between these positions. It is proposed that compounds **2** and **3** are two isomers of (3*R*)-7,10-epoxy-2,6,10-trimethyl-3-(3-*p*-hydroxyphenylpropanoyloxy)-dodec-11-ene-2,6-diol.

The two new chiral carbons, C-6 and C-7, can generate four diastereoisomers, and the synthesis of these compounds was achieved. The first approach involved epoxidation at the C-6–C-7 double bond and ether formation by nucleophilic ring opening of the epoxide with the hydroxyl group on C-10 (Fig. 2). The reaction was carried out by using MCPBA to yield compounds **2** and **3**. Epoxide ring opening occurred under the epoxidation conditions. This reaction is an *anti* addition that provided the isomers (6*R*,7*S*) and (6*S*,7*R*).

The most stable conformer of the isomer with the relative configuration 6*S**, 7*R**, 10*S** that was found by PM3 calculations (Fig. 3) suggested an alignment of H-7 and methyl groups at 14 and 15 with the presence of a hydrogen bond between the hydroxyl group on C-6 and the tetrahydrofuranic oxygen. The nuclear Overhauser effect (NOE) experiment on **3** showed a clear effect between H-7 and the methyl groups 14 and 15, and the structure of compound **3** is thus established as (3*R*,6*S**,7*R**,10*S**)-7,10-epoxy-2,6,10-trimethyl-3-(3-*p*-hydroxyphenylpropanoyl-oxy)-dodec-11-ene-2,6-diol.

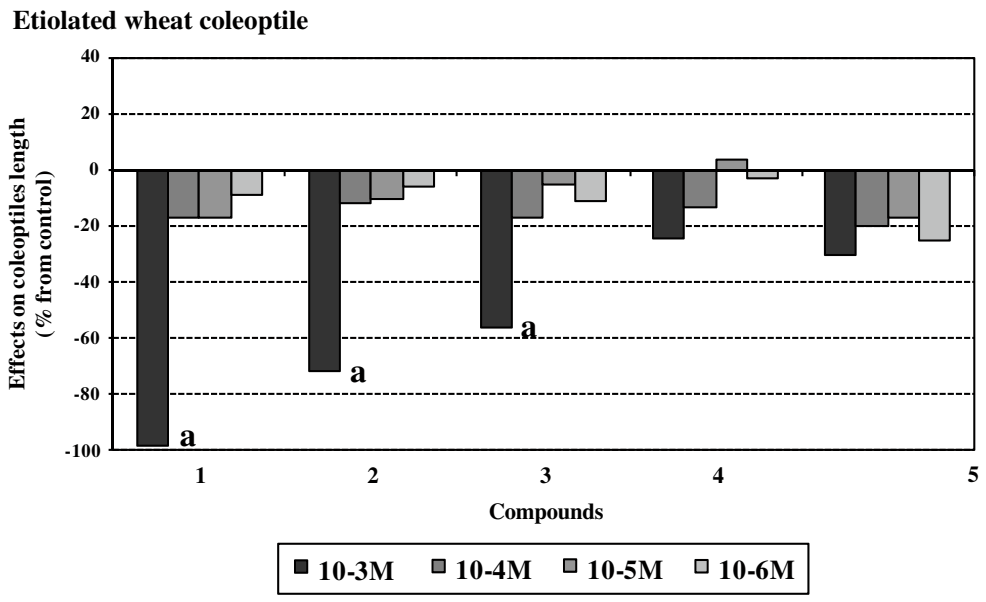

Fig. 4 Results of the etiolated wheat coleoptile assay on compounds **1**–**5**. Values are expressed as percentage differences from the control. If a letter is not indicated, then $P>0.05$ for Welch's test; *a* values significantly different at $P<0.01$

In contrast, the most stable conformer of the isomer with the relative configuration 6*R**, 7*S**, 10*S** (Fig. 3) had an alignment of H-7 and the methyl group 14 but not with methyl 15. The results of the nuclear Overhauser effect spectroscopy experiment on **2** confirmed this. The structure of compound **2** was established as (3*R*,6*R**,7*S**,10*S**)-7,10-epoxy-2,6,10-trimethyl-3-(3-*p*-hydroxyphenylpropanoyloxy)-dodec-11-ene-2,6-diol. These compounds have not been reported previously.

The first bioassay we carried out was the etiolated wheat coleoptile bioassay (Castellano 2002). This bioassay is intended to be a descriptive preliminary test. Our main objective was to perform a screening with low levels of compound, thus allowing a wider range of concentrations to be tested. This provides a general view of the possible bioactivities including plant growth regulators, herbicides (Cutler 1984; Macías et al. 2008), antimicrobials, mycotoxins, and pharmaceuticals (Jacyno and Cutler 1993).

Etiolated wheat coleoptile growth (Fig. 4) was inhibited ($P<0.01$, 98%) by a 10^{-3}-M solution of **1**. The degradation compounds **2** and **3** showed 72% and 56% of inhibition at 10^{-3} M, respectively. In contrast, the sesquiterpene and phenolic moieties (**4** and **5**) of compound **1** did not show significant activity.

The results of this screening showed that the natural product is the most active compound with the presence of sesquiterpene and phenolic moieties in the molecule as an apparent prerequisite for activity. The degradation of the compound lead to a diminution of the effect.

The phytotoxicity bioassay on STS (Macías et al. 2000) was applied to compounds **1**–**3** bearing in mind the possible degradation of compound **1** in the soil. The assay

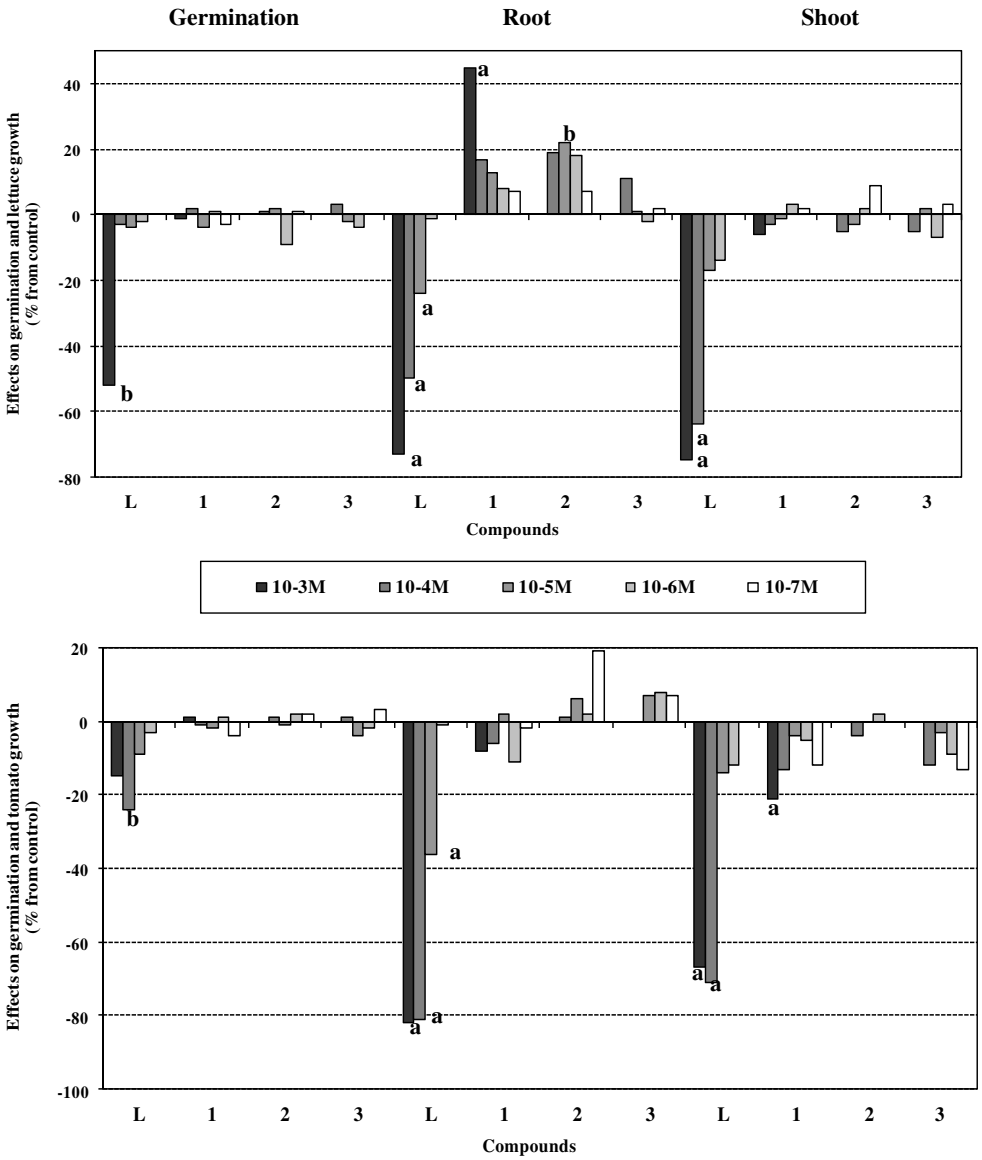

Fig. 5 Germination and growth effects of compounds **1**–**3** and LOGRAN on lettuce (*L. sativa*) and tomato (*L. esculentum*). Values are expressed as percentage differences from the control. If a letter is not indicated, $P>0.05$ for Welch's test; *a* values significantly different at $P<0.01$, *b* values significantly different at $0.01<P<0.05$

showed the effect of a series of aqueous solutions of compound **1** on the germination and growth of dicotyledonous (*L. sativa, L. sativum*, and *L. esculentum*) and monocotyledonous (*A. cepa* and *T. aestivum*) species. Data are presented as percentage differences from the control; positive values represent stimulation of the studied variable and negative values represent inhibition. The commercial herbicide LOGRAN® was used as a positive control.

Inhibition effects were not observed for lettuce (*L. sativa*), tomato (*L. esculentum*), onion (*A. cepa*), or wheat (*T. aestivum*) seeds (Figs. 5 and 6). However, there was a stimulation (average=40%) of the root growth of lettuce and wheat.

Cress seeds (*L. sativum*) were the most sensitive to the compounds tested (Fig. 7). Megalanthine (**1**) was phytotoxic to cress at 10^{-3} M, showing inhibition values of 34% for germination, 43% for root length, and 62% for shoot length. The degradation compounds **2** and **3** had reduced activity compared to compound **1**. Compounds **1**–**3** again showed a stimulation (average=40%) of the root length of cress at concentrations ranging from 10^{-4} to 10^{-7} M, as described previously for root growth of lettuce and wheat. These results suggest that megalanthine probably has no relevant role in the plant–plant defense.

In order to explore other possible roles for megalanthine (**1**), we tested megalanthine for antifeedant and antifungal effects on several target organisms. It had a moderate antifeedant effect (Table 3) on the lepidopteran *S. littoralis* without postingestive toxicity. It was a stronger antifeedant to *L. decemlineata*, but proved to be inactive to the aphid *M. persicae*. This compound was a selective cytotoxic

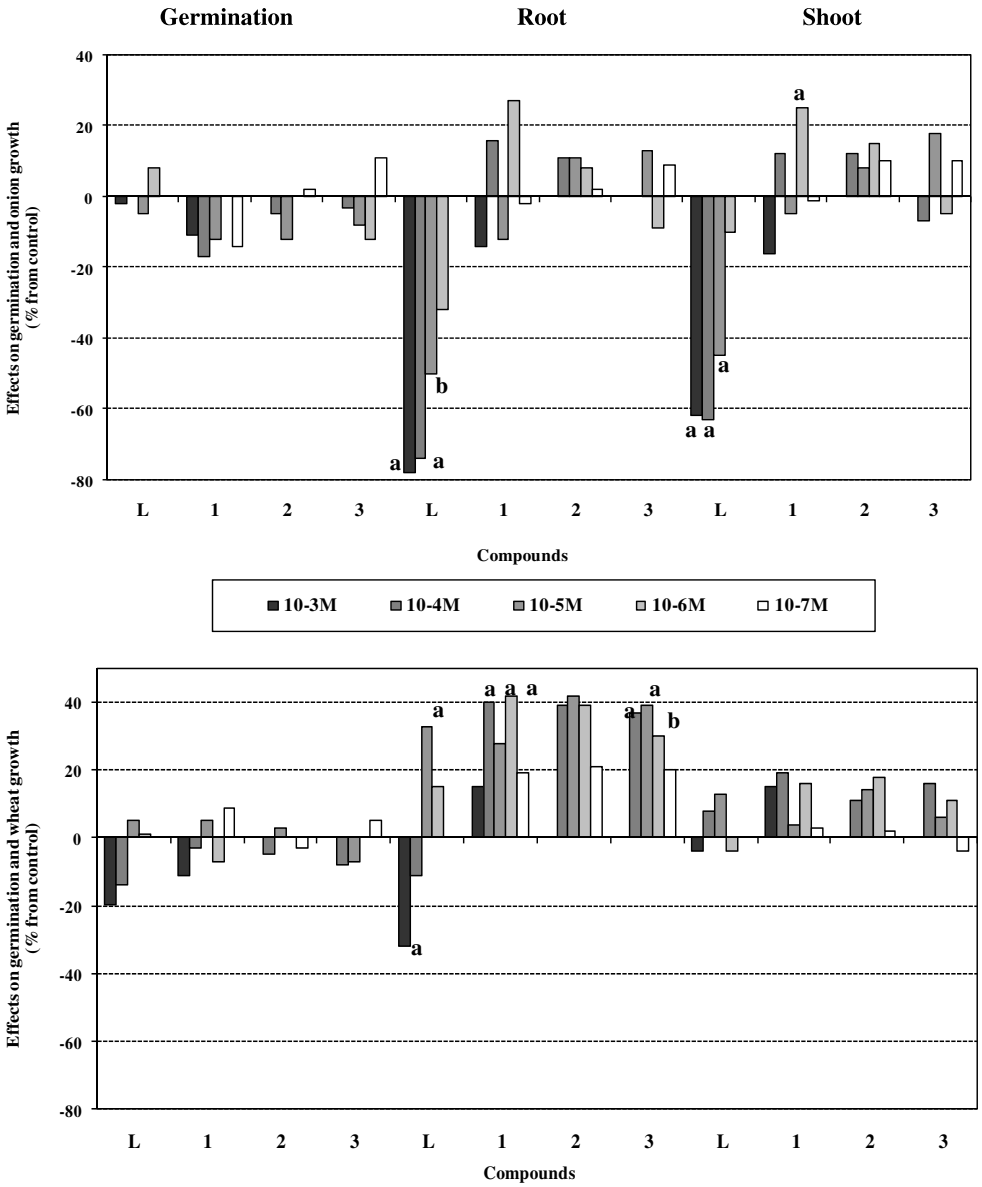

Fig. 6 Germination and growth effects of compounds **1**–**3** and LOGRAN on onion (*A. cepa*) and wheat (*T. aestivum*). Values are expressed as percentage differences from the control. If a letter is not indicated, $P>0.05$ for Welch's test; *a* values significantly different at $P<0.01$, *b* values significantly different at $0.01<P<0.05$

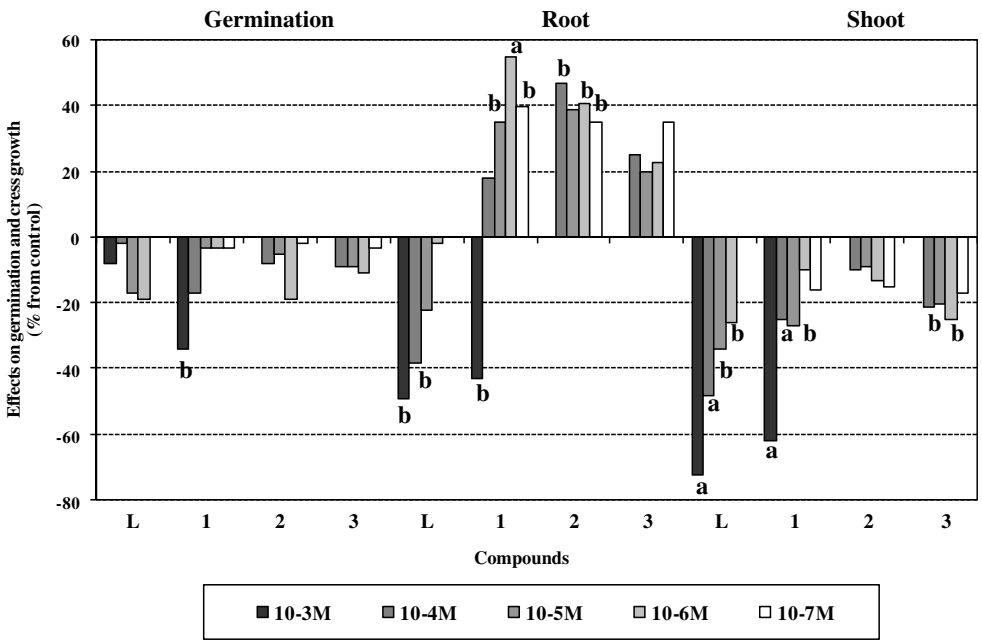

Fig. 7 Germination and growth effects of compounds **1**–**3** and LOGRAN on cress (*L. sativum* L.). Values are expressed as percentage differences from the control. If a letter is not indicated, $P>0.05$ for Welch's test; *a* values significantly different with $P<0.01$, *b* values significantly different with $0.01<P<0.05$

agent to insect-derived Sf9 cells, thus suggesting that the lack of *in vivo* toxicity on *S. littoralis* larvae could be the result of metabolic detoxification. Megalanthine (**1**) showed a significant and selective mycelial growth inhibition against the plant pathogen *Fusarium solani*.

The species-dependent antifungal and antifeedant effects with insect-selective cytotoxicity of megalanthine support a plant-defensive role against herbivorous insects and phytopathogens.

Our previous work on the alkaloidal fraction of this plant resulted in the isolation of an antifeedant with low to moderate selectivity to *S. littoralis*, the PA lycopsamine (Reina et al. 1998). However, the phenylpropanoid sesquiterpene (**1**) studied shows stronger antifeedant and antifungal action than lycopsamine. Phenylpropanoids have a multiplicity of functions in plants. The biosynthesis responds to environmental stresses such as wounding, pathogen infection, and UV radiation (Kliebenstein 2004; Dixon et al. 2002).

Table 3 Biological effects of megalanthine (**1**) on a series of biological targets related to plant defense: herbivorous insects (*S. littoralis*, *L. decemlineata*, and *M. persicae*), insect and mammalian cells (Sf9 and CHO), and phytopathogens (*Fusarium* spp.)

Target organism	Biological effects				
	Insecticidal			Cytotoxic	Antifungal
	Antifeedant	Postingestive			
		ΔB	ΔI		
S. littoralis	6.5×10^{-8} (1.8×10^{-8}, 23.2×10^{-8})[a]	109	99		
L. decemlineata	2.1×10^{-8} (1.0×10^{-8}, 4.2×10^{-8})[a]

Isolation of Three Diterpenoid Acids from Sunflowers, as Oviposition Stimulants for the Banded Sunflower Moth, *Cochylis hospes*

Bruce D. Morris · Laurence D. Charlet · Stephen P. Foster

Received: 7 March 2008 / Revised: 24 September 2008 / Accepted: 28 October 2008 / Published online: 18 December 2008

Abstract The banded sunflower moth (BSFM), *Cochylis hospes* Walshingham (Lepidoptera: Cochylidae) is a specialist insect, the larvae of which feed on sunflowers, *Helianthus* spp., and a few other species of Compositae. It is one of the most important pests of sunflower in the USA. Previous work on *H. annuus*, the cultivated sunflower, revealed two diterpenoids that function as oviposition stimulants for female BSFM, and that other, more polar compounds also stimulated oviposition. Using a bioassay-guided approach, we isolated three additional diterpenoids, grandifloric acid (**1**), 15β-hydroxy-*ent*-trachyloban-19-oic acid (**2**), and 17-hydroxy-16α-*ent*-kauran-19-oic acid (**3**), from polar fractions of pre-bloom sunflower head extracts. In laboratory bioassays, purified natural samples of each of these compounds stimulated oviposition by female BSFM. Structure–activity relationships of the five diterpenoids known to stimulate oviposition by female BSFM are discussed.

Keywords Grandifloric acid · 15β-hydroxy-*ent*-trachyloban-19-oic acid · 17-hydroxy-16α-*ent*-kauran-19-oic acid · Lepidoptera · Cochylidae · *Helianthus annuus*

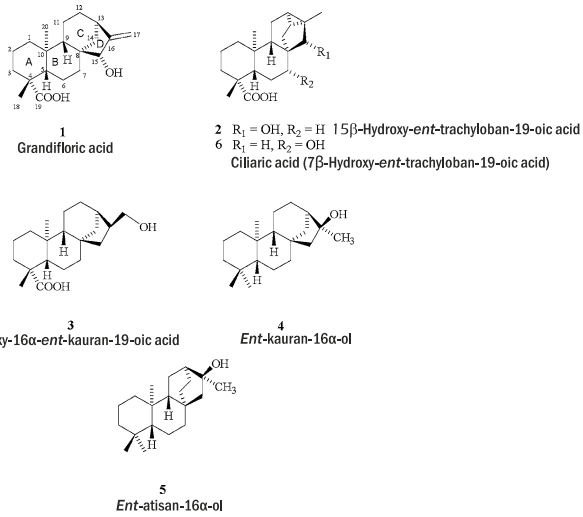
Introduction

The banded sunflower moth (BSFM), *Cochylis hospes* Walshingham (Lepidoptera: Cochylidae) is endemic to North America. Larvae of this species feed on the heads of sunflowers, *Helianthus* spp, and a few other species of Compositae. This insect is recognized as one of the most important pests of cultivated sunflower, *H. annuus* L., in the USA, particularly in the principal growing area of the northern Great Plains (Charlet et al. 1997).

As for many species of Lepidoptera, the adult female BSFM plays an important role in selection of a host on which their larvae will feed. Female BSFM oviposit predominantly on the outer whorl of involucral bracts of pre-bloom (R2-R4 stage, Schneiter and Miller 1981) sunflower heads. Upon hatching, the larvae feed initially upon bracts before moving to the disk flowers and consuming the developing seeds. Initial studies by Barker (1997) and Foster et al. (2003) indicate that nonpolar (pentane) and moderately polar (dichloromethane) extracts of sunflower bracts contain compounds that stimulate oviposition by female BSFM. Using a bioassay-driven approach, two diterpenoid alcohols, *ent* -kauran-16α-ol (**4**) and *ent*-atisan-16α-ol (**5**) were isolated from a dichloromethane extract of pre-bloom sunflower heads and found to stimulate oviposition by female BSFM. Two diterpenoid acids, *ent*-trachyloban-19-oic acid and *ent*-kaur-16-en-19-oic acid, found in relatively high abundance, also were isolated from the extract, but these compounds did not stimulate oviposition by female BSFM (Morris et al. 2005). During this work, bioassay-guided fractionation on normal-phase silica gel indicated that, apart from **4** and **5**, there were additional, more polar (later eluting) compounds that also stimulated BSFM oviposition. In this paper, we focus on the isolation and bioassay of stimulatory compounds in the more polar

fractions of pre-bloom sunflower head extracts, and report the identification of three diterpenoid acids, grandifloric acid (**1**), 15β-hydroxy-*ent*-trachyloban-19-oic acid (**2**), and 17-hydroxy-16α-*ent*-kauran-19-oic acid (**3**) that also stimulate oviposition by female BSFM.



Methods and Materials

General Fractionation and Characterization Flash column chromatography used either reversed-phase C-18 silica gel (Sigma-Aldrich, Milwaukee, WI, USA) or Diol-derivatized silica gel (Biotage, Uppsala, Sweden). Gel permeation chromatography was carried out in MeOH on lipophilic Sephadex LH-20 (Pharmacia, Uppsala, Sweden). High-performance liquid chromatography (HPLC) employed a Shimadzu LC-6A pump and SPD-10A UV detector, set to 220 nm, with an Alltech Apollo semipreparative column (5 μm C-18 reversed-phase silica, 250×10 mm) and an Alltech guard column (same media, 33×7 mm; Phenomonex, Torrance, CA, USA). Solvents used were Malinckrodt nanograde (for column chromatography), Burdick and Jackson HPLC grade (for HPLC), or redistilled AR grade. Solvents were evaporated from fractions by rotary evaporation at 40°C for larger volumes, or by a gentle stream of nitrogen for smaller volumes.

Bis(trimethylsilyl)trifluoroacetamide (BSTFA) + 1% TMCS, used to trimethylsilylate acid and alcohol groups, was from Pierce (Rockford, IL, USA). Trimethylsilylation was carried out on dried subsamples in 2-ml, Teflon-capped vials, with 20–40 μl of BSTFA and 1% TMCS added. The mixture was heated for 16 h at 50°C, after which the BSTFA was evaporated under a stream of N_2, and the residue was re-dissolved in hexane for gas chromatography-mass spectrometry (GC-MS) analysis.

GC-MS was performed on a Hewlett-Packard 5890 Series II Plus gas chromatograph interfaced with a Hewlett-Packard 5792 quadrupole mass spectrometer operated (70 eV ionizing energy) in full scan mode (mass range *m/z* 35–550). A Zebron ZB-5 capillary column (30 m, 0.25 mm i.d., 0.25 μm film thickness, Phenomonex) was used for analyses, with a GC oven temperature program of 80°C (4 min hold) to 350°C at 15°C min^{-1}. Splitless injection was used, with an injector temperature of 350°C. Helium was the carrier gas, at an initial linear velocity of 30 cm sec^{-1} (constant flow setting). Mass spectra were compared with those in the Wiley Registry of Mass Spectral Data (7th Ed., John Wiley and Sons, NY, USA). Nuclear magnetic resonance (NMR) spectra were obtained on an 11.7 T Varian Inova instrument (499.67 MHz for ^1H and 125.65 MHz for ^{13}C). All spectra were recorded in $CDCl_3$ (Sigma-Aldrich). ^1H chemical shifts were referenced to residual $CHCl_3$ at 7.26 ppm, and ^{13}C shifts to the solvent signal at 77.0 ppm. The multiplicity of carbon signals was determined using DEPT experiments.

Extraction and Isolation Sunflower plants (*H. annuus* restorer line 'RHA 274') were grown in a greenhouse at 20–30°C between February and April 2004. Pre-bloom heads (R3-R4 stage, 1,651 heads, 2–3 cm diameter) were extracted in batches of 80, by dipping them into 400 ml of 3:1 MeOH/CH_2Cl_2 for 60 s, as previously described (Morris et al. 2005). The combined extracts were concentrated by rotary evaporation, leaving a MeOH solution, which was cooled to −20°C, precipitating a white waxy material. The waxy material was filtered from the extract by Buchner funnel, and the filtrate was redissolved by washing the filter paper with MeOH then CH_2Cl_2. Analysis of the filtrate by GC-MS showed it to be composed of wax aldehydes, which previously (Morris et al. 2005) had been found not to stimulate oviposition by female BSFM; therefore, this fraction was not investigated further. Celite (5 g) was added to the supernatant and the solvent removed by rotary evaporation. Rotary evaporation was stopped 5 min after apparent dryness, giving approximately 4 g dry weight of material. This material was subjected to further fractionation and bioassay.

Fractionation by reversed-phase (C-18) flash column chromatography, on 80 g of media, used a stepped solvent gradient (H_2O 200 ml, fraction 1; H_2O/CH_3CN (9:1) 200 ml, fraction 2; H_2O/CH_3CN (4:1) 200 ml, fraction 3; H_2O /CH_3CN (7:3) 200 ml, fraction 4; H_2O /CH_3CN (3:2) 200 ml, fraction 5; H_2O /CH_3CN (1:1) 200 ml, fraction 6; CH_3CN 200 ml, fraction 7; CH_2Cl_2 200 ml, fraction 8). All of these fractions were tested for the ability to stimulate oviposition by female BSFM.

Fraction 7 (624 mg) stimulated oviposition in the bioassay (see "Results" section). Therefore, an EtOH

solution of this fraction was dried onto celite (0.5 g) by rotary evaporation, then further fractionated by flash column chromatography on 25 g of Isolute Diol silica gel (hexane 150 ml, fraction 1; hexane/Et_2O (9:1) 100 ml, fraction 2; hexane/Et_2O (4:1) 100 ml, fraction 3; hexane/Et_2O (7:3) 100 ml, fraction 4; hexane/Et_2O (1:1) 100 ml, fraction 5; hexane/Et_2O (3:7) 100 ml, fraction 6; Et_2O 100 ml, fraction 7; CH_3CN 100 ml, fraction 8). Bioassay of these fractions indicated that 5 and 6 stimulated oviposition and, consequently, further effort was focused on isolating the major compounds (as detected by GC-MS) in these fractions.

Compounds **1** and **2** were isolated from Diol fraction 5 (dry weight 212 mg) by gel permeation chromatography on 50 g of Sephadex LH-20, followed by C-18 reversed-phase HPLC. Most of **1** and **2** eluted from the Sephadex LH-20 column between 160 and 190 ml of MeOH, giving 88.8 mg (dry weight). Half of this was dissolved in 500 µl of MeOH and separated by HPLC using H_2O + 0.1% *v/v* CH_3COOH/MeOH (17:83) at 5 ml min^{-1} as the mobile phase (isocratic). The peaks for **1** (7.4 min) and **2** (8.1 min) were collected as separate fractions over 23 injections resulting in 8 mg of **1** and 1.5 mg of **2**.

Compound **3** was isolated from Diol fraction 6 (dry weight 113 mg) using a method similar to that above. Fractionation on 17 g of Sephadex LH-20 gave 44.5 mg dry weight of **3** eluting between 58 and 67 ml. This was dissolved in 200 µl of MeOH and separated by HPLC as above. A peak eluting at 8.7 min was collected over ten runs giving pure compound **3** (6 mg).

Insects BSFM were obtained from a laboratory colony established in 1988 and maintained at the USDA-ARS Northern Crop Science Laboratory, Fargo, North Dakota. The colony was established from larvae collected in North Dakota and reared on a semisynthetic diet (Barker 1988). Annual addition of wild insects from North Dakota, use of R2 stage sunflower heads for oviposition in the rearing cycle, and regular tests for selectivity toward sunflower were carried out to ensure that the colony did not lose specificity to the host plant (Barker 1997). Adult BSFM were obtained <24 h after emergence and kept as mixed-sex groups (approximately 100 insects) in 8-l clear plastic, ventilated containers, at 25±1°C, 35% RH, and 16L: 8D photoperiod, for 24 to 48 h to allow mating.

Bioassay The bioassay was a modification of that described by Morris et al. (2005). Fractions, or purified compounds **1**–**3**, were applied as solutions to 10 mm diameter disks of scored chromatography paper, which were then attached to inverted glass vials (35 mm high×11 mm diameter) with a piece of mounting putty (Manco Inc., Avon, OH, USA). The disks were prepared by scoring parallel grooves, approximately 1.5 mm apart and 0.5 mm deep (seven grooves per paper disk), on a sheet of chromatography paper with a scalpel. Scoring provided physical stimulation which, along with chemical stimulation, enhances oviposition by female BSFM (Foster et al. 2003). A solution was applied to the top surface of a disk over 5 min and held by an alligator clip in the air flow of a fume hood.

Fractions 1–8 from the initial C-18 flash column fractionation of extract were taken to dryness (for weighing) then re-dissolved in solvent (H_2O for fractions 1–3, MeOH for fractions 4 and 5, MeOH/CH_2Cl_2 (1:1) for fractions 6 and 7, and CH_2Cl_2 for fraction 8). For each treatment, 50 µl [ten head equivalents (HE); one HE was the mean weight of fraction per head] of a fraction were applied to a paper disk, with 50 µl each of H_2O, MeOH, and CH_2Cl_2 for a solvent control. Vials were attached to the base of the bioassay container (17 cm diameter×14 cm high, Rubbermaid, Wooster, OH, USA) with mounting putty, and spaced evenly around the perimeter, approximately 3 cm from the wall. A replicate consisted of one treatment of each fraction plus a control, all in the same container. A circle (10 cm diameter) was removed from the lid of the arena and replaced with fine nylon mesh to allow ventilation. The arena floor was covered with moist vermiculite.

Fractions 1–8 from the Diol fractionation were tested in the same way, except all fractions were dissolved in Et_2O, and Et_2O-only solvent controls were used.

For the dose-response bioassays, purified compounds **1**–**3** were dissolved in the appropriate amount of MeOH, and 20 µl of solution were applied to paper disks to give 50, 10, and 2 µg dosages/disk; 20 µl of MeOH was used for the solvent control. HPLC-purified compounds **1**–**3** were used due to the unavailability of synthetic samples, and the difficulty of their chemical synthesis (Toyota et al. 2000). Based on the weight of these compounds recovered after Sephadex LH-20 clean-up, 50 µg is approximately one HE for compound **1**, five HE for **2**, and two HE for **3**. Replicates consisted of one treatment of each dosage of a compound, plus a MeOH-only control placed in the same container. For these experiments, vials were placed in Rubbermaid containers (14 cm diameter×11 cm high), modified as above.

Insects were sexed and placed into the bioassay containers 2–3 h before the start of scotophase. Between 15 and 30 females (24 or 48-h old), and six to ten males were used for each replicate. After five to six nights, the number of eggs on the top surface of each of the paper disks was counted. Eggs that were not laid wholly on the surface of the disks were excluded from the analysis.

Statistical Analysis Data from the bioassay of fractions were normally distributed (Shapiro-Wilk *W* test) and were

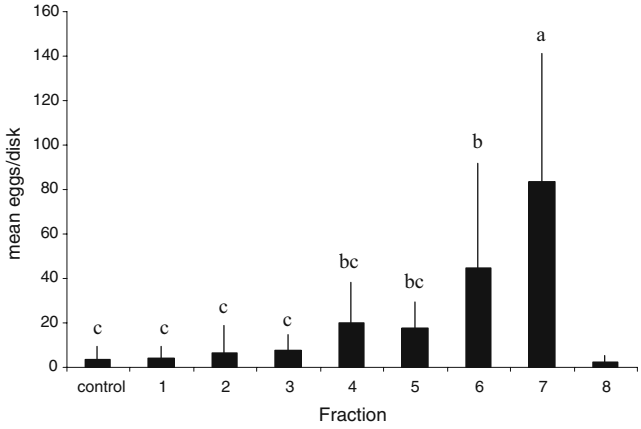


Fig. 1 Mean numbers of eggs laid by *Cochylis hospes* females on paper disks treated with fractions (ten head equivalents/fraction) from a C-18 reversed-phase silica gel flash column fractionation of an extract of 1651 R2-R4 sunflower heads. Means were calculated from five replicates. Means with different letters are significantly different at $P<0.05$, Student's *t* test. *Bars* are SE of means

analyzed by Student's *t* test using JMPin software (SAS Institute, version 4.0.4) and comparing each treatment with the control. Data from the dose-response bioassays were normal after log-transformation (Shapiro-Wilk *W* test), and analyzed by Student's *t* test, using JMPin software.

Results

Bioassay of Fractions from Sunflower Head Extract Initial fractionation of the sunflower head extract (1,651 heads) on reversed phase C-18 silica gel resulted in eight fractions that were tested in the egg-laying bioassay. Fraction 7 (eluting in 100% acetonitrile) had a greater number of eggs laid on it than on the control ($P<0.05$; Fig. 1). GC-MS analyses of TMS-derivatized fractions 5–8, showed that diterpenoids were the major class of compounds in these fractions, with angelate esters in fraction 5, diterpenoids with carboxylic acid and alcohol functional groups in fractions 6 and 7, and *ent*-trachyloban-19-oic acid and *ent*-kaur-16-en-19-oic acid in fraction 8 (previously isolated and identified by us; Morris et al. 2005).

Fraction 7 from the C-18 fractionation was further fractionated on Diol silica gel, giving eight fractions that were bioassayed. Fractions 5 and 6 [eluting in hexane/Et_2O (1:1) and hexane/Et_2O (3:7), respectively] had a greater number of eggs laid on them than were laid on the control ($P<0.05$); Fig. 2). GC-MS analyses of these two fractions (TMS-derivatized) indicated that compounds **1** and **2** were the major components of fraction 5, and compound **3** was the major component of fraction 6. Compounds **1**–**3** were purified by HPLC as described in the "Methods and Materials" section.

Identification of Compounds **1**–**3** Mass spectra of the TMS derivatives of compounds **1** and **2** {*m/z* (rel. int.): 462 (5) $[M]^+$, 447 (10) $[M\text{-}CH_3]^+$, 372 (5) $[M\text{-}(CH_3)_3SiOH]^+$, 357 (5), 332 (5), 255 (6), 254 (6), 239 (12), 198 (19), 156 (80), 73 (100)} and **2** {462 (6) $[M]^+$, 447 (8) $[M\text{-}CH_3]^+$, 372 (16) $[M\text{-}(CH_3)_3SiOH]^+$, 357 (6), 255 (7), 254 (7), 239 (7), 223 (11), 169 (23), 73 (100)} both had a molecular ion of *m/z* 462 (corresponding to *m/z* 318 before the addition of two TMS groups), suggesting they were diterpenoid acids with 5 degrees of unsaturation (rings or double bonds), similar to acids **6** and **7**, but with an additional alcohol group. Only four diterpenoids with a molecular weight of *m/z* 318 have been reported from *Helianthus* spp.; compounds **1**, **2,** and ciliaric acid, (**6**), 7β-hydroxy-*ent*-trachyloban-19-oic acid have been found in *H. annuus* (and other species) and 16β-hydroxy-*ent*-kaur-11-en-19-oic acid from *H. debilis*, *H. radula*, *H. argophyllus*, *H. ciliaris*, *H. angustifolius*, and *H. silicifolius*, but not *H. annuus* (Bjeldanes and Geissman 1972; Ohno et al. 1979; Gershenzon et al. 1981, Herz et al. 1982, 1983; Watanabe et al. 1982; Herz and Kulanthaivel 1983; Melek et al. 1985; Connolly and Hill 1991). This suggested that the compounds isolated from this *H. annuus* extract were **1**, **2**, or ciliaric acid (**6**).

Comparison of the ^{13}C NMR spectrum (Table 2) of isolated **1** with that previously reported for the 15-angeloyl ester of **1** (Ohno et al. 1979) showed that **1** was grandifloric acid. Comparison of ^{13}C NMR shifts of a number of kauranoid diterpenes (Hanson et al. 1976) indicated that the only significant effect of esterification of the 15-OH group was an upfield shift of approximately 6 ppm for C-16

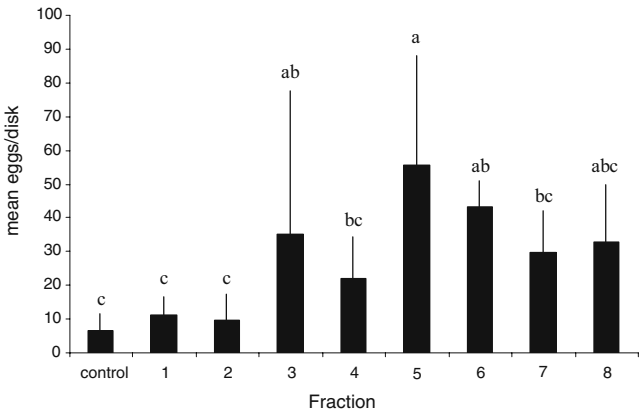

Fig. 2 Mean numbers of eggs laid by *Cochylis hospes* females on paper disks treated with fractions (ten head equivalents/fraction) from a Diol normal-phase silica gel flash column fractionation of fraction 7 in Fig. 1. Means were calculated from six replicates. Means with different letters were significantly different at $P<0.05$, Student's *t* test. *Bars* are SE of means

[a] Referenced to $CDCl_3$ at 77.00 ppm, multiplicities were determined by DEPT experiments
[b] From Ohno et al. (1979). Data for 15-angeloyl ester of **1**. Referenced to internal TMS
[c] Assignments may be interchanged
[d] From Harrigan et al. (1994).
[e] It is apparent that the data reported in Harrigan et al. (1994) for **2** from *Xylopia aethiopica* is for the 15 α-OH epimer of **2**, resulting in an upfield shift for C-9. C-9 gives a signal at 52.8 ppm in *ent*-trachyloban-19-oic acid (Beale et al. 1883), similar to that for **2** we isolated from *Helianthus annuus*. The single crystal X-ray structure of **2** from *H. annuus* shows it to have a β-OH group (Ferguson et al. 1982).
[f] From Wu et al. (1996), referenced to internal TMS.

downfield by 0.38 ppm due to being adjacent to the hydroxyl group. Signals at 5.08 and 5.21 ppm for **1** showed it had a kaurane skeleton with a double bond, rather than the trachylobane skeleton of **2** and *ent*-trachyloban-19-oic acid. The multiplicity of carbons on rings C and D (from a DEPT experiment) agreed with a kauranoid diterpene structure.

^{1}H and ^{13}C NMR spectra of compound **2** (Tables 1 and 2) showed it to be 15β-hydroxy-*ent*-trachyloban-19-oic acid, the trachylobane equivalent of **1**. Comparison of ^{13}C NMR data for **2** with that published (Harrigan et al. 1994, Table 2) showed some differences; upfield shifts for C-9, C-12, C-13, and C-15 in the published data, which all could be attributed to the compound in Harrigan et al. (1994) being the 15α-OH epimer, rather than the 15β-OH epimer. Compound **2** from *H. annuus* has been shown to be the 15β-OH epimer from a single crystal X-ray structure of its methyl ester (Ferguson et al. 1982). Comparing the ^{13}C NMR spectra of **1** and **2**, carbon signals for **1** at 160.26 ppm (singlet, C-16) and 108.32 ppm (triplet, C-17) (doubly bonded carbons) plus a triplet carbon for C-12 (32.55 ppm), were replaced in **2** by a singlet carbon at 25.3 ppm (C-16), a methyl carbon at 18.5 ppm (C-17), and a doublet carbon at 20 ppm (C-12), due to the presence of a cyclopropane ring in **2** instead of the C-16:C-17 double bond of **1**. The ^{1}H NMR spectrum of compound 2 matched published data (Mullin et al. 1991, Table 1), and showed that **2** could not be ciliaric acid (**6**), due to the ^{1}H NMR spectrum of **2** having a singlet at 3.28 ppm (H-15), instead of the multiplet at 3.64 ppm found for H-7 of **6** (Bjeldanes and Geissman 1972). A NOESY experiment showed a weak NOE crosspeak between the 3.28 ppm signal (H-15) and H-17 (1.21 ppm), indicating that the hydroxyl group was on C-15 in **2**.

The TMS derivative of compound **3** had a mass spectrum {*m/z* (rel. int.): 464 (7) $[M]^{+}$, 449 (32) $[M–CH_3]^{+}$, 374 (45) $[M–(CH_3)_3SiOH]^{+}$, 347 (55), 332 (7), 257 (27), 256 (24), 242 (20), 73 (100)} with a molecular ion at *m/z* 464, indicating that it was similar to **1** and **2**, but with one less degree of unsaturation. The ^{1}H NMR spectrum of **3** (Table 1) contained resonances for only two methyl protons, along with a doublet of doublets at 3.40 ppm (J= 5.7 Hz), suggesting a hydroxymethylene moiety, likely due to addition of H_2O across the double bond of grandifloric acid (**1**). Comparison of the ^{13}C NMR spectrum of **3** (Table 2) with those reported for the 16α and 16β epimers of 17-hydroxy-16-*ent*-kauran-19-oic acid (Etse et al. 1987; Wu et al. 1996), particularly considering the chemical shifts of C-12 and C-17, indicated that **3** was the 16α epimer, 17-hydroxy-16α-*ent*-kauran-19-oic acid, isolated previously

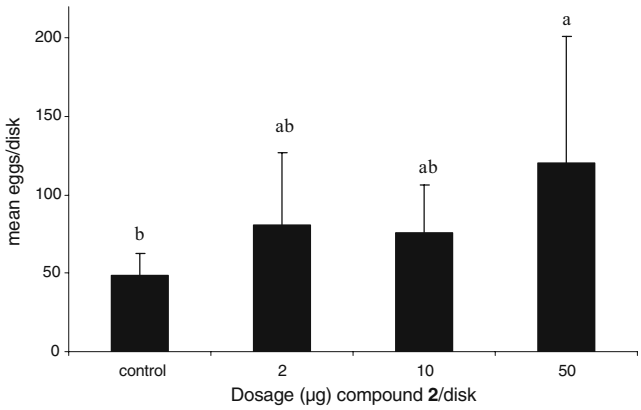

Fig. 3 Mean numbers of eggs laid by *Cochylis hospes* females on paper disks treated with different amounts of grandifloric acid (**1**). Means were calculated from six replicates, *bars* are SE of means. Means with different letters were significantly different at $P<0.05$ when log-transformed data were compared by Student's t test

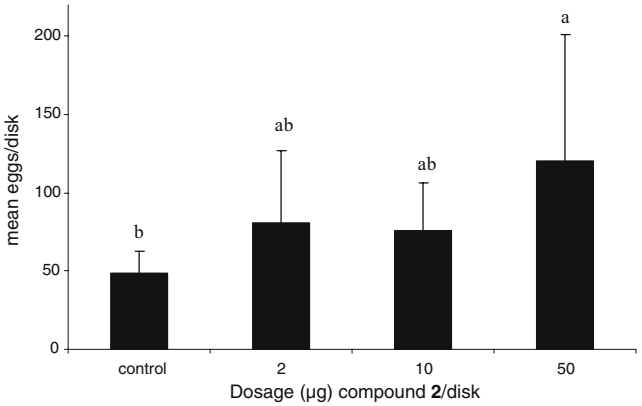

Fig. 4 Mean numbers of eggs laid by *Cochylis hospes* females on paper disks treated with different amounts of 15β-hydroxy-*ent*-trachyloban-19-oic acid (**2**). Means were calculated from six replicates, *bars* are SE of means. Means with different letters were significantly different at $P<0.05$ when log-transformed data were compared by Student's t test

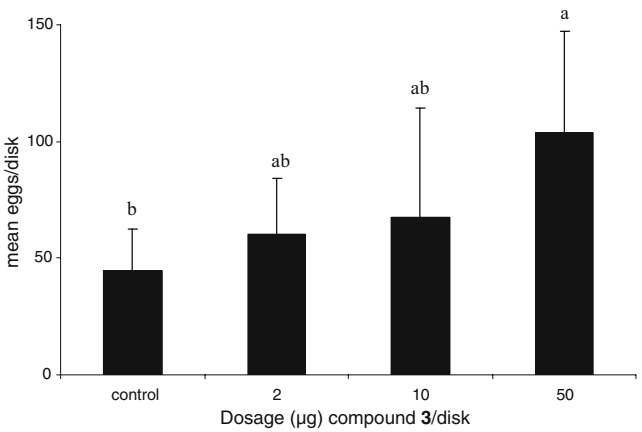

Fig. 5 Mean numbers of eggs laid by *Cochylis hospes* females on paper disks treated with different amounts of 17-hydroxy-16α-*ent*-kauran-19-oic acid (**3**). Means were calculated from five replicates, *bars* are SE of means. Means with different letters were significantly different at $P<0.05$ when log-transformed data were compared by Student's t test

from the Compositae (Moreno et al. 1980; Bohlmann et al. 1982).

The ^{1}H NMR spectra of purified **1**–**3** showed no cross-contamination of fractions, based on the methyl signals, and appeared clean of any other contamination. The absolute configuration of compound **2** from *H. annuus* is *enantio*, shown by the crystal structure of its methyl ester (Ferguson et al. 1982), and therefore, the absolute configuration of compounds **1** and **3** is also assumed to be *enantio*, as has been found for kauranoid and trachylobanoid diterpenes previously isolated from *H. annuus* (Connolly and Hill 1991). This is equivalent to (−)-kaurene and (−)-trachylobane skeletons.

Bioassay of Compounds **1**–**3** More eggs were laid on paper disks with 10 or 50 μg of grandifloric acid (**1**) than on the control (Fig. 3). 15β-Hydroxy-*ent*-trachyloban-19-oic acid (**2**) and 17-hydroxy-16β-*ent*-kauran-19-oic acid (**3**) had similar dose-response profiles (Figs. 4 and 5), with significantly ($P<0.05$) more eggs laid on paper disks treated with 50 μg of each purified compound, than on the respective controls.

Discussion

We have identified three diterpenoid acids, grandifloric acid (**1**), 15β-hydroxy-*ent*-trachyloban-19-oic acid (**2**), and 17-hydroxy-16α-*ent*-kauran-19-oic acid (**3**) from sunflower heads by using bioassay-guided liquid chromatographic fractionation. These compounds stimulate oviposition by female BSFM. In addition, two other diterpenoids, *ent*-kauran-16α-ol (**4**) and *ent*-atisan-16α-ol (**5**) (Morris et al. 2005), found in sunflower are known to stimulate oviposition by female BSFM. Comparison of the chemical structures of these five compounds shows that all five have an alcohol functional group on ring D (at positions 15, 16, or 17). This group may be a key structural feature for stimulating oviposition in female BSFM since the diterpene acids *ent*-trachyloban-19-oic acid and *ent*-kaur-16-en-19-oic acid, which do not stimulate oviposition by female BSFM (Morris et al. 2005), are structurally identical to compounds **2** and **1,** respectively, but lack the 15-OH group. The C-19 carboxylic acid group of compounds **1**–**3**, may not be important for stimulating oviposition since (inactive) *ent*-trachyloban-19-oic acid and *ent*-kaur-16-en-19-oic acid contain this group, whereas (active) **4** and **5** lack it. Other diterpenes with an alcohol group at position 16 or 17 on ring D (e.g., 16β-hydroxy-*ent*-kaur-11-en-19-oic acid) are widespread in *Helianthus*, having been isolated from at least 11 species (Gershenzon et al. 1981; Herz et al. 1982, 1983, Herz and Kulanthaivel 1983). If the structure–activity relationship above is correct, then more diterpenoids, found in a range of *Helianthus* species, could function as ovipositional stimulants for BSFM. In addition to the BSFM–sunflower system, diterpenoids have been identified as oviposition stimulants for other moth species. Duvane and labdane diterpenes (from *Nicotiana* leaves) stimulated oviposition by the tobacco budworm, *Heliothis virescens* (Jackson et al. 1986, 1991). Females of another heliothine moth, *Helicoverpa zea*, are stimulated to oviposit by two sequiterpene carboxylic acids, (+)-(*E*)-endo-β-bergamoten-12-oic acid and (+)-(*E*)- α-santalen-12-oic acid from tomato (*Lycopersicon hirsutum*) (Coates et al. 1988).

Compounds **1** and **2** have been previously isolated from *Helianthus* species, whereas compound **3** has not**,** to our knowledge. Compound **3** has been found in *Beyeria* sp. (Euphorbiacea) (Jefferies and Payne 1965), *Eupatorium tinifolium* (Compositae) (Moreno et al. 1980), and *Baccharis minutiflora* (Compositae) (Bohlmann et al. 1982). Compound **2** occurs in isolable amounts only in *H. annuus* (Connolly and Hill 1991; Gershenzon et al. 1981, Mullin et al. 1991), while compound **1**, its angeloyl ester or acid methyl ester, has been found in many species of *Helianthus* [e.g., *H. debilis* (Ohno et al. 1979), *H. radula* (Herz and Kulanthaivel 1983), *H. occidentalis* and *H. simulans* (Herz et al. 1983), *H. grosseserratus* (Gershenzon et al. 1981), and *H. niveus* (Ohno and Mabry 1980)], all of which are known hosts of BSFM (Charlet et al. 1997).

Apart from the various diterpenoid compounds discussed, the major nonvolatile components of our sunflower head extracts, identified by GC-MS, were waxes (mainly C_{20} to C_{34} even-numbered *n*-aldehydes and lesser amounts of the corresponding alcohols) and diterpene angelate esters. Sunflower head waxes do not stimulate ovipositional activity in female BSFM (Morris et al. 2005), while diterpene angelate esers were either present in too low an amount, or their fractions were relatively inactive compared with those containing compounds **1**–**3** (**1**–**3** were in fractions 6 and 7, diterpene angelate esters were in fraction 5). It is possible that esterification of diterpene alcohol groups in compounds such as **1**–**3** reduces or eliminates the ovipositional activity of the diterpenoid, especially given the structure–activity relationship discussed above.

These diterpenoids are relatively nonvolatile, and are likely perceived by female BSFM only when the female is in contact with the plant (and therefore with the diterpenoids). However, volatile compounds from sunflower are involved in host selection behavior of female BSFM (Foster et al. 2003). Future work will aim to identify these volatile chemicals.

Phenology of Semiochemical-Mediated Host Foraging by the Western Boxelder Bug, *Boisea rubrolineata*, an Aposematic Seed Predator

Joseph Schwarz · Regine Gries · Kirk Hillier · Neil Vickers · Gerhard Gries

Received: 2 May 2008 / Revised: 30 October 2008 / Accepted: 1 December 2008 / Published online: 3 January 2009

Abstract The western boxelder bug (BEB), *Boisea rubrolineata* (Heteroptera: Rhopalidae), is a specialist herbivore of boxelder trees, *Acer negundo*. We tested the hypothesis that BEBs use semiochemicals to locate host trees. Headspace volatiles from trees bearing staminate inflorescences ("staminate trees") and from trees bearing pistillate inflorescences ("pistillate trees") were collected throughout the season and bioassayed in Y-tube olfactometer experiments. Headspace extracts of early-season, pollen-bearing staminate trees and midseason pistillate trees with mature samaras (seed pods) attracted female and male BEBs. By using coupled gas chromatographic-electroantennographic detection and gas chromatography-mass spectrometry, we identified and tested a five-component synthetic blend of candidate semiochemicals (hexanol, pentyl acetate, phenylacetonitrile, 2-phenethyl acetate, and *trans*-nerolidol). This blend attracted females, males, and fifth-instar nymphs. Phenylacetonitrile by itself was as attractive as the five-component blend to both adults and nymphs. By responding to phenylacetonitrile emitted by pollen-bearing staminate trees and pistillate trees with maturing seeds, BEBs appear to track and exploit the availability of nutrient-rich food sources, suggesting that the bugs' reproductive ecology is synchronized to the phenology of their host boxelder tree.

Introduction

It is well documented that the relationship between heteropteran phytophagous insects and their hosts is governed by ephemeral resources (Carroll 1988; Grimm and Führer 1998; Carroll et al. 2005; Kohno and Bui Thi 2005) such as pollen and seeds. Adaptations of western boxelder bugs (BEBs), *Boisea* (formerly *Leptocoris*) *rubrolineata* (Heteroptera: Rhopalidae), to plants with ephemeral resources appear diverse and may include recognition of plant semiochemicals and timing of breeding season according to resource availability. Indeed, the evolutionary trend in heteropteran true bugs from generalist predators to phytophagous specialists may be driven by interactions with host plants (Cobben 1978), thus leading to synchrony of the plants' and insects' reproductive phenologies (Aldrich et al. 1979; Bowers 1990).

The basic biology of BEBs is poorly understood. BEBs belong to the scentless plant bugs (Aldrich et al. 1990b) and feed primarily on seeds of boxelder maple, *Acer negundo* (Robinson 1996). When the weather warms in the spring, adults emerge from diapause and feed on fallen seeds (Tinker 1952) and dead insects in the soil, flowering buds in the canopy of pistillate trees, as well as anthers and associated tissues of staminate trees (JJS, unpublished data). Females deposit eggs on or near pistillate trees.

First-generation nymphs usually are found on low vegetation near trees. They reach adulthood in about 60 days (Smith and Shepherd 1937) by early to midsummer, feeding heavily on maturing seeds of pistillate trees (Long 1928; Tinker 1952). During the summer, a second, overlapping generation may emerge. By late summer into the fall, non-mating adults cease feeding, depart from senescing host trees (Tinker 1952), and form large aggregations in protective shelters for overwintering diapause.

The related and well-studied soapberry bugs, *Jadera haematoloma*, assemble on seed-bearing specimens of their host tree goldenrain, *Koelreuteria elegans* (Carroll et al. 1998). Feeding by *J. haematoloma* (Carroll 1988) or *Jadera obscura* (Tanaka and Wolda 1988) on their respective host trees attracts male and/or female conspecifics, likely mediated by semiochemicals that originate from the bugs, the plant, or both. Emission of herbivore- or wound-induced semiochemicals or semiochemicals associated with a particular stage of the host's phenology may also attract BEBs to boxelder host trees. If mate choice is tied to host choice (Feder et al. 1994; Carroll et al. 1998; Linn et al. 2004), then an assembly cue may facilitate feeding and mating during host colonization, thus driving host-specific foraging by BEBs.

If BEBs do indeed forage in response to the presence of ephemeral and highly nutritional pollen and seed resources, BEBs should be capable of exploiting semiochemical cues that might be associated with these resources. We tested the hypotheses that (1) BEBs are attracted to volatiles of early-season, pollen-bearing staminate trees but not to those of pistillate trees; (2) profiles of volatile chemicals of pistillate trees change as samaras mature and senesce; (3) BEBs discern changing volatile blends of pistillate trees and are attracted only to those associated with mature samaras (encasing maturing seeds); and (4) specific semiochemicals mediate attraction of BEBs to boxelder trees with pollen or seed resources.

Methods and Materials

Collection and Maintenance of Experimental Insects Late-instar nymph and adult BEBs were field-collected weekly on or near pistillate trees of *A. negundo* or *Acer saccharinum* in Kelowna, Westbank and Princeton, British Columbia (Canada) during June to September 2005, 2006, and 2007. BEBs were maintained at 22–30°C, 30–70% relative humidity, and a natural photoperiod. They were provisioned with water and new-growth shoots, with intact leaves and seeds, of *A. negundo* that were clipped weekly at insect collection sites (see above) and transported to Simon Fraser University (SFU) in 19-l buckets of water. Post-diapause, adult BEBs of unknown age were field-collected in March/April, separated according to sex, maintained on water in separate cages, and used in bioassays as needed. Newly molted, sexually immature adult females or males were kept separate and bioassayed within 14 days, before they reached sexual maturity (Smith and Shepherd 1937). In 2007, newly molted adults were bioassayed when 4–6 days old, an age at which long-lived seed predators feed most heavily prior to reaching sexual maturity (Caldwell and Rankin 1974). Reproductive adults (as evidenced by mating activities) were >1 month old when used in bioassays.

Collection of A. negundo volatiles Clipped branches (four to six ramates) with (1) intact leaves and reproductive parts devoid of apparent insect or mechanical damage, (2) BEBs feeding on them, or (3) mechanical damage were placed in separate water beakers (200 ml) to allow for transpiration and enclosed in separate cylindrical Pyrex® glass chambers (each 14×37.5 cm). The above treatments were chosen to discriminate between effects caused by mechanical damage or BEB herbivory. Ramates were from four different sources: (1) early-spring, pollen-bearing staminate trees or pistillate trees with swollen and opening buds, unfurling leaves, and inflorescences; (2) midspring pistillate trees with developing samaras (encasing ovules) and unfurled leaves; (3) midsummer pistillate trees with maturing seeds; and (4) late-summer pistillate trees with senescing foliage and ripened seeds.

We simulated BEB-induced mechanical damage by puncturing leaf veins, petioles, and samara ovaries with a 000-pin: each leaf received three to four vein punctures, each petiole two to three punctures, and each samara two punctures. We studied the effect of herbivory by allowing 25 3-day-starved male and 25 3-day-starved female BEBs to feed on intact branch clippings housed in a cylindrical Pyrex® glass chamber (14×37.5 cm). Charcoal-filtered air was drawn for 3 days at ~0.5 l min^{-1} through the chamber and a Pyrex® glass tube (14×1.3 cm OD) containing 500 mg of Porapak-Q (50–80 mesh, Waters Associates, Inc., Milford, MA, USA). Volatiles were eluted from the Porapak-Q with 2 ml of redistilled pentane, and extracts were concentrated as needed under a stream of nitrogen. The dry weight of ramates with attached foliage was obtained to determine gram-hour-equivalents (GHE; 1 GHE=volatiles released from 1 g of ramate biomass during 1 h), a measurement of the stimuli tested in bioassays. The procedures for obtaining control stimuli were identical to those described above, except that aeration chambers did not contain insects or plant material.

Analyses of Extracts Aliquots of headspace (above sample) extracts were analyzed by coupled gas chromatographic-electroantennographic detection (GC-EAD; Gries et al., 2002), employing a Hewlett Packard 5890A gas chromatograph equipped with a DB-5 (J&W Scientific, Folsom, CA,

USA) column (30 m×0.25 ID), helium as carrier gas (35 cm s^{-1}) and with the following temperature program: 50°C (2 min), then 10°C min^{-1} to 280°C (5 min). GC-mass spectrometry (MS) analyses of compounds that (1) elicited responses from antennae of male or female BEBs and (2) varied in abundance as the season progressed employed a Saturn 2000 Ion Trap (Varian) fitted with the DB-5 column. Compounds (Table 1) were identified by comparing

General Bioassay Procedures Walking responses of 3-day-starved adults or 3- to 4-day-starved fifth instar nymphs to 10 GHE of headspace extracts (a dose found suitable in preliminary experiments) or to synthetic chemicals were bioassayed at 25–28°C in a horizontal Y-shaped Pyrex® glass olfactometer (stem 20×2.5 cm ID; side-arms at 120°; 18 cm long) illuminated from above by two horizontal fluorescent mercury lamps (GE™, Ecolux; 5,000 K, 32 W). For each replicate, treatment and control stimuli were randomly (coin toss) assigned to and pipetted onto Whatman® 1.5-cm filter paper, positioned near the orifices of the side-arms. In all experiments, a water aspirator drew humidified air at 0.5 l min^{-1} through the Y-tube, carrying volatiles from the treated filter paper to the insect released from a holding tube at the base of the Y-tube. For each replicate, a clean Y-tube and a new insect were employed. An insect was scored as a responder if it approached within 2.5 cm of a stimulus within 5 min. Nonresponding insects were excluded from statistical analyses. Olfactometers were washed in warm water with Sparklene™ detergent, rinsed with cold tap and distilled water, and oven-dried at ca. 125°C for at least 1 h.

Specific Experiments Experiments 1–8 were designed to test whether or not the attractiveness of pistillate and staminate trees changes as the growing season progresses (Fig. 1; Table 2). Experiments 9–14 were designed to identify semiochemicals mediating attraction of BEBs to volatiles of pistillate trees with mature samaras by testing two synthetic blends: one consisting of the 22 chemicals that elicited an antennal response (Table 1) and the other

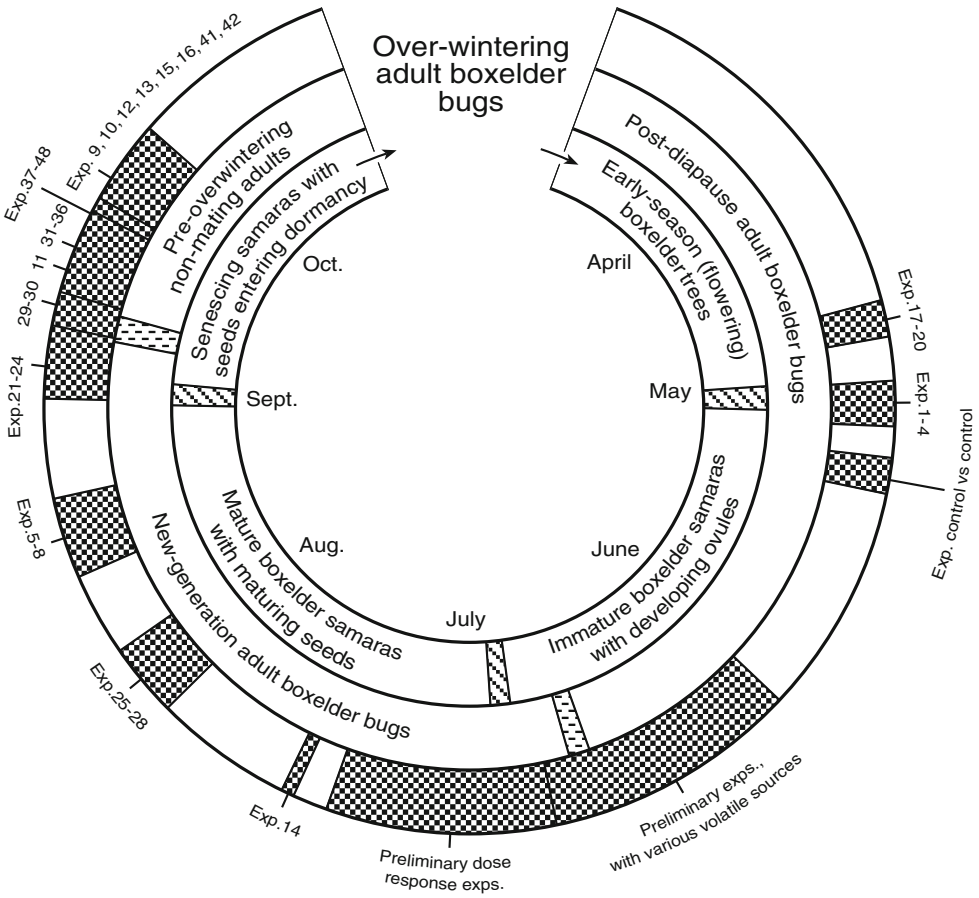

Fig. 1 Illustration depicting aspects of the seasonal phenology of boxelder trees, *A. negundo*, and western boxelder bugs, *B. rubrolineata*, and the time of season (*shaded sections in the outer ring*) during which experiments were conducted

[a] Experiments 1-4, 5-8, 9-16, 17-20, 21-24, 25-28, 29-30, 31-34, 35-36, 37-40, and 41-42, respectively, were run in parallel
[b] Dose–response experiments (not listed here) determined that 10 GHE was a suitable dose
[c] A control- vs. control-stimulus experiment revealed no side bias of the bioassay setup
[d] The control stimulus (pentane) consisted of the same amount of solvent (10 µl) as dispensed with the treatment stimulus
[e] Headspace chemicals of early-season staminate and pistillate trees in 2006 were tested in parallel at 10 GHE, at quantities of ca. 900 ng and ca. 1,000 ng, respectively. In 2007, volatiles of early-season staminate trees, when tested in parallel to either the five- or 22-component synthetic blends, were tested at ca. 930 ng in 10-µl aliquots (equivalent to the amount of the 22 antennal stimulatory components in pistillate trees with maturing seeds at 10 GHE)
[f] N=number of insects bioassayed
[g] Bearing pollen
[h] Immature samaras contain ovules
[i] Mature samaras contain maturing seeds
[j] The blend comprised 1-hexanol (24 ng), pentyl acetate (6 ng), phenylacetonitrile (5 ng), 2-phenethyl acetate (7 ng), and *trans*-nerolidol (27 ng)
[k] For blend constituents and their quantities, see columns 5 and 6 of Table 1
[l] Senescent samaras contain ripening seeds entering dormancy
[m] The amounts of synthetic test chemicals reflect those of natural constituents in head space volatiles of pistillate trees with maturing seeds at 10 GHE
[n] The amount of synthetic test chemical reflects that of the natural constituent in head space volatiles of early-season staminate trees at 10 GHE
[o] Adult age unknown
[p] Less than 14-days-old adults (note: pre-overwintering adults are in reproductive diapause)
[q] Four- to 6-day-old adults (note: pre-overwintering adults will enter reproductive diapause)
[r] More than 30-days-old adults

consisting of five components (1-hexanol, pentyl acetate, phenylacetonitrile, 2-phenethyl acetate, and *trans*-nerolidol) that were selected based on their changing seasonal abundance. Experiments 15 and 16 were "negative controls" that used volatiles from pistillate trees with senescing foliage and samaras. Experiments 17–28 were designed to explore whether the attractiveness of volatile blends, from previous experiments, varied with time of season and the insect's life history stage and reproductive status. Experiments 29–42 aimed to determine the essential components (s) in the five-component blend. Experiments 29 and 30 tested a two-component blend of phenylacetonitrile and 2-phenethyl acetate. Follow-up experiments 31–34 tested this two-component blend against the five-component blend, while experiments 35–42 tested single components against the different sexes and life stages.

Statistical Analyses Data of all experiments were analyzed by the χ^2 goodness-of-fit test, using Yates' correction for continuity (α=0.05; Zar 1999). Logistic regression analyses (Table 3) were used to test for effects of insect sex, developmental stage, and reproductive state, host type, season, and synthetic chemical blend, and interactions thereof (α=0.05). Fisher's exact test was used to test for differences in response by fifth-instar nymphs to synthetic chemical blends (α=0.05). All analyses employed JMP™ software (SAS®, Cary, NC, USA).

Results

Headspace volatiles of early-season staminate, but not of pistillate, trees attracted both male and female post-diapause BEBs (Fig. 2; experiments 1–4). Host type had a significant effect on the insects' responses, but sex of insect did not (Table 3). Volatiles of branches with immature samaras did not attract females or males (Fig. 2; experiments 5–6), whereas those of branches with mature samaras did (Fig. 2; experiments 7–8). Host season had a significant effect on the insects' responses, but sex of insect did not (Table 3).

In GC-EAD recordings of extracts that were found attractive in experiments 7 and 8, 22 volatile components (Table 1) elicited antennal responses, most of which are shown in Fig. 3. We considered likely essential components of an attractive blend to be those that elicited an antennal response (Fig. 3) and varied in relative abundance in volatile profiles of pistillate trees throughout the season (Fig. 4). Based on these criteria, five components [1-hexanol, pentyl acetate, phenylacetonitrile, 2-phenethyl acetate, and *trans*-nerolidol] were selected and bioassayed at quantities and ratios equivalent to those found in 10 GHE of pistillate trees with mature samaras (Table 1). In experiments 9–14 (Fig. 5), both the five-component and the 22-component blends of antennal stimulatory components (Fig. 3; Table 1) attracted females (Fig. 5, experiments 9, 12), males (Fig. 5, experiments 10, 13), and fifth-instar nymphs (Fig. 5, experiments 11, 14). These results suggested that essential semiochemicals were present in the five-component blend. In experiments 9–14, insect sex and developmental stage had no effect on the insects' responses (Table 3).

Considering that these five components were present at much reduced quantities in headspace volatile extracts of trees with senescing samaras (Fig. 4), we predicted that such extracts would not be attractive to BEBs. The results of experiments 15 and 16 confirmed this prediction (Fig. 5). Thus, host season had a significant effect on the insects' responses but sex of insect did not (Table 3).

The insects' responses to attractive blends did not vary with time of season, the insects' life history stage, or sex (Fig. 6, experiments 17–24; Table 3), but it did vary with the insects' reproductive state (Fig. 6, experiments 25–28; Table 3). In particular, reproductively active males, but not females (Fig. 6, experiment 27, 28), were attracted to the five-component blend. The attraction of post-diapause and new-generation females and males to the volatile extract of early-season staminate trees (Fig. 6, experiments 19, 20, 23, 24) suggested that it contained essential constituents. The presence of phenylacetonitrile and 2-phenethyl acetate (trace) in this extract was confirmed by GC-MS analysis.

In experiments 29 and 30, the synthetic blend of phenylacetonitrile and 2-phenethyl acetate attracted females and males (Fig. 7). In follow-up and parallel-run experiments 31–34, this 2-component blend was as effective as the five-component blend in attracting females and males (Fig. 7; Table 3). In experiments 35 and 36, 2-phenethyl acetate attracted both females and males (Fig. 7). In parallel-run experiments 37–39, 2-phenethyl acetate and phenylacetonitrile as single components were as effective as the five-component blend in attracting females (Table 3). Similarly, in experiment 40, phenylacetonitrile attracted males. In experiments 29–40, neither sex nor blend composition affected the insects' responses (Table 3). In parallel-run experiments 41–42, phenylacetonitrile, but not 2-phenethyl acetate, attracted fifth-instar nymphs (Fig. 7).

Discussion

Our data support the hypotheses that (1) BEBs are attracted to volatiles of early-season staminate trees bearing pollen; (2) volatile profiles of pistillate trees change as the season progresses; (3) pistillate trees with mature samaras are

attractive to BEBs; and (4) specific semiochemicals mediate attraction of BEBs to boxelder trees with pollen or seed resources.

Insects emerging from overwintering diapause seek food sources that increase their reproductive potential prior to mating (Tanaka et al. 1987; Tanaka and Wolda 1988; Kalberer et al. 2001). Post-diapause female and male BEBs are attracted to volatile blends of early-season pollen-bearing staminate boxelder trees, but also feed on new-growth tissue of both staminate and pistillate trees. Pollen is a rich supply of protein for the growth, development, and performance of many phytophagous insects (Strong et al. 1984) and likely supplements the diet of BEBs, which are also facultative cannibals and insect scavengers (Brown and Norris 2004). Similarly, western conifer seed bugs, *Leptoglossus occidentalis*, and plum curculio beetles, *Conotrachelus nunuphar*, feed on staminate flowers in the spring (Blatt 1997; Leskey and Prokopy 2000). BEBs may feed on pistillate trees in the spring because they have fed on seeds the preceding year and then over-wintered nearby.

Locating host trees rapidly is an effective means of exploiting ephemeral food resources and explains why both *Jadera* spp. (Aldrich et al. 1990a) and BEBs respond to semiochemicals that indicate seed availability (Schwarz 2008). As suggested for the respective hosts of the heteropteran seed feeders *Jadera* (Carroll and Loye 1987) and *Pachycoris* (Grimm and Führer 1998), boxelder trees may escape seed predation by producing mature seeds late in the season with little time for BEB populations to increase and significant seed predation to take place.

Although volatile blends of early- and late-season pistillate trees were not attractive in bioassays, field observations indicate that pistillate trees in spring and early summer suffer feeding damage by BEBs and other herbivores, such as aphids and thrips. Clipped branches of

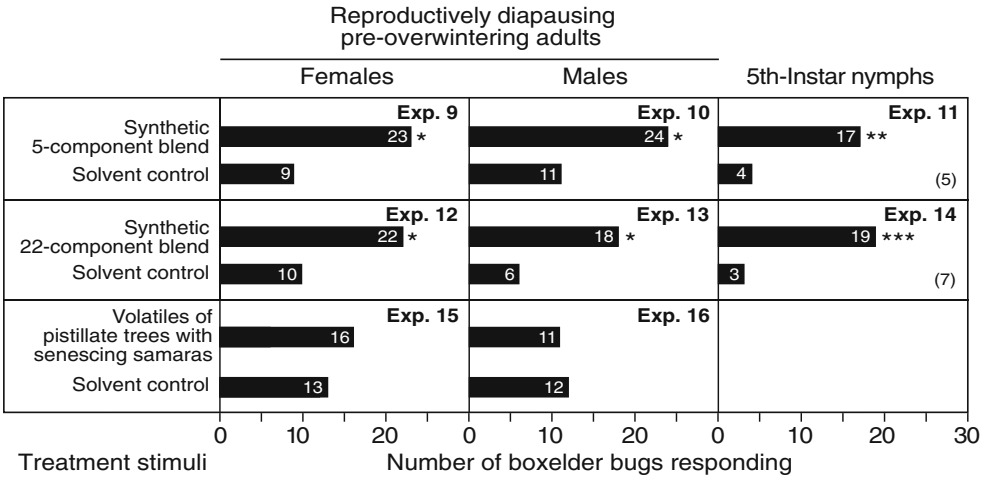

Fig. 5 Responses of fifth-instar nymph and virgin adult female and male western boxelder bugs, *B. rubrolineata*, in Y-tube olfactometer experiments to five- or 22-component synthetic blends of candidate semiochemicals and to headspace volatile extract of pistillate (♀) trees with senescing samaras. Constituents of the synthetic blends are listed in Table 1. *Numbers in parentheses* indicate numbers of nonresponding insects. An asterisk indicates a significant preference for a particular test stimulus (χ^2 test; *$P<0.05$, **$P<0.01$, ***$P<0.001$)

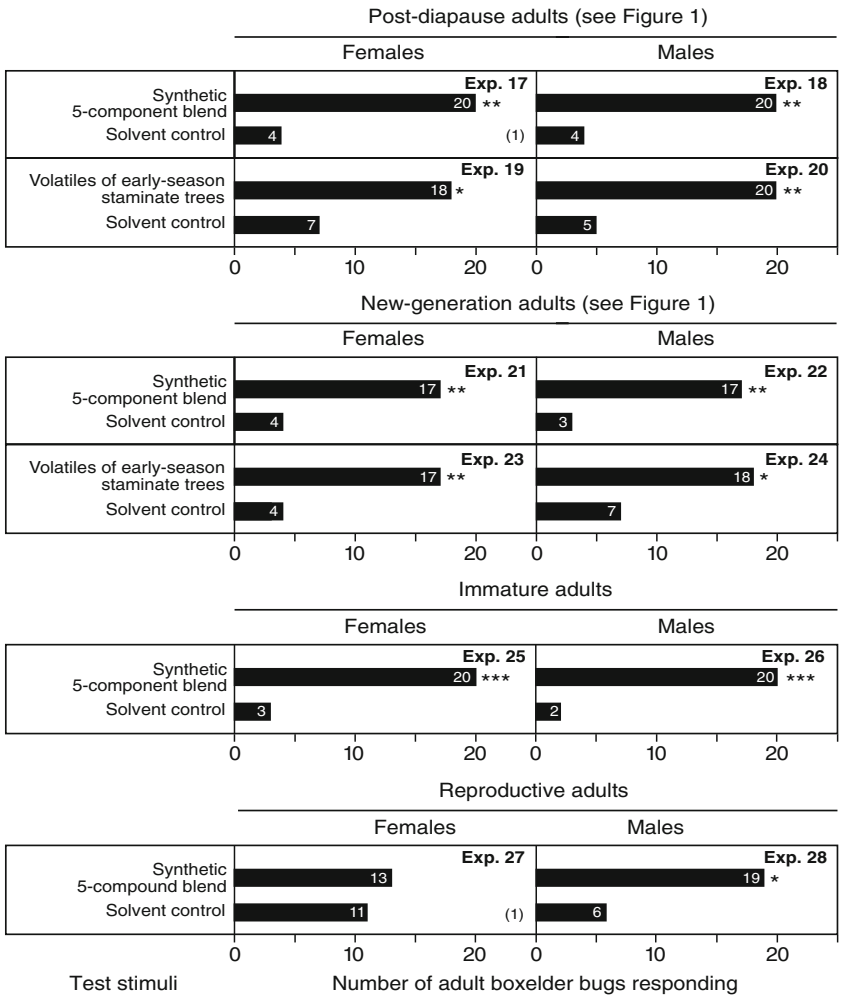

Fig. 6 Responses of female and male western boxelder bugs, *B. rubrolineata*, of different life history stage and reproductive status to a five-component synthetic blend (see Table 1) or to headspace volatile extract of early-season staminate (♂) trees. *Numbers in parentheses* indicate numbers of nonresponding insects. An *asterisk* indicates a significant preference for a particular test stimulus (χ^2 test; *$P<0.05$, **$P<0.01$, ***$P<0.001$)

pistillate trees, with BEBs feeding or with mechanical damage, were more attractive to BEBs, and they released higher levels of phenylacetonitrile and 2-phenethyl acetate, than did clipped branches with foliage devoid of insect or mechanical damage (data not shown). This suggests that herbivory may promote the apparency of trees with seeds near maturity, thus influencing colonization by BEBs. Many of the compounds that elicited antennal responses from BEBs have been identified from plants in response to herbivore or mechanical damage and may be used as foraging cues by herbivores (Walling 2000 and references therein).

Availability and quality of food resources affect the decisions of insects regarding when to stay and feed and when to leave (Dingle 1974). When boxelder seeds enter dormancy and BEBs cease to reproduce, phenylacetonitrile and 2-phenethyl acetate levels released by the plant have declined to trace quantities, rendering the volatile blend unattractive to BEBs, even though in laboratory bioassays pre-overwintering BEBs are attracted to synthetic blends that contain phenylacetonitrile and 2-phenethyl acetate. Pre-overwintering BEBs that feed on senescing hosts (JJS, personal observation) are probably not attracted to them but have remained to feed on "last-minute" nutrients that may be needed to complete development as adults as well as to build nutritional reserves for overwintering survival. This has been observed previously in ladybird beetles, *Coccinella septempunctata* (Barron and Wilson 1998).

The reproductive state of BEBs modulates their responses to host semiochemicals. Gravid females no longer responded to the five-component blend, suggesting a physiological change in accord with the insect's ecology. Gravid females likely are already present on resources needed for food and oviposition and therefore may no longer engage in host-finding behavior. Moreover, ovipositing females may trade off the mobility required in host-finding for increased fecundity. In female cotton stainer seed bugs, *Dysdercus* spp., availability of food (and oviposition sites) induced histolysis of wing muscles and

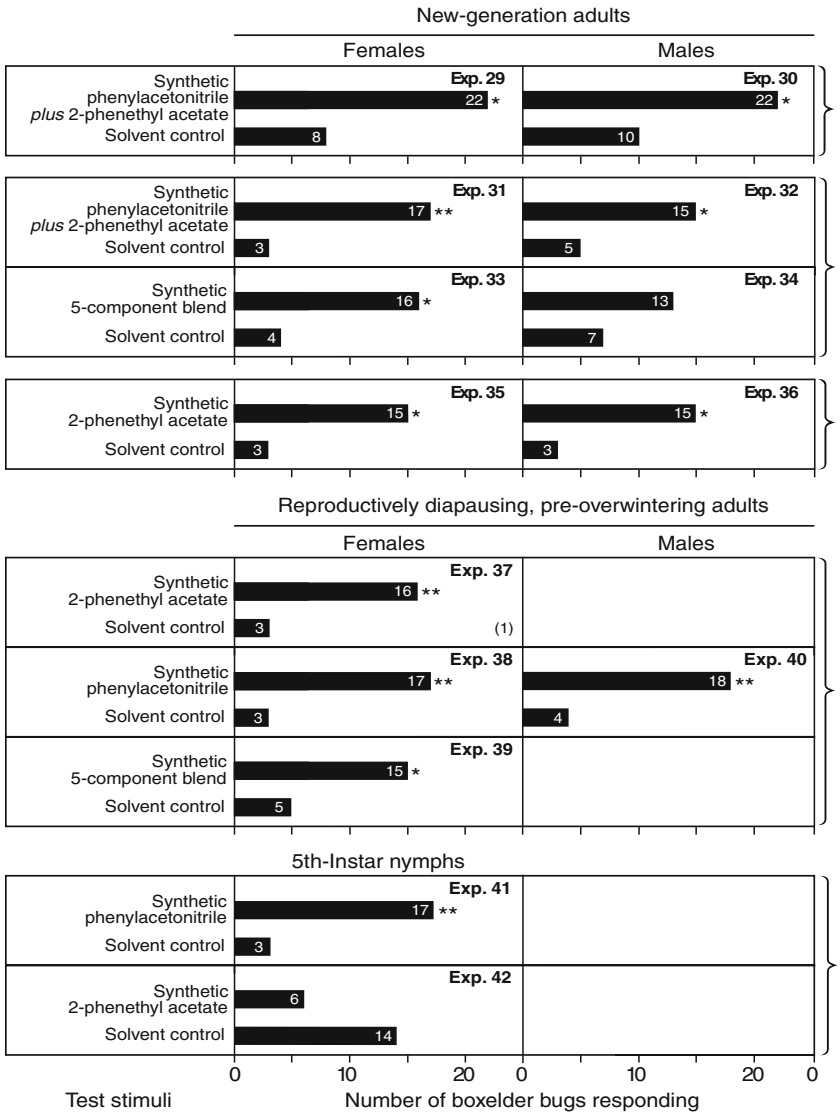

Fig. 7 Responses of fifth-instar nymph and sexually immature adult female and male western boxelder bugs, *B. rubrolineata*, to various synthetic blends of candidate semiochemicals. Constituents of the five-component blend are listed in Table 1. *Numbers in parentheses* indicate numbers of nonresponders. An asterisk indicates a significant preference for a particular test stimulus (χ^2 test; *$P<0.05$, **$P<0.01$). Note: experiment 40 was run not in parallel with experiments 37–39; in experiments 41 and 42, the test stimulus had a significant effect on response of fifth-instar nymphs (Fisher's Exact Test, $\alpha=0.05$, one-tailed, $df=1$, $P<0.001$)

rapid development of eggs (Dingle and Arora 1973). That reproductively active BEB males, unlike sedentary gravid females, remain responsive to the five-component blend may allow them to seek further food resources and mating opportunities with females.

Phenylacetonitrile appears to be an essential host tree kairomone for BEBs as it was the only single compound that attracted both adults and nymphs. Plants that produce phenylacetonitrile are known to store secondary metabolites (e.g., flavonoids, cyanogenic glycosides, glucosinolates) that specialist herbivores may sequester for aposematic defense. BEBs attain their aposematic coloration by ingesting flavonoids (Palmer and Knight 1924) and may gain secondary defense by ingesting or metabolizing cyanogenic toxins from seeds of host trees, as do other aposematic true bugs (Braekman et al. 1982; Aldrich et al. 1990a). Phenylacetonitrile has been reported as a semiochemical metabolite of benzylglucosinolates of oil seed rape, *Brassica napus* and *Brassica rapa*, and attracts both the specialist cabbage seed weevil, *Ceutorhynchus assimilis* (Bartelt et al. 1997; Smart and Blight 1997), and the specialist cabbage butterfly, *Pieris rapae* (Ômura et al. 1999). 2-Phenethyl acetate is a widespread constituent of floral and fruit scents (Knudsen and Tollsten 1993) that likely forms from 2-phenylethanol by alcohol acetyltransferases unique to plants (Guterman et al. 2006).

In summary, our data indicate that specific semiochemicals from the boxelder tree attract the specialist boxelder bug. Phenylacetonitrile attracts BEBs to early-season, pollen-bearing staminate trees and to midseason pistillate trees with maturing seeds. By responding to phenylacetonitrile, BEBs appear to track and exploit nutrient-rich food sources.

Acknowledgments We thank Geoffrey Scudder for confirming the taxonomic identity of *Boisea rubrolineata* (Barber); Grigori Khaskin for the synthesis of (*E*)-4,8-dimethyl-1,3,7-nonatriene; Cory Campbell and Melissa Cook for conducting some bioassays; Sharon Oliver and Mike Cheng for word processing; Bob Birtch for graphical illustrations; Ian Wilson, Bruce and Louise Babiuk, Denise Canuel, Jim McMillan, Marcie and Kelly, and John Sandness for access to, and guidance on, field sites; Bernhard Roitberg, Scott P. Carroll, and one anonymous reviewer for constructive comments; and Eberhard Kiehlmann for editorial review. The research was financially supported by SFU Graduate Fellowships to Joseph Schwarz and by a Natural Sciences and Engineering Research Council of Canada (NSERC)—Industrial Research Chair to G.G. with Pherotech International Inc., SC Johnson Canada, and Global Forest Science (GF-18-2007-226; GF-18-2007-227) as industrial sponsors.

RAPID COMMUNICATION

Lichen Substances Prevent Lichens from Nutrient Deficiency

Markus Hauck · Karen Willenbruch · Christoph Leuschner

Received: 6 October 2008 / Revised: 5 December 2008 / Accepted: 8 December 2008 / Published online: 17 January 2009

Abstract The dibenzofuran usnic acid, a widespread cortical secondary metabolite produced by lichen-forming fungi, was shown to promote the intracellular uptake of Cu^{2+} in two epiphytic lichens, *Evernia mesomorpha* and *Ramalina menziesii*, from acidic, nutrient-poor bark. Higher Cu^{2+} uptake in the former, which produces the depside divaricatic acid in addition to usnic acid, suggests that this depside promotes Cu^{2+} uptake. Since Cu^{2+} is one of the rarest micronutrients, promotion of Cu^{2+} uptake by lichen substances may be crucial for the studied lichens to survive in their nutrient-poor habitats. In contrast, study of the uptake of other metals in *E. mesomorpha* revealed that the intracellular uptake of Mn^{2+}, which regularly exceeds potentially toxic concentrations in leachates of acidic tree bark, was partially inhibited by the lichen substances produced by this species. Inhibition of Mn^{2+} uptake by lichen substances previously has been demonstrated in lichens. The uptake of Fe^{2+}, Fe^{3+}, Mg^{2+}, and Zn^{2+}, which fail to reach toxic concentrations in acidic bark at unpolluted sites, although they are more common than Cu^{2+}, was not affected by lichen substances of *E. mesomorpha*.

Keywords Lichenized Ascomycetes · Dibenzofurans · Depsides · Metal homeostasis · Copper

Introduction

Lichens are known for their ability to cope with extreme environments. They can adapt to extreme temperatures, drought, inundation, salinity, high concentrations of heavy metals (Nash 2008), or even survive in outer space (Sancho et al. 2007). Another outstanding character of lichens is tolerance to nutrient-poor environments. Mechanisms that enable a lichen to deal with shortages of nutrients have been poorly scrutinized, although most cannot compete with vascular plants at well-supplied sites.

Lichen substances are a chemically diverse group of more than 800 mostly phenolic compounds largely specific to lichen-forming fungi. They recently were shown to specifically inhibit the intracellular uptake of toxic amounts of transition metals, whereas other metals absent at toxic concentrations from the environment of the lichen could pass (Hauck 2008). Due to the high specificity of the role of lichen substances in metal tolerance, we tested the hypothesis that the opposite effect, the promotion of the uptake of metals needed as micronutrients, may be realized in the lichen symbiosis in nutrient-poor environments. We studied Cu^{2+} uptake in lichens with usnic acid (UA), a widespread cortical dibenzofuran in lichen-forming fungi. This example was selected, as Cu^{2+} is, after Mo, usually the rarest micronutrient in the microhabitats of epiphytes of nutrient-poor bark (Gauslaa 1995). Moreover, UA forms complexes with Cu^{2+} (Takani et al. 2002). We selected two UA-producing epiphytic lichens characteristic of nutrient-poor, acidic bark, *Evernia mesomorpha* Nyl. and *Ramalina menziesii* Taylor. The former lichen produces the depside divaricatic acid (DA) in addition to UA, whereas the latter lichen only synthesizes UA.

Methods and Materials

Lichens were collected in Mongolia (Khentey, Eroo, Khonin Nuga; *E. mesomorpha*) and the USA (Oregon, Benton County, Porter Lake; *R. thrausta*). Thalli were

M. Hauck (✉) · K. Willenbruch · C. Leuschner

e-mail: mhauck@gwdg.de

stored in air-dry condition at −18°C in the dark before the experiment. After thawing, extracellular lichen substances were extracted with acetone from one half of the lichen thalli. Samples were submersed in acetone (4×10 min). The efficacy of this treatment at removing lichen substances was controlled by high-pressure liquid chromatography by using a reverse-phased column and gradient elution. Viability of lichen thalli was controlled by measuring the chlorophyll fluorescence yield (Φ_2) of light-adapted samples at photosystem II after the acetone treatment with a PAM-2100 chlorophyll fluorometer (Walz, Effeltrich, Germany).

Five pieces of the fruticose thalli of up to 5-cm length were used in each replicate sample and combined on a Petri dish with a moist cellulose filter. For acclimatization, Petri dishes with thalli were stored in a growth chamber for 2 days at 80% RH, a day temperature (for 13 h daily) of 13°C with a photon flux density of 30 μmol m^{-2} s^{-1}, and a night temperature of 10°C. Lichens then were exposed for 30 min to 50 ml of 20 μM $CuCl_2$, which is typical of the microhabitats of the studied lichens under unpolluted conditions on a shaker at pH 4. The uptake of Fe^{2+}, Fe^{3+}, Mg^{2+}, Mn^{2+}, and Zn^{2+} from chloride salt solutions was studied in *E. mesomorpha* in comparison. These salts were applied at a higher concentration (100 μM) than $CuCl_2$ because their concentrations in stemflow, throughfall, and bark, which form important nutrient sources for epiphytes, are higher than that of Cu^{2+} (Gauslaa 1995). Moreover, these metals cause less membrane damage than Cu^{2+}, which would impair the experiment. After exposure to the metal solution, the extra- and intracellular cations were sequentially extracted. For this purpose, samples were shaken with deionized water (2×20 ml) to remove free apoplastic ions. Metal ions bound to hydroxylic or carboxylic exchange sites of the cell wall were exchanged by shaking samples with $NiCl_2$ (2×20 ml). Afterwards, all samples were shaken with acetone (2×20 ml) to remove metal ions potentially bound to extracellular lichen substances. Samples were dried at 105°C, homogenized, and digested with 65% HNO_3 in order to analyze intracellular concentrations of Cu, Fe, Mg, Mn, or Zn with atomic absorption spectrometry (AAS Vario 6, Analytik Jena, Germany). The measuring error inherent to the AAS amounted to <1%.

Statistical analyses were computed with SAS 6.04 software (SAS Institute Inc., Cary, NC, USA). All data are given as arithmetic means±standard error and were tested for normal distribution with the Shapiro–Wilk test. Samples were tested for significant differences with Student's *t* test for pairwise comparisons.

Results and Discussion

Samples containing their natural content of lichen substances took up significantly more Cu^{2+} than acetone-extracted samples, both in *E. mesomorpha* (*t* test, $P \leq 0.01$, $df=4$) and in *R. menziesii* ($P \leq 0.05$; Fig. 1a, b). The promotion of metal uptake was highly specific for Cu^{2+}. Uptake of Fe^{2+}, Fe^{3+}, Mg^{2+}, and Zn^{2+} in *E. mesomorpha* was not influenced by lichen substances. Intracellular uptake of Mn^{2+} was even reduced ($P \leq 0.05$; Fig. 1c). This makes sense, as peak concentrations of Mn^{2+} leached from the canopy are known to limit the abundance of lichens on acidic bark (Hauck and Paul 2005), as has been found in conifers and some broad-leaved trees such as beech and oak. Hence, reduced uptake broadens the ecological niche of lichens, although Mn^{2+} is essential in minor amounts. Partial inhibition of Mn^{2+} uptake by lichen substances is already known from epiphytic lichens at Mn^{2+}-rich sites (Hauck 2008).

Stronger promotion of Cu^{2+} uptake in *E. mesomorpha* than in *R. menziesii* (Fig. 1) suggests that DA in addition to UA could contribute to Cu^{2+} uptake. However, although members of the same family (Parmeliaceae), both lichens differ in their morphology, which is also likely to affect element uptake. Complex formation of UA and Cu^{2+} in the pH range preferred by UA-producing lichens (pH 3.5–6;

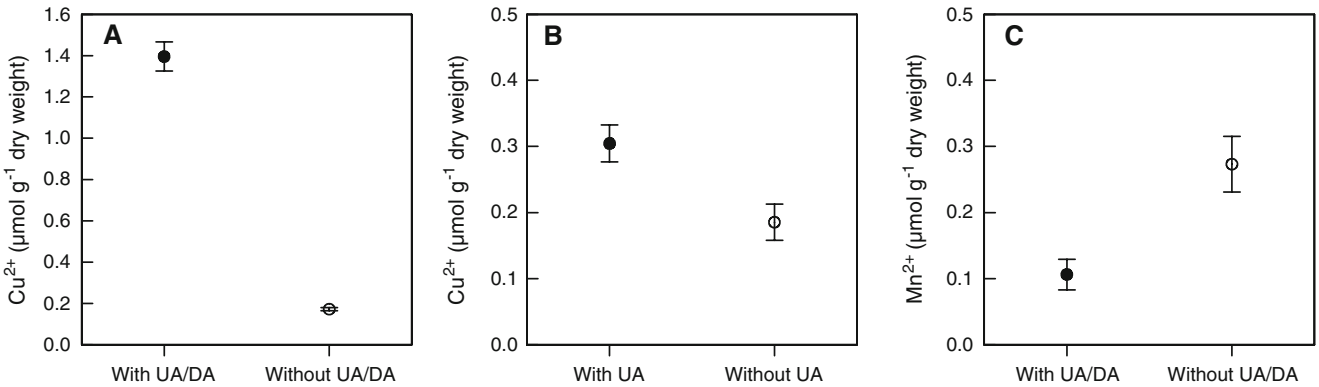

Fig. 1 Intracellular concentrations of Cu^{2+} in **a** *E. mesomorpha* and **b** *R. menziesii* and **c** Mn^{2+} in *E. mesomorpha* with and without their natural content of lichen substances after exposure to $CuCl_2$ or $MnCl_2$ solution for 30 min ($N=5$). *Error bars* indicate standard error

Takani et al. 2002; Hauck and Jürgens 2008; Hauck et al. 2009) suggests that these complexes are involved in the observed promotion of Cu^{2+} uptake. Whether such lipophilic complexes directly cross the phospholipid membrane (as proven for uncomplexed UA; Abo-Khatwa et al. 1996; Hauck and Jürgens 2008) or Cu^{2+} ions are transferred to transporters is unclear. Given the multitude of compounds and their widespread ability to interact with metal ions (Hauck and Huneck 2007), it is likely that promotion of nutrient uptake will be seen in other lichen symbioses. Recent UV-spectroscopic studies in yellow and orange lichen substances, including UA, suggested that promotion of metal uptake by lichen substances might be widespread (Hauck et al. 2009). Lichen compounds that occur in lichens of nutrient-poor sites form complexes with metal ions precisely at the pH ranges preferred by the respective lichens. Lichens growing under pH conditions, at which lichen substances do not bind to metals, are limited to substrata rich in mineral nutrients (Hauck et al. 2009). Research is necessary to elucidate the extent to which lichen substances are involved in the metal homeostasis of lichens.

Assessment of the Allelopathic Potential of *Juniperus ashei* on Germination and Growth of *Bouteloua curtipendula*

G. P. Young · J. K. Bush

Received: 30 October 2008 / Revised: 1 December 2008 / Accepted: 18 December 2008 / Published online: 20 January 2009

Abstract Potential allelopathic compounds of *Juniperus ashei* Buchh. (Ashe juniper) and their effect on a native grass were determined in laboratory and field studies. Solid-phase microextraction and gas chromatography/mass spectrometry were used to determine if monoterpenes found in the essential oils of *J. ashei* are released in leaf and litter leachate, as well as volatilized from leaf tissue. Camphor, bornyl acetate, and limonene were found in leaf and fresh litter leachates; however, degraded litter did not contain any of these compounds. Camphor was the most common potentially allelopathic compound found in *J. ashei* leaf and litter leachate and in volatiles from leaf tissue. The effects of leaf and litter tissue on the germination of *Bouteloua curtipendula* (Michx.) Torr. (side-oats grama) was tested by using the "sandwich agar method". The highest germination of *B. curtipendula* (29.6%) occurred in the control, which was significantly higher than fresh litter (13.2%) and degraded litter (16.2%). The lowest germination (6.2%) occurred with *J. ashei* leaves. In the field experiment, aboveground dry mass of *B. curtipendula* was evaluated in relation to position within the canopy and intercanopy of *J. ashei* adult trees when light and water were held constant across locations. Aboveground dry mass of *B. curtipendula* was significantly greater in the intercanopies of *J. ashei* (163.7 g m^2) compared to the dry mass in the understory (44.8 g m^2) and dripline (44.5 g m^2), suggesting some negative influence by *J. ashei*. Chemical analyses indicate that monoterpenes are released through leaching and volatilization from *J. ashei*, and germination and field studies suggest that these compounds inhibit *B. curtipendula*.

Introduction

Juniperus ashei Buchh. (Ashe juniper) is native to the limestone slopes of Central Texas, USA (Bryant and Shafer 1977; Adams 2004). Co-occurring over much of *J. ashei*'s range is the native grass *Bouteloua curtipendula* (Van Auken 2008; Van Auken and McKinley 2008). Grass and forb production and species diversity are greatly reduced under the canopy of *J. ashei* (Schott and Pieper 1985; Wayne and Van Auken 2008). This could be due to competition for water, nutrients, and sunlight. The possibility of an allelopathic effect between *J. ashei* and neighboring plants has been implied (Jameson 1966, 1967, 1970), but not thoroughly investigated.

Allelopathic substances may be released by a variety of mechanisms from various plant structures (see Chou and Patrick 1976; Barney et al. 2005; Nichida et al. 2005; Bonanomi et al. 2006; Gawronska and Golisz 2006 for a review). From the emanation of allelochemicals, plants can regulate the soil microbial community in their immediate vicinity, affect herbivory, encourage beneficial symbiosis, change the chemical and physical properties of the surrounding environment, and directly inhibit the growth of competing plant species (Pedrol et al. 2006). Allelopathic compounds play important roles in the determination of plant diversity, dominance, succession, and climax of natural vegetation and in the plant productivity of agroecosystems (Chou 1999). Allelopathy also may be one of

several attributes which enable a plant to establish in a new ecosystem (Bais et al. 2003; Callaway and Aschehoug 2000; Kilronomos 2002; Callaway and Ridenour 2004) although this has been debated (Blair et al. 2006). Additionally, allelopathy is important in establishing and maintaining community boundaries (Richardson and Williamson 1988; Weidenhamer and Romeo 1989; Williamson et al. 1991).

The purpose of this research was to: (1) determine if the most abundant monoterpenes (camphor, bornyl acetate, and limonene) found in the essential oils of *J. ashei* leach from leaf tissue and from fresh and degraded litter, (2) determine if these monoterpenes are volatilized from leaves of *J. ashei* and if temperature has an effect on the relative abundance of the monoterpenes, (3) determine the effect of *J. ashei* leaves and litter on the germination of *B. curtipendula* (side-oats grama), and (4) evaluate the growth of *B. curtipendula*, in relation to the proximity of mature *J. ashei* trees, when water and light were held constant.

Materials and Methods

Solid-Phase Microextraction and Chromatography New techniques such as solid-phase microextraction (SPME) have proven promising in tracking compounds within plants (Loi et al. 2008). Chromatograms, in combination with the mass spectra, were used to establish presence or absence and relative abundance of limonene, camphor, and bornyl acetate in representative leachate and headspace samples.

Capturing natural rainfall and throughfall was the method of choice. However, the lack of precipitation events during the study period led to creation of an alternative method of obtaining leachate. Litter leachate was created from fresh recently fallen litter, or from aged degraded litter. Samples containing 100 g of each litter type were collected from underneath mature *J. ashei* trees located in a natural area on the University of Texas at San Antonio campus. Geologically, the campus lies on the Balcones Escarpment, an area that defines the southern boundary of the Edwards Plateau of Central Texas. The litter samples were placed in separate beakers that contained 1 l of deionized water. Each beaker was covered with Parafilm™, placed on a stir plate, and stirred for 12 h. A 12-h time frame was chosen to approximate a precipitation event during which litter accumulates in flat areas underneath the canopy and water pools. A fresh branch of *J. ashei* was collected from a mature tree located in the same natural area on the campus of the University of Texas at San Antonio, and approximately 100 g were placed in a beaker that contained 1 l of deionized water. Parafilm™ was placed over the mouth of the beaker, and it was left undisturbed at room temperature (23°C) for 12 h. Litter and leaf material was not ground or fragmented before water extraction. Resulting leachates were filtered to 25 μm by using a sieve, poured into amber bottles, and placed in the refrigerator at 6°C.

Taking into consideration the size, volatility, and polarity of camphor, bornyl acetate, and limonene, Supelco SPME portable field samplers that contained 75-μm-thick fiber coated with Carboxen™/polydimethylsiloxane as the stationary phase (no. 504831, Supelco, Sigma-Aldrich Co., Bellefonte, PA, USA) were chosen. The SPME fibers were conditioned initially for 75 min at 300°C, following manufacturer's directions. Standards and leachate samples were prepared and analyzed with gas chromatography coupled with a mass spectrometer (GC/MS).

For aqueous extraction, 25 ml of the appropriate aqueous sample (standard or leachate) were placed into a 40-ml vial with septum cap and brought to room temperature (23°C). The septum was pierced with the SPME needle, and the fiber was injected into the sample. The fiber was exposed and submerged in the aqueous sample for 10 min while the sample was stirred continually to enhance extraction and reduce extraction time. For headspace extraction, 25 ml of the appropriate aqueous sample were placed into a 40-ml vial with septum cap. Deionized water was used as a control. The vials were heated to 40°C in a water bath. The fiber was exposed in the headspace above the aqueous sample and remained in the headspace of the vial for 15 min, while the sample was continually stirred to enhance extraction and reduce extraction time. The fiber was then retracted into the needle sleeve, withdrawn from the sample vial, and introduced into the GC/MS. The fiber was desorbed and reconditioned by leaving it in the injection port at 300°C for 15 min after each injection.

The compounds volatilized from fresh *J. ashei* leaves at 6°C (refrigerated), 23°C (room temperature), and 60°C (oven) were extracted by placing a branch of fresh leaves in a tightly sealed Reynolds Oven Roasting Bag® (Dalusky, personal communication) that was then held at the appropriate temperature for 4 h. An empty bag was sampled as a control. The first two temperatures tested were chosen because they are the average minimum temperatures recorded in the area for the months of February (6°C) and August (23°C; NOAA 2004). The soil surface temperatures in August consistently reached a temperature of 60°C (data were collected by using Spectrum Watchdogs®, but are not presented); therefore, volatilization at this elevated temperature was considered. The bag was pierced with the SPME needle, and the fiber was exposed for 15 min. The fiber was then retracted into the needle sleeve, withdrawn from the sample, and introduced into the GC/MS. It was desorbed and reconditioned by leaving it in the injection port at 300°C for 15 min after each injection.

Compound desorption and analyses were carried out on a Thermo Finnigan Trace GC gas chromatograph with a

Restek RTX-5MS 30-m×0.5-mm×0.25-μm capillary column coupled with a Finnigan Polaris Q ion trap spectrometer. Splitless injection was employed with an injection temperature of 300°C and ion source temperature of 280°C. The column temperature was programmed to rise from an initial temperature of 60°C to 200°C at a rate of 3°C min^{-1}. Helium was used as carrier gas with a flow rate of 1 ml min^{-1}. A full-scan mass spectrum was obtained and compared to that of commercially purchased and prepared standards of camphor, bornyl acetate, and limonene.

Laboratory Germination Procedures *J. ashei* leaves, freshly fallen litter (fresh litter), and degraded litter were collected from randomly selected trees on the University of Texas at San Antonio campus. Leaves or litter were placed between two layers of agar using the "sandwich method" (Fujii et al. 2004). Purified commercially available agar was prepared at 0.5% *w/v* and autoclaved at 115°C for 15 min. Fresh, clipped *J. ashei* leaves (2.5 g), fresh litter (2.0 g), or degraded litter (2.0 g) was spread in a thin layer in the bottom of 10 (100×15 mm) Petri plates. Fresh litter was distinguished from degraded litter by its recent deposition, surface location, and golden color. Ten Petri plates were prepared without leaves or litter and designated as a control. Twenty milliliters of autoclaved agar were added to each plate. After gelatinizing the agar at room temperature (25°C), another 20 ml of autoclaved agar were dispensed on top of the previous agar layer in each plate creating an "agar sandwich". Seeds of *B. curtipendula* were purchased from Native American Seed Company, Junction, TX, USA (http://www.seedsource.com/). Seeds were collected from the company farms located on the South Llano River just outside the town of Junction, TX, USA. Fifty seeds of *B. curtipendula* were placed onto each of ten leaf, fresh litter, degraded litter, and control agar sandwiches resulting in ten replicates for each agar type. All plates were placed in ambient light and temperature (~23°C) in the laboratory. Germination (rupture of seed coat and emergence of radicle) was determined daily for 14 days.

Percent germination of *B. curtipendula* was analyzed statistically by using analyses of variance with treatment (leaf, fresh litter, degraded litter, and control) as the main effect. Shapiro–Wilk *W* test was used to evaluate normality and the Bartlett's test for homogeneity of variance (Sall et al. 2005). Data were not normal; therefore, percent germination data were arc-sine transformed. Transformed data were normal and variances equal. Tukey–Kramer honestly significant difference (HSD) was used to compare means (Sall et al. 2005).

Field Assessment Methods A field site was established at Government Canyon State Natural Area. Government Canyon State Natural Area is an approximately 3,489 ha site in northwestern Bexar County Texas, just outside of San Antonio and within the Edwards Plateau Region of Central Texas. Aboveground dry mass of *B. curtipendula*, in relation to proximity to *J. ashei*, was evaluated in the field by establishing *B. curtipendula* at three locations associated with mature *J. ashei* trees—at the drip line (edge of the tree), understory (halfway between the trunk and the drip line), and in an intercanopy area (2–3 m away from the drip line). Trees were selected based on size (>50 cm trunk diameter), canopy diameter (minimum of 5 m), and adequate intercanopy space. All planting locations were located on the NW to SW side of the trees. *B. curtipendula* was planted in 20×50-cm (0.1 m^2) plots in nine understory locations, nine drip-line locations, and nine intercanopy locations resulting in a total of 27 plots. Debris, existing vegetation, and existing litter were removed from each plot. Soil was loosened to a depth of 2 cm, smoothed, and leveled. Fifteen grams of *B. curtipendula* seeds were scattered evenly across each plot and pressed lightly into the soil. To reduce the possibility of seed predation or herbivory, wire exclosures were constructed around each plot, using 1×1-cm wire mesh. To minimize variance in ambient temperatures and light between plot locations, the intercanopy plots were draped with shade cloth. To compare light levels at the various locations and to permit the use of light level as a covariate in the analysis of variance if necessary, Spectrum Watch Dogs® were set to record photosynthetically active photon flux density (PFD) per plot location on a clear sunny day from sunrise to sunset. No significant differences in light levels were found among the locations.

The study site preparation began on April 8, 2006, and planting occurred on April 12, 2006. All plots were watered a minimum of once daily to keep the soil moist and promote germination. Prior to establishment, watering was increased sometimes to twice daily when the temperature was high and humidity was low. After establishment and when natural precipitation did not occur at an amount and frequency adequate for viability, the plots were watered manually. Water was sprayed with a hose-end sprayer into the overlying tree canopy allowing the drip to fall onto the plots. The planting plots continued to be observed daily and watered as necessary through October 14, 2006 at which time the aboveground (flower + stem + leaf) biomass was harvested. Aboveground total dry mass was determined by drying at 100°C to constant mass and weighing.

Early in the study, it was observed that germination of one of the intercanopy plots was almost nonexistent, lagging far behind the other plots. Rabbit droppings were routinely found on top of the exclosure. A decision was made to remove this plot from the statistical analysis. Analysis of variance of aboveground total dry mass was performed with location (understory, dripline, intercanopy)

as the main effect in the model. In addition, the mean daily PFDs for each position were entered into the model as a covariate. Photosynthetically active photon flux density was not a significant factor (i.e., light levels were not significantly different among the locations) and was removed as a covariate from the model. The Shapiro–Wilk *W* test was used to check for data normality, and the Bartlett's test was used to test for homogeneity of variance. Due to unequal variances, aboveground dry mass was log transformed. A Tukey–Kramer HSD comparison for all pairs was performed.

Results

Solid-Phase Microextraction and Chromatography The approximate retention time of camphor was 14.72 min, of bornyl acetate was 20.75 min, and of limonene was 9.66 min. Table 1 indicates the occurrence of the analytes in the representative samples. The results of the GC/MS analysis of the aqueous leachate confirm the presence of camphor, bornyl acetate, and limonene in leachate derived from fresh leaves and fresh litter but not in leachate derived from degraded litter (Table 1). When analyzing leaf- and fresh litter leachate for the three compounds, camphor was the most abundant, bornyl acetate was intermediate, and limonene was the least abundant.

The results of the GC/MS analysis of the headspace over aqueous leachate samples derived from fresh *J. ashei* leaves and fresh *J. ashei* litter confirm the presence of all three compounds in the headspace, but not in the headspace of samples of leachate derived from degraded litter (Table 1). With leaf tissue, camphor was the most abundant, bornyl acetate was intermediate, and limonene was the least abundant; however, with fresh litter, camphor was the most abundant, followed by limonene, and only a trace of bornyl acetate.

Table 1 Occurrence of camphor, bornyl acetate, and limonene in leachate and volatilized headspace samples analyzed using solid phase microextraction coupled with GC/MS

Sample type	Camphor	Bornyl acetate	Limonene
Aqueous submerged			
Juniperus ashei leaves	1	2	3
Juniperus ashei fresh litter	1	2	3
Juniperus ashei degraded litter	0	0	0
Aqueous headspace			
Juniperus ashei leaves	1	2	3
Juniperus ashei fresh litter	1	TR	2
Juniperus ashei degraded litter	0	0	0
Volatilized (headspace)			
6°C	2	1	3
23°C	1	2	3
60°C	1	3	2

Abundance ranking are 0—absent, 1—highest, 2—second highest, 3—least abundant
TR trace (present but in amounts <1%)

The results of the GC/MS analysis of the compounds volatilized from fresh *J. ashei* leaves at 6°C (refrigerated), 23°C (room temperature), and 60°C (oven) confirm the presence of camphor, limonene, and bornyl acetate in all samples (Table 1; Fig. 1). The relative abundance of bornyl acetate was the highest at 6°C and decreased as the temperature rose. Bornyl acetate became the least abundant relative to camphor and limonene when the temperature reached 60°C. The relative abundance of camphor increased with increasing temperature. Amounts of limonene ranked relatively low in all samples but surpassed that of bornyl acetate when the temperature reached 60°C (Table 1; Fig. 1).

Laboratory Germination Experiment Analysis of variance indicated a significant difference between mean germination (arcsine transformation) of *B. curtipendula* ($P<0.001$). The highest germination of *B. curtipendula* (29.6%) occurred in the control, which was significantly greater than the fresh litter treatment (13.2%) and the degraded litter treatment (16.2%; Fig. 2). The lowest germination (6.2%) occurred in the leaf treatment, which was significantly lower than all other treatments (Fig. 2).

Field Experiment Analysis of variance of *B. curtipendula* aboveground dry mass indicated a significant difference between locations ($P=0.002$). The highest mean aboveground dry mass occurred in the intercanopy locations (163.7 g m^{-2}) which was significantly greater than the mean of both the understory locations (44.8 g m^{-2}) and the dripline locations (44.5 g m^{-2}; Fig. 3). The mean aboveground dry mass of the understory and dripline plots were not significantly different from each other.

Discussion

Studies have identified camphor at 68.5%, bornyl acetate at 12.2%, and limonene at 5.8% in the essential oils of *J. ashei* acquired through steam distillation (Adams 2000). However, to our knowledge, it has not been shown that these compounds can be leached from leaf tissue or litter, and/or volatilized from the leaves of *J. ashei*, or other species of *Juniperus*. Studies have noted suppression of understory vegetation beneath *Juniperus* species (Lavin et al. 1968; Fuhlendorf et al. 1996; Wayne and Van Auken 2008), and while the role of allelopathy has been investigated for some species of *Juniperus* (Jameson 1966, 1970; Lavin et al. 1968; Horman and Anderson 2003), no studies have shown allelopathy by *J. ashei*.

Essential oils and individual monoterpenes, such as camphor, bornyl acetate, and limonene, strongly inhibit seed germination and plant growth (Duke and Olivia 2002; Barney et al. 2005). Research has shown that even dilute unsaturated solutions of monoterpenes may act as potent biological inhibitors (Weidenhamer et al. 1993). Additionally, the activity of monoterpenoids has been shown to be species selective (Williamson et al. 1992; Abrahim et al. 2000; Vokou et al. 2003; Loi et al. 2008)

There is evidence that monoterpenes inhibit mitosis, inhibit cell nucleus and organelle DNA synthesis, and cause deterioration of membrane integrity (Dayan et al. 2000; Romagni et al. 2000; Duke and Olivia 2002). Lipophilic monoterpenes cause dewaxing and induce stomatal opening, which causes increased transpiration and death of *Arabidopsis thaliana* (Schulz et al. 2007). The molecular mode of action of most monoterpenes is not well investigated, and we did not look at mode of action in this study.

Characteristics of monoterpenes that affect their volatilization, such as vapor pressure, have been evaluated at various temperatures (Li and Perdue 1998). Similar to this study where bornyl acetate seemed to be the compound most affected by changes in temperature, *Psuedotsuga menziesii* leaves from plants grown at different temperatures showed reductions in the concentration of bornyl acetate but no changes in camphene or limonene at elevated temperatures (Snow et al. 2003). Apparent higher total terpene emission from *Rosmarinus officinalis* plants when ambient air temperatures were the highest were not significant in a previous study (Peñuelas and Llusià 1997). It is unclear whether the variations in relative abundance in this study are due to chemical properties of the compounds, metabolic properties, or something else.

While no camphor, bornyl acetate, or limonene was detected in the aqueous sample or headspace of degraded litter, germination of *B. curtipendula* on the degraded "sandwich" agar treatment was not significantly different from fresh litter samples. A fungal growth developed on

seeds in the degraded litter samples during the germination portion of the study. This fungus was not present in any of the other treatments. Decreased germination in the degraded litter sample could be due to fungal effects on seeds. Fungi can have saprophytic or pathogenic effects on seeds (Christensen 1989), and fungal seed pathogens may inhibit or stimulate seed germination (Harman 1983).

The overall effect of one plant on another is the result of multiple interacting mechanisms, and resource competition should always be considered. Therefore, our experimental design adjusted for anticipated light and water differences. The results indicated that the difference in aboveground dry mass was not due to light or water. Other factors that may have contributed to the differences in aboveground dry mass, however, include temperature, pH, nutrient availability, soil microfauna, microbiological differences, and the presence of allelopathic compounds introduced by *J. ashei* (Callaway 1995; Gawronska and Golisz 2006).

In early successional xeric, semiarid, and arid savannas, soil C and N are the highest underneath the canopy of shrubs (Bush 2008). In mesic *J. virginiana* and associated grassland communities, ecosystem C and N stocks revealed significant C and N accrual in both plant biomass and soils in newly established *J. virginiana* forests (McKinley and Blair 2008). Based on these studies, we hypothesize that nutrient levels would be higher underneath the canopy, resulting in greater growth of *B. curtipendula* beneath the canopy and at the dripline. This is contrary to our findings, thus suggesting that the significant difference in aboveground dry mass observed among locations is probably due to a factor other than C and N availability.

Leachates in this study were generated artificially due to lack of precipitation events, and we did not quantify the concentrations of camphor, bornyl acetate, and limonene released through leaching or volatilization; however, our results show that all three chemicals are released into the environment from *J. ashei*. Combination of the chemical analyses with the germination and field studies strengthens the hypothesis that allelopathic compounds may be influencing germination and growth of *B. curtipendula*.

Acknowledgments We express our gratitude to Dr. S. Bach for the use of GC/MS and to Texas Parks and Wildlife and the staff of Government Canyon State Natural Area for access to facilities.

Identification of Sex Pheromone Components of the Hessian Fly, *Mayetiola destructor*

Martin N. Andersson · Jenny Haftmann · Jeffrey J. Stuart · Sue E. Cambron · Marion O. Harris · Stephen P. Foster · Stephan Franke · Wittko Francke · Ylva Hillbur

Received: 15 May 2008 / Revised: 15 September 2008 / Accepted: 5 November 2008 / Published online: 10 December 2008

Abstract Coupled gas chromatographic (GC)–electroantennographic detection (EAD) analyses of ovipositor extract of calling Hessian fly, *Mayetiola destructor*, females revealed that seven compounds elicited responses from male antennae. Four of the compounds—(2*S*)-tridec-2-yl acetate, (2*S*,10*Z*)-10-tridecen-2-yl acetate, (2*S*,10*E*)-10-tridecen-2-yl acetate, and (2*S*,10*E*)-10-tridecen-2-ol—were identified previously in female extracts. Two new EAD-active compounds, (2*S*,8*Z*,10*E*)-8,10-tridecadien-2-yl acetate and (2*S*,8*E*,10*E*)-8,10-tridecadien-2-yl acetate, were identified by GC–mass spectroscopy (MS) and the use of synthetic reference samples. In a Y-tube bioassay, a five-component blend (1 ng (2*S*)-tridec-2-yl acetate, 10 ng (2*S*,10*E*)-10-tridecen-2-yl acetate, 1 ng (2*S*,10*E*)-10-tridecen-2-ol, 1 ng (2*S*,8*Z*,10*E*)-8,10-tridecadien-2-yl acetate, and 1 ng (2*S*,8*E*,10*E*)-8,10-tridecadien-2-yl acetate) was as attractive to male Hessian flies as a similar amount of female extract (with respect to the main compound, (2*S*,10*E*)-10-tridecen-2-yl acetate). The five-component blend was more attractive to male flies than a three-component blend lacking the two dienes. Furthermore, the five-component blend was more attractive than a blend with the same compounds but that contained one tenth the concentration of (2*S*,8*E*,10*E*)-8,10-tridecadien-2-yl acetate (more accurately mimicking the ratios found in female extract). This suggests that the ratios emitted by females might deviate from those in gland extracts. In a field-trapping experiment, the five-component blend applied to polyethylene cap dispensers in a 100:10 μg ratio between the main component and each of the other blend components attracted a significant number of male Hessian flies. Also, a small-plot field test demonstrated the attractiveness of the five-component blend to male Hessian flies and suggests that this pheromone blend may be useful for monitoring and predicting Hessian fly outbreaks in agricultural systems.

Introduction

The Hessian fly, *Mayetiola destructor* (Say) (Diptera: Cecidomyiidae), is one of the most destructive pests of wheat (*Triticum* spp) in the US and North Africa (Gagné 1989; El Bouhssini et al. 1999; Berzonsky et al. 2003; Harris et al. 2003). In addition, it is considered a pest in

many European countries (Barnes 1956). In common with other species in the family Cecidomyiidae (gall midges), Hessian fly adults are short-lived, have a highly synchronized period of flight activity, and may be present in crops for brief periods of time only (Harris and Foster 1999). Typically, outbreaks are sporadic, local, and difficult to predict (*ibid*.). As a consequence, Hessian flies are normally discovered only after they have become a serious problem.

Various methods are used to control Hessian flies including delayed planting of winter wheat, use of resistant wheat varieties, and application of broad-spectrum insecticides (Buntin et al. 1992; El Bouhssini et al. 1999; Rausher 2001; Berzonsky et al. 2003). All of these methods might be improved by a sensitive method for the detection of early infestations (Buntin et al. 1990, 1992; Cox and Hatchett 1986; Harris et al. 2003). One potential method for field monitoring might employ the use of sex pheromone-baited traps (Harris and Foster 1999). Earlier work demonstrated the presence of a sex pheromone in the Hessian fly (McKay and Hatchett 1984). One component of the female-produced sex pheromone, (2*S*,10*E*)-10-tridecen-2-yl acetate [2*S*-10*E*-13:OAc], was identified (Foster et al. 1991b). However, when tested alone in a wind tunnel, this compound attracted significantly fewer Hessian fly males than did female extract (Harris and Foster, 1991). In a field study, traps baited with the compound also failed to attract male Hessian flies (Harris and Foster 1999). In the wind tunnel, male responses were tested to binary blends of 2*S*-10*E*-13:OAc and racemic mixtures of three other chemicals—(10*Z*)-10-tridecen-2-yl acetate, (10*E*)-10-tridecen-2-ol, and tridec-2-yl acetate (Foster et al. 1991b; Harris and Foster 1991)—found in female extract (Millar et al. 1991). However, none of these blends attracted more males than 2*S*-10*E*-13:OAc alone. In this study, we identified additional compounds produced by female Hessian fly and formulated a blend that is attractive to male flies in the field.

Methods and Materials

Insect Rearing Wheat plants (*Triticum aestivum* L., genotype "Blueboy") that contained Hessian fly puparia of the "Great Plains" biotype (provided by the US Department of Agriculture-Agricultural Research Service (USDA-ARS) and the Department of Entomology, Purdue University, West Lafayette, IN, USA) were put into Plexiglas cages (29×34×29 cm) held in an environmental chamber (25°C, 70% relative humidity (RH) and 12:12 L:D photoperiod; lights on 09:00) at Alnarp, Sweden. Infested plants were watered daily to avoid desiccation of developing flies. Typically, adults emerged 7–14 days later, and the sexes were separated and used for pheromone extraction, coupled gas chromatographic–electroantennographic detection (GC–EAD) analyses, and Y-tube bioassays. Hessian flies used in the small-plot test were reared on hard red spring wheat, *T. aestivum* L. (genotype "Reeder"), in a greenhouse at North Dakota State University. These flies were also of the "Great Plains" biotype and originated from approximately 5,000 puparia, obtained in 2000, from the USDA-ARS laboratory at Purdue University.

Pheromone Extraction The pheromone gland in Hessian fly females is associated with the eighth and ninth abdominal intersegmental membrane epidermis (Solinas and Isidoro 1996). Gland extracts were prepared by excising the terminal abdominal segments of virgin calling females (Bergh et al. 1990; Foster et al. 1991a). Ovipositors were placed into a vial partially immersed in liquid nitrogen. When sufficient ovipositors (approximately 30) were collected, the vial was allowed to warm to ambient temperature, and the tissue was extracted for 1–1.5 min in distilled hexane (LabScan). Following extraction, the solvent was decanted into glass vials (2 ml) and stored at −18°C until use. All dissections were made between 09:00 and 11:30.

GC–EAD Recordings GC–EAD (Arn et al. 1975) was used to analyze female gland extracts and synthetic compounds. A Hewlett-Packard 6890 GC (Palo Alto, CA, USA) with flame ionization detection and an Innowax column (30 m× 0.25 mm i.d., H-P), programmed from 80°C (held for 2 min) to 220°C at 10°C/min, was used. Whole male bodies were mounted in an antennal holder (JoAC, Lund, Sweden), as described by Hillbur et al. (2001). Both antennae were exposed simultaneously to a charcoal-filtered and humidified air stream at a rate of approximately 0.3 m/s through a glass tube (8-mm diameter). The signals from the antennae were amplified (JoAC) before they were recorded and were analyzed with ElectroAntennoGraphy software (Syntech, Hilversum, The Netherlands).

Structure Elucidation Coupled GC–MS analyses of extracts of female Hessian fly were generally carried out as described earlier (Hillbur et al. 2005). Separations were achieved with a 60 m, 0.25-mm i.d. fused silica capillary, DB-5/MS (J&W Scientific, Folsom, CA, USA) under temperature program: 3 min at 60°C, then programmed to 280°C at a rate of 5°C/min. An additional fused silica column, 50 m, 0.25 mm i.d., Permabond FFAP (Macherey & Nagel, Düren, Germany), was also used.

Enantioselective GC was carried out with a 25 m, 0.25-mm i.d. fused silica capillary coated with a 1:1 mixture of heptakis 6-*O*-*tert*.butyldimethylsilyl-2,3-di-*O*-methyl β-cyclodextrin and OV 17 at 100°C isothermal and using hydrogen as the carrier gas.

^{1}H nuclear magnetic resonance (NMR) spectra of synthetic compounds were recorded on a Bruker AMX-400 instrument (Karlsruhe, Germany) using tetramethylsilan as the internal standard.

Syntheses If not otherwise stated, starting material, reagents, and solvents were purchased from Aldrich and were of highest available grade. Syntheses were carried out under dry argon and synthetic compounds were purified by column chromatography using silica 60 Å, 32–63 mesh (MP Eco Chrom) under 0.5-bar pressure.

The stereogenic center in each of the six target compounds was introduced via a Grignard-type reaction of a suitable precursor with commercially available (2*S*)-2-methyloxiran of 98% optical purity similar to the approach of Millar et al. (1991). The enantiomeric purity of the products corresponded with commercial (2*S*)-2-methyloxiran (checked by enantioselective GC). The Grignard reagent was produced from commercially available 1-bromodecane and used to produce (2*S*)-tridec-2-yl acetate [2*S*-13:OAc]. Synthesis of the mono-unsaturated compounds (i.e., 2*S*-10*E*-13:OAc, (2*S*,10*E*)-10-tridecen-2-ol [2*S*-10*E*-13:OH], and (2*S*,10*Z*)-10-tridecen-2-yl acetate [2*S*-10*Z*-13:OAc]) involved 7-decyn-1-ol as the educt (Yadav et al. 1995). Reduction of the ynol to (7*E*)-7-decen-1-ol (Rossi and Carpita 1977) or to (7*Z*)-7-decen-1-ol (hydrogenation over Lindlar catalyst), transformation to the corresponding alkenyl bromides (Wiley et al. 1964), and formation of the Grignard products followed by chain elongation with (2*S*)-2-methyloxiran furnished 2*S*-10*E*-13:OH and its (*Z*)-isomer in good yields and purities of approximately 96–98%. Standard laboratory acetylation produced the corresponding acetates. Analytical data of all these known compounds were in good accord with expected values and those reported in the literature (Millar et al. 1991; Yadav et al. 1995).

The scope of the syntheses of (2*S*,8*Z*,10*E*)-8,10-tridecadien-2-yl acetate [2*S*-8*Z*-10*E*-13:OAc] and (2*S*,8*E*,10*E*)-8,10-tridecadien-2-yl acetate [2*S*-8*E*-10*E*-13:OAc] is shown in Figs. 3 and 4, respectively.

The synthesis of 2*S*-8*Z*-10*E*-13:OAc (Fig. 3) started from commercially available 5-bromopentan-1-ol (**I**), which was converted to the silyl ether **II** and subsequently transformed to the Wittig reagent using triphenyl phosphane. Wittig reaction with (2*E*)-2-butenal yielded **III**. Deprotection and transformation of the obtained alcohol to the corresponding bromide (Horner et al. 1959) produced (5*Z*,7*E*)-5,7-decadien-1-yl bromide (**IV**). Chain elongation with (2*S*)-2-methyloxiran followed by acetylation afforded the target compound 2*S*-8*Z*-10*E*-13:OAc.

The synthesis of 2*S*-8*E*-10*E*-13:OAc (Fig. 4) started from commercially available 4-bromo-1-butene (**V**). Chain elongation with (2*S*)-2-methyloxiran furnished (2*S*)-7-hepten-2-ol. Reaction with 3,4-dihydro-2*H*-pyran and ozonization followed by reductive workup produced (5*S*)-5-(2-tetrahydropyranyloxy)hexan-1-ol (**VII**) via the protected alkenol **VI**. Transformation of the primary hydroxyl group to the bromide **VIII** and chain elongation of its Grignard product with (2*E*,4*E*)-2,4-heptadien-1-yl acetate (Samain et al. 1978) employing cuprate coupling (Fouquet and Schlosser 1974) yielded (2*S*,8*E*,10*E*)-2-(2-tetrahydropyranyloxy)trideca-8,10-diene (**IX**). Acid-catalyzed deprotection and acetylation afforded the target compound 2*S*-8*E*-10*E*-13:OAc.

*5-Bromo-1-tert.butyldimethylsilyloxypentane (**II**)* A solution of 5.70 g (34.1 mmol) 5-bromopentane-1-ol (**I**; purchased from TCI Europe, Zwijendrecht, Belgium) and 6.18 g (90.9 mmol) imidazole in 5 ml of abs. dimethylformamide was cooled to 0°C. After addition of 6.84 g (45.5 mmol) *tert*.butyldimethylsilylchloride, the mixture was stirred for 3 h, warmed to 10°C, and stirred for an additional 2 h. Workup started with the addition of 150 ml diethyl ether and 200 ml of saturated aqueous sodium bicarbonate, separation of the organic layer, and extraction of the aqueous layer (3×150 ml diethyl ether). The organic solutions were combined, washed with brine, and dried over magnesium sulfate. After removal of the solvent, the residue was chromatographed on silica using hexane–diethyl acetate 95:5, yielding 7.25 g (25.7 mmol, 75%) of **II** as a colorless liquid.

^{1}H-NMR (400 MHz, $CDCl_3$) δ [ppm] = 0.85 (s, 9H, SiC(CH_3)$_3$); 1.39–1.55 (m, 4H, 2-H, and 3-H); 1.79–1.88 (m, 2H, 4-H); 3.36 (t, 2H, *J*=6.87 Hz, 5-H); 3.57 (t, 2H, *J*=6.11 Hz, 1-H)

^{13}C-NMR (100.6 MHz, $CDCl_3$) δ [ppm] = −5.14 (q, 2C, Si(**C**H$_3$)$_2$); 24.75 (t, 3-C); 26.12 (q, 3C, SiC(*C*H$_3$)$_3$); 32.07 (t, 2-C); 32.78 (t, 4-C); 33.95 (t, 5-C); 63.01 (t, 1-C)

MS (70 eV) m/z [%] = 169 (40); 167 (41); 139 (40); 137 (42); 115 (6); 101 (10); 99 (7); 89 (10); 88 (5); 85 (6); 75 (44); 73 (27); 70 (11); 69 (100); 61 (5); 59 (13); 58 (9); 57 (16); 55 (5); 47 (6); 45 (9); 43 (7); 41 (45); 39 (9)

*(5Z,7E)-5,7-Decadienyloxy-tert.butyldimethylsilane (**III**)* A mixture of 7.18 g (23.6 mmol) of the bromide **II**, 13.4 g (51.1 mmol) triphenyl phosphane, and 813 mg (7.70 mmol) sodium carbonate in 50 ml acetonitrile was refluxed for 24 h. The solvent was removed from the suspension, and the residue was dissolved in 50 ml dichloromethane. Filtration of the oily solution over silica, using dichloromethane as the eluent, provided unreacted starting material, while the Wittig salt (11.0 g, 20.2 mmol, 79%) was isolated using a 1:1 mixture of dichloromethane and methanol as the eluent.

^{1}H-NMR (400 MHz, $CDCl_3$) δ [ppm] = 0.85 (s, 9H, SiC(CH_3)$_3$); 1.50–1.75 (m, 8H, 2-H to 5-H); 3.60 (t, 2H, *J*=6.1 Hz, 1-H); 7.71–7.91 (m, 15H, H_{Ph})

^{13}C-NMR (100.6 MHz, $CDCl_3$) δ [ppm] = −5.54 (q, 2C, Si(CH_3)$_2$); 22.25/27.93/28.09 (t, 3-C to 5-C); 26.10 (q, 3C, SiC(CH_3)$_3$); 32.07 (t, 2-C); 63.43 (t, 1-C); 131.32 (d, 6C, $C_{Ar)}$; 134.57 (d, 9C, C_{Ar}); 136.02 (s, 3C, C_{Ar})

A solution of 10.6 g (20.0 mmol) of the Wittig salt, obtained in the previous step, in 100 ml abs. tetrahydrofuran was cooled to 0°C. Subsequently, 26.2 ml of a solution of potassium hexamethyldisilazane (0.5 mmol in toluene, equal to 3.26 g, 16.3 mmol KHMDS) was added slowly, with stirring continued for 2 h. Subsequently, the mixture was cooled to −78°C and 1.34 g (16.0 mmol); (2*E*)-2-pentenal, dissolved in 20 ml abs. tetrahydrofuran, were added dropwise. After stirring for another half hour, the mixture was warmed to 20°C, and 350 ml of a saturated aqueous solution of ammonium chloride was added. The mixture was extracted five times with 150 ml diethyl ether. The combined organic solutions were washed with brine and dried over magnesium sulfate. Removal of the solvent *in vacuo* and chromatography on silica using hexane–ethyl acetate (97:3) yielded 2.77 g (10.3 mmol, 55%) of the protected dienol **III** as a colorless oil.

^{1}H-NMR (400 MHz, $CDCl_3$) δ [ppm] = 0.94 (t, 3H, *J*= 7.5 Hz, 10-H); 0.99 (s, 9H, SiC(CH_3)$_3$); 1.42–1.57 (m, 4H, 2-H, and 3-H); 1.96–2.05 (m, 2H, 9-H); 2.11–2.25 (m, 2H, 4-H); 3.52 (t, 2H, *J*=6.3 Hz, 1-H); 5.31–5.38 (m, 1H, 5-H); 5.59–5.68 (m, 1H, 8-H); 6.06–6.13 (m, 1H, 6-H); 6.38–6.48 (m, 1H, 7-H)

^{13}C-NMR (100.6 MHz, $CDCl_3$) δ [ppm] = -5.13 (q, 2C, Si(CH_3)$_2$); 13.91 (q, 10-C); 26.20 (q, 3C, SiC(CH_3)$_3$); 26.28 (t, 3-C); 26.44 (t, 9-C); 27.82 (t, 4-C); 32.77 (t, 2-C); 63.13 (t, 1-H); 125.42 (d, 7-C); 129.61 (d, 6-C); 129.92 (d, 5-C); 136.27 (d, 8-C)

MS (70 eV) m/z [%] = 211 (41); 155 (33); 135 (20); 129 (5); 115 (8); 107 (13); 101 (13); 99 (5); 95 (9); 93 (25); 91 (8); 89 (12); 81 (10); 79 (28); 77 (11); 76 (9); 75 (100); 73 (26); 69 (7); 67 (13); 59 (11); 57 (6); 55 (10); 41 (13)

*(5Z,7E)-5,7-Decadienyl bromide (***IV***)* To a solution of 2.77 g (10.3 mmol) **III** in 50 ml tetrahydrofuran was added 14.4 ml (14.4 mmol) of a 1-M solution of tetra-*n*-butylammonium fluoride in tetrahydrofuran, and the mixture was stirred for 6 h at 20°C. Workup started with the addition of 100 ml diethyl ether and 100 ml of a saturated aqueous solution of ammonium chloride, separation of the layers, and extraction of the aqueous layer (6×100 ml diethyl ether). The combined organic layers were washed with brine and dried over magnesium sulfate. Removal of the solvent *in vacuo* and purification by silica chromatography (hexane–ethyl acetate 4:1) gave 1.52 g (9.85 mmol, 96%) (5*Z*,7*E*)-5,7-decadien-1-ol.

^{1}H-NMR (400 MHz, $CDCl_3$) δ [ppm] = 0.68 (br.s, 1H, OH); 0.92 (t, 3H, *J*=7.3 Hz, 10-H); 1.28–1.41 (m, 4H, 2-H, and 3-H); 1.96–2.05 (m, 2H, 9-H); 2.08–2.16 (m, 2H, 4-H); 3.32 (t, 2H, *J*=6.1 Hz, 1-H); 5.27–5.33 (m, 1H, 5-H); 5.59–5.68 (m, 1H, 8-H); 6.05–6.15 (m, 1H, 6-H); 6.37–6.46 (m, 1H, 7-H)

^{13}C-NMR (100.6 MHz, $CDCl_3$) δ [ppm] = 13.91 (q, 10-C); 26.26 (t, 9-C); 26.30 (t, 3-C); 27.81 (t, 4-C); 32.67 (t, 2-C); 62.54 (t, 1-H); 125.38 (d, 7-C); 129.59 (d, 6-C); 129.84 (d, 5-C); 136.32 (d, 8-C)

MS (70 eV) m/z [%] = 154 (5); 136 (14); 121 (7); 111 (6); 108 (8); 107 (14); 98 (9); 97 (9); 95 (28); 94 (10); 93 (33); 91 (20); 84 (7); 83 (14); 82 (15); 81 (30); 79 (100); 78 (9); 77 (27); 72 (6); 71 (7); 70 (16); 69 (13); 68 (24); 67 (81); 66 (9); 65 (12); 57 (8); 56 (5); 55 (33); 54 (8); 53 (14); 51 (5); 43 (6); 41 (24); 39 (14)

A solution of 2.62 g (10.0 mmol) triphenyl phosphane and 680 mg (10.0 mmol) imidazole in a mixture of 50 ml abs. diethyl ether and 2 ml abs. acetonitrile was cooled to 0°C. Subsequently, 1.62 g (10.0 mmol) of bromine was added dropwise, and a yellowish suspension was formed that was stirred for 2 h at 20°C. A solution of 1.52 g (9.85 mmol) of (5*Z*,7*E*)-5,7-decadien-1-ol, obtained in the previous step, in 20 ml abs. diethyl ether was added slowly, and the mixture was stirred overnight. Workup started with the addition of 100 ml diethyl ether and 100 ml of a saturated aqueous solution of ammonium chloride, separation of the layers, and extraction of the aqueous layer (6× 100 ml diethyl ether). The combined organic solutions were washed with brine and dried over magnesium sulfate. After removal of the solvent, the residue was chromatographed on silica (hexane–ethyl acetate 97:3) yielding 1.57 g (7,23 mmol, 73%) of the bromide **IV** as a colorless oil.

^{1}H-NMR (400 MHz, $CDCl_3$) δ [ppm] = 0.92 (t, 3H, *J*= 7.5 Hz, 1-H); 1.17–1.27 (m, 2H, 8-H); 1.43–1.53 (m, 2H, 9-H); 1.92–2.05 (m, 4H, 2-H, and 7-H); 2.91 (t, 3H, *J*= 6.8 Hz, 10-H); 5.13–5.21 (m, 1H, 3-H); 5.58–5.67 (m, 1H, 6-H); 6.01–6.10 (m, 1H, 4-H); 6.29–6.39 (m, 1H, 5-H)

^{13}C-NMR (100.6 MHz, $CDCl_3$) δ [ppm] = 13.88 (q, 1-C); 26.28/27.0 (t, 2-C, and 7-C); 28.37 (t, 8-C); 32.46 (t, 9-C); 33.41 (t, 10-C); 125.15 (d, 5-C); 129.02 (d, 3-C); 129.88 (d, 4-C); 136.64 (d, 6-C)

MS (70 eV) m/z [%] = 218 (11); 216 (11); 109 (9); 107 (7); 96 (7); 95 (100); 93 (13); 91 (10); 82 (17); 81 (48); 80 (7); 79 (26); 77 (15); 69 (7); 68 (23); 67 (66); 65 (7); 55 (18); 53 (9); 41 (23); 39 (13).

2S-8Z-10E-13:OAc To a mixture of 353 mg (14.5 mmol) freshly crushed magnesium turnings and 30 ml abs. tetrahydrofuran kept at 60°C, a solution of 1.57 g of **IV** in 30 ml tetrahydrofuran was added dropwise. The solution of the Grignard product was added dropwise to a suspension of 420 mg (7.23 mmol) of (2*S*)-2-methyloxiran and 140 mg (0.72 mmol) copper-I-iodide in 10 ml abs. tetrahydrofuran that was cooled to −78°C. After warming to room temperature, the mixture was stirred for another hour. Workup started with the addition of 50 ml diethyl ether and 100 ml of a saturated aqueous solution of ammonium chloride, separation of the layers, and extraction of the aqueous layer (4×50 ml hexane–ethyl acetate 1:1). The combined organic solutions were dried over magnesium sulfate and concentrated *in vacuo*. The obtained (2*S*,8*Z*,10*E*)-8,10-tridecadien-2-ol was purified by column chromatography on silica (hexane–ethyl acetate 1:1) yielding 654 mg (3.33 mmol, 46%) of (2*S*,8*Z*,10*E*)-trideca-8,10-dien-1-ol.

^{1}H-NMR (400 MHz, $CDCl_3$) δ [ppm] = 0.93 (t, 3H, *J*= 7.4 Hz, 13-H); 0.99 (d, 3H, *J*=6.1 Hz, 1-H); 1.15–1.39 (m, 9H, 3-H to 6-H and OH); 1.96–2.07 (m, 2H, 12-H); 2.13–2.21 (m, 2H, 7-H); 3.45–3.55 (m, 1H, 2-H); 5.32–5.42 (m, 1H, 11-H); 5.60–5.70 (m, 1H, 8-H); 6.09–6.15 (m, 1H, 10-H); 6.42–6.39 (m, 1H, 9-H)

^{13}C-NMR (100.6 MHz, $CDCl_3$) δ [ppm] = 13.94 (q, 13-C); 23.81 (q, 1-C); 26.03 (t, 12-C); 26.31 (t, 7-C); 28.07/29.61/30.14/39.70 (t, 3-C to 6-C); 67.68 (d, 2-C); 128.22 (d, 9-C); 129.42 (d, 11-C); 130.08 (d, 10-C); 136.26 (d, 8-C)

MS (70 eV) m/z [%] = 149 (7); 135 (7); 125 (13); 122 (5); 121 (13); 114 (8); 111 (8); 110 (16); 109 (13); 108 (14); 107 (25); 100 (9); 97 (14); 96 (52); 95 (59); 94 (18); 93 (83); 91 (20); 83 (12); 82 (52); 81 (63); 80 (26); 79 (91); 78 (11); 77 (23); 71 (14); 69 (11); 68 (17); 67 (100); 66 (11); 65 (10); 57 (6); 55 (31); 54 (9); 53 (13); 45 (48); 43 (19); 41 (33); 39 (14)

A solution of 641 mg (3.26 mol) of the aforementioned tridecadien-2-ol and 10 mg of *N*,*N*-dimethyl-4-aminopyridine in 10 ml abs. pyridine was cooled to 0°C. Subsequently, 916 mg (9.09 mmol) acetic anhydride, dissolved in 5 ml tetrahydrofuran, were added dropwise. After warming to room temperature, the mixture was stirred for 2 h. Workup started with the addition of 50 ml diethyl ether and 100 ml of an ice-cold saturated aqueous solution of sodium bicarbonate, separation of the layers, and extraction of the aqueous layer (five times with 50 ml diethyl ether). The combined organic solutions were washed with 50 ml of an aqueous saturated solution of copper-II-sulfate and 50 ml of brine and dried over magnesium sulfate. After removal of the solvent *in vacuo*, the crude product was chromatographed on silica (hexane–ethyl acetate 95:5), yielding 1.29 g (5.35 mmol, 36%) of 2*S*-8*Z*-10*E*-13:OAc as a colorless oil.

^{1}H-NMR (400 MHz, $CDCl_3$) δ [ppm] = 0.93 (t, 3H, *J*=7.4 Hz, 13-H); 1.08 (d, 3H, *J*=6.3 Hz, 1-H); 1.12–1.35 (m, 7H, 3-H_a, and 4-H to 6-H); 1.49–1.61 (m, 1H, 3-H_b); 1.72 (s, 3H, $COCH_3$); 1.96–2.06 (m, 2H, 12-H); 2.10–2.19 (m, 2H, 7-H); 4.92–5.01 (m, 1H, 2-H); 5.30–5.38 (m, 1H, 11-H); 5.60–5.70 (m, 1H, 8-H); 6.07–6.15 (m, 1H, 10-H); 6.39–6.50 (m, 1H, 9-H)

^{13}C-NMR (100.6 MHz, $CDCl_3$) δ [ppm] = 13.91 (q, 13-C); 20.08 (q, 1-C); 20.95 (q, CO**C**H_3); 25.66 (t, 12-C); 26.28 (t, 12-C); 27.98/29.38/29.99 (t, 4-C to 6-C); 36.26 (t, 3-C); 70.70 (d, 2-C); 125.41 (d, 9-C); 129.54 (d, 11-C); 129.82 (d, 10-C); 136.30 (d, 8-C); 169.77 (s, *C*O)

MS (70 eV) m/z [%] = 178 (14); 149 (13); 136 (5); 135 (11); 122 (6); 121 (11); 111 (5); 110 (43); 109 (18); 108 (18); 107 (24); 97 (8); 96 (50); 95 (61); 94 (37); 93 (52); 92 (5); 91 (16); 87 (8); 83 (8); 82 (50); 81 (65); 80 (28); 79 (95); 78 (9); 77 (18); 71 (6); 69 (10); 68 (21); 67 (100); 66 (12); 65 (8); 55 (35); 54 (8); 53 (11); 43 (92); 42 (6); 41 (32); 39 (10). For a plotted spectrum, see Fig. 2B.

(2S)-2-(2-Tetrahydropyranyloxy)hept-6-ene (**VI**) Starting from 10 g (74.1 mmol) 4-bromo-1-butene, dissolved in 10 ml abs. tetrahydrofuran and 2.71 g (111 mmol) freshly cut magnesium turnings, a Grignard reagent was prepared at 60°C. This was added dropwise to a suspension of 4.3 g (74.1 mmol) (2*S*)-2-methyloxiran and 1.41 g (7.41 mmol) copper-I-iodide in 50 ml abs. tetrahydrofuran that was cooled to −78°C. After warming to room temperature, the mixture was stirred for an additional hour. Workup started with the addition of 50 ml ethyl acetate and 100 ml of a saturated aqueous solution of ammonium chloride, separation of the layers, and extraction of the aqueous layer (five times with a 1:1 mixture of hexane and ethyl acetate). The combined organic layers were washed with brine and dried over magnesium sulfate. After removal of the solvent *in vacuo*, the crude product was purified by silica column chromatography (hexane–ethyl acetate 1:1), yielding 8.46 g (74.1 mmol, 100%) of (2*S*)-6-hepten-2-ol which was immediately used for the next step. A solution of 8.46 g (74.1 mmol) of (2*S*)-6-hepten-2-ol and 1.80 g (9.92 mmol) *p*-toluene sulfonic acid monohydrate in 70 ml dichloromethane was cooled to −10°C. Subsequently, a solution of

9.67 g (115 mmol) 3,4-dihydro-2*H*-pyran in 20 ml dichloromethane was added dropwise with the temperature kept below 0°C. Stirring was continued for 24 h at 4°C. Workup started with the addition of 200 ml hexane and 200 ml saturated aqueous solution of sodium bicarbonate, separation of the layers, and extraction of the aqueous layer (4×200 ml of a 4:1-mixture of hexane and ethyl acetate). The combined organic layers were washed with brine and dried over magnesium sulfate. After removal of the solvent *in vacuo*, the product was purified by silica column chromatography (hexane–ethyl acetate 97:3), yielding 8.09 g (40.8 mmol, 55%) of the THP derivative **VI**.

^{1}H-NMR (400 MHz, $CDCl_3$) δ [ppm] = 1.30 (d, 3H, *J*= 6.35 Hz, 1′-H); 1.45–1.70 (m, 8H, 3′-H, 4′-H, 3-H_a, 4-H_a, and 5-H); 1.70–1.95 (m, 1H, 3-H_b); 1.85–1.95 (m, 1H, 4-H_b); 2.08–2.20 (m, 2H, 5′-H); 3.52–3.61 (m, 1H, 6-H_a); 3.75–3.90 (m, 1H, 2′-H); 3.92–4.30 (m, 1H, 6-H_b); 4.68–4.80 (m, 1H, 2-H)

^{13}C-NMR (100.6 MHz, $CDCl_3$) δ [ppm] = 19.87 (t, 4-C); 21.70 (q, 1′-C); 25.32 (t, 4′-C); 25.72 (t, 5-C); 31.36 (t, 3-C); 37.12 (t, 3′-C); 62.95 (t, 6-C); 71.04 (d, 2′-C); 98.79 (d, 2-C); 114.50 (t, 7′-C); 139.08 (d, 6′-C)

MS (70 eV) m/z [%] = 101 (18); 96 (20); 86 (5); 85 (100); 84 (5); 81 (7); 67 (12); 57 (10); 56 (25); 55 (52); 54 (9); 45 (5); 43 (14); 41 (29); 39 (12)

*(5S)-5-(2-tetrahydropyranyloxy)hexan-1-ol (***VII***)* A solution of 8.09 g (40.8 mmol) of **VI** in 130 ml of a 1:1 mixture of dichloromethane and methanol was cooled to −78°C. At this temperature, ozone was bubbled through the solution until it turned slightly bluish (about 1 h). Subsequently, oxygen was bubbled through the solution for 10 min. After the addition of 3.11 g (81.6 mmol) solid sodium borohydride and warming to room temperature, stirring was continued for 12 h. Workup started with the careful addition of 100 ml water, separation of the layers, and extraction of the aqueous layer (9×50 ml ethyl acetate). The combined organic layers were dried over magnesium sulfate, and the solvent was removed *in vacuo*. The crude product was chromatographed on silica (hexane–ethyl acetate 4:1) yielding 5.11 g (25.3 mmol, 66%) of the alcohol **VII** as a colorless oil.

^{1}H-NMR (400 MHz, $CDCl_3$) δ [ppm] = 1.20 (d, 3H, *J*= 6.11 Hz, 6-H); 1.35–1.65 (m, 11H, 2-H to 4-H, 3′-H_a, 4′-H_a, 5′-H, and OH); 1.65–1.75 (m, 1H, 3′-H_b); 1.75–1.90 (m, 1H, 4′-H_b); 3.45–3.55 (m, 1H, 6′-H_a); 3.65 (t, 2H, *J*= 6.35 Hz, 1-H); 3.70–3.80 (m, 1H, 5-H); 3.80–3.95 (m, 1H, 6′-H_b); 4.55–4.77 (m, 1H, 2′-H)

^{13}C-NMR (100.6 MHz, $CDCl_3$) δ [ppm] = 20.10 (t, 4′-C); 21.97 (q, 6-C); 25.88 (t, 3-C); 25.91 (t, 5′-C); 31.16 (t, 2-C); 31.61 (t, 3′-C); 39.45 (t, 4-C); 62.78 (t, 6′-C); 67.90 (t, 1-C); 68.39 (d, 5-C); 99.32 (d, 2′-C)

MS (70 eV) m/z [%] = 101 (45); 86 (5); 85 (100); 84 (10); 83 (51); 67 (14); 57 (12); 56 (15); 55 (39); 45 (7); 43 (16); 42 (9); 41 (28); 39 (9)

*(5S)-5-(2-Tetrahydropyranyloxy)hexyl bromide (***VIII***)* A solution of 7.29 g (27.8 mmol) of triphenyl phosphane and 1.89 g (27.8 mmol) imidazole, in a mixture of 120 ml abs. diethyl ether and 40 ml abs. acetonitrile, was cooled to 0°C. Subsequently, 4.44 g (27.78 mmol) bromine were added slowly until a yellowish suspension was formed, and stirring was continued at 20°C for 2 h. After the addition of 5.11 g (25.3 mmol) (5*S*)-5-(2-tetrahydropyranyloxy)hexan-1-ol, dissolved in 15 ml abs. diethyl ether, the mixture was stirred for another 1 h. Workup started with the addition of 150 ml water, separation of the organic layer, and extraction of the aqueous layer (6×120 ml diethyl ether). The combined organic extracts were washed with brine and dried over magnesium sulfate. After removal of the solvent *in vacuo*, the crude product was purified upon column chromatography over silica (hexane–ethyl acetate 96:4). As a result, 5.07 g (19.1 mmol, 75%) of the target bromide **VIII** were obtained as a colorless oil.

^{1}H-NMR (400 MHz, $CDCl_3$) δ [ppm] = 1.23 (d, 3H, *J*= 6.1 Hz, 1′-H); 1.40–1.60 (m, 8H, 3-H_a, 4-H_a, 5-H, 3′-H, and 4′-H); 1.65–1.75 (m, 1H, 3-H_b); 1.78–1.95 (m, 3H, 4-H_b, and 5′-H); 3.42 (t, 2H, *J*=6.87, 6′-H); 3.45–3.54 (m, 1H, 6-H_a); 3.70–3.85 (m, 1H, 2′-H); 3.85–3.95 (m, 1H, 6-H_b); 4.58–4.72 (m, 1H, 2-H)

^{13}C-NMR (100.6 MHz, $CDCl_3$) δ [ppm] = 20.25 (t, 4-C); 21.98 (q, 1′-C); 24.83 (t, 4′-C); 25.94 (t, 5-C); 31.60 (t. 5′-C); 31.64 (t, 3-C); 34.18 (t, 6′-C); 36.01 (t, 3′-C); 63.04 (t, 6-C); 71.23 (d, 2′-C); 99.20 (d, 2-C)

MS (70 eV) m/z [%] = 165 (12); 163 (12); 129 (8); 101 (20); 86 (6); 85 (100); 84 (5); 83 (33); 67 (8); 57 (11); 56 (31); 55 (30); 45 (6); 43 (14); 41 (23); 39 (6)

2S-8E-10E-13:OAc Starting from a mixture of 440 mg (18.1 mmol) freshly crushed magnesium turnings and 40 ml abs. tetrahydrofuran, a Grignard reagent was prepared at 60°C using 2.93 (14.8 mmol) of the bromide **VIII**, dissolved in 10 ml abs. tetrahydrofuran. At −20°C, this solution was added dropwise to a cold solution of 1.52 g (9.87 mmol) (2*E*,4*E*)-2,4-heptadienyl acetate and 3.95 ml (396 mmol) of a 1-M solution of lithium tetrachlorocuprate in tetrahydrofuran. After the addition was complete, stirring

was continued for 5 h at 0°C. Workup started with the addition of 100 ml diethyl ether and 60 ml of a saturated aqueous solution of ammonium chloride, separation of the organic layer, and extraction of the organic layer (5×40 ml diethyl ether). The combined organic solutions were washed with brine and dried over magnesium sulfate. The crude product was purified by silica–10% silver nitrate column chromatography (Ikan 1982) and hexane–ethyl acetate 98:2 as the eluent. A final distillation at 10 Torr per 117°C yielded 1.40 g (4.99 mmol, 51%) of the protected dienol **IX**.

^{1}H-NMR (400 MHz, $CDCl_3$) δ [ppm] = 1.00 (t, 3H, *J*=7.27 Hz, 13′-H); 1.20 (d, 3H, *J*=6.27 Hz, 1′-H); 1.25–1.45 (m, 6H, 4′-H to 6′-H); 1–45–1.65 (m, 6H, 3-H_a, 4-H_a, 5-H, and 3′-H); 1.65–1.75 (m, 1H, 3-H_b); 1.75–1.90 (m, 1H, 4-H_b); 2.00–2.13 (m, 4H, 7′-H, and 12′-H); 3.45–3.52 (m, 1H, 6-H_a); 3.65–3.81 (m, 1H, 2′-H); 3.85–3.95 (m, 1H, 6-H_b); 4.60–4.75 (m, 1H, 2-H); 5.50–5.70 (m, 2H, 8′-H, and 11′-H); 5.95–6.0 (m, 1H, 9′-H); 6.0–6.05 (m, 1H, 10′-H)

^{13}C-NMR (100.6 MHz, $CDCl_3$) δ [ppm] = 14.03 (q, 13′-C); 20.15 (t, 4-C); 21.96 (q, 1′-C); 25.71 (t, 12′-C); 25.97 (t, 5-C); 26.11 (t, 6′-C); 29.67 (t, 4′-C); 29.78 (t, 5′-C); 31.65 (t, 3-C); 32.94 (t, 7′-C); 36.85 (t, 3′-C); 62.82 (t, 6-C); 71.51 (d, 2′-C); 99.01 (d, 2-C); 129.80 (d, 9′-C); 130.80 (d, 10′-C); 132.79 (d, 8′-C); 134.31 (d, 11′-C)

MS (70 eV) m/z [%] = 109 (13); 101 (5); 97 (5); 96 (13); 95 (32); 93 (7); 86 (8); 85 (100); 83 (5); 82 (8); 81 (11); 79 (13); 69 (7); 67 (30); 57 (9); 56 (7); 55 (16); 43 (10); 41 (19)

Deprotection was carried out by stirring a solution of 1.40 g (4.99 mmol) of **IX** and 290 mg (1.56 mol) *p*-toluene sulfonic acid monohydrate in 100 ml methanol for 30 min at 50°C. Subsequently, 835 mg (10.0 mmol) of sodium bicarbonate were added. The solvent was removed *in vacuo*, and the residue was dissolved in 100 ml diethyl ether. The organic solution was dried over magnesium sulfate and concentrated *in vacuo*. Silica column chromatography (hexane–ethyl acetate 4:1) yielded 900 mg (4.59 mmol, 92%) of (2*S*,8*E*,10*E*)-8,10-tridecadien-2-ol as a colorless oil.

^{1}H-NMR (400 MHz, $CDCl_3$) δ [ppm] = 1.00 (t, 3H, *J*=7.52 Hz, 13-H); 1.18 (d, 3H, *J*=6.02 Hz, 1-H); 1.29–1.50 (m, 9H, 3-H to 6-H and OH); 2.02–2.14 (m, 4H, 7-H, and 12-H); 3.74–3.84 (m, 1H, 2-H); 5.50–5.68 (m, 2H, 8-H, and 11-H); 5.95–6.0 (m, 1H, 9-H); 6.0–6.05 (m, 1H, 10-H)

^{13}C-NMR (100.6 MHz, $CDCl_3$) δ [ppm] = 14.02 (q, 13-C); 23.90 (q, 1-C); 25.55/26.01/29.55/29.76/32.89 (t, 4-C to 7-C and 12-C); 39.69 (t, 3-C); 68.53 (d, 2-C); 129.76 (d, 9-C); 130.84 (d, 10-C); 132.63 (d, 8-C); 134.35 (d, 11-C)

MS (70 eV) m/z [%] = 149 (5); 135 (5); 125 (8); 121 (8); 110 (6); 109 (8); 108 (11); 107 (16); 97 (11); 96 (49); 95 (52); 94 (11); 93 (37); 91 (13); 83 (11); 82 (49); 81 (56); 80 (22); 79 (77); 78 (8); 77 (17); 71 (14); 69 (10); 68 (16); 67 (100); 66 (10); 65 (7); 57 (5); 55 (37); 54 (10); 53 (11); 45 (36); 43 (21); 41 (35); 39 (12)

A solution of 900 mg (4.59 mmol) of (2*S*,8*E*,10*E*)-8,10-tridecadien-2-ol and 10 mg *N*,*N*-dimethyl-4-aminopyridine in 10 ml abs. pyridine was cooled to 0°C. Subsequently, 1.29 g (12.8 mmol) acetic anhydride, dissolved in 10 ml tetrahydrofuran, were added dropwise. After warming to room temperature, the mixture was stirred for 2 h. Workup started with the addition of 80 ml diethyl ether and 150 ml of an ice-cold saturated aqueous solution of sodium bicarbonate, separation of the layers, and extraction of the aqueous layer (5×50 ml diethyl ether). The combined organic solutions were washed with 50 ml of an aqueous saturated solution of copper-II-sulfate and 50 ml brine and dried over magnesium sulfate. After removal of the solvent *in vacuo*, the crude product was chromatographed on silica (hexane–ethyl acetate 97:3), yielding 960 mg (4.03 mmol, 88%) of 2*S*-8*E*-10*E*-13:OAc.

^{1}H-NMR (400 MHz, $CDCl_3$) δ [ppm] = 0.99 (t, 3H, *J*=7.38 Hz, 13-H); 1.20 (d, 3H, *J*=6.36 Hz, 1-H); 1.25–1.40 (m, 6H, 4-H to 6-H); 1.43–1.51 (m, 1H, 3-H_a); 1.52–1.62 (m, 1H, 3-H_b); 2.02 (s, 3H, $COCH_3$); 2.02–2.12 (m, 4H, 7-H, and 12-H); 4.84–4.93 (m, 1H, 2-H); 5.50–5.68 (m, 2H, 8-H, and 11-H); 5.95–5.99 (m, 1H, 9-H); 6.00–6.04 (m, 1H, 10-H)

^{13}C-NMR (100.6 MHz, $CDCl_3$) δ [ppm] = 14.01 (q, 13-C); 20.33 (q, 1-C); 21.75 (q, CO**C**H_3); 25.64/25.95/29.36/29.67/32.84 (t, 4-C to 7-C and 12-C); 36.25 (t, 3-C); 71.40 (d, 2-C); 129.75 (d, 9-C); 130.87 (d, 10-C); 132.53 (d, 8-C); 134.35 (d, 11-C); 171.14 (s, *C*O)

MS (70 eV) m/z [%] = 178 (8); 149 (8); 135 (6); 121 (8); 110 (14); 109 (9); 108 (14); 107 (15); 97 (6); 96 (43); 95 (44); 94 (16); 93 (33); 91 (11); 87 (7); 83 (6); 82 (33); 81 (41); 80 (19); 79 (66), 78 (7); 77 (15); 69 (6); 68 (12); 67 (74); 66 (9), 65 (7); 55 (32); 54 (7); 53 (11), 43 (100); 42 (6); 41 (37); 39 (13). Y-tube Bioassay The attractiveness of various synthetic pheromone blends and female gland extract were studied in a glass Y-tube olfactometer (modified from Jönsson et al. 2005). The arms of the Y-tube were 14 cm long, with the stem and inner diameter 12.5 and 2.2 cm, respectively. Charcoal-filtered and humidified air was pumped (Micro pump NMP 30 KNDC, 12 V, KNF Neuberger, Germany)

through Teflon tubes and entered each arm via a 9.5-cm-long glass tube. Experiments were conducted between 09:30 and 11:30 at 25°C and 70% RH. The airflow through each arm of the Y-tube was 500 ml/min (approximately 2 cm/s; BA-4AR, Kytölä, Muurame, Finland). For testing chemical stimuli, the stimulus (in hexane) was applied to a piece of filter paper (1.5×0.5 cm) attached to a steel wire (approximately 1.5 cm long); the solvent was allowed to evaporate, and the filter paper was positioned at the tube center. In bioassays in which virgin calling females were used as a stimulus, females were held in small glass tubes (5 cm long, 2.1 cm o.d.; both ends closed by a fine mesh) and placed inside the distal part of one of the Y-tube arms. During tests, a single male was taken from a rearing cage and placed into a glass tube (5 cm long, 2.1 cm o.d.; a fine mesh on the distal end) that was then immediately placed 5 cm into the stem of the Y-tube. Each male was given 5 min to respond. A male was regarded as a responder if it progressed 7 cm up one of the arms of the Y-tube within 5 min. If a male moved 7 cm up one side arm but then moved downwind and then upwind into the other arm, the first arm was regarded as its choice. Males that did not move into one of the two arms were not included in statistical analyses.

Binary-choice bioassays were performed to evaluate differences in attractiveness of the main pheromone component, 2*S*-10*E*-13:OAc (abbreviated 1), a three-component blend (blend abbreviated 3), consisting of 2*S*-10*E*-13:OAc, 2*S*-10*E*-13:OH, and 2*S*-13:OAc, two different four-component blends, consisting of the compounds in blend 3 and with either 2*S*-8*Z*-10*E*-13:OAc (blend abbreviated 4Z) or 2*S*-8*E*-10*E*-13:OAc (blend abbreviated 4E) added, and two five-component blends, both consisting of all compounds included in the other blends but with 2*S*-8*E*-10*E*-13:OAc in different amounts (low amount of 2*S*-8*E*-10*E*-13:OAc abbreviated 5L, high amount 5H). Synthetic pheromone blends were applied in ratios of 10 ng of the main component, 2*S*-10*E*-13:OAc, and 1 ng of the other components in all blends except for 5L in which 0.1 ng of 2*S*-8*E*-10*E*-13:OAc was used. Synthetic blends were compared with a female pheromone gland extract of comparable concentration (with respect to the main component) as well as to five calling females. A blank–blank (hexane only) treatment was also bioassayed to check for non-odor-mediated directional preferences. A maximum of six consecutive males (or 10-min time limit) was tested before filter papers were changed. Potential non-odor-mediated preferences were eliminated by switching sides of the two stimuli during a bioassay. All glass equipment were cleaned by heating at 320°C for 8 h before tests.

Small-Plot Test A small-plot test was done on a fly-free lawn (grass being 6–10 cm high) in Fargo, ND, USA, using delta traps with sticky inserts (PheroNet, Alnarp, Sweden). Seven blocks were run on separate days (September 6–10 and 12–13, 2006), and each block contained six treatments with randomized positions. The three-component blend (2*S*-10*E*-13:OAc, 2*S*-10*E*-13:OH, and 2*S*-13:OAc) and the five-component blend (2*S*-10*E*-13:OAc, 2*S*-10*E*-13:OH, 2*S*-13:OAc, 2*S*-8*E*-10*E*-13:OAc, and 2*S*-8*Z*-10*E*-13:OAc) were tested on two dispenser materials, polyethylene (PE; PE stoppers, 10 mm i.d., Semadeni, Ostermundigen, Switzerland) and cotton (Dental Rolls No. 3 (cut in half), IVF Hartmann AG, Neuhausen, Switzerland). Compounds were applied to the dispensers in a hexane solution. The ratio between 2*S*-10*E*-13:OAc and the other components was 100:10 µg (see also Fig. 6). Empty cotton and PE dispensers were used as controls. Lures and traps were used only once. Newly emerged adult males were collected between 16:00 and 21:00 the night before the test and placed in cylindrical plastic cages (10-cm diameter, 20 cm high, and with a ceiling of cotton netting material) placed over a pot that contained moist potting soil (for further details, see Harris and Foster 1991). At each time of collection, males were evenly distributed between four to five cages. Traps were placed directly on the grass in a line running south to north at 07:00. Since males were released from point sources (cages), we reduced the likelihood of potential position effects by maintaining a small distance (i.e., 30 cm) between traps. At 07:15, cages were taken outside and placed 60 cm apart in a line parallel to the traps. Cages were placed 3 m east (the prevailing wind was from the west) of the trap line with the opening facing the traps. Males were released when all cages were in position. The following numbers of males were released on the 7 days when tests were run: 30, 50, 30, 30, 70, 45, and 30, respectively. Each day, traps were collected at 18:00, and the number of males in each trap was counted. Temperatures ranged from 7°C when males were released to 23°C when traps were collected. Because temperatures were low and the air humid, males that were not attracted to traps probably survived for more than 1 day. Thus, males caught in a trap could have been from previous days' releases.

Field Test A field test was performed in fields of wheat stubble (10–25 cm high) outside Wichita, KS, USA, 15–26 September 2006. A total of 190 delta traps with sticky inserts (same type as in small-plot test) were used, divided into ten blocks with 19 treatments. Traps within a block were placed 5 m apart, and blocks were separated by 10 m. The traps were placed <1 cm above ground level. Three synthetic pheromone treatments were tested: the main component (2*S*-10*E*-13:OAc), the three-component blend (2*S*-10*E*-13:OAc, 2*S*-10*E*-13:OH, and 2*S*-13:OAc), and the five-component blend (2*S*-10*E*-13:OAc, 2*S*-10*E*-13:OH, 2*S*-13:OAc, 2*S*-8*E*-10*E*-13:OAc, and 2*S*-8*Z*-10*E*-13:OAc).

The ratio between the main component and each of the other components was 10:1. Three different doses of each blend were tested, 1, 10, and 100 μg, based on the main component (see also Fig. 7). All blends were tested on PE and cotton dispensers (same types as in small-plot test; dispenser preparation is also the same). A blank unbaited trap was included as negative control. Treatments were placed randomly within blocks and positions were maintained throughout the experiment. Trap catches were checked daily and sticky inserts changed.

Statistics Y-tube bioassay data were analyzed by *chi-square* tests. The data from the small-plot test and field test did not fulfill the requirements for parametric testing due to unequal variances (*Levene's* test, $P<0.001$); catch proportions within blocks were, thus, analyzed by the *Kruskal–Wallis* test. *Mann–Whitney U* tests were used in pairwise comparisons. The *Bonferroni* method was used to calculate experiment-wise error rate with differences at $P<0.005$ for the small-plot test and $P<0.001$ for the field test, being regarded as significant.

Results

GC–EAD recordings of female extracts showed that male antennae responded to seven components. Comparison of mass spectra and retention times of synthetic compounds with corresponding data of the natural products allowed structure elucidation of six volatile substances. The fact that the two laboratories involved in the investigation used GC columns with slightly different selectivity did not present problems. The known pheromone component 2*S*-10*E*-13:OAc served as an orientation marker and, supported by GC–MS analyses, facilitated structural assignments since the target compounds belonged to the same chemical classes. Structure assignments based on GC–MS analyses in Hamburg were scrutinized and verified by GC–EAD in Alnarp. Compound 2 proved to be 2*S*-13:OAc, compound 3, 2*S*-10*Z*-13:OAc, compound 4, 2*S*-10*E*-13:OAc, and compound 5, 2*S*-10*E*-13:OH (Fig. 1). All four compounds had been identified previously (Foster et al. 1991b; Millar et al. 1991). Compounds 1 and 7 were present in insufficient quantities for MS analysis. In contrast, the mass spectrum of compound 6 (Fig. 2a) had a molecular ion at *m*/*z* 238 and signals at *m*/*z* 178 (M^+-60, i.e., loss of acetic acid) and *m*/*z* 61 (protonated acetic acid), as well as intense signals at *m*/*z* 43 (acetyl fragment), *m*/*z* 79, and *m*/*z* 67 (indicating an unsaturated system). These data suggested that the compound was an acetic acid ester of a doubly unsaturated alcohol with 13 carbon atoms. The diagnostic fragment at *m*/*z* 87 revealed the acetate moiety to keep position 2 along the chain (α-cleavage). The relatively large abundance of the molecular ion (approximately 5–6%) suggested a conjugated double-bond system (Löfstedt and Odham 1984). As the main pheromone component, compound 4 has a double bond in position 10, we assumed that compound 6 was a 2-acetoxytridecadiene with double bonds in positions 8,10 or 10,12. Because of the relatively small difference in retention times between the diene 6 and the monoene 4, the 8,10 system seemed a more likely candidate compared to the terminally unsaturated 10,12 system, which, due to its higher polarity, would be expected to have a much longer retention time. This was supported by the presence of a pronounced signal at *m*/*z* 149, indicating a terminal ethyl group (M+-acetic acid-ethyl). In addition, compound 6 was hypothesized to keep (2*S*)-configuration, as other compounds identified in the Hessian

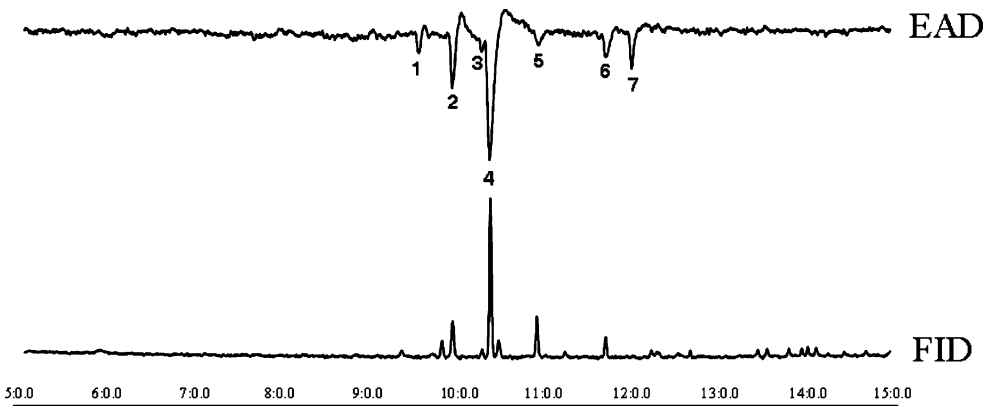

Fig. 1 Coupled flame ionization (*FID*) and electroantennographic detection (*EAD*) of female Hessian fly extract (20 female equivalents). Male antennal responses were recorded to seven compounds: *1* unknown, *2* (2*S*)-tridec-2-yl acetate [2*S*-13:OAc], *3* (2*S*,10*Z*)-10-tridecen-2-yl acetate [2*S*-10*Z*-13:OAc], *4* (2*S*,10*E*)-10-tridecen-2-yl acetate [2*S*-10*E*-13:OAc], *5* (2*S*,10*E*)-10-tridecen-2-ol [2*S*-10*E*-13:OH], *6* (2*S*,8*Z*,10*E*)-8,10-tridecadien-2-yl acetate [2*S*-8*Z*-10*E*-13:OAc], and *7* (2*S*,8*E*,10*E*)-8,10-tridecadien-2-yl acetate [2*S*-8*E*-10*E*-13:OAc]

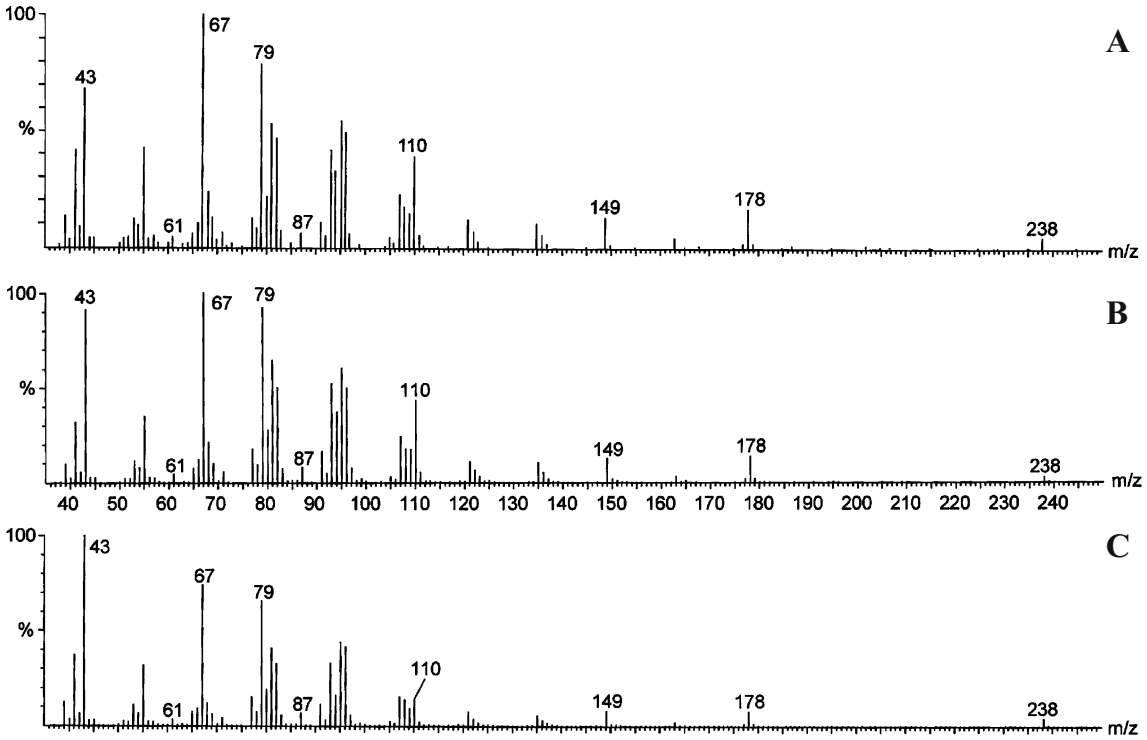

Fig. 2 The 70-eV mass spectra of **a** compound 6 present in Hessian fly females, **b** synthetic (8*Z*,10*E*)-8,10-tridecadien-2-yl acetate, and **c** synthetic (8*E*,10*E*)-8,10-tridecadien-2-yl acetate

fly pheromone gland (Foster et al. 1991b; Millar et al. 1991). Consequently, (2*S*,8*Z*,10*E*)-8,10-tridecadien-2-yl acetate [2*S*-8*Z*-10*E*-13:OAc] and its (8*E*,10*E*)-isomer [2*S*-8*E*-10*E*-13:OAc] were synthesized for comparison.

The preparative routes to the synthetic products are summarized in Figs. 3 and 4. The compounds were obtained in overall yields of approximately 10%. With respect to the conjugated double-bond system, the stereochemical purity of 2*S*-8*Z*-10*E*-13:OAc was 96%, containing approximately 4% of the (*E*,*E*)-isomer while that of 2*S*-8*E*-10*E*-13:OAc was 98% and contained approximately 2% of its stereoisomers. Enantioselective gas chromatography proved 2*S*-8*Z*-10*E*-13:OAc to show an excess of the (*S*)-enantiomer over the (*R*)-enantiomer of at least 98%, while 2*S*-8*E*-10*E*-13:OAc showed an enantiomeric excess of 96%.

The mass spectra of the two synthetic compounds were very similar. However, a significant difference in the intensity of the signal at *m*/*z* 110 was found. The mass spectrum and retention time of synthetic 2*S*-8*Z*-10*E*-13:OAc matched perfectly the corresponding data of the natural compound 6. In addition, the synthetic compound elicited behavioral (see below) and electrophysiological activities. A small impurity in the synthetic sample of 2*S*-8*Z*-10*E*-13:OAc (regarded as the 8*E*,10*E*-isomer, an expected by-product of the Wittig reaction) matched the retention time of compound 7. Because the concentration of this compound was very low, a mass spectrum of the natural product could not be obtained. However, by using an Innowax column, the GC retention time of synthetic 2*S*-8*E*-10*E*-13:OAc corresponded precisely to the retention

time of the compound that elicited antennal response number 7 (Fig. 1). As GC–EAD recordings were not carried out on an enantioselective GC column, the enantiomeric composition of the tentatively identified tridecadien-2-yl acetate remains unknown. However, the synthetic (*S*)-enantiomer elicited behavioral responses from males (see below) as well as electrophysiological activity. We, therefore, postulate 2*S*-*E*8-*E*10-13:OAc to be the natural substance causing response 7 in Fig. 1.

Y-tube Bioassay The proportion of males responding was high in all bioassays (86–100%), except in the blank–blank treatment (53%). The blank–blank bioassay demonstrated that males did not have non-odor-mediated directional preferences; ten of the responding males chose the right arm and 11 chose the left arm (χ^2=0.048, P>0.05). When a blank was tested against the main pheromone compound 2*S*-10*E*-13:OAc (attractant 1), males were more attracted to the latter component (χ^2=33.92, P<0.001; Fig. 5). However, when 2*S*-13:OAc and 2*S*-10*E*-13:OH were added to the main component, males were more attracted to the three-component blend (attractant 3) than to the main component alone (1; χ^2=10.29, P<0.01). A tendency for increasing numbers of males responding to the blend was observed when either 2*S*-8*E*-10*E*-13:OAc or 2*S*-8*Z*-10*E*-13:OAc was added to the three-component blend (attractants 4E and 4Z, respectively), but these blends did not attract significantly more males than blend 3 (3 vs. 4E: χ^2=1.72, P>0.05; 3 vs. 4Z: χ^2=1.53, P>0.05). There was also no difference between the responses to 3 and the five-component blend with the low amount (0.1 ng) of 2*S*-8*E*-10*E*-13:OAc (attractant 5L; χ^2=0.022, P>0.05). However, when 2*S*-8*E*-10*E*-13:OAc was present in the same amount (1 ng) as the other minor components (attractant 5H), the five-component blend attracted more males than the three-component blend (3; χ^2=8.40, P<0.01). 4Z and 5H were both compared with gland extract. The results from these comparisons showed that gland extract was more attractive than the four-component blend (4Z; χ^2=17.47, P<0.001) but that there was no difference between the gland extract and the five-component blend (5H; χ^2=1.28, P>0.05). The responses of males to 5H or five calling females (5FE) did not differ significantly either (χ^2=2.00, P>0.05).

Small-Plot Test During the 7 days of testing, a total of 285 males were released; 218 were caught in the traps. Traps containing the five-component blend caught more male Hessian flies than blank traps (Fig. 6; Z=−3.343, P<0.001 for both dispenser types) or the three-component blend (Z=−3.144, P<0.001 for both dispenser types). Traps baited with the three-component blend did not catch significantly more males than blank traps. The attractiveness of the five-component blend did not differ between dispenser types.

Field Test During the 9 days of field testing, a total of 963 male Hessian flies were caught. Of these, only eight individuals were caught in the cotton dispenser traps. Therefore, we excluded results from traps with this type of dispenser from further analysis. In traps with PE dispensers, a total of 848 males were caught at the largest dose (100 µg) of the five-component blend (blend 9, Fig. 7), while 93 males were caught in traps containing the same blend, but at the lower dose (10 µg, blend 8, Fig. 7). Mean trap catches of these treatments differed significantly from catches in the blank (Z=−3.963, P<0.001 for both doses) and from each other (Z=−3.780, P<0.001; Fig. 7). To ensure the specificity of this system, sticky inserts with trapped midges were characterized for species and sex; all midges caught were Hessian fly males (R. Gagné, personal communication). Reference males are stored in the North Dakota State University insect collection (reference number 6543, lot # 0610677).

Discussion

We have shown that a synthetic blend of five out of seven electrophysiologically active compounds found in Hessian fly female sex pheromone gland extract was highly attractive to laboratory-reared males and to males from natural populations. A sixth compound, the *Z*-isomer of the main pheromone component, 2*S*-10*E*-13:OAc, was not

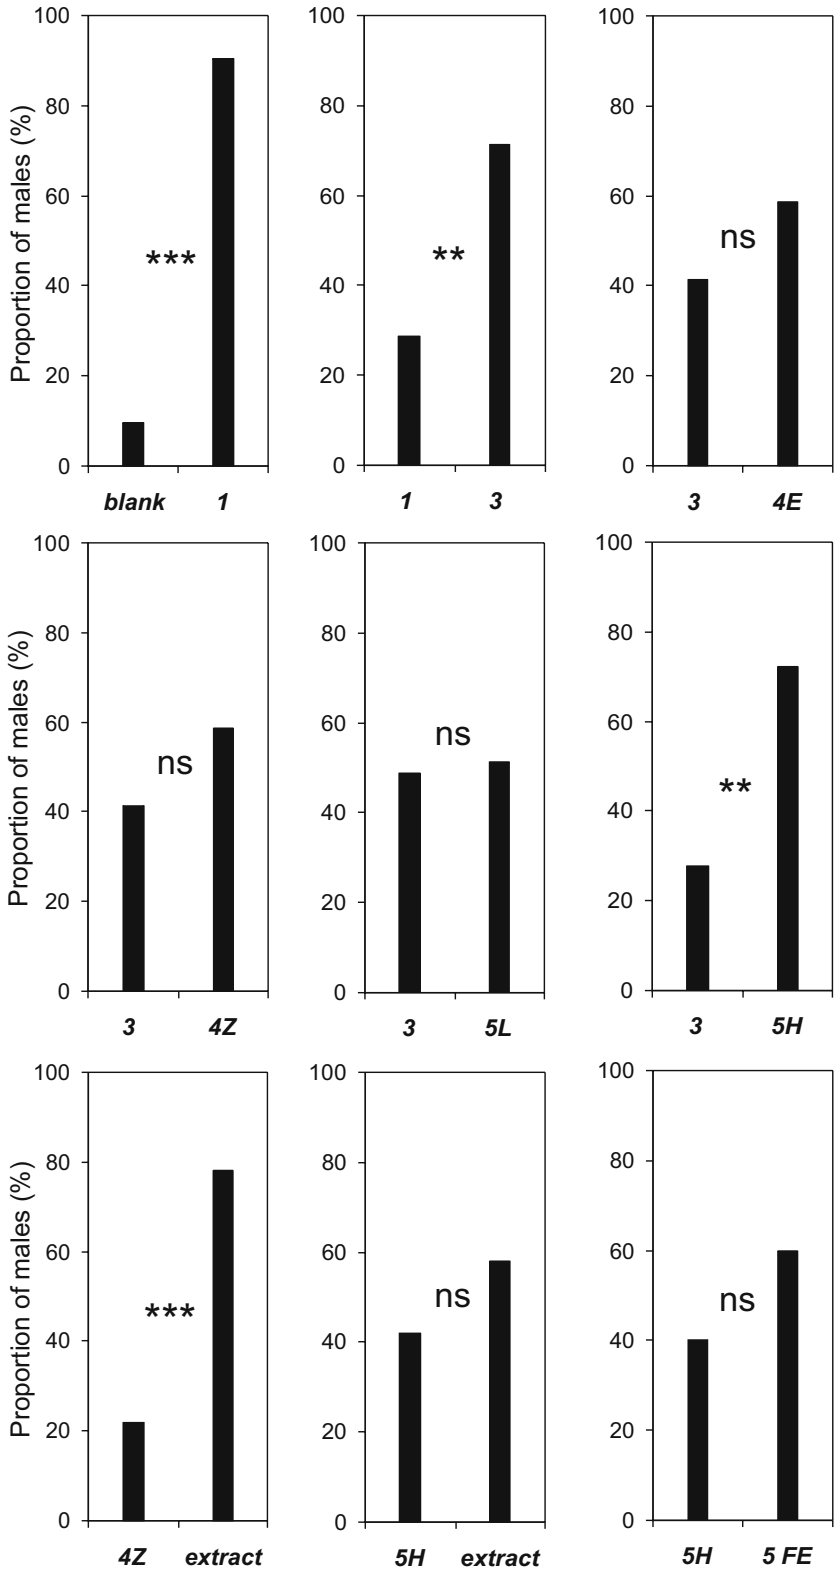

Fig. 5 Responses of male Hessian flies in binary-choice bioassays. Abbreviations: *1*: 2*S*-10*E*-13:OAc (10 ng), *3*: 2*S*-10*E*-13:OAc, 2*S*-13:OAc, and 2*S*-10*E*-13:OH (10:1:1 ng), *4E*: 2*S*-10*E*-13:OAc, 2*S*-13:OAc, 2*S*-10*E*-13:OH, and 2*S*-8*E*-10*E*-13:OAc (10:1:1:1 ng), *4Z*: 2*S*-10*E*-13:OAc, 2*S*-13:OAc, 2*S*-10*E*-13:OH, and 2*S*-8*Z*-10*E*-13:OAc (10:1:1:1 ng), *5L*: 2*S*-10*E*-13:OAc, 2*S*-13:OAc, 2*S*-10*E*-13:OH, 2*S*-8*Z*-10*E*-13:OAc, and 2*S*-8*E*-10*E*-13:OAc (10:1:1:1:0.1 ng), *5H*: as *5L* but (10:1:1:1:1 ng) and *5FE:* five calling females. *N*=40–60, * = $P<0.05$, ** = $P<0.01$, and *** = $P<0.001$

included in the blend as a separate synthetic chemical. However, due to the isomeric purity of the synthetic 2*S*-10*E*-13:OAc (98%), a small amount of the *Z*-isomer was present in the blend. A low ratio of the *Z*-isomer was also found in female extract (Millar et al. 1991). Since an earlier wind tunnel study had demonstrated that different *E*/*Z* ratios of the main component did not influence male attraction (Harris and Foster 1991), no other ratios were tested.

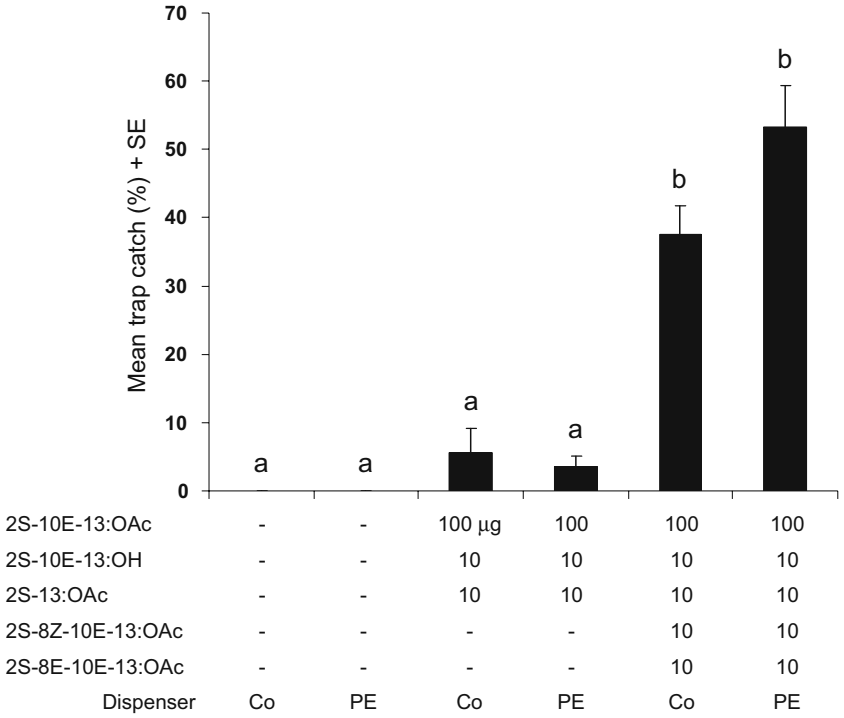

Fig. 6 Mean male Hessian fly trap catch (%)+SE in the small-plot test. *Numbers* represent microgram amounts per compound. *Bars* with different *letters* are significant at $P<0.001$. *Co* = cotton, *PE* = polyethylene

The five-component blend was as active as female extract in the Y-tube bioassays and sufficiently active for monitoring field populations of Hessian fly. Since the highest catch was in traps with the highest dose, we do not know whether we reached the optimal dose for attraction by this blend. However, in pheromone-based monitoring systems, it is desirable to reach sufficient attraction at low doses. For this reason, it would be of interest to identify the seventh EAD-active compound (response 1 in Fig. 1), as nothing is known regarding its capacity to mediate behavior. Studies of various moth species have shown that addition of minor components lowers the behavioral response threshold

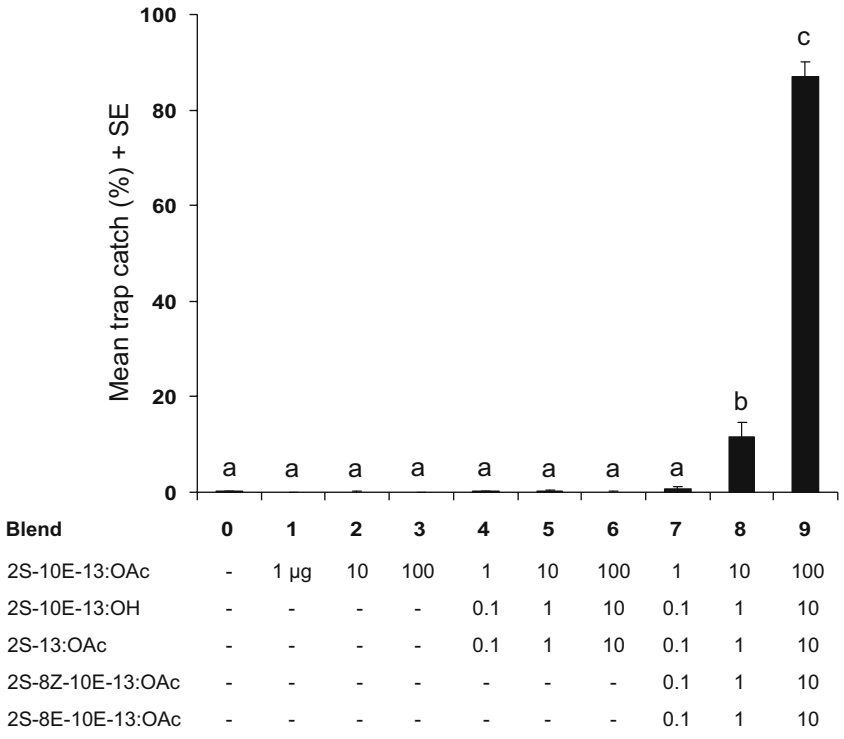

Fig. 7 Mean male Hessian fly trap catch (%)+SE in traps with polyethylene dispensers in the field test. *Numbers* represent microgram amounts per compound. Catch in blank traps is also shown. *Bars* with different *letters* are significant at $P<0.001$

to the pheromone blend (reviewed by Linn and Roelofs 1995), and it is possible that attractiveness to pheromone traps could be achieved at a lower dose, should this component be added. However, this minor compound is present in very low levels in gland extracts, as is the compound corresponding to response 7 (see Fig. 1) tentatively identified as 2*S*-8*E*-10*E*-13:OAc. Despite the minute amounts of 2*S*-8*E*-10*E*-13:OAc in the extract, the Y-tube experiment indicates that this compound must be present in higher amounts (the same amount as for the other minor compounds) in order to increase the attractiveness of the pheromone blend. The ratios of compounds found in the gland extract might thus not be reflective of the compound ratios released by calling females, suggesting that collection of volatiles released from females might allow the collection of greater quantities of this compound and facilitate structure confirmation. This may also apply to the unknown compound associated with response 1 (Fig. 1).

The structures of Hessian fly sex pheromone components are similar to other gall midge pheromones in that they are chiral compounds with odd-numbered carbon chains and a functional group at the C-2 position (Foster et al. 1991b; Harris and Foster 1991; Gries et al. 2000, 2002, 2005; Hillbur et al. 1999, 2000, 2001, 2005; Choi et al. 2004). In contrast, the attractive sex pheromone blends from other cecidomyiids are composed of either one (Gries et al. 2000, 2002; Choi et al. 2004) or three compounds (Hillbur et al. 1999, 2005; Gries et al. 2005), compared to the complex Hessian fly blend. In the laboratory, the main Hessian fly pheromone component attracted 56% of males when tested in a wind tunnel (Harris and Foster 1991). In our study, more than 90% of the responding males were attracted to this component when tested against a blank in the Y-tube. When tested against more complex blends, the main component alone was not attractive. The attractiveness of the main Hessian fly sex pheromone component probably is reflective of the different challenges faced by male flies when orienting to the pheromone in highly controlled laboratory conditions vs. variable field conditions. In the field, synthetic pheromone lures presumably compete with calling females. The presence of calling females around traps in the field might have contributed to the low attractiveness of the main component and the three-component blend. The only discrepancy between the trap catches in the small-plot test and in the field test was that cotton dispensers were as attractive as PE dispensers in the small-plot test. Chemicals are typically released from cotton dispensers at a faster rate than from polyethylene ones. In the small-plot test, we were able to change the dispensers daily but did not do so in the field trial. This may explain the differences between the two types of tests.

The sex pheromone blend that was identified in this study could be used as a tool for detecting the presence and abundance of Hessian flies in the field. The Hessian fly is a major pest of winter wheat. A common approach to reduce infestation levels in the field is to delay crop planting until Hessian fly activity has ceased in autumn (Buntin et al. 1990). Since flight activity is highly variable from year to year, a pheromone-based detection method could enable farmers to better judge when Hessian fly activity is over for the season. The traps that were used in the small-plot test and field assay were placed at (or almost at) ground level. The fact that male Hessian flies were caught at this height suggests that they fly close to the ground, at least for within-field dispersal. This has also been demonstrated for both the swede midge (Hillbur et al. 2005) and the pea midge (Wall et al. 1991).

An important characteristic of a pheromone-based monitoring system is that it is specific for the target species and does not catch insects that are morphologically similar. In our field trial, the only midges caught in traps baited with our synthetic pheromone blend were Hessian fly males. With this specificity and the highly synchronized emergence of Hessian fly adults (Harris and Foster 1999), it appears that the five-component blend may be a useful tool for monitoring and predicting Hessian fly outbreaks in crops.

Acknowledgements We thank Thiago Benatti and Rajat Aggarwal (Dept. Entomology, Purdue University, West Lafayette, IN, USA) for insect rearing. We also thank Elin Isberg for assistance in rearing and Y-tube bioassays. Many thanks also to Gary Cramer (Sedgwick County Extension, Wichita, KS, USA) for field assistance and Ray Gagné (Dept. Entomology, Smithsonian Institute, Washington, DC, USA) for the identification of insects. This study was partly funded by USDA-NRI, grant #2004-03099 (J. J. Stuart) and by the Royal Swedish Academy of Agriculture and Forestry, grant FS-234 (M. N. Andersson). W. Francke acknowledges the support of the Fonds der Chemischen Industrie.

Male-Produced Aggregation Pheromone of the Cerambycid Beetle *Rosalia funebris*

Ann M. Ray · Jocelyn G. Millar · J. Steven McElfresh · Ian P. Swift · James D. Barbour · Lawrence M. Hanks

Received: 22 October 2008 / Revised: 26 November 2008 / Accepted: 3 December 2008 / Published online: 13 January 2009

Abstract We report the identification, synthesis, and field bioassays of a volatile, male-produced aggregation pheromone of a long-horned beetle, the banded alder borer, *Rosalia funebris* Mots. Headspace collections from males contained a major male-specific compound, (*Z*)-3-decenyl (*E*)-2-hexenoate, and several minor components, identified as (*Z*)-3-decenol, (*Z*)-3-nonenyl (*E*)-2-hexenoate, and (*Z*)-3-decenyl (*E*)-3-hexenoate. The antennae of both males and females responded strongly to (*Z*)-3-decenyl (*E*)-2-hexenoate. We collected significant numbers of adult *R. funebris* in field bioassays using traps baited with this compound. This pheromone structure is unprecedented in the literature of cerambycid pheromones and distinct from the more common diol/hydroxyketone pheromone motif of many other species of the diverse subfamily Cerambycinae. This is the first pheromone identified for a species in the tribe Rosaliini.

Keywords Aggregation pheromone · Sex pheromone · (*Z*)-3-decenyl (*E*)-2-hexenoate · Cerambycidae · Banded alder borer · Long-horned beetle · Woodborer

Introduction

To date, male-produced sex or aggregation pheromones have been reported for 11 species in three tribes of the cerambycid subfamily Cerambycinae (reviewed by Ray et al. 2006; Hanks et al. 2007; Lacey et al. 2008b). Pheromones of most of these species are comprised of one to four compounds that are 6, 8, or 10 carbons in length and that share a common structural motif of hydroxyl or carbonyl groups at C_2 and C_3 (Hanks et al. 2007; Lacey et al. 2008b). Exceptions include *Phymatodes lecontei* Linsley, males of which appear to produce only (*R*)-2-methylbutan-1-ol (Hanks et al. 2007), and *Megacyllene caryae* (Gahan), in which males produce a pheromone blend comprised of 2,3-hexanediols, terpenoids, and an aromatic alcohol (Lacey et al. 2008b). Pheromones of male cerambycines of many species are emitted through male-specific gland pores in the prothorax (Ray et al. 2006; Hanks et al. 2007). In some cerambycine species, however, prothoracic gland pores are absent in both sexes, suggesting that adults either do not produce volatile pheromones or produce them from other sources (Ray et al. 2006).

Here, we report the identification, synthesis, and field bioassays of the male-produced aggregation pheromone of a cerambycine species, the banded alder borer *Rosalia funebris* Mots., that lacks male-specific prothoracic pores (Ray et al. 2006). This attractive black-and-white patterned species is endemic to western North America (Linsley 1964) and, in fact, was one of the first insects described from this region (Linsley 1995). Larvae of *R. funebris* develop in woody tissues of trees in the genera *Alnus*, *Fraxinus*, *Quercus*, *Salix*, and *Umbellularia* (Linsley 1964). Adults emerge from April to August (depending on latitude, elevation, and ambient temperature) and mate. Females oviposit on trees that have recently died (Linsley 1964, 1995). The adults are diurnal but rarely encountered in their natural habitat. Consequently, little is known of their biology and behavior (Essig 1943; Linsley 1964, 1995). Both sexes occasionally aggregate on hot days on buildings that have been recently painted, and these aggregations have been the subject of many reports in the popular press (Chemsak and Linsley 1971; Linsley 1995). In the work reported here, we provide evidence that (*Z*)-3-decenyl (*E*)-2-hexenoate is the major component of the male-produced aggregation pheromone of *R. funebris*.

Materials and Methods

Identification of Pheromone Components Adult *R. funebris* of both sexes (mating status unknown) were collected on 24–27 June 2007 from an aggregation on a building that was painted shortly prior to this period (Chipotle Mexican Grill, 3409 E. Foothill Blvd., Pasadena, CA, USA; 34°9′1″ N, 118°04′49″ W, 218 m elevation). Headspace volatiles were collected from six females and five males, held individually in either 3 cm diameter×20 cm long, glass aeration chambers or 263-ml glass canning jars with the screw-cap metal lids modified to accommodate air inlet and outlet tubes. Beetles in chambers were provided with water in 2-ml glass vials plugged with cotton wicks. Air entering the chambers was purified by passage through activated charcoal with the volatile chemicals trapped on a 5-mm plug of thermally desorbed activated charcoal (50–200 mesh) held in place by glass wool plugs in a section of 7-mm OD glass tubing attached to the chamber outlet. Air was pulled through the chambers at ~300 ml min^{-1} by vacuum. Aerations were conducted in an environmentally controlled room (25°C, 50% room temperature, 16:8 h ratio of light/dark, fluorescent lighting). Aerations were run for 2–7 days, before collectors were extracted with three 200-µl rinses of methylene chloride. The extracts were combined and analyzed as described below. In total, 24 and 33 beetle days of volatiles were collected from males and females, respectively.

Aliquots of crude extracts of volatiles collected from both sexes were analyzed by gas chromatography–electroantennogram detection (GC–EAD) with custom-built equipment as described in McElfresh and Millar (1999), using antennal sections from three male and three female *R. funebris* captured in 2007 (see above). Antennal preparations consisted of the terminal 1–2 cm of a beetle antenna, with the tip cut off with a razor blade, suspended between two saline-filled glass electrodes. Extracts were analyzed with Hewlett-Packard 5890A or 5890 series II GCs (Hewlett-Packard, Palo Alto, CA, USA) with helium carrier gas, splitless injection at 250°C, and a DB-5 column (30 m×0.25 mm ID, 0.25 µm film; J&W Scientific, Folsom, CA, USA) programmed from 40°C (held for 1 min) to 275°C at 10°C min^{-1}. We confirmed that synthetic (*Z*)-3-decenyl (*E*)-2-hexenoate elicited strong responses from antennae of beetles of both sexes by GC–EAD, using beetles collected during field bioassays in 2008 (see below).

Electron impact mass spectra (EIMS; 70 eV) were recorded with an HP 6890 gas chromatograph interfaced to an HP 5973 mass selective detector (GC–MS). An HP5-MS column (30 m×0.25 mm ID) was used in splitless mode with helium carrier gas, programmed from 40°C (held for 1 min) to 250°C at 10°C min^{-1}, with injector and transfer line temperatures at 275°C and 280°C, respectively. Compounds were identified by comparison of retention times and mass spectra with those of authentic standards. To further verify identifications, extracts and synthetic standards were analyzed on a polar DB-Wax column (30 m×0.25 mm ID×0.25 µm film, J&W Scientific) programmed from 50°C (held for 1 min) to 250°C at 10°C min^{-1}.

Microchemical Reactions on Aeration Extracts Reduction was carried out by adding approximately 1 mg of 5% Pd on carbon to a 1.5-ml vial containing 100 µl of a crude aeration extract from a male beetle. The vial was flushed with H_2 and sealed and held under H_2 atmosphere while stirring for 1 h. The mixture was then filtered through a plug of Celite® to remove the catalyst and analyzed by GC–MS.

Positions of double bonds were determined by epoxidation of an aliquot of the extract (Hogge and Millar 1987). Thus, an aliquot was treated with two drops of a CH_2Cl_2 solution of *m*-chloroperbenzoic acid (5 mg/ml), and the mixture held at room temperature for 1 h, swirling periodically. The mixture was diluted with 1 ml pentane and extracted twice with 0.5 M aqueous NaOH. The pentane layer was dried over Na_2SO_4, concentrated under a stream of N_2, and analyzed by GC–MS as described above. Samples of synthetic (*Z*)-3-decenol and (*Z*)-3-decenyl (*E*)-2-hexenoate were submitted to the same procedure to provide standards for comparison with aeration extracts.

Chemicals Decyl hexanoate and (*Z*)-4-decenol were available from our in-house library of insect semiochemicals. (*Z*)-3-Decenol and (*Z*)-3-decenyl (*E*)-2-hexenoate were synthesized as follows:

(Z)-3-Decenol This compound was prepared by P-2 nickel reduction of 3-decyn-1-ol (Brown and Ahuja 1973). Ni $(OAc)_2 \cdot 4H_2O$ (1.5 g, 6 mmol) was dissolved in 120 ml EtOH, and the solution degassed by bubbling N_2 for ~15 min. Then, still under N_2 atmosphere, 1 M $NaBH_4$ solution (6 ml of a solution prepared from 0.4 g $NaBH_4$, 9.5 ml EtOH, and 0.5 ml 1 M NaOH, filtered to remove suspended material) was added by syringe, with vigorous stirring. Ethylene diamine (2.4 ml) was added to the resulting black solution, the flask was fitted with a balloon filled with H_2, the N_2 line was removed, and the solution was stirred 15 min before adding 3-decyn-1-ol (10 g, 64 mmol, Alfa-Aesar, Ward Hill, MA, USA) dropwise over 10 min. The mixture was stirred until the starting material had been consumed completely (determined by GC, ~1.5 h). The flask then was flushed with N_2, and the mixture was filtered through a plug of Celite® (~2 cm) and activated charcoal (~1 cm top layer). The resulting violet colored solution was concentrated, taken up in ether, and extracted with 1 M HCl. The ether layer was washed with saturated aqueous $NaHCO_3$ and brine, concentrated, and Kugelrohr distilled (bp ~70°C, 0.2 mm Hg), giving a quantitative yield of the alcohol as a colorless oil EIMS (70 eV); *m/z* (percent abundance): 156 (1), 138 (12), 110 (20), 95 (59), 81 (81), 67 (100), 55 (75), and 41 (51); ^{1}H nuclear magnetic resonance (NMR; 400 MHz, $CDCl_3$): δ 5.55 (m, 1H, H-3), 5.34 (m, 1H, H-4), 3.62 (t, 2H, *J*= 7.4 Hz, H-1), 2.31 (br overlapped dt, 2H, H-2), 2.04 (br overlapped dt, 2H, H-5), 1.47 (br s, 1H, OH), 1.4–1.2 (m, 8H, H6–H9), and 0.86 (t, 3H, *J*=7.0 Hz, H-10); and ^{13}C NMR: δ 133.8, 125.1, 62.5, 31.9, 31.0, 29.9, 29.2, 27.6, 22.9, 14.3].

(Z)-3-Decenyl (E)-2-hexenoate A mixture of (*E*)-2-hexenoic acid (6.84 g, 60 mmol; Acros Organics, Morris Plains, NJ, USA), (*Z*)-3-decenol (6.2 g, 40 mmol), and *p*-toluenesulfonic acid (0.5 g) was refluxed overnight in 50 ml benzene, with a Dean-Stark trap to remove water. After cooling to room temperature, 100 ml of saturated aqueous $NaHCO_3$ were added, and the mixture was stirred 10 min. The layers were separated, and the organic layer was washed with aqueous $NaHCO_3$ and brine, dried over anhydrous Na_2SO_4, and concentrated. The residue was purified by Kugelrohr distillation (oven temperature ~105–120°C, 0.05 mm Hg), yielding 9.5 g of the ester as a colorless oil (94%, purity >96% by GC) EIMS (70 eV); *m/z* (percent abundance) 252 (trace), 138 (70), 115 (12), 110 (42), 97 (95), 81 (55), 68 (81), 55 (100), and 41 (45); ^{1}H NMR (400 MHz, $CDCl_3$) δ 6.94 (dt, 1H, *J*=15.6, 7 Hz, H-3′), 5.79 (d, 1H, *J*=15.6 Hz, H-2′), 5.48 (m, 1H, H-3), 5.35 (m, 1H, H-4), 4.11 (t, 2H, *J*= 6.6 Hz, H-1), 2.38 (br overlapped dt, 2H, *J*=~7, 7 Hz, H-2), 2.16 (overlapped dtd, 2H, *J*=~7, 7, 1.6 Hz, H-4′), 2.02 (br overlapped dt, 2H, *J*=~7 Hz, H-5), 1.47 (overlapped tq, 2H, H-5′), 1.4–1.2 (m, 8H, H6-H9), 0.92 (t, 3H, *J*=7.6 Hz, H6′), and 0.87 (t, 3H, *J*=6.8 Hz, H-10); and ^{13}C NMR δ 167.0, 149.5, 133.2, 124.6, 121.5, 63.9, 34.4, 32.0, 29.8, 29.2, 27.5, 27.1, 22.8, 21.5, 14.3, and 13.9].

Authentic samples of (*Z*)-3-nonenyl (*E*)-2-hexenoate and (*Z*)-3-decenyl (*E*)-3-hexenoate, for confirming the identities of the minor components, were synthesized by analogous esterification reactions between (*Z*)-3-nonenol (TCI America, Portland, OR, USA) and (*E*)-2-hexenoic acid and (*Z*)-3-decenol and (*E*)-3-hexenoic acid (Aldrich Chem. Co., Milwaukee, WI, USA).

Field Bioassays of Synthetic Compounds The responses of adult *R. funebris* to the major component of the male aeration, (*Z*)-3-decenyl (*E*)-2-hexenoate, were tested in field bioassays at Placerita Canyon Natural Area (Los Angeles Co., CA, USA). Black flight-intercept panel traps (1.2 high×0.3 m wide, model PT Intercept™, APTIV, Portland, OR) were used in the trials. Traps were modified by replacing the collection basin with a 1.9-l plastic funnel that was attached to a clear plastic jar (1.9 l, General Bottle Supply Company, Los Angeles, CA, USA), in order to capture beetles alive. The funnel spout was cut off to leave a 3.5-cm-diameter hole at the bottom, a ~10-cm hole was cut into the threaded lid of the jar, and the funnel spout was hot-melt glued to the lid so that the spout was inside the jar. Traps were hung from tree branches ~2 m above the ground. Lures consisted of clear low-density polyethylene press-seal bags (Bagette model 14770, 5.1×7.6 cm, 0.05 mm wall thickness, Cousin Corp., Largo, FL, USA). The plastic bags were sealed and suspended with wire in the central open area of traps.

A sentinel trap baited with 100 μl of neat (*Z*)-3-decenyl (*E*)-2-hexenoate was used to monitor adult *R. funebris* at the Placerita Canyon Natural Area. The trap was set up on 18 June 2008, based on a report of an adult *R. funebris* observed in the Natural Area on that date in 2007 (AMR, unpublished data). The field bioassay was started on the day that the first adult was captured, 22 June 2008, and continued daily through 3 July 2008 (clear skies, no precipitation, maximum air temperatures 28–42°C). Traps were hung from tree branches, with traps separated by ~10 m, in a northeasterly transect through a canyon containing mature California sycamore, *Platanus racemosa* Nutt., and coast live oak, *Quercus agrifolia* Neé (position of first trap: 34°22′ 39″ N, 118° 28′ 1″ W, 466 m elevation). Many trees in the area had been burned by recent wildfires. We tested the responses of beetles to two concentrations of

(*Z*)-3-decenyl (*E*)-2-hexenoate: neat material (100 μl) and a lower dose (10 μl of neat material in 90 μl absolute ethanol). The trap transect included one trap baited with the lower concentration and two traps baited with the neat material, all positioned to alternate with three control traps having lures that contained 100 μl of ethanol. The experiment was replicated over 12 days. Lures were replaced every 3 days, and treatments were rotated one position along the transect every 4 days to control for positional effects. Traps were checked for beetles daily at ~1100 and 1800 hours.

The sex of adult *R. funebris* captured was determined by using the sexually dimorphic characters of antennal length and form of the fifth abdominal sternite (Linsley 1964). Differences between numbers of females and males captured were tested with the χ^2 goodness-of-fit test (Sokal and Rohlf 1995). Differences between treatments in numbers of beetles captured (sexes combined) were tested with the nonparametric Friedman's test (blocking by replicate; PROC FREQ with CMH option; SAS Institute 2001) because assumptions of analysis of variance were violated by heteroscedasticity (Sokal and Rohlf 1995). Differences between pairs of means were tested with the Ryan–Einot–Gabriel–Welsch (REGWQ) means-separation test to control maximum experiment-wise error rates (SAS Institute 2001). Six dates on which fewer than three beetles in total were captured were excluded from the analysis.

We also tested for the presence of adult *R. funebris* in a variety of different habitats in southern California (Table 1) by setting up pairs of traps: one baited with 100 μl of the 10% solution of synthetic (*Z*)-3-decenyl (*E*)-2-hexenoate in a plastic bag lure and the other a control trap with a solvent lure. These bioassays were conducted for varying periods between 28 June and 18 August 2008. Traps were checked for beetles every 1–5 days, and lures were replaced before the liquid had completely evaporated. Voucher specimens of *R. funebris* were deposited at the Entomology Research Museum at the University of California, Riverside.

Results

Identification of Pheromone Components Coupled GC–EAD analyses of headspace volatiles collected from live adult males of *R. funebris* showed that antennae of both sexes responded strongly to the major component in extracts from males (peak 4, Fig. 1). Several minor components in extracts elicited weaker responses from antennae of males (peaks 1–3, Fig. 1). The compounds (peaks 1–4) were produced in a ratio of 10.2±9.1:0.3± 0.3:15.3±9.9:100, respectively (mean ± standard deviation of four extracts), and all of these compounds were present only in extracts from males. Three aeration extracts from female beetles also were analyzed by GC–EAD, using antennae from three different males. The antennae did not respond to any components in the extracts, indicating that females of this species do not produce volatile sex pheromones, at least under the aeration conditions used in these studies.

GC–MS analyses of extracts showed that peak 1 (Fig. 1; Kovats index [KI] 1256 on DB-5 column) gave a weak molecular ion at *m/z* 156 (trace), with the first significant ion occurring at *m/z* 138 (12%) from loss of water, and a base peak at *m/z* 68 (for full mass spectrum, see Supplementary data). From comparison with database spectra and the retention times and mass spectrum of a (*Z*)-4-decenol standard (KI 1259), it appeared likely that this compound was a straight-chain decenol, with (*Z*)-3-decenol being the best match to database spectra. The spectrum of one of the two other minor components (peak 3, Fig. 1; KI 1770) and the major component (peak 4, Fig. 1; KI 1823) were very similar to each other, suggesting that

Table 1 Additional study sites in southern California where field bioassays were conducted (one trap baited with dilute [*Z*]-3-decenyl [*E*]-2-hexenoate and one control trap) in 2008 and the number and sex of adult *R. funebris* captured in baited traps

No *R. funebris* were captured in control traps at any site

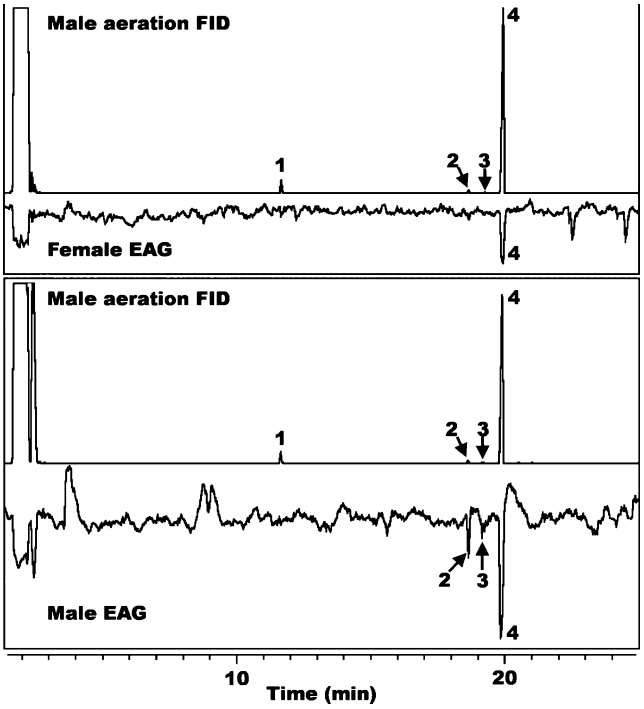

Fig. 1 Gas chromatogram (*top traces*) and corresponding electroantennogram (*EAG*) traces from antennae of female (*top*) and male (*bottom*) *Rosalia funebris*, in response to extract from a headspace collection of a male. A DB-5 column was used for coupled gas-chromatogram-EAD. A DB-5 column for the coupled gas chromatogram–EAG. *1* (*Z*)-3-decenol, *2* (*Z*)-3-nonenyl (*E*)-2-hexenoate, *3* (*Z*)-3-decenyl (*E*)-3-hexenoate, and *4* (*Z*)-3-decenyl (*E*)-2-hexenoate

they were isomers. The major, later-eluting isomer showed a weak molecular ion at *m/z* 252, with the first significant fragment at *m/z* 138 (74%), a strong peak at *m/z* 97 (95%), and a weaker fragment at *m/z* 115 (12%; for full mass spectrum, see Supplementary data). The latter two fragments would be expected from hexenoate esters so that, in total, these data suggested that the compound might be a decenyl hexenoate. Reduction of the crude extract with H_2 and a palladium-on-carbon catalyst gave a small, early-eluting peak (KI 1273) of which the mass spectrum and retention time matched those of decanol. The reduction collapsed peaks 3 and 4 into one peak (KI 1785) with the mass spectrum and retention time matching those of decyl hexanoate. These data provided support for the tentative identifications of peak 1 as a decenol and peaks 3 and 4 as decenyl hexenoate isomers. The fact that the retention time of the major component (peak 4) was significantly longer than that of decyl hexanoate on the nonpolar HP5-MS GC column suggested that the double bond in the hexenyl portion of the ester was conjugated with the carbonyl group.

The decenol component of the crude extract was confirmed as (*Z*)-3-decenol by epoxidation of crude extract. The retention times and mass spectra of both the underivatized (*Z*)-3-decenol and the epoxidized (*Z*)-3-decenol matched those of synthetic standards. Although we did not know which stereoisomer was correct a priori, these matches confirmed both the position and the geometry of the double bond (Hogge and Millar 1987). These data also suggested that the major component in the extract was a (*Z*)-3-decenyl 2-hexenoate, and the retention time and mass spectrum of a synthesized standard of (*Z*)-3-decenyl (*E*)-2-hexenoate matched those of the major component on both nonpolar DB-5 and polar DB-Wax columns. As with the determination of the double bond stereochemistry of (*Z*)-3-decenol described above, we did not know the stereochemistry of the conjugated acid portion of the ester a priori, but the retention time and mass spectral matches with the synthetic standard provided good evidence for (*E*)-2 stereochemistry. This stereochemistry was verified by epoxidation of the ester components in the insect extract. Although the epoxidation of the extract did not proceed cleanly, possibly due to acid-catalyzed rearrangements of the initial diepoxide products, epoxidation of pure synthetic (*Z*)-3-decenyl (*E*)-2-hexenoate resulted in a pattern of peaks that was qualitatively similar to those in the epoxidized insect extract, with matching retention times and mass spectra. Furthermore, antennae from beetles of both sexes responded strongly to synthetic (*Z*)-3-decenyl (*E*)-2-hexenoate in GC-EAD bioassays. Finally, the retention indices of (*Z*)-3-decenol and (*Z*)-3-decenyl (*E*)-2-hexenoate on a polar DB-Wax column (KI 1767 and 2168, respectively) exactly matched those of standards. In sum, these data confirmed that the major male-specific compound in the aeration extracts from male *R. funebris* was (*Z*)-3-decenyl (*E*)-2-hexenoate and that the early-eluting trace component (peak 1) was (*Z*)-3-decenol.

The ester isomer with the slightly lower KI value than the major component (KI value 1770; peak 3, Fig. 1) was tentatively identified as a deconjugated analog of the main compound (for full mass spectrum, see Supplementary data) because it was generated as an impurity during attempted esterification of (*E*)-2-hexenoic acid with (*Z*)-3-decenol using 4-(*N,N*)-dimethylaminopyridine and dicyclohexylcarbodiimide (Hasner and Alexanian 1978). This tentative identification was confirmed by synthesis of an authentic standard of (*Z*)-3-decenyl (*E*)-3-hexenoate, the retention time and mass spectrum of which matched those of the insect-produced compound. Fortuitously, the (*E*)-3-hexenoic acid starting material was contaminated with a small amount of the (*Z*)-isomer, the ester of which had a different retention time, so that the identification of the stereochemistry in the natural compound was unequivocal.

A partial mass spectrum was obtained for peak 2, and the fragments suggested that it was a homolog of the main component, with a nine-carbon alcohol component to the

ester. A molecular ion was not seen, but significant ions included *m/z* 124 (54), 115 (8), 97 (76), 82 (66), 68 (74), 55 (100), and 41 (53). The ions at *m/z* 97 and 115, corresponding to fragments from a hexenoate ester, indicated that it was the alcohol rather than the acid portion of the ester that was one carbon shorter than the equivalent portion in the major component, and the KI value of 1725, almost exactly 100 KI units less than that of the main component, provided further evidence that it was probably a homolog that was shorter by one carbon. The identification was confirmed by synthesis of an authentic standard (for full mass spectrum, see Supplementary data), with spectral and retention time data matching those of the insect-produced compound.

Field Bioassays of Synthetic Compounds The sentinel trap at Placerita Canyon Natural Area captured the first adult *R. funebris* on 22 June 2008. We subsequently captured 48 adults in the field bioassay (four males and 44 females; sex ratio significantly different from 1:1, $\chi^2=33.3$, $P<0.001$), with a maximum of 12 adults (including three of the four males) over a 24-h period in one trap baited with neat (*Z*)-3-decenyl (*E*)-2-hexenoate. The number of beetles trapped per day reached a peak of 18 after 1 week but fell to one and zero over the last 4 days. Treatment means were significantly different (Fig. 2; sexes combined, Friedman's $Q_{2,35}=18.2$, $P<0.001$). Traps baited with diluted and neat (*Z*)-3-decenyl (*E*)-2-hexenoate captured significantly more beetles than did controls (Fig. 2), but the pheromone treatment means were not significantly different from one another. All but two of the beetles were captured between 1100 and 1800 hour. Traps baited with synthetic pheromone did not capture any other insect species in consistent or significant numbers.

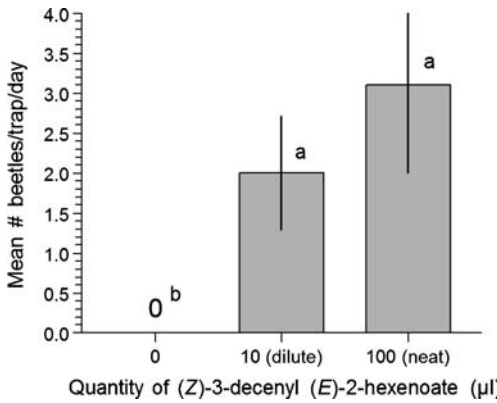

Fig. 2 Mean (± standard error) number of adult (sexes combined) *Rosalia funebris* captured from 22 June to 3 July 2008 at Placerita Canyon Natural Area in panel traps baited with 100 µl neat (*Z*)-3-decenyl (*E*)-2-hexenoate, 10 µl of (*Z*)-3-decenyl (*E*)-2-hexenoate in 90 µl of ethanol, or 100 µl of ethanol (solvent control). Bars with different letters are significantly different (REGWQ test $P<0.05$)

Traps baited with dilute (*Z*)-3-decenyl (*E*)-2-hexenoate captured a total of nine adult *R. funebris* (four males, five females) at additional study sites (Table 1), with no beetles being caught in control traps. Some of these sites yielded no beetles, even though baited traps were in place for several weeks (Table 1).

Discussion

Attraction of both sexes of *R. funebris* in field bioassays to lures baited with synthetic (*Z*)-3-decenyl (*E*)-2-hexenoate suggested that this compound is an aggregation rather than a sex pheromone, as appears to be true for pheromones produced by many other cerambycine species (Hanks et al. 2007; Lacey et al. 2008b). The strong female bias of adult *R. funebris* captured in the replicated field trial suggests that the sexes differ either in their sensitivity or their responses to the compound. However, it is impossible to draw conclusions about differential responses of the sexes to the pheromone based on these data without information about the sex ratio of the local population. Also, males that were captured alive in the traps may have emitted pheromone and so could have influenced subsequent trap catches of conspecifics. Nevertheless, most of the females were captured in traps that did not contain males, so their response to the pheromone treatment was unequivocal.

The small numbers of beetles captured at the additional sites suggest that our choice of study site for the field bioassays, Placerita Canyon Natural Area, was fortuitous and attest to the general rarity of *R. funebris*, as has been previously noted (Essig, 1943; Linsley 1964, 1995). It is possible that *R. funebris* was more abundant in that area because of recent wildfires. Studies on this species suggest that females oviposit in burned trees (IPS, personal observation). The brief period of time that adult *R. funebris* were captured in traps at Placerita Canyon Natural Area (~9 days) is consistent with other reports and observations that adults of this species are only active for a short period (Chemsak and Linsley 1971; IPS, personal observation).

That we captured 12 beetles in one trap in a single day indicates that (*Z*)-3-decenyl (*E*)-2-hexenoate is sufficient to attract *R. funebris* in significant numbers when adults are active. Nevertheless, it is possible that the minor components identified may form part of the natural pheromone and that traps baited with a more complete reconstruction of the blend could attract greater numbers of beetles. Unfortunately, the full identification and syntheses of the minor components was not completed in time for these chemicals to be included in the field trials.

The function of the aggregation pheromone of *R. funebris* is probably similar to that of other cerambycid species. Both sexes of many cerambycid species are attracted to volatile compounds emanating from patches of larval host plants (Hanks 1999; Ginzel and Hanks 2005). Once in a patch of host plants, volatile pheromones may further facilitate mate location by bringing males and females together on hosts (Ginzel and Hanks 2005). Nonvolatile contact chemical signals also play a role, once the sexes are in the same vicinity, in males identifying conspecific females (Ginzel and Hanks 2003, Ginzel et al. 2003a, b; Lacey et al. 2008a). Consistent with these behaviors for other cerambycid species, adult *R. funebris* of both sexes aggregate on larval hosts (Linsley 1995). Aggregation also may expedite host colonization, a distinct adaptive advantage, because the quality of larval hosts (dying trees) declines rapidly as hosts are colonized by other types of wood-boring insects and saprophytes (Hanks 1999).

The structure of the male-produced pheromone of *R. funebris* is unprecedented among the cerambycid pheromones that have been reported to date and unlike the diol/hydroxyketone motif of the volatile pheromones of most other cerambycine species (see "Introduction"). Although the diol/hydroxyketone pheromone motif is common, it is by no means universal among members of this large and diverse subfamily, as further indicated by the pheromones of *P. lecontei* and *M. caryae* (Hanks et al. 2007; Lacey et al. 2008b). The unique structure of the pheromone of *R. funebris* is consistent with this species being relatively distantly related to other cerambycines for which pheromones have been identified. *Rosalia funebris* is the sole representative of the tribe Rosaliini in the Western Hemisphere, whereas the other cerambycine species for which pheromones have been identified are in the tribes Anaglyptini, Callidiini, and Clytini (Ray et al. 2006; Hanks et al. 2007; taxonomy according to Monné and Hovore 2005). Furthermore, *R. funebris* lacks the distinctive prothoracic glands and gland pores that are the source of pheromones of other cerambycine species (Ray et al. 2006), and we do not yet know either the source or the mechanism of release of the *R. funebris* pheromone. The only other known pheromone glands of cerambycids that are not in the prothorax are those on the ovipositor of females of the more distantly related species *Prionus californicus* Mots. (Barbour et al. 2006; Cervantes et al. 2006).

To our knowledge, (*Z*)-3-decenyl (*E*)-2-hexenoate or any of the minor components of the volatiles produced by male *R. funebris* are NOT similar in structure to volatile compounds released by house paint. Therefore, it seems likely that the attraction of both sexes to newly painted structures, which has been observed and documented a number of times, may be due to some structural similarity among volatile compounds emanating from paint and compounds released by larval host plants, rather than similarity to the pheromone. It also seems unlikely that the observed attraction is due to color or other optical properties of the paint, which presumably persist over time, unlike the release of volatile chemicals from drying paint.

Acknowledgments We thank Dianne Erskine-Hellrigel, Agustin Hernandez, Chris Sapovchak, and Ian Wright for assistance with laboratory and field work and Michael Long and the Los Angeles County Department of Parks and Recreation for permission to conduct research in Placerita Canyon Natural Area. This project was supported by a Francis M. and Harlie M. Clark Research Support Grant (UIUC, to AMR), the Alphawood Foundation (to LMH), and the National Research Initiative of the USDA Cooperative State Research, Education and Extension Service, grant number #2006-35302-17457 (to JGM and LMH). This research was in partial fulfillment of a Ph.D. degree for AMR from UIUC.

Behavioral Evidence for a Contact Sex Pheromone Component of the Emerald Ash Borer, *Agrilus Planipennis* Fairmaire

Jonathan P. Lelito · Katalin Böröczky · Tappey H. Jones · Ivich Fraser · Victor C. Mastro · James H. Tumlinson · Thomas C. Baker

Received: 5 September 2008 / Revised: 17 December 2008 / Accepted: 18 December 2008 / Published online: 20 January 2009

Abstract The cuticular hydrocarbon profiles of emerald ash borers, *Agrilus planipennis*, were examined to determine if there are differences in these compounds between the sexes. We also assessed feral male EAB in the field for behavioral changes based on the application of a female-specific compound to dead, solvent-washed beetles. Males in the field spent significantly more time attempting copulation with dead, pinned female beetles coated with a three-beetle-equivalent dose of 3-methyltricosane than with solvent-washed beetles or those coated in 3-methyltricosane at lower concentrations. Males in the field spent the most time investigating pinned dead, unwashed female beetles. In the laboratory, sexually mature males were presented with one of several mixtures applied in hexane to filter paper disks or to the elytra of dead female beetles first washed in solvent. Male EAB also spent more time investigating dead beetles treated with solution applications that contained 3-methyltricosane than dead beetles and filter paper disks treated with male body wash or a straight-chain hydrocarbon not found on the cuticle of EAB.

Introduction

The emerald ash borer (EAB), *Agrilus planipennis* Fairmaire (Coleoptera: Buprestidae) is a growing threat to the ash (*Fraxinus* sp.) resource of North America (reviewed in Poland and McCullough 2006). The beetle is spreading rapidly, and efforts to detect new infestations are of paramount importance to slowing further spread. Thus far, no species-specific trap is available for wide deployment. The use of girdled "trap trees" has proven to be an effective but cost- and labor-intensive method of detecting new infestations (Cappaert et al. 2005). Progress toward development of a widely deployable trap has been made on the grounds of trap color (Francese et al. 2005), with purple traps being the most effective at capturing adult EAB. Induced volatiles from ash trees are antennally active in adult EAB (Rodriguez-Saona et al. 2007) and incorporated into purple prism traps for a significant gain in trapping effectiveness (Crook et al. 2008). Green leafy volatiles derived from ash trees also have been identified and shown to improve the capture of adult EAB on traps (De Groot et al. 2008).

Field and the laboratory studies on the mating system of this beetle found that vision plays a key role in male mate-location (Lelito et al. 2007), similar to the mating systems of other buprestids examined to date (Carlson and Knight 1969; Matthews and Matthews 1978; Gwynne and Rentz 1983). Further, males appear to discriminate between the sexes once contact is made; feral males spend significantly

more time attempting copulation with females than males or solvent-washed beetles of both sexes, suggesting the use of a contact cue (Lelito et al. 2007).

In an effort to understand the role of any sex-specific compounds the beetle may employ in mate recognition, we conducted solvent dipping and SPME sampling of the cuticles of both immature and mature male, as well as female, beetles. These samples revealed characteristic differences between the sexes once they are mature. Here, we examine the behavioral role of 3-methyltricosane, a long-chain hydrocarbon present on the cuticles of mature females, but only in traces on the cuticles of male or immature female EAB. The compound was tested for behavioral activity in the field, using dead adult EAB as lures in a manner similar to that used in the past to identify precopulatory behavior (Lelito et al. 2007), as well as in a laboratory bioassay to assess the arrestant and/or attractant properties of the compound.

Methods and Materials

Insects Newly emerged adult beetles were provided by the staff of the Brighton, MI (USA 48116) USDA APHIS PPQ laboratory. These were segregated by sex upon emergence from rearing barrels, maintained in separate rearing tubs, and fed on ash foliage obtained from trees grown indoors. Beetles used for solvent and SPME sampling were either 3 ("young") or at least 10–12 days post-eclosion ("mature"). Live beetles used in laboratory behavior assessments were between 8 and 18 days of age and were considered "mature" (Bauer et al. 2004; Lyons et al. 2004). The beetles we used as field lures were also mature, killed by freezing, pinned through the thorax, and allowed to dry.

Solvent Dipping and SPME Sampling Young and mature beetles of both sexes were extracted in groups of three in 300 µl of dichloromethane (B&J, High Purity Solvent) or hexane (B&J, Ultra Resi-Analyzed). We did not detect significant differences between the dichloromethane and hexane washes of the beetles; therefore, we used the hexane solutions for quantification and further analysis. Hexane was evaporated in a gentle stream of nitrogen and samples redissolved in 60 µl of 50 ng/µl of 16-methyl hexatriacontane as an internal standard in hexane. For each of the four treatments, we performed four replicates.

The spatial distribution of cuticular compounds on the surface of mature males and females was investigated by using SPME fibers coated with 7 µm of polydimethylsiloxane (Supelco, Bellefonte, PA, USA). Body tagmata (head, thorax, and abdomen) of three mature EAB of each sex were sampled for 2 min each by rubbing a SPME fiber gently against the cuticle of the beetle. We prepared three replicate SPME samples of each body part. Beetles were held in place with soft forceps during fiber application.

Chemical Analysis All samples were analyzed with an Agilent 6890 GC-FID system equipped with an Equity-5 column (30 m×0.2 mm×0.2 µm; Supelco, Bellefonte, PA, USA) for quantification purposes. To identify components, selected samples were analyzed on an identical column in an Agilent 6890N GC coupled with a 5973N MSD system in EI mode (+70 eV). The oven temperature program was 50°C (1 min)−20°C/min−210°C−3°C/min−320°C (10 min) for all GC analyses. The temperature of the injector was held at 280°C, and the FID in the GC and the transfer line in the GC-MS were kept at 300°C. Samples were injected splitless (0.75 min) and run at an average linear flow velocity of 25 cm/s in the GC and 30 cm/s in the GC-MS. SPME samples were analyzed using the same settings.

Identification of the compounds was based on their MS spectra (NIST05, Masslib), their Kovats indices on the Equity-5 column described elsewhere (Böröczky et al. 2008), and by comparison with authentic standards. Quantification of hydrocarbons was based on their peak area values obtained from our data acquisition and analysis software (Chemstation, Agilent). Peak area values were corrected with the relative response factors described elsewhere (Böröczky et al. 2008). Percent composition was calculated as percentage of the sum of all identified compounds. Absolute amounts were calculated relative to the internal standard. The FID response was linear in the concentration range of the compounds we analyzed.

Synthesis of 3-Methyltricosane A solution containing 0.78 g (2.8 mmol) of eicosanal in 30 ml of anhydrous ether was added to an excess of ethereal 2-butyl magnesium bromide under an argon atmosphere. The mixture was stirred overnight and after careful addition of 10% HCl; the ether layer was separated, washed with saturated $NaHCO_3$, and dried over anhydrous $MgSO_4$. After filtration, the residue was taken up in 7 ml of pyridine and treated with 0.31 ml of methane sulfonyl chloride at 0°C and stirred overnight. After the addition of 50 ml of ether, the mixture was washed with 10% HCl; the ether layer was separated, washed with saturated $NaHCO_3$, and dried over anhydrous $MgSO_4$. After filtration, the solvent was removed in vacuo, and the residue was taken up in 50 ml of ethyl acetate and hydrogenated over 100 mg of PtO_2 under 3 Atm of hydrogen overnight. After the mixture was filtered and the solvent was removed, flash chromatography (silica gel/hexane) provided 521 mg of 3-methyltricosane, *m/z* 338 [M^+](0.2), 309(10), 281(2), 25312), 239(2), 225(3), 211(3), 197(3), 183(3), 169(4), 155(5), 141(7), 127(9), 113(13), 99 (19), 97(9), 85(41), 83(9), 71(65), 69(14), 57(100), 56(36), 55(22), 43(57), 41(24). GC-MS was carried out in the EI

mode using a Shimadzu QP-2010 GC-MS equipped with an RTX-5, 30 m×0.25 mm i.d. column. The instrument was programmed from 60°C to 250°C at 10°C/min and held at 250°C for 40 min.

The synthetic compound had a Kovats index (2371 on the Equity-5 column used above) and MS spectrum identical to that of the compound found in the body washes.

Field Behavior The dead, pinned female "beetle-lures" used for these experiments were either: unwashed, "U"; washed in dichloromethane for 10 min and then dried for 24 h, "W"; or solvent-washed, dried, and then coated with one of our experimental treatments. Ten microliters of 4 ng/μl *n*-eicosane ("E"; an impurity resulting from our synthesis of 3-methyltricosane); 2 ng/μl 80%/20% 3-methyltricosane/*n*-eicosane mixture ("T1"); 6 ng/μl 80%/20% 3-methyltricosane/n-eicosane mixture ("T2"); or 20 ng/μl 80%/20% 3-methyltricosane/*n*-eicosane mixture ("T3") were applied to the dorsal cuticle of a dead, dichloromethane-washed, and dried female EAB. T1, T2, and T3 represented 16, 48, and 160 ng of 3-methyltricosane, respectively. All applications were made with a 1-μl glass pipette, which was cleaned between applications by three separate washes with 10 μl of hexane. We prepared fresh beetle-lures for each replicate of the field experiment.

Field experiments took place between 7 June and 5 July 2007 between the hours of 1000 AM and 1600 PM EST, on days without heavy rain. Each 2-h replicate (one per suitable day, for a total of 17 replicates) was performed in an area of high-density EAB population located in Livingston County, MI, USA, south of the town of Howell. The site used was private agricultural and forest land, containing a large number of green ash trees (*F. pennsylvanica*). Experiments were conducted prior to and through the peak EAB flight period. Individual ash trees selected for these experiments were between 10 and 20 m tall and had healthy branches accessible at 2–3 m height from ground level for the pinning of beetle-lures. Each tree used was selected randomly on each day, with the precondition that at least five live EAB could be seen on that tree from ground level (i.e., a presumably infested tree).

For each replicate of field experiment, we pinned three beetle-lures of each treatment (U, W, E, T1, T2, and T3), on individual terminal leaflets of compound ash leaves on the sunny side of a selected ash tree, between 2 and 3 m from ground level. Beetle-lures were positioned randomly (not blocked by treatment), between 10 and 30 cm apart. We then observed these lures from the ground for a 2-h period and timed the duration of any feral EAB attempts at copulation and investigation of a lure. We defined "investigation" as a feral EAB remaining in contact with a pinned beetle-lure subsequent to an airborne approach and copulation attempt.

Laboratory Behavior We prepared experimental arenas by using a plastic 100-mm diameter Petri dish (Cat. No. 08-757-12, Fisher Scientific) lined with a 100-mm diameter filter paper insert (Cat. No. 1001-100, Whatman). For each experiment, we applied 10 μl of hexane as a control to the filter paper at each of two opposite points along the diameter of the dish, both 40 mm from the center of the filter paper. We then applied 10 μl of one of the experimental solutions (in hexane; Table 1) to the paper at the other two opposite points along the perpendicular diameter. We prepared both

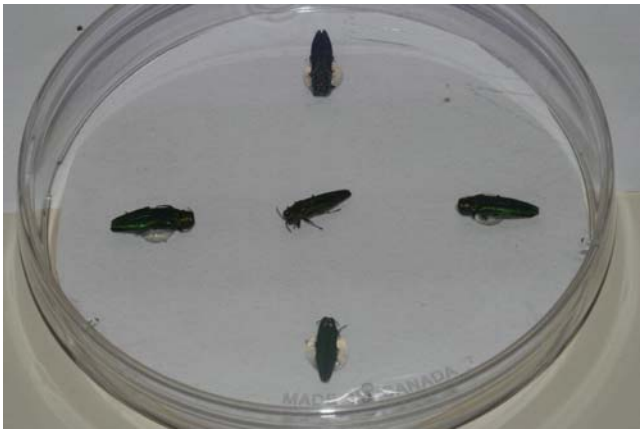

Fig. 1 The Petri dish used as an experimental arena for the *Agrilus planipennis* laboratory behavioral assay; the *beetle in the center* is a live male at the release point. The *other four beetles* are the dead, solvent-washed female beetles used as dummies for the application of either solvent controls or experimental lipid applications

male and female body washes by placing 12 mature individual EAB into 100 μl of hexane in a 2-ml glass vial, gently agitating for 2 min, and extracted the remaining liquid. We used the same approach for the lower dosage of one beetle-equivalent (1BE) but only extracted four mature beetles in 100 μl of hexane. We prepared fresh body wash solution at both dosages as needed and stored any remaining solution in a capped 2-ml glass vial in a standard freezer.

We performed 25 trials of each treatment at three and one BE. A new arena was prepared at the start of each trial, and the assay began when we placed individual mature (8–18 days post-eclosion) male EAB into the dish at the center-point of the filter paper. Each EAB male was then observed for a period of 10 min, while we recorded the number and duration of entries into the 1-cm diameter area centered on the application points.

We repeated the same assay but this time the solutions were applied to the dorsal cuticle of a dead, solvent-washed female EAB that had been hot-glued to the filter paper at the typical application points (Fig. 1) less than 24 h before and stored in a freezer prior to use. We recorded the number of direct male to female-beetle-lure contacts, the duration of each contact, and the number of times the male attempted to copulate.

We also conducted a series of trials to test mature female EAB for their response to beetle-lures using the same experimental treatments for mature males at the 3BE dosage described above. We recorded the number and duration of female-to beetle-lure contacts for each treatment.

A total of 25 individual 10-min trials were conducted for each treatment/lure combination (e.g., 3BE dosage, filter paper application) from 10 February to 15 March 2008, between 900 AM and 1400 PM EST. Three trials were run concurrently, with arenas approximately 10 cm apart under full-spectrum fluorescent lighting at 25°C. The lighting was situated on wooden supports such that all arenas were lit from directly overhead the center of the arena from a height of approximately 40 cm. Within each experiment, treatments were completely randomized within a day so that all treatments had an equal chance of occurring at a given time of day. The live EAB of both sexes were used only once, and following the assay were frozen and discarded.

For the laboratory experiments and the field experiments outlined above we purchased *n*-eicosane and *n*-tetracosane from Aldrich Chemical Co. (99% purity, St. Louis, MO, USA) and synthesized the 3-methyltricosane mixtures as outlined above.

Statistical Analyses We compared the mean investigation time of each treatment of beetle-lure in the field experiment time using a two-way ANOVA (analysis of variance), with replicate and treatment of the lure as factors. Treatment means were separated by in pair-wise comparisons by Tukey's Honestly Significant Differences test. We employed a binomial test of proportions to detect any treatments that were contacted more often than their paired hexane control (a significant deviation from a 50–50 ratio could indicate either attraction to, or avoidance of, a given treatment). Laboratory bioassay data were log-transformed prior to analysis to achieve a normal distribution. We utilized PROC GLM in SAS for comparisons of mean times of investigation between treatments by male EAB, using both the lure type and the chemical treatment of the

lure as factors with investigation time as the dependent variable. We performed all statistical analyses in SAS Version 9.1.3 (SAS Institute 2006).

Results

Solvent Dipping and SPME Sampling Major components of the cuticle of both male and female EAB were found to be saturated and monomethyl branched odd-chain (C23–C29) hydrocarbons. The methyl branch typically was in the middle of the chain. Terminally branched monomethyl alkanes, dimethyl alkanes, and unsaturated hydrocarbons were minor components. More polar lipids, such as fatty acids, ethers, and acetate and butyrate esters of long-chain alcohols, were also detected in the body wash samples of both sexes.

There were characteristic differences between the cuticular chemistry of mature male and female beetles (Fig. 2). 3-Methyltricosane is a minor component of the female body wash but is present in only trace amounts in that of males. Furthermore, it was found in limited quantity on the cuticle of the young female EAB, but it increased to approximately 50 ng of material coincident with sexual maturity. Other terminally branched mono-methylalkanes showed a similar trend but not as strongly as 3-methyltricosane (Table 2). We did not detect any variation in expression of 3-methyltricosane between the tagmata of the females with SPME.

Field Behavior Replicates were not a significant source of variation (ANOVA, df=16, F=1.65, P=0.104), and male EAB flew to and landed on all types of lures equally (ANOVA, df=5, F=0.536, P=0.739). However, there was a significant treatment effect (ANOVA, df=5, F=20.66, P<0.001) once contact was made, with unwashed females being investigated significantly longer than all other lures (Fig. 3). Treatments T3 and E were investigated for significantly longer than the washed female control, while T1 and T2 were not (Fig. 3).

Laboratory Behavior Both lure type (ANOVA, df=1, F=12.30, P<0.001) and treatment (ANOVA, df=25, F=4.34, P<0.001) had a significant effect on male behavior so data

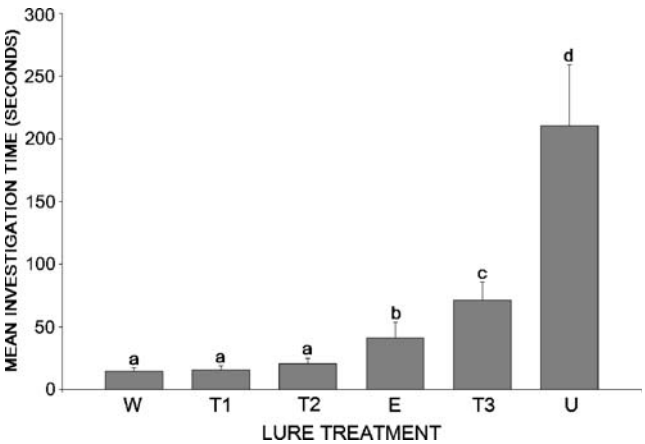

Fig. 3 Columns represent the mean time (in seconds) spent by feral male *Agrilus planipennis* in investigation of beetle-lures in the field in response to different treatments during each 2-h period of observation, with a total of 17 replicates. Treatments are listed in the following order on the x-axis: *W* a solvent-washed dead female EAB; *T1* 2 ng/μl 3-methyltricosane mixture application onto a washed female EAB; *T2* 6 ng/μl 3-methyltricosane mixture application; *E* 4 ng/μl eicosane application; *T3* 20 ng/μl 3-methyltricosane mixture application; *U* a nonsolvent-washed dead female EAB. *Bars* represent one standard error of the mean. *Columns having no letters in common* are significantly different (df=5, F=19.73, P<0.001). This experiment was performed between 7 June and 5 July 2007 South of Howell, Michigan

Table 3 Mean investigation time (seconds ± S.E.M.) by treatment in the male *Agrilus planipennis* laboratory arena bioassay

The bioassay utilized droplet applications to filter paper discs and dead, solvent-washed *A. planipennis* adults

[a] Pooled control value. Individual controls were analyzed pairwise with Tukey's HSD against the experimental treatments. Individual controls paired with each experimental treatment did not vary statistically from one another by ANOVA, $P>0.05$

[b] Means within a column having no letters in common are significantly different according to Tukey's HSD, $P<0.05$

were separated by lure type and analyzed separately for treatment effects by using a one-way ANOVA. The chemical treatment applied to the lure had an effect on male behavior for both beetle-lures (Table 3; ANOVA, $df=12$, $F=4.79$, $P<0.001$) and filter paper applications (Table 3; ANOVA, $df=12$, $F=2.72$, $P=0.002$). A greater number of cuticular lipid applications onto dead female EAB (treatments FBW3, TRM3, TRP3; Table 3) evoked significant differences in male behavior over their respective controls than did the corresponding lipid applications directly onto filter paper (treatment FBW3 only; Table 3).

The number of contacts made by male EAB with the different beetle-lures or the number of male EAB entering the treated areas on the filter paper, did not differ significantly between treatments (binomial test of proportions, $P>0.05$ for all treatment-control pairs). However, treatment affected the incidence of copulation attempts to beetle-lures (ANOVA, $df=12$, $F=6.032$, $P<0.001$) with FBW3 and TRP3 eliciting more than other treatments and hexane-only controls (Fig. 4, black columns). At 1BE, no significant differences were observed (Fig. 4, grey columns).

Female EAB did not exhibit a significant preference for any treatment either with respect to initial contact (Binomial test of proportions, $P>0.05$ for all treatment-control pairs) or time remaining at the lure (ANOVA, $df=6$, $F=0.472$, $P=0.829$).

Discussion

Although the approach phase of the EAB mating system relies on visual cues, our results confirm the earlier suggestion that a female contact sex pheromone influences male behavior (Lelito et al. 2007). Males in the laboratory spent more time investigating beetle-lures to which we had reapplied female body wash or synthetic mixtures containing 3-methyltricosane than solvent-only controls, a preference we observed among feral male EAB tested in the field as well. However, males still spent significantly more time investigating unwashed female EAB than any dosage of 3-methyltricosane. Therefore, it is likely that the behavioral effect of 3-methyltricosane may be synergized by the perception of other compounds naturally secreted onto the cuticular surface of the unwashed beetle-lures.

The results of our assays support the pheromonal role of the cuticular hydrocarbon 3-methyltricosane, and the identification of this compound represents the first contact

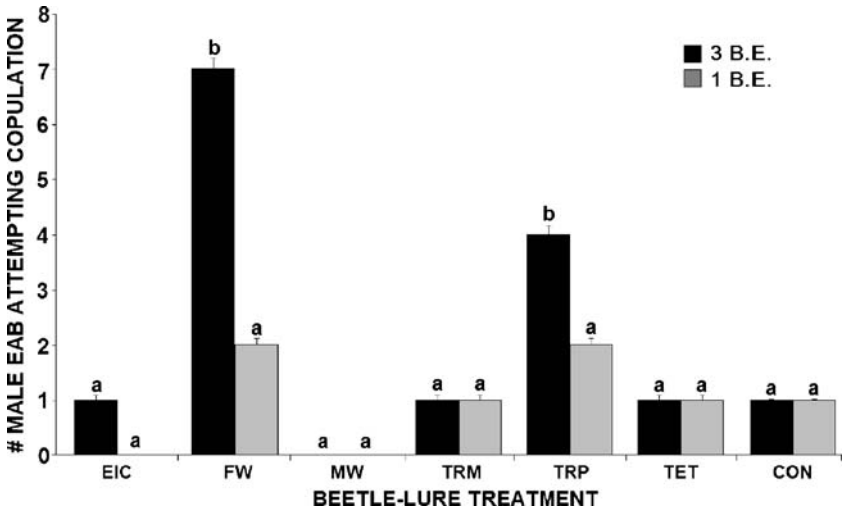

Fig. 4 Columns represent the total number of copulation attempts performed by male *Agrilus planipennis* to each experimental treatment of beetle-lure. *Black columns* indicate three beetle-equivalent dosage, *grey columns* indicate one beetle-equivalent dosage. Treatment abbreviations on the x-axis are the same as in Fig. 4. *Bars* represent two standard errors of the mean. *Columns having no letters in common* are significantly different from one another ($df=12$, $F=6.03$, $P<0.001$)

sex pheromone identified in the family Buprestidae. However, this compound has a chiral center at position 3, and it will be necessary to synthesize and test both enantiomers to determine if chirality is important.

Males do not differentiate over a distance between beetles treated with 3-methyltricosane and those treated with female body wash or solvent only in either the laboratory or the field, suggesting that 3-methyltricosane is likely perceived only as a contact cue. Although it is possible that males might be able to detect the presence of females from outside their visual range either directly or indirectly, through olfactory cues such as volatiles given off by the damaged host (Crook et al. 2008), 3-methyltricosane is unlikely to serve as a long-range attractant.

The continuous antennation of the treated substrate, especially obvious when the male encountered an affixed beetle to which female extract or 3-methyltricosane had been applied, suggests that the specific sensillae are on the antennae. Male chemoreception may not be limited to the antennae: males were also observed to "scratch" their tarsi against both the filter paper and the affixed beetles in many cases. This behavior was often followed by renewed bouts of vigorous antennation. This needs to be examined in greater detail.

Development of an Efficient Pheromone-Based Trapping Method for the Banana Root Borer *Cosmopolites sordidus*

G. V. P. Reddy · Z. T. Cruz · A. Guerrero

Received: 2 July 2008 / Revised: 25 November 2008 / Accepted: 15 December 2008 / Published online: 13 January 2009

Abstract The banana root borer *Cosmopolites sordidus* (Germar) (Coleoptera: Curculionidae) is a major pest of bananas throughout the world. Chemical control is both undesirable and expensive, where biological control alternatives are limited, and pheromone-based trapping results in low captures. In this study, several important factors that affect pheromone-based catches, such as trap type, trap dimensions, and color and position of the traps, were optimized. Ground traps were found to be superior to ramp and pitfall traps, and larger traps (40×25 cm and above) were more efficient than smaller ones (30×15 cm). In a color-choice test, the banana weevil clearly preferred brown traps over yellow, red, gray, blue, black, white, and green, with mahogany being more attractive than other shades of brown. In addition, pheromone baited ground traps positioned in the shade of the canopy caught significantly more adults than those placed in sunlight. Therefore, mahogany-brown ground traps 40×25 cm appear to be the most efficient at catching *C. sordidus* adults and have the greatest potential for use in mass trapping and programs for eradication of this pest.

Introduction

The banana root borer *Cosmopolites sordidus* (Germar) (Coleoptera: Curculionidae) is native to Malaysia and Indonesia but is now a major pest in most banana-growing regions of the world (Gold et al. 2001), particularly those producing dessert and cooking bananas (Sikora et al. 1989). In recent times, this borer has become a serious problem in Guam and other parts of Micronesia, raising concern among local authorities because all varieties of bananas appear to be attacked, and losses may reach 100% if the pest is left uncontrolled (Koppenhöffer et al. 1994).

Budenberg et al. (1993) provided the first evidence of a male-produced aggregation pheromone in *C. sordidus*, and Beauhaire et al. (1995) detected six male-specific compounds that elicited electroantennogram activity in vapor form, including the male pheromone (sordidin; 1S,3R,5R, 7S-1-ethyl-3,5,7-trimethyl-2,8-dioxabicyclo[3.2.1]octane). The structure and absolute stereochemistry of the natural attractant were confirmed by synthesis (Mori et al. 1996; Fletcher et al. 1997) and racemic sordidin proved attractive to both sexes (Ndiege et al. 1996; Jayaraman et al. 1997). Sordidin, formulated by ChemTica Internacional, S.A., San José, Costa Rica, is used to monitor the banana borer (Tinzaara et al., 2002, 2003) in Costa Rica (Alpizar et al. 1999; Oehlschlager et al. 2000) and Uganda (Tinzaara et al. 2000). In the Caribbean, four baited pitfall traps/hectare reduced corm damage (to <10%) and increased bunch weights (by 10–20% over a crop cycle) in commercial plantations (Alpizar et al. 1999, 2000). However, in Africa, the use of sordidin was ineffective for mass trapping (Tinzaara et al. 2005). Therefore, there is an urgent need for an efficient semiochemical-based trapping method for the control of *C. sordidus*. Here, we report a study directed toward improving trapping methods to control the pest and also toward a better understanding of the pheromone ecology of the pest.

Methods and Materials

Trap Types Three different types of traps—ground, ramp, and pitfall—were evaluated. The ground trap (Fig. 1A) was constructed in our laboratory from a 120×60×0.5-cm piece of white corrugated plastic board, with a 50×8-cm slit baffle fitted at the top to prevent borers from escaping (Reddy et al. 2005). Traps were sealed in all four corners and along edges with marine adhesive sealant, and water, mixed with a dishwashing liquid detergent (1–3%), was put in the bottom container to retain adults. The lower outer edges of the ground traps were covered with earth to prevent weevils from crawling under the traps.

The ramp trap used was commercially available from ChemTica Internacional S.A. (San José, Costa Rica; Fig. 1B). It was made of durable polyethylene and consisted of two box-shaped components, each 14 cm wide by 4 cm high (inside dimensions). Four sloping ramps led from the four cardinal directions into the sides of one of the open boxes. Each ramp was 4 cm high, 13 cm long, and 12 cm wide and slid into a slot in the floor of the box component. The other box had four corner ridges (6 cm high) that extended downward into the bottom box. As in the ground trap, the bottom container was filled partially with soapy water to retain attracted borers.

Pitfall traps were cylindrical, translucent white plastic cups (10-cm diameter, 1.5-L capacity; Fig. 1C). Four drainage holes (24-mm diameter) were drilled at 90° from each other in the sides of the cup, at least 5 cm from the bottom. The pheromone lure was suspended from the top of the cup on a vinyl-clad steel wire (12 cm long) threaded through a 3-mm hole. Traps were placed in holes dug 10 cm into the ground so that the upper edge of the cup was at the level of the soil.

Pheromone Lures Pheromone lures (Cosmolure), sealed in a polymer membrane release device and optimized for *C. sordidus*, were obtained from ChemTica Internacional S.A. (San José, Costa Rica). The lure packs, each containing 90 mg of pheromone and having a release rate of 3 mg/day (Tinzaara et al. 2005), were stored at 4°C until use. Lures were hung on 2-cm wires suspended across the tops of the ground and pitfall traps. In the case of the ramp trap, a hook-shaped wire with the lure was inserted (2 cm) through a hole in the top side of the trap. The lures were changed when the transparent container with the pheromone appeared empty, usually once or twice a month, although occasionally more frequent changes were necessary.

Effect of Trap Type on Capture Efficiency Ground, ramp, and pitfall traps with synthetic pheromone lures were

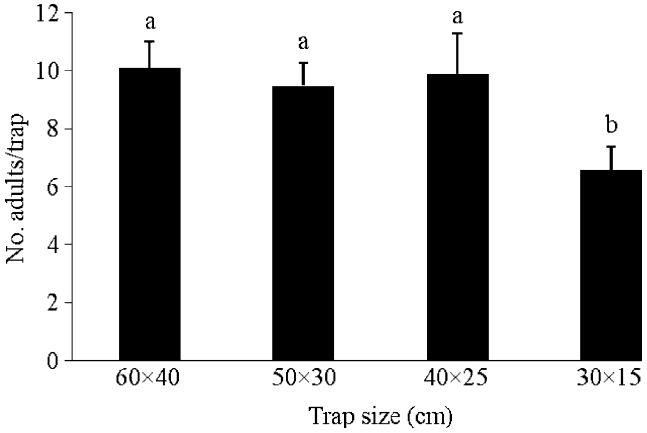

Fig. 3 Mean (± SE) numbers of adult *Cosmopolites sordidus* caught in pheromone-baited ground traps of different sizes. *Different lowercase letters* indicate significant differences between treatments (one-way ANOVA using Poisson model, Least Square Means, $P<0.05$)

placed at randomly chosen locations about 5 m apart on the ground of banana plantations in the villages of Dededo, Yigo, Agaña, and Yoña (Guam, USA; replicated ×4 at each site). Every week, the banana root borers trapped were removed and counted. Traps were washed and rinsed, and new detergent water was added. We randomized the traps across the field to avoid any possible trap-placement effect. Traps without lure were used as controls. The experiment was carried out from January to March 2007.

Effect of Trap Size The relative efficacy of four different sized ground traps (60×40, 50×30, 40×25, and 30×15 cm) was investigated. The ground trap was selected because it caught significantly more weevils than the ramp and pitfall traps. In each village, one trap of each size was set up, and their position rotated every week to prevent any location effect. The experiment was conducted from April to June 2007.

Effect of Trap Color Brown-, black-, gray-, yellow-, red-, white-, green-, and blue-colored vinyl tapes were adhered to all sides of 40×25-cm ground traps and tested independently (one trap of each color per location). The experiment was carried out from July to August 2007. The hue angle (h°) and chroma (C*) and the average of three readings for each color were determined by using a Konica Minolta CR-410 Chromameter (Minolta Instrument Systems, Ramsey, NJ, USA). The hue angle indicates the sample color, whereas the chroma provides a measure of the color intensity, and these were calculated by using the equations of Wrolstad et al. (2005). The hue angle is expressed on a 360° grid where 0°=red, 90°=yellow, 180°=green, and 270°=blue, respectively.

Effect of Shade of Brown Brown traps caught significantly more adults than traps of other colors so ground traps of different shades of brown (dark brown, mahogany brown, russet brown, saddle brown, and light brown) were evaluated (one trap of each shade in each village). The experiment was conducted from September to November 2007.

Relative Effects of Visual and Olfactory Cues To determine the relative importance of the visual and olfactory components of attraction, we repeated the experiment with mahogany brown ground traps baited with pheromone lures or unbaited. There were four replicates in each village, tested from December 2007 to February 2008.

Effect of Trap Shading Baited mahogany brown ground traps were placed in the shade and in sunlight, with four replicates in each village from March to May 2008. During the experiments, the color of the trap was measured by using a chromameter in the morning (0830 hours), noon (1200 hours), and afternoon (1600 hours). The data were averaged, and means were compared. Similarly, the

Green	43.50±0.08	−27.32±0.03	1.72±0.09	27.37±0.03	176.39±0.19
Blue	36.02±0.10	15.19±0.10	−35.82±0.12	38.91±0.14	292.98±0.08

Data represent means of three observations

*L** indicates lightness of the color and it runs through the center of the color chart, where 100 at the top represents white and zero at the bottom represents black, *a** runs left to right on the color chart, and indicates a red shade when greater than zero (positive) and a green shade when lower than zero (negative), *b** runs vertically through the color chart, and indicates a yellow shade when positive and a blue shade when negative

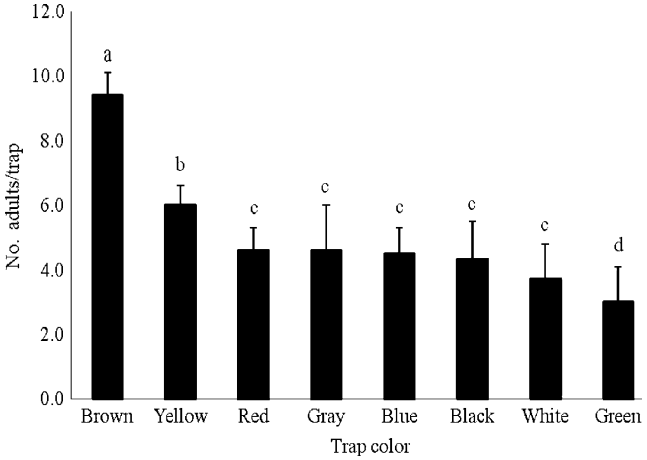

Fig. 4 Mean (± SE) numbers of adult *Cosmopolites sordidus* caught in pheromone-baited ground traps of different colors. *Different lowercase letters* indicate significant differences between treatments (one-way ANOVA using Poisson model, Least Square Means, $P<0.001$)

temperature within the different traps was recorded using a pocket weather meter (Kestrel®3000, Boothwyn, PA, USA).

Statistical Analysis Because all the response variables used in the experiments are count variables, a one-way Poisson analysis of variance model was fitted using the GLIMMIX Procedure SAS Version 9.13 (SAS Institute Inc. 2004). The Least Square Means test was used to make multiple comparisons for significant differences between treatments.

Results

Effect of Trap Type Baited ground traps captured more adult borers than baited ramp or pitfall traps ($F=48.88$, $df=2$, $P<0.001$; Fig. 2). Control traps captured no adult borers.

Effect of Trap Size The three larger trap sizes performed equally ($F=3.59$, $df=3$, $P<0.05$) but were significantly better than the smallest one (mean of 10.1±0.9, 9.5±0.8 and 9.9±1.4 adults/trap for 60×14, 50×30, and 40×25 cm, respectively; Fig. 3). For economy and ease of handling, 40×25-cm traps were chosen for further study.

Effect of Trap Color Trap color measurement values (L*, a*, b*, chroma, and hue angle) are given in Table 1. Brown ground traps were more attractive to banana borers than those of any other color tested ($F=6.74$, $df=7$, $P<0.001$; Fig. 4). There was a significant difference ($P<0.001$) between yellow and red colors. For the other colors, yellow attracted more banana borers than red, gray, blue, black, white, and green.

Effect of Shade of Brown Trap color measurement values (L*, a*, b*, chroma, and hue angle) for the different shades of brown are given in Table 2. The shade of brown affected adult catches in ground traps ($F=7.31$, $df=4$, $P<0.001$; Fig. 5), with mahogany brown traps catching significantly more adult borers than other shades. Dark brown, russet brown, and light brown did not differ significantly, whereas saddle brown traps were the least attractive.

Relative Effects of Visual and Olfactory Cues Mahogany brown ground traps baited with pheromone lures caught significantly more adults than those without ($F=33.32$, $df=1$, $P<0.001$; Fig. 6).

Effect of Trap Shading Pheromone-baited mahogany brown ground traps positioned in the shade of banana plants caught more adults than did similar traps placed in sunlight ($F=9.27$, $df=1$, $P<0.05$; Fig. 7). There was no significant difference in the color measurements of the mahogany brown traps placed in the sun (L=34.4, a=4.2, b=4.4, hue angle=46.7, and chroma=6.1) and shade (L=34.5, a=4.0, b=4.3, hue angle=46.5, and chroma=5.9). Similarly, only a marginal difference (<1°C) was observed among the temperatures of the different traps placed in both locations.

Table 2 Color measurements of the different shades of brown tested in the trapping of *C. sordidus* in Guam

Trap color	L*	a*	b*	Chroma (C)	Hue angle (h°)
Dark brown	35.26±0.18	3.98±0.03	3.94±0.02	5.60±0.03	44.66±0.06
Mahogany brown	35.91±0.01	5.44±0.02	4.35±0.03	6.97±0.03	38.65±0.13
Russet brown	38.99±0.03	11.37±0.05	9.00±0.01	14.51±0.03	38.37±0.07
Saddle brown	48.37±0.01	9.25±0.06	20.62±0.05	22.60±0.03	65.83±0.10
Light brown	61.13±0.03	4.50±0.02	21.87±0.02	22.33±0.01	78.38±0.03

Discussion

Pseudostem trapping was recommended for reducing populations of the banana borer (Gold et al. 2002; Koppenhöffer et al. 1994) but proved impractical and labor intensive (Gold et al. 2002). In Uganda, use of baited pitfall traps caught up to 18 times as many adults as pseudostem traps probably because they lasted longer (1 month vs. 3–7 days, Gold et al. 2001). While there have been several reports of successful trapping of banana borers with pheromone lures (Ndiege et al. 1996; Jayaraman et al. 1997; Alpizar et al. 1999), pheromone traps were not effective in reducing *C. sordidus* populations in Cameroon (Messiaen 2001). Tinzaara et al. (2005) failed to catch >3% of adults at either low or high trap density, and there was no reduction in damage to the plants (Tinzaara et al. 2005). Moreover, our recent studies indicate that, although ramp traps baited with Cosmolure are useful for monitoring *C. sordidus*, they do not reduce corm damage at several locations in Guam (G. V. P. Reddy, personal observation).

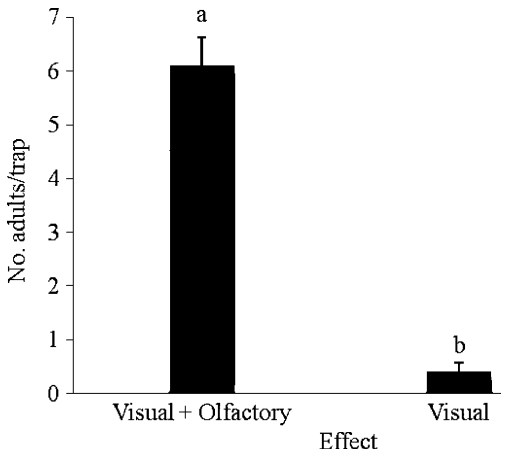

Fig. 6 Mean (± SE) numbers of adult *Cosmopolites sordidus* caught in mahogany-brown ground traps with and without pheromone lures. *Different lower-case letters* indicate significant differences between treatments (one-way ANOVA using Poisson model, Least Square Means, $P<0.001$)

Trap type is known to influence adult catches of many insects (Wyatt 1998; Reddy et al. 2005), yet no systematic study of trap features for more effective trapping of the banana borer had been conducted previously. Clearly, ground traps are superior to both ramp and pitfall traps under field conditions, as well as being cheaper and easier to use (Reddy 2007). Previous studies have shown that efficacy of traps for beetles can be strongly affected by their position (Lanier et al. 1976), color (Lanier et al. 1976; Ladd and Klein 1986; Smart et al. 1997), height above ground (Cuthbert and Peacock 1975), and surface texture (Lie and Bakke 1981), but few reports have been published on the effect of trap size. Tilden et al. (1979) found that larger traps caught significantly more western pine beetles *Dendroctonus brevicomis* than smaller traps. The same was reported for the European elm bark beetle, *Scolytus multistriatus* (Lanier et al. 1976), but not for the old-house borer, *Hylotrupes bajulus* (Reddy 2007).Trap diameter affected catches of spiders and ants (Brennan et al. 1999; Borgelt and New 2005), so it was surprising to find no difference between the three larger traps tested.

Some insects use visual pheromone cues to find a mate (Thornhill and Alcock 1983; Reddy et al. 2002), and these may act in combination (Carlton and Cardé 1990; Fukaya et al. 2004; Reddy and Guerrero 2004). Color has been shown to influence the efficacy of pheromone traps, and our results for the banana weevil show that not only is brown preferred

over the other colors tested but also that mahogany is preferred to other shades of brown. The borer's preference for mahogany brown did not obviate the need for a chemical attractant; however, pheromone-baited traps caught significantly higher numbers of adults than unbaited ones.

Finally, we studied the effect of shading on trap catches as placement is an important factor affecting trap efficacy (Blackmer et al. 2008). Although few reports address the effect of shade or sunlight on trap catches, our results are consistent with those of Arbogast et al. (2007), who reported a marked preference of the small hive beetle, *Aethina tumida* (Murray) (Coleoptera: Nitidulidae), for shaded traps over those placed in sunshine. As there were no significant differences in the temperature of traps placed in the shade or in the sun, it is unlikely that differences in trap catch were related to differential emission rates of the pheromone. Furthermore, as we recorded no differences in either the hue angle or chroma of the traps in sun and shade, it would appear that the differences were not related directly to the color properties of the traps, although this needs to be investigated. The most likely explanation relates to a behavioral preference for shade, possibly because beetles are subject to desiccation in sunlight.

In summary, we have shown that 40×25-cm mahogany brown ground traps baited with pheromone lures and placed in shaded areas of the banana plantation are an efficient tool for catching adult male and female banana borers. Although our experiments were conducted on a small Pacific island, we expect the new trap design to be useful for monitoring and mass trapping of this important pest in larger banana plantations in the mainland.

Detection and Discrimination of Mixed Odor Strands in Overlapping Plumes Using an Insect-Antenna-Based Chemosensor System

Andrew J. Myrick · Kye Chung Park · John R. Hetling · Thomas C. Baker

Received: 23 May 2008 / Revised: 27 October 2008 / Accepted: 5 December 2008 / Published online: 20 January 2009

Abstract Olfactory signals, a major means of communication in insects, travel in the form of turbulent odor plumes. In terrestrial environments, an odor blend emitted from a single point source exists in every strand of the plume, whereas, in confluent plumes from two different odor sources, the strands have some chance of being coincident and comprising a new third odor in those strands. Insects have the ability to detect and interpret necessary olfactory information from individual filamentous odor strands in complex multifilament odor plumes. However, behaviorists have had no way to measure the stimulus situations they are presenting to their temporally acute insect subjects when performing Y-tube olfactometer or confluent pheromone plume wind tunnel assays. We have successfully measured the degree of plume-strand mixing in confluent plumes in a wind tunnel by using a multichannel insect-antenna-based chemosensor. A PC-based computer algorithm to analyze antennal signals from the probe portion of the system performed real-time signal processing and, following a short training session, classified individual odorant/mixture strands at sub-second temporal resolution and a few tens of millimeters of spatial resolution. In our studies, the chemosensor classified a higher frequency of strands of two different odorants emitted from two closely spaced filter papers as being "mixed" when the sources were located only 1 or 2 cm apart than when the sources were 5 or 10 cm apart. These experiments demonstrate the chemosensor's potential to be used for measuring odor stimulus situations in more complex multiple-plume environments.

Introduction

Insects have demonstrated in behavioral experiments that use experimentally pulsed pheromone puffs that they are capable of discriminating pheromone plume strands of incompletely mixed components that are separated by only 1 mm from each other or equivalently by 1/1,000 of a second (Baker et al. 1998). However, researchers involved in presenting odors to insects that emanate from natural point source plumes in more complex contexts have not had the ability to measure the sub-second odor stimulus conditions against background odor plumes that may be experienced by insects in determining their behavioral responses. The ability to measure on a sub-second basis the degree of mixing of, for instance, plume strands of plant volatiles with those of synthetic or natural pheromone components or alternatively two different species' pheromone plumes would provide a quantitative basis for understanding olfactory temporal acuity that affects behavioral responses. The high time resolution of insect antennae to various odorants and the well-established signal recording technique from insect antennae such as electroantennogram (EAG) and

single-cell recording previously had given researchers the idea of using insect antennae as olfactory chemosensors to detect various volatile compounds of interest and ascertain fine-scale plume structure features (Baker and Haynes 1989; Sauer et al. 1992; Huotari and Mela 1996; Schöning et al. 1998; van der Pers and Minks 1998; Park et al. 2002).

In natural environments, point source odor plumes with their fine-scale plume-strand structures do not exist in solitude. The strands of a plume from one source can intermingle with those from another. The degree of confluent plume-strand coincidence or separation can have significant effects on behavior (Vickers and Baker 1992; Baker et al. 1998) or on olfactory receptor neuron (ORN) activity (Nikonov and Leal 2002; Ochieng and Baker 2002). We have had, to this point, however, no way of measuring the stimulus situations actually experienced by insects under various odor plume presentation regimes that affect their subsequent responses.

With single-antenna EAG recordings, odor discrimination cannot be performed due to the confounding effects of concentration and chemical composition. However, in recent studies, we showed that a four-channel insect-antenna-based chemosensor system that uses an array of slightly differentially tuned insect antennae, named the "Quadro-probe," could be used to discriminate various odors on a strand-by-strand basis (Park et al. 2002; Hetling et al. 2003; Myrick et al. 2005). The Quadro-probe has sub-second temporal resolution of individual odor strands (and a few millimeters of spatial resolution) that enables detailed odor-plume-strand structure and composition to be performed. A dedicated analysis software package (Hetling et al. 2003; Myrick et al. 2005) that can be trained to recognize EAG patterns across particular arrays of different insect antennae in response to different odors was also developed. The system has enabled the performance of real-time high-throughput odorant signal classification and monitoring. In the present study, the Quadro-probe system was used to investigate the degree of mixing of overlapping odor plume strands emitted from dual point sources, which provides a proof-of-concept foundation for investigating more complex multiple-point-source strand discrimination.

Our hypotheses were: first, that we should be able to differentiate between strands sheared from a single-source two-odorant mixture and those emitted from two closely spaced separate odorant sources; second, that there should be a greater degree of plume-strand coincidence downwind from two overlapping plumes of different odorants when the upwind sources are closer together than when the sources are more widely spaced. The ability to confirm or falsify these hypotheses and the ability to measure the degrees of plume-strand mixing have potential impact on various insect chemical ecology studies under natural conditions where plant volatiles may interact to influence olfaction and behavioral response to pheromones (Ochieng and Baker 2002) or where pheromone plumes of two species might interfere with males' behavioral responses (Witzgall and Priesner 1991; Liu and Haynes 1992; Vickers and Baker 1997; Nikonov and Leal 2002).

Methods and Materials

Insects One- to 3-day-old virgin male moths of the corn earworm, *Helicoverpa zea*, and the cabbage looper, *Trichoplusia ni* (Lepidoptera: Noctuidae), were used. Laboratory colonies of these species were maintained on artificial diet under controlled conditions (14:10 h L:D, 23°C, 60% relative humidity) in a rearing room. Male pupae were kept in separate containers, and emerged adults were collected daily and provided with 8% sucrose solution until use.

Test Chemicals Two compounds, (*Z*)-11-hexadecenal (Z11-16:Ald) and (*Z*)-7-dodecenyl acetate (Z7-12:Ac), were used in experiments 1 and 2. These compounds are the major sex pheromone components of *H. zea* and *T. ni*, respectively. Each compound (Bedoukian, >99% chemical and isomeric purity) was diluted in hexane to give a 1-μg/μl solution. A 1:1 mixture of these two compounds also was prepared at the same concentration. Filter papers (Whatman no. 1) cut to 8×40 mm were impregnated with the test solutions containing 10 μg of one of the three odors (Z11-16:Ald, Z7-12:Ac, or the 1:1 blend of the two compounds) and were then used to produce odor plumes in our wind tunnel. Each filter paper dispenser was used for less than 1 h and discarded. In experiment 3, a plant-related compound, citronellal (Acros Organics, 93% pure) at a dose of 100 μg per filter paper, was used as a second odorant to accompany the first odorant, Z11-16:Ald, at 10 μg per filter paper. A blend of these two compounds at these two doses emitted from a single filter paper comprised the blend, i.e., the third odor.

Wind Tunnel Experiments were carried out by using a Plexiglas® wind tunnel (1×1×2.5 m). Airflow was created by a large fan system, filtered with activated charcoal filter layers, and sent through a buffer area of three layers of fine mesh nets. An exhaust suction tube (50-cm diameter) was located at the downwind end of the tunnel to scavenge odor-bearing air from the plumes out of the wind tunnel room. The rest of the air from the tunnel was re-circulated through the room. Airflow rate was controlled by using a variable AC transformer to change electrical current for the fan system. A constant wind speed of 50 cm/s was maintained inside the tunnel, and the temperature was maintained at 23°C during experiments.

Experiment 1

Experimental Setup Two male *T. ni* and two male *H. zea* antennae were excised with micro-scissors from the heads and placed between stainless steel reference and recording electrodes to create the four input channels of the Quadro-probe. The bases of the four excised antennae were placed individually on each of the four reference electrodes, and their distal ends were brought into contact with the four different recording electrodes after clipping off a few terminal antennal segments. Electrical connections between the antennae and metal electrodes were secured with an electroconductive gel (Spectra 360, Parker Laboratories Inc., USA). EAG signals from the Quadro-probe were acquired with a headstage amplifier, amplified further with a main amplifier (Syntech, The Netherlands) and then processed and stored on a laptop PC. The Quadro-probe antennal preparation was placed within the time-averaged boundaries of the plume(s) in the middle of the tunnel at a downwind distance of 1.5 m during training sessions and at 1.5, 1.0, or 0.5 m downwind of the filter paper sources during various test situations. The filter paper dispensers were affixed to paper clips hung from metal stands 50 cm above the tunnel floor and 30 cm from the upwind end of the tunnel. Before the beginning of trials each day, a burning incense stick was placed at the upwind position where the stimulus dispenser was to be located. The plume of incense smoke was observed to ensure that the plume strands would be contacting the Quadro-probe antennal preparations.

Analysis Software A computer algorithm (Myrick et al. 2005) was used to acquire, process, and analyze four-channel EAG signals from the Quadro-probe; this system was run on a Labview-based platform (National Instruments, USA). The program carried out noise filtration, EAG signal identification and classification, and reporting of results. The classifier used a supervised *k*-nearest-neighbor (*k*-NN) procedure that was trained at the start of the experiment to recognize strands as being either Z7-12:Ac, Z11-16:Ald, or a 1:1 blend of the two compounds emitted from a single filter paper source. EAG "events" across the array were synchronized according to their occurrence within a 160-ms window. For instance, when a significant EAG depolarization (measured from trough to peak) having the greatest amplitude occurred on channel 1, the program created a 160-ms swath to look down onto the other channels to quantify the amplitudes of any other significant EAG events occurring on the other three channels.

Training and Classification with Single-Odor Plumes The session started with a period of training of the algorithm to three pheromone odor sources and clean air by subjecting the antennal array to plume strands from filter papers 1.5 m upwind that were dosed with 10 μg of test compounds (blank, Z11-16:Ald, Z7-12:Ac, and the 1:1 blend of Z11-16:Ald and Z7-12:Ac) for either a 20- or a 60-s period at a distance of 1.5 m downwind of the odorant source. These training periods were then used as criteria for odor strand classification during the subsequent test periods by the algorithm. We also tried a 60-s training period to see if classification accuracy would be improved. During the test periods, the antennal array was subjected to each test stimulus dispenser in random order for >120 s at 0.5, 1.0, and 1.5 m downwind of the odorant source, and the signals were digitized and stored. The number of replicates for each distance/stimulus combination is indicated in Table 1. For each test session, the signals were analyzed off-line by the computer algorithm for signal processing and odor classification.

Classification of Strands From Confluent Dual-Source Odor Plumes The degree of mixing of odor strands within overlapping plumes originating from two different closely positioned pheromone point sources was assessed by using the Quadro-probe system by detecting and classifying

Table 1 Comparison of performance of the EAG signal processing computer algorithm in positive signal identification (true positive) for odor strands of two sex pheromone components, (*Z*)-7-dodecenyl acetate and (*Z*)-11-hexadecenal, and their 1:1 mixture between two different training durations performed at 150 cm downwind and then tested at three different downwind distances

Distance (cm)	Stimuli	Percent correct recognition at training period of (mean±SE)		Number	*P* value
		20 s [total number of EAG signals]	60 s [total number of EAG signals]

	Mixture	88.5±4.35 [100]	86.7±5.02 [79]	3	0.55
50	*Z*11-16:Ald	70.3±4.01 [161]	74.6±9.61 [138]	3	0.39
	*Z*7-12:Ac	100.0±0.00 [52]	97.0±3.03 [49]	3	0.30
	Mixture	100.0±0.00 [145]	98.1±1.20 [188]	3	0.08

Average number of EAG signals (depolarizations) in 20-s recording durations was 32.7±1.44 (mean±SE, N=84, range 7~73).

individual odor strands in the confluent plumes. Following the training session to the three separate odors from single sources, the same antennal preparation was used for the test sessions. The Z11-16:Ald and Z7-12:Ac odor sources were suspended on the rod with a 5-cm lateral separation between them at the upwind end. During this test period, signal acquisition and classification was performed for 120 s. Data were stored on a laptop PC for later analysis.

Experiments 2 and 3

Experimental Setup In the second and third experiments, live-moth preparations were used instead of excised antennae. Two male *T. ni* and two male *H. zea* were immobilized in tapered aerated plastic tubes and placed in a custom four-channel preamplifier (Fig. 1). With an electrolytically sharpened tungsten electrode inserted into the eye as a ground reference, the two antennae of each moth (with the antennal tips intact) were draped over the amplifier electrodes using Spectra 360 electroconductive gel to establish a connection to the amplifier.

Training Sessions Initial training sessions of approximately 100 s in plumes of each of three different odors, i.e., odorant 1 alone, odorant 2 alone, and a blend of odorants 1 and 2 at their initial dosages emitted from a single filter paper source, were conducted at the start of each experiment. EAG recordings were taken for an unpredetermined duration in the plume, but frequencies of classified odorant/odor "events" were standardized according to an events-per-second criterion.

Experiment 2 Once the training sessions had ceased, the Z11-16:Ald and Z7-12:Ac filter papers were suspended at the upwind end of the tunnel, beginning with a 1-cm lateral separation of the filter paper sources. After a period of sampling of approximately 100 s (ranging from 38 to 115 s) of strands from within a zone of confluence of the two plumes, the two sources were then separated by 2, then 5, and finally 10 cm. A second series of recordings was performed in reverse order, starting with the 10-cm source separation and working back to the 1-cm separation. Three experiments were performed, and because both increasing and decreasing the separation of the filter papers were known sources of potential variance, these experiments were broken into six blocks. Using Minitab ver. 14, two-way (distance of filter paper separation, block) analysis of variance (ANOVA) was performed on a general linear model of the strand frequencies of each odor. Tukey's pairwise comparisons were also performed on the model.

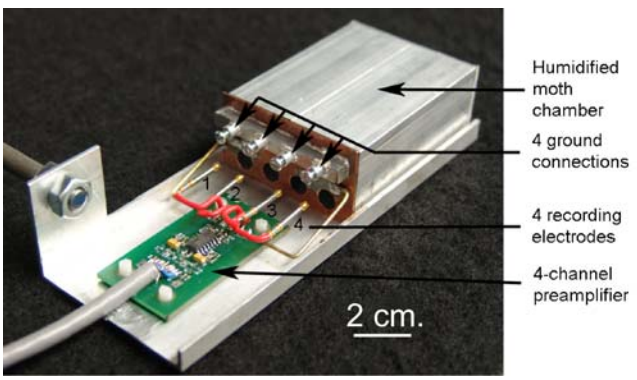

Fig. 1 Photograph of the whole-body preparation of the four-antenna Quadro-probe chemosensor probe using whole moths confined in plastic tubes within an aerated humidified aluminum chamber

Experiment 3 As in experiment 2, once the training sessions had ceased, the Z11-16:Ald and citronellal filter papers were suspended at the upwind end of the tunnel, beginning with a 1-cm lateral separation of the filter paper sources. After a period of sampling the odor strands within the confluent plumes, the two sources were separated by 2, then 5, and finally 10 cm, with data at all these distances being reported by the whole-body four-channel EAG preparation and stored on laptop PC for later analysis. Similar to experiment 2, a second series of recordings was performed in reverse order, starting with the 10-cm source separation and working back to the 1-cm separation. Two experiments were performed, and because both increasing and decreasing the separation of the filter papers were known sources of potential variance, these experiments were broken into four blocks. Using Minitab ver. 14, two-way (distance, block) ANOVA was performed on a general linear model of the strand frequencies of each odor. Tukey's pairwise comparisons also were performed on the model.

Classification of Odor Strands from Dual-Source Plumes In the second and third experiments that used live-moth preparations, the classifier made use of a Gaussian model for the probability density functions describing each odor. The preamplifier, seated in the whole-body apparatus, was connected to the recording system as described in Myrick et al. (2005). Data were filtered with a 2–15-Hz digital finite impulse response band pass filter prior to feature extraction. The feature type utilized in classification included time-synchronized EAG depolarization trough-to-peak voltages (TPV) only. When a depolarization occurred, trough-to-peak voltages (where a peak describes a *negative*-going depolarization) on different channels with (negative) peak times occurring within 160 ms were grouped to form a four-dimensional feature vector, called an event, with a feature corresponding to each channel. Missing data (when no peak was found on a channel) were filled with a value of 0. Any event (collection of four time-correlated trough-to-peak voltages) with no peaks larger than 100 μV was discarded as a simple strand detection procedure. The

trough-to-peak voltages in the remaining events were normalized by using the same constant so that the standard deviation of all the trough-to-peak values in the training set on all of the channels was unified. Note that this operation retains concentration information. The same value was used to keep noise levels relatively equal on each channel.

After collecting several hundred training events (100 s) for each odor, the probability densities of each odor were modeled by using a multidimensional Gaussian distribution. The Gaussian is able to model the unique correlation between the channels for each odor. The distribution was derived from a four-dimensional model, where variation along the covariance matrix eigenvector with the largest eigenvalue was ignored, so that the dimensionality of the distribution was reduced by 1. The component of any feature vector that points along this eigenvector is considered to be a measure of signal strength. The multidimensional Gaussian density (MDG) may be expressed by the following equation (Theodoridis and Koutroumbas 1999).

$$f(x) = \frac{1}{\sqrt{(2\pi)^d |\sum|}} \exp\left(-1/2(\mathbf{x}-\mu)^T \sum^{-1} (\mathbf{x}-\mu)\right)$$

where $\mathbf{x}$ is a vector of d (four) elements containing the feature values of an event (i.e., trough-to-peak measurements from multiple antennae); $\mathbf{\Sigma}$ is the sample covariance matrix of the trough-to-peak measurements for the odor, and $\boldsymbol{\mu}$ is the vector containing the feature means. The exponent of the MDG may be written as a summation in terms of the eigenvectors and eigenvalues of the covariance matrix. The sample covariance matrix may be expressed in terms of the eigenvectors and eigenvalues, known as spectral decomposition, or eigendecomposition, making its inverse simple to calculate (Johnson and Wichern 1992). We write it this way to explicitly remove dependence of the probability density in the direction of the eigenvector with the largest eigenvalue, so that the probability density near the mean is extrapolated through the origin. This estimates the density near the origin, where background and noise reside, since it cannot be measured directly. The problem of not having the ability to train on pure odor (that is only odor + background or background is available during training for an odor) is known as the imperfect teacher problem (Krishnan 2001) for mixture densities. It also makes the classification result independent of any prior knowledge of the distribution of signal strength for a particular odor. Let the index of the largest eigenvector and corresponding eigenvalue be $n$max. The reduced dimensionality MDG may be written

$$f(x) = \frac{1}{\sqrt{(2\pi)^{d-1} \prod_{n=1, n\neq n\max}^{d} \lambda_n}} \exp\left(-\frac{1}{2} \sum_{n=1, n\neq n\max}^{d} \frac{(\mathbf{e}_n \bullet (\mathbf{x}-\mu))^2}{\lambda_n}\right)$$

where $\mathbf{e}_n$ and λ_n are the nth eigenvector and eigenvalue of the sample covariance matrix for a particular odor, respectively. An example that illustrates the odor density functions superimposed on training data for two channels (rather than four channels) is shown in Fig. 2. Class membership of a new normalized vector (event) is then determined by using Bayesian inference assuming each odorant has an equal prior probability. Details regarding pattern recognition techniques can be found in the following reference (Theodoridis and Koutroumbas 1999).

Quadro-probe Longevity and Odor Classification Longevity After conducting the plume-strand-mixing trials in experiments 2 and 3, each Quadro-probe preparation was maintained and tested at several time intervals, ending at 24 h after the initial wind tunnel tests. For the responses of the antennal array to strands from a plume of each of the odorants 1 and 2 and also to strands of the mixture of the two odorants on a single filter paper (odor 3), the subsequent analyses of odor strand classification were carried out and compared as scatter diagrams to those that were made by the system during the first hour of recording.

Maximum EAG Longevity To determine the maximum longevity of antennal responsiveness using another version of the whole-body preparation, a male *T. ni* moth was restrained on a Plasticine block with U-shaped thin copper wires. A fine-tip reference capillary glass electrode filled with 0.5-M KCl solution was inserted into a compound eye, and another capillary glass electrode filled with electro-conductive gel was brought into contact with antennal tip after cutting a few terminal antennal segments. The antenna was then placed in a charcoal-filtered humidified continu-

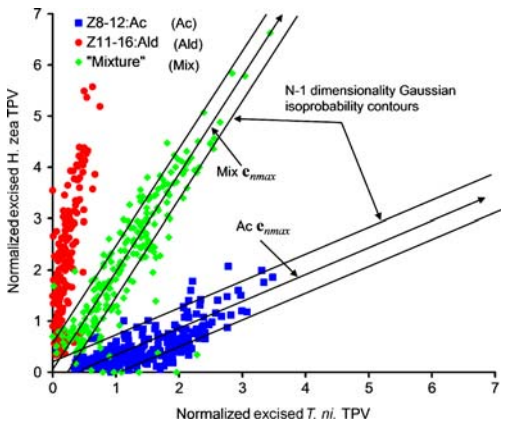

Fig. 2 Two-channel scatterplots of events obtained from four-channel simultaneous recordings of excised antennae from male *Trichoplusia ni* and male *Helicoverpa zea* antennae. These data were thresholded at 100 μV, as described in the text. Two-dimensional eigenvectors (purely illustrative) corresponding to the largest eigenvalues for Z8-12:Ac and mixture are shown. Isoprobability contours for these odors are drawn on either side of the eigenvectors

ous airflow (600 ml/min) at ~3 cm from the air outlet of a glass tube (8 mm ID). Stimuli were delivered by giving single 30-ms puffs (2-ml volume) of charcoal-filtered air through a large opening of a Pasteur pipette containing a filter paper strip (8×40 mm, Whatman no. 1) containing 0, 1, 10, or 100 ng of Z7-12:Ac, while the small opening of the Pasteur pipette was placed in the airflow through a small (3-mm diameter) opening in the glass airflow tube. EAG responses were measured at several different times each day until no EAG responses were observed. Three antennal preparations were tested; three consecutive stimuli were delivered at each measurement time.

Results

Experiment 1 In the wind tunnel, EAG responses to clean air (i.e., baseline activity) were usually lower than 50 μV at various airflow rates. Although some drift of baseline amplitude was observed in some antennae, it did not appear to significantly affect our chemosensor system performance. When two male *H. zea* antennae and two male *T. ni* antennae were used for the Quadro-probe and Z11-16:Ald, Z7-12:Ac, and 1:1 mixture of these two compounds were tested (all three odors emitted from single filter papers), *H. zea* antennae showed strong responses to Z11-16:Ald and the mixture (Fig. 3 Ald, mixture), and *T. ni* antennae showed strong responses to Z7-12:Ac and the mixture (Fig. 3 Ac, mixture).

The EAG depolarizations in response to odor strands from the two antennae of the same species were synchronized (Fig. 2) and exhibited consistent response proportionality over a wide range of pheromone strand flux strengths (Fig. 4a). The ratio of EAG amplitudes in response to the two-component mixture of *H. zea* antennae and *T. ni* antennae also was maintained regardless of the flux (amplitude of the EAGs) of the mixture odor strands (Fig. 4b). The Quadro-probe system thus was able to classify and discriminate the strands of these three different

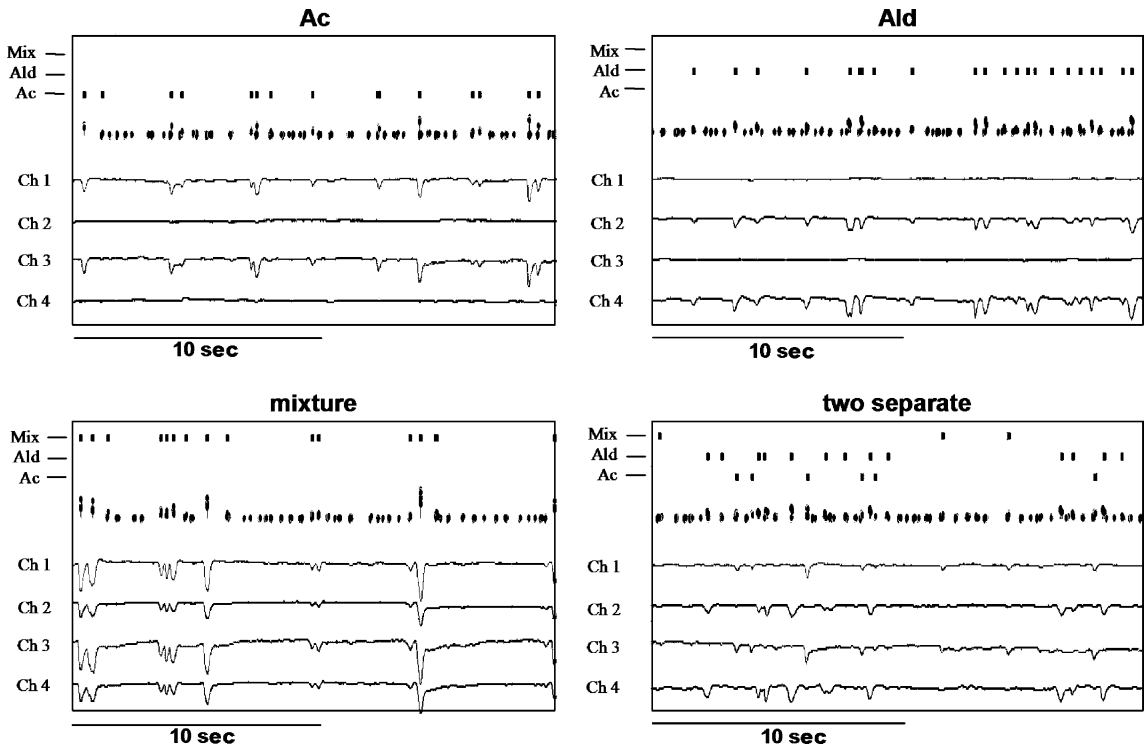

Fig. 3 Recordings from the four-antenna chemosensor system in different odor plumes in the wind tunnel. *Horizontal scale bar* 10 s. *Vertical scale* is 4 mV separation between channels. Each depolarizing peak (downward deflections in the four continuous-time traces) was an EAG response to contact with an individual odor filament. Four different moth antennae were used for the four-channel chemosensor probe. Ch 1 and ch 3 are male *T. ni*. Ch 2 and 4 are male *H. zea*. The probe was placed 1.5 m downwind from the filter paper test odor dispensers. Wind velocity was maintained at an average of 50 cm/s. The system was "trained" first to a plume of "Ac" (*Z*7-12:Ac), then to "Ald" (*Z*11-16:Ald), and finally to a mixture of the Ac and Ald placed on a single source ("mixture"). These sources were then used in the test situations illustrated here. The two separate sources of Ac and Ald were placed 5 cm crosswind from each other. *Lollipop-type symbols* along the *fourth line* from the *top* indicate depolarization "events" on individual channels that were detected by the system, and the *height* of each *oval* indicates the amplitude of each depolarization; channels are not indicated. Among these signals, those over an operator-determined threshold level were further analyzed and classified as Ac (*lowest row* of *squares*), Ald (*middle row* of *squares*), or a mixture of the two (*upper row* of *squares*)

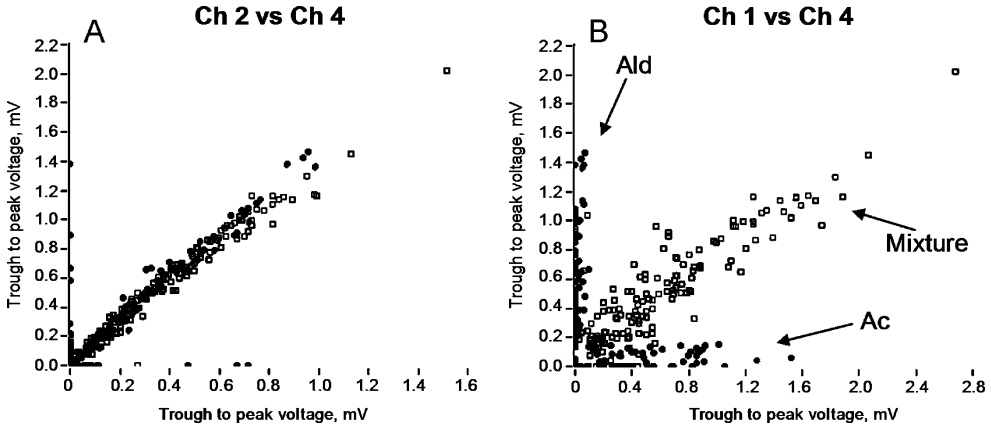

Fig. 4 The response amplitude relationships between two different antennae in the array, illustrating the profiles generated between two *T. ni* antennae (**A**, channel 2 vs. channel 4) and one *T. ni* and one *H. zea* antenna (**B**, channel 1 vs. channel 4) when exposed to strands from single filter paper sources of the Ac, Ald, or mixture of Ac + Ald, respectively. Regardless of EAG depolarization amplitude, same-species antennae (**A**) show a high-fidelity linear relationship regardless of the odor strand flux they are sampling. Two different species' antennae (**B**) also exhibit high-fidelity linear relationships regardless of the strand flux strength, but now these are exhibited in three distinct odor spaces that are characteristic of the three odors. Multidimensional *k*-nearest-neighbor analysis using clusters from all combinations of the four channels was the basic criterion used by the algorithm for odor classification

pheromone odors over a wide range of EAG amplitude flux with high accuracy (Table 1).

There was no significant difference in odorant recognition performance of the algorithm whether the training session was 20 or 60 s long (Table 1; there were no significant differences in odorant recognition performance when the tests were conducted at distances closer to the source than the 1.5 m training distance, except for Z11-16:Ald being less often correctly identified at 0.5 m than at the two longer distances). *P* values obtained from 2×2 (correct/incorrect × 20/60 s) chi-squared tests are listed in Table 1. Over all trials and all three test distances from the source, this experiment showed 98%, 86%, and 86% correct odor identification rates for Z11-16:Ald, Z7-12:Ac, and their mixture on a single source, respectively. When two different point odor sources (Z11-16:Ald and Z7-12:Ac) were placed 5 cm laterally apart at the usual upwind position in the wind tunnel, the Quadro-probe chemosensor system identified the individual strands from the confluent plumes of the two odors, plus instances in which the strands coincided within the 160 ms time window, registering a classification as the mixture (Table 2).

Experiment 2 The degree of synchronous arrival of plume strands arriving at the probe within the 160 ms time window conforms to the prediction of a higher frequency of occurrence of mixed strands when the sources are very close together. When the two pheromone odorant sources were separated laterally by 1 or 2 cm, there was a greater number of strands per second contacting the four-antenna probe downwind that were classified as "mixture" than when the sources were separated by 5 or 10 cm (Fig. 5). A mean of 1.75 strands per second was classified as being mixed at 1-cm filter paper separation compared to 0.69 strands per second at 5-cm separation and 0.34 strands per second at 10 cm separation that were classified as being mixed (Fig. 5).

The frequency of mixed strands (1.75 per second) as a proportion of the frequency of all three types of strands classified by the system (3.39 per second) was 0.52 at the 1-cm filter paper spacing, whereas it was 0.12 at the 10-cm spacing (0.34 per second mixed versus 2.93 per second total strands (Fig. 5); at the 5-cm spacing, this proportion was 0.18 (0.69 per second mixed versus 3.92 per second total strands). At the 2-cm filter paper spacing, there was

Table 2 Identification performance of the four-antenna chemosensor system for odor strands of two sex pheromone components, (*Z*)-7-dodecenyl acetate (Ac) and (*Z*)-11-hexadecenal (Ald), in a wind tunnel

Odor stimuli	Percent ratio identified as (mean±SE)			Total no. of EAG signals	Number
	Ac	Ald	Mixture		
Ac	86.1±6.41	5.4±1.30	8.5±5.96	66	3
Ald	2.4±2.38	97.6±2.38	0.0±0.00	75	3
Mixture of Ac and Ald on single source	2.6±1.29	11.4±5.56	86.0±5.18	149	5
Ac and Ald on two separate sources placed laterally 5 cm apart	38.7±7.75	42.3±6.22	19.0±4.21	509	13

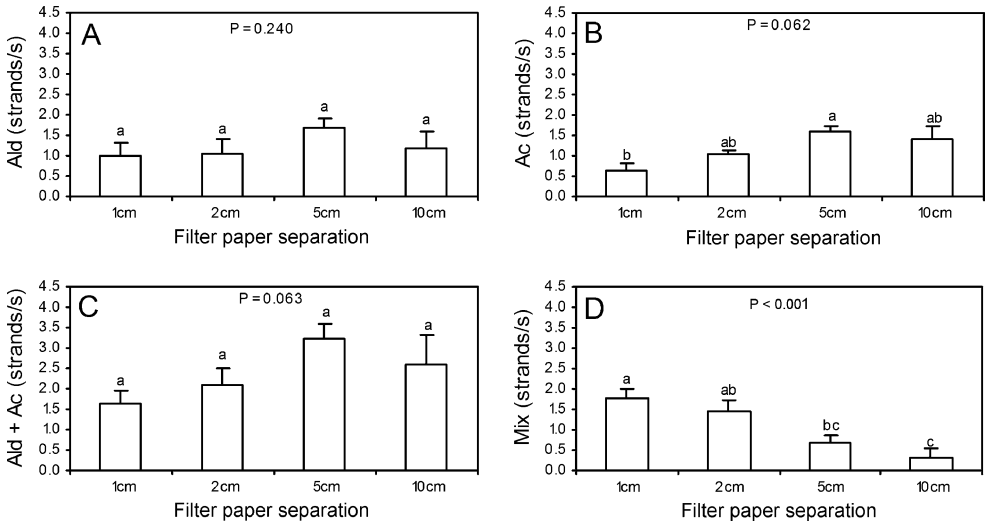

Fig. 5 Histograms (mean±SE) of the response frequencies, per second, of classified odor strands using a whole-body Quadro-probe preparation placed 1.5 m downwind of two closely spaced filter paper odor sources in the wind tunnel. Trials were conducted by using a filter paper emitting Z11-16:Ald and a second filter paper emitting Z7-12:Ac that were separated by 1, 2, 5, and 10 cm crosswind at the upwind end of the tunnel. EAG responses from the probe were classified as **a** Z11-16:Ald strands (Ald), **b** Z7-12:Ac strands (Ac), or else **d** "mixed" strands arriving coincidentally on the four-antenna array (mix). The sum of single strands classified as either Ald or Ac is shown in **c**. The more widely the filter papers were spaced, the less likely were plume strands to be judged as "mixed" (**d**) by the Quadro-probe system. A multidimensional Gaussian distribution was the basis for the classifier algorithm. N=3 antennal preparations, with two blocks each. Two-way (distance, block) ANOVA was performed on a general linear model of the strand frequencies of each odor, yielding P values of 0.240, 0.062, 0.063, and <0.001 for Ald, Ac, Ald + Ac, and mix, respectively. Tukey's pairwise comparisons resulted in 95% confidence groupings indicated by *lettering* located *above* each *bar*; means having no letters in common are significantly different at $P \leq 0.05$. The mean number of strands classified (all three odors) in each of the replicates in this experiment was 257 for the 1-cm filter paper separation, 276 for 2 cm, 262 for 5 cm, and 138 for 10-cm separation. Total strand frequency (all three odors) diminished as spacing increased, going from 3.84, 3.52, and 3.94 to 2.93 per second at 1-, 2-, 5-, and 10-cm filter paper separation, respectively

nearly as high a proportion (0.41) of mixed strands as at the 1-cm spacing (0.52). At 2 cm, the frequency was 1.44 per second mixed versus 3.52 per second total strands (Fig. 5). Thus, the asynchronous arrival of pheromone odor strands from two different pheromone sources can be detected and discriminated by the Quadro-probe system and varies according to odor source separation distance.

Experiment 3 Although the proof-of-concept ability of the insect-antenna-based probe plus software to discriminate odor strands separated in time downwind was demonstrated in experiment 2, we conducted a third study involving citronellal, a plant-volatile-based compound that provided a non-pheromonal background-noise plume against the signal from a pheromone plume. This situation that might occur when a female moth emits pheromone against a background of point source floral odors or induced plant volatiles from leaves.

Following training to citronellal, Z11-16:Ald, and a mixture of the two emitted from a single filter paper, the whole-moth-body 4-antenna system classified a greater frequency of odor strands as "mixture" when the plant- and pheromone-based sources were separated by 1 or 2 cm than when they were more widely separated by 5 or 10 cm (Fig. 6). A mean of 1.62 strands per second were classified as being mixed at the 1-cm filter paper separation compared to 0.56 and 0.28 strands per second that were classified as being mixed at the 5- and 10-cm separations, respectively.

The mixed strand frequency (1.62 per second) as a proportion of the total strand frequency of all three odors (3.45 per second) was 0.47 at the 1-cm filter paper spacing, whereas it was 0.10 at the 10-cm spacing (0.28 per second mixed strands versus 2.83 per second total strands (Fig. 6). At the 5-cm spacing, this proportion was 0.13 (0.56 per second mixed strands versus 4.24 per second total strands). At the 2-cm filter paper spacing, the proportion of mixed strands was 0.24 (0.87 per second mixed versus 3.56 per second total). Thus, the asynchronous arrival of plant odor strands and pheromone odor strands was detected and discriminated by the Quadro-probe system. As in experiment 2 that used two pheromone sources, the degree of synchronous arrival of plant odor strands and pheromone strands arriving at the probe within the 160-ms time window conforms to the prediction of a higher frequency of occurrence of mixed strands when the sources are very close together.

Whole-Body Quadro-probe Antennal Longevity The responsiveness of the Quadro-probe system array was preserved over 24 h (Fig. 7). The scatter diagrams show normalized training data (TPVs) obtained during three trials. Information obtained from two antennae are shown

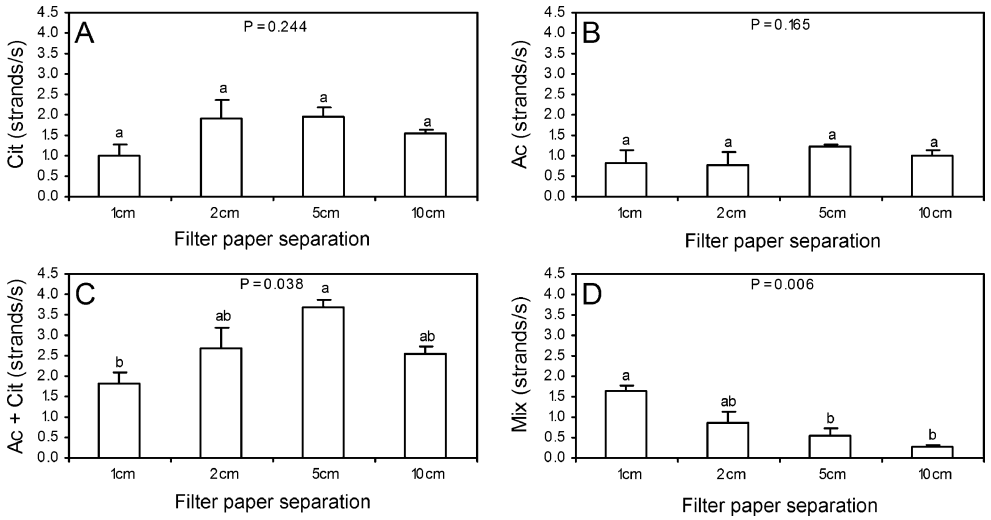

Fig. 6 Histograms (mean±SE) of the response frequencies, per second, of classified odor strands using a whole-body Quadro-probe preparation placed 1.5 m downwind of two closely spaced filter paper odor sources in the wind tunnel. Trials were conducted by using a filter paper emitting citronellal and a second filter paper emitting Z11-16:Ald that were separated by 1, 2, 5, and 10 cm crosswind at the upwind end of the tunnel. EAG responses from the probe were classified as **a** citronellal strands (Cit), **b** Z11-16:Ald strands (Ald), or else **d** "mixed" strands arriving coincidentally on the four-antenna array (mix). The sum of single strands classified as either Ald or Cit is shown in **c**. The more widely the filter papers were spaced, the less likely were plume strands to be judged as "mixed" (**d**) by the Quadro-probe system. A multidimensional Gaussian distribution was the basis for the classifier algorithm. N=2 antennal preparations, with two blocks each. Two-way (distance, block) ANOVA was performed on a general linear model of the strand frequencies of each odor, yielding P values of 0.244, 0.165, 0.038, and 0.006 for Cit, Ac, Cit + Ac, and mix, respectively. Tukey's pairwise comparisons resulted in 95% confidence groupings indicated by *lettering* located *above* each *bar*; means having no letters in common are significantly different at $P \leq 0.05$. The mean number of strands classified (all three odors) in each of the replicates in this experiment was 383 for the 1-cm filter paper separation, 418 for 2 cm, 459 for 5 cm, and 414 for 10-cm separation. Total strand frequency (all three odors) diminished as spacing increased, going from 3.45, 3.54, and 3.80 to 2.83 per second at 1-, 2-, 5-, and 10-cm filter paper separation, respectively

in each panel, after strand detection. Training data obtained at 0 and 24 h for trial 1 are shown in Fig. 7a, b, respectively. Similarly, training data collected at 0 and 24 h are shown in Fig. 7c, d for trial 2 and Fig. 7e, f for trial 3. Only two channels were recorded in trial 1, while four (two of each species) were recorded (only two shown) in trials 2 and 3. The reason trial 1 has less data near the origin is that there is less noise immunity with only two channels. To show that the live preparations are effective for at least 24 h, we measured the performance of the classification system in terms of error rate for each trial at 0 and 24 h. We used the empirical error rate measure on re-substituted training data with the two-stage classification method outlined in Myrick et al. (2008). Briefly, this method uses a detection procedure (stage 1) to separate "significant" (compared to baseline activity) strands from "insignificant" strands prior to classification using a k-NN method (stage 2). Stage 2 allows for the rejection of ambiguous responses, which was not utilized here (ambiguity reject parameter of 0.0). The percent correct classification for each odor is shown in each panel with the order being (clockwise from the upper left) Z7-12:Ac, mixture, and Z11-16:Ald (Fig. 7).

Single Antenna Longevity When a different form of the whole-body preparation was employed and monitored by using single *T. ni* antennae, EAG responsiveness to different amounts of the major sex pheromone component, Z7-12:Ac, lasted for longer than 60 h (Fig. 8). The EAG responsiveness of the whole-body preparation was maintained without reduced amplitude compared to the first hour for greater than 50 h, with a relatively steep drop-off thereafter.

Discussion

Whole antennae have been used for EAGs that report the peak-to-trough fluctuations in odor strand flux that occur on a several Hertz basis in natural odor plumes (Vickers and Baker 1994; Baker et al. 1998; Vickers et al. 2001; Bau et al. 2002, 2005; Vickers 2006). Experimentally pulsed odorant strands showed that there is a temporal resolution of EAGs that is much higher than this: up to 25 Hz in *Bombyx mori*, 5 Hz for *Lymantria dispar* (Bau et al. 2005), 33 Hz for *Spodoptera exigua* and *Cadra cautella*, and up to 25 Hz in *Pectinophora gossypiella* (Bau et al. 2002). Characterization of the antenna as an information transducer revealed a simple linear first-order low-pass filter with a −3-dB bandwidth of approximately 10 Hz (*S. exigua*) and information carrying capacity of up to 37 bits/s. (Justice et al. 2005)

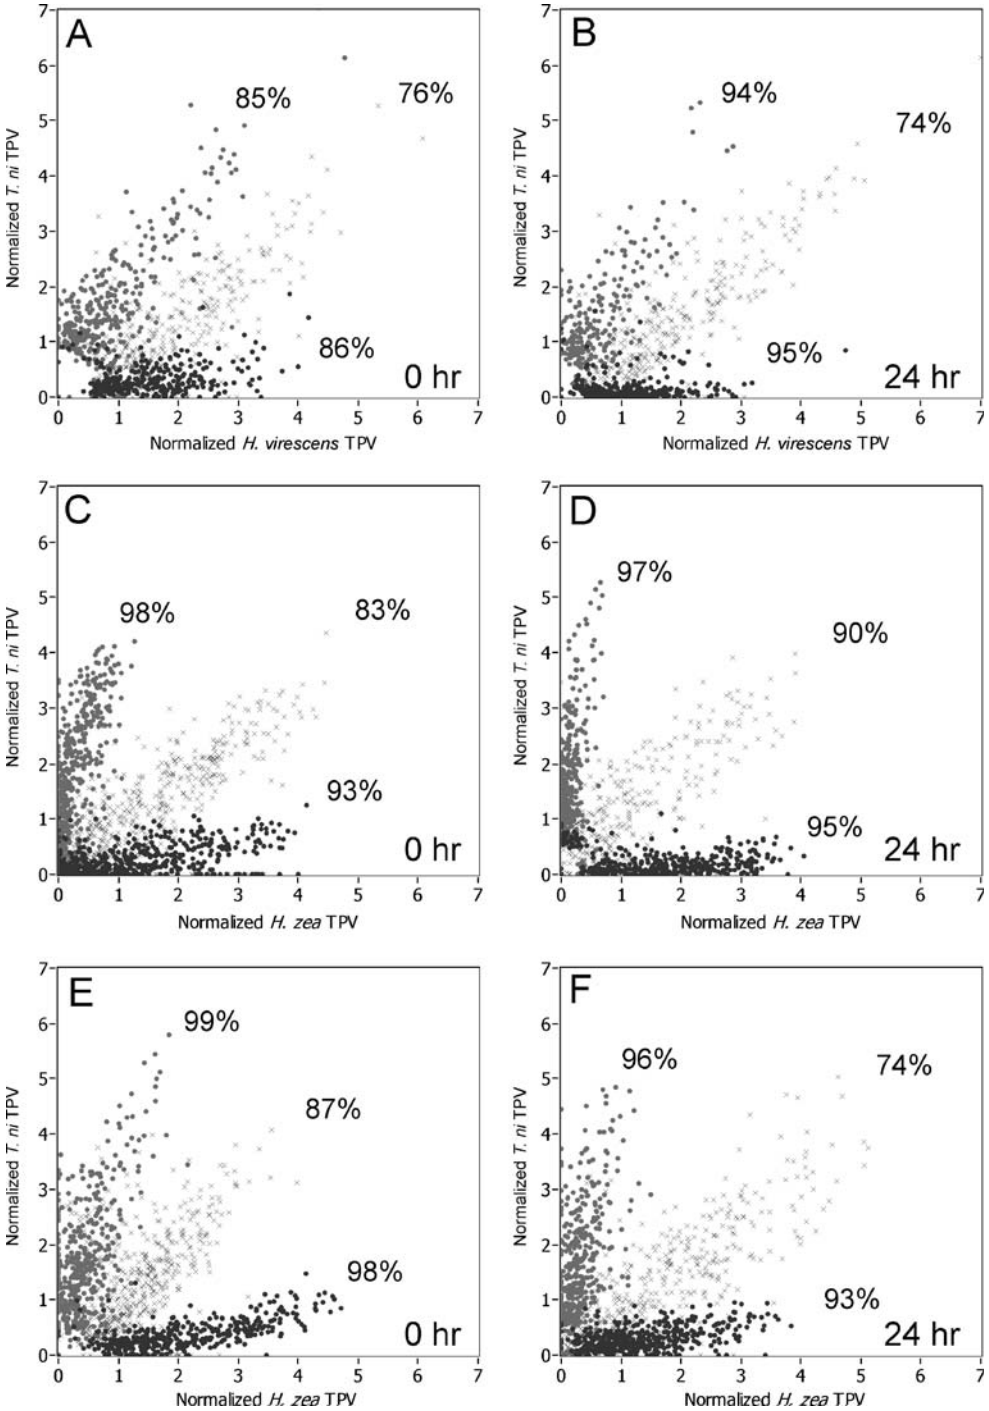

Fig. 7 Training data and classification accuracies (in percent) obtained from the Quadro-probe whole-body preparations over 24 h in response to strands of Z11-16:Ald, Z7-12:Ac, and the mixture of the two on the same filter papers presented as single-point-source odor plumes in the wind tunnel. *TPV* is trough-to-peak voltage. The four-antenna preparation was placed 1.5 m downwind of the filter paper source. Each *shaded symbol* is a classified response to an individual odor strand. *Black* = "aldehyde," *dark gray* = "acetate," *X symbol* = mixture. Highest depolarization amplitudes in response to odor strands were approximately 2 mV. **a**, **b** Trial 1 training data at 0 and 24 h, respectively. **c**, **d** Trial 2 training data at 0 and 24 h, respectively. **e**, **f** Trial 3 training data at 0 and 24 h, respectively. Each trial is a different whole-moth preparation. Error rates obtained (see text) for each re-substituted set of training data are converted into percent correct and labeled near the data corresponding to each odor; the percentages correspond to Ac, mix, and Ald in *clockwise* direction on each panel. Only one *T. ni* and one *H. zea*/*virescens* whole-moth EAG channel could be used for each two-dimensional depiction. N=3 replicates (trials)

Despite these previous successes of using single-antenna EAGs, quantification of the degree of odor strand mixing within overlapping odor plumes has not been possible to date because of an inability not only to detect but to classify on a strand-by-strand basis the odor strands in plumes comprised of different odorants. The present study shows that we can resolve incompletely mixed intertwined strands of odor within confluent plumes and classify their composition.

Our results show that two confluent plumes that on a time-averaged basis would appear to be perfectly mixed are in fact incompletely mixed when examined with the resolution provided by the insect antennal flux-detector tissue. We should now be better able to quantitatively relate an insect's behavior in response to complex odor plume interactions to the degree of mixing of plume strands that the insect experiences downwind. Experiments can be performed now not only with experimental pulses but also

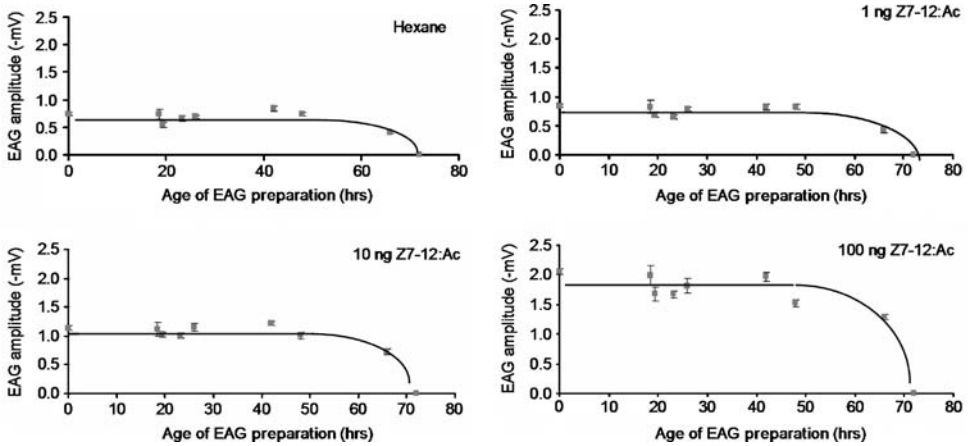

Fig. 8 EAG responsiveness of a whole-body preparation of male *T. ni* to different doses of Z7-12:Ac acetate over time (Mean± SE, $N \approx 7–45$)

with more natural point source plumes that overlap to different degrees.

The ability of the Quadro-probe to quantify incompletely mixed strands of odors that emanate from two or more different point sources is an apparent advantage of the insect antenna-based chemosensor over many other existing biomimetic artificial nose systems. In our experiments, only a small percentage of strands from two confluent plumes separated by more than 5 cm at their source in the wind tunnel arrived closely enough in time that the system declared them to be a "mixture." Further improvements on the system's range of odor measurement abilities will, of course, improve its applicability to more varied semi-ochemical systems that involve different combinations of odor plumes. In addition, improvement of the temporal resolution of the analysis software by further reducing its current 160-ms time window for declaring strands to be mixed vs. separate will more closely mirror insect olfactory systems' temporal resolution abilities.

Insects have been shown in behavioral experiments to discriminate between two confluent odor plumes as opposed to a blend of the two odorants placed on a single source (Witzgall and Priesner 1991; Liu and Haynes 1992; Baker et al. 1998). In behavioral studies, *H. zea* was able to distinguish between experimentally generated odor strands separated by 0.001 s in time and 1 mm in space (Baker et al. 1998; Fadamiro et al. 1999). There is also evidence in scarab beetles that puffs of two different pheromone components that arrive on ORNs with less than 1-ms separation cause different levels of ORN stimulation than when they arrive simultaneously (Nikonov and Leal 2002). Thus, the resolving power for this olfactory feat, at least in part, appears to result from mixture interactions that occur "on-site" (Baker et al. 1998; Todd and Baker 1999) between intimately associated ORNs that are co-compartmentalized within individual sensory hairs, pegs, or plates.

One of the most fragile aspects of any insect-antenna-based chemosensor has been its longevity of responsiveness. This has typically been less than 1 h (van Giessen et al. 1994; Hardie et al. 1994; Visser et al. 1996; Visser and Piron 1997; Park et al. 2002). The limited lifetime of the preparation has been a limitation in various other studies that employ living tissues as olfactory chemosensors (Kuwana and Shimoyama 1998; Kuwana et al. 1999; Schroth et al. 1999; Schütz et al. 1999). However, we have shown in this study that the longevity of the Quadro-probe EAG preparations can be improved significantly by using the entire moth bodies (Park and Hardie 1998; Park et al. 2002). Indeed, when whole-body preparations were used instead of isolated antennae, EAG responsiveness was shown to last up to 50 h with no decline in amplitude, and the fidelity of classifying odorants and blends of odorants by the multiantenna system could last as long as at least 24 h without significant reduction of response.

The extremely high sensitivity of insects' olfactory systems has been well documented (Angioy et al. 2003). A recent comparison between the peripheral position of this insect system, the antennae, and one of the most sensitive commercial electronic noses, the Cyranose 320, showed that insects have one to two orders of magnitude better sensitivity than the electronic nose (Rains et al. 2004). A BioFET chemosensor was developed by connecting an insect antenna to a field-effect transistor, showing that it could detect 1-ppb concentration of *Z*-3-hexen-1-ol (Schöning et al. 2000). We can hope that fully non-tissue-based chemosensors (Schaller et al. 1998; Walt et al. 1998; Drake et al. 2003) can be developed that mimic some of the features of insect antennae, especially their high sensitivity flux-detection abilities that can be of use for detecting and classifying strands of different odors in overlapping plumes.

Acknowledgements We dedicate this paper to the late Dr. Jan van der Pers of Syntech (Hilversum, The Netherlands) for his passionate devotion to developing wonderful research tools for insect olfaction and for providing a basis, through his lifelong research and technology development efforts, for understanding the rudiments of insect pheromone and host-odor olfaction. We also thank Bryan Banks,

Penn State University, for rearing the test insects and Drs. Junwei Zhu and Samuel Ochieng for helpful comments related to earlier versions of this study. This research was funded initially by the Controlled Biological Systems Program of Defense Advanced Research Projects Agency (DARPA) and subsequently by the Office of Naval Research (ONR) and the Defense Threat Reduction Agency (DTRA), through grants to TCB at Iowa State University (DARPA) and at Penn State University (ONR Counter-IED Program; DTRA). This research was also supported by a Keystone Alliance grant from the State of Pennsylvania, through Penn State University. The authors gratefully acknowledge the funding support from these sources.

Volatile Signals During Pregnancy: A Possible Chemical Basis for Mother–Infant Recognition

Stefano Vaglio · Pamela Minicozzi · Elisabetta Bonometti · Giorgio Mello · Brunetto Chiarelli

Received: 11 April 2008 / Revised: 2 August 2008 / Accepted: 28 October 2008 / Published online: 10 December 2008

Abstract Human pheromones play a role in regulating relationships and apparently influence partner choice and mother–infant recognition. We analyzed the chemical content of volatiles from sweat patch samples from the para-axillary and nipple–areola regions of women during pregnancy and after childbirth. Solid phase microextraction was used to extract the volatile compounds, which were then characterized and quantified by gas chromatography–mass spectrometry. During pregnancy, women developed a distinctive pattern of five volatile compounds common to the para-axillary and nipple–areola regions (1-dodecanol, 1-1′-oxybis octane, isocurcumenol, α-hexyl-cinnamic aldehyde, and isopropyl myristate). These compounds were absent outside pregnancy and had slightly different patterns in samples from the two body areas. Differentiation of the volatile patterns among pregnant women may help newborns to distinguish their own mothers.

Introduction

In animal species, recognition between individuals is a prelude to any kind of further interaction. Recognition between mother and newborn is a fundamental behavioral interaction that is worthy of systematic investigation. The emotional relationship between a mother and her newborn begins with mutual recognition, which starts during gestation and continues through and after birth, augmented by body contact and lactation. Imprinting takes place through visual, auditory, and olfactory learning, which occurs very early during the so-called "critical period" (Chiarelli 2003). Consequently, from the beginning of pregnancy, olfaction seems to represent an Ariadne's thread that permits the infant after birth to find its mother.

Pheromones regulate reproductive behavior in many mammalian species. Once released in the environment, through urine or glandular secretions, these volatiles reach other individuals, signaling mating availability and strengthening ties between mother and offspring, as well as regulating social relationships (Scalfari 1994; Chiarelli 2001). In nonhuman vertebrates, pheromones are detected by a specific sensory apparatus, the vomeronasal system, composed of a peripheral organ located at the base of the nasal septum, the vomeronasal nerve, and a nerve center, the accessory olfactory bulb. The vomeronasal system is

separated and independent from the main olfactory system (Døving and Trotier 1998; Chiarelli 2003). It is triggered by a different class of volatiles called "odorants" and is present in many reptiles and in almost all mammals, but it is absent in fish and birds, even if they possess a main olfactory system.

Primates, long considered functionally nonmicrosomatic, were thought previously to show complex olfactory communication only in prosimians and in some New World monkeys. Now, it is known that even higher primates use pheromones to recognize conspecific individuals and to mark territory (Michael and Keverne 1968; Michael et al. 1971; Keverne 1983). Furthermore, protein–pheromone complexes present in the secretions released by scent marking of some nonhuman primates have been shown to activate vomeronasal receptors, particularly for sexually related behaviors and intraspecific identification of individuals (Smith et al. 2001; Hayes et al. 2004; Palagi et al. 2004; Vaglio et al. 2004).

Formerly, it was widely held that the human vomeronasal organ was vestigial, and even the existence of pheromonal communication in humans was contested. Support for a role of pheromones in human behavior came from observational studies, e.g., synchronization of the menstrual cycle (Mc Clintock 1971), but this role was often denied because there seemed to be an insufficient neuroanatomic basis for such complex behavior (Pelucchi 2006).

Recently, a new class of olfactory receptors (trace amino-associated receptors) was discovered in the olfactory epithelium of mice (Liberles and Buck 2006). Genes similar to those responsible for the control of these receptors in mice have been identified in humans and fish, which suggest evolutionary conservation and lend support to the hypothesis that the human pheromonal response is mediated by receptors located in the main olfactory system (Pelucchi 2006).

Putative human pheromones are steroids present in the secretions of exocrine glands (Taylor 1994; Stern and Mcclintock 1998; Grosser et al. 2000; Pause 2004; Grammer et al. 2005; Hauser et al. 2005). Estrogen derivatives are present in females (the so-called copulins—mixtures of aliphatic acids such as acetic, propionic, butyric, isovaleric, and isocaproic acid with estratetraenol), and androgen derivatives are present in males (androstenol, androstenone, and androstadienone). Studies concerning the most volatile compounds of human sweat (Zeng et al. 1991, 1996a, b; Bernier et al. 2000; Curran et al. 2005) have shown that the characteristic odor produced by the para-axillary region is due to the presence of volatile C6–C11 acids; the most abundant is *E*-3-methyl-2-hexenoic acid.

Human pheromones also may play a role in offspring identification. Odor cues from newborns are salient to their mothers (Kaitz et al. 1987). Mothers can distinguish the odor of their own newborn baby from that of other newborns (Schaal et al. 1980; Kaitz et al. 1987; Chiarelli 2001). Experiments also have demonstrated that adults can recognize gender and individuality of nonrelated children (Ligabue Stricker 1991; Chiarelli 2001). Thus, body odors can provide humans with information about the individual identity of their offspring (Doty 1981; Porter and Moore 1981; Porter et al. 1983, 1985; Russell et al. 1983; Curran et al. 2005; Olsson et al. 2006).

Children usually prefer parts of clothes that have been in contact with the axilla and worn by their own mothers to clothes worn by other mothers (Schaal et al. 1980). Thus, pheromones seem to have a fundamental role in the mechanism of mother–child identification (Porter et al. 1983; Porter and Winberg 1999). Breast-fed versus bottle-fed infants show different reactions to maternal odors. Breast-fed infants are exposed to salient maternal odors and rapidly become familiarized with their mother's unique olfactory signature (Cernoch and Porter 1985). Apparently, orientation to lactating-breast odors is an inborn adaptive response of a newborn (Porter et al. 1991).

Without doubt, naturally occurring odors play a role in mediating infant behavior. Even fetal olfactory learning seems to occur (Varendi et al. 1996), and breast odors from the mother exert a pheromone-like effect at the newborn's first attempt to locate the nipple. Newborns generally are responsive to breast odors produced by lactating women (Porter and Winberg 1999). Olfactory recognition may be implicated in the early stages of the mother–infant attachment process, when newborns learn to recognize the own mother's unique odor signature: This process is facilitated possibly by high norepinephrine release and the arousal of the locus coeruleus at birth (Winberg and Porter 1998). Human infants are responsive to maternal odors that begin shortly after birth. They show an attraction to amniotic fluid (AF) odor that may reflect fetal exposure to that substance (i.e., prenatal olfactory learning; Varendi et al. 1996). Moreover, human AF seems to carry individualized odor properties, which are hypothesized to initiate parent–infant interactions (Schaal and Marlier 1998).

On the basis of these literature findings, we hypothesized that women probably develop a volatile profile through pregnancy and childbirth that enables identification of the mother by the newborn. The aim of the present research was to understand how the volatile pattern of pregnant women changes during pregnancy and, consequently, provide the possible chemical basis for mother–infant olfactory recognition.

Methods and Materials

Sampling Procedures Sweat samples were collected from a group (N=20) of 30- to 40-year-old pregnant women (mean

age=36.8 year). Sweat patches (PharmChem Inc., Fort Worth, TX, USA) were applied to para-axillary and nipple–areola regions for at least 24 h. The patch is basically a large band aid with an untreated cellulose pad that is sterile and devoid of chemical additives. Blank patches were prepared under the same experimental conditions and used as controls. Isopropanol was used to clean the skin prior to application of the patch. The patches can be worn for up to 7 days, with a minimum of 24 h, whereas patch "overlays," included in the kit, can be placed over the original to provide even more adhesion.

Samples were collected between July 2006 and October 2007 from three periods during pregnancy and after childbirth to permit an evaluation of the volatile pattern during and after the gestational period: (1) the second month of gestation (7–10th week of gestation), (2) the last month of gestation (at about the 35th week of gestation), and (3) after childbirth (at least 6 months after birth). These particular three-time periods were selected on the basis of pragmatic criteria: (1) the earliest possible time period during pregnancy (based on first awareness of pregnancy), (2) the latest possible time period during pregnancy (based on avoiding the risk of premature births), and (3) a distant time period after pregnancy (based on the need for the subject women to begin their regular rhythm of life and, above all, their menstrual cycles).

All participants in the study signed an informed consent form for this totally noninvasive investigation. Italian protocols for human subjects were followed. The participants also responded to a short questionnaire. On the first day, a brief personal obstetrician anamnesis (personal history) was developed, and on the second, questions were asked regarding potential food and/or emotional anomalies (e.g., stressful occurrences, sexual activity) encountered during the period of sweat patch application that could potentially modify the pheromonal profile. Sample collection was carried out from the para-axillary and nipple–areola regions with the following protocol: (1) Banned fragrances and deodorants were not used in the previous 24 h; (2) unusual food and/or stresses and emotional behaviors were not present in subjects; (3) sweat patches were applied, one to the para-axillary and one to the nipple–areola region; (4) sweat patches were removed after at least 24 h and inserted into 20-ml solid phase microextraction (SPME) vials, which were hermetically closed by teflon-faced rubber septa and aluminium seals with a fit hand crimper; and (5) vials with the sweat patches were maintained at −20°C and were transported to the laboratory for analysis.

Extraction, Characterization, and Quantification of Volatile Compounds A SPME syringe needle, coated with 30 μm of polydimethylsiloxane, was introduced through the vial septum (Supelco, Bellefonte, PA, USA). The vial was held at 60°C, and the fiber was exposed to the headspace above the sample for 20 min. Adsorbed volatile analytes were analyzed by gas chromatography–mass spectrometry (GC-MS) by using a DSQ mass spectrometer (Thermo Electron Corporation, Waltham, MA, USA) operated in electron impact (EI; 70 eV) mode and directly coupled to a Focus gas chromatograph (Thermo Electron Corporation, Waltham, MA, USA). The GC was equipped with a fused silica HP 5-MS capillary column (30 m×0.25 mm crossbonded 5% phenyl–95% dimethylpolysiloxane, film thickness 0.50 μm, Agilent Technologies, Santa Clara, CA, USA). The injector and transfer line temperatures were maintained at 220°C and 250°C, respectively. Injections were made in splitless mode with a constant flow of helium carrier gas of 1.1 ml/min. The oven temperature program, started at 40°C, was held for 3 min and then raised by 10°C/min to 100°C and in a second step by 5°C/min to the final temperature of 250°C. The eluted compounds were tentatively identified by comparing the experimental spectra with those of the NIST mass spectral library, Version 2.0 (Thermo Electron Corporation, Waltham, MA, USA). Authentic standards for confirmation of compound identities were purchased from Sigma Aldrich, Milan, Italy. The relative amounts of the compounds of interest were determined by integrating the areas of the corresponding peaks in the total ion current (TIC) profile. Percentages were calculated with respect to the most abundant compound.

Statistical Analyses The peaks in the TIC profile were taken as measures of the relative amounts of the volatile compounds of interest. Each compound was considered as a variable and, for further analysis, we assigned each compound a categorical value of 0 or 1: 1 indicated the presence of compound and 0 its absence. Questionnaires provided information about lactation, menstrual cycle, and the contingent occurrence of food and/or emotional anomalies.

The goal of the statistical analysis was to determine whether the presence/absence of the five volatile compounds was influenced by body area (A = para-axillary region, B = nipple–areola region), sampling time (1 = beginning of gestation, 2 = end of gestation, or 3 = after childbirth), and other variables collected on the questionnaire as listed above. To study these possible associations, we used a multiple logistic regression model, a particular type of generalized linear model for binary data that is used to study the relationship among dependent variables (also known as response and independent binary variables; statistical package "R", Version 2.7.2, Free Software). The dependent variable was the presence/absence of each volatile compound (1-dodecanol, 1-1′-oxybis octane, isocurcumenol, α-hexyl-

cinnamic aldehyde, or isopropyl myristate, see below), whereas the independent variables were the body area, the sampling time, the contingent occurrence of food and/or emotional anomalies, and the possible presence of lactation and/or menstrual cycle.

A reweighted least squares method (statistical package "R", Version 2.7.2, Free Software) was used to fit the data in the regression model. Statistical significance of the associations was determined by analysis of variance (α= 0.1 for significance; statistical package "R", Version 2.7.2, Free Software).

Results

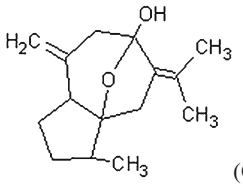
Identification of Volatile Compounds During pregnancy, all women developed a distinctive volatile pattern represented by five compounds common to the para-axillary and nipple–areola regions (see below). The five compounds (R_t) are (**A**) 1-dodecanol (17.83 min), (**B**) 1-1′-oxybis octane (21.60 min), (**C**) isocurcumenol (21.79 min), (**D**) α-hexyl-cinnamic aldehyde (23.27 min), and (**E**) isopropyl myristate (24.54 min). Identification of all commercially available compounds (**A**, **B**, **D**, **E**) was confirmed by comparison of the retention times and mass spectra with those of authentic standards. Compound **C** was identified as isocurcumenol by comparison with the EI mass spectrum of isocurcumenol reported in the literature (Yang et al. 2005), where the mass spectrum of the isomer curcumenol also is reported: The fragmentation of the two isomers is completely different.

$CH_3(CH_2)_{11}OH$ (**A**)

$[CH_3(CH_2)_7]_2O$ (**B**)

$C_6H_5CH{=}C[(CH_2)_5CH_3]CHO$ (**D**)

$CH_3(CH_2)_{12}COOCH(CH_3)_2$ (**E**)



(**C**)

The five compounds, which were absent in the analysis of blank patches, were the only recurrent volatile compounds within the three sample periods. They were not detected in an equivalent control sample of nonpregnant and nonlactating females (Fig. 1). Thus, the volatile composition changes during pregnancy.

Effect of Body Area, Time, Lactation, Menstrual Cycle, Food, and/or Emotional Anomalies The effects of various independent variables from the multiple logistic regression

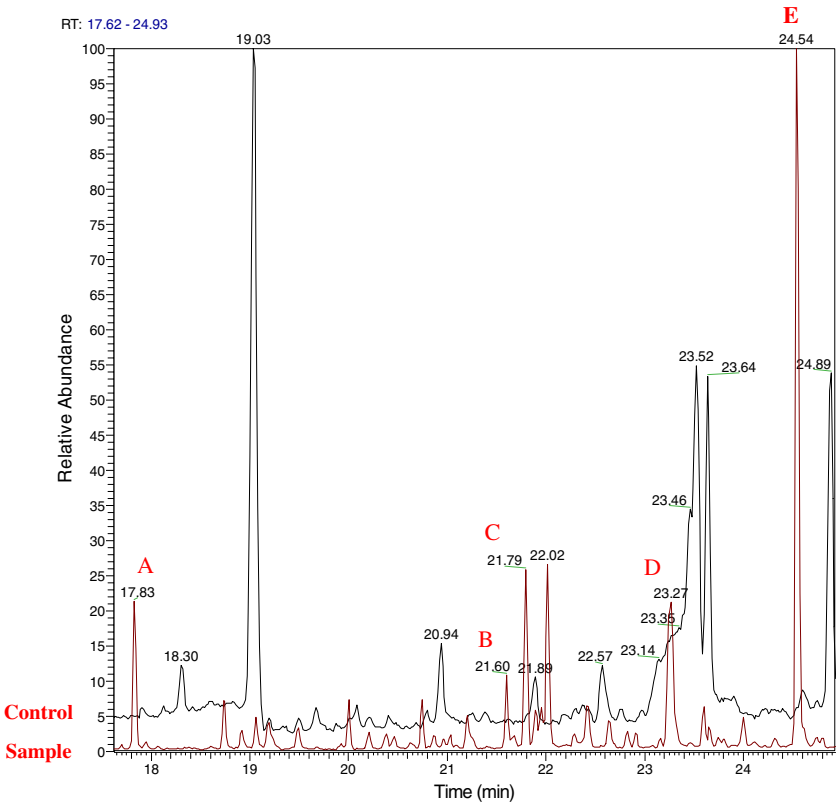


Fig. 1 TIC profile of a nipple–areola sample during pregnancy (*red*/*bottom*) compared to a similar sample from a nonpregnant and nonlactating control (*black*/*top*). The range corresponds to the elution of the five frequently occurring compounds (1-dodecanol, R_t=17.83 min, *A*; 1-1′-oxybis octane, R_t= 21.60 min, *B*; isocurcumenol, R_t=21.79 min, *C*; α-hexyl-cinnamic aldehyde, R_t=23.27 min, *D*; isopropyl myristate, R_t= 24.54 min, *E*). It focuses on the period between R_t=17.60 and 25.00 min that has been normalized. The unlabeled peaks reflect compounds not common to all samples

on the dependent variables (presence/absence of 1-dodecanol, 1-1′-oxybis octane, isocurcumenol, α-hexyl-cinnamic aldehyde, or isopropyl myristate) are as follows:

1. The occurrence of lactation during the third sampling period (after childbirth) did not affect the presence/absence of any volatile compound (1-dodecanol, $P=1$; 1-1′-oxybis octane, $P=0.400$; isocurcumenol, $P=0.209$; α-hexyl-cinnamic aldehyde, $P=0.270$; or isopropyl myristate, $P=1$), nor did the return of the menstrual cycle (1-dodecanol, $P=0.209$; 1-1′-oxybis octane, $P=0.400$; isocurcumenol, $P=0.209$; α-hexyl-cinnamic aldehyde, $P=0.270$; or isopropyl myristate, $P=1$).
2. No independent variable (body area, sampling time, food, and/or emotional anomalies) affected the presence of α-hexyl-cinnamic aldehyde (model with food anomalies as independent variable—body area, $P=0.142$; second sample period, $P=0.998$; third sample period, $P=0.788$; and food, $P=0.469$; model with emotional anomalies as independent variable—body area, $P=1$; second sample period, $P=0.998$; third sample period, $P=0.584$; and emotions, $P=0.436$).
3. No independent variable (body area, sampling time, food, and/or emotional anomalies) affected the presence of isopropyl myristate (model with food anomalies as independent variable—body area, $P=1$; second sample period, $P=1$; third sample period, $P=1$; and food, $P=1$; model with emotional anomalies as independent variable—body area, $P=1$; second sample period, $P=1$; third sample period, $P=1$; and emotions, $P=1$).
4. The combination of body area with food anomalies ($P=0.066$) and emotional anomalies ($P=0.046$) affected the presence of isocurcumenol.
5. The combination of sampling time with food anomalies ($P=0.051$) and emotional anomalies ($P=0.073$) affected the presence of 1-1′-oxybis octane.
6. The combination of sampling time and emotional anomalies ($P=0.053$) affected the presence of 1-dodecanol.

Additionally, a chi-square test supports these conclusions (data not shown). Since the control values were equal to 0, they were not included in the statistical analysis.

Qualitative Analyses The patterns of the relative occurrence of the five volatile compounds in the samples varied with the body regions and the time of sampling (Fig. 2). In early gestation, nearly all samples from the nipple–areola region contained all five volatile compounds. Fewer samples from the para-axillary region had the compounds during early gestation. In late gestation, the five components were detected in nearly all samples from both body areas, whereas after childbirth, the fraction of samples that contained the compounds declined dramatically in both body areas. After childbirth, 1-1′-oxybis octane was not detected in any of the nipple–areola region samples and in only 20% of the para-axillary samples. Only isopropyl myristate was present at a high frequency in the samples after childbirth.

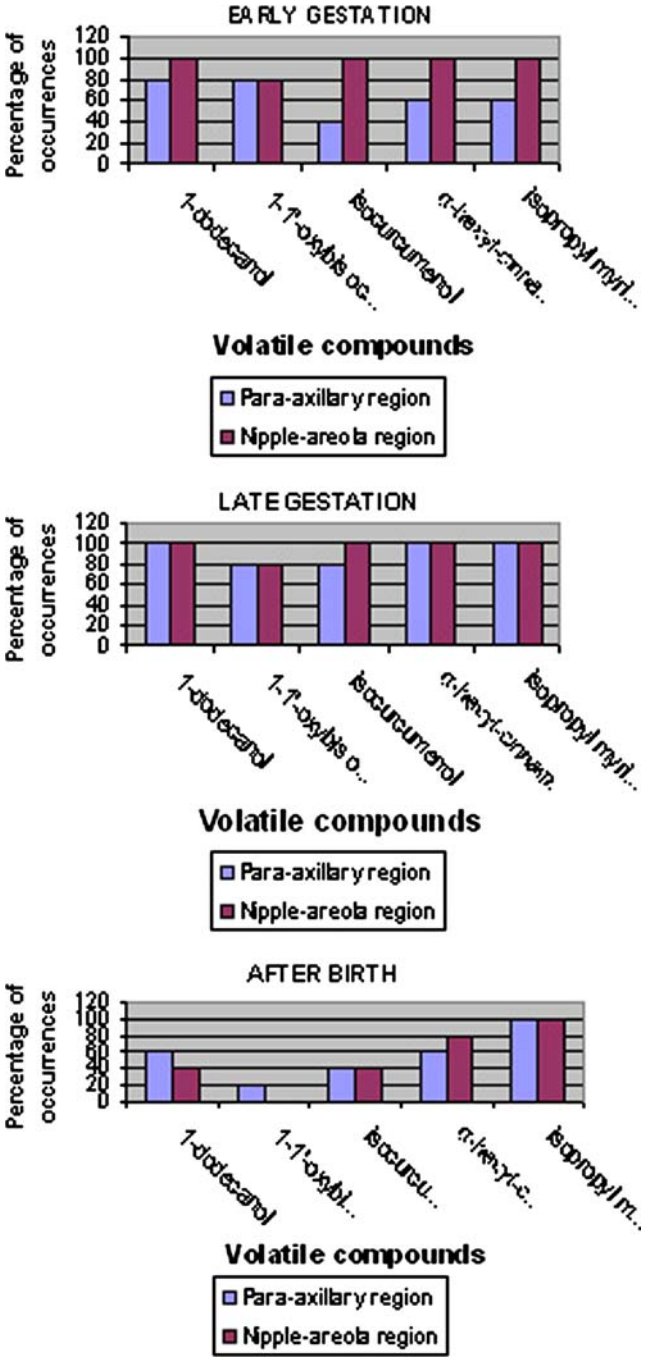

Fig. 2 Comparison of relative frequency of occurrence of volatile compounds in samples from the para-axillary and nipple–areola regions from women ($N=20$) during three sampling periods

Relative Quantitative Analyses The amounts of the five compounds relative to the most abundant compound in each

sample also varied with sampling period in the two different body areas. The para-axillary region (Fig. 3) was characterized by a pattern with generally high levels of 1-dodecanol, 1-1′-oxybis octane, isocurcumenol, and α-hexyl-cinnamic aldehyde during pregnancy and a subsequent decline in abundance to nearly complete disappearance of most of these compounds after childbirth. The relative amount of isopropyl myristate in the para-axillary samples was high during pregnancy and increased after childbirth. The nipple–areola region (Fig. 4) was characterized by a similar pattern but with greater relative amounts of isocurcumenol during late gestation and lower relative amounts of isopropyl myristate during pregnancy.

Discussion

Our data showed that during pregnancy, all women developed a distinctive olfactory pattern that involved at least five volatile compounds. This pattern was absent in

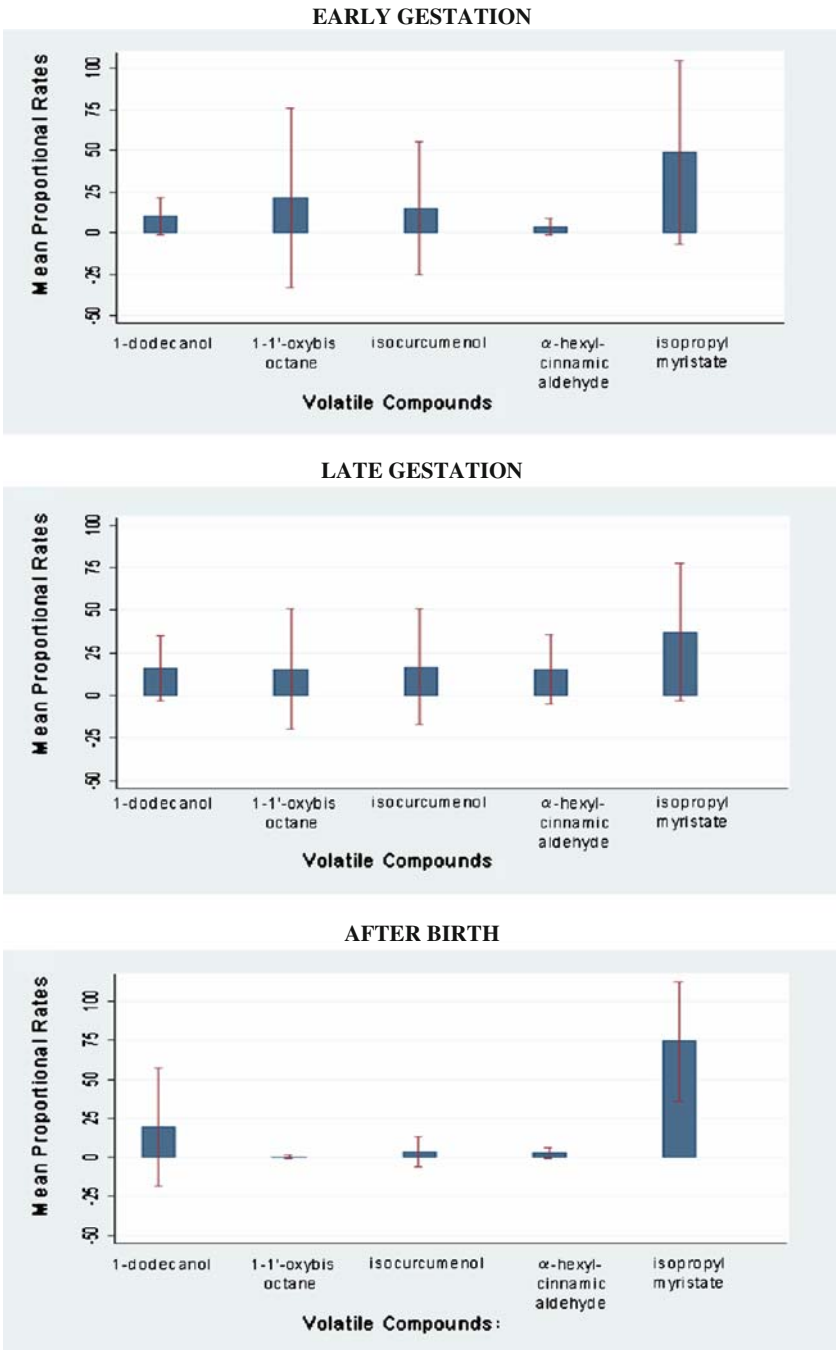

Fig. 3 Relative amounts (mean ± 2 standard error, N=20) of five volatile compounds in samples from the para-axillary region during three sampling periods

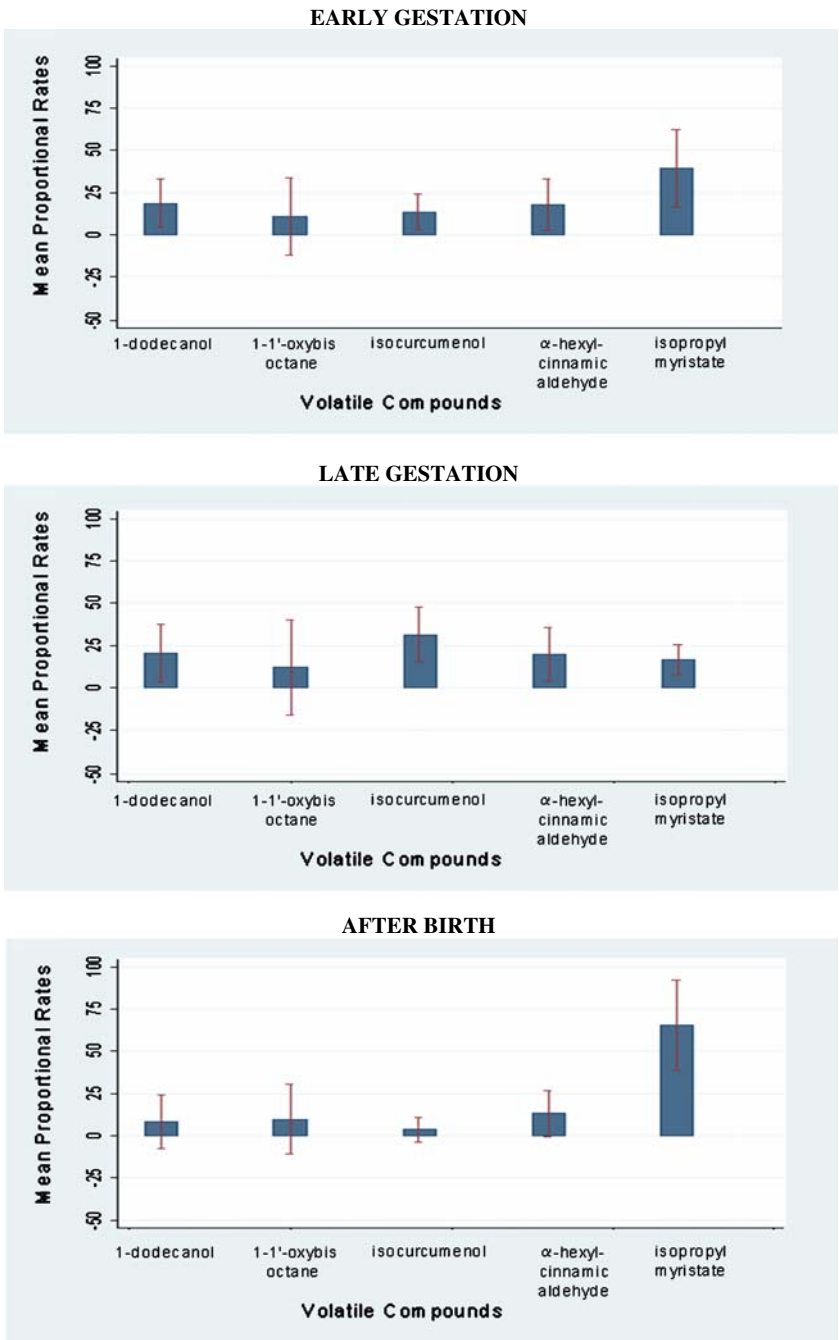

Fig. 4 Relative amounts (mean ± 2 standard error, N=20) of five volatile compounds in samples from the nipple–areola region during three sampling periods

samples from nonpregnant and nonlactating control subjects but was present in samples taken during pregnancy as well as after childbirth. The compounds were present in samples from both the para-axillary and the nipple–areola regions. The precise time periods selected for sample collection were chosen on the basis of pragmatic criteria. The collection times that produced the above mentioned results were not fixed points but a series of "windows" suitable for collection.

From a qualitative point of view (Fig. 2), we can infer that α-hexyl-cinnamic aldehyde and isopropyl myristate remain constant like a matrix in the pattern, isocurcumenol functions as a distinctive signal between para-axillary and nipple–areola regions, and 1-dodecanol and 1-1′-oxybis octane behave as indicators for different periods of the pregnancy. Surprisingly, after childbirth, this pattern did not appear to be influenced by factors such as lactation or the menstrual cycle but was modified by food and emotional anomalies. In particular, 1-1′-oxybis octane was affected by food anomalies; 1-1′-oxybis octane and 1-dodecanol were affected by emotional anomalies (data not shown). From the relative quantitative results, we infer that isopropyl

myristate represents a matrix of the pattern in both body regions and during all three sample periods, whereas 1-dodecanol, 1-1′-oxybis octane, isocurcumenol, and α-hexyl-cinnamic aldehyde behave as indicators for different phases of pregnancy, contemporaneously working as distinctive signals between the para-axillary and nipple–areola regions.

The presence of these volatile compounds and the related pheromonal role for some of them in other species may have implications from the point of view of evolution and phylogeny. First, three of the compounds identified in this study (oxybis octane, isocurcumenol, and α-hexyl-cinnamic aldehyde) have not been found previously in any other animal species. Oxybis octane for instance has apparently never been found to have a significant biological role, and isocurcumenol is rather widespread but as a volatile compound produced by some plants (Ha et al. 2002; Yang et al. 2005; Zhou et al. 2007). α-Hexyl-cinnamic aldehyde has frequently been utilized as a fragrance in both cosmetic and detergent products (Rastogi et al. 1996; Kanei et al. 1999). Dodecanol and isopropyl myristate have been suggested previously to have a pheromonal role in both humans and other animal species. For example, 1-dodecanol has been identified as a volatile compound from the plant *Houttuynia cordata* Thunb. (Liang et al. 2005), as precursor of the main sex pheromone of the female of the crab, *Erimacrus isenbeckii* (Masuda et al. 2002), as a pheromone in the anogenital marking of males and females of *Lemur catta* (Hayes et al. 2004), and as a volatile compound of human sweat (Meijerink et al. 2000, 2001). Isopropyl myristate is one of the main volatile compounds produced by the human axilla, and it is also often utilized as a component of deodorants and other cosmetic products (Labows et al. 1979). This compound is a volatile component of the head, thorax, and alimentary canal of the ant *Iridomyrmex humilis* (Cavill and Houghton 1974) and as a sex pheromone that (together with heneicosane, docosane, nonacosane, and octadecanes) stimulates oviposition in the mosquito, *Aedes aegypti* (Corkum and Belanger 2007).

Based on our results, we hypothesize that the distinctive chemical pattern of the para-axillary area could be useful for newborns to recognize their own mothers and distinguish them from other individuals. The pattern of volatiles from the nipple–areola region may function as an aid to finding sustenance. The results also demonstrate the effectiveness of the methodology. By using this collection and analysis method, we investigated the volatile compounds in a systematic way. Previously, such phenomena often have been investigated with inadequate methodologies, and as a consequence, the role of volatile compounds likely has been underestimated. The behavioral mechanisms related to these potential chemical signals bear future investigation in humans.

There are practical implications of the present research. The study of the mechanism of mother–child identification is important for the acquisition of new knowledge concerning the emission of signal molecules essential for mother–child identification and also for setting the proper conditions for establishing solid mother–child bonding. An understanding of the mechanisms of newborn recognition of mothers also could have practical health implications. Moreover, the research provides a basis for testing hypotheses about the role of pheromones in the evolution and phylogeny of humans. It seems apparent that pheromones influence a wide range of reproductive behavior, a central theme to the survival of any species, a subject long underestimated for its impact on human behavior and evolution.

Acknowledgment We thank the women who participated in the present research. We also thank Benedetta Zavelle de Louvigny for sharing in data collection, Domenico Rocco for supervising SPME extractions and GC–MS analyses, Franca Ligabue Stricker for valuable suggestions for this research, Roscoe Stanyon for a review of the manuscript, and IN.SER. s.p.a. for financial support.

Is (−)-Catechin a Novel Weapon of Spotted Knapweed (*Centaurea stoebe*)?

Received: 31 October 2008 / Revised: 5 December 2008 / Accepted: 10 December 2008 / Published online: 20 January 2009

Abstract The novel weapons hypothesis states that some invasive weed species owe part of their success as invaders to allelopathy mediated by allelochemicals that are new to the native species. Presumably, no resistance has evolved among the native species to this new allelochemical (i.e., the novel weapon). In their native habitat, however, the plants that co-evolved with these invasive species have theoretically evolved defenses that obviate the allelochemical advantage. Previous studies have claimed that catechin is such a novel weapon of spotted knapweed (*Centaurea stoebe* = *C. maculosa*), an invasive species in the non-native habitat of North America. These studies indicated that (−)-catechin is more phytotoxic than (+)-catechin. Other studies have not found sufficient catechin in field soils to support this theory. We report that (−)-catechin and (+)-catechin are essentially equal, but poorly phytotoxic to a variety of plant species in bioassays without soil. In a dose/response experiment with Montana soils, we found the lowest dose for a growth reduction of two native Montana grasses (*Koeleria macrantha* and *Festuca idahoensis*) by a racemic mixture of (±)-catechin that ranged from about 25 to 50 mM, concentrations, orders of magnitude higher than expected in nature. Autoclaving the soil before adding the catechin did not affect the activity of catechin. We found (−)-catechin to be a potent antioxidant, in contrast to a previous claim that it acts as an allelochemical by causing oxidative stress. Our findings suggest that catechin is not a novel weapon of spotted knapweed and that other allelochemical(s) or alternative mechanisms must be found to explain the success of this species as an invader in North America.

Introduction

Some invasive plant species are apparently allelopathic and may owe part of their success in new habitats to this trait (Weston and Duke 2003). Claims have been made that the success of *Centaurea stoebe* (= *C. maculosa*; spotted knapweed) in North America results from allelopathy via the release of (−)-catechin [(2*S*,3*R*)-(−)-catechin] (Bais et al. 2002, 2003; Weir et al. 2003; Thelen et al. 2005; Callaway and Ridenour 2004; Inderjit et al. 2008). This compound was reported to be exuded from the roots of spotted knapweed, and it was identified as the putative allelochemical of this invasive species (Bais et al. 2002). The (+)-catechin enantiomer [(2*R*,3*S*)-(+)-catechin] is also

produced by the plant, but was initially reported to be nonphytotoxic (Bais et al. 2002) and later 1.5 to two times less active than (−)-catechin (Veluri et al. 2004, erratum).

Catechin is a commonly found flavonoid present in fruits, wine, vegetables, and cocoa products, as well as in many nonfood plants. Grape seeds contain a significant amount of (+)-catechin and (−)-epicatechin. Most foods contain the (+)-enantiomer of catechin, but chocolate mainly contains (−)-catechin together with (−)-epicatechin. (+)-Catechin is the most commonly found enantiomer in nature. Both enantiomers possess antioxidant properties. The two enantiomers have identical nuclear magnetic resonance (NMR) spectra and high-performance liquid chromatography (HPLC) retention times and identical R_f values in thin layer chromatography (TLC). The only difference is in optical rotation and the CD spectra, where these two compounds rotate plane polarized light equally in opposite directions. The CD spectra of these enantiomers are antipodal. The mirror image differences in molecular shape can result in differences in biological activity (e.g., Donovan et al. 2006).

Multiple studies have examined various aspects of the role of (–)-catechin as an allelochemical (Bais et al. 2003; Weir et al. 2003, 2005; Veluri et al. 2004; Callaway et al. 2005; Perry et al. 2005; Thelen et al. 2005). This work, in part, laid the groundwork for the novel weapons hypothesis, which states that the success of some exotic invasive plant species may be due to the production of allelochemicals that native species have never encountered and, thus, to which they have not evolved defenses (Callaway and Ridenour 2004).

Blair et al. (2005, 2006, 2009) questioned the findings of (−)-catechin as the allelochemical responsible for the successful invasion of spotted knapweed. They found that the methods for catechin extraction described in previous papers (Bais et al. 2002, 2003; Weir et al. 2003) could not extract catechin from liquid media and produced low recovery efficiencies from soil. With methods that were much more efficient for catechin extraction, they quantified levels of production up to two orders of magnitude less with plants grown in media than stated in earlier publications. A grass species (*Festuca idahoensis*) native to some of the spotted knapweed-infested areas of North America was only slightly affected by racemic catechin concentrations 20-fold higher than those previously reported to cause 100% mortality (Blair et al. 2005). Lastly, no measurable concentrations of catechin could be detected in soil samples from two spotted knapweed sites in Montana, USA. The last issue was countered with the argument (Inderjit et al. 2006) that catechin can be found only at certain times in these soils and that Blair et al. (2005) had sampled at the wrong time of the year (October, 2004). Blair et al. (2006) sampled three field sites through the summer and fall of 2005 and detected catechin at only one time point at two of the field sites at levels, three orders of magnitude lower than what they had previously reported to reduce growth of *F. idahoensis*. Later, Perry et al. (2007) found little or no catechin in 402 soil samples from 11 *C. stoebe* sites, except on one sampling date, when all of the samples from one site had levels of catechin of 0.65±0.45 (SD) mg g^{-1}. In this paper, the authors were less firm than they were previously in their hypothesis that catechin plays a role in the allelopathy of spotted knapweed.

Although many natural compounds can be shown to be phytotoxic in the laboratory or greenhouse, to prove allelopathy, it is ultimately necessary to demonstrate the presence of the compound under natural field conditions at concentrations high enough to have an impact on neighboring plants (Cheng 1995; Romeo 2000). In solution, catechins can be phytotoxic to plants, including algae (Buta and Lusby 1986; D'Abrosca et al. 2006), but there is inadequate evidence of its activity in soil. In this paper, we present evidence that is consistent with the findings of Blair et al. (2005, 2006, 2009) and others (Tharayil et al. 2008). We report that both (+)- and (−)-catechin are weak phytotoxins on a variety of plant species in liquid or agar cultures and that they are essentially inactive as phytotoxins in soil.

Methods and Materials

Plant Material Lettuce seeds (*Lactuca sativa* L. cv. Iceberg A) were obtained from Burpee Seed Company and creeping bentgrass seeds (*Agrostis stolonifera* var. Penncross) from Turf-Seed (Hubbard, OR, USA). Duckweed (*Lemna paucicostata* Hegelm. 6746) was from a stock maintained in our laboratory since it was brought to us from Japan (Matsumoto and Duke 1990). These species were selected because we have used them to evaluate thousands of synthetic and natural compounds for phytotoxicity (e.g., Dayan et al. 2000, Michel et al. 2004).

Arabidopsis thaliana (accession Columbia-0/Redei-L206440) seeds were obtained from Lehle Seeds (Round Rock, TX, USA). *Arabidopsis* was used because the original papers that claimed (−)-catechin to be a novel weapon used it as one of their test species (Bais et al. 2002, 2003).

Seeds of junegrass (*Koeleria macrantha*) and Idaho fescue (*F. idahoensis*) were obtained from Western Native Seed (P. O. Box 188, Coaldale, CO, USA). These species were selected because they are native to the areas infested by spotted knapweed in North America, and they had been reported previously to be sensitive to catechin (Bais et al. 2003).

Chemicals The three catechins used [(+)-catechin hydrate, (−)-catechin, and (±)-catechin hydrate] were obtained from Sigma-Aldrich, for experiments in which small amounts were needed. The enantiomeric structures of (−)- and (+)-catechin in different lots of these chemicals were verified by circular dichroism spectroscopy (JASCO, Model J-715). All concentrations of catechins used in nonsoil bioassays were prepared by serial dilution from 10 mM stock solutions prepared in 5% (*v*/*v*) acetone. Epicatechin, catechinic acid, mannitol, and quercitin also were purchased from Sigma-Aldrich.

For soil studies, (−)–catechin was synthesized by adding 5 g of (−)-epicatechin to N_2 gas-saturated aqueous 5% NaOH (*w*/*v*) (75 ml) and stirring under N_2 for 10 min at 65°C. The mixture was cooled on ice, acidified to about pH 3 with about 60 ml of ice cold 2 N HCl, and extracted with ethyl acetate (3×200 ml). The organic layer was dried over anhydrous Na_2SO_4, and the viscous solution (ca 30 ml) was applied to a Sephadex LH-20 column (35 mm id×40 cm) equilibrated with ethanol/H_2O (85:15, *v*/*v*). The fractions were monitored by TLC and HPLC using (+)-catechin as the reference. The two enantiomers have the same retention time. (−)-Catechin-enriched fractions were pooled and concentrated to obtain 1.5 g of material. This was further purified with a C-18 gravity column (12 cm× 3.4 cm id) equilibrated with 10% MeOH and water. (−)-Catechin-enriched fractions were pooled, evaporated at 40°C to remove MeOH, freeze dried, and crystallized with methanol and CH_2Cl_2 to yield 420 mg of white needle-like crystals. The identity of the compound was confirmed as catechin by HPLC and NMR, and the absolute configuration was determined by comparison of CD spectra with those of (+)- and (−)-catechin.

Bioassays without Soil Lettuce seeds were surface disinfected with a 10% Chlorox® solution (6.15% *w*/*v* sodium hypochlorite) for 20 min, followed by 1 h of continual rinsing with sterile distilled water. Seeds were air-dried overnight in a Nuaire Biological Safety cabinet. Sterile techniques were used when handling.

Two milliliters of the appropriately diluted solutions of (−), (+), or (±)-catechin (initially dissolved in acetone to give a 5% acetone concentration in the final dilution) were added under sterile conditions to a 9-mm circle of sterile filter paper (Whatman no. 1) in a sterile, disposable Petri dish (Falcon no. 351005 Optilux Petri dish 100×20 mm). A solvent control set of dishes was prepared in the same manner using 5% acetone. In one experiment, the pH values of the test solutions were adjusted with either 0.1 M NaOH or 0.1 M HCl, depending on the pH desired. Fifteen lettuce seeds were added to the moistened paper. The dish was covered, sealed with a strip of parafilm, wrapped in aluminum foil to prevent light from entering, and then placed in a dark incubator (Percival Scientific, Model E-30LED3) at 25°C for a 7-day incubation period. Growth was in darkness in order to obtain maximal hypocotyl growth. Four replicates were prepared for each catechin concentration and the control. After 7 days, the dishes were removed, unwrapped from the foil, and placed under light in another incubator (Percival Scientific, Model CU-36L5) at 25°C for 1 day in order for chloroplast development to occur. After the 24-h light cycle, the dishes were removed from the incubator, and the root and hypocotyl lengths were determined. In all treatments, including the control, there were a few ungerminated and/or stunted seedlings, so only the ten most robust plants in each dish were measured. Averages from the measurements from the ten plants per dish were determined. The average of the four means and SE of the means from the four dishes were plotted. Bentgrass bioassays were conducted as previously described (Dayan et al. 2000).

Highly phytotoxic compounds, especially those that cause photooxidative damage, eventually cause loss of chlorophyll. Chlorophyll analysis was done by extracting at least 10 mg of lettuce cotyledon or bentgrass leaf tissue with 2 ml of dimethyl sulfoxide (DMSO) for 1 h at 60°C to 62°C according to the method of Hiscox and Israelstam (1980). There was no further diluting necessary prior to spectrophotometric analysis (Shimadzu UV-3101 PC UV-VIS-NIR). The chlorophyll–DMSO extracts were cooled to room temperature and absorbance at 645 and 663 nm measured with DMSO as the blank. Chlorophyll concentration was determined by the equation of Arnon (1949). The average of the chlorophyll content in lettuce cotyledons or bentgrass leaves was determined.

Duckweed plants were grown and treated with catechins as previously described for herbicides (Michel et al. 2004). Growth was determined nondestructively by image analysis of frond area as described in detail by Michel et al. (2004). Each treatment was conducted in quadruplicate, with SEs of means generated from the data.

A. thaliana plants were treated with catechin in a manner similar to that of Bais et al. (2003). Seeds were sterilized by the method of Baerson et al. (2005) and then placed in filter paper-lined, 6-cm Petri dishes in 3 ml of half strength MS medium (Murashige and Skoog 1962) under a 16:8-h L:D photoperiod at 21°C. The plates were sealed with 3 M surgical tape. Plants were grown for 10 days under these conditions, and then the most robust plants were transferred to 24-well plates (three seedlings per well) containing half strength MS medium with different amounts of (+), (−), or (±)-catechin (initially dissolved in acetone to give a 5% final acetone concentration) or control wells. There were 12 wells of three plants each for each treatment. After 4 days, root lengths were determined, and then all plants were replaced in 24-well plates with half strength MS medium without catechins for 4 days.

In another experiment, square Petri dishes (9×9×1.5 cm) were used for *A. thaliana* bioassays as before (Baerson et al. 2005) with the following modifications. Seeds were germinated and seedlings grown on sterile, semisolid Gamborg's B5 (Gamborg et al. 1968) at a pH of 5.7 with minimal organics (Sigma-Aldrich) supplemented with 10 g/l sucrose. The media of some of the plates was amended with (+)-catechin, (+/−)-catechin, or (−)-catechin. Acetone was used as a solvent where each plate contained 1.0% (*v*/*v*) acetone. The controls contained the same amount of acetone. Plants were grown in a controlled environment chamber (Percival) under a photoperiod of 16 h light illuminated at 100 μmol m^{-2} s^{-1} photosynthetically active radiation (PAR) and 8 h dark at 22°C for 14 d. Photographs were taken at day 14.

Bioassays in Soil Metromix 350 potting soil (Hummert International, Earth City, MO, USA) was used in some studies. This mixture contains horticultural grade vermiculite, peat moss, processed bark ash, nutrients, dolomite limestone, and a wetting agent.

In other studies, soil from near the towns of Nelson Gulch and Jens, Montana collected in October, 2005 was used. GPS coordinates for the two sites are: Nelson Gulch 46°34.373′ N 112°8.820′ W 4,273 m and Jens Exit 46° 36.359′ N 113°00.832′ W 4,136 m. Further details of the collection sites are provided in Blair et al. (2006). These soils were shipped to Oxford, MS, USA, where they were stored at room temperature until use in bioassays. The storage time varied from days to months, depending on when the experiment was done. The Montana soils were screened to remove rocks and larger organic fragments with a sieve used for sifting flour and then finally screened with a USA standard testing sieve (Tyler 35 mesh equivalent, 425 μm). Ten grams of air-dried soil was placed in 6-cm Petri dishes with different amounts of (±)-catechin or (−)-catechin. Catechins were incorporated by sifting the soils several times with the appropriate amount of the dry chemical. In some studies, the soils were autoclaved (three cycles of 30 min at 121°C, followed by 30 min cooling) before use to eliminate potential effects of soil microflora on catechin. Seeds of junegrass or Idaho fescue pretreated with 0.2% (*w*/*v*) KNO_3 to induce uniform germination were planted (25 seeds/dish) in soils from Nelson or Jens soil to which 5 ml of distilled water were added. The dishes were then placed in growth chambers at 24°C with 14-h photoperiods and 70 μmol m^{-2} s^{-1} PAR. The five most robust plants from each dish were selected, and plant height, fresh weight, and, in some cases, dry weight were determined 10 to 13 days after planting.

Determination of Free Radical Quenching of Catechins The method of Cespedes et al. (2001) was used to detect ROS quenching of natural compounds. Silica gel TLC plates (GF_{254} 250 μm, Analtech) were spotted with approximately 2.5 μl (2 mg/ml in methanol) of (+)-catechin, (−)-epicatechin, (−)-catechin, the antioxidant quercetin (Hollman et al. 1997; Zhang et al. 2008), and the nonquenching compound mannitol. Plates were developed in toluene/acetone/methanol (6:3:1) with two drops of acetic acid per 10 ml. After eluting, TLC plates were dried and sprayed with a 0.2% 2,2-diphenyl-1-picrylhydrazyl (DPPH) solution (*w*/*v*) in methanol. Plates also were exposed to iodine vapor. The plates were photographed 30 min after spraying. Antioxidant activity was evidenced by appearance of yellow spots against a purple background.

Analysis of Data Experiments were repeated in time and space. Data were analyzed with the SAS Software release 9.1 (SAS Institute, Cary, NC, USA). Analysis of variance was performed for each compound concentration, and means were tested with Duncan multiple range test. SEs are also provided to show the variation associated with particular means. Data from dose–response experiments were analyzed with the add-on package for dose–response curves (drc; Ritz and Streibig 2005), for R version 2.2.1 (R Development Core Team 2005) using a four-parameter logistic function. Means and SEs were obtained using the raw data, and I_{50} values were one of the parameters in the regression curves. The regression curves were imported into SigmaPlot version 10 (Systat Software, San Jose, CA, USA).

Results

Soil-free bioassays When *A. thaliana* was bioassayed in a manner similar to that of Bais et el. (2002, 2003), (+)-, (−)-, and (±)-catechin significantly inhibited root growth at 0.33 and 1 mM, with (−)-catechin being slightly more active than (+)-catechin (Fig. 1). As described by Bais et al. (2003), roots darkened after exposure to catechins (Fig. 2). When plants were transferred to a catechin-free medium after 4 days of catechin exposure, root growth resumed (Fig. 2). The new root growth was not dark, and the darkening in the old roots was less intense. Healthy root hairs were seen in all treatments (Fig. 3) after removal from catechin.

In agar, there was little or no growth reduction of *A. thaliana* roots or shoots when grown continuously on 0.17 or 0.35 mM (−) or (+) catechin, respectively (Fig. 4). There was marked root growth reduction at 0.7 mM, accompanied by browning of the roots. The effects were similar for both enantiomeric forms of catechin.

In solution, catechin can degrade to epicatechin and catechinic acid under some conditions (Kiatgrajai et al.

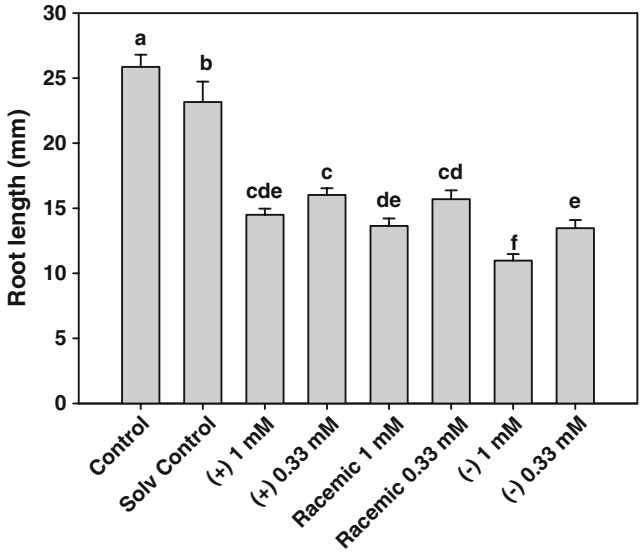

Fig. 1 Root lengths of *A. thaliana* plants grown for 10 days in MS medium and then transferred to 24-well plates for 4 days containing the indicated media. *Error bars* are ±1 SE of the mean. *Means with the same letters above them* are not statistically different at the α= 0.05 level, using Duncan's multiple range test

1982). We found neither of these compounds to be phytotoxic to lettuce, bentgrass, or duckweed at concentrations up to 1 mM (data not shown).

With bentgrass, there was a slight and similar reduction in chlorophyll with both (−)- and (+)-catechin at 3.3 mM (Fig. 5). Studies with duckweed found that both enantiomeric forms of catechin reduced growth at 3.3 mM and that the dose–response curves were similar for both enantiomers (Fig. 6). There was a slight reduction of lettuce hypocotyl growth by 333 μM (+)-catechin (Fig. 7a). Growth of lettuce roots was affected slightly, but significantly, by both enantiomers of catechin at 33 μM and more strongly by 333 μM (−)-catechin (Fig. 7b). Lettuce seedlings, germinated and grown for 8 days in 3.3 mM racemic catechin, were not appreciably stunted (Fig. 8), but browning of the hypocotyl and roots occurred. Chlorophyll levels of the cotyledons of lettuce were not affected at any concentration of any form of catechin tested (data not shown). The stability of catechin in water is affected by pH (Courbat et al. 1977; Hashida et al. 2003; Ho et al. 1995; Blair et al. 2005; Labrouche et al. 2005) with catechin becoming less stable above pH 5. We found

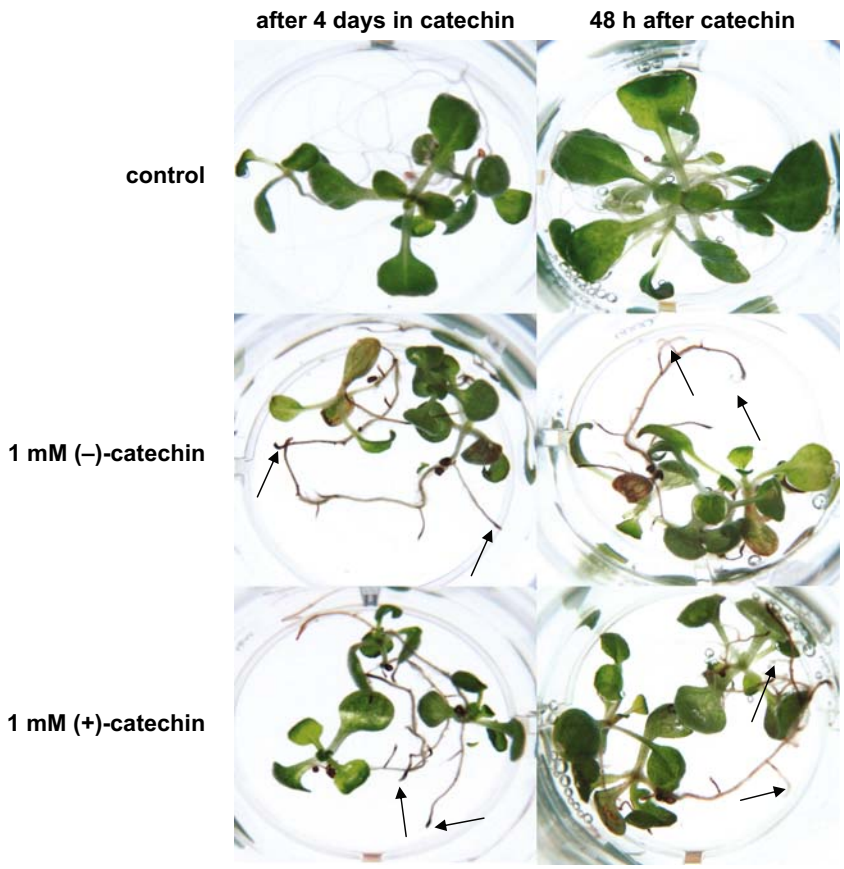

Fig. 2 *A. thaliana* plants grown for 10 days in MS medium and then transferred to 24-well plates for 4 days to the indicated media, after which all treatments were transferred to media without catechins. *Arrows in the first column of photographs* indicate darkened root tips. *Arrows in the second column of photographs* indicate white root tips after 2 days without catechin

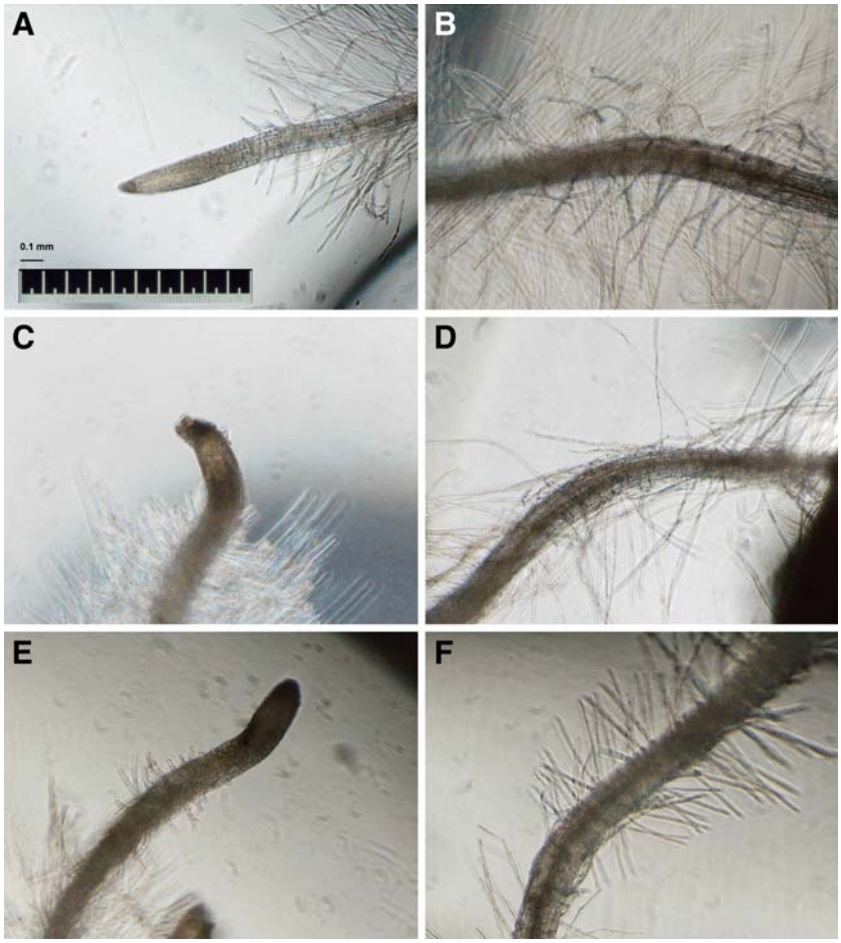

Fig. 3 Root tips (**a**, **c**, **e**) and regions of roots just behind root tips (**b**, **d**, **f**) of 10-day-old *A. thaliana* seedlings grown on half strength MS medium with no catechin (**a**, **b**), 1 mM (+)-catechin (**c**, **d**) or 1 mM (−)-catechin (**e**, **f**) for 4 days, followed by transfer to media without catechin for 4 days

no pronounced effect of pH between 5 and 8 on activity of 3.3 mM catechin on lettuce after 7 days (Fig. 9). Racemic catechin at 3.3 mM slightly stimulated growth of hypocotyls at pH 7 and 8 and roots at pH 6.

Studies in Soil There was no marked effect on growth of either Idaho fescue or junegrass by a racemic mixture of catechin in Metromix 350 potting soil at concentrations up to 10 mg/g dry weight after 13 days of growth (Fig. 10).

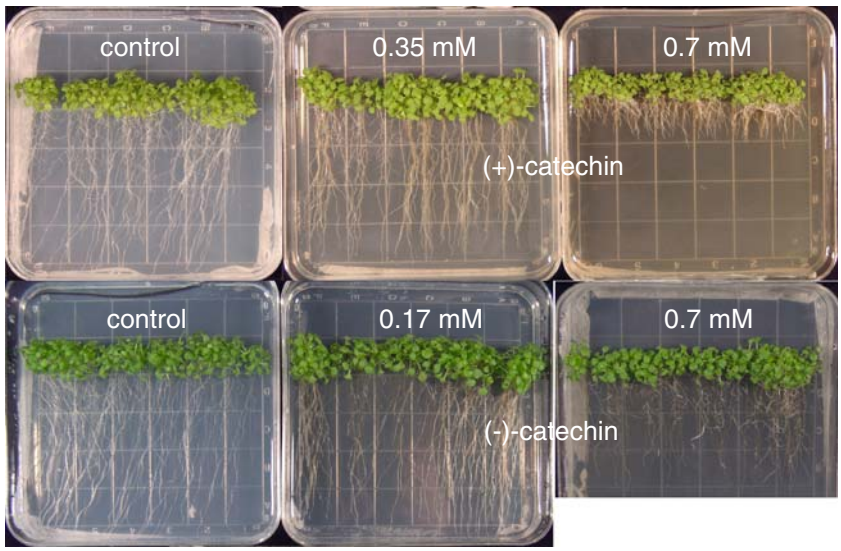

Fig. 4 Effects of different forms of catechin incorporated into the Gamborg's B5 agar media of *A. thaliana* after 14 days of growth

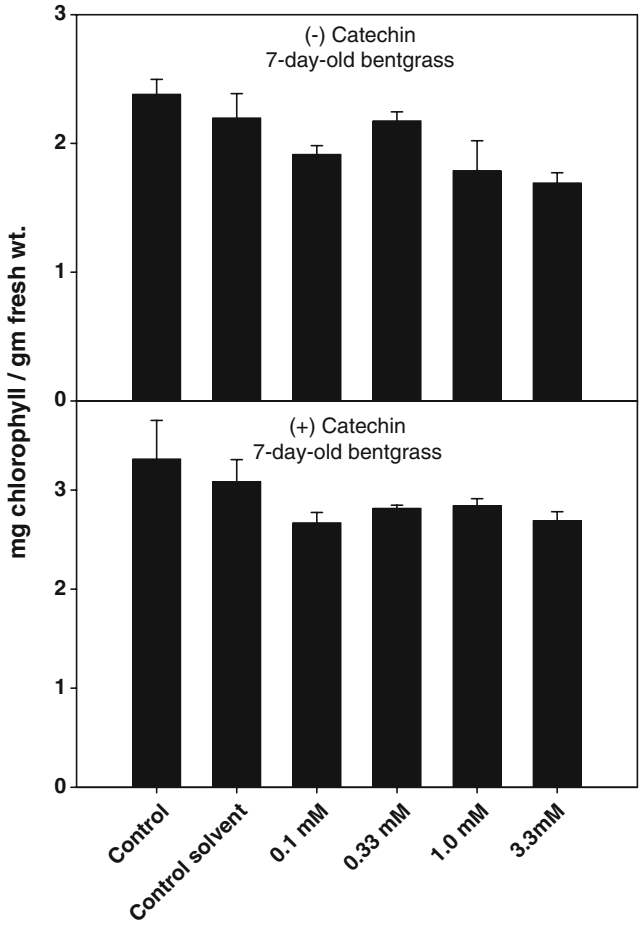

Fig. 5 Effects of different concentrations of (−)- and (+)-catechin on bentgrass chlorophyll levels after 7 days of growth in distilled water with and without the catechins. *Error bars* are ±1 SE of the mean

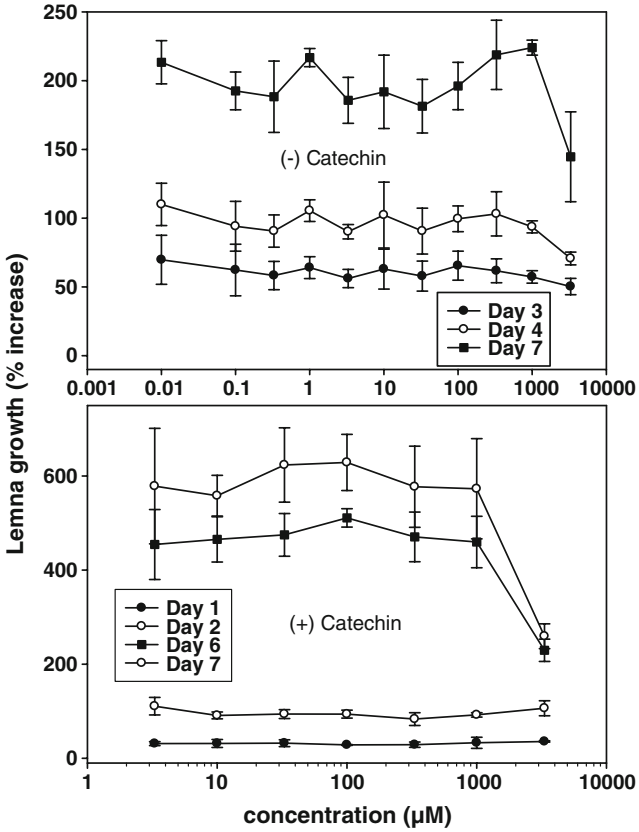

Fig. 6 Effects of different concentrations of (−)- and (+)-catechin on duckweed growth in Hoagland's solution with or without the catechins after different periods of exposure. *Error bars* are ±1 SE of the mean

Analysis of the dose–response curves using a four-parameter logistic function calculated nearly identical I_{50} values for catechin on Idaho fescue and junegrass, at 15.4 and 15.6 mg/g, respectively. The potential concentration of the combined two enantiomers in the soil at 15 mg/g dry weight is 12.5 mM. At this concentration and above, growth was significantly reduced, but the plants remained green and retained turgor.

Soils contain microflora that can convert phytotoxins to more active or less active compounds. Autoclaving can eliminate this possibility. By using autoclaved and non-autoclaved soils from Jens (Fig. 11a) and Nelson (Fig. 12a), we found little or no effect of a racemic mixture of catechin on growth of Idaho fescue plants after 10 days at concentrations below 10 mg/g dry soil (ca 8.33 mM). There was no difference between results with autoclaved and nonautoclaved soil, except at 30 and 100 mg/g of soil (ca 25 and 83 mM, respectively) in Jens and Nelson soils, respectively, and these differences were small. In non-autoclaved Nelson soil, 15 mg/g dry weight (ca 12.5 mM) of (−)-catechin had no significant effect on growth (Fig. 11A).

We considered the possibility that, over a longer time period, catechin could be converted to a more toxic compound by soil microflora, so we incubated the catechin in autoclaved or nonautoclaved moist soil for 2 weeks before planting Idaho fescue and then repeated the experiment (Figs. 11b and 12b). The relative effects of racemic catechin were similar to results from soil that had not been preincubated, but plants grew better in autoclaved than nonautoclaved soil after this 2-week incubation period in nonamended soils and those with less than 3 and 30 mg of catechin/g of soil (ca 2.5 and 25 mM, respectively) in Jens and Nelson, respectively. Idaho fescue grown in (−)-catechin-augmented Nelson soil for 12 days was stunted by 10 and 30 mg/g of soil dry weight (ca 8.33 and 25 mM, respectively; Fig. 13), but the plants were still green and turgid.

Finally, we showed that (−)-catechin is apparently as active as an antioxidant as (+)-catechin, (−)-epicatechin, and quercitin, all known to be antioxidants (Fig. 14).

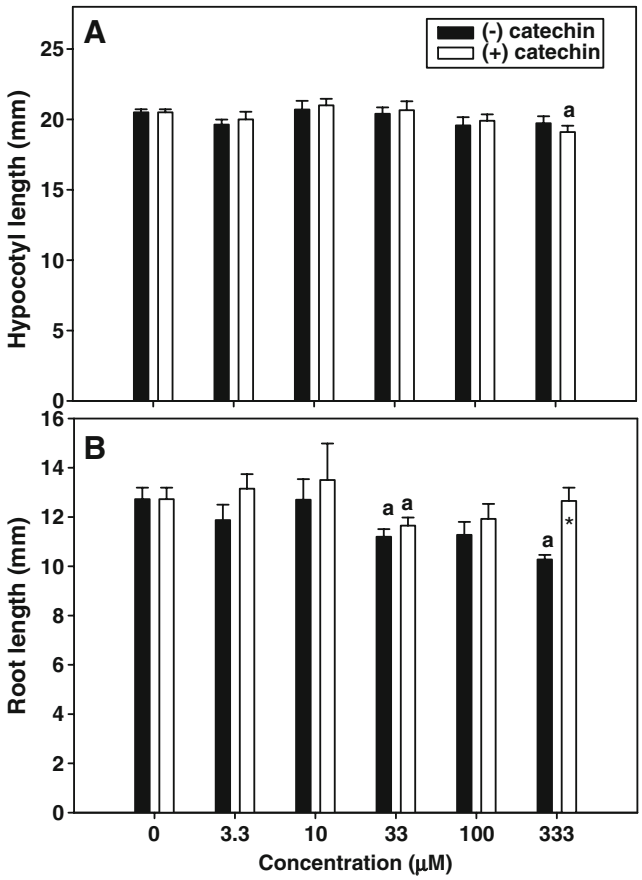

Fig. 7 Effects of different concentrations of (−)- and (+)-catechin on growth of hypocotyls (**a**) and roots (**b**) of lettuce seedlings grown in distilled water with or without the catechin after 8 days of exposure. *Error bars* are ±1 SE of the mean. Those *means with letters over them* are significantly different from the corresponding control at α=0.05, using Duncan's multiple range test. The *bar with an asterisk* in it is significantly different from the same concentration (−)-catechin treatment at α=0.05, using Duncan's multiple range test

Discussion

Our findings indicate that (+)- and (−)-catechin are not highly phytotoxic compounds in either soil-free or soil studies. Their level of phytotoxicity is much lower than that associated with many other natural phytotoxins that we have assayed in identical soil-free bioassays, such as 2β-angeloyloxy-10β-hydroxyfuranoeremophilane from the Eurasian plant *Ligularia macrophylla*, the chaparrinone-type quassinoids from *Ailanthus* spp., or the triketone leptospermone from *Leptospermum scoparium* with an IC_{50} values between 1 and 4 µM for duckweed or lettuce (Dayan et al. 1999, 2007; Cantrell et al. 2007). With respect to the novelty of the compounds, catechin is a fairly common compound, being found in plant species native to the Americas (e.g., cacao), as well as the rest of the world (e.g., tea, lentils, grapes) for which no allelopathic properties have been claimed.

The recent literature states widely varying phytotoxicity results for catechins. For example, Weir et al. (2003) report 100% mortality of Idaho fescue at 50 ppm (ca 0.17 mM), while Blair et al. (2005) only report reduced growth of this same species at 1,000 ppm (ca 3.1 mM). We found 3.3 mM (±)-catechin to have no effect on root growth of lettuce, and Tharayil et al. (2008) reported no effect of (±)-catechin on lettuce growth up to the limits of its solubility. However, Buta and Lusby (1986) reported lettuce root growth reduction of about 70% by 1 mM (+)-catechin. Some of these disparities could be due to differences in growing conditions, method of treatment, and/or biotype or variety assayed. The bioassay conditions of Buta and Lusby (1986) were not provided, making explanation of differences in results impossible. We found catechins to stunt roots of *A.*

Fig. 8 Appearance of lettuce seedlings grown with and without 3.3 mM (±)-catechin in distilled water for 8 days

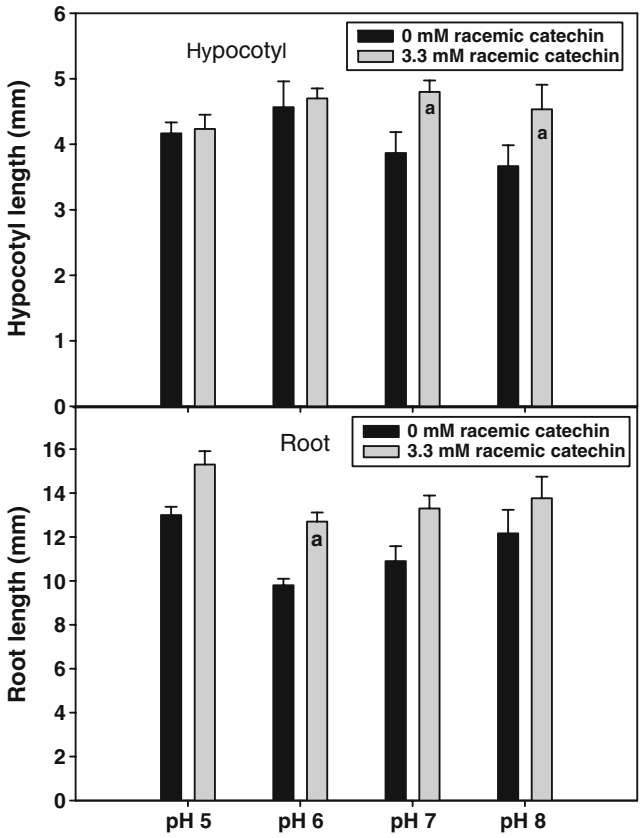

Fig. 9 Effect of 3.3 mM (±)-catechin at different pH values in distilled water (adjusted with NaOH or HCl) on growth of 8-day-old lettuce roots and cotyledons. *Error bars* are ±1 SE of the mean. Those *bars with letters* over them are significantly different from the corresponding control at α=0.05, using Duncan's multiple range test

thaliana grown continuously on agar with concentrations greater than 0.35 mM (100 μg/mL; Fig. 4). Bais et al. (2002) found 0.17 mM (+)-catechin to have little or no effect on *A. thaliana* root growth, whereas (−)-catechin was a strong inhibitor. Simões et al. (2008) found (+)-catechin to strongly inhibit root growth at concentrations above 0.35 mM when the plants were transferred into a liquid culture containing (+)-catechin that was shaken. In a similar experiment to those of Bais et al. (2002) and Simões et al. (2008), we found 1 mM catechin of either enantiomer to reduce *A. thaliana* root growth (Fig. 1), but the effects were temporary if the catechin were removed. In this experiment, the two enantiomers had similar activity, although (−)-catechin was slightly more active. In an erratum to the Bais et al. (2002) paper, the authors reported that (−)-catechin was ~1.5 to twofold more active than the positive (+) enantiomer. Our results do not support such a difference in activity.

More recently, Broeckling and Vivanco (2008) state that catechin's instability and ability to form complexes in soil confound the understanding of this compound as an allelochemical. The presence of other phenolic compounds in soil increases catechin's half-life, but it can also form a short-lived procyanidin dimer in soil, which reduces persistence and phytotoxicity of the compound (Tharayil et al. 2008). This latter paper also found (±)-catechin to be essentially nonphytotoxic to both monocotyledonous and dicotyledonous plants, even though they observed similar root browning to that attributed to necrosis by Bais et al. (2003). Tharayil et al. (2008) attributed the root browning

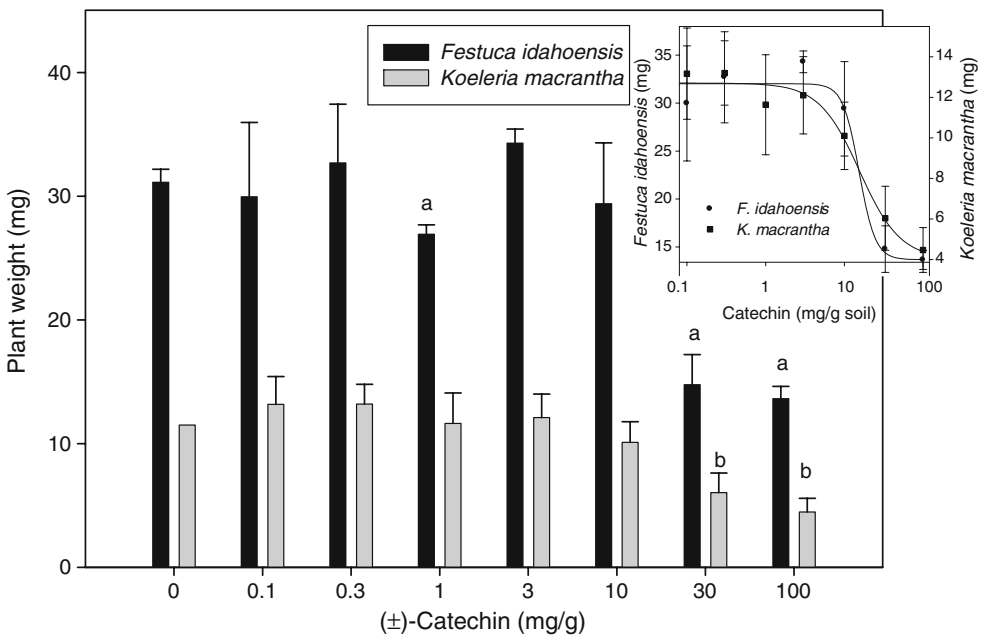

Fig. 10 Effect of different concentrations of (±)-catechin in Metromix 350 potting soil on growth of Idaho fescue (*F. idahoensis*) or junegrass (*Koeleria macrantha*) after 13 days of growth. *Error bars* are ±1 SE of the mean. Those *means with letters over them* (*a* for Idaho fescue and *b* for junegrass) are significantly different from the corresponding control at α=0.05, using Duncan's multiple range test. The *inset* shows the *R* plots of data used to generate the I_{50} values

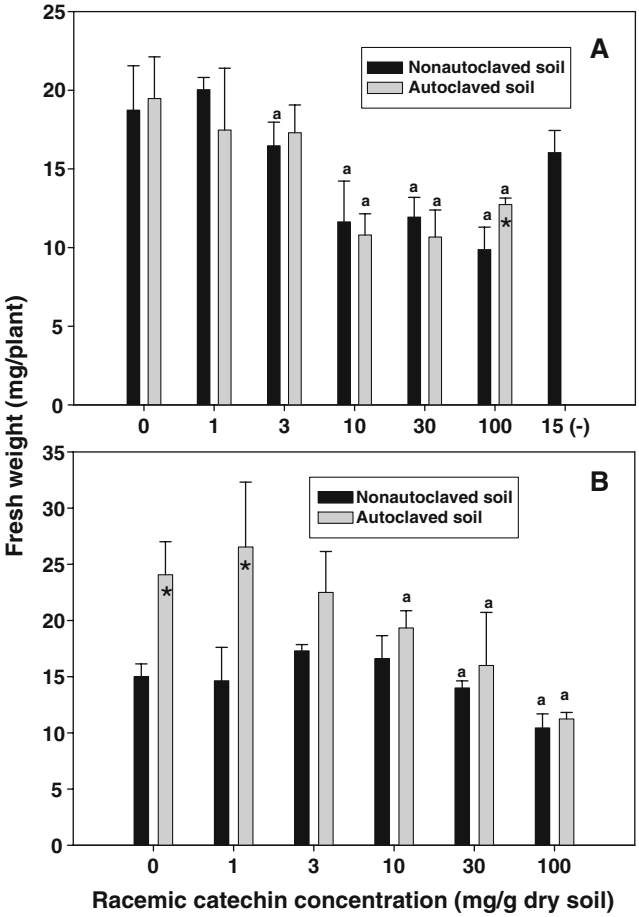

Fig. 11 Effects of different concentrations of (±)-catechin and 10 mg/g of soil (−)-catechin in autoclaved or nonautoclaved Jens soils planted with Idaho fescue immediately after amendment with the catechin (**a**) or 2 weeks after amendment (**b**). Measurements were taken 10 days after planting. *Error bars* are ±1 SE of the mean. Those means with letters over them are significantly different from the corresponding control at α=0.05, using Duncan's multiple range test. Those *bars with an asterisk* in them are significantly different from the same nonautoclaved soil treatments at α=0.05, using Duncan's multiple range test

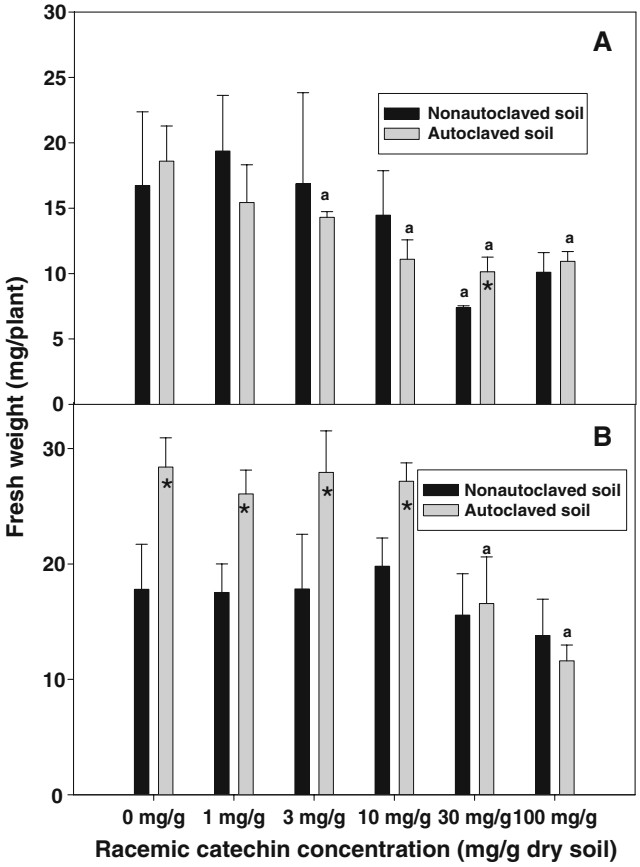

Fig. 12 Effects of different concentrations of (±)-catechin in autoclaved or nonautoclaved Nelson soils planted with Idaho fescue immediately after amendment with the catechin (**a**) or 2 weeks after amendment (**b**). Measurements were taken 10 days after planting. *Error bars* are ±1 SE of the mean. Those means with letters over them are significantly different from the corresponding control at α=0.05, using Duncan's multiple range test. to enzyme-mediated (peroxidases or polyphenol oxidase) polymerization of catechin to brown polymers, an effect that should not contribute to toxicity. We found root browning to be somewhat reversible (Fig. 2).

Errata were published to the papers by Veluri et al. (2004), Weir et al. (2003), and Bais et al. (2002), in which the claims of differential phytotoxicity of (−) and (+) catechin and the degree of phytotoxicity of (−)-catechin were reduced, as well as the levels of catechin produced by individual plants. The same laboratory (Prithiviraj et al. 2007) then reported that low doses of catechin can stimulate growth of *A. thaliana*. They attributed this effect to induction of low levels of reactive oxygen species (ROS). Stimulatory effects of nontoxic doses of phytotoxins (hormesis) are common (Duke et al. 2006). Prithiviraj et al. (2007) also reported that these doses induced pathogen resistance, an effect observed with low doses of other chemical inducers of ROS (Duke et al. 2007).

In one of the original catechin papers (Bais et al. 2003), the mechanism of action of (−)-catechin was linked to induction of ROS. Weir et al. (2006) produced evidence that oxalate, whether produced by a plant or present in the soil, blocks the phytotoxic activity of (−)-catechin by preventing production of ROS. That ROS is involved in the mode of action of catechins as a phytotoxin is debatable because catechins are well-known antioxidants (e.g., Almajano et al. 2007). In fact, more than 1,500 papers mention catechin as an antioxidant (SciFinder® search, as of October, 2008). We are unaware of any papers that show that (−)-catechin is an antioxidant as we have (Fig. 14), but

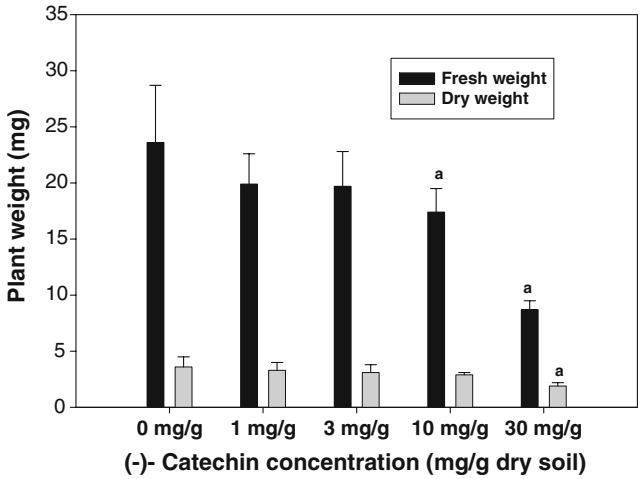

Fig. 13 Effects of (−)-catechin in Nelson soil on fresh and dry weight per plant of Idaho fescue grown for 12 days. *Error bars* are ±1 SE of the mean. Those *means with letters* over them are significantly different from the corresponding control at α=0.05, using the Duncan's multiple range test

chirality should not influence this type of activity. Antioxidants quench ROS, rather than producing them.

In soil, we found the activity of catechins to be even less than in soil-free systems, with little or no effects at theoretical concentrations in soil water as high as almost 10 mM. This approximation is probably low, as the molarity in soil would be expected to increase with time as the soil dries, provided the catechin does not degrade. At higher levels, the plants were stunted, but not killed. No one has suggested that spotted knapweed generates levels of catechin in soils that would approach 10 mM. Such high concentrations could cause growth reduction by reducing water potential. The results with regard to catechin were the same in autoclaved soils, suggesting that there is no microbial bioactivation or inactivation. Catechin is unstable in soil, especially at high pH (Furubayashi et al. 2007). Inderjit et al. (2008) also noted that (±)-catechin degrades rapidly in soil, so that the level of catechin available to cause a biological effect may be much smaller than what is actually applied. The same could be said of catechin in solution. If catechin is the causal agent of any effect, its instability would contribute to its very weak effects. Inderjit et al. (2008) found catechin to be more phytotoxic in sand or soil with organic matter mixed in it than in soil without organic matter, and they considered junegrass to be highly sensitive to (±)-catechin in soils from Montana, Romania, and India. This conclusion is in marked conflict with our results with this species. In their study, water stress increased the phytotoxicity of (±)-catechin.

In a field situation, catechin is likely to be found in combination with other potential allelochemicals. Tharayil et al. (2006, 2008) found that the individual half-lives of such compounds in soil are extended by the presence of similar compounds. Synergism of simple phenolic compounds in causing phytotoxicity in the absence of soil has not been found in carefully conducted studies (e.g., Duke et al. 1983; Gerig et al. 1989; Jia et al. 2006).

In summary, our results do not support the view that either enantiomer of catechin is involved in allelopathy of spotted knapweed. Our findings, and the fact that catechin is found in many plant species throughout the world, casts doubt on the concept that catechin is a novel weapon that enables spotted knapweed in North America to succeed against native plant species. Nevertheless, the finding by Ridenour and Callaway (2001), in greenhouse carbon addition experiments, that spotted knapweed may cause allelopathic effects on native species through an allelochemical calls for further study of this phenomenon. Rigorous bioassay-directed isolation of the responsible compound(s) might solve this mystery.

Essential Oil of *Artemisia scoparia* Inhibits Plant Growth by Generating Reactive Oxygen Species and Causing Oxidative Damage

Harminder Pal Singh · Shalinder Kaur · Sunil Mittal · Daizy Rani Batish · Ravinder Kumar Kohli

Received: 13 July 2008 / Revised: 26 November 2008 / Accepted: 3 January 2009 / Published online: 5 February 2009

Abstract We investigated the chemical composition and phytotoxicity of the essential oil extracted from leaves of *Artemisia scoparia* Waldst. et Kit. (red stem wormwood, Asteraceae). GC/GC-MS analyses revealed 33 chemical constituents representing 99.83% of the oil. The oil, in general, was rich in monoterpenes that constitute 71.6%, with β-myrcene (29.27%) as the major constituent followed by (+)-limonene (13.3%), (*Z*)-β-ocimene (13.37%), and γ-terpinene (9.51%). The oil and β-myrcene were evaluated in a dose–response bioassay under laboratory conditions for phytotoxicity against three weeds—*Avena fatua, Cyperus rotundus*, and *Phalaris minor*. A significant reduction in germination, seedling growth, and dry matter accumulation was observed in the test weeds. At the lowest treatment of 0.07 mg/ml *Artemisia* oil, germination was reduced by 39%, 19%, and 10.6% in *C. rotundus, P. minor*, and *A. fatua*, respectively. However, the inhibitory effect of β-myrcene was less. In general, a dose-dependent effect was observed and the growth declined with increasing concentration. Among the three weeds, the inhibitory effect was greatest on *C. rotundus*, so it was selected for further studies. We explored the explanation for observed growth inhibition in terms of reactive oxygen species (ROS: lipid peroxidation, membrane integrity, and amounts of conjugated dienes and hydrogen peroxide)-induced oxidative stress. Exposure of *C. rotundus* to *Artemisia* oil or β-myrcene enhanced solute leakage, indicating membrane disintegration. There were increased levels of malondialdehyde and hydrogen peroxide, indicating lipid peroxidation and induction of oxidative stress. We conclude that *Artemisia* oil inhibits plant root growth through generation of ROS-induced oxidative damage.

Keywords *Artemisia scoparia* · Conjugated dienes · Electrolyte leakage · Essential oil · Growth inhibition · Hydrogen peroxide · Lipid peroxidation · β-Myrcene · Oxidative damage

Introduction

Aromatic plants and their volatile oils have been in use since antiquity in flavor and fragrances, in medicines, as antimicrobial and insecticidal agents, and to repel insects and stored product pests (Bakkali et al. 2008; Batish et al. 2008). However, due to fumigant and insecticidal activity, the interest in volatile oils has increased tremendously during the last decade or so. Volatile terpenes act as pollinator attractants, provide an important defense strategy against herbivores and pathogenic fungi, play a significant role in plant–plant interactions, and depict an evolutionary relationship with their functional roles (Langenheim 1994; Batish et al. 2008). Of late, volatile oils and their constituents are being explored for weed and pest management and viewed as an important source of lead molecules (Romagni et al. 2000; Batish et al. 2004; Singh et al. 2005; Bakkali et al. 2008). It is, thus, pertinent to explore and characterize the phytotoxic properties of aromatic plants and their volatile oils.

The genus *Artemisia* (commonly wormwoods; family Asteraceae) consists of a diverse group of around 200 herb

and shrub species distributed throughout the world (Anonymous 1993). The plants are rich in volatile oils that exhibit a wide spectrum of biological activity and find extensive use in medicine (Anonymous 1993). Additionally, the volatile oil of certain *Artemisia* species (*Artemisia tridentata*, *Artemisia princeps*, and *Artemisia vulgaris*) inhibits emergence and growth of nearby plants (Weaver and Klarich 1977; Yun et al. 1993; Barney et al. 2005). The characteristic vegetation patterning around *Artemisia californica* thickets that is due to volatile terpenes is one of the classical examples of allelopathy (Muller et al. 1964). *Artemisia scoparia* (red stem wormwood) is an annual aromatic species growing wild in India. It forms monospecific strands along canals, agricultural fields, roadsides, and wastelands (Anonymous 1993). However, the role of its volatile oil in suppressing the emergence and growth of other plants in its vicinity remains largely unknown. We, therefore, extracted and characterized oil from leaves of *A. scoparia*, and assessed the phytotoxicity of both the oil and its major constituent. We selected *Avena fatua* and *Phalaris minor* (weeds of wheat crop), and *Cyperus rotundus* (a weed of rice crop) as bioassay plants with a view to test *Artemisia* oil as a weed suppressant and its potential use as a novel bioherbicide. We further explored the possible mechanism of phytotoxicity of *Artemisia* oil in terms of reactive oxygen species (ROS: lipid peroxidation, membrane integrity, and amounts of conjugated dienes and hydrogen peroxide)-induced oxidative stress.

Methods and Materials

Extraction of the Oil Volatile oil was extracted from fresh leaves of *A. scoparia* Waldst. & Kit. (red stem wormwood; hereafter *Artemisia*) by hydrodistillation using Clevenger's apparatus. For this, during the second week of June 2007 (summer season), leaves were collected from *Artemisia* plants growing in wastelands around Chandigarh.

Leaves (250 g) were chopped and mixed with distilled water (1 l) in a round bottom flask (2 l) and boiled for 3 h. The oil was collected from the nozzle of the condenser, dried under sodium sulfate, and stored at 4°C for identification and bioassay. The oil was clear yellow in color with a yield of 0.17% (*v*/*w*, fresh weight basis).

Oil Analysis The extracted oil was analyzed by gas chromatography (GC) and gas chromatography–mass spectroscopy (GC-MS) as per Singh et al. (2009).

GC was done on a Shimadzu GC-17A gas chromatograph equipped with a flame ionization detector (FID) and DB-5 column (60 m×0.25 mm, i.d., film thickness 0.25 μm). Helium (He) at a split ratio 1:20 and a flow rate 1 ml min^{-1} was used as carrier gas. The injector and detector temperature were set at 250°C and 280°C, respectively. Initially, the oven temperature was 50°C, held isothermally for 2 min, then increased to 260°C at the rate of 4°C min^{-1}, and finally held at 260°C for 3 min. The relative amount of different constituents was determined by computerized peak area normalization based upon three injections of the oil, without any correction factor. Peaks were compared with data from GC-MS.

GC-MS analysis was performed on a Shimadzu QP 2010 mass spectrophotometer equipped with fused silica (SGE BP 20) capillary column (30 m×0.25 mm, i.d., 25 μm film thickness). He at a split ratio of 1:50 and a linear velocity of 38.5 cm s^{-1} was used as carrier gas. The injector and detector temperature were set at 220°C and 250°C, respectively. The temperature was programmed from 70°C (held isothermally for 4 min) to 220°C at the rate of 4°C min^{-1} and held at 220°C isothermally for 5 min. Mass spectral range was recorded from *m/z* 40 to 600 amu. The identification of different constituents was based on: (1) the comparison of their retention times with those of pure reference samples from Sigma-Aldrich (St. Louis, MO, USA), Fluka (Buchs, Switzerland), Acros (Geel, Belgium), AlfaAeser (Ward Hill, MA, USA), and TCI (Tokyo, Japan); (2) co-elution with available authentic standards; (3) comparison of retention indices (RI) with reference to a homologous series of *n*-alkanes (C_7-C_{30}; Supelco, Bellefonte, PA, USA); and (4) computer matching of mass spectra by using library search system HP-5872 (Hewlett-Packard) and consulting data bases of Wiley 275 and NBS 75K Libraries (McLafferty 1989), NIST 98 (Stein 1990), and compilation by Adams (1995).

Procurement of Materials For laboratory bioassay, seeds of *A. fatua*, *C. rotundus*, and *P. minor* were collected locally from agricultural fields on the outskirts of Chandigarh. These were surface-sterilized with sodium hypochlorite (1%, *w*/*v*) for 2 min, washed under running tap water (for 5 min) followed by distilled water and stored for further use. β-Myrcene (the major component of *Artemisia* oil) of technical grade (purity 90%) was used in the bioefficacy experiments and purchased from AlfaAesar (Ward Hill, MA, USA). All other chemicals were of analytical grade and purchased from the best available sources (Sisco Research Laboratory, Mumbai, India; Loba-Chemie, Mumbai; Sigma-Aldrich, St. Louis, MO, USA).

Laboratory Bioassay *Artemisia* oil and β-myrcene were evaluated for phytotoxicity in a dose–response manner under laboratory conditions. Seeds of test plants were imbibed in distilled water for 16 h. Pre-imbibed seeds (15 of *A. fatua* or 25 of *C. rotundus* and *P. minor*) were placed in 15-cm diameter Petri dishes on Whatman No. 1 filter paper moistened with 7 ml of distilled water. Different amounts (0.5–5.0 μl) of *Artemisia* oil or β-myrcene were loaded onto

the inner side of the lid of the Petri dish to obtain concentrations of 0.07, 0.14, 0.35, and 0.70 mg/ml. After treatment, dishes were sealed with Parafilm®. A set of Petri dishes without oil or β-myrcene served as a parallel control. For each treatment, including control, five Petri dish replicates were maintained in a randomized block design. All dishes were kept in a growth chamber set at 25±2°C temperature, 16/8 h L/D photoperiod with photosynthetic photon flux density of ~225 μmole m^{-2} s^{-1} and a relative humidity of nearly 80%. After 1 week, the number of seeds that germinated was counted and the length (from tip of root to tip of shoot) and dry weight (by oven drying at 60°C for 48 h) of emerged seedlings were measured. Among the three weeds, the inhibitory effect was the greatest on *C. rotundus*, so it was selected for further biochemical studies by exploring the induction of oxidative damage as a possible mechanism of phytotoxicity. Roots of *C. rotundus* were excised and kept at 4°C prior to further studies/analyses.

Determination of Cell Survivability Cell survivability was determined spectrophotometrically by using 2,3,5-triphenyl tetrazolium chloride (TTC) as per Singh et al. (2002). It provides an indirect method of measurement of cell respiration since TTC absorbs electrons from the respiratory chain (Batish et al. 2007a). Absorbance was read at 530 nm and the values expressed with respect to control.

Effect on Membrane Integrity Effect of *Artemisia* oil or β-myrcene was studied on membrane integrity (an indicator of cellular damage) in terms of ion leakage from the roots of *C. rotundus* by measuring conductivity of the bathing medium (Duke and Kenyon 1993). Roots (200 mg) were incubated in 5 ml of 1 mM MES buffer (2-[N-morpholino] ethanesulphonic acid sodium salt, pH 6.5) containing 2% sucrose with *Artemisia* oil or β-myrcene (0.14 and 0.35 mg/ml; selected on the basis of the laboratory bioassay) dissolved in Tween-80. A parallel set up without *Artemisia* oil or β-myrcene, but containing MES buffer and Tween-80 only, was maintained as control. The conductivity of the bathing medium containing *C. rotundus* roots with or without treatment was measured with a conductivity meter (ECOSCAN CON5, Eutech Instuments Pte. Ltd., Singapore) at regular intervals in dark (0, 1, 2, 4, 8, 12, 16, 18, and 20 h) followed by exposure to light for a further 10 h (i.e., at 22, 24, 26, 28, and 30 h). The maximum electrolyte leakage from root tissue was determined by boiling the roots for 15 min. The experiment was repeated twice with five replicates and the data are presented as means.

Lipid Peroxidation Lipid peroxidation was measured in terms of malondialdehyde (MDA) and conjugated dienes content. MDA, a major thiobarbituric acid reactive species, was determined as per Heath and Packer (1968). Roots (100 mg) of *C. rotundus* were homogenized in 5 ml of trichloroacetic acid (TCA, 0.1%, *w*/*v*) in a pre-chilled pestle and mortar and centrifuged at 10,000×*g* for 10 min. One milliliter of the supernatant was added to 4 ml of thiobarbituric acid (0.5%, *w*/*v*, in 20% TCA). The mixture was heated at 95°C for 30 min, cooled over ice, and then centrifuged at 10,000×*g* for 10 min. The absorbance of the supernatant was read at 532 nm and corrected for non-specific absorbance at 600 nm. MDA content was determined by using the extinction coefficient (ε) of 155 mM cm^{-1} and expressed as nmol g^{-1} FW (fresh weight).

Conjugated dienes content was determined by homogenizing roots (100 mg) of *C. rotundus* in 5 ml of 95% (*v*/*v*) ethyl alcohol (Singh et al. 2007). The mixture was centrifuged at 10,000×*g* for 10 min, and the absorbance was read at 234 nm. The content of conjugated dienes was determined by using an extinction coefficient of 26.5 mM cm^{-1}, and expressed as μmol g^{-1}FW.

Determination of Hydrogen Peroxide (H_2O_2) Content

Roots (100 mg) of *C. rotundus* were homogenized with 5 ml of 0.1% TCA (*w*/*v*) in a pre-chilled pestle and mortar and centrifuged at 12,000×*g* for 15 min (Singh et al. 2007). To 0.5 ml of supernatant, 0.5 ml of phosphate buffer (pH 7), and 1 ml of 1 M potassium iodide were added. The absorbance of reaction mixture was measured at 390 nm. H_2O_2 content was determined by using an extinction coefficient (ε=0.28 μM cm^{-1}) and expressed as nmol g^{-1}FW.

Statistical Analyses The relative amount of different constituents of *Artemisia* oil determined by GC/GC-MS analyses was based upon three injections of the oil. The dose–response laboratory bioassay was conducted in a randomized block design with five replications, each comprised of a single Petri dish. Five independent tissue samples were used as replicates for each analysis. The data are presented as mean±SE and analyzed by one-way ANOVA followed by the comparison of mean values using post-hoc Tukey's test at $P \leq 0.05$.

Results and Discussion

Composition of Essential Oil from Young Leaves GC and GC-MS analyses of *Artemisia* oil revealed it to be a mixture of monoterpenoids, sesquiterpenes, aromatic compounds, aliphatic esters, ketones, and alcohols, which eluted between 4.16 to 40.29 min. A total of 33 chemical constituents representing 99.83% of the essential oil, were identified (Table 1). Of these, β-myrcene (29.27%) was the

main constituent, followed by (+)-limonene (13.3%), (*Z*)-*β*-ocimene (13.37), *γ*-terpinene (9.51%), and acenaphthene (17.8%). These together constituted ~86% of the oil (Table 1). The oil, in general, was rich in monoterpenes (71.6%), while the other compounds constituted 28.23%. The composition of the characterized oil was in sharp contrast to earlier reports. Earlier, 1-phenyl-penta-2,4-diyne, *β*-pinene, limonene, and (*E*)-*β*-ocimene (Safaei-Ghomi et al. 2005), or methyl eugenol (Basher et al. 1997), or thujone, camphor, and 1,8-cineole (Mirjalili et al. 2007) were identified as the main constituent of the oil from aerial parts of *A. scoparia*. These components were either absent or present in small amounts in the present study. Nevertheless, our observations are parallel to earlier studies that reported *β*-myrcene as the main constituent in the oil extracted from leaves and residues of *A. scoparia* (Singh et al. 2008, 2009). The observed variations in oil composition among those reported in literature are apparently largely due to differences in growth stages, plant parts, harvesting time, variations in edaphic and climatic factors, and geographical region (Batish et al. 2006b, 2008).

Effect on Germination and Early Growth A significant reduction in germination of test weeds was observed in response to *Artemisia* oil and *β*-myrcene (Table 2). At the lowest treatment of 0.07 mg/ml *Artemisia* oil, germination was reduced by 39%, 19%, and 10.6% in *C. rotundus*, *P. minor*, and *A. fatua* (Table 2). The inhibitory effect of *β*-myrcene was less. Inhibitory effects were greatest on *C. rotundus*, followed by *P. minor* and then *A. fatua*. In general, a gradual decline in germination with increasing concentration was observed, thus indicating a dose-dependent effect.

Table 1 Chemical constituents identified by GC-MS in the essential oil extracted from leaves of *Artemisia scoparia*

Retention time (min)	Compound[a]	RI[b]	Percent amount[c]	Identification

Within a column, means with common letters are not significantly different at $P \leq 0.05$, according to Tukey's test

Artemisia oil and β-myrcene significantly reduced radicle growth and seedling dry weight of test weeds (Tables 3 and 4). Radicle elongation of *A. fatua* was reduced by ~47% and 26% in response to 0.14 mg/ml of *Artemisia* oil and β-myrcene, respectively. At 0.35 mg/ml concentration of *Artemisia* oil and β-myrcene, radicle growth was reduced in the range of 37–94% and 12–63%, respectively (Table 3). Upon exposure to 0.35 mg/ml *Artemisia* oil, ~94% reduction in root length was observed. Parallel to root growth, a significant reduction in dry weight of the emerged seedlings also was observed in response to both *Artemisia* oil and β-myrcene (Table 4).

Reduction in germination and radicle growth by volatile terpenes from *A. scoparia* is not surprising. Earlier, the volatile oils from *A. tridentata*, *A. princeps*, *A. vulgaris*, and *A. scoparia* were reported to inhibit emergence and growth of associated vegetation (Weaver and Klarich 1977; Yun et al. 1993; Barney et al. 2005; Singh et al. 2008). Several studies have documented that the oil from aromatic plants and volatile terpenes are potent inhibitor of seed germination and root elongation. For example, Muller et al. (1964) demonstrated that volatile oils from *Salvia leucophylla* and *Artemisia californica* reduced the growth of associated plants, thus resulting in characteristic vegetational patterning. Batish et al. (2004, 2006a, b) reported a growth inhibitory effect of volatile oil from *Eucalyptus citriodora* on the emergence, radicle, and early seedling growth of several plants.

Phytotoxicity of volatile oils and terpenes also has been implicated as one of the possible reasons for successful colonization by invasive weeds (Kong et al. 1999; Barney et al. 2005; Ens et al. 2008). Kong et al. (1999) characterized a number of allelopathic constituents from the essential oil of *Ageratum conyzoides* that possibly are responsible for its invasive nature. Similarly, Barney et al. (2005) identified a number of volatile allelochemicals from the fresh leaves of invasive weed mugwort (*A. vulgaris*). These workers showed that nine of the identified monoterpenes act synergistically, impart phytotoxicity to the weed, and thus help in successful colonization, and habitat invasion (Barney et al. 2005). Recently, volatile sesquiterpenes (β-maaliene, α-isocomene, β-isocomene, δ-cadinene, 5-hydroxycalamenene, and 5-methoxycalamenene) that emanate from roots of the invasive plant bitou bush (*Chrysanthemoides monilifera* spp. *rotundata*) were shown to inhibit the seedling growth of associated native vegetation, and thus possibly help in successful invasion in the introduced sites (Ens et al. 2008). Additionally, several constituent terpenes are potent inhibitors of seed germination and seedling growth. These include: 1,4-and 1,8-cineole (Romagni et al. 2000), citronellal, citronellol, linalool (Singh et al. 2002, 2006b), α-pinene (Abrahim et al. 2000; Singh et al. 2006a), and limonene (Abrahim et al. 2000).

Inhibition of germination and root growth by oil from foliage of *A. scoparia* suggests that under natural conditions these volatile terpenes may emanate from the plant, enter the soil, and may be involved in suppression of associated vegetation, thus resulting in the formation of its monospecific strands. The soil from underneath the *A. scoparia* plants

contains a mixture of mono-and sesquiterpenes. The major ones include limonene, eugenol, 1,8-cineole, ocimene, and caryophyllene oxide (data not presented), and all these are potent germination inhibitors (Singh et al. 2003).

Although the mode of inhibitory action of the oils remains somewhat unclear, volatile oils and monoterpenes inhibit cell division and induce structural breakdown and decomposition in roots (Romagni et al. 2000; Nishida et al. 2005; Singh et al. 2006a, b). Vaughn (1991) reported that essential oil from *Cinnamomum zeylanicum* and *Thymus vulgaris* inhibit the sprout growth in potato by killing meristematic cells. Batish et al. (2007b) reported that volatile oil from *E. citriodora* inhibited root growth by suppressing mitotic activity. Earlier, Scrivanti et al. (2003) reported that essential oil from *Tagetes minuta* and ocimene (a constituent monoterpene) induce severe lipid peroxidation and membrane disintegration in maize. Recently, it was demonstrated that α-pinene, a volatile monoterpene, inhibits root growth of *Cassia occidentalis* by inducing oxidative stress measured in terms of increased lipid peroxidation, H_2O_2 accumulation, and membrane disintegration (Singh et al. 2006a).

Effect on Cell Survivability *Artemisia* oil caused a significant reduction in cellular survivability (measured as % TTC reduction) in roots of test weeds (Table 5). The cellular survivability decreased 12–24% and 6–22% in response to 0.07 mg/ml of *Artemisia* oil and β-myrcene, respectively. It declined further with increasing concentrations. In general, inhibition in cellular survivability was the greatest in *C. rotundus* followed by *A. fatua,* and *P. minor*, respectively (Table 5).

Cell viability provides an indirect measurement of cell respiration (Batish et al. 2007a). In viable (respiring) tissue, TTC absorbs electrons from the mitochondrial transport chain, get reduced, and thus correlates positively with respiratory activity (Batish et al. 2007a). The decrease in cellular survivability (thus respiration) upon exposure to *Artemisia* oil or β-myrcene implies an interference with energy metabolism involved in synthesis of macromolecules, thus resulting in reduced growth. These observations are in agreement with earlier studies (Abrahim et al. 2000; Singh et al. 2005). Abrahim et al. (2000) demonstrated that monoterpenes, due to their high lipophilicity, act as uncouplers of oxidative phosphorylation, and imbalance the cellular energy levels.

Effect on Membrane Integrity Membrane disruption by monoterpenoids has been suggested as one of the mechanisms for fungicidal and bactericidal activity (Singh et al. 2006a); we, therefore, studied the effect of *Artemisia* oil and β-myrcene on membrane integrity. *Artemisia* oil and β-myrcene caused a significant ion leakage from roots of *C. rotundus* as indicated by increased electrical conductivity of the bathing medium (MES buffer). The ion leakage

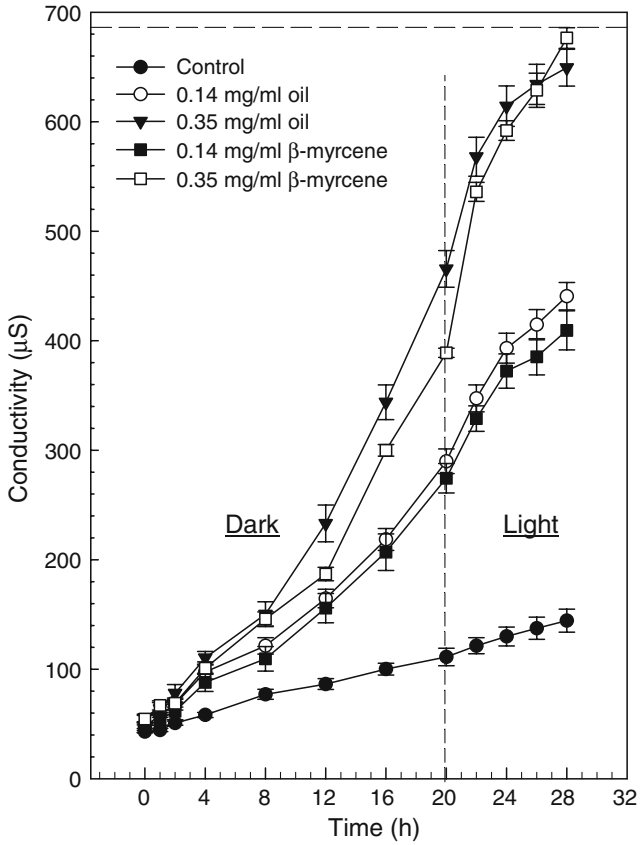

Fig. 1 Effect of *Artemisia* oil and *β*-myrcene on membrane integrity measured as electrolyte leakage from roots of *Cyperus rotundus*. The *dotted line* at the top represent maximum conductivity (685.2 µS) measured upon boiling of plant tissue. *Vertical line* marks the time period after which the samples were exposed to light

increased with time up to 20 h in the dark and then for another 8 h in light (i.e., up to 28 h). After 28 h, conductivity of the bathing medium in response to 0.14 and 0.35 mg/ml of *Artemisia* oil or *β*-myrcene was in the range of 60–64% and 95–99%, respectively, of the maximum leakage (685.2 µS; observed upon boiling the root tissue) (Fig. 1).

The increased conductivity of the bathing medium indicates cellular membrane disruption resulting in excessive solute leakage. These results are in agreement with earlier reports that essential oil and the monoterpenes (citronellal, α-pinene, and (+)-pulegone) cause ion leakage from plant tissue (Maffei et al. 2001; Singh et al. 2006a, b). Maffei et al. (2001) demonstrated that essential oil from *Mentha*×piperata and its pure component, (+)-pulegone, induced membrane depolarization in cucumber roots that resulted in an altered flux of ions across the membrane. Dayan et al. (2000) opined that a loss in membrane integrity relates to induction of oxidative stress. In fact, enhanced electrolyte leakage is an indicator of membrane damage due to generation of reactive oxygen species (Singh et al. 2006a). Montillet et al. (2005) reported that membrane disruption occurs due to peroxidation of polyunsaturated fatty acids or lipids in biomembranes and results in formation of byproducts such as malondialdehyde. Thus, we measured the MDA content, amount of conjugated dienes, and hydrogen peroxide content (as indicators of oxidative stress) in response to *Artemisia* oil or *β*-myrcene exposure.

Effect on Lipid Peroxidation Exposure to *Artemisia* oil significantly (at $P<0.05$) enhanced the MDA content in roots of *C. rotundus* (Table 6). It increased by 1.24- to 2.3-fold upon exposure to *Artemisia* oil or *β*-myrcene over that of control (Table 6). Increased content of MDA (a major thiobarbituric acid reactive substance) indicates enhanced lipid peroxidation and damage to membranes. These observations are in conformity with earlier reports that essential oil and monoterpenes induce membrane damage, and thus inhibit root growth (Scrivanti et al. 2003; Zunino and Zygadlo 2004; Singh et al. 2006a). The volatile oil from *Tagetes minuta* and *Schinus areira* and its monoterpenes (ocimene, ocimenone, α-pinene, 1,8-cineole, thymol, geraniol, menthol, and camphor) have been reported to inhibit maize growth by causing lipid peroxidation (Scrivanti et al. 2003; Zunino and Zygadlo 2004). Singh et al. (2006a) demonstrated that α-pinene induced severe lipid peroxidation in roots of *C. occidentalis*, damaged cellular membranes, and inhibited root growth.

Within a column, means with common letters are not significantly different at $P\leq0.05$, according to Tukey's test

Enhanced MDA content due to lipid peroxidation indicates an induction of ROS-generated oxidative stress.

Membrane damage upon exposure to *Artemisia* oil or β-myrcene was confirmed further by a significant decline in conjugated dienes content (Table 6). Upon exposure to ≥0.14 mg/ml of *Artemisia* oil or β-myrcene, the conjugated dienes content in roots of *C. occidentalis* decreased by 21–59% and 9–13%, respectively (Table 6). Decreased conjugated dienes further indicate a ROS-induced damage to biological membranes (Singh et al. 2007).

Effect on H_2O_2 Content Parallel to MDA accumulation, the amount of H_2O_2 increased significantly in roots of *C. rotundus* upon exposure to *Artemisia* oil or β-myrcene (Table 6). *Artemisia* oil and β-myrcene exposure increased H_2O_2 by 1.3- to 1.7-fold and 1.2- to1.5-fold, respectively, compared with control. At 0.35 mg/ml of *Artemisia* oil or β-myrcene, H_2O_2 content increased by 1.5- and 1.7-fold, respectively, over control (Table 6). Accumulation of H_2O_2 in *C. rotundus* roots further enhances lipid peroxidation, thus resulting in increased oxidative stress, and leading to disruption of metabolic activities in the cell. In general, H_2O_2 hinders the activity of ~SH group containing enzymes, impairs the photosynthetic activity in chloroplasts, and thereby reduces plant growth (Takeda et al. 1995). Among the different ROS produced in cells in response to environmental stresses, H_2O_2 acts as a signaling molecule. At low concentrations, it aids in cellular defense, and provides tolerance against stress, whereas at high concentrations, it induces cellular damage (Stone and Yang 2006). H_2O_2 is removed by antioxidant enzymes such as catalases, and ascorbate peroxidases, which were not studied in the present study.

In summary, the present study concludes that *Artemisia* oil inhibits germination and plant root growth through generation of ROS-induced oxidative stress associated with membrane disruption, enhanced lipid peroxidation, and accumulation of H_2O_2. Whether this induction of oxidative stress in response to *Artemisia* oil was accompanied by any alteration of antioxidant/scavenging enzymatic machinery in the plant roots remains to be studied.

Herbivore-Induced Volatiles in the Perennial Shrub, *Vaccinium corymbosum*, and Their Role in Inter-branch Signaling

Cesar R. Rodriguez-Saona · Luis E. Rodriguez-Saona · Christopher J. Frost

Received: 27 June 2008 / Revised: 9 December 2008 / Accepted: 11 December 2008 / Published online: 22 January 2009

Abstract Herbivore feeding activates plant defenses at the site of damage as well as systemically. Systemic defenses can be induced internally by signals transported via phloem or xylem, or externally transmitted by volatiles emitted from the damaged tissues. We investigated the role of herbivore-induced plant volatiles (HIPVs) in activating a defense response between branches in blueberry plants. Blueberries are perennial shrubs that grow by initiating adventitious shoots from a basal crown, which produce new lateral branches. This type of growth constrains vascular connections between shoots and branches within plants. While we found that leaves within a branch were highly connected, vascular connectivity was limited between branches within shoots and absent between branches from different shoots. Larval feeding by gypsy moth, exogenous methyl jasmonate, and mechanical damage differentially induced volatile emissions in blueberry plants, and there was a positive correlation between amount of insect damage and volatile emission rates. Herbivore damage did not affect systemic defense induction when we isolated systemic branches from external exposure to HIPVs. Thus, internal signals were not capable of triggering systemic defenses among branches. However, exposure of branches to HIPVs from an adjacent branch decreased larval consumption by 70% compared to those exposed to volatiles from undamaged branches. This reduction in leaf consumption did not result in decreased volatile emissions, indicating that leaves became more responsive to herbivory (or "primed") after being exposed to HIPVs. Chemical profiles of leaves damaged by gypsy moth caterpillars, exposed to HIPVs, or non-damaged controls revealed that HIPV-exposed leaves had greater chemical similarities to damaged leaves than to control leaves. Insect-damaged leaves and young HIPV-exposed leaves had higher amounts of endogenous *cis*-jasmonic acid compared to undamaged and non-exposed leaves, respectively. Our results show that exposure to HIPVs triggered systemic induction of direct defenses against gypsy moth and primed volatile emissions, which can be an indirect defense. Blueberry plants appear to rely on HIPVs as external signals for inter-branch communication.

Introduction

Herbivore feeding often activates direct and indirect defenses in plants, which are mainly regulated by the hormone jasmonic acid (JA; Karban and Baldwin 1997). Direct defenses alter the palatability and/or toxicity of leaf tissues (Agrawal 1998, 1999), while indirect defenses function by attracting natural enemies of herbivores (Turlings et al. 1990;

Vet and Dicke 1992; Dicke and Van Loon 2000). One important type of indirect defense is the emission of a class of volatile organic compounds termed herbivore-induced plant volatiles (HIPVs). Such defense responses against herbivores occur locally, i.e., at the site of feeding, but can also occur systemically, i.e., in non-damaged leaves of damaged plants (Turlings and Tumlinson 1992; Paré and Tumlinson 1998; Mattiacci et al. 2001). Systemic defenses can be induced in plants by internal signals that move primarily through vascular traces (see review by Orians 2005). The movement of internal signals can be restricted by the degree of vascular connectivity between parts of a plant (Orians et al. 2000; Schittko and Baldwin 2003). For instance, leaves with vascular connections to damaged leaves have stronger induction of defenses compared to those without vascular connections (Davis et al. 1991). This restriction can render some systemic regions of an herbivore-damaged plant vulnerable to future herbivory.

In addition to internal signals, plants may respond to external (e.g., airborne) signals emitted from other plants (inter-plant) or from other tissues within a plant (intra-plant). To date, most studies have investigated the role of external cues in inter-plant signaling (Baldwin and Schultz 1983; Dicke et al. 2003). Plants can respond to HIPVs from neighboring plants (Arimura et al. 2002; Farag and Paré 2002; Ruther and Kleier 2005; Ton et al. 2007), although concern exists about whether amounts of airborne signals emitted from damaged plants are abundant enough to maintain concentrations over sufficient distances to trigger the induction of volatiles from neighbors (Preston et al. 2001, 2004; Frost et al. 2008a). As an alternative mechanism, plant volatile signals might not induce defenses immediately but rather sensitize or 'prime' neighboring plants for an enhanced response when attacked by herbivores (reviewed in Frost et al. 2008b). For example, exposure to the green leaf volatiles (*Z*)-3-hexenal, (*Z*)-3-hexen-1-ol, or (*Z*)-3-hexenyl acetate from neighboring plants primes maize plants for defenses (Engelberth et al. 2004). Moreover, HIPVs can induce or prime defenses among systemic parts of the same plant (Frost et al. 2007; Heil and Silva Bueno 2007).

Little is known about the systemic induced responses in long-lived (perennial) shrubs. Individual branches in most shrubs are thought to share limited, if any, vascular connectivity with each other. With such restricted potential for internal systemic wound signaling, shrubs may be particularly vulnerable to mobile herbivores that can move among branches and evade induced defenses. External signals may be able to compensate for such vulnerability. For instance, systemic induced resistance in sagebrush, *Artemisia tridentata* Nutt., is facilitated by air contact with mechanically clipped branches (Karban et al. 2006). Considering that mechanical damage and insect feeding often induce different volatile response in plants (e.g., Mattiacci et al. 1994), the role of HIPVs in mediating systemic induction of resistance in shrubs still remains unclear.

Here, we studied induced local and systemic defense responses in the temperate woody perennial shrub *Vaccinium corymbosum* L. (highbush blueberry; Ericaceae). *V. corymbosum* grows by initiating adventitious shoots from a basal crown, which produce new lateral branches; this type of growth likely constrains vascular connection between shoots and branches within plants, and in turn restricts movement of internal signals. We hypothesized that external signals play an important role in induction of defenses between branches in *V. corymbosum*. This hypothesis was tested by determining whether prior exposure to naturally produced HIPVs from branches damaged by gypsy moth caterpillars activates or primes branches for enhanced defenses against insect attack. We asked the following specific questions: (a) Are volatile responses in *V. corymbosum* induced both locally and systemically by feeding by the generalist herbivore gypsy moth, *Lymatria dispar* L.? (b) Are volatiles induced by methyl jasmonate (MeJA), the volatile derivative of JA, and mechanical damage? (c) Does exposure to gypsy moth-induced volatiles trigger defense responses in neighboring branches? (d) Does exposure to HIPVs reduce larval consumption in neighboring branches? If so, (e) is there an effect on subsequent volatile emissions? We addressed these questions through a series of seven experiments to determine local and systemic emissions of volatiles from blueberry plants and the role of HIPVs in inter-branch signaling. These studies were complemented by three experiments to investigate the degree of vascular connectivity within blueberry plants and to measure internal changes in leaf chemistry.

Methods and Materials

Plants and Insects Actively growing 2-year-old highbush blueberry plants (*V. corymbosum* var. Duke) with 15–20 fully expanded leaves were used in all experiments. 'Duke' highbush blueberry is a vegetatively propagated line (Draper et al. 1987), and therefore genetically identical between individuals. Plants were purchased from A. G. Ammons Nursery (Chatsworth, NJ, USA), grown individually in 1-gal pots (16.5 cm diam) containing a 50:50 mix of sand and peat (Premier Pro-Moss, Red Hill, PA, USA; pH=4–5), watered three times a week, fertilized with 20–20–20 N–P–K all purpose water soluble Miracle-Gro (Scotts Miracle-Gro Products, Marysville, OH, USA), and maintained in a climatic controlled greenhouse (20±2°C; 70±10% RH; 15:9 L/D). All plants used were grown under similar conditions.

To induce defense responses in the blueberry plants, we used gypsy moth (*Lymantria dispar*) caterpillars, which are generalist herbivores that induce direct and indirect defenses in other plant species (Havill and Raffa 1999; Frost et al. 2007; Staudt and Lhoutellier 2007). Gypsy moths are exotic, naturalized pests of oaks and other hardwood species in the northeast USA (Liebhold et al. 1992); they also cause damage to leaves and flowers of blueberry plants, which can be severe in outbreak years. A gypsy moth colony was initiated from egg masses and caterpillars obtained from the USDA-ARS lab, Newark, DE, USA. Field-collected caterpillars were added to the colony prior to the study. Caterpillars were reared on a high wheat germ diet (Bell et al. 1981) and maintained at 24±1°C, 65% RH, and 14:10 h L/D.

Local Induction of HIPVs in Blueberry Leaves

Experiment 1 Blueberry plants were subjected to one of the following treatments: insect damage, mechanical damage, or control. Two branches of each plant were bagged with a spun polyester sleeve (Rockingham Opportunities Corp., Reidsville, NC, USA). All plants, including controls, were bagged to control for any bag effects. In the insect damage treatment, six gypsy moth caterpillars (second to third instars) were placed inside the bags and allowed to feed on plants for 2 days prior to volatile collection. HIPV emissions were collected on day 3. Polyester sleeves remained on plants to prevent insects from escaping. At the end of volatile collection, gypsy moth caterpillars consumed 9.8%±2.1 (SE) per leaf, measured visually as the percent of leaf area removed. In the mechanical damage treatment, damage to plants was inflicted by punching holes to mimic the amount of leaf area removed by gypsy moth. Five leaves per plant were injured with two 7-mm holes located at the base and upper portion of the leaves at the end of days 1 and 2 (1700 h), and volatiles were collected on day 3. The control treatment did not receive insect or mechanical damage. Volatiles from the three treatments were collected concurrently on a given day and each treatment was replicated eight times.

Experiment 2 This experiment investigated the effect of the amount of insect damage on HIPV emissions. Plants were damaged either by zero, two, four, or six gypsy moth caterpillars for 2 days; volatiles were collected on day 3. After volatile collections, larval consumption (in square centimeter) was measured by tracing the area removed from each leaf using Scion Image software (Scion Corporation, Frederick, MD, USA). Treatments were run concurrently and the experiment was replicated three times.

Experiment 3 This experiment tested the role of the jasmonate pathway in the volatile emissions from blueberry leaves. Blueberry plants were treated with 10 mL of either a 1.0- or 1.5-mM solution of MeJA (Sigma-Aldrich, St. Louis, MO, USA) in a 0.1% Tween-20 solution. MeJA was sprayed by using a 2-oz spray bottle (Setco Inc., Cranbury, NJ, USA). Control plants were sprayed with 10 mL of a 0.1% Tween-20 solution. Plants were treated at 1600 h and kept in the greenhouse for 15 h inside a 17-cm diam and 35-cm high Plexiglas chamber (with the entire top and three 2-cm diam holes on the sides of each chamber, covered with a fine mesh for ventilation) prior to volatile collections. After use, Plexiglas chambers were cleaned with tap water and 70% ethanol. Each treatment was replicated four times.

Systemic Induction—Internal Signaling

Experiment 4 One lower branch of a blueberry plant was bagged with a spun polyester sleeve and damaged by placing six (second to third instars) gypsy moth caterpillars inside the bag. The damaged branch remained outside the volatile collection chamber, while the branches above the damaged branch were placed inside the chamber. Caterpillars were allowed to feed on the bottom branch for 2 days. Starting on day 3, volatiles were collected from the undamaged portion of damaged plants. Volatiles were collected for seven consecutive days. Control plants were treated in a similar manner but did not receive insect damage. Treatments were replicated four times.

Vascular Connectivity To determine the degree of vascular connectivity between leaves within a branch and from different branches, we conducted a Rhodamine-B (Sigma-Aldrich) dye assay (Orians et al. 2000). The terminal portion of a lower branch from blueberry plants ($N=7$) was cut so that it could support a floral water pick containing 6 mL solution of the dye (0.25% *w*/*v*). Movement of the dye through the plant was monitored daily for 7 days. After 7 days, the percent of red staining was visually assessed for 30 randomly collected leaves from different positions of the plants. Leaves were sampled from the following positions: branches containing the dye, branches directly above the branch containing the dye (orthostichous branches), branches located across the branch containing the dye, and branches located in a different shoot.

Systemic Induction—External Signaling

Experiment 5 Branches within a plant were either exposed to HIPVs from an adjacent branch or received no exposure to HIPVs. To expose branches to HIPVs, one lower branch was bagged with a polyester sleeve and six (second to third instars) gypsy moth caterpillars were placed inside bags. This treatment allowed movement of significant amounts of

volatiles outside the bags as indicted by experiments testing local induction of volatiles (see "Results"). The aerial portion of the plant was caged inside a Plexiglas chamber similar to those described above. Insects were allowed to feed on plants for 2 days, such that adjacent branches were exposed to volatiles emitted from the induced branch. After exposure (day 3), exposed branches were placed inside the volatile collection chamber, leaving the insect-injured branch outside. Volatiles from HIPV-exposed branches were collected, and the amount of leaf area consumed from the lower branch was measured. Each treatment was replicated four times.

Experiment 6 To determine whether plants were "primed" after HIPV exposure, eight plants were treated as in experiment 5. In half of the plants, branches were exposed to HIPVs from an induced adjacent branch, while the other half was exposed to undamaged branches. On day 3, four early second instar gypsy moth caterpillars were placed on each plant, and volatiles were collected. The size of caterpillars was standardized by obtaining initial larval weights; each set of four caterpillars averaged 50±5 mg. After volatile collections, leaves initially damaged by gypsy moth caterpillars, as well as those that were damaged on day 3, were excised, and the amounts of leaf area consumed were measured. Treatments were replicated four times.

Experiment 7 An additional experiment similar to experiment 6 was conducted but 25×25 cm plastic ziplog bags (National Bag, Hudson, OH, USA) were used instead of polyester sleeve bags. Ziplog bags prevented HIPV contact with leaves from undamaged branches within a plant. Each treatment was replicated four times.

Chemical Analyses

HIPV Collection and Analysis HIPV emissions were sampled in the greenhouse (20±5°C; 70±10% RH; 15:9 h L/D). Volatiles were collected using a push–pull system (Rodriguez-Saona et al. 2001, 2006). The above ground portion of potted plants (stem, branches, and leaves), including caterpillars in the insect damage treatment, were placed inside a 4-L volatile collection chamber (Analytical Research Systems, Inc. Gainesville, FL, USA). A two-piece guillotine supported the base of plants. Purified air entered the top of each chamber at a rate of 2 L/min. Volatiles were collected in traps filled with 30 mg of Alltech Super-Q adsorbent (Analytical Research Systems, Inc), by pulling air from the chambers at a rate of 1 L/min. The volatile collection apparatus consisted of four chambers, allowing for simultaneous collections of volatiles from four different plants. Collections were conducted during daytime from 0900 to 1700 h. After collection, all leaves from plants were harvested, oven dried at 60°C, and weighed, and chambers were rinsed with tap water and 70% ethanol.

The collected volatiles from Super-Q traps were eluted with dichloromethane (150 μL), and 400 ng of *n*-octane (Sigma-Aldrich) were added as internal standard. Separation and quantification of compounds was done on a Hewlett Packard 6890 Series Gas Chromatograph (GC), equipped with a flame ionization detector (FID) and an Agilent HP-1 column (10 m×0.53 mm×2.65 μm), and using He as carrier gas (constant flow=5 mL/min, velocity=39 cm/s). The temperature program started at 40°C kept for 1 min, increased at 14°C/min to 180°C (2 min), then at 40°C/min to 200°C, and kept at 200°C for 2 min. Individual compounds (nanogram per gram of dry material per hour) were quantified based on comparison of peak areas from GC–FID with that of the internal standard.

Identification of compounds was carried out on a Varian 3400 GC coupled to a Finnigan MAT 8230 mass spectrometer (MS), equipped with a Supelco MDN-5S column (30 m×0.32 mm×0.25 μm), and with He as the carrier gas. The program started at 35°C (1 min), increased at 4°C/min to 170°C, then at 15°C/min to 280°C. The MS data were acquired and processed in a Finnigan MAT SS300 data system. Compounds were identified by comparison of spectral data with those from NIST library and by GC retention index (Jennings and Shibamoto 1980; Adams 2001) and confirmed by comparing their retention times with those of commercially available compounds.

A completely randomized one-way ANOVA (Minitab Statistical Software, Release 13, State College, PA, USA) was used to determine differences in volatile emissions among treatments. If a treatment effect was significant, a Tukey test was conducted. Differences in volatile emissions and leaf area eaten between two treatments were determined using *t* tests. Data were transformed by $\ln(x)$, or $\ln(x+0.05)$ if data included zero values, prior to analyses. The amount of insect damage was correlated against the amount of volatiles emitted.

Quantification of Jasmonic Acid, Salicylic Acid, and Linolenic Acid In a separate experiment, a lower branch of three blueberry plants was damaged by six (second to third instars) gypsy moths, as described in experiment 5. On day 3, all leaves from each plant were collected for phytohormone analyses. Leaves from the insect-damaged branch and from young and old leaves of HIPV-exposed branches were sampled separately (young leaves were those soft leaves in branches at the top of plants, and old leaves were those hard leaves in branches at the base of the plant). Samples were also collected from three other plants that received no insect damage (controls). Samples were placed

directly into liquid N_2, and care was taken to not allow the tissue to thaw at any point prior to extraction.

Extraction and quantification were performed as previously described (Schmelz et al. 2003, 2004). Briefly, ~100 mg frozen ground tissue of each sample was transferred to 2-mL screw-cap FastPrep tubes (Qbiogene, Carlsbad, CA, USA) containing ~1 g of Zirmil beads (1.1 mm; SEPR Ceramic Beads and Powders, Mountainside, NJ, USA). Dihydro-JA and $^2H_6$-SA (CDN Isotopes, Pointe-Claire, Quebec, Canada) and gamma-LA (Matreya LLC, Pleasant Gap, PA, USA) were added as internal standards to the 2-mL tubes before sample addition (100 ng each). The samples were mixed with 400 mL of 1-propanol/H_2O/HCl (2:1:0.002) and shaken for 40 s in a FastPrep FP 120 tissue homogenizer (Qbiogene). Dichloromethane (1 mL) was added to each sample, re-shaken for 40 s in the homogenizer, and centrifuged at 10,000×*g* for 1 min. The bottom organic phase (dichloromethane) was transferred to a 4-mL glass screw-cap vial and evaporated by a constant air stream (~10 min). Each sample was reconstituted in 100 mL diethyl ether/methanol (9:1, *v*/*v*), and carboxylic acids were converted into methyl esters by adding 2.3 μL of a 2.0-M solution of trimethylsilyldiazomethane in hexane (Sigma-Aldrich). The vials were capped, vortexed, and incubated at room temperature for 30 min. The reaction was stopped by the addition of hexane/acetic acid (78:12 *v*/*v*), followed by brief vortexing and incubation for 30 min at room temperature. Volatile metabolites were separated from the complex mixture by vapor-phase extraction as described in Schmelz et al. (2004). The methylated products were eluted with 150 μL of dichloromethane and analyzed by chemical ionization−GC–MS.

Differences in amounts of JA, salicylic acid (SA), and linolenic acid (LA) between damaged and undamaged leaves were determined by using *t* tests. Differences in the amounts of these phytohormones between HIPV-exposed and -unexposed leaves were analyzed with a two-way ANOVA with treatment (exposed vs. unexposed) and leaf age (young vs. old) as main effects. If significant differences were found, a Tukey test was conducted. Data were transformed by ln(*x*) prior to analysis.

Fourier-Transform Infrared Phenolic extracts of each treatment were compared by using Fourier-transform infrared (FT-IR) to investigate if differences exist in the chemical profiles. This technique allowed us to compare spectral differences among treatments across broad wavenumbers (4,000–600 cm^{-1}), particularly those associated with phenolic compounds (~1,400 to 1,000 cm^{-1}). Branches of 12 different blueberry plants were either (a) exposed to HIPV emissions, (b) damaged locally by six gypsy moth caterpillars, or (c) left undamaged, as described above. Leaves from each branch were excised after 2 days of treatment, frozen in liquid N_2, stored at −70°C, and used for FT-IR analysis. Frozen leaves were sonicated (sonic dismemberator model 100; Fisher Scientific, Pittsburgh, PA, USA) with 70% aqueous acetone (*v*/*v*) for 30 s with an output of 8 W. Chloroform was added to the suspension, and phase separation was achieved by using a microcentrifuge (Model 5415R, Eppendorf, Westbury, NY, USA) operating at 16,100×*g* for 3 min. The top aqueous layer was collected, concentrated under a stream of nitrogen, and further fractionated by using a modified solid-phase extraction (SPE) method described by Giusti et al. (1999). Briefly, the sample was loaded onto a Sep-Pak Vac (1 g) C18 cartridge (Waters, Milford, MA, USA) that had been preconditioned with 10 mL of acidified methanol (0.1% HCl) and 10 mL of acidified DD water (0.1% HCl) and then washed with 5 mL of acidified DD water. Phenolics were eluted from the column with 5 mL of acidified methanol. An aliquot of the phenol-rich fraction was dried under nitrogen flow and reconstituted by adding 500 μL of 30% methanol containing 0.1% HCl. An aliquot (10 μL) was applied onto a SpectCONC-IR (Tienta Sciences, Indianapolis, IN, USA) slide and vacuum-dried to yield a homogeneous film. The use of the SpectCONC-IR slide provides a high IR reflectance surface and the ability to concentrate samples up to ten times due to the presence of a hydrophobic coating.

Infrared spectra were collected on an infinity corrected FT-IR microscope (UMA 600 series IR microscope interfaced with a FTS Excalibur 3500GX FTIR spectrometer; Varian, Walnut Creek, CA, USA), equipped with a motorized x–y stage and a broadband mercury cadmium telluride detector. The spectrometer was controlled by Win-IR Pro control software programmed to collect spectra over the frequency range 4,000–600 cm^{-1}. The spectral resolution was 4 cm^{-1} and to improve the signal-to-noise ratio, 128 spectra were co-added and averaged. Spectra were displayed in terms of absorbance as calculated from the transmittance spectra by using the Win IR Pro software. Infrared spectral data transformations included area normalization and second derivative based on a Savitzky–Golay polynomial filter. Sample residual and Mahalanobis distance were used for outlier diagnostics.

Spectral differences among treatments were determined by using multivariate data analyses. The spectra were imported as JCAMP-DX files into the Pirouette statistical software (Version 3.02 for Windows NT, Infometrix, Inc., Woodinville, WA, USA), and multivariate training models were produced using soft independent modeling of class analogy (SIMCA). Analysis by SIMCA, a supervised method for sample classification, consists of assigning training sets to classes and then a principal component model is created for each class with different confidence

regions (De Maesschalck et al. 1999). Class projection plots were used to illustrate the ability of SIMCA to differentiate FT-IR data based on the first three principal components. This plot was used for the visualization of clustering among samples (sample patterns, groupings, or outliers). SIMCA analysis was carried out by Pirouette pattern recognition software (Version 3.02 for Windows NT, Infometrix, Inc., Woodinville, WA, USA). The interclass distances were used as a diagnostic for a SIMCA model, which essentially is the Euclidian distance between the centers of each group where large interclass distances imply well-separated classes. SIMCA's discrimination power was used as a measure of variable importance (i.e., infrared frequency), which contributes to the development of the classification models (Dunn and Wold 1995).

Results

Local Induction of HIPVs in Blueberry Leaves

Twenty-two volatile compounds were identified by GC–MS from blueberry leaves (Fig. 1; Table 1). Mechanical damage and feeding by gypsy moth caterpillars increased volatiles emissions from blueberries by four- and ninefold, respectively, compared to controls (Table 1). Mechanical damage increased emissions of (*Z*)-3-hexenyl acetate, benzene acetonitrile, γ-cadinene, α-farnesene, and caryophyllene oxide ($P \leq 0.05$). In addition to these, feeding by gypsy moth increased volatile emissions of 12 other, mostly terpene, compounds including α-pinene, eucalyptol, linalool, myrcenone, caryophyllene, humulene, and β-

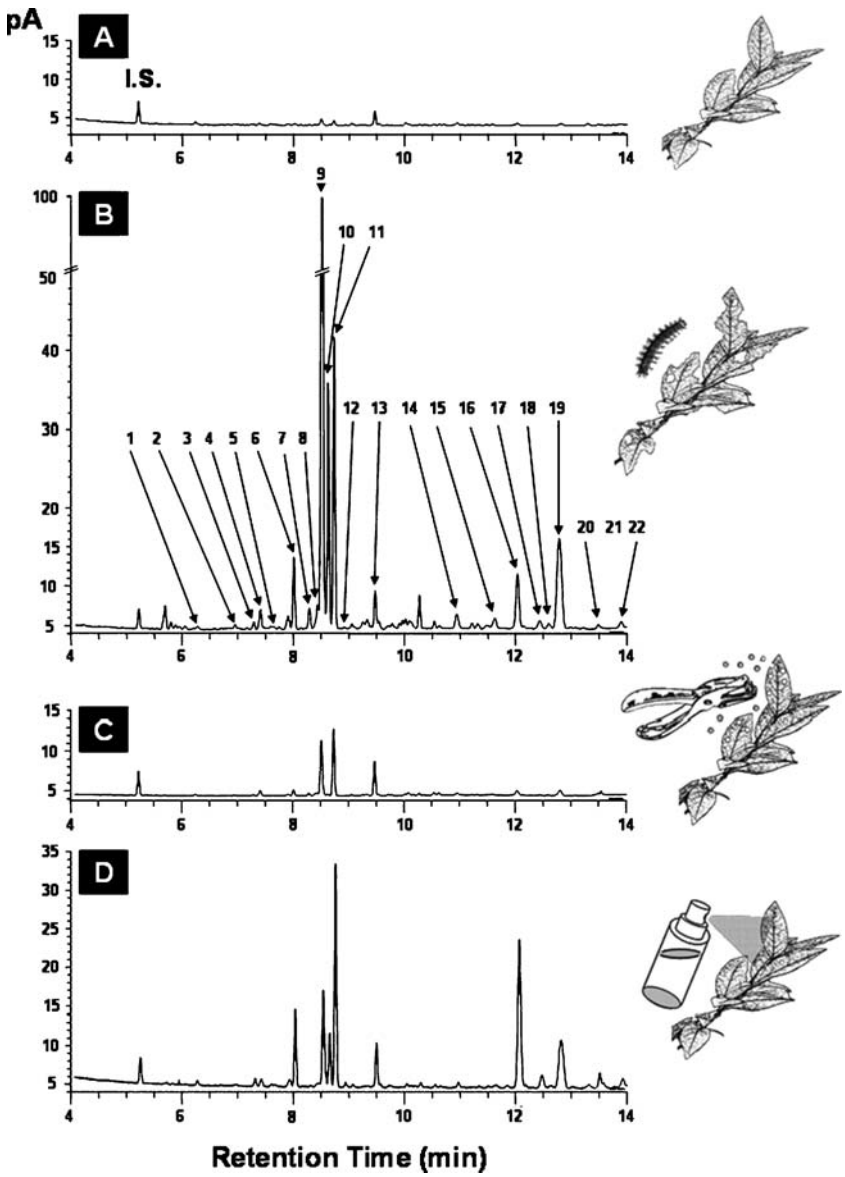

Fig. 1 Representative GC–FID profiles of headspace volatiles collected from 2-year-old highbush blueberry, *Vaccinium corymbosum*, plants. Treatments are: undamaged plants (**A**), plants damaged by six, second to third instar, gypsy moth caterpillars (**B**), plants damaged mechanically (**C**), and plants treated with 1.0 mM MeJA (**D**). Compound names **1**–**22** are listed in Tables 1 and 2. *I.S.* internal standard (*n*-octane). Volatiles were collected from 0900 until 1700 h

farnesene ($P\leq0.05$; Table 1). There was a strong, positive correlation between the amount of gypsy moth damage and volatile emissions ($F=41.4$; $df=1, 10$; $P<0.001$; $r^2=0.79$; Fig. 2).

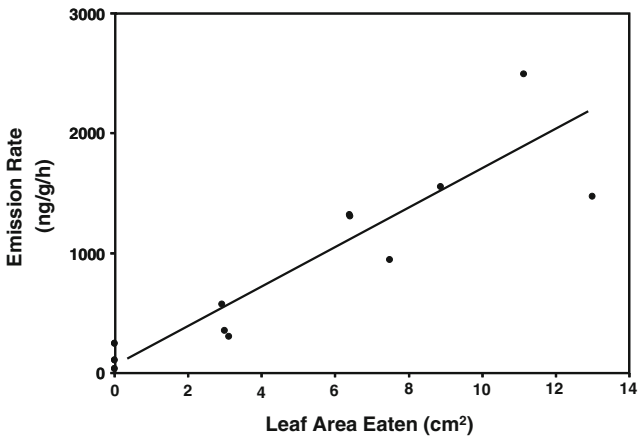

Fig. 2 Correlation of the volatile emission rates with the amount of leaf area eaten by gypsy moth caterpillars in blueberry plants. Emission rates were calculated by dividing the total relative amounts of volatiles by the dry weight of plant material and the total number of hours for each collection. The relative amount of volatiles for a particular compound was calculated as the ratio of its peak area to the peak area of the internal standard. Amount of leaf area eaten was measured by tracing the area removed from each leaf by caterpillars

Compared to caterpillar feeding, the MeJA treatment induced 11 out of the 17 compounds induced by gypsy moth (Table 2). Compounds significantly increased by gypsy moth but not by MeJA were 2,5 hexanedione, α-pinene, (*Z*)-3-hexenyl acetate, *cis*-linalool oxide, β-bourbonene, and caryophyllene oxide. Five chemicals (β-pinene, hexyl acetate, methyl salicylate, copaene, and farnesol) were not increased by any treatment.

Systemic Induction—Internal Signaling

There was no evident induction of volatiles from undamaged leaves of gypsy moth-damaged plants 7 days after initial feeding damage (day 3: control (undamaged)= 167.7±54.4 ng/h (mean ± SE volatile emissions), treatment (systemic induction)=173.8±63.3 ng/h, $t=0.15$, $P=0.88$; day 4: control=126.9±35.5 ng/h, treatment=140.4±41.7 ng/g, $t=0.11$, $P=0.92$; day 5: control=129.6±59.7 ng/h, treatment=121.5±52.4 ng/h, $t=0.07$, $P=0.95$; day 6: control=171.2±96.7, treatment=88.8±28.0, $t=0.11$, $P=0.92$; day 7: control=181.6±41.0, treatment=230.8±92.5, $t=0.08$, $P=0.94$).

Vascular connectivity among leaves depended heavily on their relative position. On days 1–3, we observed very slow movement of the red dye such that there was little staining

in leaves other than those in branches containing the dye. On day 4, some staining occurred in branches close to those containing the dye (mainly in orthostichous branches, i.e., vertically aligned in a shoot), but most staining was limited to one or two leaves close to the shoot. After 1 week, we found high vascular connectivity between leaves within a branch (Fig. 3A), intermediate-to-low connectivity between leaves from orthostichous branches (Fig. 3B), low connectivity between leaves from non-orthostichous branches (i.e., on opposite sides of a shoot; Fig. 3C), and a lack of connectivity between leaves from branches located on different shoots (Fig. 3D).

Systemic Induction—External Signaling

Herbivore-induced plant volatiles mediated systemic resistance among blueberry branches. There was no difference between volatile concentrations emitted from branches exposed to HIPVs vs. those not exposed to HIPVs ($t=0.58$; $P=0.59$; Fig. 4A). However, *L. dispar* caterpillars fed on leaves previously exposed to HIPVs consumed 70% less leaf material than did those fed on unexposed control leaves ($t=8.62$; $P=0.003$; Fig. 4B). Despite the reduction in leaf consumption, total volatile emissions between HIPV-exposed and HIPV-unexposed branches were similar (total volatile emissions for HIPV-unexposed branches=1,127.4±180.9 ng/g/h, HPIV-exposed branches=1,313.9±435.1 ng/g/h; $t=0.01$; $P=0.99$). As a result, amounts of volatiles emitted per amount of leaf area consumed in HIPV-exposed branches were fourfold higher compared to unexposed

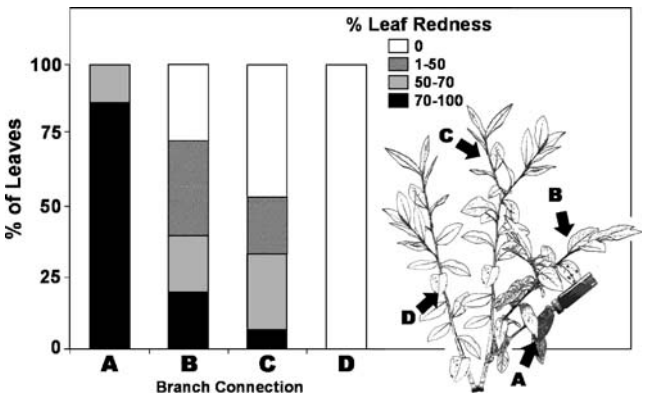

Fig. 3 Rhodamine-B (red dye) was used to determine the degree of vascular connectivity between leaves within a branch, and from different branches within blueberry plants. (*Left*) Percent of leaves with different amounts of red staining. The amount of red staining (0%, 1–50%, 50–70%, and 70–100%) was visually assessed for 30 randomly collected leaves from each of four positions *A–D* of blueberry plants ($N=7$). Leaf samples were taken after 7 days. (*Right*) Location of leaves sampled within a plant. Leaves were sampled from: branches containing the dye (*A*), branches directly above the branch containing the dye (*B*), branches located across the branch containing the dye (*C*), and branches located in a different shoot (*D*)

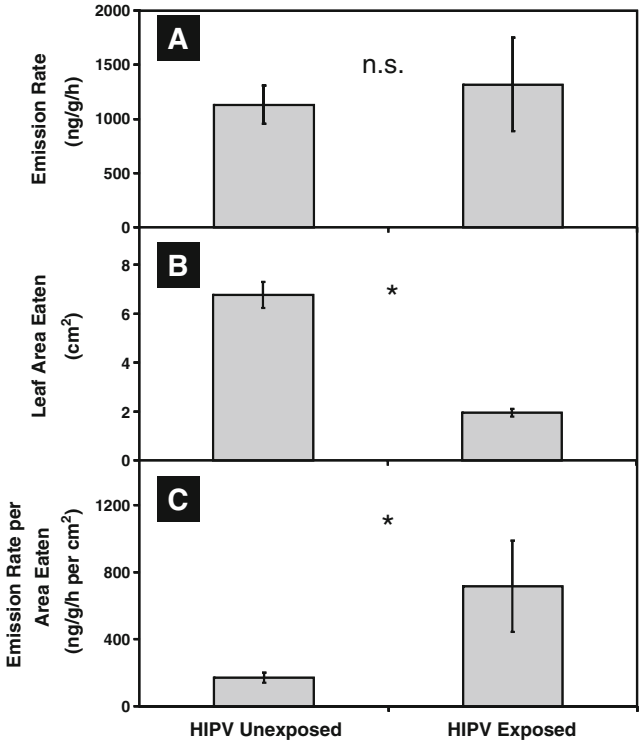

Fig. 4 Induction and priming of blueberry volatiles by herbivore-induced plant volatiles (HIPVs). **A**) Volatile emission rates of blueberry branches that were either exposed to HIPVs (*HIPV Exposed*) from an adjacent branch of the same plant, or received no exposure to HIPVs (*HIPV Unexposed*). **B**) Amount of leaf area eaten by gypsy moth caterpillars on HIPV-unexposed and HIPV-exposed branches. **C**) Amount of volatiles emitted per amount of leaf area consumed in HIPV-unexposed and HIPV-exposed branches. *Asterisks*, significant differences between treatments (N=4, $P \leq 0.05$); *n.s.* not significant

branches (t=2.78; P=0.05; Fig. 4C), indicating that leaves from HIPV-exposed branches were more responsive to herbivory (i.e., they were primed).

The priming effect was eliminated when undamaged branches were prevented from being exposed to HIPVs from damaged branches within a plant (emission rate per leaf area eaten=588.7±159.4 ng/g/h per cm^2 for HIPV-unexposed branches and 399.4±120.5 ng/g/h per cm^2 for HIPV-exposed branches; t=0.97; P=0.376). Differences in priming between these experiments were not due to differences in the amounts of leaf area consumed by gypsy moth in the lower branches of plants (initial damage; total amount of leaf area consumed=7.8±4.6 cm^2 (experiment 6) and 12.4±3.2 cm^2 (experiment 7); t=1.64, P=0.16).

Internal Leaf Chemistry

Endogenous JA was induced by both gypsy moth feeding and HIPV exposure. Gypsy moth feeding strongly increased amounts of JA at the site of damage (*cis*-JA: control=0.9±0.2 ng/g, treatment=94.6±34.4 ng/g, t=10.44, P=0.002; *trans*-JA: control=1.7±0.5 ng/g, treatment=27.8±8.2, t=6.17, P=0.009). More surprisingly, leaf exposure to HIPVs had an effect on amounts of *cis*-JA concentrations (F=6.73; df=1, 8; P=0.03). This effect was influenced by leaf age, such that *cis*-JA levels in young leaves exposed to HIPVs were 20 times greater than unexposed leaves (significant treatment-by-age interaction; F=5.33; df=1, 8; P=0.05; Fig. 5). Older leaves did not have higher concentrations of *cis*-JA, and exposure to HIPVs had no effects on amounts of *trans*-JA (F=0.09; df=1, 8; P=0.77).

In contrast to JA concentrations, no differences in the concentrations of SA and LA were found between control and damaged leaves (SA: control=3.0±1.6 ng/g, treatment=5.8±1.5 ng/g, t=1.4, P=0.256; LA: control=235.6±131.3 ng/g, treatment=93.9±43.6 ng/g, t=0.90, P=0.434). Moreover, exposure to HIPVs had no effect on concentrations of SA (F=2.41; df=1, 8; P=0.16) or LA (F=1.77; df=1, 8; P=0.22). However, SA concentrations were higher in younger leaves compared to old leaves within a plant (F=22.7; df=1,

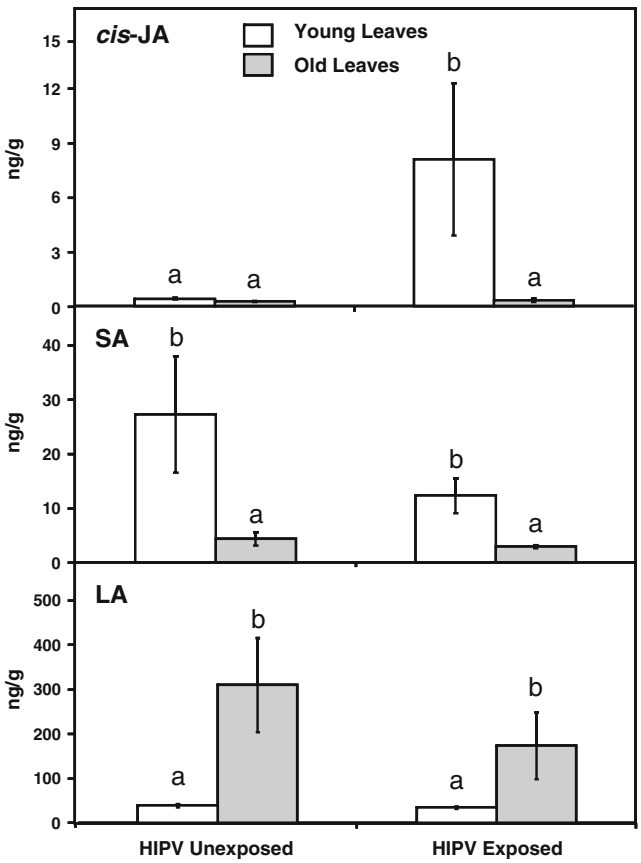

Fig. 5 Levels of endogenous jasmonic acid (*cis-JA*), salicylic acid (*SA*), and linolenic acid (*LA*) in blueberry leaves from branches that were either exposed to HIPVs from adjacent branches within a plant (*HIPV Exposed*), or not exposed (*HIPV Unexposed*). Young and old leaves were analyzed separately. *Different letters above bars* indicate differences in the levels between treatments (N=3, $P \leq 0.05$)

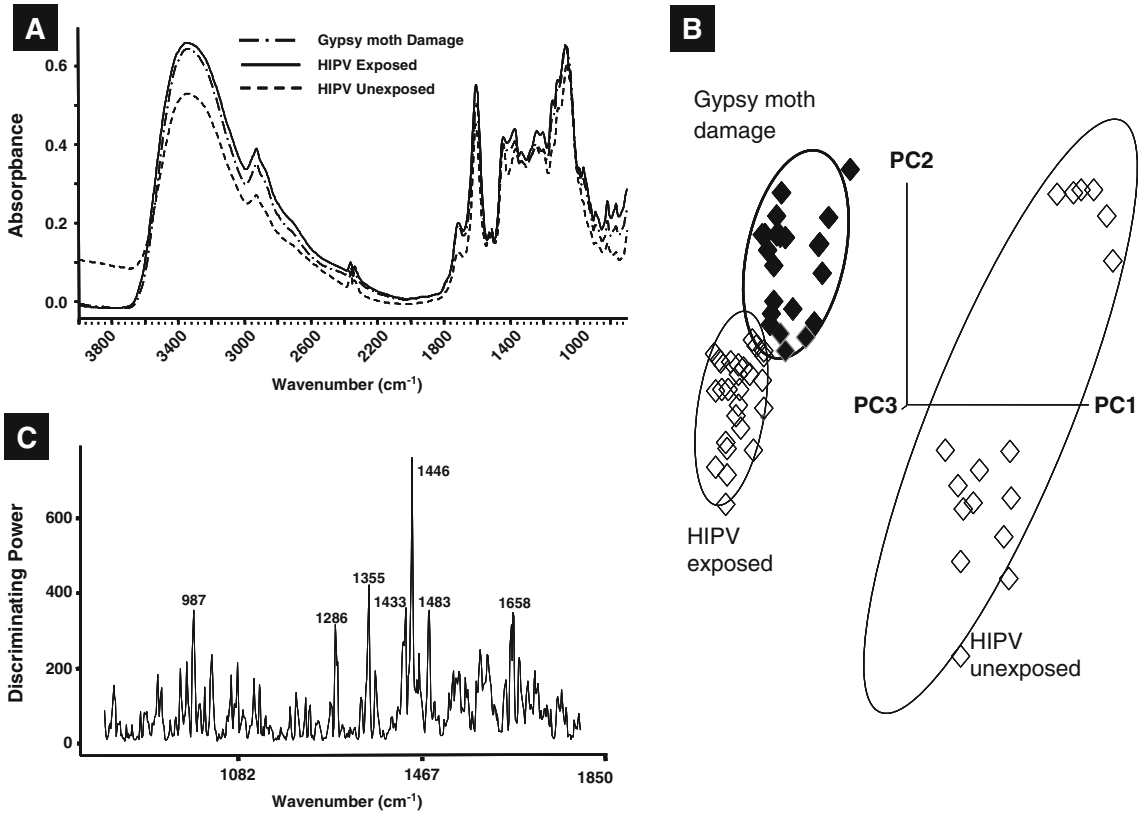

Fig. 6 **A**) Characteristic FT-IR spectrum from blueberry leaves that were either damaged by the gypsy moth, exposed to HIPVs (*HIPV Exposed*), or not exposed to HIPVs (*HIPV Unexposed*). **B**) A three principal component analysis showing good class separation among treatments. **C**) Soft independent modeling of class analogy (SIMCA) discrimination power showing bands associated with the classification of the samples; these bands are related to vibrations of aromatic and/or glycosylated functional groups such as quinone (1,670 cm^{-1}), the benzene structure (1,584 and 1,450 cm^{-1}), secondary C–O–H (1,317 and 1,171 cm^{-1}) structure of phenolic –OH groups and sugar moieties, and the pyranose rings (962 cm^{-1})

8; P=0.001); while LA concentrations in young leaves were lower than in old leaves (F=34.04; df=1, 8; P<0.001; Fig. 5). There was no effect of leaf age on amounts of *trans*-JA or treatment-by-age interaction for *trans*-JA, SA, and LA (all P values>0.05).

Infrared microspectroscopy (FT-IR) detected differences in chemical profiles among gypsy moth damaged, HIPV-exposed, and HIPV-unexposed blueberry leaves. FT-IR further indicated that the HIPV-exposed leaves were more chemically similar to leaves damaged by gypsy moths than to control leaves. Observation of the spectra showed differences among treatments particularly in the frequency region ranging from 1,800 to 900 cm^{-1} (Fig. 6A). The SIMCA pattern recognition model showed good class separation among treatments, zero misclassifications, "tight" cluster of samples, and large distances (2.01 to 8.04) between classes (Fig. 6B). SIMCA models showed interclass distance values of 6.5 for HIPV-unexposed vs. HIPV-exposed leaves, and 8.0 for HIPV-unexposed vs. gypsy moth damage leaves; class distances above 3.0 are generally considered good for discrimination (Kvalheim and Karstang 1992). Interestingly, the interclass distance between clusters for spectra collected from the phenolic fraction of HIPV-treated and gypsy moth damage leaves was 2.01, indicating similarities in their chemical profiles. Using SIMCA's discrimination power, we found bands associated with the classification of the samples that are related to vibrations of aromatic and/or glycosylated functional groups such as quinone (1,670 cm^{-1}), the benzene structure (1,584 and 1,450 cm^{-1}), secondary C–O–H (1,317 and 1,171 cm^{-1}) structure of phenolic −OH groups and sugar moieties, and the pyranose rings (962 cm^{-1}; He et al. 2007; Fig. 6C).

Discussion

This study provides the first insights into the volatile response of the perennial shrub *V. corymbosum* to herbivory by gypsy moth caterpillars and new evidence for the role of HIPVs in intra-plant signaling. As expected, caterpillar feeding increased endogenous JA concentrations and volatile emission rates at the site of damage. In addition, exogenous MeJA application induced 65% of the same

volatiles induced by caterpillar feeding, indicating that the JA pathway plays a key role in the induction of HIPVs in *V. corymbosum*. The JA pathway has been shown to induce the emissions of volatiles in several other plant species (e.g., Hopke et al. 1994; Boland et al. 1995; Gols et al. 1999; Rodriguez-Saona et al. 2001). Under control conditions (i.e., no previous exposure to volatiles), HIPV emission rates correlated linearly with the amounts of damage and exogenous MeJA application within the range tested in this study, such that greater damage and MeJA concentration triggered higher volatile emissions. However, undamaged leaves with previous exposure to naturally occurring HIPVs had higher volatile emission rates than were expected once they were fed upon by gypsy moth, which indicates that HIPV exposure had a priming effect on undamaged leaves. Since gypsy moth caterpillars and their excrement are odorless (Staudt and Lhoutellier 2007), they are not a confounding source of volatiles in our experiments.

Based on our results, *V. corymbosum* cannot and does not rely on internal signals to induce defenses among vascularly isolated branches. Blueberry plants have a complex architectural structure that limits vascular connectivity among branches. As a result, systemic responses to herbivores are highly variable in space and time. For example, when we collected volatiles from the upper branches of damaged plants, we failed to find a systemic volatile response 7 days after initial insect damage. When observed in other systems, systemic responses in plants often occur within 7 days after damage (Mattiacci et al. 2001). From an ecological perspective, systemic responses that fail to activate within 7 days are likely to fail to provide adequate defenses. While priming (rather than induction) of systemic volatile emissions via vascular connections has been shown in *Populus* saplings (Frost et al. 2007), the important point for blueberry plants is that vascular connections are limited.

In contrast to vascular systemic signaling, airborne compounds are capable of acting as systemic wound signals among branches of *V. corymbosum*. Indeed, our results indicate that HIPV-mediated signaling is an effective mediator of systemic defenses and, more importantly, resistance against herbivory. For instance, we found that exposure to HIPVs reduced gypsy moth feeding by 70% in adjacent leaves from different branches compared to controls. Blocking exposure to HIPVs prevented these results, indicating that HIPVs are necessary for intra-plant signaling among vascularly isolated branches. Previous studies also have shown that exposure of HIPVs induces resistance against insects between (Karban et al. 2003; Ton et al. 2007) and within (Heil and Silva Bueno 2007) plants. Although the exact identity of compounds responsible for the changes in chemical profiles among treatments remains unknown, they are likely associated with polyphenolic compounds, and thus, it is possible that increases in *cis*-JA in HIPV-exposed leaves induced production of antiherbivore compounds. Alternatively, HIPV exposure might not trigger insect resistance per se, but rather prime exposed leaves for an increased response to insect damage. Although we found significantly higher levels of *cis*-JA in exposed leaves, insect-damaged leaves had more than ten times higher levels of *cis*-JA than did HIPV-exposed leaves. HIPV-exposed leaves had chemical profiles that were more similar, but not identical, to damaged leaves than to controls (Fig. 6). Thus, the levels of JA in HIPV-exposed leaves may not have been sufficient to reduce feeding by gypsy moth, but rather may have primed these leaves to respond more rapidly and/or strongly to insect attack. For instance, corn seedlings previously exposed to HIPVs from neighboring plants induce rapid production of JA in response to a wounding treatment (Engelberth et al. 2004).

The effects of HIPVs on *cis*-JA induction were greater in young leaves than older leaves within a plant. This agrees with previous results that showed volatile-mediated systemic induced resistance only in young, actively growing sagebrush (Shiojiri and Karban 2006). Gypsy moth occurrence in *V. corymbosum* synchronizes with the plant's ontogeny such that caterpillars become active early in the season when blueberry plants are developing new growth. Gypsy moth caterpillars have a preference for young *V. corymbosum* leaves (C.R.-S. personal observation), thus protection of young leaves might be adaptive.

Although HIPV exposure did not induce volatile emissions, HIPV-exposed branches were nonetheless primed for an increased volatile response to gypsy moth feeding. Based on the amount of gypsy moth damage (approx. 2 cm^2) inflicted in HIPV-exposed branches (Fig. 4), we would expect a volatile emission rate of ~500 ng/g/h (based on Fig. 2). Instead, the observed amount was 1,314 ng/g/h, or an emission rate more than 2.5 times higher than that expected. Whether the full HIPV blend is required or whether specific compounds in the blend are responsible for the observed priming remains unclear. Corn seedlings previously exposed to HIPVs from neighboring plants induced greater volatile emissions than unexposed plants, a response also primed by (*Z*)-3-hexenyl acetate (Engelberth et al. 2004). In our study, (*Z*)-3-hexenyl acetate was emitted following herbivory and mechanical damage but not MeJA applications, and thus might represent a non-specific response in *V. corymbosum* due to physical damage to leaves. Despite the lack of specificity in its release, (*Z*)-3-hexenyl acetate activates plant defenses and has priming activity (Engelberth et al. 2004; Ruther and Kleier 2005; Kost and Heil 2006).

Responding to HIPVs by an increase in volatile emissions in the absence of herbivores might incur ecological as well as physiological costs, because HIPVs might provide unreliable information to the herbivores'

natural enemies. Instead, a more adaptive strategy might be for plants to prime themselves for an increased volatile response after exposure to HIPVs. This increased rate of volatile emission from HIPV-exposed leaves might serve as an indirect defense by preferentially attracting the natural enemies of herbivores (e.g., Ton et al. 2007). In addition, increased volatile emissions from HIPV-exposed leaves might serve a direct defense role since several volatiles induced by gypsy moth in *V. corymbosum*, including linalool and farnesenes, can have repellent effects on caterpillars (Markovic et al. 1996).

In summary, our results show that leaves from damaged *V. corymbosum* branches transmit information through volatiles that minimize insect feeding damage and prime volatile emissions in the receiving leaves of adjacent branches. These results are consistent with those from Karban et al. (2006) who found that sagebrush branches typically do not exchange signals via vascular connections but instead use external signals to activate resistance. The hypothesis that plants use airborne signals to transfer information to other parts of plants at risk of herbivore attack was first proposed by Farmer (2001), and Orians (2005) later expanded this hypothesis by suggesting that high architectural complexity within many plants might necessitate such external wound signaling. Our results combined with those by Karban et al. (2006), Heil and Silva Bueno (2007), and Frost et al. (2007) provide strong evidence that HIPVs play a role in intra-plant signaling. Indeed, external signaling via volatiles appears particularly important among branches of shrubs such as blueberries, where mobile caterpillars may be able to move relatively short distances among branches and evade induced defenses. Previous studies showed that HIPVs increase and/or prime defenses in neighboring plants (see review by Frost et al. 2008b). However, the ecological role of HIPVs in plant-to-plant communication remains unclear because the receiver plant often has to be in close proximity to the emitter plant (within 15 cm; Karban et al. 2003). In our study, the HIPV-emitting and -receiving branches were 10–15 cm apart; this distance is similar to that found between branches in natural settings (C.R.-S., personal observation). Thus, the effects of HIPVs in intra-plant signaling in blueberries likely occur also in nature, as shown in other systems (Karban et al. 2006; Heil and Silva Bueno 2007). This study provides compelling evidence for the role of HIPVs in intra-plant signaling and further demonstrates the multi-functional effects of HIPVs.

Acknowledgments We are grateful to Drs. Paul Paré and Nicholi Vorsa for their comments on the manuscript. We thank Robert Holdcraft for his help with the tables and figures, Vera Kyryczenko-Roth for technical assistance, Dr. Philip Taylor (USDA-ARS, Beneficial Insects Introduction Research Unit, Newark, DE) for the supply of gypsy moth egg masses and caterpillars, and Dr. Thomas Hartman (Rutgers University, Mass Spectrometry Support Facility, New Brunswick, NJ) for identification of volatiles. Funding for this study was provided by USDA-CREES Special Grant (Project No. 2006-34155-17118) and hatch funds (Project No. NJ08192) to C.R.-S., and by the USDA-NRI (Project No. 2007-35302-18087) to C.J.F.

Received: 7 May 2008 / Revised: 27 December 2008 / Accepted: 5 January 2009 / Published online: 22 January 2009

Abstract Phenylalanine ammonia-lyase (PAL), polyphenol oxidase (PPO), and peroxidase (POD) are considered important biochemical markers in host plant resistance against pest insects. Constitutive activity of these enzymes was analyzed in resistant and susceptible wheat cultivars against cereal aphid *Sitobion avenae* (F.) at various developmental stages, i.e., tillering, stem elongation, flag leaf, and ear. Following aphid infestation, the activity of these enzymes was determined at the flag leaf and ear stages. Resistant cultivars exhibited greater constitutive PAL activity than susceptible ones at the tillering, stem elongation, and flag leaf stages. Aphid infestation enhanced levels of PAL activity in the flag leaf and ear stages in both resistant and susceptible cultivars. Constitutive PPO activity was higher in the resistant cultivars at all developmental stages. Aphid infestation induced increases in PPO activity in the flag leaf and ear stages of one susceptible cultivar, whereas induction in resistant cultivars was weaker. Resistant cultivars showed greater constitutive POD activity in the tillering, stem elongation, and flag leaf stages, while aphid infestation induced POD activity in all cultivars, especially in susceptible ones. The potential role of PAL, PPO, and POD in wheat defense against aphid infestation is discussed.

Introduction

Host plant resistance to herbivores can suppress herbivore population densities and offers a promising approach for managing insect pests in a sustainable, economical, and environmentally safe manner (Heng-Moss et al. 2004). Plant secondary metabolites play an important role in plant defense against insects and pathogens (Cai et al. 2004), the levels of which are often mediated by defense-related enzymes, such as phenylalanine ammonia-lyase (PAL), polyphenol oxidase (PPO), and peroxidase (POD; Carver et al. 1992; Rosenthal and Berenbaum 1992; Bi and Felton 1995; Bi et al. 1997a, b, c).

PAL is a key enzyme in the phenylpropanoid pathway that converts phenylalanine into *trans*-cinnamic acid. *Trans*-cinnimaic acid can be further hydroxylated and methylated to produce compounds (i.e., coumaric, caffeic, and ferulic acids) that are toxic to herbivores and pathogens (Cole 1984; Leszczynski et al. 1989; Verpoorte and Alfermann 2000; Morelló et al. 2005; Wang et al. 2006). PPO and POD are oxidases that catalyze the formation of quinones from various phenolic precursors (Hildebrand et al. 1986; Mayer 1987; Felton et al. 1989; Duffey and Stout 1996).

PAL, PPO, and POD are associated with plant defense against insects (Felton et al. 1992; Stout et al. 1999; Chaman et al. 2001, 2003; Ni et al. 2001). However, little is

known about the dynamic changes of these enzymes during plant development and the influence of aphid infestation on their activity in resistant vs. susceptible cultivars, especially in wheat. The present research was initiated to investigate the constitutive and induced activity of these enzymes in *Sitobion avenae*-resistant and *S. avenae*-susceptible wheat cultivars at various developmental stages.

Methods and Materials

Plants and Insects Wheat cultivars KOK1679, L1, Beijing 411, and Beijing 837 were grown in 2003 and 2004 at the Science Park of China Agricultural University, Beijing, China. Wheat seeds were sown 20 cm apart in a 2-m single-row plot on October 14, 2003. Each plot was used as one replicate and covered with white nylon mesh to protect plants from insects and mechanical damage during the growth.

KOK1679 and L1 cultivars are resistant and repellant to the cereal aphid species *S. avenae*, while Beijing 411 and Beijing 837 are susceptible and attractive to this species (Liu et al. 2001). In addition, both KOK1679 and L1 have antibiotic properties against *S. avenae* compared to Beijing 411 and Beijing 837 (Cai et al. 2004 and unpublished data).

S. avenae nymphs and adults were collected from field-grown wheat and maintained on the aphid-susceptible wheat cultivar, Beijing 411, under field conditions. Insects over one generation were used for the experiment. When the unfolded flag leaf and ear emerged in 49–56 and 58–60 of Zadoks code (Zadoks et al. 1974), 20 flag leaves or ears from each experimental plot were selected and evenly divided for experimental and control treatments. Ten nymphs (second to third instar) were released onto each flag leaf and ear in each treatment. The flag leaves and ears were covered with nylon mesh cages (15×4 cm) to prevent the aphids from escaping (Rafi et al. 1996; Argandona et al. 2001). The experiments were arranged in a randomized complete block design, and each treatment was replicated three times.

Sample Collection A total of 60 tillers from each plot were sampled randomly at various developmental stages to determine the constitutive enzyme activity in wheat tissue. Whole plants, including stems and leaves at Zodaks stage 21–23 and the upper 3–5 young leaves and stem at Zadoks stage 31–34, were sampled (Zadoks et al. 1974). Flag leaves at stage 49–56 and ears at stage 58–60 also were sampled. Flag leaves and ears of all the treatments and controls were individually excised and collected 9 days after aphid release (Ni et al. 2001). Upon collection, samples were wrapped in aluminum foil and immediately dropped into liquid nitrogen for transport to a −80°C freezer before enzymatic analyses.

Plant Protein and Enzyme Assays Plant tissue (100 mg) from each sample was ground in liquid nitrogen and homogenized in 20 mM HEPES buffer (500 µl; pH 7.2). The resulting mixture was centrifuged (Himac CR22E, Hitachi Koki Co. Ltd. Japan) at 10,000×*g* for 20 min at 4°C. The supernatant was used for analyses of total protein content and enzymatic activity.

The Bradford method (Bradford 1976) was used to determine total protein content in samples. Three aliquots (20 µl) of each sample were mixed with Bio-Rad reagent (180 µl, Bio-Rad, Richmond, CA, USA). Absorbance of the reaction mixture was determined at 595 nm, and protein content was determined from a standard curve established by using known quantities of bovine serum albumin (from Sigma Chemical Co.) and the above reagent.

PAL activity was determined following the method of Wang and Xue (1980) with enzyme extract (0.25 ml) in sodium borate buffer (1.5 ml, 30 mM; pH 8.8). The decrease of L-phenylalanine was monitored at 290 nm. PAL activity was estimated from dA_{290}. The assay was replicated three times.

POD activity was measured following a method previously described (Hildebrand et al. 1986; Hori et al. 1997). Enzyme extract (10 µl) was mixed with 1 ml of substrate containing hydrogen peroxide (10 µl; 30%, *w*/*w*), guaiacol (1 µl; 20 mM), and HEPES (100 µl; 200 mM, pH 7.0) in deionized water. POD activity was estimated from the increase in A_{470}. The measurement was repeated three times.

PPO activity was determined following the method of Hori et al. (1997). Enzyme extract (100 µl) was mixed with a solution containing catechol (500 µl; 1.6% *w*/*w*), HEPES buffer (100 µl; 200 mM, pH 6.0), and deionized water (800 µl). PPO activity was estimated from the increase in A_{470}. The analysis was repeated three times.

Statistical Analysis Analysis of variance (ANOVA) in SPSS (SPSS 11.0) was used to analyze PAL, POD, and PPO activity in wheat cultivars at various developmental stages. Pairs of treatment means were compared and separated ($\alpha=0.05$) by the least significant difference (LSD) procedure. Before the ANOVA and LSD procedure, PAL, POD, and PPO activity was transformed using the logarithm transformation (ln) to normalize the data.

Results

Protein Content Total protein content among wheat cultivars was significantly different at the different developmental stages (i.e., tillering, stem elongation, flag leaf, and ear stages), as well as at the flag leaf and ear stages in plants infested by aphids ($df=3, 11$, $F_{TS}=7294.6$, $F_{SES}=4887.1$, $F_{FL}=11040.8$, $F_{H}=9939.9$, $F_{AFL}=4883.9$, $F_{AH}=8267.3$, $P<0.001$). The constitutive protein content of

Table 3 Constitutive polyphenol oxidase activity (dA_{470} per minute per milligram protein) of four wheat cultivars at tillering and stem elongation stages

stage	KOK1679	L1	Beijing 837	Beijing 411
Tillering	4.176±0.587 a	3.689±0.922 a	2.151±0.409 b	1.955±0.367 b
Stem elongation	4.594±0.348 a	4.108±0.487 a	3.106±0.632 b	3.078±0.414 b

Means in a row followed by different letter are significantly different at $P<0.05$

KOK1679 and L1 was lower than that of Beijing 411 and Beijing 837 at all stages, with the exception that the protein content of KOK1679 was higher than that of Beijing 837 at the flag leaf stage (Table 1, Fig. 1). However, after flag leaf and ear stages were infested by aphids, total protein content increased in flag leaves of all cultivars and in ears of KOK1679 and L1 ($P<0.05$; Fig. 1).

Defense-Related Enzymes KOK1679 and L1 exhibited greater constitutive PAL activity than Beijing 411 and Beijing 837 in the tillering and stem elongation stages (df=3, 11; F_{TS}=28.13, $P<0.01$; F_{SES}=6.53, P=0.02; Table 2). The constitutive PAL activity was also higher in KOK1679 and L1 than in Beijing 411 and Beijing 837 in the flag leaf (df=3, 11; F_{FL}=26.58, $P<0.001$), but not in the ear stage (Fig. 2). Aphid infestation strongly enhanced the levels of PAL activity in the flag leaf and ear stages of all four cultivars ($P<0.05$; Fig. 2).

Constitutive PPO activity was higher in KOK1679 and L1 than in Beijing 837 and Beijing 411 at all developmental stages (df=3, 11; F_{TS}=9.81, P=0.005; F_{SES}=7.34, P=0.011; F_{FL}=18.72, P=0.001; F_{E}=21.33, $P<0.001$; Table 3, Fig. 3). Aphid infestation caused significant increases in PPO activity in the flag leaf and the ear stages of Beijing 837 and Beijing 411 and in the ear stage of KOK 1679 (Fig. 3).

KOK1679 and L1 exhibited greater constitutive POD activity than Beijing 837 and Beijing 411 in the tillering and stem elongation stages (df=3, 11; F_{TS}=21.78, $P<0.001$; F_{SES}=15.28, P=0.001; Table 4). The constitutive POD activity was also higher in the flag leaf stage of KOK1679 and L1 than in Beijing 837 and Beijing 411 (df=3, 11; F_{FL}=15.79, P=0.001; Fig. 4). Aphid infestation boosted POD activity in all cultivars, especially in Beijing 837 and Beijing 411 ($P<0.05$; Fig. 4).

Discussion

Active defense in plants can be induced by both biotic and abiotic factors (Karban and Baldwin 1997; Kant et al. 2004). PAL, PPO, and POD are among the most important enzymes involved in the defensive responses of plants to insects and pathogens. PAL plays a key role in corn resistance to the maize sheath blight *Rhizoctonia solani* (Jin et al. 2003) as well as to *Helminthosporium maydis* and *Helminthosporium turcicum* (Wang and Xue 1980). Cole (1984) demonstrated that PAL activity is related to lettuce resistance to the lettuce root aphid *Pemphigus bursarius* (L). *S. avenae* infestation resulted in increased PAL activity in the flag leaf and ear stages of resistant and susceptible winter wheat cultivars (Ciepiela 1989; Havlickova et al. 1996). Increased PAL activity also was found in the leaves of *Brassica oleracea* seedlings infested by green peach aphid *Myzus persicae* (Sulzer; Zhang et al. 2005).

S. avenae-resistant wheat cultivars (i.e., KOK1679 and L1) had significantly higher levels of PAL activity than susceptible cultivars (Beijing 411 and Beijing 837) at the

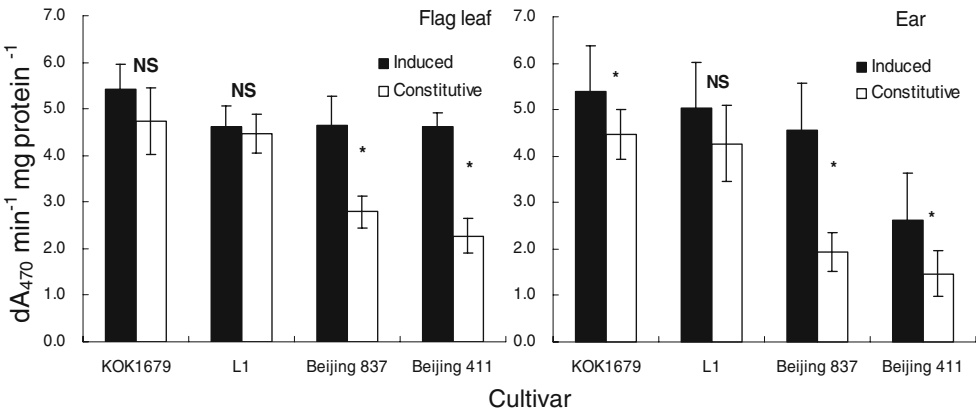

Fig. 3 Effect of *S. avenae* infestation on PPO activity in flag leaf and ear stages of resistant and susceptible wheat cultivars. Significant difference at *$P<0.05$; *NS* no significant difference ($P>0.05$)

Table 4 Constitutive peroxidase activity (dA_{470} per minute per milligram protein) of four wheat cultivars at tillering and stem elongation stages

Stage	KOK1679	L1	Beijing 837	Beijing 411
Tillering	68.643±1.059 a	65.058±1.037 a	24.649±1.067 b	24.616±1.025 b
Stem elongation	79.897±1.215 a	53.944±1.344 b	29.894±1.470 c	18.639±1.249 c

Means in a row followed by different letter are significantly different at $P<0.05$

tillering and stem elongation developmental stages. PAL activity in the flag leaf and ear stages of aphid-resistant cultivars increased more dramatically than that in the aphid-susceptible ones after *S. avenae* infestation, suggesting that the resistant cultivars may have a stronger capability to synthesize secondary metabolites related to insect susceptible ones.

Increased PPO activity in susceptible wheat can be induced by both aphids and methyl jasmonate (Leszczynski 1985; Boughton et al. 2006). Our study showed that constitutive PPO activity was higher in nutritional organs of resistant wheat cultivars compared to susceptible ones (Table 3). PPO activity in the ear and flag leaf stages of both resistant and susceptible cultivars increased when plants were infested with aphids; the increase was greater in susceptible cultivars (Fig. 3). However, Chrzanowski et al. (2003) reported that PPO activity in the ear stages of both resistant and susceptible spring wheat cultivars was decreased by *S. avenae* infestation. This discrepancy may be due, at least in part, to genetic differences in the wheat cultivars. Ni et al. (2001) reported that *Diuraphis noxia* feeding did not elicit changes in PPO activity in either resistant or susceptible cultivars of wheat or barley. This difference may be associated with the specific feeding behaviors exhibited by different aphid species, e.g., *D. noxia* feeding elicits leaf-chlorosis while *S. avenae* feeding does not.

Previous studies have demonstrated that POD activity can be enhanced by insects and elicitors such as ethephon and methyl jasmonate (Bi and Felton 1995; Bi et al. 1997a, b; Takahama and Oniki 1997; Kielkiewicz 1998). Buffalograss that is resistant to *Blissus occiduus* had higher POD activity compared to susceptible plants (Heng-Moss et al. 2004). Andres et al. (2001) reported that wheat root resistance to the cereal cyst nematode was associated with increased POD activity. POD activity in *B. oleracea* leaves infested with *M. persicae* increased significantly compared with control leaves (Zhang et al. 2005). *Macrosiphum euphorbiae* (Thomas) feeding induced greater POD activity in tomato leaves (Stout et al. 1998). Our results revealed that at the tilling and stem elongation stages, resistant wheat cultivars had a greater constitutive POD activity compared with susceptible cultivars, whereas at the flag leaf stage, the constitutive POD activities were similar between the resistant and susceptible cultivars (Table 4, Fig. 4). Also, aphid infestation of susceptible wheat cultivars at the flag leaf and ear stages induced a higher POD activity (Fig. 4). The differences in POD activities among the growing stages may be attributed to normal wheat plant growth (Ni et al. 2001).

In summary, *S. avenae*-resistant wheat cultivars had greater constitutive PAL, PPO, and POD activity at the tillering, stem elongation, and flag leaf stages of development. When the flag leaf and ear stages were attacked by aphids, PAL activity increased more dramatically in the resistant cultivars than in the susceptible ones. Aphid infestation increased activities of PPO and POD more dramatically in the susceptible cultivars than in the resistant ones.

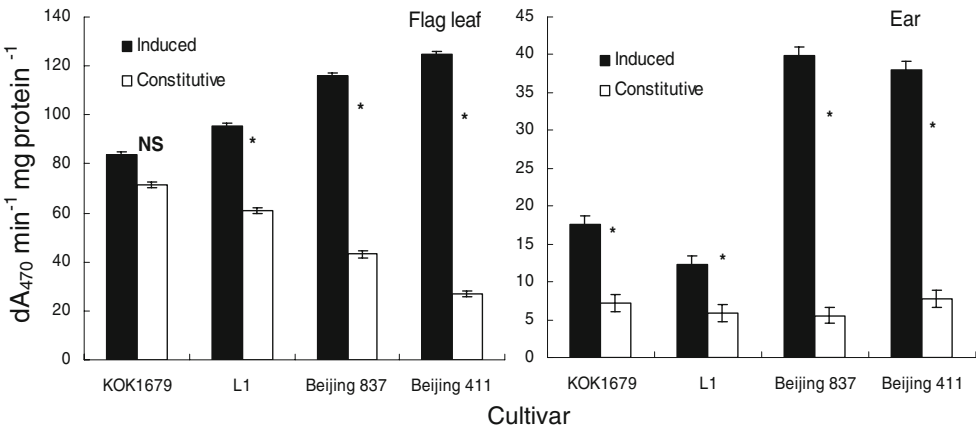

Fig. 4 Effect of *S. avenae* infestation on POD in flag leaf and ear of resistant and susceptible wheat cultivars. Significant difference at $*P<0.05$; *NS* no significant difference ($P>0.05$)

Ecological Significance of Induction of Broad-Substrate Cytochrome P450s by Natural and Synthetic Inducers in *Helicoverpa zea*

Zhimou Wen · Ren Sen Zeng · Guodong Niu · May R. Berenbaum · Mary A. Schuler

Received: 1 May 2008 / Revised: 13 January 2009 / Accepted: 13 January 2009 / Published online: 6 February 2009

Abstract The polyphagous corn earworm *Helicoverpa zea* relies on cytochrome P450 monooxygenases with broad substrate specificities to cope with the wide diversity of phytochemicals it encounters among its numerous host plants. These enzymes also contribute to the ability of this insect to tolerate toxins from sources other than its hosts, including microbial and synthetic toxins. Although upregulation of xenobiotic-metabolizing P450s in some herbivorous insects is closely linked to host plant toxins, transcriptional and/or post-transcriptional regulation of detoxification in this polyphagous species also appears to be relatively unspecialized. Reverse transcription polymerase chain reaction and metabolic analyses indicate that rare and infrequently encountered phytochemicals, as well as synthetic substances, can enhance metabolic activity in an adaptive fashion against both natural and synthetic toxins.

Keywords Cytochrome P450 monooxygenases (P450s) · Plant–insect interactions · Transcriptional regulation · *Helicoverpa zea*

Introduction

Cytochrome P450 monooxygenases (P450s) catalyze the NADPH-associated reductive cleavage of oxygen to produce a functionalized product and water. The genes encoding these enzymes constitute one of the largest gene superfamilies known, and some insect genomes can contain upwards of 100 P450 genes (Tijet et al. 2001; Ranson et al. 2002; Feyereisen 2005; Strode et al. 2008; http://p450.sophia.inra.fr; http://drnelson.utmem.edu/CytochromeP450.html). The enormous proliferation of these proteins is, in part, a reflection of their functional diversity because, across their range, individual enzymes are capable of catalyzing a wide variety of transformations, including biosynthetic, bioactivation, and detoxification reactions (Fogleman et al. 1998; Feyereisen 1999, 2005; Scott 1999; Li et al. 2007). Especially relevant to the evolution of these loci and their encoded proteins in insects is that P450s mediate the metabolic detoxification of exogenous xenobiotics such as insecticides, mycotoxins, and plant toxins.

The diversity of reactions catalyzed by P450s presents an ecological challenge in terms of their transcriptional regulation. Upregulation of the appropriate isozymes is

Wen and Zeng contributed equally.

important in order to avoid the adverse consequences of bioactivation, rather than detoxification, of toxins. Little is known, however, about the mechanisms by which herbivorous insects regulate the multiplicity of P450s that detoxify host plant phytochemicals. In the black swallowtail *Papilio polyxenes*, the CYP6B1 protein is highly specialized for metabolizing linear furanocoumarins (Hung et al. 1997; Chen et al. 2002; Wen et al. 2003, 2006), the principal phytochemicals found in the apiaceous host plants of this oligophagous species. The promoter of the *CYP6B1* locus contains a strong positive regulatory element from −136 to −119 that is required for both basal and inducible transcription (Prapaipong et al. 1994; Petersen et al. 2003; Brown et al. 2005). This regulatory element appears to be specialized for furanocoumarins, consistent with the narrow host plant range of the insect. Similarly, the *CYP6B4* locus that encodes a P450 in the congeneric tiger swallowtail *Papilio glaucus* is transcriptionally induced in the midgut by dietary furanocoumarins (Hung et al. 1997; Li et al. 2001). Its promoter contains an overlapping EcRE/ARE/XRE-xan element similar to that used for basal and xanthotoxin-inducible expression of the *CYP6B1* promoter (McDonnell et al. 2004); this EcRE/ARE/XRE-xan element is necessary for CYP6B4 induction by xanthotoxin but not for its minimal basal expression. In addition to these elements, the *CYP6B4* and *CYP6B1* promoters also contain putative XRE-AhR elements identical to the aryl hydrocarbon response elements of many mammalian phase I detoxification genes (Hung et al. 1996). Transfections of the *CYP6B4* and *CYP6B1* promoters that contain EcRE/ARE/XRE-xan and XRE-AhR elements demonstrate that both are inducible by the furanocoumarin xanthotoxin as well as by benzo-α-pyrene (Prapaipong et al. 1994; Petersen et al. 2003; McDonnell et al. 2004; Brown et al. 2005), an aryl hydrocarbon combustion product that is widespread in terrestrial environments.

Transcriptional regulation of P450s by dietary constituents should be particularly challenging for broadly polyphagous species, which can encounter dozens of biosynthetically distinct toxins across their range. Given the diversity of P450s within an insect genome and the multiplicity of functions, including the differential potential to bioactivate or detoxify, induction of particular isoforms may actually enhance, rather than reduce, toxicity. As a broadly polyphagous herbivore, *Helicoverpa zea* encounters a wide range of phytochemicals in its >100 species of plant hosts. Inasmuch as many of its common hosts, including *Zea mays*, are susceptible to infection by *Aspergillus* fungi that produce aflatoxins, *H. zea* also routinely encounters these mycotoxins. Moreover, due to their ability to inflict economic damage on a diversity of crop plants, these insects are also frequent targets of synthetic insecticides. Previous studies have shown that certain widespread phytochemicals, including plant hormones and defense compounds (Li et al. 2002a, b; Zeng et al. 2007), can upregulate certain P450s in this species. Phytochemicals that are frequently (coumarin), occasionally (indole-3-carbinol), or rarely (xanthotoxin) encountered by *H. zea* larvae substantially reduced the toxicity of aflatoxin B1 (AFB1) to *H. zea*, despite the fact that certain *H. zea* P450s can bioactivate aflatoxins (Zeng et al. 2007). As well, diets that contain coumarin or xanthotoxin reduce the mortality rates of caterpillars exposed to the insecticides diazinon and carbaryl, indicating that consumption of plant chemicals can ameliorate toxicity of natural and synthetic toxins in this species by inducing P450s that detoxify these chemicals (Zeng et al. 2007).

For this study, we examined transcriptional regulation in this polyphagous species to test whether the frequency of evolutionary encounter, as indicated by origin (synthetic or natural) and distribution across plant families (unique to one or widespread), is predictive of the ability of compounds to induce transcriptional regulation of broadly substrate-specific P450s. Specifically, we compared the induction ability of phytochemicals that are extremely restricted in distribution (flavone, reported in *Primula malacoides* (Weller et al. 1953)); phytochemicals occurring in a number of genera in one or two families (khellin and visnagin, furanochromones restricted to the Apiaceae; imperatorin, a furanocoumarin restricted to the Apiaceae and Rutaceae); phytochemicals present in a wide range of plant families (rutin, a flavonoid glycoside present in >12 plant families); and a synthetic chemical (β-naphthoflavone). We also tested whether P450s that metabolize wide range of substrates including phytochemicals, mycotoxins (aflatoxins), and synthetic insecticides (diazinon, carbaryl, cypermethrin), are as likely to be upregulated by synthetic compounds as by naturally occurring compounds and whether extremely rare phytochemicals are as likely to induce generalized P450s as are widely distributed phytochemicals.

Methods and Materials

Chemicals and Insects AFB1, flavone, β-naphthoflavone (β-NF), rutin, khellin, and visnagin were obtained from Sigma (St. Louis, MO, USA) and imperatorin from Feinbiochemica (Heidelberg, Germany). Diazinon, carbaryl, aldrin, and α-cypermethrin were purchased from Chem Service (West Chester, PA, USA). Analytical grade dimethyl sulfoxide (DMSO) was purchased from Fisher Scientific.

Larvae of *H. zea* were obtained from a colony maintained by the UIUC Department of Entomology, founded originally from individuals obtained from Abbott Laboratories (Chicago, IL, USA) and supplemented intermittently with wild-caught individuals from Champaign

County, IL. Larvae were individually reared on semisynthetic diet containing wheat germ (Waldbauer et al. 1984) and maintained in an insectary kept at 23–26°C with a photoperiod of 16-h L: 8-h D.

Heterologous Expression and Metabolism of Insecticides by CYP6B8, CYP6B27, and CYP321A1 Heterologous expression of P450s with house fly P450 reductase and *in vitro* insecticide metabolism assays for each enzyme were conducted as described in Wen et al. (2003) and Sasabe et al. (2004) with some modifications. Briefly, recombinant CYP6B8, CYP6B27, or CYP321A1 viruses were co-expressed with house fly P450 reductase virus in Sf9 cells at a multiplicity of infection ratio of 1:1, 1:1, and 2:2, respectively. Microsomes prepared from Sf9 cells infected with combinations of P450 and P450 reductase viruses were analyzed in *in vitro* metabolism assays as described in Rupasinghe et al. (2007). Duplicate reactions were set up, initiated with the addition of NADPH, and incubated at 30°C for 30 min. Reactions were stopped by adding 250 µl acetonitrile that contained the same amount of internal standard to normalize for procedural variations. Parathion was used as an internal standard for diazinon, diflubenzuron for carbaryl, and methoxychlor for both aldrin and α-cypermethrin. The final reactions were mixed by vortexing and microcentrifuged at full speed for 10 min, and the supernatant was passed through a 0.45-µM Alltech–Microspin filter (Alltech, Deerfield, IL, USA) by centrifugation at 5,000 rpm in an Eppendorf centrifuge for 5 min. The filtered supernatants were run on reverse phase high-performance liquid chromatography (XTerra 5-µm column, 150×4.6 mm) to analyze the proportion of substrate remaining. For analyses of diazinon and carbaryl, acetonitrile/water (55:45) was used as solvent and run at a flow rate of 1 ml/min. For analyses of aldrin and α-cypermethrin, acetonitrile/water (70:30) was used as solvent with a flow rate of 1.2 ml/min. To detect each chemical and its internal standard, UV monitoring was at 235 nm for diazinon, 280 nm for carbaryl, and 220 nm for both aldrin and α-cypermethrin. By using the solvent conditions listed above, the retention times for each chemical were 4.0 min for carbaryl, 5.2 min for methoxychlor, 8.6 min for diazinon, 8.9 min for diflubenzuron, 11.0 min for aldrin, 11.8 min for parathion, and 9.2 min for α-cypermethrin. P450 enzymatic activities are reported as substrate disappearance and expressed in nanomole substrate disappearance per minute per nanomole P450. Each metabolic assay was replicated in at least three biological replicates with each *in vitro* assay done in duplicate.

Reverse Transcription Polymerase Chain Reaction (RT-PCR) Gel Blot Analysis of P450 Transcripts from Corn Earworms Exposed to Inducers Fifth instar *H. zea* molted within a 12-h period and with a weight range from 170–270 mg/larva were randomly grouped. Larvae in each group of 20 were individually switched to diets containing inducers at a concentration of 0.1% (*w*/*w*) for flavone, β-NF, and rutin, 0.015% for khellin and visnagin, and 0.01% for imperatorin. These concentrations were selected because they represent the highest concentration that can be ingested without adverse effects on growth or development (data not shown). Each inducer was first dissolved in DMSO corresponding to about 0.2% diet weight (*v*/*w*) for even distribution. Larvae feeding on a diet that contained 0.2% DMSO served as the control. After larvae fed for 48 h, their midguts were dissected and cleaned in 0.1 M sodium phosphate buffer (pH 7.8). Total RNA from each group was extracted with TRIzol reagent (Invitrogen, Carlsbad, CA, USA), treated with RQ DNase I (Promega, Madison, WI, USA), reisolated with TRIzol reagent, and finally suspended in sterile water and stored at –80°C.

RT-PCR gel blot Southern analysis was used to quantify the CYP6B8, CYP6B27, and CYP321A1 transcripts in midguts as described in Zeng et al. (2007), with actin primers included with one set of P450 primers in each reaction to minimize variation. RT-PCR Southern analyses were repeated two times with RNA samples prepared from midguts of larvae in two independent biological series.

Effects of Inducers on the Ability of H. zea to Tolerate Insecticides To test the effects of these inducers on *H. zea* challenged with insecticides, fifth instars that had molted within a 12-h period were provided for 48 h with diets containing the inducers flavone, β-NF, or rutin or with DMSO (as a control) as described. These caterpillars then were exposed to topically applied insecticides corresponding to 300 µg diazinon, 100 µg carbaryl, or 150 ng α-cypermethrin per larva. These diagnostic doses were determined in a series of preliminary bioassays. Following topical application of insecticides in 3 µl acetone, the caterpillars that were still feeding were kept in an incubator at a temperature of 28°C and a photoperiod of 16-h L: 8-h D. Mortality was checked periodically 4 h after insecticide application, with caterpillars considered dead if they were unable to right themselves when on their backs. These bioassays were replicated at least three times with 20 larvae tested for each treatment.

Effects of Inducers on H. zea Ability to Tolerate AFB1 To test the effects of natural and synthetic inducers on *H. zea* challenged with AFB1, caterpillars concurrently exposed to AFB1 and an inducer were compared with those exposed to either AFB1 or the inducer alone. In separate experiments, either fourth or fifth instars that had molted within a 12-h period were randomly distributed among four groups, with 20 caterpillars in each group. Caterpillars were

switched individually to 30-ml plastic cups that contained diets supplemented with (1) DMSO, (2) an inducer, (3) AFB1, or (4) an inducer and AFB1. The final concentrations of inducers and AFB1 in the diet (*w*/*w*) were 0.1% for flavone and β-NF, 0.015% for visnagin, 0.01% for imperatorin, and 1 μg/g for AFB1. All were prepared in DMSO so that they could be dispersed evenly in the diet at a final concentration of 0.2% (*v*/*w*).

Caterpillars feeding on these different diets were individually reared in an insectary at 23–26°C with a photoperiod of 16-h L: 8-h D. Pupation rates and pupal weight were examined as described in Zeng et al. (2007), with each set of bioassays replicated three times.

Statistical Analyses All data were evaluated by one-way factorial analysis of variance (ANOVA) with treatment differences among means tested at $P = 0.05$ by Tukey post-hoc test. All data are means from three replicates with 20 caterpillars/treatment.

Results

Heterologous Expression and P450 Activities Previous studies have determined that *H. zea* CYP6B8 and CYP321A1 have a broad range of substrates. CYP6B8 metabolizes phytochemicals from at least four biosynthetic classes (including the flavonoids quercitin, rutin, and flavone, the furanocoumarin xanthotoxin, the glucosinolate precursor indole-3-carbinol, and the phenolic chlorogenic acid) and at least four synthetic chemicals (β-naphthoflavone, the insecticides diazinon, cypermethrin, and aldrin; Li et al. 2004; Rupasinghe et al. 2007), whereas CYP321A1 metabolizes furanocoumarins (xanthotoxin, angelicin), a mycotoxin (aflatoxin B1), and the same four synthetic compounds (Sasabe et al. 2004, Rupasinghe et al. 2007). Heterologous expression of CYP6B8 or CYP321A1 simultaneously with house fly P450 reductase has allowed us to add to the known substrate specificities of these two enzymes. Heterologous expression of the related CYP6B27 protein with house fly P450 reductase has permitted side-by-side activity comparisons of these three P450s (Table 1). All three enzymes can metabolize four different classes of insecticides: cyclodienes (aldrin), pyrethroids (α-cypermethrin), organophosphates (diazinon), and carbamates (carbaryl). The metabolic activities of CYP6B8 and CYP6B27, which are closely related (88% amino acid identity; Li et al. 2004), are higher than that of CYP321A1 for all insecticides except for carbaryl, against which all three enzymes have similar activities. The metabolic activities of the CYP6B8 and CYP6B27 enzymes are similar, with the rank order aldrin > α-cypermethrin ≈ diazinon > carbaryl.

Table 1 Metabolic activities of CYP6B8, CYP6B27 and CYP321A1 against insecticides

Substrate	metabolic activity ± SE (nmol/min/nmol P450)		
	CYP6B8	CYP6B27	CYP32141[a]
Aldrin	14.33 (1.85)	18.14 (0.54)	5.28 (0.85)
Diazinon	2.33 (0.12)	2.31 (0.08)	1.35 (0.21)
Carbaryl	0.28 (0.06)	0.27 (0.03)	0.26 (0.07)
α-cypermethrin	2.44 (0.65)	2.01 (0.38)	1.60 (0.33)
Aflatoxin B1	ND[a]		2.60 (0.20)

ND not detectable

Effects of Inducers on P450 Transcript Accumulation Although the six inducers differentially upregulate the transcription of the *CYP6B8* and *CYP321A1* loci, there is no obvious pattern whereby the natural compounds are superior to synthetic compounds as inducers, nor is there any consistent pattern demonstrating that ubiquitous phytochemicals are more effective inducers than are rarely encountered phytochemicals. Compared to the transcript levels in midguts of control larvae feeding on a diet

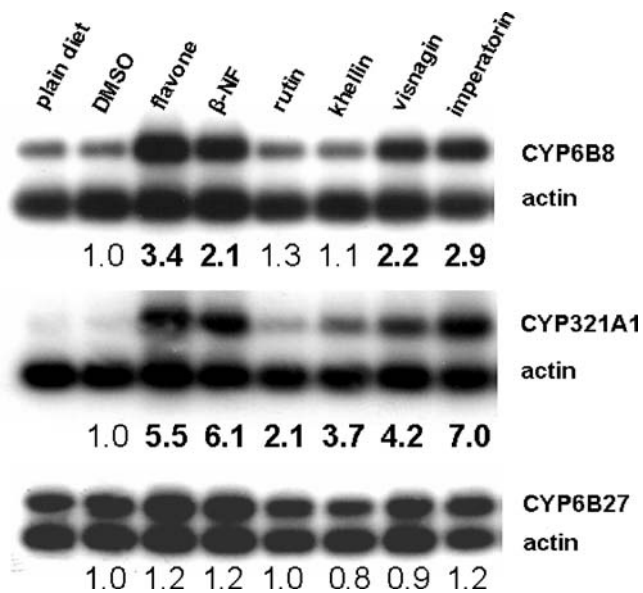

Fig. 1 P450 transcript induction in the midguts of fifth instar *H. zea* by synthetic and natural inducers. Newly molted fifth instars were fed an artificial control diet, a diet containing DMSO (0.2% *w*/*w*), or a diet containing an inducer dissolved in DMSO and incorporated into the diet. RT-PCR products detected with gene-specific primers and probes correspond to: (*1*) control unamended diet and diets containing (*2*) 0.2% DMSO, (*3*) 0.1% flavone, (*4*) 0.1% β-NF, (*5*) 0.1% rutin, (*6*) 0.015% khellin, (*7*) 0.015% visnagin, (*8*) 0.01% imperatorin

containing 0.2% DMSO, the *CYP321A1* transcript levels from midguts of larvae feeding on diets containing any one of the six inducers were higher, ranging from 2.1-fold for rutin to 7.0-fold for imperatorin (Fig. 1). Relative to larvae on diets lacking inducers, *CYP6B8* transcript levels were induced for larvae feeding on diets containing flavone (3.4-fold), β-NF (2.1-fold), visnagin (2.2-fold), and imperatorin (2.9-fold). In contrast, despite the close relationship of its amino acid sequence with CYP6B8, transcription of the *CYP6B27* locus was not apparently induced by any of the compounds tested.

Effects of Inducers on the Ability of H. zea to Tolerate Insecticides and Mycotoxins Irrespective of whether prior exposure was to synthetic (β-NF) or to natural inducers (flavone, rutin), *H. zea* larvae experienced significantly lower mortality upon subsequent exposure to α-cypermethrin or diazinon (Fig. 2). In these trials, flavone had the most dramatic effect in decreasing the mortality of *H. zea* exposed to organophosphates (as represented by diazinon), carbamates (carbaryl), or pyrethroids (α-cypermethrin). Compared to approximately 90% mortality in control corn earworms challenged with diazinon, no mortality was observed for diazinon-treated larvae that had ingested flavone diet before insecticide treatment, and all of these larvae pupated. Similarly, concurrent exposure of either fourth (Fig. 3) or fifth instar (Fig. 4) corn earworm to aflatoxin B1 along with synthetic (β-NF) or natural plant allelochemicals (flavone, visnagin, and imperatorin) significantly improved larval performance in comparison with larvae exposed only to aflatoxin B1, as demonstrated by pupation rates and pupal weights (Figs. 3 and 4).

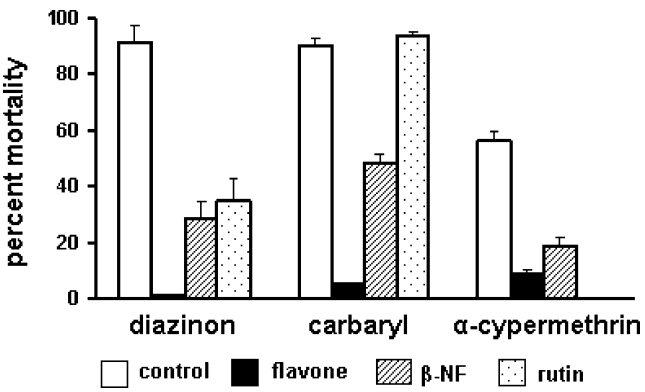

Fig. 2 Effects of inducers on *H. zea* tolerance of insecticides. Twenty newly molted fifth instar *H. zea* were fed either a control diet or a diet containing one of three inducers (0.1% flavone, β-NF, or rutin) for 48 h. These larvae were then topically treated with one of three insecticides (300 μg diazinon, 100 μg carbaryl, or 150 ng α-cypermethrin per larva) and mortality was tabulated 18 h post-treatment

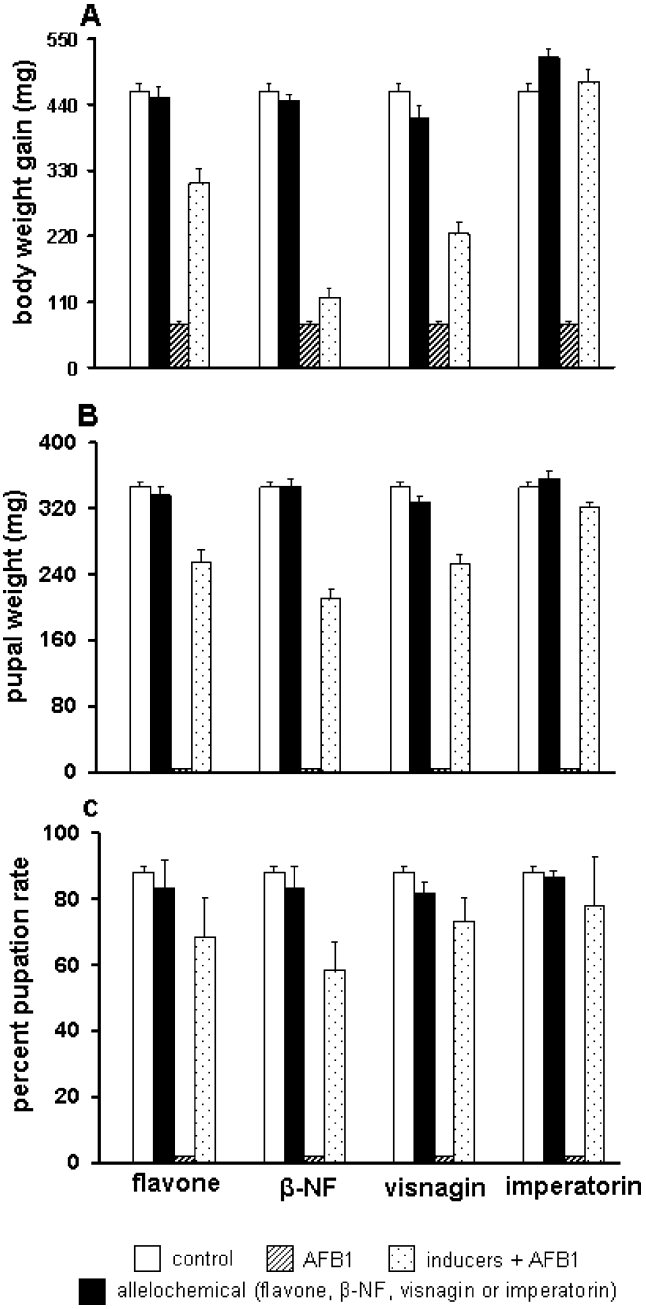

Fig. 3 Effects of inducers on fourth instar *H. zea* tolerance of aflatoxin B1. Newly molted fourth instar *H. zea* fed artificial diet containing DMSO (0.2% *w*/*w*), an inducer, AFB1, or a combination of an inducer and AFB1. The final concentrations of inducers and AFB1 in the diet (*w*/*w*) were 0.1% for flavone and β-NF, 0.015% for visnagin, 0.01% for imperatorin, and 1 μg/g for AFB1. **A** body weight gain in 6 days; **B** pupal weight; **C** pupation rate

Discussion

H. zea evidently relies on multiple P450s with broad substrate specificity to metabolize a wide variety of both natural and synthetic substrates that include plant allelo-

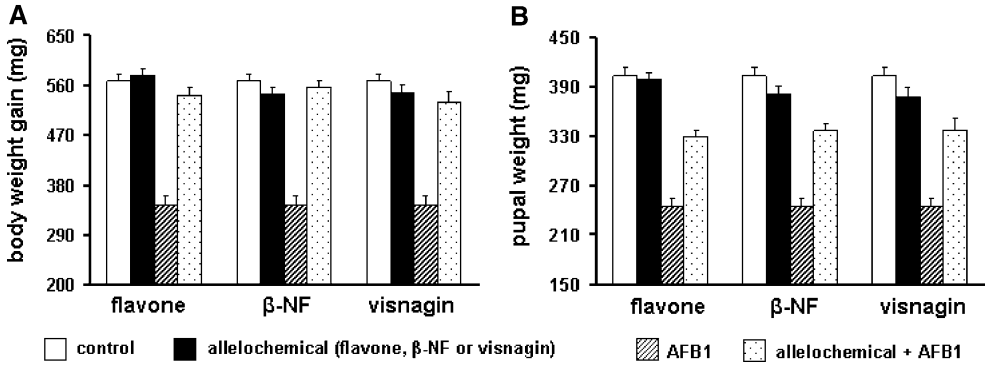

Fig. 4 Effects of inducers on fifth instar *H. zea* tolerance of aflatoxin B1. Newly molted fifth instar *H. zea* fed artificial diet containing DMSO (0.2% *w*/*w*), an inducer, AFB1, or a combination of an inducer and AFB1. The final concentrations of inducers and AFB1 in the diet (*w*/*w*) were 0.1% for flavone and β-NF, 0.015% for visnagin, 0.01% for imperatorin, and 1 μg/g for AFB1. **A** body weight gain in 3 days; **B** pupal weight

chemicals, insecticides, and mycotoxins. Even though the number of P450s examined in this species was small, these loci varied in their respective inducibilities. That the P450 with the overall lowest level of activity toward this array of substrates, CYP321A1, showed the highest level of inducibility resembles the pattern observed in the oligophagous *P. polyxenes*, in which CYP6B3, with overall lower levels of activity against furanocoumarin substrates, displays a greater induction response than does CYP6B1, with higher levels of activity against those same substrates (Hung et al. 1995). In contrast with *P. polyxenes*, which is characterized by specialized P450s that are tightly regulated by promoter elements responsive to specific host plant constituents (Prapaipong et al. 1994), the P450s in *H. zea* are regulated by a broad range of chemicals. Synthetic substances are equal to or more effective than widespread phytochemicals at upregulating transcripts for detoxification enzymes, and even rare phytochemicals, which may never be encountered by this insect, are effective at inducing transcription.

The specificity of transcriptional responses to inducers has been examined in relatively few insect systems, so establishing a general pattern is difficult. Le Goff et al. (2006) used DNA microarray hybridization and real-time PCR to examine P450 transcript accumulation patterns in response to two synthetic inducers (phenobarbital and atrazine) in *Drosophila melanogaster*. These authors found that only 11 of 86 P450 loci were induced by phenobarbital and only seven by atrazine. Three of these loci (CYP6A2, CYP6A8, CYP12D1) are associated with resistance to insecticides, suggesting that broad specificity (and the ability to metabolize evolutionarily novel substrates) is associated at least in some cases with a lack of specificity in transcriptional and/or post-transcriptional regulation, although the strength of that association is difficult to assess in view of the absence of information on the substrate profiles of other P450s in this genome. In contrast, Willoughby et al. (2006), also by using microarray analysis with *D. melanogaster*, failed to find a detectable induction response of detoxification enzymes, including P450s, to the insecticides spinosad, diazinon, nitenpyram, lufenuron, and dicyclanil; DDT exposure led to minimal induction of a single P450. The phytochemical caffeine, which likely is not naturally encountered by *D. melanogaster*, induced a variety of P450s under the same experimental conditions, as did the synthetic drug phenobarbital. In another dipteran, *Aedes aegypti*, Poupardin et al. (2008) used the *Aedes* Detox Chip microarray and quantitative real-time PCR to examine the inducibility of genes that encode detoxification enzymes by a variety of environmental xenobiotics, including insecticides. They found a selective response in fourth instar larvae, with only seven of 168 P450 genes in the genome responsive to any of the agents tested.

Based on a limited number of studies, then, it appears that transcriptional and/or post-transcriptional regulation of P450s in polyphagous insects is opportunistic and evolutionarily flexible. Indeed, Amichot et al. (1998) documents variation in induction responses among strains of *D. melanogaster*. Given the overall importance of P450s in such phenomena as the evolution of insecticide resistance and host shifts in polyphagous herbivores, understanding the mechanisms that provide that flexibility might well provide novel targets for sustainable pest management.

Acknowledgments We thank Allen Lawrance for assistance in rearing *H. zea* and Dr. Arthur Zangerl for comments on the manuscript. Enzyme Induction as a Possible Mechanism for Latex-Mediated Insect Resistance in Romaine Lettuce

Received: 23 September 2008 / Revised: 7 January 2009 / Accepted: 8 January 2009 / Published online: 28 January 2009

Abstract Plant latex is a known storehouse of various secondary metabolites with demonstrated negative impact on insect fitness. A romaine lettuce cultivar, "Valmaine", possesses a high level of latex-mediated resistance against the banded cucumber beetle, *Diabrotica balteata* LeConte (Coleoptera: Chrysomelidae), compared to a closely related cultivar "Tall Guzmaine". Latex from damaged Valmaine plants was much more deterrent to adult *D. balteata* feeding than latex from undamaged plants when applied to the surface of artificial diet under choice conditions; no such difference was found in choice tests with latex from damaged and undamaged Tall Guzmaine plants. The intensities of whiteness and browning were significantly higher in Valmaine latex than in Tall Guzmaine latex. The activities of three enzymes (phenylalanine ammonia lyase, polyphenol oxidase, and peroxidase) significantly increased over time in latex from damaged Valmaine plants (i.e., 1, 3, and 6 days after feeding initiation), but they remained the same in Tall Guzmaine latex. The constitutive levels of phenylalanine ammonia lyase and polyphenol oxidase also were significantly higher in Valmaine latex than in Tall Guzmaine latex. These studies suggest that Valmaine latex chemistry may change after plant damage due to increased activity of inducible enzymes and that inducible resistance appears to act synergistically with constitutive resistance against *D. balteata*.

Introduction

Lettuce, *Lactuca sativa* L., is an important vegetable crop grown throughout the world (Ryder 1998). Lettuce growers suffer huge economic losses due to various insect pest infestations because of the high cosmetic standards demanded by consumers (Palumbo et al. 2006). The romaine lettuce cultivar, "Valmaine", exhibits a high level of resistance against various insect pests, including the leafminer, *Liriomyza trifolii* (Burgess; Nuessly and Nagata 1994), banded cucumber beetle, *Diabrotica balteata* LeConte (Coleoptera: Chrysomelidae; Huang et al. 2002), and two moths, *Trichoplusia ni* (Hübner) and *Spodoptera exigua* (Hübner; Sethi et al. 2006). Valmaine's resistance would be useful in an integrated pest management program; however, this cultivar is not popular among growers because of its susceptibility to thermodormancy, premature bolting, lettuce mosaic virus, and corky root rot (Guzman 1986). Plant breeders have attempted to improve the horticultural characteristics of Valmaine through breeding, but unfortunately, the horticulturally improved and currently used cultivar, "Tall Guzmaine", lost resistance to insects during the improvement process (Sethi et al. 2006). Tall Guzmaine was selected from a cross between "Short

Guzmaine" and "Parris White", and Short Guzmaine was a selection from a cross between Valmaine and Florida 1142 (Guzman 1986).

Our previous research revealed that latex extracted from undamaged Valmaine plants and applied to the surface of artificial diet deterred feeding of adult *D. balteata*, whereas latex from Tall Guzmaine did not (Sethi et al. 2008). We hypothesized that constitutive levels of compounds in Valmaine's latex may explain the feeding deterrence shown by Valmaine against multiple insect species. Furthermore, Valmaine plants previously damaged by feeding *D. balteata* showed an increased localized resistance to *D. balteata* feeding compared to undamaged plants, suggesting the involvement of an inducible mechanism of resistance (Huang et al. 2003). Tall Guzmaine showed no such inducible resistance.

Latex is an aqueous suspension or solution of complex mixtures of molecules found in specialized secretory cells of plants known as laticifers (Pickard 2008). Laticifers possess high metabolic activity; in addition to synthesizing numerous molecules (lipids, sugars, and proteins) required to achieve basic physiological functions, laticifers also are known to synthesize and store diverse secondary metabolites in appreciable amounts in latex (El Moussaoui et al. 2001). Many defensive compounds with demonstrated negative impact on insect fitness are stored in latex (Evans and Schmidt 1976; Matile 1976; Nishio et al. 1983; Rees and Harborne 1985; Konno et al. 2004, 2006; Ramos et al. 2007). Latex whiteness arises due to differences in the refractive indices of the dispersing particles (terpenoids, alkaloids, tannins, proteins, and sterols) and the dispersing medium (Van Die 1955; Esau 1965; Archer et al. 1969; Groeneveld 1976; Fox and French 1988). Various organic compounds, such as terpenoids and phenolics, have been reported in latex of *Lactuca* spp. (Cole 1984; Dupont et al. 2000; Sessa et al. 2000), but their biological activity against insects has not been reported in lettuce. Their defensive role as phytoalexins, however, has been reported against plant pathogens (Bennett et al. 1994).

Activity of defense-related enzymes, such as phenylalanine ammonia lyase (PAL) and polyphenol oxidase (PPO), is much higher in the laticifers than in the leaves of rubber tree, *Hevea brasiliensis* H.B.K. (Kush et al. 1990; Wititsuwannakul et al. 2002). Wounding of laticifers is also known to induce various defense-related enzymes in latex of papaya (Azarkana et al. 2004), fig tree, *Ficus carica* L. (Kim and Mullin 2003), rooster tree, *Calotropis procera* Ait. (Freitas et al. 2007), and Albanian spurge, *Euphorbia characias* L. (Mura et al. 2005, 2007). Thus, alteration in the constituents of latex upon insect damage can enhance its defensive properties.

Latex commonly turns brown after exuding from plant wounds. Browning is due to contact with oxygen of reactive *ortho*-quinones produced when polyphenol oxidase contacts its chemical substrates in plant tissues damaged during insect feeding (Constabel and Ryan 1998). The reactive *ortho*-quinones readily form alkylated amino acids, which ultimately result in protein modification, cross-linking, and precipitation. This protein modification significantly impacts insect pests by preventing efficient digestion and assimilation of nitrogen (Duffey and Stout 1996).

The purpose of this study was to determine whether the previously reported induced resistance in Valmaine lettuce (Huang et al. 2003) is also mediated through latex, as is Valmaine's constitutive resistance (Sethi et al. 2008). If beetle damage did indeed trigger an increase in feeding deterrence of latex, our next objective was to determine whether that increase in deterrence was correlated with an increase in activities of inducible enzymes. Hence, *D. balteata* adults were given choices between artificial diets treated topically with latex from damaged and undamaged plants within the same cultivar (Valmaine or Tall Guzmaine) to look for changes in latex deterrence after beetle damage. We then compared the induction over time of defense-related enzymes, in particular PAL, PPO, and peroxidase (POX), in latices of resistant Valmaine and susceptible Tall Guzmaine with and without *D. balteata* damage. We then studied the relationship between the activities of these enzymes and the weight gain of the beetles fed on the plants. We also investigated change in color characteristics of latex (whiteness and browning) from damaged and undamaged plants in response to beetle damage.

Methods and Materials

Plants Seeds of romaine lettuce cultivars Valmaine and Tall Guzmaine (provided by R. T. Nagata, Everglades Research and Education Center, University of Florida, Belle Glade, FL, USA) were germinated overnight on moistened filter paper. Germinated seeds were planted in transplant trays filled with Metro-Mix 200 (Sun Gro Horticulture, Bellevue, WA, USA) in a glasshouse with ambient light at a mean temperature of 27°C (21–30°C) and a mean relative air humidity (RH) of 71% (53–89% RH). Healthy seedlings were transplanted 2 weeks later into plastic pots (12.5× 9 cm, diameter × depth). Plants were watered daily and fertilized with 15 ml of Peters 20-20-20 solution (10 g/l; W. R. Grace, Fogelsville, PA, USA) every week. Six-week-old lettuce plants (9–10 true-leaf stage) were used for experiments. Bush lima bean seeds, *Phaseolus lunatus* L. (Fabaceae), of the cultivar Fordhook 242 (Illinois Foundation Seeds, Champaign, IL, USA) were planted in transplant trays filled with Metro-Mix 200 and fertilized with the same solution used for lettuce plants.

Insects The colony of *D. balteata* was started from adults collected in 2003 from weeds [spiny amaranth, *Amaranthus spinosus* L. (Amaranthaceae), and primrose willow, *Ludwigia peruviana* (L.) H. Hara (Onagraceae)] in Belle Glade, FL, USA. Wild adults were added to the established colony in 2005 and 2006 to increase genetic diversity. Larvae were reared on the roots of corn seedlings, and adults were fed on lima bean leaves and sweet potato tubers (Huang et al. 2002). Newly emerged adults were maintained at 27±1°C in an incubator at a photoperiod of 14:10 h ratio of light to dark and supplied with water through a dental wick placed in a container with a hole in the lid. Adults less than 48 h old were used for experiments.

Artificial Diet Freshly made southern corn rootworm, *Diabrotica undecimpunctata howardi* Barber, artificial diet (Bio-Serv, Frenchtown, NJ, USA) was prepared according to Sethi et al. (2008) and used in all experiments. One-centimeter-thick disks were punched out from cooled artificial diet with a 1.5-cm-diameter cork borer.

Color Characteristics of Latex from Damaged and Undamaged Plants Thirty plants of each cultivar were placed individually in cylindrical plastic cages (18.5 cm diameter× 61.0 cm height) with three screened ventilation holes. Two male–female beetle pairs were placed into half (15 plants) of the cages of each cultivar; the other 15 plants of each cultivar were used as undamaged checks. Latex was collected from plants 1, 3, or 6 days after beetles were released into cages. Out of 30 plants of each cultivar, latex was collected from ten (five damaged and five undamaged checks, i.e., five replications per treatment) at each beetle exposure period (i.e., 1, 3, and 6 days after initiation of feeding damage). Latex (30 μl) was collected with a silanized glass microcapillary tube (Drummond Scientific Company, Broomall, PA, USA) from the leaf base (site of leaf lamina attachment to the stem and of rapid latex exudation upon cutting) of young and middle-aged leaves of individual plants immediately after cutting the tissue with a disposable scalpel blade (Feather, Osaka, Japan). Latex was applied, immediately after collection, onto the surface of a clear acetate plastic disc (2.5 cm diameter) with a microcapillary tube. A ring of felt (2.5 and 2.0 cm o.d. and i.d., respectively, and 3 mm thick) was placed on top of the latex-covered plastic disk. The nosecone of a color meter (ColorTec-PCM™, Clinton, NJ, USA) was placed on the felt ring to measure latex color. The color meter provides values for three parameters L^*, a^*, and b^*, specified by the Commission Internationale de 1'Esclairage. L^*, a^*, and b^* are three dimensions of the measured color, which provide a specific color value of the material; L^* represents the light–dark continuum with a range from 0 (black) to 100 (white); a^* represents the green–red continuum with a range from −60 (green) to +60 (red); and b^* represents the blue–yellow continuum with a range from −60 (blue) to +60 (yellow; Moss and Otten 1989). The data on latex L^*, a^*, and b^* were recorded at ten different time periods after collecting latex from a plant (0.5, 1, 2, 3, 5, 7, 9, 11, 13, and 15 min). The average of duplicate recordings was reported for each period.

The L^*, a^*, and b^* values were used to calculate two indices describing color characteristics of latex from damaged and undamaged plants: (1) whiteness index (WI; Eq. 1), as a measurement of whiteness, and (2) browning index (BI; Eq. 2), representing the purity of the brown color (Lohman and Hartel 1994; Maskan 2001).

$$\mathrm{WI} = 100 - \left[(100 - L^*)^2 + a^{*2} + b^{*2}\right]^{1/2} \quad (1)$$

$$\mathrm{BI} = \frac{[100(x - 0.31)]}{0.17} \quad (2)$$

where $x = \frac{a + 1.75L}{(5.645L + a - 3.012b)}$.

Collection of Latex for Feeding Bioassay and Enzyme Quantification One hundred and eighty plants of each cultivar were placed individually in cylindrical plastic cages (18.5 cm diameter×61.0 cm height) with three screened holes. Two male–female beetle pairs were placed into half (90 plants) of the cages of each cultivar; the other 90 plants of each cultivar were used as undamaged checks. Latex was collected from plants 1, 3, or 6 days after beetles were released into the cages. Out of the 180 plants of each cultivar, latex was collected from 60 (30 damaged and 30 undamaged checks) at each beetle exposure period (i.e., 1, 3, or 6 days after initiation of feeding damage). Out of each batch of 30 plants, latex from 15 was used for diet disk choice tests and latex from the other 15 plants was used to assess enzyme activity, as explained below. Each group of 15 plants was further divided into five groups (replicates) of three plants each for the collection of latex. An aliquot of 70 μl of latex was collected from each group of three plants for use in the assays described below. Females were weighed individually before releasing them on plants used for enzyme analysis and again either 1, 3, or 6 days after they were released into the cages, to determine weight change. The weight change was averaged over the six females per three plants as one replication of a total of five replications.

Choice-Test Bioassays with Latex from Damaged and Undamaged Plants Latex (70 μl) collected from plants as described above was applied immediately after collection to the top and side surfaces of a diet disk.. The experimental unit for the choice-test bioassay consisted of two diet disks: one treated with latex from beetle-damaged plants and the

other with latex from undamaged checks within each cultivar. In the control experimental units, two untreated diet disks were used. The diet disks were placed on the bottom of a plastic ventilated container (10×10×8 cm), and three male–female pairs of beetles were allowed to feed on the disks for 24 h at 25±1°C in a laboratory under a photoperiod of 14:10 h ratio of light to dark. The number of adults feeding on each diet disk was recorded 1, 2, 3, and 4 h after their release into the bioassay units. Dry weight of the diet consumed in 24 h was calculated as previously described (Sethi et al. 2008). Total diet consumed per three pairs of adults in 24 h was calculated by adding the consumption of the two diet disks in each replicate of each treatment.

Enzyme Activity Assays Activity of the enzymes PAL, PPO, and POX was assayed in the latices of Valmaine and Tall Guzmaine 1, 3, and 6 days after initiation of beetle damage. Collected latex was dispensed into −20°C chilled 1.5-ml microcentrifuge tubes on ice and immediately stored at −80°C until analyses.

Frozen latex (70 µl) was dissolved in 5 ml of 50 mM potassium phosphate buffer (pH 6.2) and centrifuged at 48,500×*g* for 45 min at 4°C (Model J2-HS, Beckman Instruments, Fullerton, CA, USA). The supernatant was collected and stored at −80°C until analyses. Total protein and enzyme activities were determined with a spectrophotometer (Model DU 640, Beckman Instruments, Fullerton, CA, USA). Total protein was estimated according to the modified Lowry's method (Peterson 1977) by using the Folin-Ciocalteau phenol reagent (Pierce Chemical, Rockford, IL, USA) and bovine serum albumin as a standard. Reaction mixture with boiled supernatant or without supernatant was used as control in all the enzyme assays.

PAL activity in latex was measured as described by Ke and Saltveit (1986) and Campos-Vargas and Saltveit (2002) with slight modifications. The supernatant was analyzed for PAL activity after addition of 200 µl of supernatant to 400 µl of 50 mM L-phenylalanine (dissolved in 20 mM potassium phosphate buffer, pH 8.8) and 400 µl of 50 mM potassium phosphate buffer (pH 8.8) and incubation at 40°C for 30 min. Absorbance was measured at 290 nm before and after incubation. PAL activity was expressed as the amount of PAL (µmol mg^{-1} h^{-1}) that produces 1 µmol of cinnamic acid in 1 h. Cinnamic acid (0–400 µmol in increments of 15 µmol) was used as a reference for quantification of PAL activity.

PPO activity was assayed following the methods of Sirinphanic and Kader (1985) and Loaiza-Velarde et al. (1997) with slight modifications. It was assessed by incubating 10 µl of supernatant with 500 µl of 1.6% catechol, 100 µl of 50 mM potassium phosphate buffer (pH 6.2), and 390 µl of distilled water. Absorbance of the mixture was read at 480 nm over a period of 2 min. One unit of PPO activity was defined as the amount of enzyme that produced an increase in absorbance of 0.1 per min at 480 nm. The linear portion of the curve was used to estimate the reaction rate. We did not add catalase to the reaction mixture prior to measurement for elimination of peroxidase-mediated phenolic oxidation. Therefore, our measured PPO activity may contain some residual peroxidase activity.

POX activity was determined by using the methods of Loaiza-Velarde et al. (1997) with slight modifications. It was determined by combining 10 µl of H_2O_2 (30%, *v*/*v*) in 50 µl of supernatant, 300 µl of 18 mM guaiacol, 100 µl of 50 mM potassium phosphate buffer (pH 6.2), and 540 µl of distilled water. Absorbance of the resulting mixture was examined at 420 nm over a period of 2 min. The POX activity (µmol mg $protein^{-1}$ min^{-1}) was determined by using guaiacol molar absorptivity (ε=26.6 M^{-1} cm^{-1}) at 420 nm. The linear portion of the curve was used to estimate the reaction rate.

Statistical Analysis The whiteness index of latex 0.5 min after collection was analyzed by using PROC GLM (SAS Institute 2003). The variables cultivar, latex type (from damaged or undamaged plants), and beetle exposure period (1, 3, or 6 days) were fixed effects, and replications were a random effect. Latex browning index was analyzed as a repeated measure by using multivariate analysis of variance (JMP release 7.0.1, SAS Institute Inc., Cary, NC, USA). The variables cultivar, latex type (from damaged or undamaged plants), and beetle exposure period (1, 3, or 6 days) were fixed. Five replications were randomly assigned to each level of latex and tested ten times (0.5, 1, 2, 3, 5, 7, 9, 11, 13, and 15 min after latex collection).

The numbers of insects feeding 1, 2, 3, or 4 h after release on diet disks treated with latex collected from plants with and without prior beetle exposure were analyzed as a repeated measures design by using PROC GLIMMIX. Separate analyses were run for disks from each cultivar at each beetle exposure period (1, 3, or 6 days). The variables latex type (from damaged or undamaged plants) and time period after beetle release (1, 2, 3, or 4 h) were fixed. Five groups of six beetles (i.e., replications) were randomly assigned to each level of latex and tested four times (1, 2, 3, and 4 h). Data on beetle fresh weight gain were analyzed by using PROC GLM with cultivar and beetle exposure period as fixed effects and replications as a random effect. Data on dry weight of diet consumed under choice tests were analyzed by using PROC GLM with latex and beetle exposure period as fixed effects. Replications were treated as a random effect for each cultivar.

Data on enzyme activities were analyzed by using PROC GLM with cultivar, latex type (damaged or undamaged), and beetle exposure period treated as fixed effects. Replications were treated as a random effect. Simple regression analysis was done to study the relationship between beetle fresh weight gain and enzymatic activities by using PROC GLM.

Tukey's honestly significant difference (HSD) test with a significance level of α=0.05 (SAS Institute 2003) was used for post hoc means separation.

Results

Color Characteristics of Latex from Damaged and Undamaged Plants The whiteness index of Valmaine latex was 1.83 times higher than that of Tall Guzmaine latex (26.20±1.01 vs. 14.49±0.92) when measured 0.5 min after collection ($F_{1,48}$= 101.60, P<0.001). It was lower in latex of damaged plants than in latex of undamaged plants (17.77±1.30 vs. 22.92± 1.44; $F_{1,48}$=19.70, P<0.001), but did not vary with length of beetle exposure period (1, 3, or 6 days; $F_{2,48}$=2.20, P= 0.122). None of the possible interactions among variables had a significant effect on the whiteness index.

Mean browning index of Valmaine latex (averaged over ten time periods after latex collection: 0.5, 1, 2, 3, 5, 7, 9, 11, 13, and 15 min) was 1.64 times higher than that of Tall Guzmaine latex ($F_{1,48}$=43.28, P<0.001; Fig. 1). It increased with beetle damage ($F_{1,48}$=23.29, P<0.001) and also with prolonged beetle exposure period (1, 3, or 6 days; $F_{2,48}$=9.91, P<0.001) and time period after latex collection (0.5, 1, 2, 3, 5, 7, 9, 11, 13, and 15 min; $F_{9,40}$=61.42, P< 0.001). Significant interaction was found between cultivar and treatment (damaged and undamaged; $F_{1,48}$=16.67, P< 0.001), but no interactions were found between cultivar and beetle exposure period ($F_{2,48}$=0.81, P=0.452), or between treatment and beetle exposure period ($F_{2,48}$=0.47, P= 0.631). Time period after latex collection interacted with beetle exposure period ($F_{9,41}$=2.62, P=0.0170), but not with cultivar ($F_{9,40}$=0.78, P=0.632) or treatment ($F_{9,40}$= 1.38, P=0.228).

Choice-Test Bioassays with Latex from Damaged and Undamaged Plants Similar mean numbers of beetles (averaged over four time periods after their release into the bioassay units—1, 2, 3, and 4 h) were counted on diet disks coated with latex from undamaged Valmaine plants and from plants that had been exposed to 1 day of feeding ($F_{1,8}$=2.08, P=0.159; Fig. 2a); however, latex collected from plants after 3 ($F_{1,8}$=18.96, P<0.001) and 6 days ($F_{1,8}$=14.43, P<0.001) of beetle exposure was significantly more deterrent than latex collected from undamaged plants. In Tall Guzmaine choice tests, similar mean numbers of beetles were counted on disks treated with latex collected from undamaged and damaged plants, regardless of the duration of beetle exposure (1 day: $F_{1,8}$= 0.075, P=0.785; 3 days: $F_{1,8}$=0.800, P=0.779; 6 days: $F_{1,8}$=0.047, P=0.830; Fig. 2b).

Adult *D. balteata* consumed less diet treated with latex from damaged Valmaine plants than diet treated with latex from undamaged plants ($F_{1,24}$=72.02, P<0.001; Table 1). There was a significant interaction between damage and beetle exposure period ($F_{2,24}$=3.67, P=0.041); beetles consumed less diet from disks treated with latex from plants that had been exposed to beetles for the longest time (6 days), whereas beetles consumed similar amounts of diet on the three sets of undamaged plants (Table 1). In the Tall Guzmaine choice test, beetle consumption of diet disks was similar, regardless of damage ($F_{1,24}$=0.216, P=0.646) or beetle exposure period ($F_{2,24}$=0.60, P=0.559; Table 1).

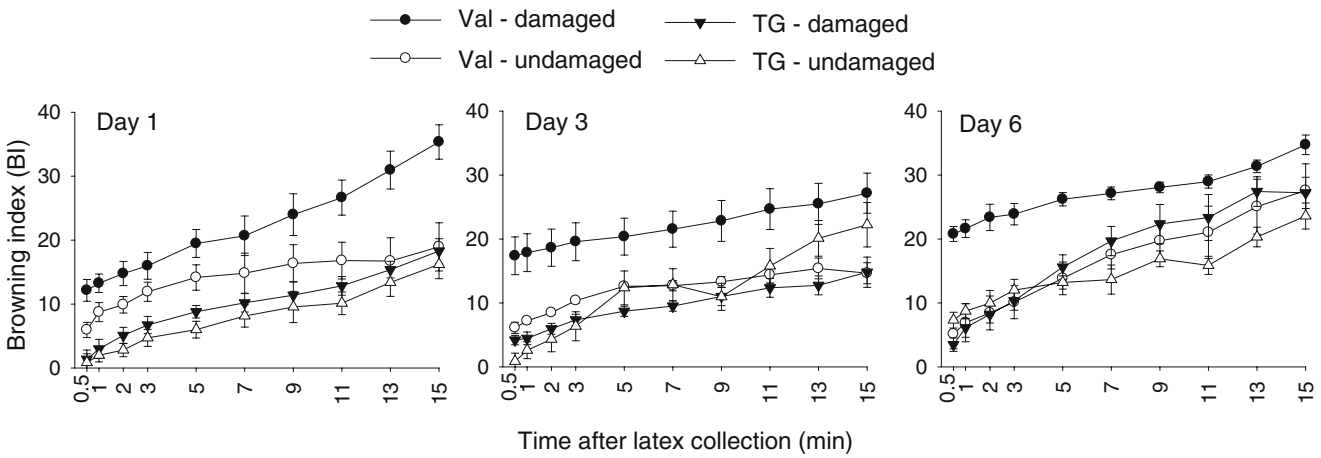

Fig. 1 Browning index (*BI*) of latex of two lettuce cultivars, Valmaine (*VAL*) and Tall Guzmaine (*TG*) 1, 3, and 6 days after initiation of feeding damage by adults of *D. balteata*. *Error bars* indicate standard error

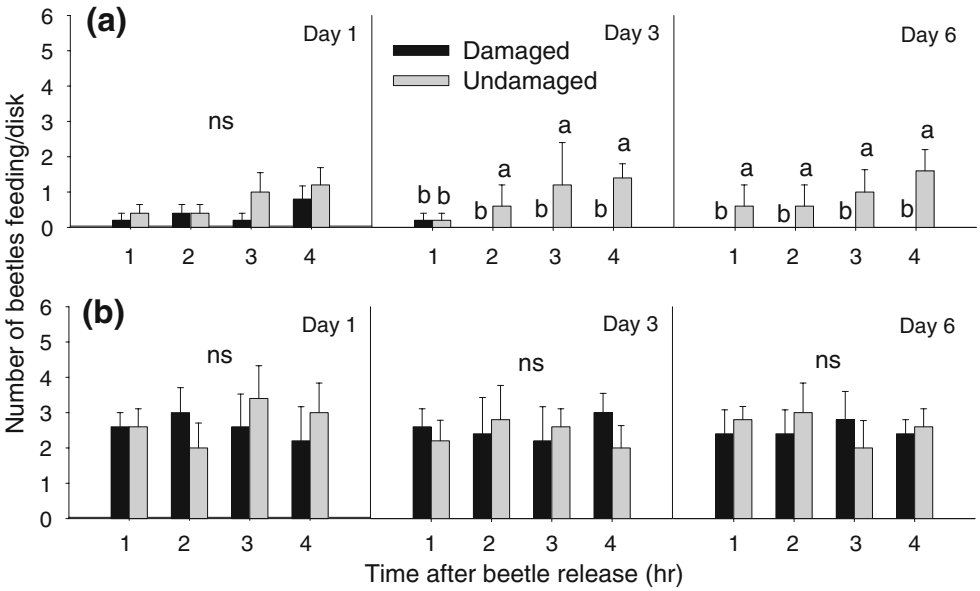

Fig. 2 Mean (+ standard error) number of adult *D. balteata* feeding on artificial diet disks when given a choice between disks treated with latex from damaged plants and disks treated with latex from undamaged plants of **a** Valmaine and **b** Tall Guzmaine 1, 2, 3, and 4 h after beetle release. *Bars capped with different letters within panel* (days 1, 3, or 6 within cultivar) differ significantly (Tukey's HSD test: $P \leq 0.05$)

Enzyme Activities and Total Protein Content Total protein content was 1.3-fold higher in Valmaine latex than in Tall Guzmaine latex ($F_{1,47}=91.77$, $P<0.001$; Fig. 3a). Interactions were found between cultivar and treatment (damaged or undamaged; $F_{1,47}=16.70$, $P<0.001$) and between cultivar and beetle exposure period ($F_{2,47}=7.61$, $P=0.001$). Total protein content in Valmaine after 6 days of feeding damage was 1.36-fold higher than after 1 day of feeding; however, there was no increase in protein content of Tall Guzmaine latex with increased duration of beetle feeding.

We did not find any enzymatic activity in either of the controls: no supernatant or boiled supernatant. In addition, the reaction mixture with boiled supernatant did not show any nonenzymatic browning. The specific activity of PAL was 3.44-fold higher in Valmaine latex than in Tall Guzmaine latex ($F_{1,47}=289.82$, $P<0.001$) and was influenced by treatment ($F_{1,47}=98.45$, $P<0.001$) and beetle exposure period ($F_{2,47}=7.96$, $P=0.001$; Fig. 3b). Interactions were found between cultivar and treatment ($F_{1,47}=20.96$, $P<0.001$) and between cultivar and beetle exposure period ($F_{2,47}=7.36$, $P=0.002$). PAL activity in Valmaine latex was significantly increased after 3 (1.81-fold) and 6 days (1.54-fold) of feeding damage, relative to the 1-day beetle exposure period. No increase in PAL activity was observed over time in the latex of Tall Guzmaine.

The specific activity of PPO was 4.37-fold higher in Valmaine latex than in Tall Guzmaine latex ($F_{1,47}=358.32$, $P<0.001$) and was affected by treatment ($F_{1,47}=80.31$, $P<0.001$) and beetle exposure period ($F_{2,47}=8.25$, $P<0.001$; Fig. 3c). Interactions were found between cultivar and treatment ($F_{1,47}=74.86$, $P<0.001$) and between cultivar and beetle exposure period ($F_{2,47}=11.65$, $P=0.002$). PPO activity in Valmaine latex was increased significantly over the 1-day activity 3 (1.74-fold) and 6 days (1.78-fold) after feeding initiation, but not in Tall Guzmaine latex.

The specific activity of POX was 2.1-fold higher in Valmaine latex than in Tall Guzmaine latex ($F_{1,47}=35.49$, $P<0.001$; Fig. 3d) and was affected by treatment ($F_{1,47}=39.29$, $P<0.001$) and beetle exposure period ($F_{2,47}=4.92$, $P=0.011$). Interactions were found between cultivar and

Table 1 Consumption of artificial diet by six *D. balteata* adults after 24 h in choice tests

Days of beetle exposure	Diet consumption (mg)[a]			
	Valmaine		Tall Guzmaine	
	Damaged	Undamaged[b]	Damaged	Undamaged[b]
1	5.7±1.1b	9.5±1.2a	19.3±1.9a	17.5±1.4a
3	3.1±0.6bc	10.4±0.7a	18.5±1.9a	16.9±2.4a
6	1.7±0.4c	10.7±1.4a	13.0±2.3a	19.0±3.0a

Each beetle was presented two diet disks: one treated with latex from plants damaged by exposure to beetles for different periods of time and one treated with latex from undamaged plants. Tests with latex from Valmaine and Tall Guzmaine were conducted and analyzed separately

[a] Mean ± standard error. Each table entry followed by different letters within a column (=cultivar-Valmaine or Tall Guzmaine) differed significantly ($P \leq 0.05$) by ANOVA and Tukey's HSD test

[b] Each beetle exposure period had separate check groups of undamaged plants

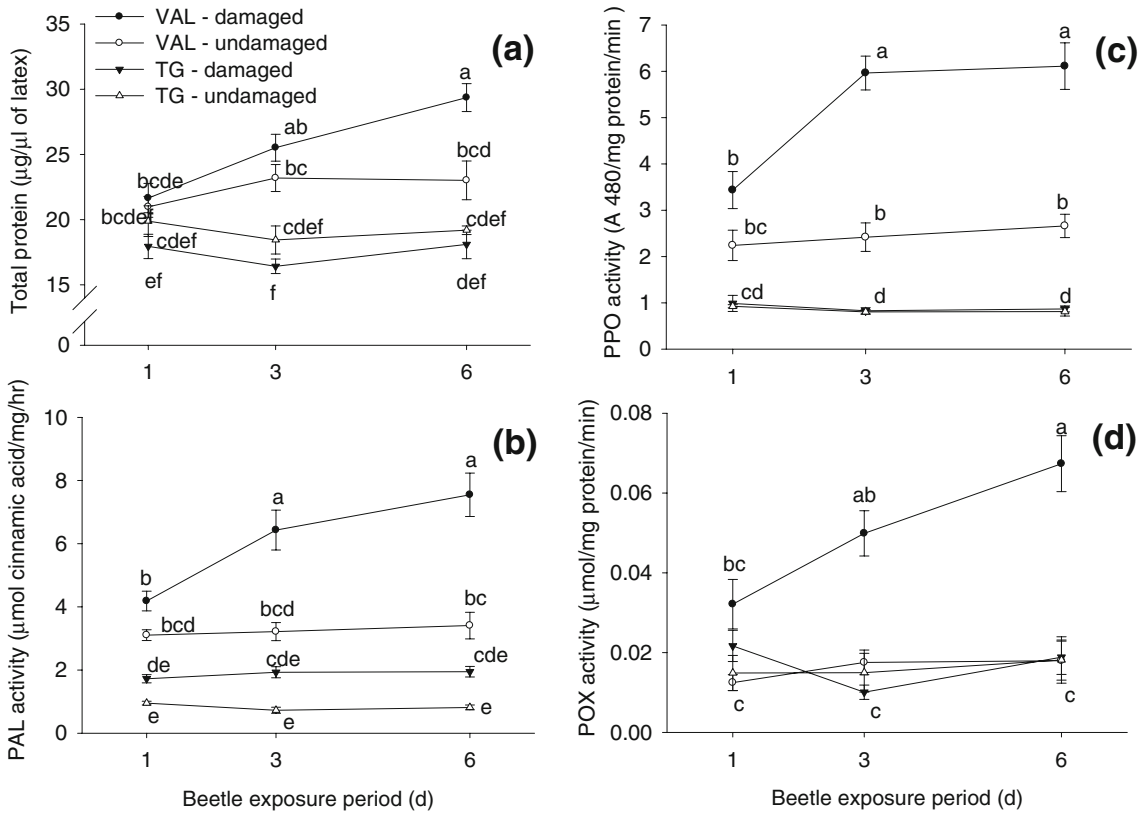

Fig. 3 **a** Total protein content and activities of three enzymes, **b** phenylalanine ammonia lyase (*PAL*), **c** polyphenol oxidase (*PPO*), and **d** peroxidase (*POX*) in two lettuce cultivars, Valmaine (*VAL*) and Tall Guzmaine (*TG*) 1, 3, and 6 days after initiation of feeding damage by adult *D. balteata*. *Error bars* indicate standard error. *Points capped with different letters within a panel* differ significantly (Tukey's HSD test: $P \leq 0.05$)

treatment ($F_{1,47}$=35.45, P<0.001) and between cultivar and beetle exposure period ($F_{2,47}$=5.16, P=0.009). POX activity in Valmaine latex was significantly increased over the 1-day activity 3 (1.56-fold) and 6 days (2.1-fold) after feeding initiation but not in Tall Guzmaine latex.

Relationship Between Female Weight Gain and Enzyme Activity Female beetles confined on Valmaine plants gained less weight than females confined on Tall Guzmaine ($F_{1,23}$=1269.92, P<0.001). Female fresh weight gain was affected by beetle exposure period ($F_{2,23}$=30.42, P<0.001) and the interaction between cultivar and beetle exposure period ($F_{2,23}$=161.35, P<0.001). Beetles caged on Tall Guzmaine for 1 day gained twice as much weight as those confined on Valmaine (0.84±0.03 mg vs. 0.38± 0.04 mg), 12 times as much when caged for 3 days (1.21± 0.03 mg vs. 0.11±0.02 mg) and 51 times as much when confined for 6 days (1.83±0.07 mg vs. −0.04±0.02 mg). Beetles lost weight the longer they were confined on Valmaine. Furthermore, significant negative linear relationships were found between female fresh weight gain and activities of each enzyme (PAL, PPO, and POX) in latex from damaged plants of Valmaine (Fig. 4). No such relationship was found between female fresh weight gain and any of the enzyme activities in latex from Tall Guzmaine.

Discussion

Resistance to *D. balteata* adults was increased in Valmaine compared to Tall Guzmaine after 24 h of feeding damage. Latex from damaged Valmaine plants was more deterrent to beetle feeding than latex from undamaged plants, whereas damage did not affect deterrence of latex from Tall Guzmaine plants. Earlier tests by Huang et al. (2003) detected localized induced resistance but no systemic resistance in Valmaine after 2 days of feeding damage by *D. balteata*. Differences in methodology between their study and ours may explain the differing results. In their study, damage was inflicted by confining a pair of beetles on an intact leaf and testing the latex from that leaf and the one directly above it for feeding deterrence. In our system, damage was inflicted by allowing two pairs of beetles to feed anywhere on a whole plant. So in our study, beetles might have damaged several leaves and consequently the plant might have responded collectively to a greater extent

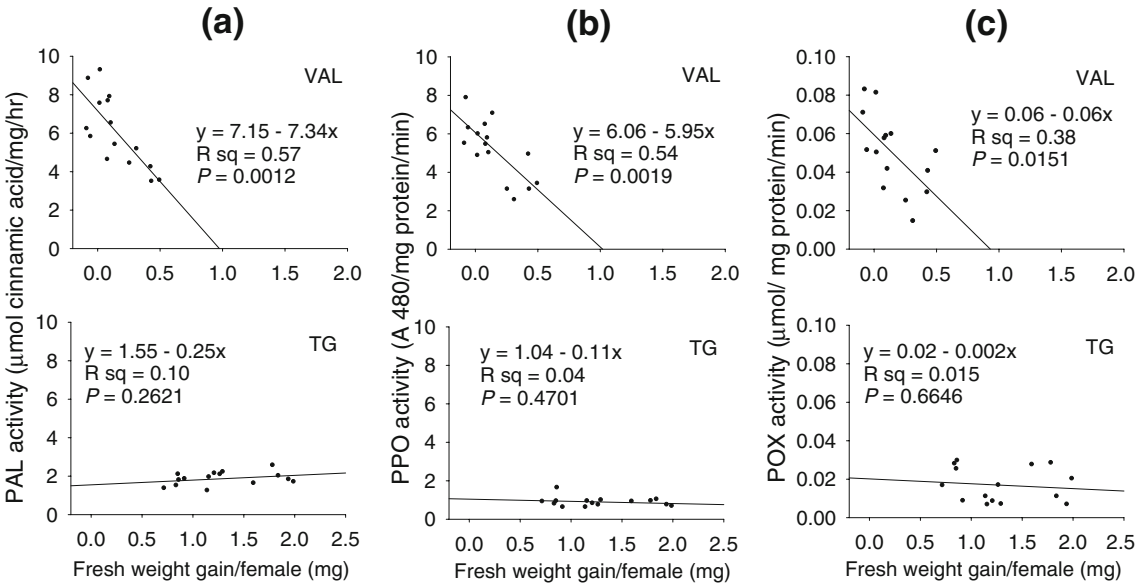

Fig. 4 Relationship between fresh weight gained by female *D. balteata* feeding on two lettuce cultivars, Valmaine (*VAL*) and Tall Guzmaine (*TG*) and activity of **a** PAL, **b** PPO, and **c** POX enzymes in latex collected from plants after 1, 3, and 6 days of exposure to beetle feeding damage

to induce systemic resistance. In addition, we used latex that was collected at several locations within the plant, thus representing three developmental ages of leaves, i.e., young, middle, and mature. The change in palatability of Valmaine latex may be due to a change in the concentration of its constituents. Malcolm and Zalucki (1996) found increased level of resistance in milkweed, *Asclepias syriaca* L. (Asclepiadaceae), 24 h after damage by monarch butterfly larvae, *Danaus plexippus* L. (Lepidoptera: Nymphalidae: Danainae), due to increase in the levels of cardenolides.

The amount of total protein increased in latex from Valmaine after beetle damage, but it did not change in Tall Guzmaine. Ni et al. (2001) also found a significant increase in the total protein content in wheat cultivars after damage by the Russian wheat aphid. Laticifer proteins from rooster tree (Asclepiadacae) greatly reduced survival and development of larval instars of the Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann; Diptera: Tephritidae), and velvetbean caterpillar, *Anticarsia gemmatalis* (Hübner; Lepidoptera: Noctuidae), when mixed in artificial diet (Ramos et al. 2007).

Latex from Valmaine was whiter than latex from Tall Guzmaine. Such differences in whiteness could indicate differences in concentrations of defensive secondary metabolites (terpenoids, alkaloids, tannins, proteins, and sterols; Esau 1965). The quantity of latex exuded by Tall Guzmaine plants decreased with increasing duration of beetle exposure, and latex collected after 3 and 6 days of feeding damage was also less viscous and more watery and translucent, whereas the consistency of Valmaine latex remained constant after damage (Sethi 2007). Latex from damaged plants was less white than that from undamaged plants, probably due to increased browning. The intensity of browning in Valmaine latex was higher in both undamaged and damaged plants compared to Tall Guzmaine plants. The latex from Valmaine plants fed upon by beetles for 3 or 6 days browned to a deeper degree than did latex collected after 1 day of feeding damage. However, the intensity of browning remained the same in Tall Guzmaine latex after beetle damage. Upon wounding, latex turns brown over time due to the production of quinones that are catalyzed by PPO (Wang and Constabel 2004). Browning intensity has been associated with higher resistance to pathogens; browning was much more intense in a disease-resistant clone of rubber tree than in a susceptible clone (Wititsuwannakul et al. 2002). Valentines et al. (2005) also found a positive relationship between browning potential and disease resistance in apples. Enhanced browning of callus and pericarp in a resistant corn line has been associated with increase in resistance against the corn earworm, *Helicoverpa zea* (Boddie; Lepidoptera: Noctuidae), and the dusky sap beetle, *Carpophilus lugubris* Murray (Coleoptera: Nitidulidae), compared to a susceptible line (Dowd 1994; Dowd and Norton 1995).

The production of phenylpropanoid compounds plays an important role in plant defense (Hahlbrock and Scheel 1989). Phenylalanine ammonia lyase is the first committed enzyme in the phenylpropanoid pathway (Dixon and Paiva 1995). Its de novo synthesis and increased activity is an initial response to mechanical wounding (Campos-Vargas and

Saltveit 2002) that ultimately results in increased concentrations of phenolic compounds in lettuce (Loaiza-Velarde et al. 1997). The phenylpropanoid pathway starts with the deamination of phenylalanine to cinnamic acid due to the action of PAL. The enhanced activity of PAL results in an increased production and accumulation of several phenolic compounds that are sequestered in the vacuole. These compounds can be oxidized to strong electrophilic quinones (brown substances) by PPO when membranes become disrupted. In addition, wounding also results in an increased expression of POX and lignin formation (Ribereau-Gayon 1972). The activities of all three oxidative enzymes were increased significantly in Valmaine latex after 3 and 6 days of *D. balteata* feeding damage, but they remained constant in Tall Guzmaine latex. Even the constitutive levels of PAL and PPO in latex from undamaged Valmaine plants were significantly higher than levels in latex from Tall Guzmaine. In addition, enzyme activities are even higher in Valmaine when expressed on a volume basis because the amount of total protein is higher in Valmaine than Tall Guzmaine. The increased intensity of browning in Valmaine latex observed in our study may be due to higher activity of PPO. Alteration in the levels of these enzymes due to insect feeding has been documented by many other researchers (Felton et al. 1994; Stout et al. 1999; Chaman et al. 2001; Ni et al. 2001; Wang and Constabel 2004).

Increases in insect resistance due to higher activity of PPO in potato, cotton, soyabean, tomato, rubber tree, poplar, and barley (Gregory and Tingey 1981; Hedin et al. 1983; Duffey and Felton 1991; Felton et al. 1994; Chaman et al. 2001; Wititsuwannakul et al. 2002; Wang and Constabel 2004) and POX in tomato (Stout et al. 1999) and barley (Chaman et al. 2001) have been correlated with decreases in insect fitness. Higher activity of PAL was found in resistant cultivars of lettuce infested with lettuce root aphid, *Pemphigus bursarius* (L.; Cole 1984) and barley infested with greenbug, *Schizaphis graminum* (Rondani; Chaman et al. 2003). The activity of PAL was also increased in strawberry leaves as a result of infestation by two-spotted spider mite, *Tetranychus urticae* (Inoue et al. 1985). We found a strong negative relationship between female beetle weight gain and activities of PAL, PPO, and POX, indicating a correlation between increased enzymatic activities and decreased beetle fitness. Female beetles confined for 1 day on Valmaine plants had gained weight, suggesting that at least 2 days of feeding are necessary to induce resistance (as shown by Huang et al. 2003). Beetles were observed tunneling and presumably feeding in the midrib tissue near the proximal end of the leaf. However, after 3 days, beetles were not observed feeding and they lost weight over the remaining 3 days of the experiment.

Based on our results, we hypothesize that increased levels of PAL, PPO, and POX in Valmaine after *D. balteata* damage result in increased production of defensive secondary metabolites. Solvent extraction of deterrent compounds from latex of undamaged Valmaine plants also suggests the presence of biologically active compounds that are constitutively expressed (Sethi 2007). Therefore, it appears that Valmaine possesses both constitutive and induced resistance mechanisms, mediated through latex, which act together to enhance its resistance against *D. balteata*. Further research is required to characterize both constitutive and insect damage-induced gene expression to understand the resistance mechanism in Valmaine against multiple insects and ultimately to support breeding programs for the development of resistant cultivars with superior horticultural traits.

Acknowledgments We thank Jennifer Hogsette (Department of Entomology and Nematology, University of Florida, Gainesville, FL, USA) and Julia Meredith (Center for Medical, Agricultural and Veterinary Entomology, United States Department of Agriculture, Gainesville, FL, USA) for help with insect rearing and lettuce growing, respectively. We also thank Murugesan Rangasamy (Department of Entomology and Nematology, University of Florida, Gainesville, FL, USA) for valuable suggestions on enzyme assays and Marty Marshall (Department Food Science and Food Nutrition, University of Florida, Gainesville, FL, USA) for use of his spectrophotometer. We are grateful to Ramandeep Kaur (Department of Entomology and Nematology, University of Florida, Gainesville, FL, USA) for help in setting up experiments and conducting enzyme assays. This research was supported by the Florida Agricultural Experiment Station and the USDA/ARS Tropical and Subtropical Agricultural Research Program.

Received: 10 July 2008 / Revised: 2 October 2008 / Accepted: 20 November 2008 / Published online: 7 February 2009

Abstract The profiles of volatile chemicals emitted by *Vicia faba* plants damaged by *Lygus rugulipennis* feeding, and by feeding plus oviposition, were shown to be quantitatively different from those released by undamaged plants. Samples of volatile chemicals collected from healthy plants, plants damaged by males as a consequence of feeding, plants damaged by females as a consequence of feeding and oviposition, plants damaged by feeding with mated males still present, and plants damaged by feeding and oviposition with gravid females still present, showed significant differences in the emission of hexyl acetate, (*Z*)-β-ocimene, (*E*)-β-ocimene, (*E*)-β-caryophyllene, and methyl salicylate. In particular, treatments with mated females present on plants had a significant increase in emission levels of the above compounds, possibly due to eggs laid within plant tissues or active feeding, compared with undamaged plants and plants damaged by males feeding, with or without insects still present. Furthermore, the pheromonal blend released by mated *L. rugulipennis* females, mainly comprising hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal, was enhanced when females were active on broad bean plants, whereas such an increase was not observed in males. Both sexes gave electroantennogram responses to green leaf volatiles from undamaged plants and to methyl salicylate and (*E*)-β-caryophyllene emitted by *Lygus*-damaged plants, suggesting that these compounds may be involved in colonization of host plants by *L. rugulipennis*. In addition, mated males and females were responsive to hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal released by mated females on *V. faba*, indicating that these substances could have a dual function as a possible aggregation pheromone in female–female communication, and as a sex pheromone in female–male communication.

Introduction

Natural "green plant odor" is a blend that comprises up to several hundred volatile compounds (Visser 1986; Price 1997), many of which are used by herbivorous insects to recognize host plants from a distance (Bernays and Chapman 1994). Plants frequently are damaged by insects in the natural habitat, and several studies have demonstrated that such damage can trigger production of volatile chemicals different from those released by undamaged or mechanically damaged plants (e.g., De Moraes et al. 1998; Turlings et al. 1998; Dicke and van Loon 2000; Kessler and Baldwin 2001).

Much of the knowledge of plant responses to herbivores has been acquired from studies on leaf-chewing insects that damage foliage extensively (e.g., De Moraes et al. 1998; Dicke and van Loon 2000; Kessler and Baldwin 2001); less is known about plant responses to non-chewing or sucking insects (Du et al. 1998, Rodriguez Saona et al. 2002; Colazza et al. 2004b). Only a few studies have focused on

induction of plant volatiles by insect oviposition and the consequent attraction of egg parasitoids (e.g., Meiners and Hilker 2000; Wegener et al. 2001; Colazza et al. 2004a, b). The profile of volatile chemicals emitted by herbivorous insects may be altered during oviposition and/or feeding on host plants, compared with the chemicals released in the absence of plants (Deng et al. 2004). Furthermore, plant stimuli can synergize the efficacy of external compounds, such as insect pheromones, and also influence herbivore sexual communication by enhancing pheromone production and release (e.g., Landolt et al. 1994; Deng et al. 2004; Yang et al. 2003).

The insect used in this study is the European tarnished plant bug, *Lygus rugulipennis* Poppius (Heteroptera: Miridae). It is the most common species of the genus *Lygus* in Europe, where it is widely distributed on both herbaceous and arboreous wild and cultivated plants, with records on more than 320 host plants (Holopainen and Varis 1991). This bug damages plants either by feeding, through injection of saliva rich in degrading enzymes, or by incisions made for oviposition with eggs embedded within the plant tissue. In the *Vicia faba–L. rugulipennis* system, it has been observed in the wind tunnel that both sexes move toward damaged host plants, and that the presence of mated conspecifics on plants enhances the responses of females, whereas the presence of conspecific eggs reduces the responses of both sexes (Frati et al. 2008). In addition, both males and females are less responsive to conspecifics alone compared to the host plant-conspecific complex (Frati et al. 2008). Virgin female *Lygus* bugs release a sex pheromone consisting of hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal (Ho and Millar 2002; Innocenzi et al. 2004, 2005).

Damage by the American species, *Lygus hesperus* Knight, that feeds on cotton, maize, and alfalfa plants, induces an increase in constitutive volatile compounds and the ex novo production of other molecules (Rodriguez-Saona et al. 2002; Blackmer et al. 2004). Induction of plant volatiles also has been shown by other non-chewing insects such as *Trialeurodes vaporariorum* (Homoptera: Aleyrodidae; Birkett et al. 2003) on *Phaseolus vulgaris*, *Nezara viridula* (Heteroptera: Pentatomidae; Colazza et al. 2004a), and *Acyrthosiphon pisum* (Harris) (Homoptera: Aphididae) on broad bean plants (Du et al. 1998), and *Murgantia histrionica* (Heteroptera: Pentatomidae) on cabbage plants (Conti et al. 2008).

The main goal of the present work was to determine whether or not oviposition and/or feeding damage by *L. rugulipennis* on the host plant, with or without the presence of conspecifics, alters the volatile chemical profile of broad bean (*V. faba* L.), and whether the sex pheromone blend is enhanced by the presence of the host plant. A second objective was to evaluate the electrophysiological responses of *L. rugulipennis* to volatile chemicals emitted by healthy and damaged plants, with and without conspecifics.

Methods and Materials

Insect Rearing *L. rugulipennis* were reared inside plastic cages (18×10.5×10 cm) containing strips of paper to increase the walking-surface area, located in a growth chamber (20±1°C, 50–60% RH, and photoperiod L12: D12). Adults were reared on fresh green beans (*P. vulgaris* L.) with food replaced three times a week. Beans containing eggs were transferred into other cages for nymph development. Upon hatching, nymphs also were fed on fresh green beans until adults emerged.

Mated *L. rugulipennis* females and males of the same age (~12–14 days old) were used in the experiments, as in behavioral assays previously carried out (Frati et al. 2008). It was assumed that insects were mated, because males and females were kept together after emergence. To reduce behavioral variability, each individual was isolated, 15–16 h before an experiment, inside a plastic pot (4 cm diam.×6.5 cm high), and allowed to feed on fresh green beans under the same conditions as the experiment.

Plants Broad bean plants, *V. faba* L. (cv. Sutton), were grown from seeds sown in plastic pots (8×8×10 cm) at a density of 1 plant/pot, using a compost mix (prepared for Rothamsted Research by Petersfield Products), and kept in a glasshouse at 20°C, photoperiod 16L:8D and 50–60% RH. In all air entrainments, only plants with four to five fully expanded true leaves were used. Plants were transferred, 2–3 h before the headspace volatile collections, into a climate-controlled chamber (20°C, 60±5% RH, and photoperiod 16L:8D).

Headspace Volatile Collection The following headspace volatile collections were carried out: (1) healthy plant as control; (2) plant damaged by feeding males with males removed; (3) plant damaged by feeding and oviposition of females with females removed; (4) plant damaged by males feeding with males present; (5) plant damaged by oviposition and feeding of females with females present; 6) mated males; and (7) gravid females. Plants damaged by *L. rugulipennis* were obtained by placing six mated adults on each plant (20°C, 60±5% RH, and photoperiod 16L:8D) inside a fine plastic mesh, and leaving the insects to feed (males) or feed and oviposit (females). After 24 h, insects were removed or left on the plant (as appropriate), and headspace collections were carried out. To verify oviposition on plants, numbers of eggs were counted after collection of volatiles, and only data from plants with ten or more eggs were used in the analysis.

In entrainments with mated adults alone, insects were placed inside a glass chamber (with an inlet and an outlet) that contained a plastic cup with moist cotton wool and no food (Frati et al. 2008). In plant entrainments, two halves of a cylindrical glass chamber (13 cm i.d.×22 cm h), with an inlet and an outlet, were placed around part of the plant, with the stem or petiole passing through a small hole in the central flange. Before use, the chamber was washed with water and detergent, wiped with acetone, and kept in an oven overnight at ~180°C. Approximately 30 min before collection started, plants, plants plus insects, or insects alone, were transferred into the chambers. Air, purified by passage through an activated charcoal filter, was pumped at a flow of ~1,300 ml min^{-1} and divided between two chambers. The air was simultaneously drawn from each chamber at 500 ml min^{-1} through a glass tube containing Porapak Q (60 mg, 80–100 mesh) to trap plant and/or insect volatiles. The Porapak was conditioned by washing with redistilled diethyl ether, and heating (132°C) overnight in a nitrogen stream (100 ml min^{-1}). Entrainments were performed in a temperature-controlled room with overhead fluorescent lights providing long-day conditions (lights on from 6:00 h to 22:00 h). Each volatile collection was repeated seven times (eight in the case of collections from mated females), beginning between 11.00–12.00 h and ending 24 h later. Traps were extracted with 700 μl of distilled diethyl ether, and extracts stored at −20°C in glass vials with Teflon cap-liners until used for analysis. Before analysis, each sample was concentrated in a nitrogen flow to approximately 200 μl.

Gas Chromatography Extracts were analyzed on a Hewlett-Packard 6890 gas chromatograph, equipped with a cool-on-column injector (30°C), a flame ionization detector (FID), and a 50 m×0.32 mm i.d. HP-1 capillary column, and hydrogen as carrier gas. The oven temperature was maintained at 30°C for 2 min and then increased at 10°C min^{-1} to 250°C. For *Lygus* volatiles, it was not possible to separate some peaks with the HP-1 column, so these extracts were further analyzed on an Agilent 6980N gas chromatograph, equipped with a cool-on-column injector (30°C), FID, and a 30 m×0.32 mm i.d. DB-Wax column, and hydrogen as carrier gas. The oven temperature was maintained at 30°C for 2 min and then increased at 10°C min^{-1} to 230°C.

Compounds were qualitatively identified, initially by comparing retention indices with a database of values for common plant volatiles, and subsequently using both gas chromatography–mass spectrometry (GC–MS) and co-injection of synthetic standards from commercial sources by using two columns of different polarity (Pickett 1990). The amount of each compound (nanogram) was estimated by comparison of peak area with that of an internal standard (dodecane, 100 ng). As different compounds may have different responses in terms of GC peak areas, the response factor for each identified compound was calculated from the area of a known amount of authentic compound.

GC–MS analyses were carried out by using a Thermo-Finnigan MAT95XP. GC columns (HP-1 and DB-wax), and conditions were similar to those described above except a temperature program of 30°C (held for 5 min) to 250°C at 5°C $min^{-1}$was used, and the carrier gas was helium.

Statistical Analysis Data were analyzed by one-way ANOVA (Statistica 6.0, Statsoft Inc. 2001). Before analysis, data were log-transformed to satisfy ANOVA assumptions (Zar 1999).

Chemicals (*E*)-2-hexenyl butanoate was synthesized from commercially available (*E*)-2-hexenoic acid by conversion to the methyl ester and reduction with diisobutylaluminum hydride to the corresponding alcohol. Reaction of (*E*)-2-hexenol with butanoyl chloride in the presence of 4-dimethylaminopyridine and triethylamine gave the desired ester in good yield after purification by flash chromatography. 4-Oxo-(*E*)-2-hexenal was prepared from 2-ethylfuran, using aqueous *N*-bromosuccinimide to promote oxidative ring opening (Moreira and Millar 2005). (*E*)-β-Ocimene was prepared using a three-step synthesis in which 3-methyl-2,5-dihydro-thiophene 1,1-dioxide, obtained by condensation of isoprene with sulfur dioxide in a sealed steel reactor, was deprotonated at low temperature in THF using sodium bis(trimethylsilyl)amide and then treated with excess 1-bromo-3-methyl-but-2-ene. The resulting 3-methyl-2-(3-methyl-but-2-enyl)-2,5-dihydro-thiophene 1,1-dioxide was treated with lithium aluminum hydride in refluxing diethyl ether to yield the (*E*)-β-ocimene in good yield and high purity (Gaoni 1977).

Authentic samples of (+) and (−)-germacrene-D were obtained by incubation of farnesyl pyrophosphate with purified, expressed (+) or (−)-germacrene-D synthase and subsequent hexane extraction and purification through a short column of silica gel (BDH, 40–63 μm)/$MgSO_4$ (10:1) (Prosser et al. 2004). (*E*,*E*)-α-Farnesene had been synthesized earlier at Rothamsted Research, as described by Cook et al. (2007), and was available to us. All other chemicals were obtained commercially (hexyl acetate: Aldrich; 1-hexanol: Sigma; linalool: Fluka; (*E*)-β-caryophyllene: Pfaltz & Bauer; (*Z*)-3-hexenol, (*Z*)-3-hexenyl acetate: Alfa Aesar; indole, methyl salicylate: Avocado Research Chemical; (*Z*)-ocimene: Bush-Boake Allen, London).

Electrophysiology Electroantennogram (EAG) recordings were made using Ag–AgCl glass electrodes filled with saline solution (as in Maddrell 1969, but without glucose). The insect head was excised, placed within the indifferent electrode, and the terminal process of the antenna, with the

Total duration of volatile collection was 24 h, starting at ~11.00–12.00 AM

[a]The mean amount of each compound (ng/h) was estimated by comparison of peak area with that of an internal standard (dodecane, 100 ng). Numbers in column followed by the same letter indicate means that are not significantly different ($P>0.05$, ANOVA).

N number of replicates, *TMTT* (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene

tip having removed to ensure good contact, introduced into the recording electrode,. The signals were passed through a high impedance amplifier (UN-06, Syntech, The Netherlands) and analyzed with a customized software package (Syntech). The stimulus was delivered into a purified airstream (1 l min^{-1}) flowing over the preparation.

The coupled GC–EAG system used has been described previously (Wadhams 1990). An AI 93 GC equipped with a cold on-column injector and a FID was used. The column was a 30 m×0.32 mm i.d. HP-WAX column, the temperature program was 40°C (held for 1 min) to 220°C at 10°C min^{-1}, and the carrier gas was hydrogen. The outputs from the EAG amplifier and the FID were monitored simultaneously and analyzed with the Syntech software package. Solutions (2 µl), of volatiles from healthy plants, from feeding and oviposition-damaged plants without females ($N=4$ for female; $N=6$ for male), and from feeding and oviposition-damaged plants with gravid females ($N=4$), were analyzed using antennal preparations of mated males and females. A peak on the GC was determined to be electrophysiologically active if it elicited a response on three or more preparations.

Results

GC analysis of the volatile chemicals trapped on Porapak Q showed significant differences in total amounts released by the different treatments of *V. faba* plants (Table 1 and Fig. 1). Probably, the biggest difference was that between *V. faba* plants with females on, and the other treatments. Among the green leaf alcohols and esters, more hexyl acetate was emitted by plants with females present (i.e., damaged by feeding and oviposition) than by undamaged plants (Table 1 and Fig. 1; $F=5.309$; $df=4, 30$; $P=0.002$). However, in the case of (*Z*)-3-hexenol ($F=2.117$; $df=4, 30$; $P=0.103$), 1-hexanol ($F=0.255$; $df=4, 30$; $P=0.905$), and (*Z*)-3-hexenyl acetate ($F=0.186$; $df=4, 30$; $P=0.944$), no significant differences were detected among treatments.

With regard to the shikimic acid pathway products, the amount of methyl salicylate released by plants on which females were present was greater than all other treatments, except that on which females had been present (Table 1 and Fig. 1). Moreover, plants on which females were or had been present, or on plants on which males were present, released significantly greater amounts of this chemical than undamaged plants. In the case of indole, there were no

significant differences (F=0.142; df=4, 30; P=0.965; Table 1) among the five treatments.

The monoterpenes (*Z*)-β-ocimene (F=3.967; df=4, 30; P=0.011) and (*E*)-β-ocimene (F=2.600; df=4, 30; P=0.040) were released in greater quantities from plants on which females were present than on undamaged plants (Table 1 and Fig. 1). A similar result (i.e., quantity released by plants with females was greater than that released by control plants) was observed for the sesquiterpene (*E*)-β-caryophyllene (Table 1 and Fig. 1; F=3.581; df=4, 30; P=0.017). In the case of linalool (F=1.520; df=4, 30; P=0.222), germacrene D (F=1.364; df=4, 30; P=0.270), (*E,E*)-α-farnesene (F=1.666; df=4, 30; P=0.184), and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (F=1.170; df=4, 30; P=0.952), there were no significant differences among treatments (Table 1).

The three main components of the sex pheromone of *L. rugulipennis*, hexyl butyrate (F=9.480; df=3, 25; P<0.001), (*E*)-2-hexenyl butyrate (F=13.627; df=3, 25; P<0.001), and (*E*)-4-oxo-2-hexenal (F=20.371; df=3, 25; P<0.001), were emitted in larger quantities by females when they were on broad beans than when they were not, whereas no such increase was observed for males (Fig. 2). Overall, females on plants released larger amounts of these three compounds than any of the other treatments (Fig. 2). In addition, when no plant was present, the amount of (*E*)-4-oxo-2-hexenal released by females was greater than that released by males (Fig. 2).

GC–EAG analysis of volatiles from undamaged plants showed that the green-leaf volatiles (*Z*)-3-hexenol, 1-hexanol, and (*Z*)-3-hexenyl acetate triggered responses in both mated females and males (Fig. 3a). When the volatiles from a female-damaged plant from which the females had been removed were tested, (*E*)-β-caryophyllene and methyl salicylate elicited EAG responses in both sexes (Fig. 3b). In addition, (*Z*)-3-hexenyl acetate elicited female and male responses in one preparation, while 1-hexanol and (*Z*)-3-hexenol triggered female and male responses in two preparations, respectively. Finally, when the volatiles from a female-damaged plant with females present were tested, only antennal responses to the three main sex pheromone components were recorded in both mated males and females (Fig. 3c).

Discussion

L. rugulipennis, during feeding and/or oviposition on broad bean plants, induces changes in the emission of several volatile compounds as compared to undamaged plants. The most profound changes were observed when mated females were present, and to a lesser extent when females had been, on the plant. The difference in the amount of volatile emissions is due possibly to endophytic oviposition by *Lygus* causing laceration of tissues, with the consequent contact between egg surface and plant cells (Rodriguez-Saona et al. 2002; Frati et al. 2008), or to the high feeding activity of females.

There were no qualitative differences in volatile emissions among the five treatments tested. This has also been shown in

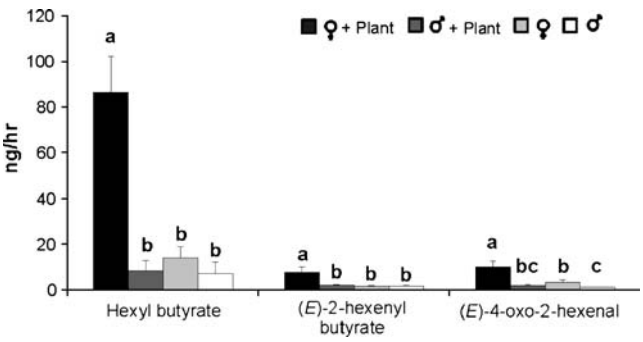

Fig. 2 Release rates of the main volatile compounds collected from mated *Lygus rugulipennis* females (N=8) and males (N=7), with and without host plant (*Vicia faba*). *Each bar* represents a mean ± SE. *Columns with the same letter* indicate means that are not significantly different (P>0.05, ANOVA)

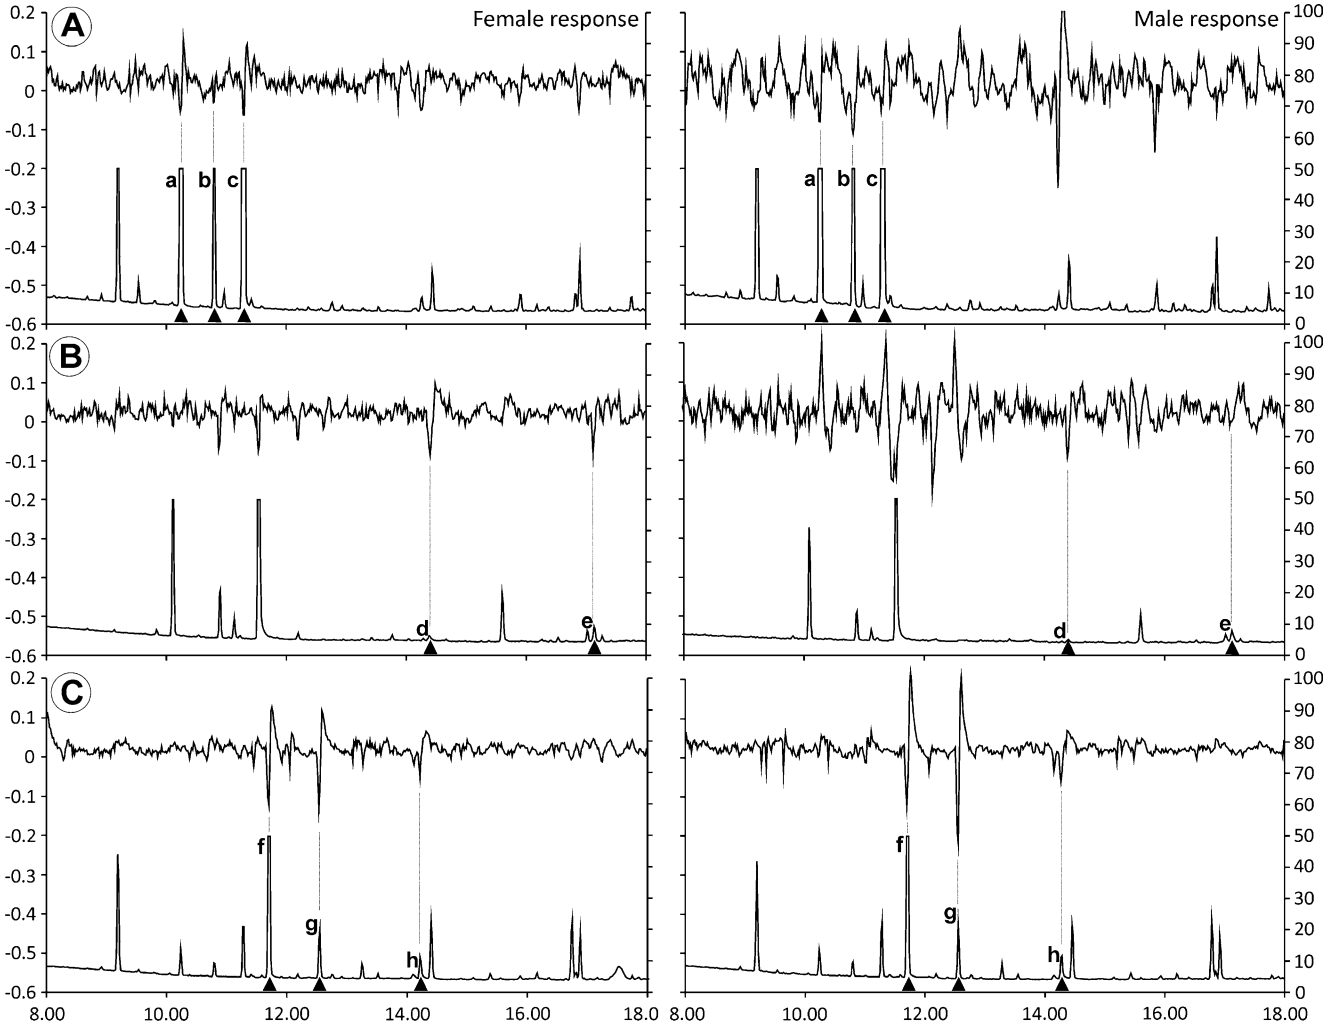

Fig. 3 Coupled gas chromatogram–electroantennograms of *Lygus rugulipennis* females and males to volatile collections from **A** healthy *Vicia faba* plants, **B** plants damaged by females that had been removed, and **C** plants damaged by females still present. *Upper trace*: response (mV, left-side axis title) of antenna; *lower trace*: flame ionization detector response (relative, right-side axis title). Compounds (only those showing electroantennogram activity on three or more preparations are given): *a* (*Z*)-3-hexenyl acetate, *b* 1-hexanol, *c* (*Z*)-3-hexenol, *d* (*E*)-β-caryophyllene, *e* methyl salicylate, *f* hexyl butyrate, *g* (*E*)-2-hexenyl butyrate, *h* (*E*)-4-oxo-2-hexenal

feeding/oviposition damage by *L. hesperus* on maize, cotton, and alfalfa (Rodriguez-Saona et al. 2002; Blackmer et al. 2004), and in other sucking insects feeding on leguminous plants, e.g., the aphid *A. pisum* (Harris) (Homoptera: Aphididae; Du et al. 1998; Guerrieri et al. 2002), greenhouse whitefly *T. vaporariorum* (Homoptera: Aleyrodidae; Birkett et al. 2003), and *N. viridula* (Heteroptera: Pentatomidae; Colazza et al. 2004b). We did, however, observe quantitative changes in emission of hexyl acetate, methyl salicylate, (*Z*)-β-ocimene, (*E*)-β-ocimene, and (*E*)-β-caryophyllene, according to treatment.

Work on maize and cotton plants found that larger amounts of (*Z*)-3-hexenal and (*Z*)-3-hexenyl acetate were emitted by plants infested with the American species *L. hesperus* than by insect-free plants (Rodriguez-Saona et al. 2002). We observed no such difference in emission of these compounds among any of our five treatments. This contrast could be due to the respective infestation levels used; our experiments on *V. faba* infested with the European species *L. rugulipennis* used six adults per plant, whereas Rodriguez-Saona et al. (2002) used the American species *L. hesperus* at an infestation of 30–40 adults per plant. Alternatively, perhaps the slight mechanical damage caused by *L. rugulipennis* feeding or ovipositing may not activate the lipoxygenase pathway, consistent with the data reported for *N. viridula* on *V. faba* (Colazza et al. 2004b).

Compared to control plants, methyl salicylate was released in greater amounts by plants with females or males present, and also by plants on which females had been present. This confirms that the shikimic acid pathway, and in particular methyl salicylate, is induced by feeding by *L. rugulipennis*. However, plants with females present

released greater amounts than plants on which males were present. This suggests that females either feed more actively than males, or that ovipositional damage (in addition to feeding damage) also induces this pathway.

Broad bean treatments also showed quantitative differences in the emission of the terpenoids, (*E*)-β-caryophyllene, (*Z*)-β-ocimene, and (*E*)-β-ocimene, particularly between plants with females present and control plants. An increase in (*E*)-β-caryophyllene emission by damaged plants has been shown to be caused by feeding damage of *Spodoptera littoralis* caterpillars on maize (Turlings et al. 1998), by oviposition of *Xanthogaleruca luteola* on *Ulmus minor* (Wegener et al. 2001), and by feeding and oviposition by *L. hesperus* on cotton and alfalfa (Rodriguez-Saona et al. 2002; Blackmer et al. 2004), and by *N. viridula* on broad beans (Colazza et al. 2004b). In addition, an increase in (*Z*)-β-ocimene and (*E*)-β-ocimene emission has been shown to result from feeding damage in several different systems (Kessler and Baldwin 2001; Blackmer et al. 2004).

Our data demonstrate that the amount of pheromone released by mated *L. rugulipennis* females is enhanced by the presence of broad bean plants, showing that host plants influence the production and/or release of sex pheromone by *L. rugulipennis*, as in other systems (McNeil and Delisle 1989; Landolt et al. 1994; Deng et al. 2004; Yang et al. 2003). Precisely how the host plant influences females remains to be determined.

In GC–EAG analyses of volatiles from healthy plants, EAG responses were recorded from both sexes to (*Z*)-3-hexenol, 1-hexanol, and (*Z*)-3-hexenyl acetate. These green-leaf volatiles could be used by females and males to locate hosts, as suggested by the responses of both sexes to healthy broad beans in a wind tunnel (Frati et al. 2008). In the case of damaged plants without insects, methyl salicylate and (*E*)-β-caryophyllene triggered EAG responses in both sexes. These compounds commonly are released from certain plants during herbivore damage (Chamberlain et al. 2001). Apparently, the greater release of these chemicals by damaged plants does not have an inhibitory effect on *L. rugulipennis*, since both males and females move toward damaged *V. faba* plants in a wind tunnel (Frati et al. 2008). Whether or not the increased release of these chemicals by damaged plants conveys any information to *L. rugulipennis* males and females is unknown.

In the GC–EAG analysis of volatiles released by plants with mated females still on the plant, EAG responses were recorded from both sexes to the three pheromone components, hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal. This suggests that these compounds may have an aggregation function rather than a strict sexual function. Female–female attraction was first proposed in *L. rugulipennis* by Glinwood et al. (2003), and subsequently was confirmed in wind tunnel and vertical open olfactometer experiments, in which the plant-conspecific complex of mated females, attracted females (Frati et al. 2008). An aggregation-type function of the pheromone produced by mated females when on the plant could be beneficial for this insect, since it could help conspecifics find a suitable food source, thus increasing the efficiency of resource use, as well as attracting mates (Dicke and van Loon 2000; Frati et al. 2008).

Acknowledgments We thank Laura Chiattelli and Donatella Marchionni for rearing *Lygus* bugs and Keith Plumb for growing *Vicia faba* plants. We also are grateful to the two anonymous reviewers and the editor for thoughtful comments. This research was financially supported by the Ministry for University and Scientific Technological Research (PRIN 2002 "Functional investigations on trophic webs, plants-Hemiptera-parasitoids, and biological control"). The authors have contributed equally to this paper.

Ring-Fluorinated Analog of Methyl Eugenol: Attractiveness to and Metabolism in the Oriental Fruit Fly, *Bactrocera Dorsalis* (Hendel)

Received: 26 September 2008 / Revised: 10 December 2008 / Accepted: 11 December 2008 / Published online: 6 February 2009

Abstract Oriental fruit fly, *Bactrocera dorsalis* (Hendel), males are highly attracted to the natural phenylpropanoid methyl eugenol (ME). They compulsively feed on ME and metabolize it to ring and side-chain hydroxylated compounds that have both pheromonal and allomonal functions. Side-chain metabolic activation of ME leading to (*E*)-coniferyl alcohol has long been recognized as a primary reason for hepatocarcinogenicity of this compound in rodents. Earlier, we demonstrated that introduction of a fluorine atom at the terminal carbon of the ME side chain significantly depressed metabolism and specifically reduced formation of coniferyl alcohol but had little effect on field attractiveness to *B. dorsalis*. In the current paper, we demonstrate that fluorination of ME at the 4 position of the aromatic ring blocks metabolic ring-hydroxylation but overall enhances side-chain metabolism by increasing production of fluorinated (*E*)-coniferyl alcohol. In laboratory experiments, oriental fruit fly males were attracted to and readily consumed 1,2-dimethoxy-4-fluoro-5-(2-propenyl)benzene (I) at rates similar to ME but metabolized it faster. Flies that consumed the fluorine analog were as healthy post feeding as ones fed on methyl eugenol. In field trials, the fluorine analog I was ~50% less attractive to male *B. dorsalis* than ME.

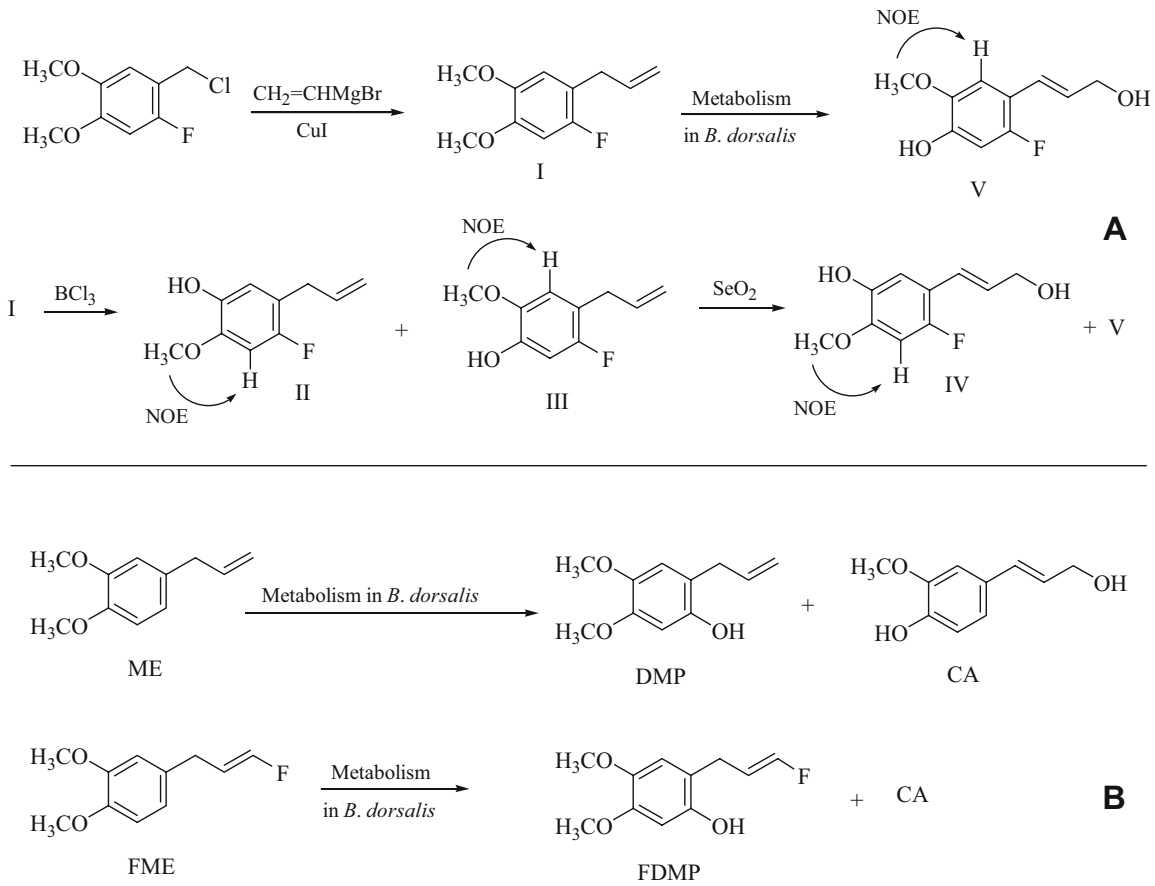
Introduction

The oriental fruit fly, *Bactrocera dorsalis* (Hendel), is a widespread pest of a broad range of tropical, subtropical, and temperate host plants (White and Elson-Harris 1992; US Department of Agriculture 1983). Males of *B. dorsalis* are strongly attracted to and compulsively feed on methyl eugenol (ME, Scheme 1; Steiner 1952), a commonly occurring plant phenylpropanoid (Metcalf 1990). The use of ME in traps and killing stations is an integral part of successful detection, control, and eradication strategies for the oriental fruit fly populations worldwide (Steiner et al. 1965; Koyama et al. 1984). The attraction to and consumption of ME by *B. dorsalis* and sibling species of the *dorsalis* complex, *B. papayae* and *B. carambolae*, have ecological significance in the fly's communication system. Mature



Scheme 1 **A** Synthesis and metabolism of the ring-fluorinated analog I in *B. dorsalis*, and chemical transformation of I to metabolite V. **B** Metabolism of methyl eugenol (*ME*) and the side-chain fluorinated analog of ME (*FME*) in *B. dorsalis*.

males, after feeding on ME, metabolize it primarily to 2-(2-propenyl)-4,5-dimethoxyphenol (DMP) and (*E*)-coniferyl alcohol (CA), which display pheromonal and allomonal properties (Nishida et al. 1988; Tan and Nishida 1996).

A potential problem to the continued use of ME in area-wide pest management programs is the decision by the National Toxicology Program, US Department of Health and Human Services to classify this compound as a carcinogen (National Toxicology Program 1998, 2002). Metabolic activation of ME and production of 1′-hydroxy metabolites through enzymatic side-chain hydroxylation are thought to be primarily responsible for hepatotoxicity and carcinogenicity of ME (Smith et al. 2002). Since early warnings about the carcinogenicity of ME (Miller et al. 1983; Schiestl et al. 1989; Sekizawa and Shibamoto 1982), a number of compounds have been evaluated as attractants for *B. dorsalis* (Metcalf et al. 1975; Mitchell et al. 1985; Khrimian et al. 1993, 1994; Liquido et al. 1998). One promising replacement for ME is a fluorine analog, (*E*)-1,2-dimethoxy-4-(3-fluoro-2-propenyl)benzene (FME, Scheme 1), which in limited field tests was as attractive to *B. dorsalis* as methyl eugenol (Khrimian et al. 1994). It is also more persistent than ME and, remarkably, about twice as active as the corresponding *Z* isomer (Khrimian et al. 1994; Liquido et al. 1998). This compound also displays a reduced propensity to oxidative biotransformations, specifically a side-chain hydroxylation in *B. dorsalis* (Khrimian et al. 2006), which is linked to the hepatotoxicity and carcinogenicity of ME (Smith et al. 2002). While the mechanism is still unclear, FME showed reduced toxicity and reduced recombinagenicity in yeast deletion assays compared to ME (Brennan et al. 1996). In the current paper, we present the results of our studies on behavioral bioassays and metabolism of yet another fluorinated ME analog, 1,2-dimethoxy-4-fluoro-5-(2-propenyl)benzene (I, Scheme 1). Of particular interest is how the fluorine introduction at a key metabolic hydroxylation site of ME would affect the overall biotransformation in oriental fruit fly. In addition, we were interested to quantify the attractiveness of compound I relative to its analogs ME and DMP, which also was highly attractive to *B. dorsalis* males (Nishida et al. 1988). There is ample information in the literature demonstrating that replacement of a hydroxy group with fluorine in the biologically active compounds may be successful (Welch 1987, 1991). In

addition, we expected such fluorine substitution to render an improved volatility compared to DMP, which may be beneficial for a fruit fly attractant.

Methods and Materials

Analytical Procedures ^{1}H NMR spectrum of I was recorded at 300 MHz in $CDCl_3$ with TMS as an internal standard on a Bruker QE-300 spectrometer. ^{1}H NMR spectra of other compounds were obtained at 500 MHz on a Bruker DRX-500 using TMS as an internal standard. Chemical shifts are reported in δ units, and coupling constants in Hz. GC analyses were performed on a Shimadzu 17A (Shimadzu Scientific Instruments, Inc., Columbia, MD, USA) gas chromatograph equipped with a flame ionization detector, an auto sampler AOC-20s and auto injector AOC-20i, and an HP-5 capillary column (30 m×0.25 mm×0.25 μm film). Hydrogen was used as carrier gas at 1 ml/min. Column temperature was maintained at 100°C for 2 min and then raised to 260°C at 10°C/min. Electron-ionization (EI) mass spectra were obtained at 70 eV with an Agilent Technologies 5973 mass selective detector interfaced with a 6890 N GC system equipped with a 30 m×0.25 mm i.d.×0.25 μm film HP-5MS column. Column temperature was maintained at 80°C for 1 min and then raised to 270°C at 10°C/min. Helium was used as carrier gas at 1 ml/min. TLC analyses were conducted on Whatman AL SIL G/UV plates using hexanes/ethyl acetate as a mobile phase with a 20% ethanol solution of phosphomolybdic acid and/or UV used for visualization of spots. Flash chromatography was carried out with 230–400 mesh silica gel (Fisher Scientific, Fair Lawn, NJ, USA).

Chemicals All reagents and solvents were purchased from Aldrich Chemical Co. unless otherwise specified.[1] Methylene chloride and hexamethylphosphoramide (HMPA; caution, it is a carcinogen!) were distilled from calcium hydride, and tetrahydrofuran (THF) was dried by distillation from sodium benzophenone-ketyl. Methyl eugenol metabolites, CA and DMP, were prepared from ferulic acid (Quideau and Ralph 1992) and 3,4-dimethoxyphenol (Benbow and Katoch-Rouse 2001), respectively. FME was prepared as described (Khrimian et al. 2006). 1-Chloromethyl-2-fluoro-4,5-dimethoxybenzene was prepared following a procedure of Furlano and Kirk (1986). The crude chloride was used in a copper-catalyzed Grignard coupling without further purification as described (Khrimian et al. 1993).

[1] Mention of commercial products does not constitute an endorsement by USDA.

1-Fluoro-4,5-dimethoxy-2-(2-propenyl)benzene (I) A solution of 1-chloromethyl-2-fluoro-4,5-dimethoxybenzene (1.62 g, 7.92 mmol) in dry THF (8 ml) was introduced under N_2 to a three-neck flask and cooled to −10°C. A solution of copper(I) iodide (150 mg, 0.79 mmol) in dry HMPA (6 ml) was added at once, followed by vinylmagnesium bromide (11.88 mmol; 11.88 ml of 1.0 M in THF) delivered slowly at −5–(−10)°C. The mixture was stirred at that temperature range for 30 min, then slowly warmed to 25°C over ~4 hr. The mixture was poured into a saturated ammonium chloride solution and extracted with ether (3×50 ml). The combined organic extracts were washed three times with saturated NH_4Cl and dried with Na_2SO_4. After evaporation of the solvent, the remainder was distilled in vacuum at 62–64°C/0.3 mm Hg to give I (800 mg, 52%) of 96% purity. Flash chromatography of this material on SiO_2 with hexanes/ethyl acetate, 8:1, gave I (600 mg) of 99% purity. ^{1}H NMR: 3.34 (dd, 2H, H-1′, J= 6.3, 1.2), 3.84 (s, 6H, OCH_3), 5.07 (m, 2H, H-3′), 5.94 (m, 1H, H-2′), 6.62 (d, $^3J_{HF}$=10.8, H-3), 6.65 (d, $^4J_{HF}$=7.5, H-6). GC-MS (EI): 196 (M^+, 100%), 181 (85), 169 (49), 165 (75), 125 (75), 109 (67).

4-Fluoro-2-methoxy-5-(2-propenyl)phenol (II) and 5-fluoro-2-methoxy-4-(2-propenyl)phenol (III) Fluorinated methyl eugenol I (980 mg, 5 mmol) was stirred with boron trichloride (6 ml of 1 M in CH_2Cl_2, 6 mmol) in dry CH_2Cl_2 (10 ml) at 0 to 25°C under N_2. After 24 hr, or when TLC showed no starting material present, the mixture was poured into ice-water and extracted with CH_2Cl_2. The combined extracts were washed with a saturated solution of sodium bicarbonate to pH ~7, then dried with sodium sulfate and concentrated. Flash chromatography with hexanes/ethyl acetate, 4:1 to 1:1, afforded a mixture of phenols II and III in a 57:43 ratio (592 mg, 65%). Phenols II and III were not separated by TLC but showed a baseline separation by GC on a DB-5 column, with phenol III being the first isomer to elute. The assignment of the isomeric phenol was done by ^{1}H NMR. GC-MS (*m*/*z*, %): II—182 (100, M^+), 167 (21), 155 (20), 151 (11), 149 (21), 139 (10), 121 (10), 109 (15), 91 (14). III—182 (100, M^+), 167 (32), 155 (18), 149 (15), 139 (8), 121 (11), 109 (15), 91 (11). ^{1}H NMR (500 MHz, $CDCl_3$): 3.28 (d, J=6.5, CH_2, II), 3.31 (d, J=6.5, CH_2, III), 3.82 (s, OCH_3, II), 3.83 (s, OCH_3, III), 5.04 (m, CH=), 5.36 and 5.67 (OH), 5.91 (m, CH_2=), 6.57 (d, $^3J_{HF}$=10.6, H-3, II), 6.61 (d, $^4J_{HF}$=6.9, H-3, III), 6.64 (d, $^3J_{HF}$=10.6, H-6, III), 6.71 (d, $^4J_{HF}$=6,9, H-6, II).

(E)-4-Fluoro-5-(3-hydroxy-1-propenyl)-2-methoxyphenol (IV) and (E)-5-fluoro-4-(3-hydroxy-1-propenyl)-2-methoxyphenol (V) Selenium dioxide (200 mg, 1.8 mmol) was dissolved in hot water (0.2 ml; ~80°C) and treated with a solution of phenols (II+III, 318 mg, 1.75 mmol) in dioxane (1.6 ml). The resulting mixture was heated in a water bath

(~85°C) for 15 min, then diluted with water (8 ml) and extracted with CH_2Cl_2 (4×5 ml). The combined organic extracts were washed with water (2×2 ml), brine (2×2 ml) and then dried with $MgSO_4$. The solution was concentrated, and the remainder was flash-chromatographed with hexanes/ethyl acetate, 3:4, to furnish some unreacted starting material (53 mg), then phenol IV (20 mg, R_f 0.44, hexanes/ethyl acetate, 1:2), a mixture of IV and V (16 mg) and, finally, phenol V (11 mg, R_f 0.38, hexanes/ethyl acetate, 1:2,). GC-MS (*m*/*z*, %): IV (Rt 14.27 min) – 198 (77, M^+), 155 (100), 142 (36), 140 (9), 137 (14), 127 (8), 121 (9), 109 (18); V (Rt 13.83 min) – 198 (71, M^+), 155 (100), 142 (36), 140 (8), 137 (12), 127 (10), 109 (16).^{1}H NMR (500 MHz, $CDCl_3$ + CD_3OD, IV): 3.77 (s, OCH_3), 4.17 (dd, *J*=6.0, 1.0, CH_2), 6.15 (dt, *J*=16.0, 5.5, H-2′), 6.49 (d, $^3J_{HF}$=11.5, H-3), 6.57 (br. d, *J*=16.0, H-1'), 6.87 (d, $^4J_{HF}$= 7.0, H-6). ^{1}H NMR (500 MHz, CD_3CN, V): 3.84 (s, OCH_3), 4.03 (dd, *J*=6.0, 1.5, CH_2), 6.25 (dt, *J*=16.0, 6.0, H-2′), 6.59 (d, $^3J_{HF}$=11.5, H-6), 6.63 (br. d, *J*=16.0, H-1'), 7.04 (d, $^4J_{HF}$=7.5, H-3).

Insects Laboratory reared oriental fruit flies (strain: Punador initiated in 1988–1989 and monitored by mating and survival tests) were obtained from the USDA-ARS-PBARC rearing facility in Honolulu, Hawaii. Pupae (60 ml) were placed in a screened aluminum cage (30×30×30 cm) and allowed to emerge. Flies were given water, sugar, and hydrolyzed yeast protein and held at 25–26°C, 50–70% relative humidity and a 12/12 hr L/D cycle before using in laboratory trials. Field bioassays were conducted with sterile laboratory reared oriental fruit fly, obtained as pupae, from a laboratory colony at the USDA-ARS-PBARC rearing facility in Honolulu, HI. Emerged adults were kept in an insectary at 24–27°C, 65–70% RH, and a photoperiod of 12:12 hr (L:D). Adults were fed water and a diet of three parts sucrose, one part protein yeast hydrolysate (Enzymatic, United States Biochemical Corporation, Cleveland, OH), and 0.5 part torula yeast (Lake States Division, Rhinelander Paper Co., Rhinelander, WI). Ten–eleven-day old, sexually mature, flies were used in the field studies.

Bioassays

Laboratory Feeding and Metabolism In Lab Trial 1, 50 laboratory-reared mature (9–10-day-old) oriental fruit fly males were placed in five ~1-l plastic containers (10/container) equipped with water inserts and screened covers. Flies were offered 10 μl of ME (2×5 μl) on a slip of filter paper (25×5 mm) taped to a blank water vial. Another 50 flies were offered the fluorine analog I (10 μl/cage), and the last group of 50 males were presented with a filter paper containing 10 μl water. Behavioral observations (landing and feeding on the source) were recorded every 5 min for 1 hr, then filter papers were removed, water containers were introduced, and the flies were left overnight with a sugar cube on the cover available for consumption. Numbers of dead flies was counted at 24 and 48 hr. Eighteen hours post feeding, the rectal glands of ten flies each fed with ME and I (cages where the landings occurred most), as well as ten control flies were dissected and placed in conical plastic vials with 20 μl ethanol. The glands were crushed with a wire rod, sealed with parafilm and centrifuged at ~4,000 rpm for 10 min. The supernatants were diluted in the same vials with ethanol to 100 μl and analyzed by GC-MS in splitless mode by injection of 1 μl solutions. External standards of CA, DMP, and V were used for quantification. The remainders of the dissected flies were individually placed in 20 μl ethanol, crashed, then flash-chromatographed on a short SiO_2 column (30×5 mm) with hexanes/ethylacetate, 3:1. The fractions containing unmetabolized ME and fluorine analog I were further combined, concentrated to 1 ml, and quantified by GC using external standards.

Lab Trial 2 was conducted analogously to Lab Trial 1 with the exception of the treatments presented which were 1 μl of ME (10 μl of 10% *v*/*v* hexane solution), 1 μl of fluorine analog I, and water as control. In Lab Trial 3, the doses of treatments were reduced to 0.1 μl. No dissections and metabolism studies were conducted in Lab Trials 2, and 3.

Field Attractiveness and Release Rate

Dispenser Preparation and Trapping For each test, cotton dental wicks (9 mm diam × 14 mm long) were treated with aliquots of a hexane-acetone stock solution (2:1 *v*/*v*) containing a test compound. Three chemicals, fluorine analogs I, ME, and FME, were tested in Field Trial 1 while four chemicals, I, ME, FME, and DMP were tested in Field Trial 2. Each wick was treated with 250 μl of the stock solution, a volume calculated to deliver ca. 10 mg of a test chemical. After allowing the solvent to evaporate (20–25 min), wicks were enclosed individually in screen-covered plastic baskets (to prevent feeding consumption by oriental fruit fly males). By using metal clips, baskets that contained wicks were hung inside Jackson traps. Each Jackson trap had a sticky basal insert and two 2.5-cm dog collar strips (Bansect® flea and tick collar for dogs, ®ConAgra Pet Products, Richmond, VA, USA) containing a knock down toxicant (15% Naled by weight; ~0.38 g/strip). Bioassays with releases of 10–11-day old laboratory-reared oriental fruit fly adults were conducted in a macadamia (*Macadamia integrifolia* Maiden and Betche) orchard in the vicinity of Hilo, Hawaii. A low-density population of wild oriental fruit flies subsisting on wild hosts inside and outside this orchard occurred naturally. The experimental design was randomized complete block with six (Field Trial 1) or five

(Field Trial 2) replications. The interblock distance was 10 m, with treatments in each block placed 8 m apart. Approximately 6,000 sterile oriental fruit fly males were uniformly released per block at the start (5 Sept., 1995 for Field Trial 1; 1 Nov., 1995 for Field Trial 2) of each of two successive 24-hr periods. After 24 hr, inserts with trapped adults from each trap were recovered, and new inserts were placed in each trap. All traps were gathered and moved to a new trapping grid of exactly the same configuration at least 500 m away (moving the traps to another trapping grid was done to approximate similar, uniform density of adults in the trapping grid for 0–24 and 24–48 hr). After 48 hr, wicks and inserts were recovered from each trap and immediately brought back to the laboratory. The total number of trapped oriental fruit fly males was determined for each retrieved insert.

Weathering of Wicks and Residue Analyses At the time of the initial wick treatment for Field Trial 2, five treated wicks of each treatment (time 0 wicks) were placed in individual glass vials, sealed with Teflon tape, and frozen. Concurrent with the distribution of treatments in Field Trial 2 (described above), the same number of additional traps of each treatment were emplaced in a randomized complete block wick weathering grid. Wicks recovered from these grids after 24 hr, together with time 0 wicks and wicks collected after 48 hr from the trap catch grid, were used to estimate the amount of compound that had volatilized from the wicks during 0–24 hr and 24–48 hr of Field Trial 2. As with wicks used in the bioassays, weathering wicks were enclosed in screen-covered baskets that were hung inside Jackson traps. Following retrieval at 24 and 48 hr, wicks were placed individually in 25-ml glass vials, sealed with Teflon tape, and shipped to Beltsville, MD, USA, for residual analyses. Gas chromatography-quality acetone was added to each vial (15 ml), vials were stoppered, and wicks were allowed to steep overnight at 25°C. A predetermined amount of an internal standard, 1,2-dimethoxy-4-ethylbenzene (synthesized following Khrimian et al. 1993) was added to each vial, and the extracts were analyzed by gas chromatography.

Data Analysis Mean data from the metabolism study (Lab Trial 1) were analyzed using PROC GLM followed by a Tukey's HSD test for mean separation. Significant differences were determined at the $P<0.05$ level. Analysis was run on SAS version 8.2 (SAS Institute 1990). Mean data from the feeding study were analyzed with a two-way ANOVA. These analyses were conducted by using STATISTICA (Statsoft 2001). Trap catch results from the field bioassays were square root transformed ($\sqrt{[x+0.5]}$; Sokal and Rohlf 1981) and then subjected to ANOVA with Tukey's HSD used for means separation (SAS Institute 2002). Treatment volatilization was analyzed by ANOVA for the 0–24-hr and 24–48-hr periods, with Tukey's HSD used for means separation (SAS Institute 2002).

Results

Syntheses of Ring-fluorinated Analog I and Metabolite V We straightforwardly synthesized the targeted fluorinated benzene I (Scheme 1, panel A) from 1-chloromethyl-2-fluoro-4,5-dimethoxybenzene by using a coupling proce-

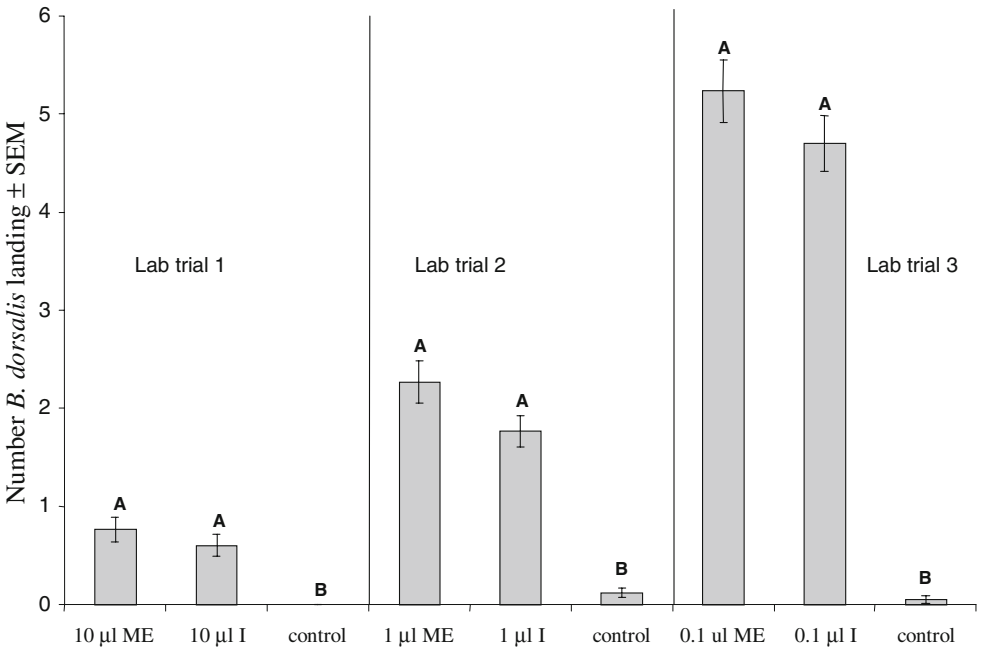


Fig. 1 Landing and feeding of *B. dorsalis* males in a cage experiments with ME and fluorine analog I. Ten males were offered two concentrations of both attractants in five replicates. A two-way ANOVA showed a significant effect of dose ($df=2.24$; $F=76.6$, $p<0.001$) but no differences between treatments within trials, ME and I ($df=1.24$; $F=1.91$; $p=0.18$). Treatment dose was nonsignificant ($df=2.24$; $F=0.16$, $p=0.85$). *Means followed by the same letter* are not significantly different. (Statsoft Inc, 2001)

dure developed earlier for alkyl-substituted analogs of methyl eugenol (Khrimian et al. 1993). Fluorinated benzene I was converted to V with a two-step procedure depicted in Scheme 1, panel A. First, compound I was demethylated with boron trichloride in methylene chloride (Dean et al. 1966) to give a 57:43 mixture of two phenols, baseline separated by GC on a DB-5 column but not by TLC. Thus, the prospect of isolating the individual phenols was uncertain, and their structural assignment presented a certain challenge. Fortuitously, signals from the aromatic protons of the two isomeric phenols were clearly separated in the ^{1}H NMR spectrum of the mixture recorded at 500 MHz, which allowed us to apply a nuclear Overhauser effect (NOE) for their assignments. A NOE difference spectrum obtained by irradiating CH_3O resonance (at about the same frequency for both isomeric phenols) showed an enhancement of two signals at δ 6.57 (d, J=10.6 Hz) and 6.61 (d, J=6.9 Hz). Based on the literature evidence of larger proton-fluorine coupling constant in the *ortho* position ($^3J_{HF}$) compared to that of in the *meta* position ($^4J_{HF}$), and the actual values of these interactions (Silverstein et al. 1980), we assigned the first doublet (of higher intensity) to the proton on C-3 of phenol II and the second to the proton on C-3 of phenol III. Conversely, the signals at δ 6.64 (d, J=10.6 Hz) and 6.71 (d, J=6.9 Hz) were assigned to protons on C-6 of phenols III and II, respectively. Thus, phenol III, needed for the completion of the synthesis of the metabolite V, was a minor component in the mixture. In the last step, phenols II and III were oxidized with selenium dioxide in an aqueous dioxane (Pan et al. 1980) to give a mixture of diols, from which pure IV and V were isolated by flash chromatography. The NOE difference technique described above was used again for structural assignments. In the case of V, irradiation of CH_3O led to the enhancement of the doublet at δ 7.04 ($^4J_{HF}$=7.5 Hz) from the proton on C-3, positioned *meta* to the fluorine atom, whereas in diol IV a NOE effect from CH_3O resonance occurred on the proton in the *ortho* position to fluorine (δ 6.49 d, $^3J_{HF}$=11.5 Hz). *Trans*-configuration of the double bonds in both IV and V was evident from $^3J_{HH}$=16.0 Hz and concurrent with the chemistry of SeO_2 oxidation of 3-phenylpropenes (Pan et al. 1980). Synthetic diol V, based on a GC retention time and mass-spectrum, matched the compound found in rectal glands of oriental fruit fly males fed with I. It was also used as a standard for quantitative analysis of gland extracts.

Feeding and Metabolism In all three experiments (Fig. 1) conducted with different doses, there was no statistically significant difference between fluorine analog I and ME in

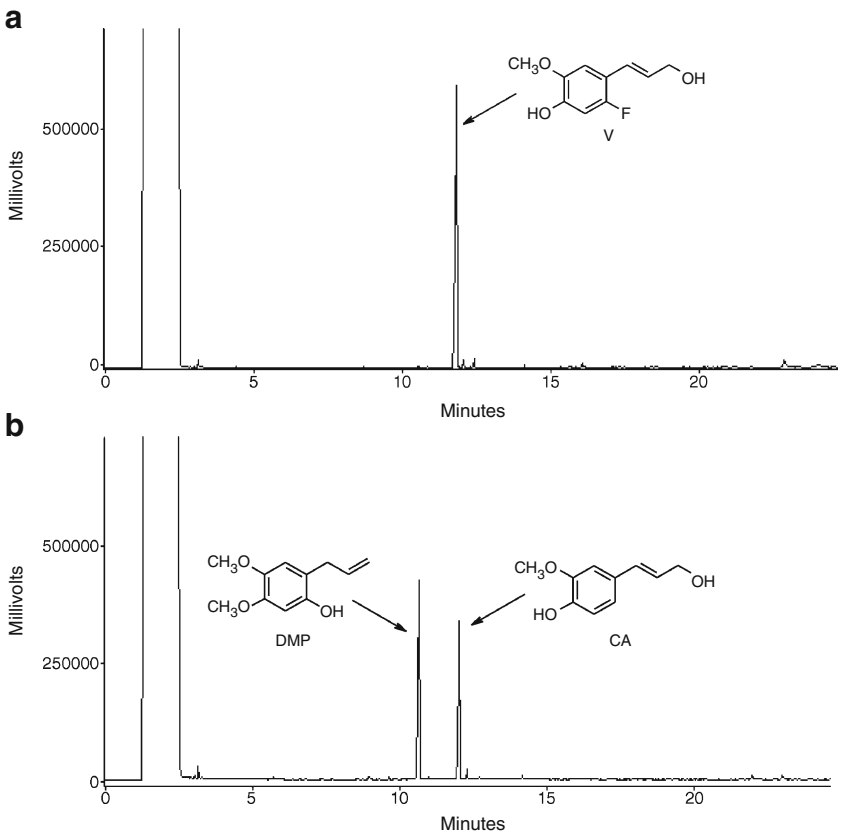

Fig. 2 Gas chromatograms (*HP-5, FID*) of gland extracts of individual oriental fruit fly males fed with: **A** fluorine analog I (Table 1, species # 3), and **B** methyl eugenol (Table 1, species # 1)

male *B. dorsalis* landing and feeding on the source (F=1.91; P=0.18). However, there was a difference between doses (df=2.24; F=76.6, P<0.001), with the most landings recorded in Lab Trial 3 (0.1 μl, ~5 landings in average out of 10). The least number of landings were observed in Lab Trial 1 (10 μl, <1 landing), and Lab Trial 2 (1.0 μl) was in the intermediate position (~2 landings). No fly landings were observed in the control cage in Lab Trial 1, and landings in control cages in Lab Trial 2 and 3 were less than in cages containing I and ME (F=76.6; P<0.001). Flies fed with compound I did not suffer significantly higher levels of mortality than those fed with ME. No mortalities were observed after 24 and 48 hr in low-dose Lab Trials 2 and 3 with either treatment. In Lab Trial 1, two flies fed with compound I were dead after 24 hr and total of five flies were dead after 48 hr. In the same high-dose experiment, the numbers of dead flies fed with ME after 24 and 48 hr were five and eight, respectively.

Results of chemical analyses of rectal glands and remaining body parts of ten flies from Lab Trial 1 are presented (Fig. 2, Table 1). A representative gas-chromatogram of a gland extract of an individual *B. dorsalis* male fed with I (Fig. 2, panel A) reveals essentially a single compound that matches the synthetic diol V by retention time and mass-spectrum. As expected, the flies fed with ME produced the well-described metabolites, coniferyl alcohol and 4,5-dimethoxy-2-(2-propenyl)phenol (Fig. 2, panel B). Unmetabolized test chemicals were not found in rectal glands but were present in the extracts of fly remains after dissection. No phenylpropanoids were found in the control flies. As shown in Table 1, total intake of test materials by ten flies offered 10 μl of each I or ME were similar: 1208 (650 +558) μg for compound I and 1509 (137+1372) μg for ME. However, a remarkable difference between the treatments was observed in the amounts of metabolites relative to intakes. At this feeding level, *B. dorsalis* males were able to metabolize, after 18 hr, on average ~64% of the fluorine analog I and only ~27% of ME (~16% of the ME intake was converted to CA). It appears, however, that at a lower consumption level (20–40 μg) flies can almost completely metabolize both compounds (Table 1, rows 7, 8 for I, and row 3 for ME).

Field Bioassay Trap capture of males from field bioassays are presented in Fig. 3 (Field Trial 1) and Fig. 4 (Field Trial 2). There were differences in trap captures by treatment in Field Trial 1 at both 24 hr (F=23.7, df=2, 15, P<0.001) and at 48 hr (F=22.2, df=2, 15, P<0.001); and in Field Trial 2 at both 24 hr (F=14.5, df=3, 16, P<0.001) and at 48 hr (F=41.5, df=3, 16, P<0.001). In Field Trial 1, at both 24 and 48 hr, there was no significant difference in captures between traps baited with ME and traps baited with FME. However, catches at traps baited with I were statistically less than at traps baited with either ME or FME. In Field Trial 2, at both 24 and 48 hr, there was again no significant difference in catches between traps baited with ME or with FME. Captures at traps baited with I were significantly less than at traps baited with methyl eugenol (but not FME) at 24 hr and were significantly less than at traps baited with either ME or FME at 48 hr. Catches at traps baited with

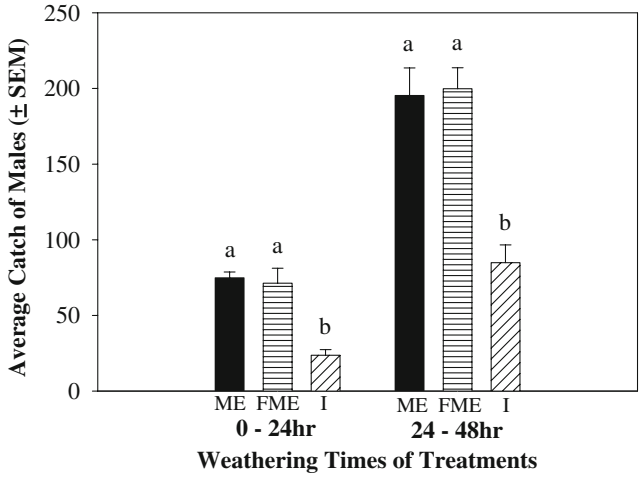

Fig. 3 Field Bioassay 1, September 1995. Average catch of male oriental fruit fly adults 0–24 and 24–48 h after field deployment of Jackson traps baited with methyl eugenol (*ME*), ring-fluorinated analog (*I*), and side-chain fluorinated analog (*FME*). *Columns within the same time period having the same letter* are not significantly different at the α=0.05 level

DMP were significantly less than catches with all other treatments at both 24 and 48 hr. There were differences in volatilization by treatment in both the 0–24 hr (F=289.4, df=3, 16, P<0.001) and 24–48 hr (F=116.8, df=3, 16, P<0.001) time periods. Release rates of I and ME from cotton wicks were not significantly different at either 24 or 48 hr, whereas release of FME was significantly lower than those of I and ME at both 24 and 48 hr. Finally, the release of DMP was significantly lower than those of any other treatments at both time intervals.

Discussion

Our laboratory studies demonstrated that the ring-fluorinated analog I is perceived by *B. dorsalis* males as an analog of natural phenylpropanoid methyl eugenol. In close range experiments, flies were attracted to and fed on analog I and methyl eugenol at similar rates. At the highest concentration of test materials in cage experiments, flies rarely touched the source. This behavior is similar to insect avoidance, observed under field conditions, of traps baited with a large amount of a pheromone (Zhang and Amalin 2005). Although few flies directly contacted the filter papers, they still absorbed appreciable amounts of vaporized I and ME. Consumption of fluorine analog I did not result in an increased mortality in *B. dorsalis* males compared to flies fed with ME, which has been reported to cause death in the oriental fruit fly when ingested in large amounts (Steiner 1952). Thus, the fitness of *B. dorsalis* males evidently is linked (among other factors) to their ability to efficiently metabolize phenylpropanoids.

Introduction of the fluorine atom on the aromatic ring of ME at a position which undergoes enzymatic hydroxylation (Scheme 1, panel B) resulted in a complete blocking of this biotransformation pathway. While this was not particularly surprising, the observation that blocking one pathway did not result in an overall slowing of metabolism was interesting. Oriental fruit fly males demonstrated a remarkable ability to shift metabolism of the consumed fluorine analog I through a side-chain hydroxylation pathway (Smith et al. 2002), leading to the fluorinated (*E*)-coniferyl alcohol V. In fact, the rate of metabolism of I was about twice that of ME under our experimental conditions (Table 1, last columns). Our previous studies with FME (Scheme 1, panel B) showed that the fluorine introduction slowed overall metabolism and specifically impeded formation of CA (Khrimian et al. 2006). Thus, the incorporation of the fluorine atom at the aromatic ring and at the

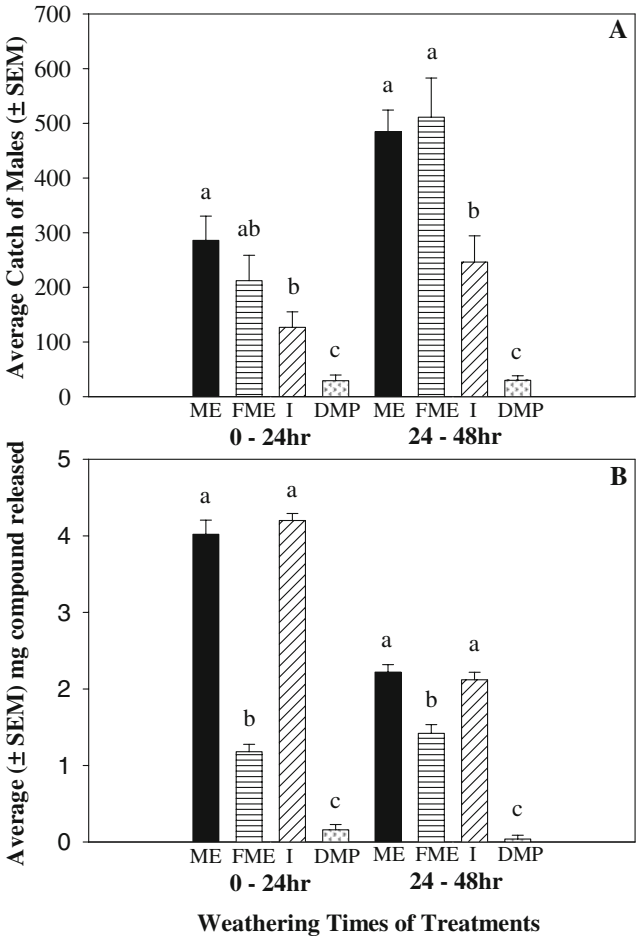

Fig. 4 Field Bioassay 2, November 1995. Average catch of male oriental fruit fly adults (**A**) and release of test chemicals (**B**) 0–24 and 24–48 h after field deployment of Jackson traps baited with methyl eugenol (*ME*), ring-fluorinated analog (*I*), side-chain fluorinated analog (*FME*), and dimethoxyphenol (*DMP*). *Columns within the same time period having the same letter* are not significantly different at the α=0.05 level

terminal carbon atom of the double bond of ME had opposite effects on the side-chain metabolic hydroxylation.

Although *B. dorsalis* males were attracted strongly to and fed on fluorine analog I in a cage experiment, field attractiveness of male oriental fruit fly to I was markedly lower than to ME. In both field bioassays, traps baited with compound I captured less than 50% of flies caught in traps baited with ME. Release rates of fluorine analog I and ME were similar (Fig. 4), so trap catches provide a valid comparison of field attractiveness of these two compounds. In contrast, the evaporation of DMP from a cotton wick was substantially (~30 times) lower compared to I, making a linkage of trap catches to attractiveness tenuous. Even at a much slower release rate, however, the average number of males caught in traps baited with DMP was only 4–8 times lower than that in analog I-baited traps. Thus, a fluorine substitution for the hydroxy group at the aromatic ring of DMP increased the volatility but did not improve attractiveness to *B. dorsalis*. Metcalf et al. (1975, 1981) studied molecular parameters of attractants and olfaction in *B. dorsalis* that involved a number of substituted *ortho*-dimethoxybenzenes. Several postulates were derived from those studies: (a) unshared electron pairs of the *ortho*-dimethoxy groups were essential for receptor depolarization, yet the methoxy group in *para* position to allyl group of ME seemed to be of a primary importance; (b) electron-donating side-chain groups produced stronger attractants than those withdrawing electrons.

We did not find in the literature any activity correlations with the substitution pattern of DMP and fluorine analog I, but because the fluorine atom is isosteric with hydrogen (and being such has been widely pursued for altering the properties of biologically active substances), it seems that it is the electronic factor of fluorine substitution that is responsible for a reduced attractiveness of analog I compared to ME. A strong electronegative effect of the fluorine atom should decrease electron density about the CH_3O groups in analog I but would primarily affect the methoxy group in the *para*-position to F (*meta* to allyl group), thus diminishing but not abolishing the attraction to *B. dorsalis*. In any case, a moderate field attractiveness combined with the propensity to side-chain metabolic oxidation (linked to a carcinogenicity) makes the analog I an unlikely replacement for ME as an attractant for the oriental fruit fly. We, however, were pleased with the performance of FME in two short field bioassays, which confirmed our earlier findings (Khrimian et al. 1994; Liquido et al. 1998) that this compound is not only equally attractive to *B. dorsalis* but also has added value as a more persistent lure.

In summary, we developed a ring-fluorinated analog of methyl eugenol that is highly attractive to the oriental fruit fly males in a laboratory cage experiment but is only moderately active in the field. This new fluorine analog is metabolized faster than methyl eugenol after being consumed by *B. dorsalis* males and produces almost exclusively fluorinated (*E*)-coniferyl alcohol.

Acknowledgments We thank Peter Bianchi, Taina Burke, Sarah Marshall, Rachel Morton, Charmaine Sylva, and Judy Yoshimoto for technical assistance with the field bioassays.

NMR Metabolomics of Thrips (*Frankliniella occidentalis*) Resistance in *Senecio* Hybrids

Kirsten A. Leiss · Young H. Choi · Ibrahim B. Abdel-Farid · Robert Verpoorte · Peter G. L. Klinkhamer

Received: 28 May 2008 / Revised: 25 November 2008 / Accepted: 19 December 2008 / Published online: 24 January 2009

Abstract Western flower thrips (*Frankliniella occidentalis*) has become a key insect pest of agricultural and horticultural crops worldwide. Little is known about host plant resistance to thrips. In this study, we investigated thrips resistance in F_2 hybrids of *Senecio jacobaea* and *Senecio aquaticus*. We identified thrips-resistant hybrids applying three different bioassays. Subsequently, we compared the metabolomic profiles of these hybrids applying nuclear magnetic resonance spectroscopy (NMR). The new developments of NMR facilitate a wide range coverage of the metabolome. This makes NMR especially suitable if there is no a priori knowledge of the compounds related to herbivore resistance and allows a holistic approach analyzing different chemical compounds simultaneously. We show that the metabolomes of thrips-resistant and -susceptible hybrids differed considerably. Thrips-resistant hybrids contained higher amounts of the pyrrolizidine alkaloids (PA), jacobine, and jaconine, especially in younger leaves. Also, a flavanoid, kaempferol glucoside, accumulated in the resistant plants. Both PAs and kaempferol are known for their inhibitory effect on herbivores. In resistant and susceptible F_2 hybrids, young leaves showed less thrips damage than old leaves. Consistent with the optimal plant defense theory, young leaves contained increased levels of primary metabolites such as sucrose, raffinose, and stachyose, but also accumulated jacaranone as a secondary plant defense compound. Our results prove NMR as a promising tool to identify different metabolites involved in herbivore resistance. It constitutes a significant advance in the study of plant–insect relationships, providing key information on the implementation of herbivore resistance breeding strategies in plants.

Keywords *Senecio* · Thrips (*Frankliniella occidentalis*) · NMR metabolomics · Pyrrolizidine alkaloids · Flavanoids · Jacaranone

Introduction

Over the last few decades, western flower thrips (*Frankliniella occidentalis*) has spread worldwide to become a key insect pest of agricultural and horticultural crops (Kirk and Terry 2003). There has been a massive increase in the international movement of plant material leading to the accidental transport of thrips. Thrips have many traits that predispose them to be successful invaders: small size, affinity for enclosed spaces, and high reproductive potential (Lawton and Brown 1986). In addition, western flower thrips is highly polyphagous infesting a wide range of about 200 wild and cultivated host species (Mantel and van de Vrie 1988). Thrips have piercing-sucking mouthparts, which enable them to feed on different types of plant cells (Hunter and Ullman

1989). Feeding on actively growing tissue leads to distortion, reduction in plant growth, and eventually yields loss, while feeding on expanded tissue results in the characteristic silver leaf scars, which affect product appearance and reduce market quality (de Jager et al. 1995a). Western flower thrips causes indirect damage as the primary vector of tospoviruses (Maris et al. 2002).

Occurrence of host plant resistance to thrips is sparse and little is known about the underlying mechanisms. Morphological plant traits were not involved in resistance to western flower thrips in chrysanthemum (de Jager et al. 1995a). Instead, resistance was influenced by the chemical composition of host plants (de Jager et al. 1995b, 1996). Thrips preferentially feed on the older chrysanthemum leaves (de Jager et al. 1995a). No specific metabolites directly related to the resistance have yet been identified. Lately, a novel isobutylamide was suggested to be associated with host plant resistance to western flower thrips in chrysanthemum (Tsao et al. 2005). Overexpression of cysteine protease inhibitors in transgenic chrysanthemum was not related to thrips resistance (Annadana et al. 2002). In contrast, transgenic potato multidomain cysteine protease inhibitors were affiliated with thrips resistance (Outchkourov et al. 2004a, b).

Plant hybridization may drive the evolution of novel secondary plant metabolites (Rieseberg and Ellstrand 1993; Orians 2000) leading to enhanced resistance to herbivores and pathogens (Fritz 1999). In an earlier study of our group the metabolic profiles of *Senecio jacobaea* and *Senecio aquaticus* and their F_1 hybrids revealed multiple putative defense compounds (Kirk et al. 2005). This plant material was used to establish a F_2 hybrid generation to obtain independent segregation of defense characters. In this study, we investigated the differences in metabolites among thrips-resistant and -susceptible hybrids of the F_2 hybrid generation of *S. jacobaea* and *S. aquaticus*. We especially looked at metabolic differences among young and old leaves.

Plants produce a wide array of metabolites which play a significant role in their interactions with other organisms. The study of chemical host plant resistance has so far, for technical reasons, been limited to the identification of single compounds. However, as is generally the case in biological processes, it is very likely that not one but several compounds are involved in plant resistance, the identity of which is, a priori, unknown. One way to get round this problem is to use an analytical tool which allows the simultaneous detection of a wide range of metabolites, providing an instantaneous image of the metabolome of the resistant plant.

Nuclear magnetic resonance spectroscopy (NMR)-based metabolomics may be one of the methods which most fit this description, allowing the simultaneous detection of many different compounds, thus contributing to a deeper holistic approach (Verpoorte et al. 2007). So far, in the field of plant metabolomics, NMR has been successfully applied to study the effect of pathogen infection on host plants such as phytoplasmas in *Catharanthus roseus* (Choi et al. 2004) and tobacco mosaic virus in *Nicotiana tabacum* (Choi et al. 2006). The effect of herbivores on plants has been studied with NMR spectroscopy for chewing insects such as the caterpillars *Plutella xylostella* and *Spodoptora exigua* in *Brassica rapa* (Widarto et al. 2006).

We present the results of three different bioassays intended to identify thrips-resistant *Senecio* F_2 hybrids on which NMR-based metabolomics was subsequently applied to study the metabolic basis of resistance. NMR data were analyzed using diverse multivariate data analyses for comparison. Classification of data was validated by permutation tests.

Methods and Materials

Plant Materials Cuttings of 33 different F_2 hybrids of *S. jacobaea* and *S. aquaticus* derived from tissue culture were transplanted into 11 cm diameter pots filled with equal parts of dune sand and potting soil in spring 2005. Three clonal replicates of each F_2 hybrid were transferred to a growth chamber (18:6 L/D, 20:15°C) and grown for 6 weeks. To obtain resistant and susceptible genotypes, we subjected the 33 F_2 hybrids to a thrips choice bioassay. We then selected the F_2 hybrids with the lowest and the highest thrips damage and confirmed their difference in resistance conducting a non-choice and a dual leaf disc bioassay. Plants of the susceptible and resistant F_2 hybrids for the bioassays as well as for NMR metabolomics were generated from tissue culture and grown as described above.

Thrips Bioassays—Whole Plant Choice Bioassay to Identify the Most Resistant and the Most Susceptible F_2 Hybrids In a fully randomized design, three clonal replicates of each F_2 hybrid were subjected to a thrips infestation with *F. occidentalis*, reared on chrysanthemum. According to van de Wetering et al. (1998), there are no significant differences in leaf area damaged between adult non-viruliferous male and female *F. occidentalis* of different ages. Per plant, ten adult thrips, two males and eight females, were used and left on the plants for 3 weeks. Thrips were directly released into the growth chamber by positioning a vial with 4×10 thrips on plant height in the center of four plants. Thrips does not cause growth damage in *Senecio*; therefore, only silver damage, expressed as the leaf area damaged in square millimeter, was visually scored per plant. The average of the three replicates was used to analyze differences in silver damage among the F_2 hybrids using a one-way

ANOVA (Sokal and Rohlf 1995). Differences in silver damage among the third youngest and the third oldest leaf were tested with a paired samples *t*-test (Sokal and Rohlf 1995). Data of thrips damage were not normally distributed and were, therefore, ln-transformed. To confirm the identification of thrips-resistant F_2 hybrids, we applied two more bioassays: the whole plant non-choice and the leaf disc dual choice bioassay.

Whole Plant Non-choice Bioassay One plant of each of the four most resistant and the four most susceptible F_2 hybrids were placed into individual thrips proof cages, consisting of plastic cylinders (80 cm height, 20 cm diameter), closed on both ends with displaceable rings of thrips proof gauze. The plants were arranged in a fully randomized design and to each cage ten adult western flower thrips were added and left for 3 weeks. Thereafter, silver damage, expressed as the leaf area damaged in square millimeter, was visually scored for each leaf. In order to investigate morphological and mechanical resistance, leaf age, hairiness, toughness, and dry weight were measured. Leaf age was counted in days, twice a week. Leaf hairiness and toughness were measured at the time of scoring for thrips damage. At two locations of each leaf the hairs per square centimeter were counted and the toughness was measured with a penetrometer. Averages per leaf were calculated. Plants were dried for 3 days in an oven at 50°C whereupon plant dry weight was measured for each leaf. Silver damage was not normally distributed. Silver damage per leaf was added up to analyze differences among resistant and susceptible hybrid plants with a Kruskall–Wallis test (Sokal and Rohlf 1995). To study the relationship between silver damage per leaf and leaf age, hairiness, toughness, and dry weight, correlations, using the non-parametric Kendall's tau *b* correlation coefficient, were applied (Sokal and Rohlf 1995).

Leaf Disc Dual Choice Bioassay Dual choice assays were used to test the thrips preference of pairs of leaf discs from resistant versus susceptible F_2 hybrids as described by Outchkourov et al. (2004a). Leaf discs deriving from three different hybrid pairs were used. Pairs were matched at random. For each pair, the bioassay was repeated five times. Two leaf discs of 21 mm in diameter were punched from mature leaves at a similar position and placed on a thin layer of 1% water agar in a 9-cm diameter Petri dish. A piece of filter paper (5×5 mm) was positioned between the discs. Ten female *F. occidentalis*, which had been starved for one night, were shortly anesthetized with CO_2, and placed on the filter paper. The Petri dishes were sealed with parafilm and placed in a growth chamber (16:8, L/D, 20:20°C). The number of thrips on each leaf disc was recorded at different time points after the start of the experiment up to 26 h. As the repeated measurements were not independent, multiple time point measurements were averaged into an early (0–6 h after starting the experiment) and a late period (21–26 h after starting the experiment). Data were analyzed with a one-sided Wilcoxon signed rank test on the absolute differences of average numbers of thrips on the susceptible and resistant leaf discs (Sokal and Rohlf 1995).

Metabolomics—Extraction of Plant Material Ten plants each of the four most resistant and the four most susceptible F_2 hybrids, as identified in the three thrips bioassays, were used for NMR metabolomics. Plants were grown under standard conditions, described above, for 6 weeks. Each third leaf from above (young leaf) and each third leaf from below (old leaf) were taken for analysis. Each sample was ground under liquid N_2 and freeze-dried. Freeze-dried plant material (50 mg) was transferred to a 2-ml microtube. Following a previous method (Choi et al. 2006), 1.5 ml of a mixture of KH_2PO_4 buffer (pH 6.0) in D_2O and methanol-d_4 (1:1) was used for the extraction of the plant samples.

For pyrrolizidine alkaloids extraction, a previously reported method was modified (Pieters et al. 1989). For this extraction, the ten replicates of each of the four thrips-resistant and -susceptible hybrids were combined. Three replicates of this combination were analyzed for each hybrid. An amount of 100 mg dried leaves was ultrasonicated for 30 min with dilute H_2SO_4 (0.5 M). After filtration, the filtrate was adjusted pH 9–10 with 10% ammonium water and fractionated two times with $CHCl_3$. The combined $CHCl_3$ fractions were dried with Na_2SO_4 and evaporated to dryness. The dried extracts were dissolved in $CDCl_3$ containing 0.447 μmol/ml of hexamethyldisiloxane (HMDSO).

NMR Analysis NMR spectra were recorded at 25°C on a 600 MHz Bruker DMX-600 spectrometer (Bruker, Karlsruhe, Germany) operating at a proton NMR frequency of 600.13 MHz. MeOH-d_4 was used as the internal lock. Each ^{1}H-NMR spectrum consisted of 256 scans requiring 8 min and 30 s acquisition time with the following parameters: 0.12 Hz/point, pulse width (PW) of 30 (11.3 μs), and relaxation delay (RD) of 2 s. A pre-saturation sequence was used to suppress the residual H_2O signal with low power selective irradiation at the H_2O frequency during the recycle delay. Free induction decay was Fourier-transformed with a line broadening factor of 0.3 Hz. The resulting spectra were manually phased and baseline corrected, and calibrated to the internal standard trimethyl silyl propionic acid sodium salt (TMSP) at 0.0 ppm using XWIN NMR (version 3.5, Bruker). The parameters of 2D NMR experiments such as J-resolved, COSY, HSQC, and HMBC were the same as those of our previous reports (Choi et al. 2006).

Table 1 Silver damage (square millimeter) of the four most resistant and the four most susceptible *Senecio* F_2 hybrid lines

	Hybrid	Silver damage
Resistant	217	8±5
	115	12±5
	119	16±6
	206	37±18
Susceptible	108	275±80
	204	288±132
	221	307±60
	114	349±167

Data are means and standard errors of three replicates

For 1D and 2D NMR analysis of pyrrolizidine alkaloids, the same parameters were used without pre-saturation of water. Calibration was performed on residual $CDCl_3$ signal at δ 7.26.

Data Analysis Spectral intensities of ^{1}H-NMR spectra were scaled to the intensity of the internal standard (TMSP, 0.05% *w*/*v*) and reduced to integrated regions of equal width (0.04) corresponding to the region of δ 0.4–δ 10.0. The regions of δ 4.8–δ 4.9 and δ 3.28–δ 3.40 were excluded from the analysis because of the residual signal of water and MeOH. Principal component analysis (PCA) and partial least square-discrimination analysis (PLS-DA) were performed with the SIMCA-P software (v. 11.0, Umetrics, Umeå, Sweden). The scaling method for PCA was Pareto and for PLS-DA the unit-variance method. ANOVA, hierarchical clustering analysis, and *t* tests were performed by MultiExperiment Viewer (v. 4.0; Saeed et al. 2003). PLS-DA models were validated by using the permutation method through 20 applications, which is a default validation tool in the software package applied (SIMCA-P). Variance (R^2) and cross-validated variance values (predictive ability of the model, Q^2) of PLS-DA using five components were calculated.

Results

Whole Plant Choice Bioassay The F_2 hybrids differed significantly in thrips damage (ANOVA, F=3.17, df=32, P<0.001). In the most resistant hybrid, an 8 mm^2 leaf area was affected by silver damage compared to 349 mm^2 in the most susceptible hybrid. Young leaves had significantly less silver damage compared to mature leaves (*t*-test, t=5.87, df=32, P<0.001). Of these 33 F_2 hybrids, the four most resistant and the four most susceptible ones (Table 1) were chosen for further testing in a whole plant non-choice and a leaf disc dual choice bioassay.

Whole Plant Non-choice Bioassay The four thrips-resistant F_2 hybrids, described in the above whole plant choice bioassay, had significantly (Kruskall–Wallis test, χ^2=5.33, df=1, P=0.029) less thrips damage per plant (94 mm^2) compared to the four susceptible hybrids (368 mm^2). The results of the plant choice and the non-choice bioassay were thus completely compatible. Resistant F_2 hybrids had on average 15 and susceptible ones 13 leaves, respectively (*t*-test, t=1.55, df=6, P=0.17). Silver damage was for all four resistant and all four susceptible F_2 hybrids significantly

Table 2 Correlations (Kendall's tau) between silver damage (square millimeter) per leaf and morphological (leaf age) as well as mechanical (toughness, hairiness, and dry weight) resistance factors of four thrips-resistant and four thrips-susceptible *Senecio* F_2 hybrid lines

	Hybrid	Leaf age	Toughness	Hairiness	Dry weight
Resistant	217	0.734	−0.354	−0.743	0.559
	N=13	P=0.003**	P=0.167	P=0.003**	P=0.022*
	115	0.716	0.279	−0.750	0.716

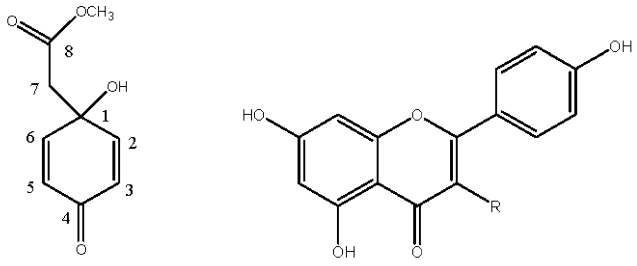
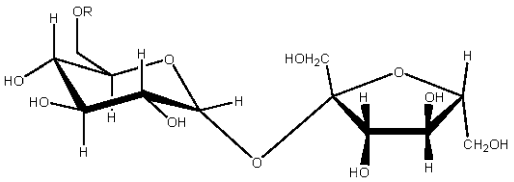
positively correlated to leaf age (Table 2). None of the morphological and mechanical factors was related to thrips resistance.

Leaf Disc Dual Choice Bioassay In all three pairs of leaf discs of resistant versus susceptible F_2 hybrids, the number of thrips in the early (0–6 h after start of the experiment) period was significantly lower on the leaf disc of the resistant hybrid (Wilcoxon signed rank test, P=0.028; 0.042; 0.018). For two out of the three leaf pairs, this was true for the late period (21–26 h after starting the experiment) as well (Wilcoxon signed rank test, P=0.043; 0.046; 0.715).

Application of the 1D and 2D NMR Spectroscopy for Elucidation of Metabolites The ^{1}H-NMR spectra of plant extracts always give congested signals. In our previous work, 2D J-resolved spectra were successfully applied to overcome the signal overlapping (Choi et al. 2006). Indeed, by applying J-resolved spectra in this study, the signals of flavanoid glycosides, raffinose, stachyose, and sucrose were clearly resolved (Fig. 1a). In the aromatic region, two isomeric phenylpropanoids, 3-*O*-caffeoyl quinic acid and 5-*O*-caffeoyl quinic acid (chlorogenic acid), as well as feruloyl quinic acid, were identified using 2D NMR spectra including COSY, HSQC, and HMBC. These metabolites were confirmed by comparison with reference compounds and reported data (Choi et al. 2006). In addition to phenylpropanoids, there were two major signals at δ 6.25 and δ 7.15, which correlated with each other in the COSY spectrum. Using HMBC and HSQC–TOCSY spectra, those two signals at δ 6.25 and δ 7.15 were assigned as H-2 and H-6, and H-3 and H-5 of jacaranone, respectively (Fig. 1b, c). The characteristic chemical shifts and the structures of the metabolites of *Senecio* F_2 hybrid leaves detected in the ^{1}H-NMR spectra are shown in Fig. 2 and Table S1.

Principal Component Analysis and Partial Least Square Regression-Discriminant Analysis of ^{1}H-NMR Data Among multivariate data analyses, the most common unsupervised method is principal component analysis (PCA). Thus, as the first step of multivariate data analysis PCA was performed on the bucketed dataset to discriminate the samples. For the dataset obtained from the ^{1}H-NMR analysis, a 22-component model explained 98.5% of the variance, with the first two components explaining 70.7%. However, as shown in Fig. 3a, there was no separation among resistant and susceptible *Senecio* F_2 hybrids. Instead, developmental stage was a key separating factor that led to a clear discrimination among young and old leaves. According to the loading plot, the levels of citric and malic acid were higher in old leaves whereas those of





R = H, sucrose

Fig. 2 Chemical structures of some metabolites identified in the NMR spectrum of *Senecio* F_2 hybrids

sucrose, raffinose, and stachyose as well as jacaranone accumulated more in young leaves (Fig. 3b).

In the dataset employed, the difference among resistant and susceptible leaves seemed to be smaller than among developmental stages. The large metabolic difference in developmental stages compared to the difference among resistant and susceptible plants was confirmed by hierarchical analysis (HCA, Fig. S1). Prior to HCA, the statistically significant signals were selected applying ANOVA. From 239 ^{1}H-NMR signals 161 were significant (P<0.05). The ANOVA was based on one factor containing four groups: resistant young leaves, susceptible young leaves, resistant old leaves, and susceptible old leaves. Two additional sets of t tests, one for young and one for old leaves comparing resistant and susceptible plants were conducted (P<0.05). These tests showed that for young leaves, 56 signals out of 239, and for old leaves, 25 signals out of 239, were related to thrips resistance. In HCA, the leaves of the same age were closely clustered but the metabolic resemblance within resistant or susceptible plants was scattered. In order to distinguish resistant leaves from susceptible ones, analysis was extended to PLS-DA, a supervised multivariate data technique.

PLS-DA uses a discrete class matrix (0 and 1) as an additional matrix. In contrast to PCA that only uses the information of the metabolomic matrix, PLS-DA also takes into account the resistance matrix. The separation of PLS-DA is achieved by the covariance of the two datasets. When PLS-DA was applied the separation of thrips-resistant and -susceptible plants considerably improved (Fig. 4a). Validation of the PLS-DA model by permutation tests resulted in a variance R^2 of 0.74 and a cross-validated variance Q^2 of 0.61. All Q^2 values of the permuted Y vectors were lower than the original ones and the regression of Q^2 lines intersected at below zero (Fig. 4c, d).

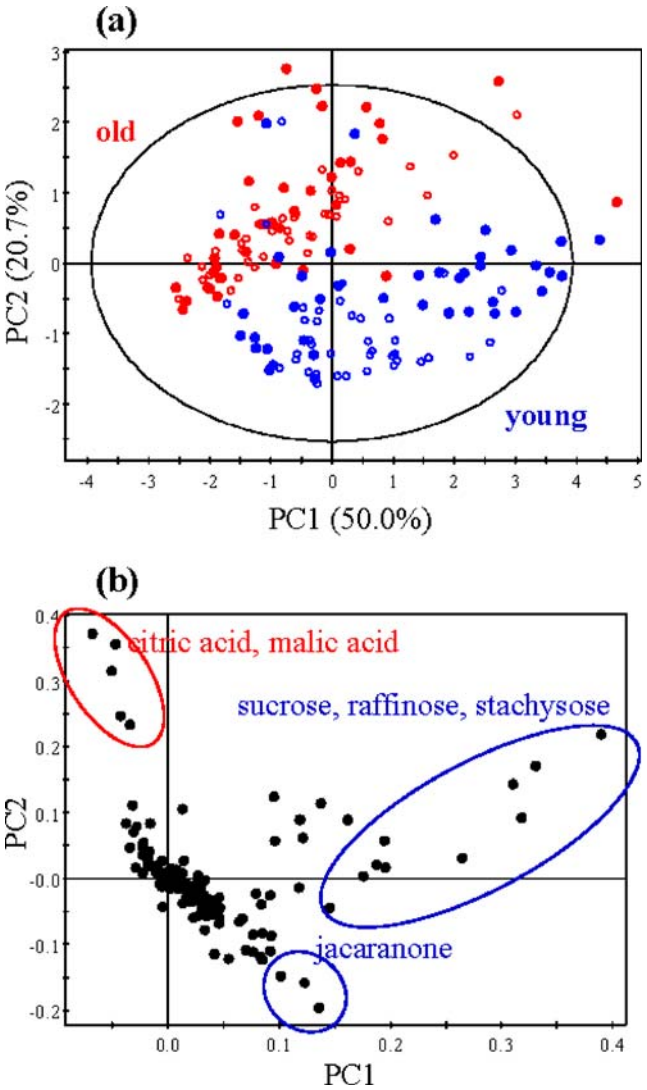

Fig. 3 Score (**a**) and loading plot (**b**) of principal component analysis based on ^{1}H-NMR spectra of *Senecio* F_2 hybrid genotypes. *Filled red circle*, old leaves of thrips-resistant genotypes (n=40); *filled blue circle*, young leaves thrips-resistant genotypes (n=40); *empty red circle*, old leaves of thrips-susceptible genotypes (n=40); *empty blue circle*, young leaves of thrips-susceptible genotypes (n=40). The *ellipse* represents the Hotelling T2 with 95% confidence in score plots

Irrespective of leaf age, resistant and susceptible F_2 hybrids were clearly clustered. The loading plot indicated that methyl signals of pyrrolizidine alkaloids (PAs) at δ 1.12 (H-19), δ 1.24 (H-21), and δ 1.36 (H-18; Pieters et al. 1989) were distinguishably higher in the resistant plants. Also, the anomeric proton of kaempferol glucoside at δ 5.50–δ 5.60 together with H-6 and H-8 of the glycoside around at δ 6.30 increased in the *Senecio* F_2 hybrids resistant to thrips (Fig. 4b). Only total PA could be determined by the methyl signals detected. Therefore, more evidence for the PAs, e.g., the signals of pyrrolizidine moiety, was required to identify specific compounds. The characteristic H-2 signal of the pyrrolizidine moiety is generally detected around at δ 6.0–δ 6.2. However, this region overlaps with the signals of jacaranone and chlorogenic acid. For the confirmation and quantification of individual PAs, we applied an acid–base extraction followed by NMR metabolomic profiling. For the acid–base extraction the ten replicates of each of the four thrips-resistant and -susceptible hybrids were mixed and three replicates of these used for the analysis.

Elucidation and Quantitation of Pyrrolizidine Alkaloids Using Acid–Base Extraction Followed by Quantitative ^{1}H-NMR The ^{1}H-NMR spectrum of the alkaloid extract, obtained by the acid–base extraction, showed two major PAs, jacobine and jaconine N-oxide. The N-oxides were confirmed by the unambiguous down field shifts (0.4–0.7 ppm) of the signals of H-3, H-5, and H-8 adjacent to the N-oxide functional group when compared with the free bases (Pieters et al. 1989; Witte et al. 1992). For the final structure confirmation, COSY, TOCSY, HSQC, and HMBC spectra were employed (Fig. S2).

The ^{1}H-NMR signals are always proportional to the molar concentrations. In the crude alkaloid extract, H-2 was detected in a non-crowded region, separated from other ones. These signals were used for quantification comparing them to the intensity of the internal standard, HMDSO (0.48 μmol/ml). As confirmed by the PLS-DA results, young and old leaves of thrips-resistant F_2 hybrids accumulated more PA N-oxide (Fig. 5). Old (t-test, df=22, P<0.001) and young (t-test, df=22, P<0.001) leaves of thrips-resistant hybrids contained significantly more jacobine N-oxide. Younger leaves of thrips-resistant hybrids also accumulated significantly more jaconine N-oxide (t-test, df=22, P=0.005). The difference of jaconine N-oxide in old leaves was close to significance (t-test, df=22, P=0.008). Young leaves in both resistant and susceptible hybrids accumulated more jacobine N-oxide (resistant hybrids: t-test, df=22, P<0.001; susceptible hybrids: t-test, df=22, P<0.001) and more jaconine N-oxide (resistant hybrids: t-test, df=22, P<0.001; susceptible hybrids: t-test, df=22, P<0.001).

Discussion

NMR proved to be successful in the simultaneous detection of different metabolites potentially involved in thrips resistance. The metabolomic profiles of thrips-resistant and -susceptible hybrids differed considerably. Thrips-resistant F_2 hybrids showed significantly higher amounts of the PAs, jaconine and jacobine N-oxide, and a flavanoid, kaempferol glucoside.

PAs have been well studied in the *Senecio* species and are regarded as constitutive defense against generalist

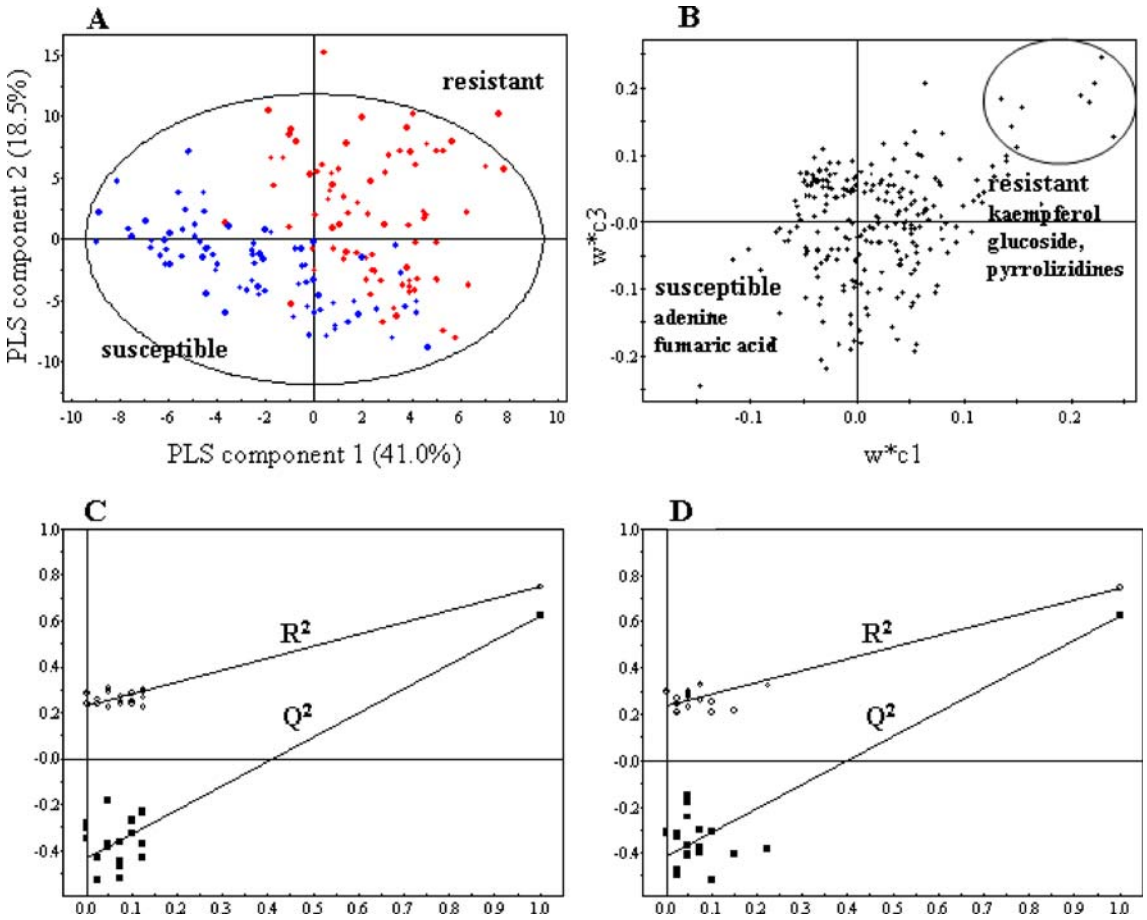

Fig. 4 Score (**a**), loading plot (**b**), and permutation validation plot of resistant (**c**) and susceptible group (**d**) of partial least square regression-discriminant analysis based on ^{1}H-NMR spectra of *Senecio* F_2 hybrid genotypes. *Filled red circle*, old and young leaves of thrips-resistant genotypes (n=80); *filled blue circle*, old and young leaves thrips-susceptible genotypes (n=80). The *ellipse* represents the Hotelling T2 with 95% confidence in score plots

herbivores. They deter chewing insects such as caterpillars (Bentley et al. 1984; van Dam et al. 1995), locusts (Macel et al. 2005), and beetles (Hägele and Rowell-Rahier 2000). PAs also have a negative effect on sucking insects such as aphids (Vrieling et al. 1991; Macel et al. 2005). So far, no inhibitory influences of PAs on thrips have been detected. Plants of *S. jacobaea* with and without *Haplothrips senecionis*, a specialist on *Senecio* species, did not yield any difference in total PA concentration (Vrieling et al. 1991). In vitro tests studying the effect of different PAs on the development of first instar larvae of the generalist *F. occidentalis* showed a significantly reduced larval survival at 10 × plant concentrations but not at 1 × plant concentrations (Macel et al. 2005). Neither jaconine nor jacobine were included in these in vitro tests. However, a significantly lower amount of thrips damage on the jacobine compared to the erucifoline chemotype of *S. jacobaea* (Macel 2003) confirms our results. Furthermore, PAs are stored in the cell vacuoles (Ehmke et al. 1988), which are ingested by the thrips being cell feeders. Both PAs, jaconine and jacobine, were present in higher concentrations in young leaves compared to the old ones. Concurrently, young leaves showed significantly less thrips damage. This is in accordance with the finding that in *Senecio* species, young leaves have relatively high concentrations of PAs compared to old leaves (Hartmann and Zimmer 1986; de Boer 1999). The more valuable plant parts are better defended against generalist herbivores than less important organs as is predicted by the optimal defense theory (Zangerl and Bazzaz 1992; van Dam et al. 1996).

Flavanoids are generally involved in plant resistance to herbivores (Bennett and Wallsgrove 1994). The presence of kaempferol in the *Senecio* F_2 hybrids confirms the findings of Kirk et al. (2005) reporting kaempferol for the first time in *Senecio* species. Kaempferol is known to convey a deterrent effect on generalist caterpillars (Onyilagha et al. 2004). Aphid resistant cow pea lines contained significantly higher amounts of flavanoids, including kaempferol, compared to

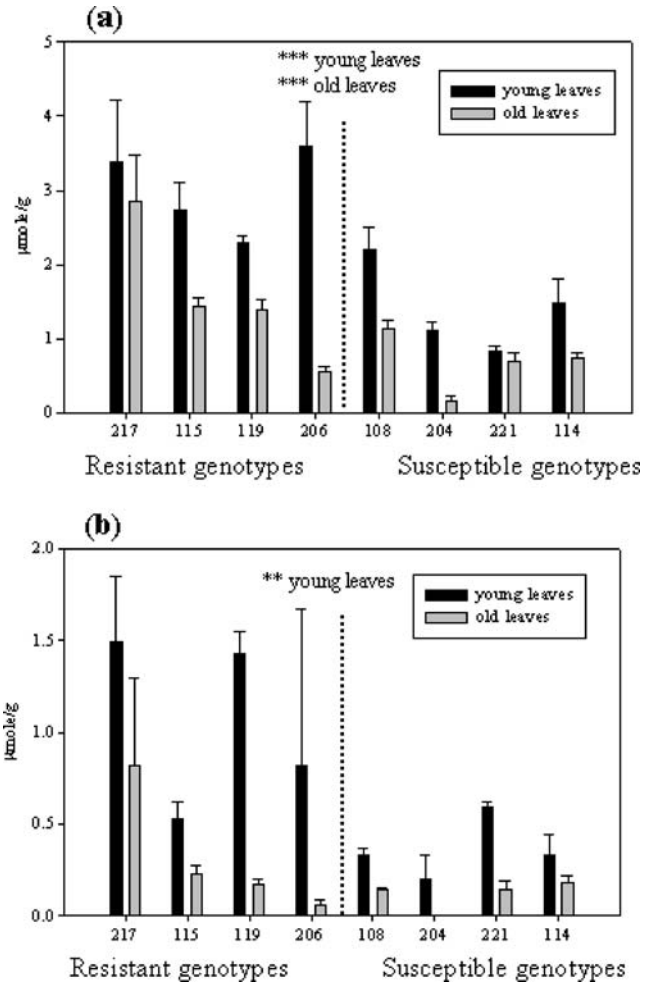

Fig. 5 Yields (mol/g) of jacobine N-oxide (**a**) and jaconine N-oxide (**b**) for young and old leaves of thrips-resistant and -susceptible *Senecio* F_2 hybrids obtained by quantitative ^{1}H-NMR analysis. Data are based on the combination of the ten replicates of each of four thrips-resistant and -susceptible hybrids, of which three replicates were analyzed per hybrid. Means and their standard deviation are presented. Data were analyzed by *t* tests. Significant differences in PAs between thrips-resistant and -susceptible hybrids are designated by ***$P<0.001$ and **$P<0.01$. Young leaves contained significantly higher amounts of both PAs in resistant and susceptible hybrids (all *t* tests $df=22$, $P<0.001$)

susceptible lines (Lattanzio et al. 2000). Recently, kaempferol has been identified to confer resistance to onion thrips (*Thrips palmi*) in golden rod (*Solidago altissima*; Wu et al. 2007). Like western flower thrips, onion thrips is a polyphagous worldwide pest, which causes significant economic losses (Kirk and Terry 2003).

Besides the PAs and flavanoids, specifically involved in thrips resistance, three other phenolic compounds involved in plant–herbivore interactions, 3-*O*-caffeoyl acid and 5-*O*-caffeoyl quinic acid (chlorogenic acid, CGA), and feruloyl quinic acid (FQA), were identified to be present in the metabolome of the *Senecio* F_2 hybrids. CGA has been described as an anti-feedant and digestibility reducer in different caterpillar species (Mallikarjuna et al. 2004; Johnson and Felton 2001; Simmonds and Stevenson 2001) and sucking insects such as aphids (Miles and Oertli 1993). FQA has been implicated in the resistance of sucking herbivores such as cereal aphids (Cabrera et al. 1995; Havlickova et al. 1996) and cereal midges (Ding et al. 2000; Abdel-Aal et al. 2001). FQA is a precursor of lignin conferring rigidity to cell walls (Bennett and Wallsgrove 1994). As such, it is linked to the resistance against stem borers in maize (Santiago et al. 2006; Mao et al. 2007) and cotton (Wang et al. 2006).

As expected, the young leaves of the *Senecio* F_2 hybrids, being photosynthetically more active, contained more primary metabolites such as sugars, compared to older leaves. They are, therefore, more attractive to herbivores and pathogens. To defend these valuable plant parts, they do contain more secondary metabolites related to plant defense. Next to the increased amount of PAs in the young leaves of the thrips-resistant *Senecio* F_2 hybrids, young leaves in general contained more jacaranone. Analogues of jacaranone are known to occur in different *Senecio* species (Lajide et al. 1996; Xu et al. 2003; Kirk et al. 2005). They have shown insecticidal activity against houseflies (Xu et al. 2003) and inhibited growth in the generalist herbivore *Spodoptera litturalis* (Lajide et al. 1996).

Our approach to apply NMR as a technique to identify metabolites differing between thrips-resistant and -susceptible plants proved to be very successful. NMR indicated three different metabolites as potential candidates for thrips resistance. While the PAs due their toxic effect on mammals (Cheeke 1988) may be interesting in developing thrips resistance in ornamentals, kaempferol and jacaranone are very promising candidates to develop host plant resistance to thrips in crops. Not only do they inhibit thrips but they also produce positive effects on human health. Jacaranone has been investigated as a potential anti-cancer agent (Loizzo et al. 2007). Flavanoids in general caused a significant extension of life span in cancer-susceptible mice (Butelli et al. 2008), while kaempferol in particular demonstrated a cytotoxic activity on human cancer cell lines (Daniela et al. 2007; Li et al. 2007). A tomato with increased amounts of flavanoids, whereby kaempferol glycoside accounted for 60% of this increase, has already been engineered (Le Gall et al. 2003).

Applying NMR to the study of herbivore resistance constitutes a significant advance in the study of plant–insect relationships, providing key information on the implementation of herbivore resistance breeding strategies in plants.

Acknowledgments We thank Victoria Twist for critically reviewing the English of the manuscript. The research was supported by SenterNovem, an agency of the Dutch Ministry of Economic affairs (grant no. ISH5078).

Abstract The raspberry cane midge, *Resseliella theobaldi*, is a widespread pest of cultivated red raspberry in Europe. Pheromone-baited traps could provide a much-needed, accurate means to monitor the pest. Volatiles collected separately from virgin female and male midges were analyzed by gas chromatography (GC) coupled to mass spectrometry (MS) to reveal four female-specific components. In analyses by GC coupled to electroantennographic (EAG) recording from the antennae of a male midge, at least three of these components elicited responses. Based on its GC retention indices and mass spectrum, we propose that the major component is 2-acetoxy-5-undecanone and confirm this by synthesis of the racemic compound in seven steps and 63% yield from 4-pentenoic acid. The three minor components were each present at approximately 30% of the major component and were identified as 2-undecanone, (*S*)-2-acetoxyundecane, and (*S*)-2-undecanol by comparison of GC retention times and mass spectra with those of synthetic standards. GC analyses of the female-produced volatiles on an enantioselective column showed that only one enantiomer of 2-acetoxy-5-undecanone was present, and this was found to be the *S*-enantiomer by hydrolytic kinetic resolution of an epoxide intermediate in the synthesis and also by enantioselective hydrolysis of the racemic acetate with a lipase enzyme. The two enantiomers were also separated by high-performance liquid chromatography on an enantioselective column for field tests. In two field trapping tests, (*S*)-2-acetoxy-5-undecanone was highly attractive to male *R. theobaldi*; the *R*-enantiomer was not attractive. The racemic compound was just as attractive as the *S*-enantiomer, and addition of the three minor components in racemic form at two different loads did not affect catches. The pheromone could be dispensed from both rubber septa and polyethylene vials for at least 1 month under field conditions, but the former was preferred as it gave more uniform release. 2-Acetoxy-5-undecanone belongs to a new group of pheromone structures in the Cecidomyiidae, most others being mono- or diesters.

Keywords 2-Acetoxyundecane · 2-Acetoxy-5-undecanone · Cecidomyiidae · Enantioselectivity · Pheromone trap · Raspberry cane midge · *Resseliella theobaldi* · Sex pheromone · 2-Undecanol · 2-Undecanone

Introduction

The raspberry cane midge, *Resseliella theobaldi* Barnes (Diptera: Cecidomyiidae), is a widespread pest of cultivated

red raspberry, *Rubus idaeus*, and occasionally loganberry, in Europe, both in field-grown crops and under protected cultivation. *R. theobaldi* overwinters as larvae in small earthen cocoons at the base of the plants. After pupation in spring, adults emerge and oviposit in natural splits or wounds in the bark of primocanes. Larvae feed on the newly exposed periderm layer causing penetrating lesions. These feeding sites are colonized by a range of pathogenic fungi, such as the cane blight fungus, *Leptosphaeria coniothyrium*, causing a disease complex known as "midge blight." Attacked canes may snap off, grow poorly, or die. Yield losses frequently exceed 50%, often making the crop unprofitable to harvest. Depending upon latitude, there are three or four generations per year (Cross et al. 2009a).

The pest is currently controlled by scheduled spraying of broad-spectrum insecticides. In the UK, the organophosphate (OP) insecticide chlorpyrifos is applied to control the first generation of larvae in the spring. This also prevents significant damage by subsequent generations, although population increase almost certainly occurs. In other countries where OP insecticides are not available for use on raspberry, synthetic pyrethroid insecticides are used, but these are less effective. Timing of sprays is critical. Traditionally, a spray was applied in late April or early May when the primocane was 20–30 cm high, with a second spray about 2 weeks later. More recently, a temperature-based forecasting model was developed by Gordon et al. (1989) for predicting spring oviposition by *R. theobaldi* to facilitate timing of sprays. The forecast is believed to be accurate to within 5 days, but it nevertheless results in recurring use of insecticides in most commercial plantations. A more locally based, specific monitoring system such as that based on pheromone traps would be preferable.

Many midge species use sex pheromones for mate location (Harris and Foster 1999). The chemical structures of the components of the female-produced sex pheromones have been identified from several species including Hessian fly, *Mayetolia destructor* (Foster et al. 1991), pea midge, *Contarinia pisi* (Hillbur et al. 1999, 2000, 2001), orange wheat blossom midge, *Sitodiplosis mosellana* (Gries et al. 2000), Douglas-fir cone gall midge, *Contarinia oregonensis* (Gries et al. 2002), aphidophagous gall midge, *Aphidoletes aphidimyza* (Choi et al. 2004), and swede midge, *Contarinia nasturtii* (Hillbur et al. 2005). The chemical structures of these pheromones are related to each other, having carbon chains with an odd number of carbon atoms and one or two ester functionalities.

The existence of a female sex pheromone in *R. theobaldi* has not been demonstrated, but it was assumed that one existed by analogy with other species. As part of a program to develop new tools for monitoring and control of this pest, we report identification of components of the female sex pheromone, and we demonstrate that the major component is attractive to conspecific males in the field. This pheromone component is a ketoester and provides a second example among midge pheromone components of this novel type of structure, first discovered by us in the apple leaf curling midge, *Dasineura mali* (Cross and Hall 2005, 2009; Hall et al. 2005; Suckling et al. 2007; Cross et al. 2009b).

Methods and Materials

Collection and Rearing of Midges Mature larvae of *R. theobaldi* were collected on 27 and 28 July 2004 from two infested commercial raspberry plantations of the primocane varieties Autumn Bliss and Joan Squire at Beech Farm, West Peckham, Kent, UK. Sections of primocane of up to 25-cm length with splits and characteristic patch lesions caused by the midge were cut from the canes and stored in ventilated plastic boxes (19×10.6×7.5 cm) with a layer of moistened paper towel in the base. The boxes each contained about 20 cane sections and were kept on the laboratory bench. Many of the mature larvae exited the lesions underneath the epidermis seeking sites to pupate on the side, the lid, or in the base of the boxes, or they pupated in situ. Over a period of 16 days, these mature larvae were collected and transferred individually to small transparent closed Perspex tubes (autoanalyzer cups with caps, internal volume 2 ml; Sarstedt, Leicester, UK). A small piece of moist filter paper was included in each tube to prevent desiccation. The tubes were held on plastic trays in incubators at approximately 18°C and 16:8 h L/D. Adult midges started to emerge on 16 August, and the newly emerged, virgin adults were collected, sexed, and transferred to the entrainment apparatus each day.

Collection of Volatiles from Virgin Midges Volatiles were collected from virgin female and virgin male *R. theobaldi* by placing the two sexes in separate, specially constructed glass containers with a glass frit at the upwind end (15×5 cm; Hamilton Laboratory Glass, Margate, Kent, UK). Air was drawn with a vacuum pump (M361C, Charles Austen Pump, Byfleet, Surrey, UK) into each vessel through a filter of activated charcoal (20×2 cm; 10–18 mesh, Fisher Chemicals, UK) and out through a collection filter consisting of a Pasteur pipette (4 mm i.d.) containing Porapak Q (200 mg, 50–80 mesh; Waters Associates, Milford, MA, USA) held between plugs of silanized glass wool. The Porapak was Soxhlet extracted with chloroform for 8 h, and the filters were washed with dichloromethane immediately prior to use. A low airflow rate (200 ml/min) was used during volatile collection to minimize desiccation stress to the insects. Calling females stood motionless on the sides of the glass vessel with their ovipositors extended to expose

the pheromone gland at the base from which the pheromone was emitted. Male midges flew around erratically. Adult *R. theobaldi* have a short life of only 1–2 days, and dead midges were removed and fresh live ones introduced daily. Porapak filters were changed approximately every week. Over a 3-week period, five collections were made from a total of 987 female midges and five collections from 633 males. Trapped volatiles were eluted with dichloromethane (pesticide grade; 3×0.5 ml), and the resulting solutions were stored at −20°C.

Analysis by Gas Chromatography Gas chromatography (GC) analyses were carried out on a fused-silica capillary column (30 m×0.32 mm i.d.×0.25 μm film thickness) coated with a polar stationary phase (Wax10; Supelco, Gillingham, Dorset, UK). Injection was splitless (220°C), detection was by flame ionization detection (FID; 250°C), and carrier gas was helium (2.4 ml/min). The oven temperature was programmed from 60°C for 2 min, then at 10°C/min to 250°C. Retention times are expressed as retention indices relative to the retention times of normal, saturated hydrocarbons.

Enantioselective GC analyses were carried out on a capillary column (25 mm×0.32 mm i.d.×0.25 μm film thickness) coated with a cyclodextrin stationary phase (Chirasil-DEX CB; Varian, Oxford, UK). Injection was splitless (220°C), detection was by FID (250°C), and carrier gas was helium (2.4 ml/min). For analysis of crude volatile collections, the oven temperature was programmed at 60°C for 2 min, then at 6°C/min to 200°C. For analysis of synthetic compounds, split injection was used, and the temperature program was isothermal (140°C).

Analysis by Gas Chromatography Linked to Mass Spectrometry Gas chromatography-mass spectrometry (GC-MS) analyses were carried out with a Carlo Erba 5130 GC (Thermoelectron, Hemel Hempstead, Hertfordshire, UK) linked directly to an ion trap detector (Finnigan ITD 700; Thermoelectron) operated in electron impact (EI) or chemical ionization with isobutane (CI) modes. The GC column (30 m×0.25 mm i.d.×0.25 μm film thickness) was coated with polar Wax10 (Supelco). The carrier gas was helium (0.5 kg/cm^2), and the oven temperature was programmed from 50°C for 2 min, then at 6°C/min to 250°C.

GC-MS analyses were also carried out on an HP 6890 GC (Agilent) coupled directly to an HP 5973 MSD (Agilent) operated in EI mode. The GC column (30 m× 0.25 mm i.d.×0.25 μm film thickness) was coated with nonpolar SPB1 (Supelco). The carrier gas was helium (1 ml/min), and the oven temperature was programmed from 60°C for 2 min, then at 6°C/min to 250°C.

Analysis by Gas Chromatography Linked to Electroantennography Gas chromatography-electroantennography (GC-EAG) analyses were carried out with an HP 6890 GC (Agilent) fitted with capillary GC columns (30 mm× 0.32 mm i.d.×0.25 μm film thickness) coated with polar (Wax10; Supelco) and nonpolar (SPB1; Supelco) phases. Injection was splitless (220°C), and detection was by FID (250°C). The oven temperature was programmed from 50°C for 2 min, then at 10°C/min to 250°C. The GC column effluents were combined and then split (1:1) between the FID and a silanized glass T-piece in the column oven. Nitrogen (200 ml/min) was blown continuously over the EAG preparation, and every 17 s, this was diverted through the T-piece for 3 s, blowing the contents over the EAG preparation, as described by Cork et al. (1990).

Following experience from working with other midge species, the EAG preparation was set up by suspending the whole insect between glass electrodes containing electrolyte (0.1 M potassium chloride with 10% polyvinylpyrrolidone added to reduce evaporation). The ends of both antennae were inserted into the recording electrode and the body into the reference electrode. The electrodes were inserted onto silver/silver chloride electrodes held in micromanipulators on the portable EAG device developed by Syntech (INR-02; Syntech, Hilversum, The Netherlands). Both FID and EAG signals were collected and analyzed with EZChrom software (Elite v3.0; Scientific Software, Pleasanton, CA, USA).

Synthetic Chemicals 2-Undecanone and racemic 2-undecanol were purchased from Sigma-Aldrich (Gillingham, Dorset, UK). Petroleum ether (b.p. 40–60°C; Fisher Scientific, Loughboroough, Leicestershire, UK) was used frequently as a solvent during chemical synthesis (see below). Other chemicals were synthesized. Nuclear magnetic resonance (NMR) spectra were recorded in $CDCl_3$ on a JEOL EX270 machine at 270 MHz for ^{1}H and 67.8 MHz for ^{13}C. Infrared (IR) spectra were recorded as thin films with a Perkin Elmer 298 grating spectrophotometer (Perkin Elmer, Beaconsfield, Buckinghamshire, UK).

2-Acetoxyundecane Acetylation of 2-undecanol with acetic anhydride in pyridine gave 2-acetoxyundecane (96%; b.p. 90°C/0.04 mmHg). Racemic 2-acetoxy-5-undecanone (I) was synthesized (Fig. 1) from a series of four key intermediates listed as follows.

1-Undecen-5-one Lithium hydroxide (7.2 g, 0.3 mol) was added to a stirred solution of 4-pentenoic acid (30 g, 0.3 mol; Sigma-Aldrich) in methanol (300 ml). There was a slight exotherm, and the solid dissolved after 30 min. After stirring for 2 h, the solvent was removed on a rotary evaporator and then a high vacuum pump to give the lithium salt as a white solid (32.0 g, 0.3 mol). Hexyl lithium was prepared from hexyl bromide (82.5 g, 0.5 mol) and lithium (7.7 g, 1.1 mol) in dry ether (300 ml) under

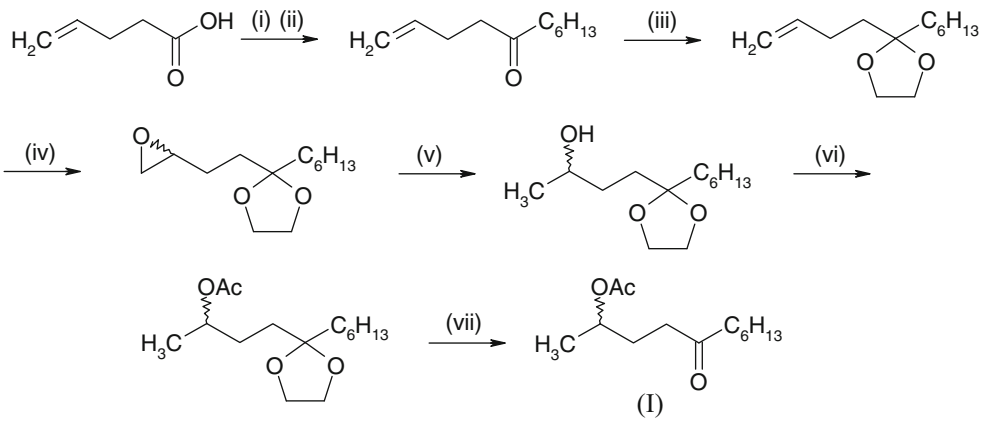

Fig. 1 Synthesis of 2-acetoxy-5-undecanone; reagents: *(i)* lithium hydroxide/methanol (100%), *(ii)* hexyl lithium/ether (83%), *(iii)* ethane diol/*p*TSA/toluene; *(iv)* 3-chloroperbenzoic acid/CH_2Cl_2; *(v)* lithium aluminum hydride/ether; *(vi)* acetic anhydride/pyridine, *(vii)* acetone/*p*TSA (76%)

nitrogen. Double titration gave a concentration of 1.1 M. The hexyl lithium (300 ml, 0.330 mol) was added dropwise to a mechanically stirred suspension of the lithium 4-pentenoate in dry ether (200 ml) under nitrogen and cooled in an ice bath. After stirring at room temperature for 48 h, the contents were poured onto ice and saturated ammonium chloride solution. The aqueous layer was extracted 2× with ether, and the extracts were washed with saturated ammonium chloride solution, dried with magnesium sulfate, and filtered through a pad of silica gel (20 g). The solvent was evaporated under reduced pressure to give the crude product (62 g), which was distilled to give a main fraction of 1-undecen-5-one (42 g, 0.25 mol, 83%) boiling at 116°C/20 mmHg. IR (film): ν 1,710 cm^{-1}; MS: *m/z* (%) 169 (10), 113 (65), 98 (18), 85(30), 83 (35), 70 (10), 55 (98), 43 (100), 41 (60).

1,2-Epoxy-5-(1,2-ethylenedioxy)undecane Ethylene glycol (37.2 g, 0.6 mol) was added to a solution of 1-undecen-5-one (42 g, 0.25 mol) in toluene (350 ml) and *p*-toluenesulfonic acid (100 mg) added as catalyst. The mixture was refluxed under a Dean and Stark head for 8 h, cooled, washed 2× with saturated aqueous sodium bicarbonate solution, and the solvent was removed on a rotary evaporator to give the ketal (65 g). MS: *m/z* (%) 157 (77), 127 (100), 99 (7), 83 (6), 55 (30), 43 (25). This was dissolved in dry dichloromethane (300 ml), and 3-chloroperbenzoic cid (77%, 57.5 g, 0.25 mol) was added portionwise to the stirred solution with ice cooling. After stirring at room temperature overnight, most of the dichloromethane was removed on a rotary evaporator, and the residue was taken up in 20% diethyl ether in petroleum ether (b.p. 40–60°C; 250 ml). After washing 2× with 2 N aqueous potassium hydroxide and drying over anhydrous potassium carbonate, the solution was filtered through silica gel (10 g), and solvents were removed on a rotary evaporator to give the epoxyketal product (58 g, 0.25 mol). ^{1}H NMR: δ 0.87 (t, *J*=6.7 Hz, 3H), 1.2–1.4 (m, 8H), 1.55–1.7 (m, 4H), 1.7–1.85 (m, 2H), 2.48 (dd, *J*=5.1, 2.6 Hz, 1H), 2.75 (dd, *J*=5.1, 4.0 Hz, 1H), 2.93 (m, 1H), 3.93 (s, 4H); ^{13}C NMR: δ 14.09, 22.60, 23.82, 26.95, 29.58, 31.81, 33.04, 37.33, 47.20, 52.26, 64.99, 111.30; MS: *m/z* (%) 157 (100), 143 (88), 125 (5), 113 (18), 99 (72), 86 (10), 69 (8), 55 (35), 43 (55), 41 (50).

2-Hydroxy-5-(1,2-ethylenedioxy)undecane 1,2-Epoxy-5-(1,2-ethylenedioxy)-undecane (58 g 0.25 mole) was dissolved in diethyl ether (400 ml) and stirred in an ice bath under nitrogen, while lithium aluminum hydride (6 g, 0.15 mol) was added portionwise. After stirring for an additional 2 h at room temperature, the reaction was carefully quenched with water (6 ml), 2 N aqueous potassium hydroxide (6 ml), and water (18 ml). Solids were filtered off, the solution dried with magnesium sulfate and filtered, and solvents were removed on a rotary evaporator to give the ketal alcohol (55.6 g). IR (film): ν 3,400 cm^{-1}; ^{1}H NMR: δ 0.88 (t, *J*=6.7 Hz), 1.19 (d, *J*=6.2 Hz, 3H), 1.25–1.4 (m, 6H), 1.45–1.65 (m, 4H), 1.65–1.85 (m, 4H), 2.14 (br d, *J*=3.7 Hz, 1H). 3.79 (br s, 1H), 3.95 (s, 4H); ^{13}C NMR: δ 14.09, 22.60, 23.53, 23.85, 29.58, 31.83, 33.23, 33.28, 37.11, 64.86, 64.89, 68.13, 111.80; MS: *m/z* (%) 168 (10), 157 (100), 145 (85), 127 (29), 111 (46), 98 (23), 83 (35), 69 (10), 55 (69), 43 (54), 41 (23).

2-Acetoxy-5-(1,2-ethylenedioxy)undecane The crude product (55.6 g) was reacted with pyridine (40 ml) and acetic anhydride (40 ml) overnight at room temperature. The mixture was dissolved in 20% diethyl ether in petroleum ether (250 ml), washed 2× with saturated sodium chloride solution and finally with a little dilute aqueous hydrochloric acid until washings were acidic. The solution was dried with magnesium sulfate, and solvents were removed on a rotary evaporator to give the acetoxyketal (66.5 g). IR (film): ν 1,725 cm^{-1}; ^{1}H NMR: δ 0.88 (t, *J*=6.7 Hz, 3H), 1.21 (d, *J*=6.2 Hz, 3H), 1.25–1.4 (m, 8H), 1.5–1.7 (m, 6H), 2.03 (s, 3H), 3.92 (s, 4H), 4.89 (hex, *J*=6.6, 1H); ^{13}C NMR: δ 14.09, 20.02, 21.36, 22.60, 23.78, 29.57, 30.15, 31.83, 32.81, 37.27, 64.63, 64.95, 70.98, 111.44, 170.71; MS: *m/z* (%) 212 (2),

167 (55), 157 (100), 127 (54), 113 (5), 99 (10), 87 (25), 83 (20), 69 (4), 55 (20), 43 (46), 41 (10).

2-Acetoxy-5-undecanone (I) The acetoxyketal was dissolved in acetone (300 ml) and stirred with *p*-toluenesulfonic acid (100 mg) for 24 h. Saturated sodium bicarbonate solution (20 ml) was added, and most of the acetone was removed on a rotary evaporator. The residue was taken up in 10% diethyl ether in petroleum ether (250 ml), washed 2× with saturated sodium chloride solution, dried over magnesium sulfate, filtered through silica gel (10 g), and solvents were removed on a rotary evaporator. The residue was distilled under reduced pressure to give a main fraction of the acetoxyketone (I) (43.0 g, 0.19 mol, 76% from 1-undecen-5-one, 63% overall) boiling at 86–90°C/0.03 mmHg). IR (film): ν 1,730, 1,710 cm^{-1}; ^{1}H NMR: δ 0.88 (t, *J*=6.5 Hz, 3H), 1.22 (d, *J*=6.2 Hz, 3H), 1.25–1.35 (m, 6H), 1.5–1.6 (m, 2H), 1.75–1.9 (m, 2H), 2.02 (s, 3H), 2.39 (t, *J*=7.6 Hz, 2H), 2.43 (t, *J*=7.6 Hz, 2H), 4.89 (hex, *J*=6.2 Hz, 1H); ^{13}C NMR: δ 14.03, 20.06, 21.28, 22.49, 23.82, 28.91, 29.73, 31.60, 38.55, 42.92, 70.30, 170.68, 210.19; MS: *m/z* (%) 229 (1), 185 (7), 168 (8), 128 (5), 113 (20), 101 (40), 98 (28), 85 (12), 83 (15), 71 (3), 55 (16), 43 (100), 41 (26).

Enantiomers of 2-Acetoxy-5-undecanone (I) The pure enantiomers were produced by separating the racemic compound by high-performance liquid chromatography (HPLC) on a column with an enantioselective stationary phase; by hydrolytic kinetic resolution of the epoxide intermediate in the synthesis (Tokunaga et al. 1997) (Fig. 2); and by enzymatic resolution.

Separation of Enantiomers of 2-Acetoxy-5-undecanone (I) by High-Performance Liquid Chromatography The racemic material (1 mg in 10 μl of hexane) was separated on a Chiralpak AD column (10×250 mm; Diacel Chemical Industry, Tokyo, Japan) eluted with 2% 2-propanol in hexane (1 ml/min) and monitored with a refractive index detector. The enantiomers eluted at 26.29 and 30.79 min. The separated enantiomers had enantiomeric excess (e.e.) of 96.1% and 98.0%, respectively, by GC analysis (Chirasil-DEX CB column).

Synthesis of Enantiomers of 2-Acetoxy-5-undecanone (*R,R*)-*N,N′*-bis(3,5-di-*tert*-butylsalicylidene)-1,2-cyclohexane-diaminocobalt (20 mg; Jacobsen catalyst; Sigma-Aldrich, Gillingham, Dorset, UK) was dissolved in toluene (200 μl) and acetic acid (35 μl) and stirred in air at room temperature for 1 h. Solvent was removed with a vacuum pump and the residue was taken up in tetrahydrofuran (2 ml). To this was added 1,2-epoxy-5-(1,2-ethylenedioxy)-undecane (0.9 g, 3.9 mM) and water (58 mg, 3.2 mM), and the mixture was stirred at room temperature. The progress of the reaction was monitored by GC (Chirasil-DEX CB column). Neither the enantiomers of the epoxyketal nor those of the 2-hydroxy-5-(1,2-ethylenedioxy)undecane were separated on this column, but those of the corresponding acetate were well separated. Accordingly, aliquots of the reaction mixture had to be worked up, reduced with lithium aluminum hydride, and then acetylated for analysis. After 72 h, the remaining epoxide was essentially one enantiomer, and the reaction was quenched with diethyl ether (10 ml) dried over magnesium sulfate, and solvents were removed on a rotary evaporator. The residue (0.85 g) was chromatographed on silica gel (30 g), and the *R*-epoxide (0.35 g) was eluted with 20% diethyl ether in petroleum ether. The corresponding diol (0.3 g) was eluted with 50% diethyl ether in petroleum ether. The epoxide was reduced with lithium aluminum hydride (38 mg, 1 mM) in diethylether (5 ml) to the alcohol (0.3 g), which was acetylated with acetic anhydride (0.2 ml) in pyridine (0.2 ml). The acetate (0.4 g) was reacted for 24 h with acetone (10 ml) and catalytic *p*-toluenesulfonic acid, and the product was Kugelrohr distilled (110°C/0.04 mmHg) to give the (*S*)-2-acetoxy-5-undecanone (0.19 g, 44%) with e.e. 93.6%. The *R*-enantiomer was prepared similarly by using the *S,S* Jacobsen catalyst and also had an e.e. of 93.6%.

Enzymatic Resolution of 2-Acetoxy-5-undecanone (I) Lipase from *Candida antarctica* on acrylic resin (25 mg; Sigma-Aldrich) was added to racemic 2-acetoxy-5-undecanone (0.456 g, 2 mM) in phosphate buffer (5 ml, pH 7), and the mixture was stirred vigorously at room temperature. Hydrolysis of the *R*-enantiomer was followed by GC analysis (Chirasil-DEX CB column) and essentially stopped after 3 h. The reaction was then extracted 3× with 20% diethyl ether in petroleum ether, the extracts were dried over magnesium sulfate, and solvents were removed on a rotary evaporator. The residue (0.4 g) was separated by flash chromatography on silica gel (20 g) eluted with 10%

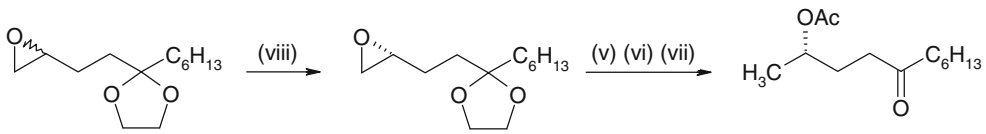

Fig. 2 Synthesis of enantiomers of 2-acetoxy-5-undecanone (*S*-enantiomer shown); reagents *(viii)* (*R*,*R*)-*N*,*N*′-bis(3,5-di-tert-butylsalicylidene)-1,2-cyclohexane-diaminocobalt (Jacobsen's reagent), acetic acid, THF, water, and chromatography, *(v)* lithium aluminum hydride/ether, *(vi)* acetic anhydride/pyridine, *(vii)* acetone/*p*TSA

and 20% diethyl ether in petroleum ether. The acetate fraction was Kugelrohr distilled (110°C/0.03 mmHg) to give the *S*-enantiomer (0.19 g, 83%) with e.e. 95.2%. The alcohol fractions were acetylated with acetic anhydride (0.25 ml) and pyridine (0.25 ml) at room temperature overnight. Aqueous workup and Kugelrohr distillation gave the *R*-acetate (0.17 g, 75%) with e.e. 96.8%.

Enzymatic Resolution of 2-Acetoxyundecane A similar treatment of racemic 2-acetoxyundecane with lipase from *C. antarctica* for 7 h gave (*S*)-2-acetoxyundecane (b.p. 70°C/0.04 mmHg; 86% yield, 97.0% e.e.) and (*R*)-2-undecanol. The latter was acetylated with acetic anhydride and pyridine to give (*R*)-2-acetoxyundecane (b.p. 70°C/0.04 mmHg; 79% yield, 99.8% e.e.).

Field Tests Field trapping tests were carried out in commercial raspberry plantations in Kent, UK. Traps were white delta traps (20×20 cm, Agrisense, Treforest, Pontypridd, UK) suspended 30–50 cm above ground level and at least 10 m apart. Pheromone dispensers were red rubber septa (20×10 mm o.d., International Pheromone Systems, Wirral, UK) or closed polyethylene vials (26×8×1.5 mm thick, Just Plastics, London, UK) impregnated with the pheromone applied in solution in petroleum ether (0.1 ml). The formulation contained 2,6-di-*tert*-butyl-4-methylphenol (BHT, 99%; Sigma-Aldrich) as an antioxidant at 20% relative to the major component.

In a first experiment, traps were baited with racemic 2-acetoxy-5-undecanone (100 μg) alone or with 2-undecanone, racemic 2-undecanol, and racemic 2-acetoxyundecane (30 μg each) in the same dispenser, released from either rubber septa or polyethylene vials. Four treatments and an unbaited control were arranged in a randomized complete block design with ten replicates (blocks). Lures were changed at 1-week intervals, and weekly counts of *R. theobaldi* males caught in each trap were made from 11 May until 7 June 2005. The total count data across 5 weeks were analyzed by using a $\log_{10}(x+1)$ transformation, the residual plot from which indicated improved and adequate variance homogeneity compared to the analysis of the untransformed data (ANOVA; Genstat for Windows version 10, VSN International, Hemel Hempstead, UK). The treatment structure used in the analysis was a control plus two dispensers × two blends factorial, and variance ratio tests were carried out on the resultant single *df* contrasts.

A second experiment was conducted in September 2005 to test the attractiveness of the individual enantiomers of 2-acetoxy-5-undecanone, separated by HPLC, in comparison with racemic 2-acetoxy-5-undecanone and blends of the latter with 2-undecanone, racemic 2-undecanol, and racemic 2-acetoxyundecane. Dispensers were rubber septa loaded with 0.01 or 0.1 μg of the major component. Eight treatments and an unbaited control were arranged in a randomized complete block design with six replicates (blocks). Weekly counts were made of the numbers of *R. theobaldi* males caught in each trap over a 3-week period until the flight period ended. The total counts were analyzed after $\log_{10}(x+1)$ transformation, which again produced adequate residual plots to indicate that the assumption of variance homogeneity was achieved. Two types of ANOVA were done. The first was an ANOVA with no partitioning of treatment factors followed by a Duncan's multiple range test to separate means (α=0.05). In the second, treatment factors for control and treated, racemic and enantiomer, loading, presence or absence of minor component were included in the analysis, which subdivided the 8 *df* for treatments into single *df*s to assess the various effects explicitly. Following this analysis, means were separated by a least significant difference test (α=0.05).

Measurement of Release Rates from Dispensers Two of each rubber septa and polyethylene vial dispensers loaded with the four-component blend containing 2-acetoxy-5-undecanone (100 μg), and 2-undecanone, 2-acetoxyundecane, and 2-undecanol (30 μg each) were maintained in a laboratory wind tunnel under constant conditions of 27°C and 8 km/h air speed. At intervals, volatiles released from the individual dispensers during 2–4 h were collected on Porapak Q resin, as described above for collection of volatiles from live insects. The collections were analyzed by GC-FID (Wax10 column) with dodecyl acetate (5 μg) as internal standard.

Results

GC-MS Analyses Analyses of collections of volatiles from male and female *R. theobaldi* showed four components in collections from females that were not present in collections from males (Fig. 3). These were a major component (I) and three earlier-eluting minor components (II, III, IV), each present at approximately 30% of the major component. Retention indices for these compounds were calculated relative to the retention times of normal hydrocarbons (Table 1).

The three earlier-eluting minor components were identified as 2-undecanone (II), 2-acetoxyundecane (III), and 2-undecanol (IV) from the spectral libraries, and by subsequent comparison of retention times and mass spectra with authentic standards. 2-Undecanone and 2-undecanol are commercially available, and 2-acetoxyundecane was synthesized by acetylation of 2-undecanol. Further examination of the chromatograms showed that the corresponding 9-carbon compounds, 2-nonanone, 2-acetoxynonane, and 2-nonanol were present at 1–2% of the major component in the collections from females, but not in collections from males (data not shown).

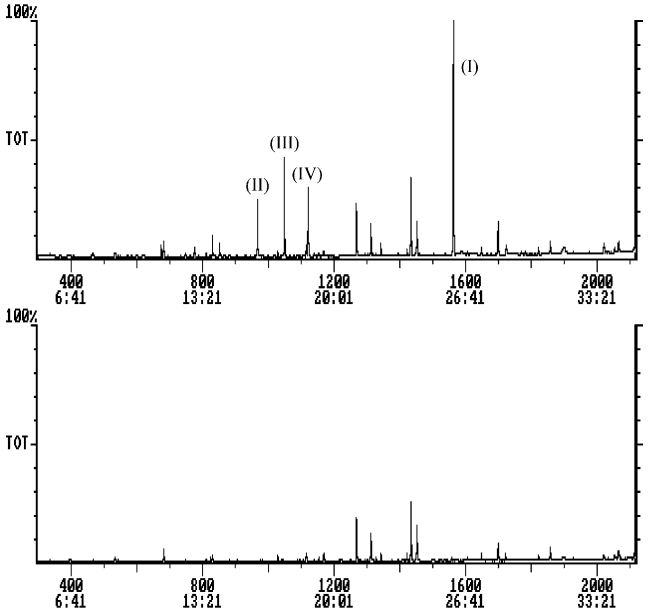

Fig. 3 GC-MS analyses on Wax10 GC column of volatiles collected from female (*upper*) and male (*lower*) *R. theobaldi* showing female-specific components

Comparison of peak areas with those of standard acetates indicated that the major component (I) was present at approximately 1.5 μg in a collection from a total of 200 females over a 1-week period. This is more than 30 times the amount of pheromone obtained from females of the apple leaf curling midge, *D. mali*, under similar conditions (Cross and Hall 2005; Hall et al. 2005).

GC-EAG Analyses In GC-EAG analyses of the collections of volatiles from female midges with a male midge EAG preparation, an EAG response always was observed to the major female-specific component. In some cases, there were also responses to 2-acetoxyundecane (III) and 2-undecanol (IV) (Fig. 4).

Chemical Structure of the Major Pheromone Component The difference in retention indices for the major female-specific component on the polar and nonpolar GC columns (Table 1) indicated that this was much more polar than any of the minor components and probably had the dioxygenated functionality characteristic of several midge pheromones identified to date. The difference in retention indices on polar and nonpolar columns for this component was intermediate to those of a diacetate structure such as 2,12-diacetoxytridecane, a component of the pheromone of *C. pisi* (Hillbur et al. 1999), and an unsaturated acetoxyketone structure such as (*Z*)-13-acetoxy-8-heptadecen-2-one, a component of the pheromone of *D. mali* (Cross and Hall 2005; Hall et al. 2005; Table 1).

The EI and CI mass spectra (Fig. 5) did not show a clear molecular ion, although the highest ion at *m/z* 229 in the ion trap spectrum suggested a molecular weight of 228 corresponding to an 11-carbon, saturated acetoxyketone. The ion at *m/z* 169 could be due to the loss of acetic acid from an acetate, as further evidenced by the ions at *m/z* 43 and 61. Hydrolysis of this component with potassium carbonate in methanol gave a product with longer GC retention time (RI 2117 on the polar column) giving a very broad peak.

Further analysis of the EI mass spectrum indicated this component to be 2-acetoxy-5-undecanone, the structure of which could explain all the main ions in the mass spectrum (Fig. 6). Hydrolysis of this would give the corresponding keto-alcohol, which could exist in cyclic or acyclic forms and might be expected to give a broad peak on GC analysis.

This compound was synthesized in seven steps (Fig. 1) and found to have identical GC retention times and mass spectra to those of the natural, female-specific component.

Stereochemistry of Pheromone Components The enantiomers of the chiral pheromone components were separated by enantioselective GC. Separations of the enantiomers of 2-acetoxyundecane and 2-acetoxy-5-undecanone were very good, but the enantiomers of 2-undecanol were only poorly separated (Fig. 7).

In analyses of the collections of volatiles from female *R. theobaldi* (Fig. 7), only a peak at the retention time of the first eluting enantiomer of the major pheromone component was present; the later-eluting enantiomer could not be detected (<0.01%). Similarly, only the first-eluting enantiomer of 2-acetoxyundecane was present; a smaller peak had a similar but significantly different retention time, but the possibility of a small amount (≤5% of the first-eluting enantiomer) of the second enantiomer being present cannot be excluded. Enantiomers of 2-undecanol were poorly

Table 1 GC retention data from GC-MS analyses of female-specific components of *R. theobaldi* and some synthetic pheromone components of other midges

Female-specific compound	Compound	Retention index[a]		
		Wax10	SPB1	Δ[b]
(II)	2-Undecanone	1600	1275	325
(III)	2-Acetoxyundecane	1665	1422	243
(IV)	2-Undecanol	1722	1290	432
(I)	2-Acetoxy-5-undecanone	2091	1549	542
	2,12-Diacetoxytridecane	2448	1955	493
	(*Z*)-13-Acetoxy-8-heptadecen-2-one	2761	2110	651

[a] Retention index (RI) relative to retention times of normal hydrocarbons

[b] Difference between RIs on polar Wax 10 and nonpolar SPB1 columns

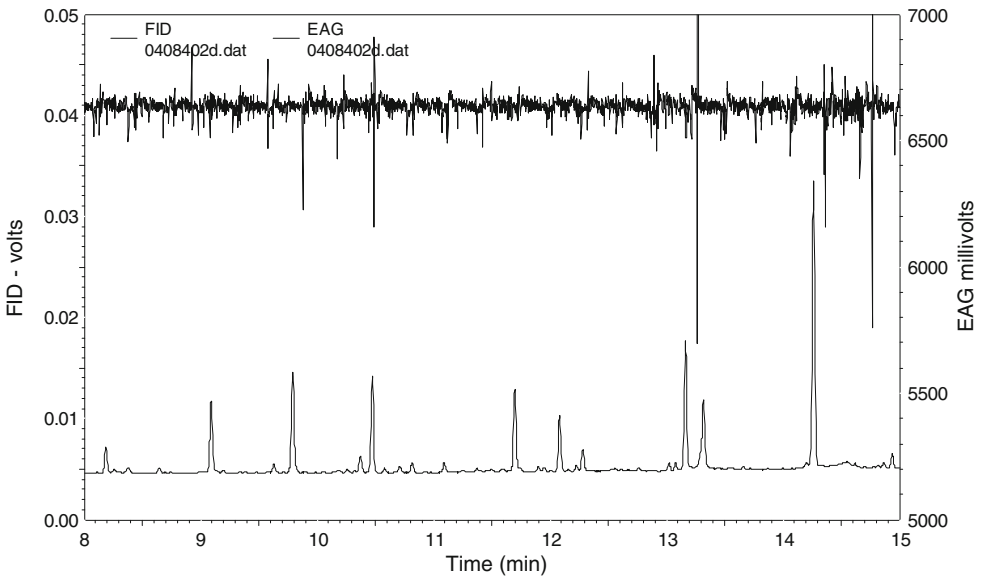

Fig. 4 GC-EAG analysis of volatiles from female *R. theobaldi* by a male *R. theobaldi* EAG preparation and Wax10 GC column (*lower trace* GC, *upper trace* EAG; EAG signals at 13.2 and 14.9 min are interference spikes)

separated, but only the first-eluting enantiomer seemed to be present in the natural pheromone collections (Fig. 7).

The enantiomers of 2-acetoxy-5-undecanone (I) were also separated by HPLC on a column with a chiral stationary phase, and milligram quantities were provided for field testing. These were analyzed by GC-FID (Chirasil-DEX CB column) and shown to have high enantiomeric purity. The enantiomer that eluted first in HPLC analyses eluted second in GC analyses.

The configurations of the enantiomers were determined by hydrolytic kinetic resolution of the epoxyketal intermediate in the synthesis of the racemic compound (Fig. 1) with the Jacobsen reagent (Tokunaga et al. 1997; Fig. 2). Reaction of the terminal epoxide with (*R*,*R*)-*N*,*N*′-bis(3,5-di-*tert*-butylsalicylidene)-1,2-cyclohexane-diaminocobalt has been reported to hydrolyze the *S*-epoxide, thus leaving the *R*-enantiomer (Tokunaga et al. 1997; Choi et al. 2004). Isolation of the *R*-epoxide followed by reduction, acetylation, and deketalization then gave (*S*)-2-acetoxy-5-undecanone (I; Fig. 2). Use of the *S,S* Jacobsen reagent gave (*R*)-2-acetoxy-5-undecanone. In GC analysis of the enantiomers, (*S*)-2-acetoxy-5-undecanone eluted first. Thus, this is the naturally occurring enantiomer.

This assignment was further confirmed by hydrolysis of the racemic 2-acetoxy-5-undecanone with lipase from *C. antarctica.* This enzyme selectively hydrolyzes the *R*-acetate (e.g., Xiao and Kitazume 1997; Gries et al. 2006). The resultant *R*-alcohol could be separated from unreacted *S*-acetate and then re-acetylated to provide a convenient preparative route to both enantiomers of the acetate in high enantiomeric purity. The unreacted *S*-acetate eluted first on the cyclodextrin GC column. The enantiomers of 2-acetoxyundecane and 2-undecanol were prepared similarly. Analysis of both by enantioselective GC showed that the *S*-enantiomers eluted first. Thus, these are the naturally occurring enantiomers.

Field Tests In the first field test, comparisons were made of catches of *R. theobaldi* males in traps baited with the racemic form of the major pheromone component, 2-acetoxy-5-undecanone, alone or combined with the three potential minor components and dispensed from rubber septa or polyethylene vials (Table 2). Over 5 weeks, total catches with all the lures were greater than those in the unbaited control ($F_{1,36}$=299.75; P<0.001), but there were no significant differences among catches with the different

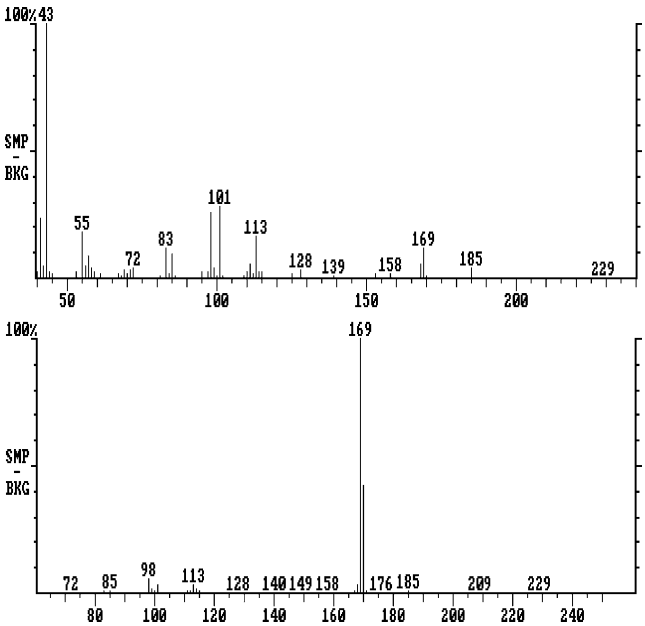

Fig. 5 Mass spectra of the major component of the sex pheromone of *R. theobaldi* in EI (*upper*) and CI (*lower*) modes

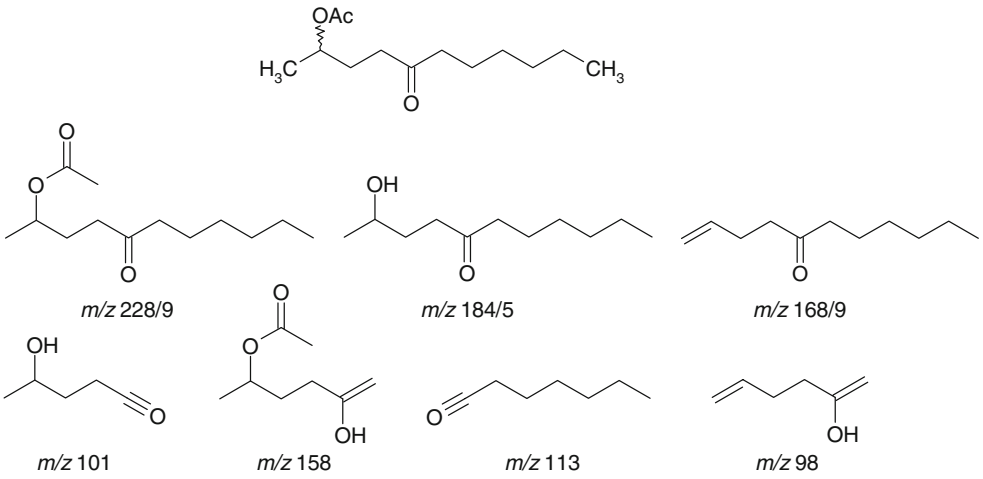

Fig. 6 Proposed structure for 2-acetoxy-5-undecanone, the major female-specific sex pheromone component in *R. theobaldi* and assignment of fragments in the mass spectrum

blends ($F_{1,36}$=3.35; P=0.076) or dispensers ($F_{1,36}$=0.017; P=0.686). The interaction between the two treatment factors also was not statistically significant ($F_{1,36}$=1.66; P=0.205).

In the second field test, total numbers of male *R. theobaldi* caught were rather small, but the treatment effect was clear (Table 3). Analysis of variance of the transformed data without inclusion of treatment factors after $\log_{10}(x+1)$ transformation gave a highly significant treatment effect ($F_{8,40}$=18.18; P<0.001). Traps baited with (*R*)-2-acetoxy-5-undecanone did not catch more *R. theobaldi* than the unbaited control at either loading (P>0.05, Duncan's multiple range test). The highest loading (100 ng) of the *S*-enantiomer or the racemate alone or with minor components added caught the largest and similar numbers of *R. theobaldi* (P>0.05). These attractive treatments at the lower load (10 ng) caught lower numbers of males, but still caught significantly more than the unbaited control traps (P<0.05). Traps baited with 10 ng of racemic 2-acetoxy-5-undecanone caught more (P<0.05) male *R. theobaldi* than those baited with 10 ng of the *S*-enantiomer, which may reflect the variability expected with the relatively low catches.

The second ANOVA of these data, which focused on treatment factors, showed that there was a strong overall dose effect for the racemic lures ($F_{1,40}$=13.31; P<0.001), with high dose > low dose > control and all differences significant (P<0.01, least significant difference test). There was no statistically significant evidence of an effect of adding the minor components ($F_{1,40}$=2.04; P=0.161) nor of any interaction with dose ($F_{1,40}$=1.08; P=0.304). There was a strong overall difference between enantiomers ($F_{1,40}$= 38.76; P<0.001) and a dose effect ($F_{1,40}$=10.76; P=0.002), but also an interaction ($F_{1,40}$=13.11; P<0.001), presumably because there was no dose effect for the inactive *R*-enantiomer, but a strong one for the active *S*-enantiomer where high dose > low dose > control (P<0.05).

Measurement of Release Rates from Dispensers Laboratory wind tunnel release rate measurements showed that the rubber septa dispensers had a roughly exponential decline in release rate of 2-acetoxy-5-undecanone (Fig. 8). The three minor components were released at approximately 30% of the rate of the major component. Release of the major component from the polyethylene vials increased during the first 10 days, remained relatively constant for the next 15 days, and then declined. Release of the minor components declined relatively evenly throughout. Apart from changes in overall release rate, the ratio of major to minor components varied dramatically from approximately 1:1 to 3:1, and back to 1:1 during the experiment. The release rate from both dispensers had declined to 10% of the maximum after 33 days at 27°C. Hence, lures should remain active for at least 1 month in the field.

Discussion

In this study, virgin females of the raspberry cane midge, *R. theobaldi*, were shown to produce (*S*)-2-acetoxy-5-undecanone accompanied by smaller amounts of 2-undecanone, (*S*)-2-acetoxyundecane, and (*S*)-2-undecanol. The major component elicited an EAG response from conspecific male midges and was highly attractive to male midges in field trapping tests. Thus, we propose that (*S*)-2-acetoxy-5-undecanone is the major component of the female sex pheromone of this species.

The structure of 2-acetoxy-5-undecanone is related to those of components of the pheromones of other midge species, having an odd number of carbon atoms in the chain and two oxygenated functionalities, one at the 2-position. It is the second example of a midge pheromone component with a ketone functional group, the only other such

Table 3 Mean total numbers of male *R. theobaldi* caught between 7 September and 4 October 2005, in commercial raspberry plantations, Kent, UK

compound being (*Z*)-13-acetoxy-8-heptadecen-2-one, the pheromone of the apple leaf curling midge, *D. mali* (Cross and Hall 2005, 2009; Hall et al. 2005; Suckling et al. 2007; Cross et al. 2009b).

Female *R. theobaldi* produce (*S*)-2-acetoxy-5-undecanone, and this enantiomer is attractive to males. The *R*-enantiomer is not attractive, but the racemic mixture is just as attractive as the *S*-enantiomer. This is the same situation as in other midge pheromones with a single chiral center, i.e., (*S*)-(*Z*,*Z*)-2-acetoxy-4,7-tridecadiene in the Douglas-fir cone gall midge, *C. oregonensis* (Gries et al. 2002); (*R*)-2-acetoxy-8-heptadecene in the locust bean midge, *Dasineura gleditchiae* (Molnár et al. unpublished data); and (*S*)-2-butyroxy-8-heptadecene in the Chinese chrysanthemum midge, *Rhopalomyia* spp. (Liu et al. unpublished data). With (*Z*)-13-acetoxy-8-heptadecen-2-one in *D. mali*, both the racemate and one of the enantiomers are equally attractive to male midges, although work is still in progress to confirm the configuration of the attractive enantiomer (Cross and Hall 2005; Hall et al. 2005). This contrasts with the situation with most midge pheromones with two chiral centers where typically one diastereomer is attractive, and one or more of the others strongly inhibits attraction. Thus, in the pea midge, *C. pisi*, a blend containing (*S,S*)-2,11-diacetoxytridecane and (*S,S*)-2,12-diacetoxytridecane is highly attractive to male midges, but addition of small amounts of the 2*S*,11*R*- or 2*R*,11*S*-isomers of the former component completely eliminates attraction (Hillbur et al. 2001).

2-Undecanone, (*S*)-2-acetoxyundecane, and (*S*)-2-undecanol are also produced by female *R. theobaldi*, and at least the latter two components elicited EAG responses from a male midge. However, addition of these as the racemic forms to racemic 2-acetoxy-5-undecanone did not have any significant effect on attractiveness. This contrasts with results for *C. pisi* where addition of racemic 2-acetoxytridecane to the blend of (*S,S*)-2,11-diacetoxytridecane and (*S,S*)-2,12-diacetoxytridecane is essential for attraction of male midges (Hillbur et al. 2000). Further work will be carried out to determine whether addition of the *S*-enantiomers of the potential minor components to the (*S*)-2-acetoxy-5-undecanone, as in the naturally produced blend, has any effect on the attractiveness of the latter component.

The pheromone of *R. theobaldi* was produced in relatively large quantities compared with that obtained from other midge species. This may have been due in part to the use of air entrainment to collect pheromone rather than gland extraction, which has been used in most other midge pheromone identifications (e.g., Hillbur et al. 1999). Air entrainment allows large numbers of midges to be processed easily, and gives a collection free of involatile material that can be concentrated for GC analysis. Thus, collection of pheromone from a total of 200 female *R. theobaldi* gave approximately 1.5 μg of the major component. However, this was more than 30 times the amount of pheromone collected from another midge species, *D. mali*, under identical conditions, so the larger amounts were not entirely due to the method of collection.

Racemic 2-acetoxy-5-undecanone was synthesized on multigram scale in seven steps and 63% overall yield from commercially available 4-pentenoic acid (Fig. 1). The basic ketone structure was set up by using reaction of an organolithium reagent with a carboxylic acid (Jorgenson 1970). The utility of this reaction has been demonstrated previously (Hall et al. 2006). As in the latter case, use of the preformed lithium salt of the carboxylic acid is more

economical in organolithium reagent and, in this case, produces a higher yield of cleaner product.

The enantiomers of 2-acetoxy-5-undecanone can be separated not only by enantioselective GC but also by HPLC. A normal-phase Chiralpak AD column (Qin et al. 1997; Gries et al. 2000) was used, and milligram quantities were produced for the field tests. The configurations of the enantiomers were determined by hydrolytic kinetic resolution of the terminal epoxide intermediate in the synthesis of the racemic material by using Jacobsen's reagent, *N*,*N*′-bis(3,5-di-*tert*-butylsalicylidene)-1,2-cyclohexane-diaminocobalt (Tokunaga et al. 1997). The *R*,*R*-reagent hydrolyzes the *S*-epoxide leaving the *R*-epoxide, which is isolated and converted to the (*S*)-2-acetoxy-5-undecanone (Fig. 2). This elutes first on the cyclodextrin GC column, as does the enantiomer produced by female *R. theobaldi*. This assignment was confirmed by hydrolysis of racemic 2-acetoxy-5-undecanone with a lipase that is known to hydrolyze selectively the *R*-enantiomer (e.g., Xiao and Kitazume 1997; Gries et al. 2006). With the ester function in the 2-position, the lipase from *C. antarctica* gives extremely high enantiomeric purity (Gries et al. 2006; Liu et al. unpublished data; Molnár et al. unpublished data). With the ester function further along the carbon chain, this lipase is less selective, and others such as Amano AK are more selective (e.g., Lacey et al. 2007; Hall et al. unpublished). Both chemical and enzymatic approaches provide convenient routes to multigram quantities of the enantiomers of 2-acetoxy-5-undecanone.

Rubber septa or polyethylene vials were used as pheromone dispensers in the first field experiment, and both proved attractive. Release rate studies on the rubber septa showed that release of 2-acetoxy-5-undecanone and the minor components, 2-undecanone, 2-acetoxyundecane, and 2-undecanol showed a "conventional" first-order decline. However, with the vials, although the minor components showed first-order release, release of the 2-acetoxy-5-undecanone took several days to reach a maximum, and then declined. This effect was also noted with (*Z*)-13-acetoxy-8-heptadecen-2-one, pheromone of *D. mali* (unpublished results) and is presumably due to the slow penetration of the more polar ketoacetate through the polyethylene. For field use, the more predictable exponential decline in release rate from the rubber septa is probably preferable. The release rate from either dispenser was still significant after 30 days in the laboratory wind tunnel at 27°C and 8 km/h airspeed. Under field conditions in the UK, where average temperatures are much lower, the life of lures is likely to be considerably longer.

Work is in progress to optimize pheromone loading, dispenser and trap design, and to investigate the use of the pheromone for control of *R. theobaldi* in commercial plantations by attract-and-kill or mating disruption. Work to correlate pheromone trap catches with field populations of the midge and plant damage was started in eight European countries in 2006 (Cross et al. 2008). A pheromone trap monitoring system and/or a nonchemical control method for control of the pest will reduce UK raspberry growers' dependence on chlorpyrifos, residues of which were found in 17% of samples of UK-produced raspberry fruit in 2003 (Anonymous 2003a, b).

Acknowledgments This work was funded by the UK Department for the Environment, Food and Rural Affairs (Projects HH3124SSF and HL0175) and the Horticultural Development Council (Project SF74). We thank Adrian Harris, Antonia Zurbuchen, and Esther Debón Verdū for assistance with the field tests.

Sex Pheromone Components of the Pear Fruit Moth, *Acrobasis pyrivorella* (Matsumura)

Jun Tabata · Makoto Minamishima · Hajime Sugie · Takehiko Fukumoto · Fumiaki Mochizuki · Yutaka Yoshiyasu

Received: 21 October 2008 / Revised: 16 December 2008 / Accepted: 6 January 2009 / Published online: 4 February 2009

Abstract We analyzed the sex pheromone of the pear fruit moth, *Acrobasis pyrivorella*, by means of gas chromatography–electroantennographic detection (GC-EAD) and GC–mass spectrometry. Two EAD-active compounds were detected in the pheromone gland extract of females. They were identified as (*Z*)-9-pentadecenyl acetate (Z9-15:OAc) and pentadecyl acetate (15:OAc). The amounts per female gland (mean ± standard error) of these compounds were 12.9±2.8 and 0.8±0.1 ng, respectively. Synthetic Z9-15:OAc (300 μg) attracted conspecific males in field trapping experiments. When 15:OAc (21 μg; 7% of Z9-15:OAc quantity) was added, the number of males trapped increased significantly. Catch in traps baited with the mixture of these compounds was greater than that in traps baited with 1–3-day-old virgin females. We, therefore, conclude that Z9-15:OAc and 15:OAc are sex pheromone components of this species.

Introduction

The pear fruit moth, *Acrobasis pyrivorella* (Matsumura) (Lepidoptera: Pyralidae, Phycitinae), is a serious pest of pears, *Pyrus pyrifolia* (Burman) or *Pyrus communis* L. (Rosaceae: Maloideae), indigenous to the temperate zone of eastern Asia, and is widely found in far-eastern Russia, northern China, Korea, Taiwan, and Japan (EPPO 2007). Synonyms for this insect include *Nephopterix pirivorella* Matsumura, *Nephopteryx pauperculella* (Wileman), *Acrobasis pirivorella* (Matsumura), *Ectomyelois pyrivorella* (Matsumura), *Eurhodope pirivorella* (Matsumura), *Numonia pirivora* (Gerasimov), *Numonia pyrivorella* (Matsumura), and *Rhodophaea pirivorella* (Matsumura) (Walker 2006). Currently, there is no indication that *A. pyrivorella* larvae feed on fruit trees other than pears (Walker 2006). Larvae (first–third instars) of *A. pyrivorella* feed on the developing buds or fresh flowers before boring into the core of the young fruit (Makaji 1965). Larvae may move from fruit to fruit, with a single larva capable of destroying up to two or three buds, one to three primordial flowers, and three fruit (Shutova 1977).

In Japan, the major fruit borers in pear orchards are the Oriental fruit moth *Grapholita molesta* (Busck), peach fruit moth *Carposina sasakii* Matsumura, yellow peach moth *Conogethes punctiferalis* (Guenée), and *A. pyrivorella* (Adachi 1999). The sex pheromones of *G. molesta* (Cardé

et al. 1979), *C. sasakii* (Tamaki et al. 1977), and *Con. punctiferalis* (Konno et al. 1982) have all been identified. Sex pheromones of *G. molesta* and *C. sasakii* are commercially available and used for monitoring their flight phenology (Chiba 2000; Tanaka 2000), as well as for mating disruption (Izawa 2000). However, the sex pheromone of *A. pyrivorella* has not been studied previously. In the present study, we analyzed sex pheromone gland extract of *A. pyrivorella* females by gas chromatography–electroantennographic detection (GC-EAD) and GC–mass spectrometry (GC-MS). Candidates for sex pheromone components were identified and synthesized, and the behavioral response they evoked in conspecific males was tested by field-trapping experiments.

Methods and Materials

Insects Approximately 500 fruit, damaged by *A. pyrivorella*, were collected from pear trees around Nagano Nannshin Agricultural Experiment Station (35.6°N, 137.9°E; Shimoina-gun, Nagano Pref.) from 1–8 August 2007. A total of 48 pupae were obtained from the fruit, from which 19 adult females and 23 adult males emerged. Adults were housed individually in a 200-ml plastic container with a piece of cotton soaked with water and placed in a rearing room (60%±5% relative humidity, L15:D9 h photoperiod, 23±1°C).

Extraction of Sex Pheromone Pheromone gland extract was obtained from 2-day-old virgin females in the last 2 h of the dark period, when most females had started calling behavior. The abdominal tip, which includes the sex pheromone gland, was excised and immersed in 20 µl hexane (Wako Pure Chemicals, Osaka, Japan). The tip was removed from the solvent after 30 min, and the extract was stored at −20°C before analysis. Four extracts were produced, from two, three, four, and five pheromone glands, respectively.

Gas Chromatography and Gas Chromatography–Electroantennographic Detection GC analyses were conducted on an Agilent 6890N gas chromatograph (Santa Clara, CA, USA) equipped with a split/splitless injector and a flame ionization detector (FID). The injector and detector were each kept at 220°C. An apolar HP-1 [25×0.2 mm inner diameter (ID), 0.33 µm film thickness; Agilent], a polar DB-wax (30×0.25 mm ID, 0.25 µm film thickness; J&W Scientific, Folsom, CA, USA), or a polar DB-23 (30×0.25 mm ID, 0.15 µm film thickness; J&W Scientific) column were used for analyses, at a constant flow rate of 1.0 ml min^{-1} helium carrier gas. Aliquots of samples (0.2–1.0 female equivalent) were injected into the GC system with a purge time of 1 min. In the quantitative measurement of compounds, samples were mixed with 2 ng of an internal standard (tridecyl acetate; Sigma-Aldrich, St. Louis, MO, USA) before injection. The column oven temperature was maintained at 60°C for 1 min, raised to 220°C at a rate of 7°C min^{-1}, and held for 8 min. GC-EAD (Struble and Arn 1984) was performed on a Hewlett-Packard (Palo Alto, CA, USA) 5890GC equipped with an EAD device (Taiyo, Tsukuba, Japan) and a DB-23 column. The conditions and equipment for the GC were the same as above. An antenna was excised from a virgin male (1 day old), and a few of the distal segments cut off. The two ends of the antenna were attached to the electrodes of the EAD device with a few droplets of electroconductive gel (Aquasol, Parker, Fairfield, NJ, USA).

Gas Chromatography–Mass Spectrometry GC-MS analyses were conducted on an Agilent 6890N/5973, in electron impact mode at 70 eV. The interface temperature was 230°C. The other conditions and equipment were the same as those for the GC-FID analysis.

Dimethyl Disulfide Derivatization Monounsaturated compounds in the crude sex pheromone gland extract were reacted with dimethyl disulfide (DMDS), to confirm double-bond location and geometry, according to the method of Buser et al. (1983). The crude extract in hexane (ca. five female equivalents) was treated with 100 µl DMDS (Wako) and one drop of iodine solution (60 mg/ml in ether). The reaction mixture was kept at 40°C on a heat block for 24 h. The cooled sample was diluted with 200 µl hexane. Iodine was removed by shaking with 5% aqueous $Na_2S_2O_3$ (100 µl). The organic phase was drawn off, and the aqueous phase was extracted in 200 µl hexane. The combined hexane solution was dried over anhydrous sodium sulfate, concentrated to ca. 10 µl, and subjected to GC-MS analysis.

Chemicals (*Z*)-9-pentadecenyl acetate (Z9-15:OAc) was synthesized via the Grignard cross-coupling reaction as follows: (*Z*)-9-chloro-6-nonene (Shin-Etsu Chemical, Tokyo, Japan) was reacted with magnesium metal in tetrahydrofuran (THF) to yield (*Z*)-3-nonen-1-yl magnesium chloride. This Grignard reagent was cross-coupled with 1-bromo-6-chlorohexane (Nippoh Chemicals, Tokyo, Japan) to give (*Z*)-15-chloro-6-pentadecene crude product (Yamamoto and Ishihara 1991). After evaporation of THF under reduced pressure, crude (*Z*)-15-chloro-6-pentadecene was reacted with sodium acetate (Daito Chemical, Tokyo, Japan) in glacial acetic acid to give Z9-15:OAc. The crude product was purified to 93% purity in a distillation tower. The product contained approximately 3% of the (*E*)-isomer (E9-15:OAc). These geometric isomers were purified further by high-performance liquid chromatography

(HP1050 series; Hewlett-Packard) in a silver-ion-coated column (Nucleosil 100-SA, 4.6 mm diameter × 250 mm length, 5 μm particle size; GL Science, Tokyo, Japan; Christie 1988). Hexane containing 30% ether was used as the elution solvent at a flow rate of 1 ml min^{-1}. The geometries of Z and E9-15:OAcs were confirmed by Fourier transformation infrared spectrophotometry (JIR-100; JEOL, Tokyo, Japan); E9-15:OAc had a unique absorption at 966 cm^{-1}. Both Z and E9-15:OAc samples contained less than 1% of the opposite isomer. Pentadecyl acetate (15:OAc) was prepared by acetylation of 1-pentadecanol (Tokyo Chemical Industry, Tokyo, Japan) with acetic anhydride in the presence of pyridine. The compounds were condensed under vacuum, redissolved in hexane, and prepared for use in field traps as described below.

Field Trap Experiments Delta-traps with 24×30-cm sticky boards (SE-trap; Sankei Chemical, Kagoshima, Japan), baited with synthetic chemicals or virgin females, were used for testing attractiveness to males in pear orchards around Nagano Nannshin Agricultural Experiment Station. Synthetic chemicals dissolved in ca. 100 μl hexane were impregnated onto rubber septa (gray, 8 mm diameter× 19 mm height; West, Singapore). The solvent was evaporated overnight at room temperature. Traps baited with natural virgin females contained two virgins (1–3 days old) held in a steel mesh cage (6 cm diameter × 5 cm height) with a cotton pad soaked with a 5% honey solution. Traps were hung (1.5–2.0 m above the ground) on pear trees at ca. 2–5-m intervals and checked every 2 days, after which their positions were rerandomized.

Experiments 1, 2, and 3 were conducted from 22 June to 9 July 2007 (checked nine times with one replicate), 22 to 27 August 2006 (checked three times with two replicates), and 18 to 27 August 2006 (checked five times with two replicates), respectively. Experiments 4 and 5 were conducted with three replicates from 17 June to 2 July 2008, and experiment 6 was conducted with three replicates from 5 to 20 August 2007 (each checked eight times). Data (x) were transformed as $(x+0.5)^{1/2}$ and analyzed by a two-way analysis of variance (ANOVA). Means of treatments were separated by the Tukey–Kramer honestly significant difference (HSD) test ($\alpha=0.05$) using JMP version 5.1.1 software (SAS Institute 1989–2004). Treatments that did not catch males were not included in the statistical analyses to avoid violating assumptions of ANOVA.

Results

Sex Pheromone Chemistry Two EAD-active compounds (A and B) were found in the crude extract of abdominal tips of virgin females (Fig. 1). The amounts of these compounds per female gland were 0.8±0.1 and 12.9±2.8 ng (mean ± standard error), respectively. In the GC-MS analysis of compound A, a characteristic fragment ion of aliphatic acetates (*m/z* 61; $CH_3COOH_2^+$) was observed (Fig. 2). Compound A had an ion at *m/z* 210 (M^+-60) and had a similar mass spectrum to acetates of saturated primary fatty alcohols, suggesting it was 15:OAc. Compound B also had an *m/z* 61 (Fig. 2). The mass spectrum of B had an ion at *m/z* 208 (M^+-60), suggesting the compound was a pentadecenyl acetate. DMDS derivatization produced an adduct with a molecular ion at *m/z* 362 (Fig. 2). Ions were observed at *m/z* 131 [$CH_3(CH_2)_4CH(SCH_3)^+$] and 231 (M^+-131), suggesting that compound B was Δ9-pentadecenyl acetate. Synthesis of 15:OAc, Z9-15:OAc, and E9-15:OAc, and comparison of retention times and mass spectra with those of compounds A and B confirmed them to be 15:OAc and Z9-15:OAc,

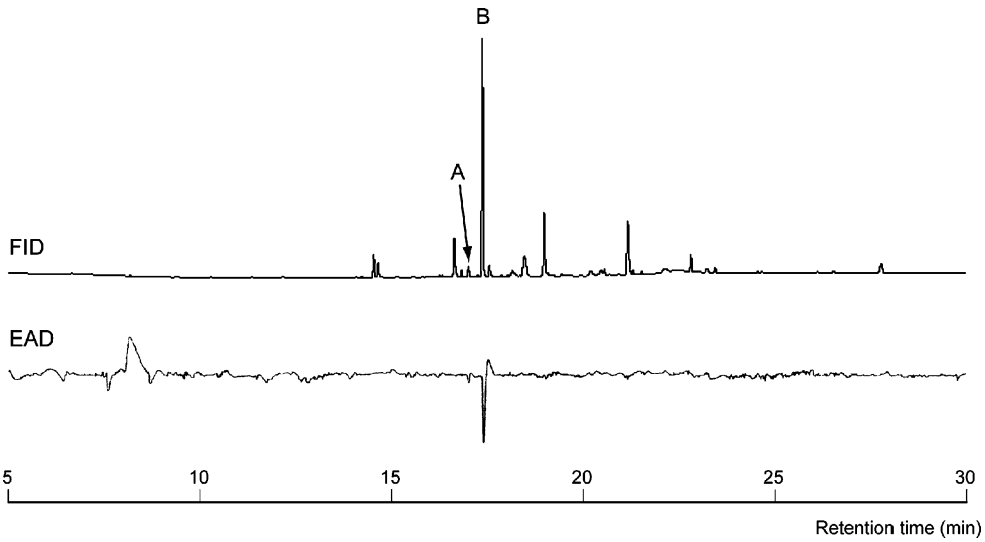

Fig. 1 Coupled gas chromatogram-flame ionization detection (*FID*; *upper trace*) and electroantennogram detection (*EAD*; *lower trace*) responses to a crude extract (ca. one female equivalent) of sex pheromone gland of *A. pyrivorella*. Compound A was subsequently identified as pentadecyl acetate and compound B as (*Z*)-9-pentadecenyl acetate

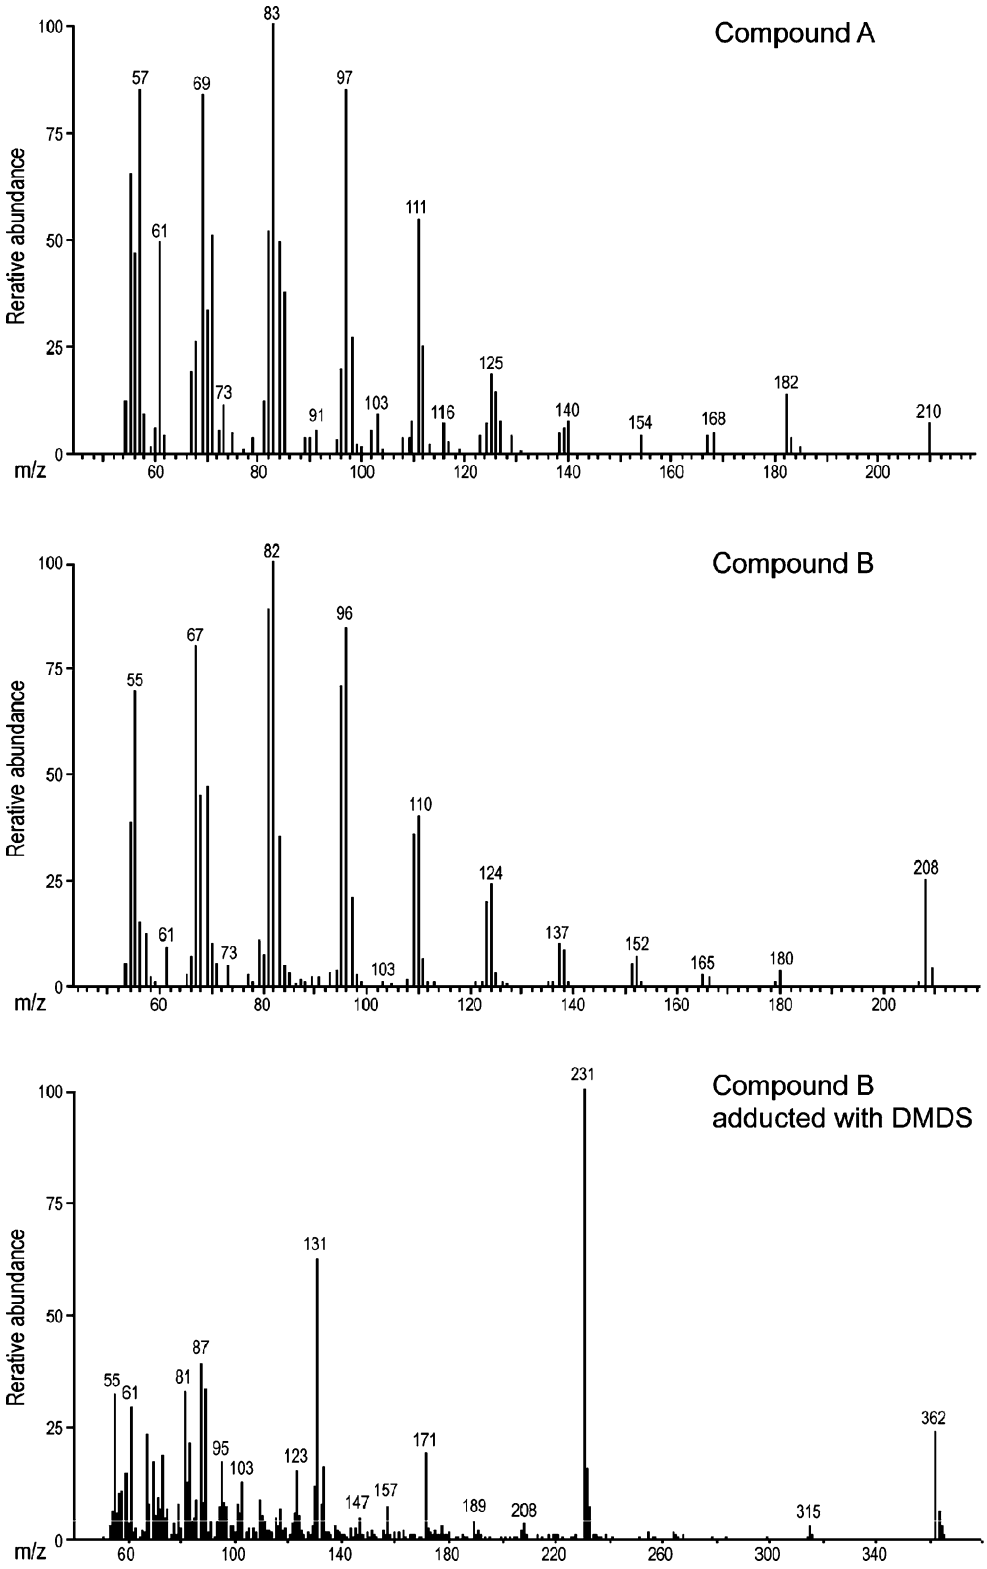

Fig. 2 Electron impact mass spectra of compound A (pentadecyl acetate), compound B [(*Z*)-9-pentadecenyl acetate], and the DMDS adduct of compound B

respectively (Table 1). The difference between the retention time of authentic Z9-15:OAc and E9-15:OAc was small, but the retention times of the respective DMDS adducts were resolved clearly (Table 1).

Male Attraction to Synthetic Pheromone Components in the Field In the first field trapping experiment, we tested the efficacy of the two compounds. Although the trap baited with 300 μg Z9-15:OAc caught males (total of 27), the trap

Table 1 Retention times (min) of EAD-active and authentic chemicals, and their DMDS adducts, on polar (DB-wax) and apolar (HP-1) columns

Column	EAD-active compound			Authentic compound[a]				
	A	B	DMDS adduct of B	15:Ac	Z9-15:OAc	E9-15:OAc	DMDS adduct of Z9-15:OAc	DMDS adduct of E9-15:OAc
DB-wax	20.66	21.11	46.47	20.66	21.11	21.06	46.47	47.53
HP-1	16.17	15.85	23.46	16.17	15.85	15.91	23.46	23.48

[a] 15:OAc: pentadecyl acetate; Z9-15:OAc: (*Z*)-9-pentadecenyl acetate; E9-15:OAc: (*E*)-9-pentadecenyl acetate.

baited with 300 μg Z9-15:OAc + 21 μg 15:OAc (7% of Z9–15:OAc quantity, the same ratio as in the extracts) caught (total of 45) significantly more (two-way ANOVA: for treatment, F=5.78, df=1, P=0.043; for block effect, F=1.77, df=8, P=0.21) (Fig. 3a). No males were caught in the trap with the lure containing 21 μg 15:OAc or in the control trap.

Experiment 2 examined the effect of E9-15:OAc on the attractive binary blend. Traps baited with Z9-15:OAc (300 μg) + 15:OAc (21 μg) + E9-15:OAc (30 μg; 10% of Z9-15:OAc) captured slightly more (30 in total) males than traps without E9-15:OAc (24), although the difference was not significant (two-way ANOVA: for treatment, F=0.005, df=1, P=0.95; for block effect, F=2.26, df=5, P=0.20).

Experiment 3 compared the attractive binary blend of Z9–15:OAc + 15:OAc with virgin females. Traps baited with the binary blend captured significantly (two-way ANOVA: for treatment, F=11.6, df=1, P=0.008; for block effect, F=1.13, df=9, P=0.87) more males (24 vs 2) than did traps baited with virgin females.

Further experiments determined the optimal ratio and dose of Z9-15:OAc and 15:OAc for attracting *A. pyrivorella* males. Experiment 4 varied the amount of 15:OAc (10.5, 21, or 42 μg) relative to Z9-15:OAc (300 μg). No significant differences were found among treatments (two-way ANOVA: for treatment, F=2.31, df=2, P=0.11; for block effect, F=1.14, df=23, P=0.35; Fig. 3b). Experiment 5 tested lures containing 100, 300, and 1,000 μg of Z9-15:OAc with 7% 15:OAc. Traps baited with a lure with 1,000 μg Z9-15:OAc captured more males than those containing 100 g or 300 μg (two-way ANOVA: for treatment, F=16.8, df=2, P<0.001; for block effect, F=1.18, df=23, P=0.31; Tukey–Kramer HSD test, α=0.05; Fig 3c). Experiment 6 tested higher concentrations: 1,000, 3,000, and 10,000 μg of Z9-15:OAc with 7% 15:OAc. Traps baited with either 3,000 or 10,000 μg Z9-15:OAc caught more males than traps with 1,000 μg (two-way ANOVA: for treatment, F=11.9, df=2, P<0.001; for block effect, F=1.80, df=23, P=0.044; Tukey–Kramer HSD test, α=0.05; Fig. 3d). No males were caught in the control (solvent only) traps in any of these experiments.

Taxonomic Reinvestigation of A. pyrivorella Roesler (1985, 1987) revised the generic status of the pear-fruit moth from *Ectomyelois pyrivorella* (Matsumura) to *Acrobasis pyrivorella*

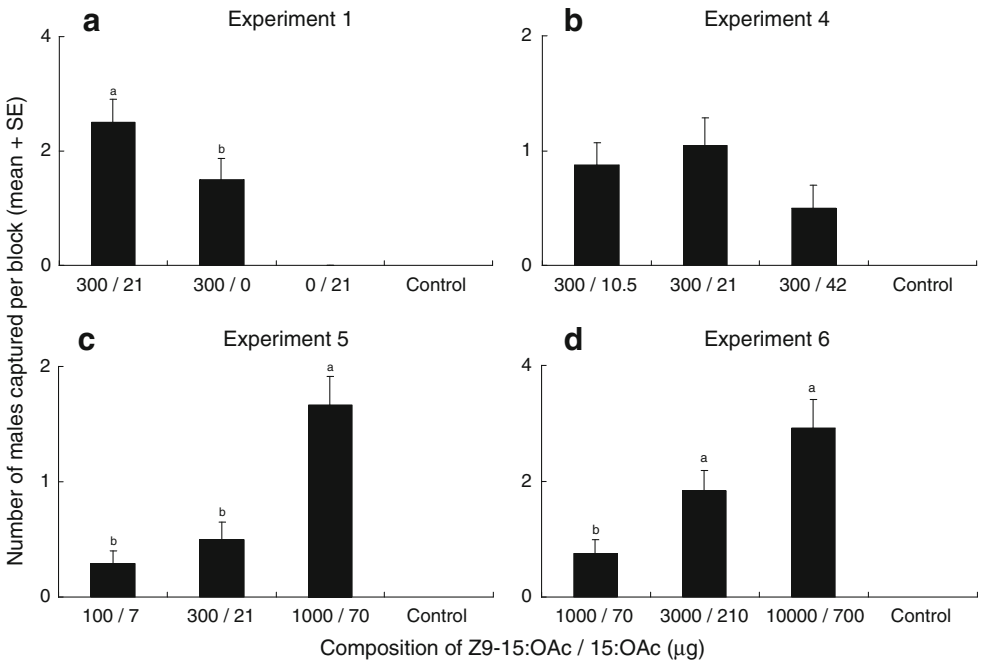

Fig. 3 Mean numbers (±SEM) of *A. pyrivorella* males captured (per block) in field experiments testing different ratios and amounts of candidate sex pheromone components, Z9-15:OAc [(*Z*)-9-pentadecenyl acetate] and 15:OAc (pentadecyl acetate). Control = solvent blank. Means with different *letters* atop bars in each experiment were significantly different by two-way ANOVA followed by the Tukey–Kramer HSD test (P<0.05)

(Matsumura). However, Japanese taxonomists have not agreed on this change, and the species is still referred to as *Ectomyelois pirivorella* in the recent list of Japanese moths (Jinbo, 2004–2008) after Inoue (1982). We therefore re-examined the morphological characters of adult *A. pyrivorella* to determine which genus it should be assigned to. Our results support assignment as *Acrobasis*: vein M2 stalked with M3 for shorter distance in hindwing (in *Ectomyelois* species M2–M3 stalked for nearly half the length); male genitalia with thicker phallus, and apical process of gnathos narrowly rounded (in *Ectomyelois*, more or less bifurcated at apical process) (Fig. 4). Other genital characters were similar to other *Acrobasis* species, including *Acrobasis consociella* (= *Acrobasis tumidella*, type species), drawn and described by Heinrich (1956).

Discussion

Z9-15:OAc and 15:OAc were identified in the pheromone gland of female *A. pyrivorella*, with Z9-15:OAc being more abundant. A lure containing only Z9-15:OAc (300 μg) attracted males in the field, but a blend of this compound with 15:OAc (21 μg; 7% of Z9-15:OAc) was significantly more attractive. Traps baited with these two chemicals caught more males than ones baited with two virgin females. We, therefore, conclude that Z9-15:OAc and 15:OAc are sex pheromone components of *A. pyrivorella*. Although changing the ratio of these two compounds (with both chemicals present) had little effect on trap catch, increasing the total amount of the compounds did, with blends containing 10,000 or 3,000 μg of Z9-15:OAc (+ 7% 15:OAc) eliciting the greatest catches of males. This blend could be used in traps to monitor for the emergence of *A. pyrivorella* or, indeed, in mating disruption leading to an efficient management program for this pest in pear orchards.

In several moth species, the geometric isomer of the pheromone component acts as an antagonist for the attraction of males. For example, the addition of more than 0.3% (*E*)-9-tetradecenyl acetate inhibited the attractiveness of the two-component mixture of (*Z*)-9- and (*Z*)-11-tetradecenyl acetate to the summer fruit tortrix *Adoxophyes orana fasciata* Walsingham (Sugie et al. 1984). In the case of *A. pyrivorella*, however, the attractiveness of the Z9-15:OAc + 15:OAc mixture was not significantly decreased by the addition of 10% E9-15:OAc (which was not detected in the pheromone gland). Hence, it is not necessary to remove small amounts of *E* isomer from synthetic Z9-15:OAc in order to use the latter as an attractant for *A. pyrivorella*. This is economically favorable for the development of the pheromone as a pest management tool.

Most moth pheromone components are even-numbered straight-chain acetates, alcohols, or aldehydes (Tamaki 1985); odd-numbered straight-chain compounds such as Z9-15:OAc and 15:OAc are rare (Witzgall et al. 2004). To our knowledge, ours is the first study to identify Z9-15:OAc and 15:OAc as true sex pheromone components of a moth. Z9-15:OAc and 15:OAc were found in the pheromone gland of a related *Acrobasis* species, the cranberry fruit worm *A. vaccinii* Riley, although neither compound had significant pheromonal activity in behavioral trials; the known pheromone blend of *A. vaccinii* consists of a mixture of (*E*,*Z*)-8,10-pentadecadienyl acetate and E9-15:OAc (McDonough et al. 1994). A few males of another *Acrobasis* species, *A. rufilimbalis* (Wileman), were captured in traps baited with Z9-15:OAc in field-screening tests of various compounds (unsaturated C_{10}–C_{16} straight-chain compounds containing a terminal hydroxyl or acetate

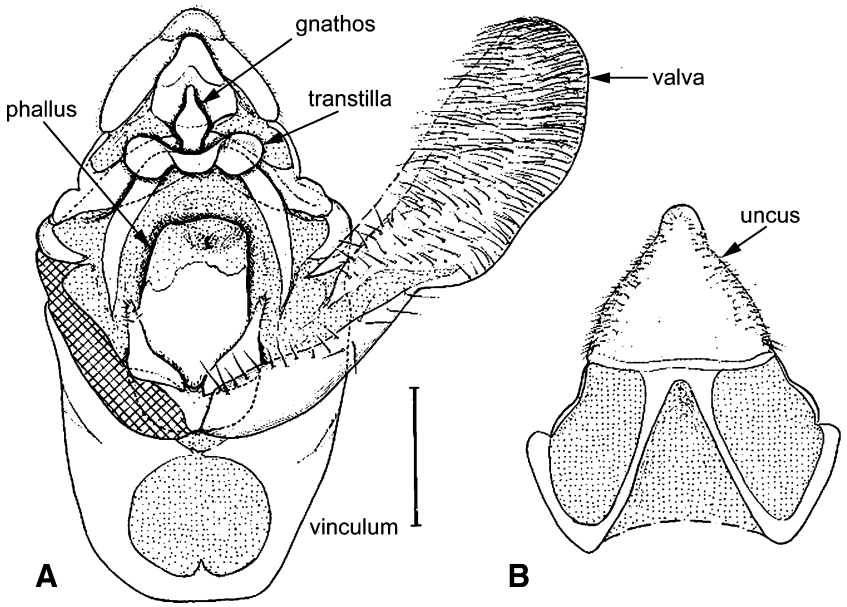

Fig. 4 Male genitalia of *A. pyrivorella*. **A** Ventral view, left valva removed; **B** dorsal view, tegumen and uncus. *Scale*: 0.5 mm

group; Ando et al. 1977). However, to date, pheromone chemicals produced by females have not been investigated in this species. Also, (*E*,*Z*)-9,11-pentadecadienal was slightly attractive to males of *A. nuxvorella* Neunzig, which produces the homologous (*E*,*Z*)-9,11-hexadecadienal as its true pheromone component (Millar et al. 1996).

In accordance with our morphological investigation, the sex pheromone components of *A. pyrivorella* are consistent with its assignment to the genus *Acrobasis* rather than *Ectomyelois*. As discussed above, C_{15} compounds are found in, or attract, other species of *Acrobasis*. The only species of *Ectomyelois* for which sex pheromone components have been identified is the carob moth, *Ectomyelois ceratoniae* (Zeller), which uses a blend of C_{14} aldehydes (*Z*,*E*)-9,11,13-tetradecatrienal, (*Z*,*E*)-9,11-tetradecadienal, and (*Z*)-9-tetradecenal (Baker et al. 1991). Thus, our combined findings support the taxonomic placement of the pear fruit moth in the genus *Acrobasis*, not *Ectomyelois*. The specimens of the pear fruit moth that we examined are deposited in the Laboratory of Applied Entomology, Graduate School of Life and Environmental Sciences, Kyoto Prefectural University, for future taxonomic investigation.

Chemical Composition of the Defensive Secretion of the Longhorned Beetle, *Chloridolum loochooanum*

Wakako Ohmura · Shojiro Hishiyama · Tadakazu Nakashima · Atsushi Kato · Hiroshi Makihara · Tatsuro Ohira · Hideki Irei

Received: 31 May 2008 / Revised: 8 December 2008 / Accepted: 15 December 2008 / Published online: 22 January 2009

Abstract Adults of the longhorned beetle, *Chloridolum loochooanum* Gressitt (Coleoptera: Cerambycidae) emit a white frothy secretion from their metasternal glands. This defensive substance contains cyclopentanoid monoterpenoids (iridodials), whose structures were elucidated by gas chromatography-mass spectrometry (GC-MS) and nuclear magnetic resonance (NMR) analyses that compared the naturally occurring structures with synthesized versions. Optically active citronellals, [(*S*)-, (*R*)-, and (*S*)/(*R*)- mixture], were used as starting materials for synthesizing the corresponding iridodials for the determination of the absolute configuration of the natural product. The retention time of (2*S*)-iridodial, derived from (*S*)-citronellal, corresponded to that of *C. loochooanum* iridodial by enantioselective GC analysis. Thus, we suggest that the absolute configuration of *C. loochooanum* iridodial is (1*R*,2*S*,5*S*)-iridodial.

Keywords Cerambycidae · Chemical defense · Coleoptera · Iridodials · Longhorned beetle · NMR

Introduction

Various strategies such as chemical defense, surface hardness, and/or mimicry have evolved that protect insects from predators. Defensive chemicals have been investigated frequently because of their diversity and species-specificity. Most defensive chemicals in beetles (Coleoptera) are odoriferous and repugnant to humans, e.g., formic acid, benzoquinones, cresols. (Eisner et al. 1977; Markarian et al. 1978; Balestrazzi et al. 1985; Kanehisa and Kawazu 1985). However, when attacked by predators, longhorned beetles in the genus *Chloridolum* are known for emitting a fragrant odor (recognizable to humans) from metasternal glands. Other defensive chemical secretions from cerambycid beetles include rose oxide and iridodials from the European musk beetle, *Aromia moschata* L. (Vidari et al. 1973); a strong but not unpleasant secretion consisting mainly of 2-hydroxy-6-methyl-benzaldehyde from the Eucalyptus longhorned borer, *Phoracantha semipunctata* (F.) (Moore and Brown 1972); and macrocyclic lactones, such as decan-9-olide, (*Z*)-dec-4-en-9-olide, and 11-hydroxytetradec-5-en-13-olide, from *Phoracantha synonyma* (Moore and Brown 1972, 1976; reviewed by Allison et al. 2004).

The longhorned beetle, *Chloridolum loochooanum* Gressit (Cerambycidae), occurs only on the islands of Amami and Okinawa in Japan (Gressitt 1933; Kojima and Hayashi 1969). *C. loochooanum* emits a delicate scent during flight (Makihara and Ohmura 2005). We were interested in the chemical composition of the defensive secretion of *C. loochooanum*, and used gas chromatography-mass spectrometry (GC-MS) and nuclear magnetic resonance (NMR) to determine the chemical structures.

Methods and Materials

Insects Fallen *Viburnum awabuki* K. Koch infested with *C. loochooanum* (Makihara 2005; Fig. 1) were collected in March and April, 2003 on Okinawa island and were sent

Fig. 1 An adult of *C. loochooanum* Gressit (Coleoptera: Cerambycidae)

immediately to the Forestry and Forest Products Research Institute (FFPRI), Tsukuba, Japan. They were maintained at 25°C until adult *C. loochooanum* emerged. Freshly emerged adults were sexed, and the defensive secretion was collected in the laboratory.

Collecting the Defensive Secretion When disturbed, *C. loochooanum* adults promptly emit a white liquid secretion from their metathoracic glands. The emitted secretion was absorbed on glass wool, which was extracted with $CDCl_3$ (Acros Organics, NJ, USA), or the secretion was absorbed directly on a solid phase microextraction (SPME) fiber (100 μm PDMS, Supelco, Tokyo, Japan) at room temperature in the laboratory.

Synthesis of Iridodials Iridodials were synthesized according to Clark et al. (1959) with a few further amendments. All unspecified reagents were purchased from Wako (Tokyo, Japan). A 3:1 mixture of (*S*)/(*R*)-citronellal [i.e., 75%-(*S*):25%-(*R*)] [(*S*)-(−)-citronellal, 96%, $[\alpha]_D^{25} = -17.3°$ (C=3, $CHCl_3$); (*R*)-(+)-citronellal, 90%, $[\alpha]_D^{25} = +14.0°$= (C=3, $CHCl_3$)] (Sigma-Aldrich, Tokyo, Japan; 25 ml), ethyleneglycol (15 ml), *p*-toluene sulfonate (30 mg), and benzene (240 ml) was refluxed in a Dean-Stark apparatus for 24 h to give the cyclic acetal in 83% yield. Selenium oxide, suspended in 50 ml of EtOH was added to the acetal in 30 ml of EtOH under reflux at 100°C for 20 h. The resulting aldehydic cyclic acetal (71% yield) was hydrolyzed and cyclized by refluxing with 50% acetic acid under Ar for 4 h. The reaction mixture was purified with silica-gel column chromatography (Silica-gel 60, 230–400 mesh, ASTM, Merck KGaA, Darmstadi, Germany) with *n*-hexane/EtOAc=4/1 as solvent. The fraction containing iridodials was re-chromatographed with CH_2Cl_2/acetone= 50/1 to obtain iridodials (0.13% yield).

Conversion of Iridodial to Nepetalinic Acid Dimethylester A compound whose chemical shifts coincided with those of *C. loochooanum* iridodial was subjected to oxidation by using pyridinium dichromate in dry dimethylformamide to form the methyl ester (O'Connor and Just 1987), in order to determine the relative configuration of *C. loochooanum* iridodial.

Chemical Analysis Capillary GC-MS analyses were carried out on a Shimadzu GC-17B system equipped with Shimadzu QP-5000 MS detector (Shimadzu Corporation, Kyoto, Japan), and a Hewlett Packard HP-6890 GC system interfaced with an HP-5973 MS detector (Agilent Technologies, Tokyo, Japan) under the following conditions: column (1) DB-1 on GC-17B (15 m×0.25 mm, film thickness 0.25 μm, J & W Scientific, Folsom, CA, USA), injection port temperature, 250°C, transfer line, 280°C, carrier gas, helium (flow, 1 ml/min), ionization voltage, 70 eV. The column temperature was kept at 50°C for 1 min, 50°C to 200°C (5°C/min); column (2) HP-5 on HP-6890 (30 m×0.25°mm, film thickness 0.25 μm, J & W Scientific), injection port temperature, 240°C, transfer line, 260°C, carrier gas, helium (flow, 1 ml/min), ionization voltage, 70 eV. The column temperature was kept at 40°C for 1 min, 40°C to 250°C (5°C/min); and column (3) β DEX 225 on HP-6890 (30m×0.25 mm, film thickness 0.25 μm, Supelco, Tokyo, Japan), injection port temperature 190°C, transfer line, 230°C, carrier gas, helium (flow, 1 ml/min). The column temperature was kept at 40°C for 1 min, 40°C to 199°C (3°C/min). When analyzing chemicals absorbed on SPME fibers on the DB-1 column, samples were introduced at 250°C via a specialized inlet liner (0.75 mm I.D., Supelco) in the injection port of the GC-MS. Samples were desorbed from the fibers for 1 min (splitless mode, 1 ml/min), and fibers were re-conditioned at 250°C for 30 min. NMR spectra were measured with JEOL LAMBDA-400 and ALPHA-500 spectrometers (JEOL, Tokyo, Japan). $CDCl_3$ was used as the solvent.

Results

A major peak and three smaller peaks were detected in the secretory volatiles from male and female *C. loochooanum* (Fig. 2). These peaks, which we assumed to be isomers of one another, were present in samples extracted both by SPME and methylene chloride. GC-MS analysis revealed similar fragmentation patterns and also the same molecular ion (*m/z* 168) for all of these peaks (Fig. 3). The diagnostic fragment ions of each peak were *m/z*: 150, 135, 111 or 109, 93, 81, and 67. Fragment ions at *m/z* 150 (M^+–18) and 135 (M^+–18–15) suggested an unstable oxygenated group and a methyl branch in the molecule. The base peak (*m/z* 81) has been observed typically in the fragment patterns of a number of iridoid monoterpenes (Regner 1972).

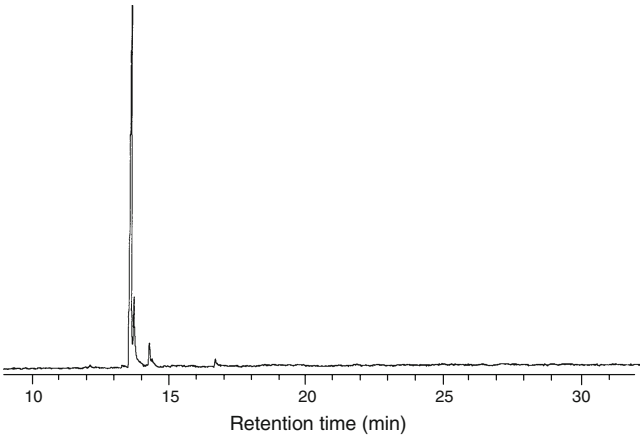

Fig. 2 Total ion chromatogram of the defensive secretion of *C. loochooanum* desorbed from an SPME fiber and analyzed with a DB-1 capillary column (15 m×0.25 mm, film thickness 0.25 μm) on a Shimadzu GC-17B instrument

The ^{1}H-NMR spectrum of the major component showed signals for 16 protons including two aldehydic protons (δ= 9.59, d, J=3.7 Hz; δ=9.63, d, J=2.4 Hz) and six methylic protons (δ=1.079, d, J=6.7 Hz; δ=1.085, d, J=7.3 Hz). No NMR analysis of the minor components was possible because of the low amount of available natural product. These chemical analyses indicated that the components were dialdehydes of cyclopentanoid monoterpenoids, i.e., various forms of iridodial.

The coupling constants of $J_{1,2}$ and $J_{1,5}$ were both 8.5 Hz, suggesting the *trans*,*trans* configuration, although some difficulties have been reported in determining the relative stereochemistry of a cyclopentanoid skeleton (Constantino and da Silva 1998). In order to determine the relative configuration of the primary defensive chemical of *C. loochooanum*, iridodials were synthesized according to Clark et al. (1959) (Fig. 4). After fractionation by silica-gel column chromatography, a compound whose chemical shifts coincided with those of the defensive secretion was subjected to oxidation according to O'Connor and Just (1987). By comparing ^{1}H- and ^{13}C-NMR spectral data of

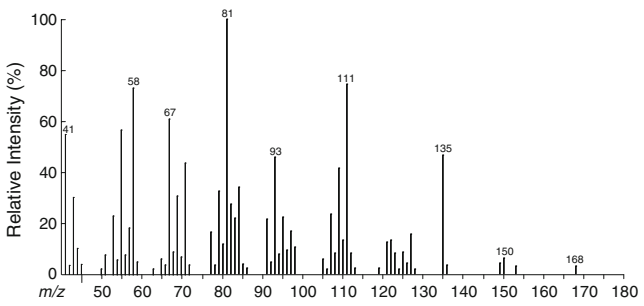

Fig. 3 Mass spectrum of the main compound in the defensive secretion of *C. loochooanum*

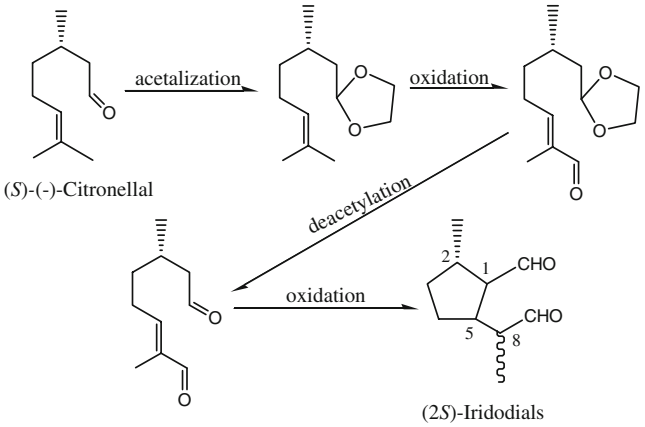

Fig. 4 Synthesis scheme of (2*S*)-iridodials from (*S*)-(−)-citronellal (Clark et al. 1959)

the resulting nepetalinic acid methyl ester with those of Sakai et al. (1981), the relative configuration of *C. loochooanum* iridodial was determined as *trans*,*trans*. According to Oldham (1994), the configuration at the 2-position in natural iridoids is exclusively (*S*)-, however, (2*R*)-isomers, e.g., boschnaloside (8-*epi*-iridodial glucoside; Murai and Tagawa 1982) and 8-*epi*-loganic acid and gmephiloside (Helfrich and Rimpler 2000) also have been reported.

The absolute configuration of *C. loochooanum* iridodial was confirmed by synthesis and GC-MS analysis. Different enantiomeric blends of citronellal, (*S*)-, (*R*)-, and a 3:1 mixture of (*S*)/(*R*), were used as the starting materials for synthesizing the corresponding iridodials. Both the defensive secretion of *C. loochooanum* and synthesized iridodials were analyzed with an enantioselective GC column by GC-MS. *C. loochooanum* iridodial coincided with iridodial synthesized from (*S*)-citronellal, but not with the one synthesized from (*R*)-citronellal (Fig. 5).

(1R,2S,5S)-Iridodial (from C. loochooanum) ^{1}H NMR (500 MHz, $CDCl_3$) δ 1.079 (3 H, d, J=6.7 Hz, H-7), 1.085 (3 H, d, J=7.3 Hz, H-10), 1.35 (1 H, m, H-3), 1.90 (2 H, m, H-3, H-4), 1.95 (1 H, m, H-4), 2.11 (1 H, t, J=3.7, 8.5, 8.5 Hz, H-1), 2.15 (1 H, m, H-2), 2.4 (1 H, t, J=1.8, 7.7, 7.7 Hz, H-8), 2.6 (1 H, m, H-5), 9.59 (1 H, d, J= 3.7 Hz, H-6), 9.63 (1 H, d, J=2.4 Hz, H-9). Discussion

Chemical ecological studies on longhorned beetles, as pests in forests, log yards, and urban settings, have advanced our knowledge of the chemical structures and biological activities of their attractants and pheromones (Fukaya et al. 1996; Allison et al. 2004). Although some cerambycids also emit defensive semiochemicals from metasternal glands (Moore and Brown 1972, 1976; Vidari et al. 1973), little is known about their function in relation to predators (Allison et al. 2004). The defensive strategies of cerambycid beetles vary among genera. Body colors are basically dark, suggesting that color mimicry of tree bark or leaves might help them hide from enemies. Some diurnally active cerambycids have aposematic coloration that mimics that of vespids (wasps), and thus protects them from predators, especially birds. For example, *Chlorophorus quinquefasciatus* (C. and G.) in the Ryukyu Islands exhibits geographic variation of its spot pattern, which coincides with vespid distribution in their habitat (Makihara 2003). In the tribe Callichromatini, *Pachytenia* sp., having a distinct two-tone color pattern, is thought to defend itself by mimicking vespids (e.g., *Vespa affinis*), whereas *Aroma moschata* (Vidari et al. 1973) and *Chloridolum* sp. are known to emit chemicals against their predators.

Our results revealed that (1*R*,2*S*,5*S*)-iridodial was secreted from the metasternal glands of the longhorned beetle, *C. loochooanum*. Iridodials are well known as defensive chemicals in many insects, e.g., the longhorned beetle, *A. moschata* (Vidari et al. 1973), ants (McGurk et al. 1968; Cavill and Houghton 1974; Attygalle and Morgan 1984; Do Nascimento et al. 1998), the stick insect, *Graeffea crouani* (Smith et al. 1979), rove beetles (Huth and Dettner 1990; Weibel et al. 2001), and leaf beetles (Burse et al. 2007). Among iridodials, *trans*,*trans*-iridodial was reported as a defensive component in the coconut stick insect, *G. crouani* (Smith et al. 1979), and in the dolichoderine ants, *Iridomyrmex* spp. (McGurk et al. 1968) and *Tapinoma nigerrium* (Oldham 1994). Structurally related iridoid monoterpenes, such as peruphasomal (Dossey et al. 2008), dolichodial (Cavill and Hinterberger 1961), anisomorphal (Meinwald et al. 1962), nepetalactone (Smith et al. 1979), chrysomelidial, and plagiolactone (Meinwald et al. 1977), also have been reported as defensive chemicals in insects. Some of these chemicals, including iridodials, have been demonstrated to have other biological activities, i.e., as attractive pheromones or interspecific repellents (allomones). In lacewings, (1*R*,2*S*,5*R*,8*R*)-iridodial has been identified as a male-produced pheromone in *Chrysopa oculata* (Chauhan et al. 2004; Zhang et al. 2004), *Chrysopa nigricornis* (Zhang et al. 2006a), and *Chrysopa septempunctata* (Zhang et al. 2006b). (4a*S*,7*S*,7a*R*)-Nepetalactone and related nepetalactols have been reported to be sex pheromones of aphids (Birkett and Pickett 2003). A silver vine, *Actinidia polygama*, produces *trans*,*cis*- and *cis,trans*-iridodials in leaves and fruits as an oviposition attractant for a gall midge, *Asphondylia matatabi*, and also produces isoiridomyrmecin, isodihydronepetalactone, and 8,9-isodehydroiridomyrmecin that are attractants and sedatives for felids (Murai and Tagawa 1994, 1997). Dolichodial and

teucrein from a cat thyme, *Teucrium marum* (Eisner et al. 2000), and nepetalactones and elemol from a catnip, *Nepeta cataria* (Schultz et al. 2004), have repellent activities for ants and house flies.

Defensive chemicals in prey are considered to cause some physiological damage to predators, and thus allow prey to escape from attack. The presence of two aldehyde groups in iridodial and related chemicals indicates high reactivity and toxicity to living cells. Various iridoidglycosides exist in plants in nonpoisonous forms derived from their aglycones, iridoid monoterpenes, which are transformed to their active forms by hydrolysis with glucosidase (Murai et al. 1987) or acetyl-transferase (Eisner et al. 2000). In insects, volatile terpenoids are stored in and emitted from glands that have cuticle layers, which are isolated from other organs (Chapman 1998). They are biosynthesized and/or sequestered from plant allelochemicals, and used for their defense (Laurent et al. 2005).

Similarly, we suggest that adult *C. loochooanum* may retain iridodial in their glands and use it during predator attacks, as residual iridodial may cause severe injury to predators. The beetle also may have other nonvolatile defenses in its body that make itself more unpalatable. Further research will be necessary to answer these ecological questions.

Acknowledgments We thank Dr. Kamlesh R. Chauhan for donation of synthetic (1*R*,2*S*,5*R*,8*R*)-, and (1*R*,2*S*,5*R*,8*S*)-iridodials for comparison with *C. loochooanum* iridodials. We also thank Dr. Motoko Tagawa for valuable advice on this work. This work was supported in part by a Grant-in-Aid for Scientific Research (nos. 16780130, 19580197) from the Japan Society for the Promotion of Science.

Effects of Soldier-Derived Terpenes on Soldier Caste Differentiation in the Termite *Reticulitermes flavipes*

Matthew R. Tarver · Eric A. Schmelz · James R. Rocca · Michael E. Scharf

Received: 18 March 2008 / Revised: 3 December 2008 / Accepted: 8 January 2009 / Published online: 6 February 2009

Abstract Primer pheromones play key roles in regulating division of labor, which is a fundamental and defining aspect of insect sociality. Primer pheromones are chemical messengers that transmit hormone-like messages among colony members; in recipients, these messages can either induce or suppress phenotypic caste differentiation. Here, we investigated soldier caste-derived chemicals as possible primer pheromones in the lower termite *Reticulitermes flavipes*, a species for which no primer pheromones have yet been identified. We determined that soldier head extracts (SHE), when provided to totipotent workers along with the insect morphogenetic juvenile hormone (JH), significantly enhanced soldier caste differentiation. When applied alone, however, SHE had no impacts on caste differentiation, survivorship, or any other aspect of worker biology. These findings support a function of soldier chemicals as primer pheromones that enhance the action of the endogenous JH. In accord with previous studies, γ-cadinene and the corresponding aldehyde, γ-cadinenal, were identified by gas chromatography–mass spectrometry and nuclear magnetic resonance analyses as the two most abundant components of *R. flavipes* SHE. Validative bioassays with commercially available cadinene confirmed activity. Several other terpenes, previously identified in *R. flavipes* soldiers, also were found to be active. These findings reveal a novel primer pheromone-like function for soldier-derived terpenes in termites and further suggest convergent evolution of terpene functions in enhancing JH-dependent soldier caste differentiation.

Keywords Termite · Soldier · Primer pheromone · Juvenile hormone · Terpene

Introduction

Social insect castes are groups of phenotypically, morphologically, and behaviorally distinct individuals that cooperate to perform colony tasks (Wilson 1971; Miura 2004). Caste differentiation plays an important and necessary role in creating an effective division of labor. Colonies must find ways to regulate caste differentiation within this system, as improper regulation could result in the overabundance or absence of specific castes, thus making colony tasks such as food acquisition, grooming, defense, and reproduction inefficient or impossible.

Polyphenisms are alternative morphological phenotypes that differentiate in response to environmental conditions (Nijhout 2003). Termites use polyphenism to produce different castes that perform complementary roles within the colony (Miura 2004). Termite colonies are made up of three distinct castes that include workers/pseudergates, soldiers, and reproductives. Only soldiers and reproductives are considered adults in lower termites, while all castes can

be adults in higher termites. Termite caste differentiation can proceed along two routes: the imaginal (winged) or the apterous (wingless) route. The first developmental branch occurs when larvae differentiate into either workers or nymphs after the second instar (Buchli 1958; Lainé and Wright 2003). Workers can (1) undergo status quo, worker-to-worker molts; (2) differentiate into presoldiers (immediately followed by soldier differentiation); or (3) differentiate into apterous and eyeless third-form reproductives, or "ergatoid neotenics". Nymphs can (1) regress into worker-like pseudergates; (2) differentiate into fully winged and eyed adult alates that disperse, mate, and become primary reproductives; or (3) differentiate into wingless and eyed nondispersive, second-form reproductives, or "brachypterous neotenics" that serve as supplemental reproductives (Buchli 1958; Lainé and Wright 2003).

Caste polyphenism in social insects is distinct from polyphenism solitary insects because multiple castes that perform nonoverlapping tasks are present in colonies at the same time (Miura 2004). Individuals in termite colonies with the same genetic background can differentiate into alternate phenotypes depending on a number of intrinsic and extrinsic factors (Lenz 1976; Greenberg and Tobe 1984; Scharf et al. 2007). One intrinsic factor is juvenile hormone (JH; Scharf et al. 2003; Park and Raina 2004, 2005; Mao et al. 2005). JH is a morphogenetic hormone produced by a neurosecretory gland, the corpus allatum, that has a broad range of developmental and physiological effects (Truman and Riddiford 1999; Gilbert et al. 2000). For example, in insects, JH plays a role in the control of larval/nymphal development and metamorphosis, diapause, migratory behavior, wing length, seasonal development, reproduction, and caste determination (Hartfelder 2000).

Primer pheromones are chemical messengers that are passed among individuals and trigger physiological responses in recipients (Wilson and Bossert 1963). Primer pheromones are distinct from "releaser" pheromones, which elicit rapid behavioral responses in recipients (Vander Meer et al. 1998). Two examples of releaser pheromones in termites are the trail pheromone, (Z,Z,E)-3,6,8-dodecatrien-1-ol (Matsumura 1968), and the phagostimulatory pheromone, hydroquinone (Reinhard et al. 2002). Although no primer pheromones have been identified in termites, JH has been proposed as one (Henderson 1998). Previous studies have shown that ectopic exposure of worker termites to JH III readily induces soldier caste differentiation (Scharf et al. 2003, 2005, 2007; Zhou et al. 2006a, b, 2007), indicating that JH can act via exogenous exposure. Under natural conditions, high endogenous JH titers in worker termites cause differentiation into presoldiers and then into soldiers (Park and Raina 2004; Mao et al. 2005). Regardless of whether it acts exogenously as a primer pheromone, an endogenous hormone, or both, the role of JH in soldier development is unique and in contrast to the immature "status quo" role of JH among insects (Henderson 1998).

It has been hypothesized that termite soldiers may play a role in regulating worker differentiation to other caste phenotypes (Henderson 1998). For example, JH titers in workers rise upon removal from the colony (Okot-Kotber et al. 1993; Mao et al. 2005) and can result in presoldier/soldier formation (Mao et al. 2005). However, if workers are held with soldiers, worker JH titers remain below threshold levels, and presoldier formation is attenuated (Mao et al. 2005; Park and Raina 2005). It has been theorized that soldiers can downregulate worker JH titers by acting as a JH "sink" (Henderson 1998; Mao et al. 2005) or by removing the inhibitory effect of another primer pheromone on worker differentiation (Park and Raina 2004, 2005; Mao et al. 2005).

Previously, Lefeuve and Bordereau (1984) investigated live soldiers and the effects of dichloromethane (DCM) soldier head extracts (SHE) on caste differentiation in the higher termite *Nasutitermes lujae* and found that SHE inhibited worker-to-soldier differentiation. They suggested that soldier termites may secrete an inhibitory pheromone that contributes to worker–soldier homeostasis in termite societies. Korb et al. (2003) also reported that DCM SHE inhibited soldier formation in the lower termite *Cryptotermes secundus*. Additionally, Okot-Kotber et al. (1991) showed that soldier formation in *Reticulitermes flavipes* was reduced by DCM SHE when co-applied in combination with synthetic JH analogs. While these studies have verified primer pheromone-like effects for SHE, no *bona-fide* termite primer pheromones have yet been identified. Thus, two important questions in termite research relate to whether or not caste-regulatory primer pheromones exist, and if so, what are their chemical structures and modes of action?

R. flavipes and its European synonym *Reticulitermes santonensis* are common and economically destructive termites in the USA and Europe. The central objective of this study was to investigate chemical constituents of *R. flavipes* SHE as possible primer pheromones. To meet this objective, we conducted studies to (1) investigate SHE effects on JH-dependent soldier caste differentiation, (2) identify SHE constituents, and (3) compare constituent activity with previously identified soldier head chemicals. Through these studies, we provide evidence supporting the idea that soldier head terpenes play roles as caste-regulatory primer pheromones in termites.

Methods and Materials

Termites R. flavipes colonies were collected from various locations on the University of Florida campus. Termites were brought to the laboratory and held for at least 2 months

before use. Laboratory colonies were maintained in darkness within sealed plastic boxes at 22°C. A total of nine colonies were tested, all of which contained male and female neotenic reproductives. Termite workers were considered workers if they did not possess any sign of wing buds or distended abdomens. Termites were identified as *R. flavipes* from sequence of the 16S mitochondrial–ribosomal RNA gene, (Szalanski et al. 2003), gut fauna (Lewis and Forschler 2004), and soldier morphology (Nutting 1990).

Dish Assays Dish assays were conducted at 27°C as described previously (Scharf et al. 2003). Paired paper towel sandwiches were treated with control, JH III, or SHE treatments in acetone. JH III (75% purity; Sigma; St. Louis, MO, USA) was provided at 112.5 μg per dish in 200 μl acetone. This quantity was chosen based on its maximal efficacy and minimal mortality observed in previous studies (Scharf et al. 2003). SHE was tested at several different quantities (see below). After solvent evaporation, sandwiches were placed in 5-cm plastic Petri dishes and then each received 150 μl of reverse osmosis water. Fifteen worker termites were placed in each dish. Every 5 days, termites were counted, presoldier formation noted, and deionized water added, if needed.

Solider Head Extracts SHE was prepared by removing and homogenizing soldier heads (~80–150 total, depending on the experiment) in acetone with a Tenbroeck glass homogenizer. SHE was fractionated with acetone through a glass Pasteur pipette, filled with approximately 250 mg of silica gel (60–200 mesh). Acetone was added to each of the resultant ten fractions to make a final volume of 50 ml.

SHE Concentration Response and Investigation of Colony Variation SHE prepared in acetone was tested on three *R. flavipes* colonies (colonies 7, 8, and 9). Seven different treatments were tested: control (300 μl acetone), JH III (200 μl acetone containing 112.5 μg JH III), SHE alone (four head equivalents), and JH III plus a range of SHE equivalents (0.5, 1, 2, and 4). Each treatment was replicated six times.

Gas Chromatography and Mass Spectrometry Thirty soldier and worker heads from two different colonies (colonies 5 and 7) were extracted as described above, and the solvent volume was reduced to 400 μl under a stream of N_2. Samples were analyzed first by gas chromatography–mass spectrometry (GC–MS; electron ionization, 70 eV) to confirm the presence of the previously identified predominant terpenoids, γ-cadinene and γ-cadinenal (Nelson et al. 2001). These compounds were quantified subsequently by using a 6890 gas chromatograph (Agilent; Santa Clara, CA, USA) coupled to a flame ionization detector as described in Schmelz et al. (2001). We also examined pine wood extracts, prepared from the same "shim" wood used to provision lab colonies (seasoned and kiln-baked), to test the hypothesis that SHE chemicals are produced in termites de novo. Fresh pine wood sawdust (1.26 g) was extracted and analyzed as described above for SHE.

To quantify semiochemical amounts in individual soldier heads, five individual soldier heads were extracted as above. Individual extracts had a final volume of 400 μl with 400 ng of nonyl acetate added as an internal standard. Samples were analyzed by GC.

Nuclear Magnetic Resonance Analysis The two main peaks of the SHE were isolated by preparative GC and analyzed by nuclear magnetic resonance (NMR). Initial preparation of SHE utilized vapor phase extraction at 80°C on polymeric adsorbent traps, followed by DCM elution to remove less volatile contaminants (Schmelz et al. 2004). Micropreparative GC used an Agilent 6890 chromatograph (He carrier gas; 5.7 ml min^{-1}; cool on-column injector set to track oven) equipped with a DB-1 column (30 m× 530 μm i.d., 0.50 μm film thickness), and with the temperature programmed from 35°C (2 min hold) at 10°C min^{-1} to 260°C (hold for 5.5 min). Recovery of GC fractions was similar to that used by Heath and Dueben (1998) with the slight modification of a glass press-fit splitter at the end of the column, coupling a 0.5-m (150-μm i.d. fused silica) capillary to the flame ionization detector (FID) and a second 0.5-m (350-μm i.d. fused silica) capillary directed to the heated transfer line. A chilled glass capillary was used for sample collection. Under these conditions, the two predominant soldier head sesquiterpenes eluted at 16.1 and 18.9 min. An authentic standard of γ-cadinene eluted at 16.1 min.

One- (1-D) and two-dimensional (2-D) NMR spectra were acquired at 20°C with standard techniques using TopSpin® (version 2.1) software on a Bruker Avance-II-600 spectrometer equipped with a 1-mm high-temperature superconducting CryoProbe (Brey et al. 2006). Solutions of SHE γ-cadinene (~10 μg/15 μl), authentic γ-cadinene (~25 μg/17 μl), and SHE γ-cadinenal (50 μg/10 μl) were prepared in $CDCl_3$ (99.96 atom % D) and analyzed in 1 mm outer dimension×0.73 mm indirect dimension (ID)× 100 mm long capillary NMR tubes (Norell, Inc.). Proton spectra were acquired at 600.23 MHz with a 2.48-s acquisition time and a 3-s relaxation delay. The ^1H chemical shift axis was referenced to $CHCl_3$ and assigned to 7.26 ppm (Gottlieb et al. 1997). Two-dimensional $^1H/^1H$-COSY data sets (SW=8 ppm, AT=0.21 s, RD=2 s, two to eight transients) were acquired with Bruker's "cosygpqf" pulse sequence as 2048 complex points in the directly detected dimension (DD) and 512 increments in the ID and

processed with sine-function apodization into 1,024×1,024 point spectra. Carbon-13 spectra were acquired at 150.93 MHz. The ^{13}C chemical shift axis was referenced to $CDCl_3$, assigned to 77.16 ppm (Gottlieb et al. 1997). Multiplicity edited 2-D $^{1}H/^{13}C$-HSQC data sets (^{1}H SW= 8 ppm, ^{13}C SW=170 ppm, AT=0.14 s, RD=2 s, 48–96 transients) were acquired with Bruker's "hsqcedetg-psisp2.2" pulse sequence as 1,348 complex points in the DD dimension and 256 increments in the ID dimension and were apodized with cosine-squared functions into 2,048× 512 point spectra.

Testing of Previously Identified Chemicals Chemicals (or close structural analogs) were tested individually in dish assays on a single *R. flavipes* colony (colony 5). All treatments were applied at 50 μg/dish, with and without JH III (300 μl acetone containing 112.5 μg JH III). Individual chemical treatments were provided at a quantity equivalent to approximately 1/2 the JH III dose; this amount (50 μg/dish) approximates endogenous cadinene levels found in 25 soldier head equivalents, based on GC–MS analysis. Treatments were as follows: controls (in 300 μl acetone), SHE (four head equivalents in acetone), α-humulene (Aldrich, St. Louis, MO, USA), β-farnesene (Bedoukian, Danbury, CT, USA), cadinene (Vigon International, East Stroudsburg, PA, USA), geranyl linalool (Acros, NJ, USA), linalool (Aldrich), farnesol (Bedoukian), (+)β-pinene oxide (Acros), limonene (Aldrich), nootkatone (Bedoukian), nerolidol (Bedoukian), α-pinene (Acros), and geranylgeraniol (Sigma Aldrich). Control treatments were acetone, JH III, SHE, and JH III+SHE. Each treatment was replicated three times.

Statistical Analyses In all experiments, the number and caste of each termite in each dish was counted every 5 days. The percentage of presoldiers formed out of the total number of workers put into each assay was used for statistical analysis (Scharf et al. 2003, 2005; Zhou et al. 2006a, b). Data were first analyzed for normality using the *Levene* test. If not normal, data were transformed to ranked averages and means separated using the Tukey–Kramer test ($P<0.05$). For bioassays of previously identified soldier chemicals, ranked averages were separated using a least significant difference Student *t* test ($P<0.05$).

Results

SHE Concentration Response Three colonies were examined in SHE dose–response bioassays using SHE (Fig. 1). Two of the three colonies responded similarly, but one (colony 9) responded slightly differently, which led to a significant *colony* effect in the analysis of variance (df= 2,117, F=4.79, P=0.01). Nonetheless, a pooled dose–response analysis of the three colonies was conducted. Presoldier induction increased significantly when termite workers were co-exposed to SHE and JH III, as compared to treatments of JH III alone ($P<0.05$). Controls treated with either acetone or SHE alone resulted in no presoldier formation. Presoldiers first appeared between days 10 and 15 and reached maximum levels by day 25 in all SHE+JH III and JH III-alone treatments. This analysis verified that SHE does indeed cause a significant increase in presoldier formation when combined with JH III; however, this effect is not dose dependent in the range of 0.5–4 head equivalents (df=6,117, F=32.32, $P<0.001$). Data from additional experiments are provided in Fig. S1 and Table S1 (see Supplementary Material).

GC–MS and NMR Analysis GC–FID analyses of SHE identified two major sets of peaks (Fig. 2). Profiles of the peaks were similar to those reported by Zalkow et al. (1981) and Nelson et al. (2001), who identified γ-cadinene and γ-cadinenal as major whole-head extract components. The major peak in the first set was identified as γ-cadinene by comparing its mass spectrum (see Fig. S2, supplementary material), GC retention time and NMR spectra (1-D ^{1}H, 2-D $^{1}H/^{1}H$-COSY, and $^{1}H/^{13}C$-HSQC) with those of an authentic sample (kindly provided by Dr. Bartelt, USDA-ARS-NCAUR; Peoria, IL, USA) and literature values (Quintana et al. 2003).

The corresponding γ-cadinenal, the major peak of the second set of peaks, was identified by comparison of its ^{1}H NMR (see data below) and mass spectra (Fig. S2, supplementary material) to those reported by Kaiser and Lamparsky (1983). Since we observed some small differences between their 400 MHz ^{1}H spectrum and ours at 600 MHz, we also report the details of our ^{1}H NMR spectrum here, along with the 15 chemical shifts for the ^{13}C NMR resonances of the SHE γ-cadinene aldehyde.

NMR results are as follows ^{1}H: δ 9.47 (s, 1 H), 6.91 s, 1H), 4.74 ("d", J=1.5, 1 H), 4.62 ("d", J=1.3, 1 H), 2.52–2.46 (m, 1 H), 2.44 (ddd, J=2.9, 4.0, 13.0, 1 H), 2.26 (d septets, J=3.3, 6.9, 1 H), 2.15–2.07 (multiplets, 2 H), 2.06 (broad dt, J=4.5, 13.1, 1 H), 1.97–1.91 (t of "five-line patterns", 1H), 1.90–1.84 (multiplets, 2 H), 1.50–1.41 (multiplet, 1 H), 1.42 (tt, J=3.2, 11.6, 1 H), 1.21 (dq, J=4.2, 12.8, 1 H), 0.99 (d, J=6.9, 3 H), and 0.82 (d, J=6.9, 3 H). ^{13}C NMR results are as follows: δ 194.76, 151.78, 151.75, 141.77, 104.65, 46.37, 46.05, 44.07, 36.05, 26.69, 26.65, 24.45, 21.87, 21.57, and 15.34.

The average amount of γ-cadinene and γ-cadinenal from soldiers was 1.44±0.29 and 9.42±1.75 μg, respectively, with the amount of γ-cadinenal being significantly higher than the amount of γ-cadinene (df=1,8, F=20.29, P=

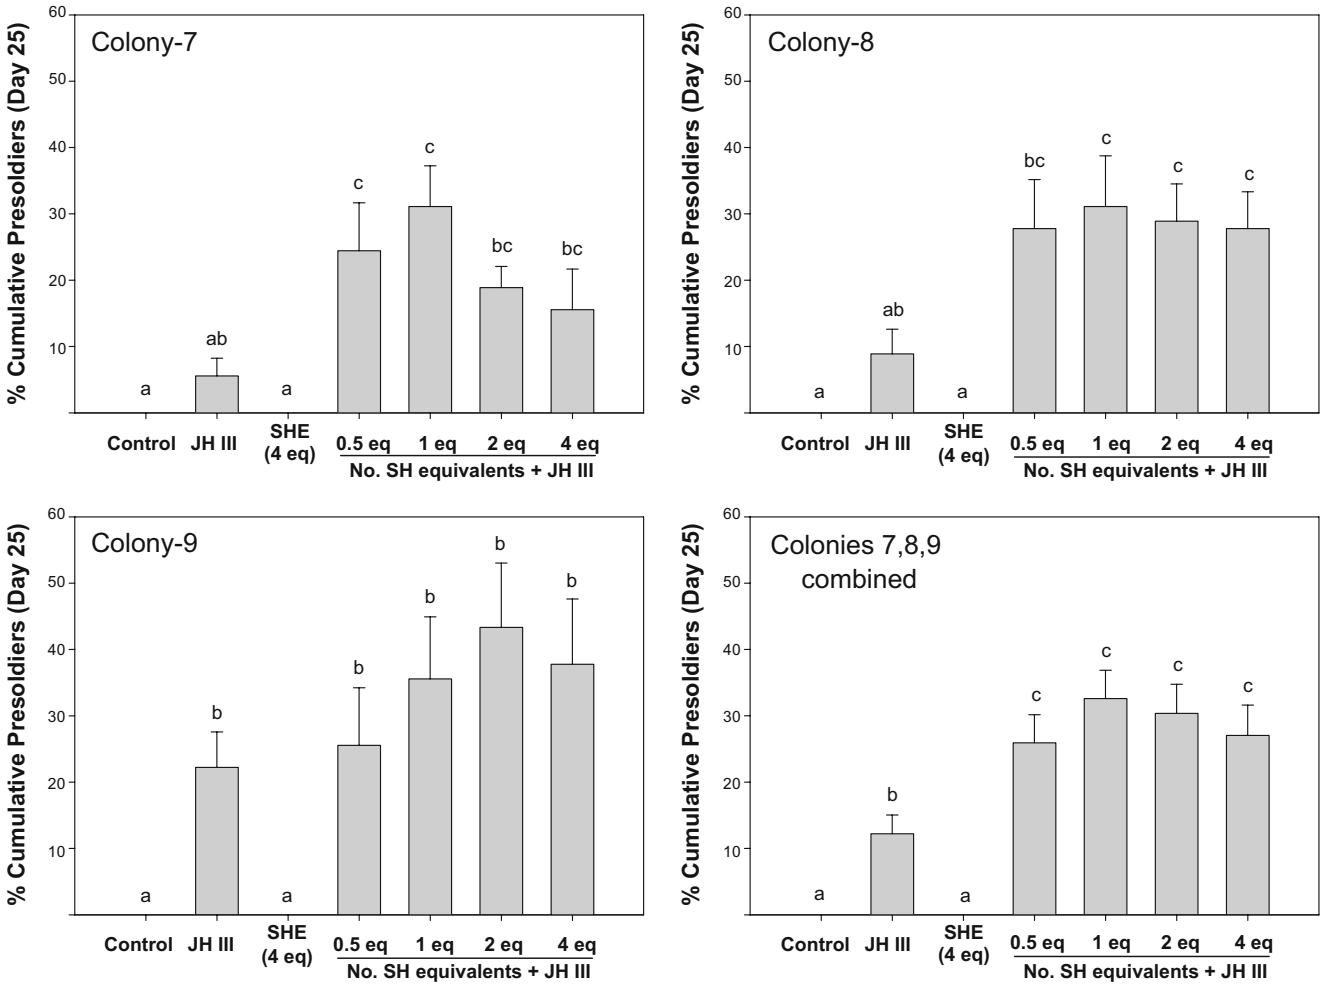

Fig. 1 Percentage formation of presoldier *R. flavipes* in various treatments of workers exposed to soldier head extract (*SHE*) dosages [head equivalents (*eq*)], juvenile hormone III (*JH III*), or control (acetone) for 25 days. Each treatment was replicated six times on three different colonies (7, 8, and 9). The *graphs* for colonies 7, 8, and 9 show cumulative average ± standard error presoldier induction through assay day 25 for each of the separate colonies. The *graph at the bottom right* shows cumulative average ± standard error presoldier induction for the combined colony responses. *Letters* represent significant differences at $P<0.05$

0.002). Although detectable in worker extracts, the respective amounts of the two chemicals was substantially less than in SHE (Fig. 2). Pine wood extracts (Fig. 2) did not have detectable amounts of the two chemicals or of related chemicals, supporting *de novo* production of cadinene and cadinenal.

Cadinene and Previously Identified Soldier Chemicals Enhance JH-Induced Presoldier Differentiation Twelve previously identified soldier head chemicals were tested for ability to induce presoldier formation in dish assays. All of these, except nootkatone and nerolidol, when tested in combination with JH III, caused significant increases in presoldier differentiation relative to JH III alone. When tested without JH III, none caused presoldier differentiation (df=26,63, F=14.46, $P<0.001$) (Fig. 3). Similar to previous assays, no presoldiers were observed in acetone controls, but high levels of presoldier induction (~80%) were observed in SHE+JH III treatments. Treatments of JH III alone induced significantly lower presoldier levels (~20%), comparable to results of preceding experiments (see above).

Discussion

In previous research, termite soldier-produced chemicals have been investigated mostly as a taxonomic tool for species identification (Zalkow et al. 1981; Prestwich 1983; Bagnères et al. 1990; Nelson et al. 2001; Quintana et al. 2003; Nelson et al. 2008). Such research has identified a number of compounds in soldier secretions, but little consideration has been given to roles of these chemicals

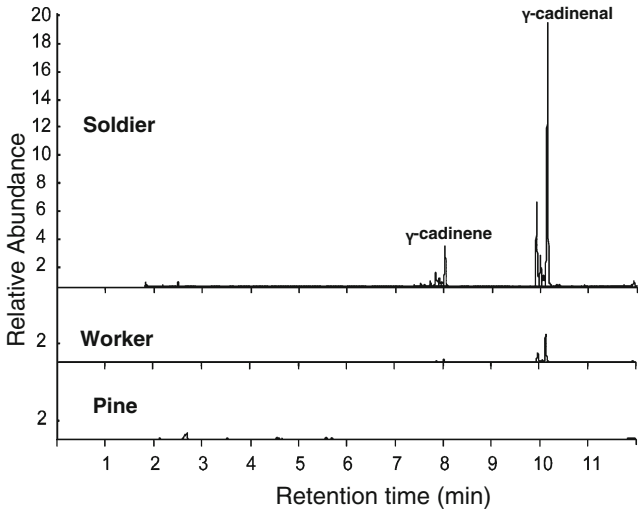

Fig. 2 Gas chromatograms (flame ionization detection) of acetone extracts prepared from heads of 30 soldier (*top*) and worker (*middle*) *R. flavipes*, as well as 1.26 g of seasoned pinewood (*bottom*). Pinewood was seasoned and identical to that used to feed termite colonies

in caste differentiation. The study presented here confirms the effects of *R. flavipes* SHE on JH-induced presoldier differentiation. Results from multiple bioassays on different colonies at different times of the year indicated that SHE synergistically increased worker to soldier morphogenesis when applied in combination with JH III. These findings support the idea that the soldier caste, in addition to playing a defensive role, also plays a part in caste regulation within termite society (Henderson 1998).

Our study also supports previous research showing that ectopic JH III treatments cause some workers to molt into presoldiers (and onto soldiers; Scharf et al. 2003, 2005, 2007; Zhou et al. 2006a, b). The JH III mediated worker-to-soldier molt is an atypical example of a JH III response when compared to other insect groups. In most insects, JH causes insects to remain as immature forms during a molt, while the absence of JH causes the insect to molt into an adult form. Thus, termites have apparently co-opted JH for a different function than other insect groups.

The combination of SHE with ectopic JH III treatments synergistically enhanced presoldier development relative to JH III alone, while SHE by itself caused no presoldier induction. This suggests that SHE probably does not contain significant quantities of JH. Preliminary thin layer chromatographic and GC-MS separations of JH III and SHE showed no common components (MRT unpublished), supporting the absence of JH III in SHE. Therefore, in our assays, we conclude that chemicals from soldier heads modulate the termite response to ectopically applied JH III, thereby enhancing JH III activity. We hypothesize that, endogenously, the synergistic effect of these SHE terpenes is manifest only in individuals with elevated JH titers.

The results from this study are in contrast with past reports that concluded that soldiers and extracts from soldiers inhibit presoldier formation (Lefeuve and Bordereau 1984; Okot-Kotber et al. 1991; Korb et al. 2003). There are several differences between the current and past research that could at least partially explain these discrepancies. First, Lefeuve and Bordereau (1984) exposed groups of 200 workers of the higher termite *N. lujae* to one of three treatments, specifically, nothing, live soldiers, or SHE extracted in DCM. Differences between this and our study include extraction solvent, termite species, and group size. Korb et al. (2003) tested the effect of precocene II, an allatectomizing agent, and SHE extracted in DCM on whole colonies of the lower termite, *C. secundus*. Differences between our study and that of Korb et al. (2003) include solvent, termite species, and treatment size. Korb et al. also did not test precocene in combination with natural JH or SHE. Okot-Kotber et al. (1991) tested combinations of methoprene and SHE extracted in DCM on *R. flavipes* in a dish assay, similar to ours, and found that the combination resulted in less presoldier formation than treatments of methoprene alone. In unreported work, we found no difference between SHE extracted in DCM or acetone (Table S1 and Fig. S1, supplementary material), eliminating the effect of solvent. However, we used JH III in our study while Okot-Kotber et al. (1991) used the JH analog methoprene. Other factors that may explain some of the differences between our study and the preceding ones may be colony conditions at the time of testing and the time of year at which testing was performed, e.g., responses to SHE and JH may vary among termite colonies as well as within a colony over a year according to season.

While our results suggest components of *Reticulitermes* SHE function as primer pheromones, soldier secretions of other termite species have bona fide defensive functions. For example, *Coptotermes* soldiers produce latex that defends against predators (Prestwich 1983, 1984; Abe et al. 2000). Also, the classic example of termite soldier defensive chemicals comes from the higher Nasute termites, which lack mandibles and defend the colony by expelling materials from their frontal gland reservoir onto their enemies (Miura and Matsumoto 2000; Hojo et al. 2005, 2007). Our proposed primer pheromone function for *Reticulitermes* head chemicals is supported by a study by Zalkow et al. (1981) who assayed a number of *R. flavipes* and *Reticulitermes virginicus* soldier head chemicals against the native fire ant, *Solenopsis geminata*. Their results indicated the ants had not been sprayed with an irritant or toxicant and that the soldier head chemicals have nondefensive functions.

No evidence was obtained in the present study to suggest that the chemicals are expelled from soldiers. One

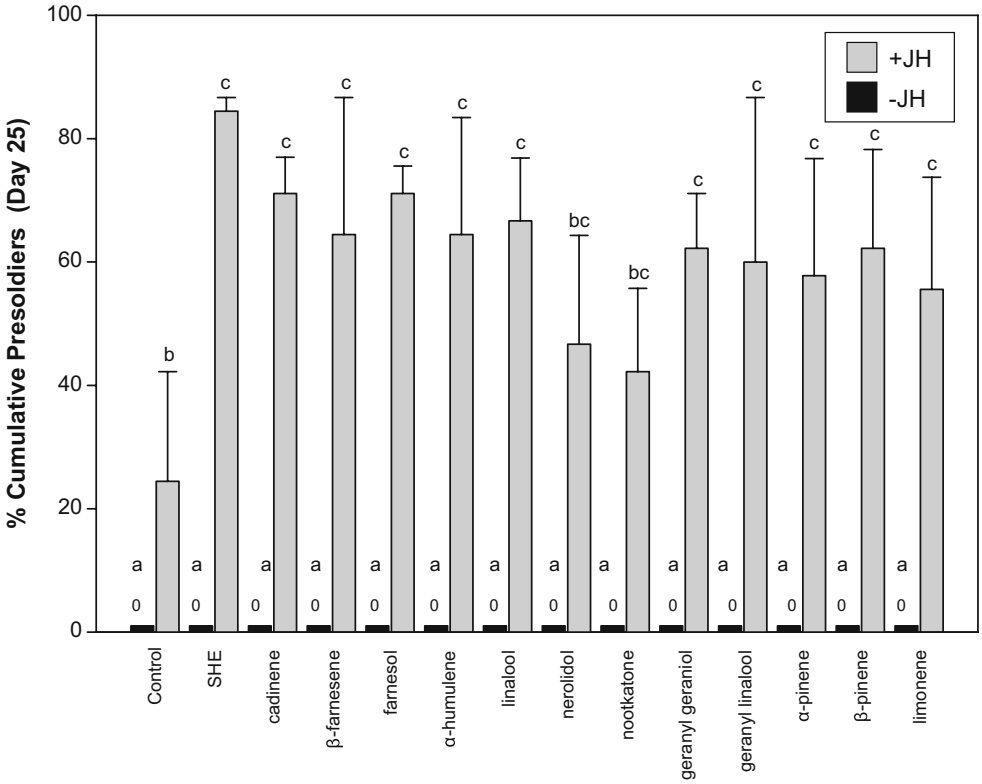

Fig. 3 Twelve previously identified soldier chemicals were tested for their ability to induce presoldier differentiation, alone and in combination with juvenile hormone III (at 150 μg), along with a control (300 μl acetone), and soldier head extract (at four head equivalents). All soldier head chemicals were tested at 50 μg/dish. Each treatment was replicated three times. The *graph* shows cumulative average ± standard error presoldier induction through assay day 25. *Letters* represent significant differences at $P<0.05$

explanation for the soldiers having a large amount of putative primer pheromone in their heads is to serve as a recruiting mechanism after an individual soldier is killed. For example, if a soldier is killed when defending the colony, the chemicals acquired while disposing of the body may signal nestmate workers to differentiate into soldiers. Since workers also contained small amounts of cadinene and cadinenal, another possibility is that soldiers may absorb and sequester these compounds away from workers thus suppressing worker differentiation. For example, live soldiers suppress worker JH titers and inhibit presoldier formation (Park and Raina 2004; Mao et al. 2005). Future research efforts will test hypotheses relating to impacts of live and dead soldiers in nestmate differentiation and terpene sequestration.

Of the soldier head terpenes identified in previous research, all but two significantly enhanced JH-induced presoldier formation when combined with JH III at a ratio of 1:2 (terpene/JH). When applied at the same concentration without JH III, however, none of the terpenes induced presoldier formation. This suggests that *Reticulitermes* have the ability to utilize an array of terpenes as cues to trigger soldier caste differentiation, provided that endogenous JH titers are above critical thresholds. Future research should determine what structural features of the terpenes are necessary for activity.

The regulation of termite caste differentiation is important in maintaining social structure and function, and therefore, the disruption of termite caste differentiation/homeostasis may be able to be used as a control method. By using the termite's own chemistry (i.e., soldier-derived terpenes), it may be possible to develop a specific termiticide that causes a large proportion of worker termites to molt into soldiers. Because soldier termites cannot feed themselves, this would likely cause the termite colony to starve or at least have a severe effect on the colony. For example, in our study (data not shown), mortality was the greatest in replicates in which a high proportion of worker termites molted into presoldiers.

In summary, the findings presented here verify a role beyond defense for the soldier caste within termite societies, as initially proposed by Henderson (1998). These results indicate that non-JH terpenes from termite soldier castes can influence caste polyphenism in nestmates. The results help identify part of the complex chemical communication system that termites utilize to maintain a balanced social environment.

Acknowledgments We thank Drs. Nancy Denslow, Daniel Hahn, Mike Haverty, Larry Cool, and Faith Oi for helpful discussions; Caitlin Buckspan for bioassay assistance; Marsha Wheeler and Jody Green for review of the manuscript; and Dr. Robert J. Bartelt (USDA-ARS NCAUR, Peoria, IL, USA) for providing an authentic sample of (+)-γ-cadinene. The authors acknowledge the National Science Foundation for financial support through the User Program of the National High Magnetic Field Laboratory, which supported our NMR studies. The 600 MHz 1-mm HTS cryogenic NMR probe used in this

work was developed through a collaboration among UF, the NHMFL, and Bruker BioSpin, which was funded by a National Institutes of Health grant (P41RR016105). This work was supported by USDA-CSREES-NRI grant no. 2007-35607-17777 to M.E.S.

Factors Influencing Responses to Alarm Pheromone by Larvae of Invasive Cane Toads, *Bufo marinus*

Mattias Hagman · Richard Shine

Received: 21 July 2008 / Revised: 18 December 2008 / Accepted: 4 January 2009 / Published online: 30 January 2009

Abstract If pheromonal communication systems of invasive species differ from those of native biota, it may be possible to control the invader by exploiting that difference. When injured, the larvae of cane toads, *Bufo marinus*, an invasive species of major concern in tropical Australia, produce species-specific chemical cues that alert conspecific tadpoles to danger. Repeated exposure to the alarm chemical reduces tadpole survival rates and body sizes at metamorphosis and, thus, could help control toad populations. To evaluate the feasibility of this approach, we need to know how the intensity of toad tadpole response to the alarm chemical is affected by factors such as water temperature, time of day, larval stage and feeding history, geographic origin of the tadpoles, and habituation. Information on these topics may enable us to optimize deployment, so that tadpoles encounter pheromone at the times and places that confer maximum effect. In our studies, tadpole density, nutritional state, larval stage, and geographic origin had little effect on the intensity of the alarm response, but tadpoles reacted most strongly in higher water temperatures and during daylight hours. Repeated, once-daily exposure to pheromone did not induce habituation, but repeated exposure at 15-min intervals did not elicit further responses after 2 h total exposure. The insensitivity of response to most factors tested means that the effectiveness of the pheromone as a control agent should be relatively robust.

Introduction

The frequency with which species are being translocated outside their natural range is increasing rapidly due to anthropogenic activities. Thus, there is need of new ways to mitigate the ecological impacts of such taxa (Newsome and Noble 1986; Hengeveld 1989; Parker et al. 1999). One of the primary criteria for any control method is that it targets the invader, without affecting native biota. Such specificity may involve any distinctive trait of the invader, but phylogenetically conservative communication systems offer special promise (Beroza and Knipling 1972; Dalesman et al. 2007). Extensive work with sex pheromones in insects has confirmed the value of this method (e.g., Pelozuelo and Frerot 2006). Vertebrates have attracted less attention in such studies, but may be suited to a similar approach. For example, larvae of many anuran species have well-developed pheromonal communication systems (Summey and Mathis 1998; Spieler and Linsenmair 1999; Rajchard 2006), and Wassersug (1997) suggested that we may be able to exploit such systems to fight invasive species of anurans.

One invasive amphibian of major concern worldwide is the cane toad, *Bufo marinus* (allocated to the genera *Chaunus* or *Rhinella* by some authors—Frost et al. 2006; Pramuk 2006), a large and highly toxic species from Central and South America (Lever 2001). Introduced to more than 30 countries worldwide in attempts to control agricultural pests, toads are now widely recognized as a major ecological problem in many of those areas. For example, the toads introduced to northeastern Australia in

1935 have since spread over tropical areas of that continent, causing extensive mortality (through poisoning) of native frog-eating predators (Burnett 1997; Crossland and Alford 1998; Phillips et al. 2003). Despite massive expenditure, current approaches to cane toad control have failed to curtail the rate of toad invasion (Peacock 2007). New approaches are needed.

Recent work has identified one such possibility. When injured, cane toad larvae produce species-specific chemicals that alert conspecific tadpoles to the proximity of danger (Hagman and Shine 2008a). Tadpoles of native frog species rarely react to this chemical cue (Hagman and Shine 2008b). Importantly, repeated exposure to the pheromone reduces not only toad tadpole survival but also body size at metamorphosis, potentially rendering the newly transformed toad more vulnerable to other mortality sources (Hagman et al. 2009). In combination, these results suggest that applying the chemical cue to natural waterbodies may reduce toad recruitment without collateral damage to native anurans (Hagman and Shine 2008b).

Despite these encouraging findings, many difficulties with practical implementation remain, with extrapolation of laboratory results to the field, problematic. One fundamental question involves the degree to which the intensity of tadpole responses to the alarm chemical depends upon external and internal factors. If the response is seen only over a limited range of external conditions (e.g., water temperatures, times of day, levels of food availability), demographic traits (e.g., population densities), or tadpole characteristics (e.g., geographic location of the source population, stage of larval development), then it may be difficult to deploy the pheromone effectively in the field. Similarly, if tadpoles rapidly habituate to the stimulus, long-term exposure may have little effect on their viability.

Ultimately, empirical evaluation of tadpole responses to such factors should be conducted in the field, and should focus on attributes (such as tadpole survivorship and body sizes at metamorphosis) tightly linked to toad population viability. In the first instance, however, it is easier logistically to conduct such an evaluation in the laboratory and to focus on the behavioral response (avoidance) elicited by the chemical cue. Although less directly linked to toad control, behavioral responses are easier to measure and seem to be part of the causal chain by which alarm chemicals reduce tadpole viability. This paper describes a series of experimental studies designed to evaluate factors that may influence tadpole responses to the alarm pheromone. The work is of interest in more general terms because the proximate determinants of anuran larval responses to chemical cues that predict predator presence are poorly known (Fraker 2008a, b).

Methods and Materials

Study Specimens and Husbandry Adult cane toads collected from populations in Queensland and the Northern Territory provided our breeding stock. Animals were kept in outdoor cages at our facilities on the Adelaide River floodplain in the Northern Territory, Australia. We induced spawning by subcutaneous injections of 0.5–0.75 ml of leuprorelin acetate (Lucrin, Abbott Australasia) diluted in amphibian Ringers' solution to a concentration of 0.25 mg/ml. After eggs hatched, tadpoles were kept in sibling groups of a few hundred individuals in plastic tubs containing 700 l of water (de-chlorinated well water, as was all water used in the experiments described below). We fed tadpoles with boiled lettuce twice a week and changed their water weekly. All tadpoles were raised to stage 21–23 (Gosner 1960) before use, except when stated otherwise.

Experimental Equipment and Procedures We prepared the stimulus by macerating 0.2 g of cane toad tadpoles (rapid crushing ensured that they were killed instantly) in 50 ml of water; this solution was diluted to a volume of 1 l (in water) and then filtered through filter paper. To score tadpole responses, we stained the stimulus green (with food dye: 421067, Queen Fine Foods, Alderley, Qld.), so that we could see when a tadpole encountered it; pilot studies (and controls run simultaneously with treatments) showed that the dye itself did not induce any responses by tadpoles. For controls, we used de-chlorinated and stained well water; these were run at the same time as each experimental group in adjacent containers (randomly allocated). Unless stated otherwise, we used 50 naïve tadpoles per trial. These tadpoles were placed in plastic containers ($0.5 \times 0.4 \times 0.3$ m) with 5 l of water. For a trial, we dispensed 5 ml of freshly prepared stimulus from a syringe along one side of the experimental arena and recorded the behavior of the first 20 tadpoles that encountered the stimulus. In earlier work, we reported that cane toad larvae flee from extracts of crushed conspecifics (Hagman and Shine 2008a, b). We scored repulsion by observing changes to the tadpole's direction of movement when it encountered the stimulus. We scored a tadpole as unaffected if it swam through the stimulus without an overt change in behavior and as repulsed if it abruptly changed its direction in a way that took it away from the stimulus. All procedures were approved by the University of Sydney Animal Ethics Committee.

Does Nutritional Status Influence Tadpole Responsiveness to These Chemical Cues? We compared the numbers of tadpoles repulsed by the stimulus as a function of the time since last feeding. One group was fed the same day as the experiment, whereas food was withheld from the other group for 3 days prior to testing. We used two clutches

from the Fogg Dam population, and our comparisons were between siblings (total of 50 trials per treatment).

Does Water Temperature Influence Tadpole Responsiveness to These Chemical Cues? We scored repulsion to cues from crushed conspecifics at three different water temperatures: 10°C, 21°C, and 31°C. Tadpoles originated from adult toads collected around the towns of Cairns, Normanton (Queensland), Fogg Dam, and Timber Creek (Northern Territory).

Does Time of Day Influence Tadpole Responsiveness to These Chemical Cues? Using tadpoles from the same clutches, as in the previous paragraph, we tested whether the tadpole responses varied throughout the day. We exposed tadpoles to cues from crushed conspecifics every third hour from 0600 to 0300 hours. To clarify the direct influence of illumination levels (versus endogenous circadian periodicity in response), we also conducted the experiment in a darkened room at noon and a brightly illuminated room (using fluorescent lighting) at midnight. Illumination levels averaged 90 lx with the lights on and were undetectably low with the lights switched off (based on a Minolta flash meter).

Does Responsiveness to Chemical Cues from Injured Conspecifics Vary With Ontogeny? We scored repulsion in tadpoles at developmental stages from 20 to 45 (Gosner 1960), in progeny from eight clutches spawned by adult toads from four populations (i.e., two clutches from each population). Two of these populations were from Queensland (Cairns and Normanton), and the other two (Timber Creek and Fogg Dam) were from the Northern Territory.

Does Tadpole Density Influence Larval Responsiveness to These Chemical Cues? We manipulated the number of tadpoles in our experimental arenas to 20, 40, 60, 80, or 100 tadpoles per container and scored repulsion as described previously. For this experiment, we used tadpoles from two clutches of the Fogg Dam population.

Do Cane Toad Larvae Become Habituated to These Chemical Cues? To explore habituation, we conducted two sets of repeated repulsion trials. In one, tadpoles were exposed daily to alarm chemical cues for 15 days in succession. In the other, we exposed a group of tadpoles to alarm chemical cues at 15-min intervals over 5 h. For both of these trials, we used tadpoles from the Cairns and Timber Creek populations.

Results

Does Nutritional Status Influence Tadpole Responsiveness to These Chemical Cues? We never observed repulsion to the control treatment (water with food dye) but both food-deprived and recently fed tadpoles showed high levels of response to the treatment (mean repulsion observed=18.63/20 food-deprived tadpoles, and 16.8/20 recently fed tadpoles). Clutch means were virtually identical ($P>0.99$), so we deleted this factor from future analyses. Two-factor analysis of variance (ANOVA) with pheromone treatment and feeding history as factors revealed a highly significant interaction term ($F_{1,92}=14.32$, $P<0.001$) because the effect of the pheromone on repulsion was higher in food-deprived, than in recently fed, tadpoles. However, the magnitude of the disparity was relatively low, as noted above.

Does Water Temperature Influence Tadpole Responsiveness to These Chemical Cues? We analyzed these data with analysis of covariance (ANCOVA; clutch identity and treatment as factors, temperature as a covariate, number of repulsed tadpoles as the dependent variable). As before, all clutch effects were nonsignificant (all main effects and interactions had $P>0.82$). Repulsion was never observed in controls, but was frequent in tadpoles exposed to chemical cues from crushed conspecifics, especially at high temperatures (Fig. 1a). The interaction between temperature and pheromone effect was significant ($F_{1,272}=867.57$, $P<0.001$) because tadpoles never exhibited repulsion at 10°C, rarely did at 21°C, but almost always did so at 31°C (Fig. 1a).

Does Time of Day Influence Tadpole Responsiveness to These Chemical Cues? We analyzed these data by using repeated-measures ANOVA, with clutch identity and exposure to the alarm pheromone as the factors, time of day as the repeated measure, and number of tadpoles (out of 20) showing repulsion as the dependent variable. Clutch effects were nonsignificant (main effects and interactions, all $P>0.075$). A highly significant interaction between treatment and time of day was apparent ($F_{7,616}=160.42$, $P<0.001$), reflecting a trend for the pheromone to induce stronger repulsion if administered during the morning (highest at 0900 and 1200 hours) than in the afternoon or at night (lowest at 2400 and 0300 hours, see Fig. 1b).

To determine whether this diel variation was induced directly by ambient illumination levels or an endogenous circadian periodicity, we repeated the experiment in a darkened room at noon and an illuminated room at midnight. Repulsion was more common in the darkened room at noon (mean=16.8/20 tadpoles repulsed) than in the illuminated room at midnight (mean=4.6/20 tadpoles repulsed; interaction pheromone treatment×illumination treatment, $F_{1,88}=306.97$, $P<0.001$). Hence, endogenous periodicity had more effect than ambient illumination on the level of tadpole response.

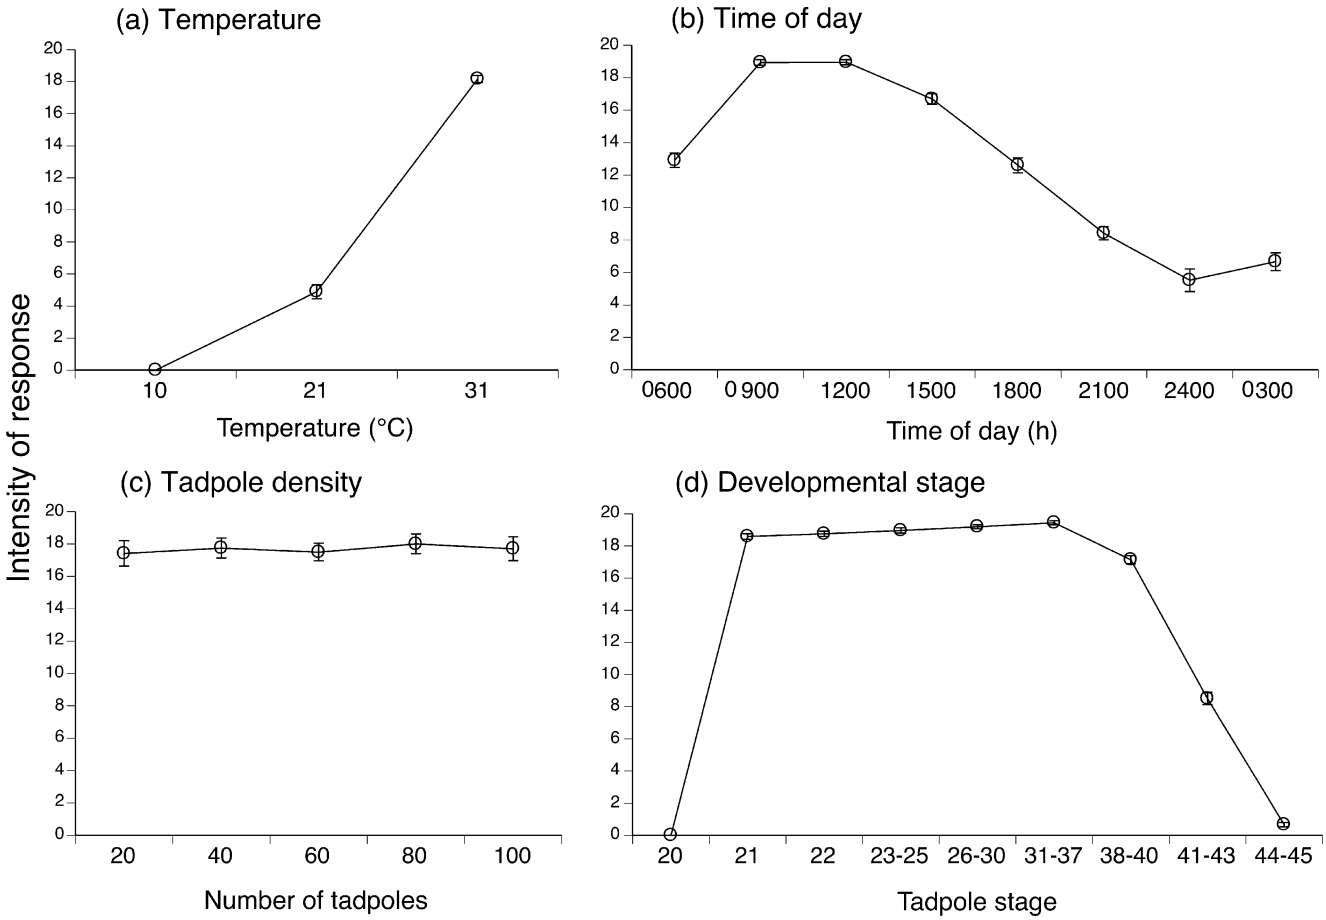

Fig. 1 Effects of experimental conditions on the mean number of cane toad, *Bufo marinus*, tadpoles (out of 20 per trial) repulsed from chemical cues from crushed conspecific tadpoles: **a** water temperature, **b** time of day, **c** tadpole density, **d** tadpole developmental stage. Controls (water without crushed-tadpole cues) were run simultaneously, but never elicited repulsion and are not shown. SEs of means are given

Does Population Density Influence Tadpole Responsiveness to These Chemical Cues? We analyzed these data with ANCOVA (clutch identity and treatment as factors, number of tadpoles per container as the covariate, number of repulsed tadpoles as the dependent variable). Exposure to alarm pheromones increased the incidence of repulsion (main effect, $F_{1,184}=496.72$, $P<0.001$), but no other factors (clutch, density, interactions) influenced repulsion rates (all $P>0.56$). Thus, over the fourfold range of densities used (20 to 100 tadpoles per container), density did not affect the tadpoles' responses to the chemical cue (Fig. 1c).

Does Responsiveness to Chemical Cues from Injured Conspecifics Vary With Ontogeny? Although we used different tadpoles at each developmental stage, we analyzed the resulting data by using repeated-measures ANOVA, with clutch identity and exposure to the alarm pheromone as the factors, developmental stage as the repeated measure, and number of tadpoles (out of 20) showing repulsion as the dependent variable. As before, clutch identity did not explain significant variance (main effect and all interactions, $P>0.12$). A significant interaction was apparent between developmental stage and treatment ($F_{8,704}=1811.34$, $P<0.001$), reflecting nonresponse in the earliest stage, high and consistent responses in tadpoles of Gosner stages 21 to 40 (i.e., most of development), and a diminution of response immediately prior to metamorphosis (stages 41 to 45: see Fig. 1d).

Do Cane Toad Larvae Become Habituated to These Chemical Cues? We analyzed these data by using repeated-measures ANOVA (clutch identity and exposure to the alarm pheromone as factors, successive exposure periods as the repeated measure, and number of tadpoles showing repulsion as the dependent variable). We looked at habituation both over a long timescale (exposure every day for 15 days, comprising most of the total larval period) and a much shorter timescale (every 15 min for 5 h).

In long timescale trials, tadpoles from a Timber Creek (NT) clutch exhibited higher repulsion levels than did a clutch from Cairns (Qld: treatment×population, $F_{1,44}=5.09$, $P<0.03$) throughout the study (interaction time×clutch, $F_{14,616}=0.95$, $P=0.51$). The mean level of repulsion also

changed over time (treatment×day no., $F_{14,616}=2.62$, $P<0.001$). However, the effect was relatively minor and perhaps not biologically significant, with mean response levels per day ranging only from 17.7 to 19.2 repulsions out of 20 (Fig. 2a).

In short timescale trials, response levels were high for the first 2 h, then declined precipitously (time×treatment, $F_{20,880}=1044.25$, $P<0.001$; Fig. 2b). As in the longer-term trials, the Timber Creek tadpoles were more responsive than their Cairns counterparts (treatment×population, $F_{1,44}=4.98$, $P<0.035$) throughout the study (interaction time×clutch, $F_{20,880}=1.31$, $P=0.17$).

Discussion

As in our earlier studies (Hagman and Shine 2008a, b), exposure to chemical cues from injured conspecifics induced a strong avoidance response in cane toad tadpoles, whereas control treatments had no effect. Sensitivity of the pheromone-avoidance behavior to our experimental treatments ranged from minimal (for tadpole density) to acute (water temperature and time of day). Clutch effects (and thus, population-of-origin effects) were minor and generally nonsignificant. Other variables we tested influenced avoidance levels only over a limited range of conditions; for example, tadpoles failed to respond to chemical cues very early and very late in development, but the response was consistent throughout the middle phase of larval life. Although nutritional status had a statistically significant effect (recently fed tadpoles were less responsive), the effect size may be too small to be important biologically. Habituation to daily pheromone exposure was minor or nonexistent, but tadpoles exposed repeatedly at 15-min intervals ceased responding after about 2 h. Below, we examine the likely biological underpinnings of these effects, before considering the implications of our results for deploying alarm pheromone to control cane toad populations.

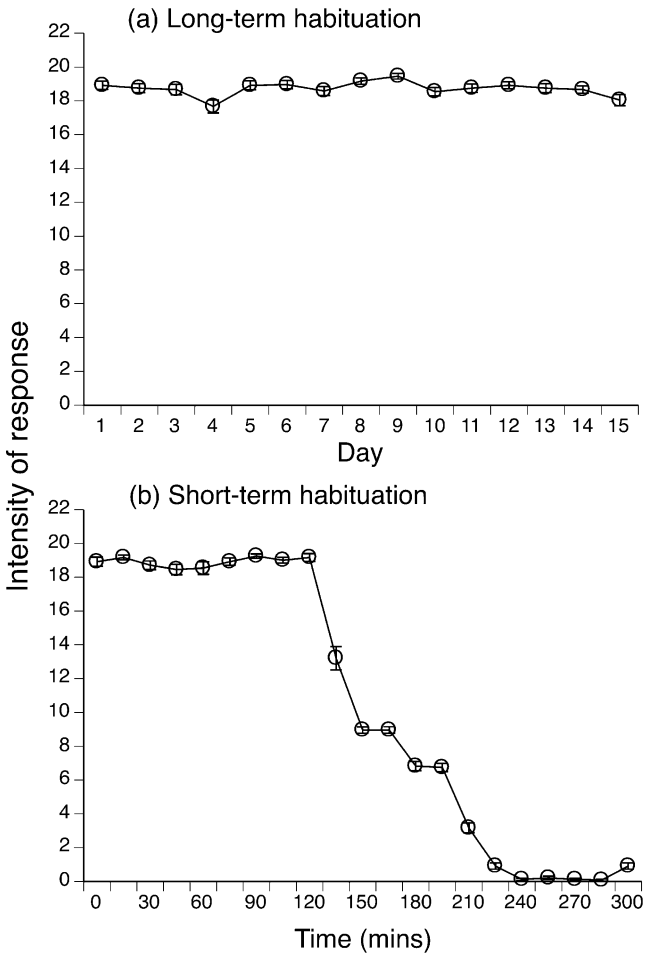

Fig. 2 Effects of **a** long-term (once daily) and short-term (15-min repetitive) exposure on habituation of cane toad, *Bufo marinus*, tadpoles to chemical cues from crushed conspecific tadpoles. The *graphs* show the mean number of tadpoles (out of 20) repulsed by the stimulus per trial. Controls (water without crushed-tadpole cues) were run simultaneously, but never elicited repulsion and are not shown. *Figures* show SEs of means

The results for nutritional state (recently fed tadpoles were less responsive to alarm pheromone) run counter to the pattern reported in previous studies (recently fed tadpoles were more responsive to predator cues: Horat and Semlitsch 1994; Fraker 2008b). Mathematical models predict that the effects of food deprivation on antipredator responses may be sensitive to a wide range of factors (Werner and Anholt 1993). We cannot identify specific reasons for the different patterns seen in our results compared to those of Horat and Semlitsch (1994) and Fraker (2008b). The results may reflect interspecific divergence, a difference in experimental stimuli (conspecific alarm cues vs. predator scent) or a difference in the tadpole behavioral traits elicited by predator cues (flight vs. quiescence). Future work should explore these alternatives.

The strong thermal effect on response intensity (Fig. 1a) cannot be due simply to locomotor ability that increases at higher temperatures: toad tadpoles were capable of swimming around (albeit slowly) even at the lowest temperature that we used in experiments. Hence, the lack of pheromone avoidance at low temperatures may reflect the tadpoles not detecting the chemical cues, or some adaptive matching of response to locomotor ability (i.e., flee only when you are capable of moving rapidly, otherwise ignore the stimulus or remain quiescent). In support of the latter, body temperature has been reported to influence antipredator tactics in many other ectothermic vertebrates (e.g., Huey and Slatkin 1976; Greene 1988; Passek and Gillingham 1997; Cooper 2000; Shine et al. 2000; Langkilde et al. 2003). The lack of the avoidance response in very early stage and very late-stage toad tadpoles (Fig. 1d) is open to the same ambiguous interpretation: it may reflect either limited locomotor ability or an adaptive adjustment of behavior to that ability.

Toad tadpoles reacted more strongly to alarm pheromone during daylight hours than they did at night (Fig. 1b), and experiments under artificial illumination suggest that this is an endogenous circadian rhythm rather than a response to ambient light levels. Recent studies on green frogs (*Rana clamitans*) also have shown that tadpole behavior is more strongly suppressed by predator cues during the day than during the night (Fraker 2008a); the same pattern we documented for cane toads. However, green frog tadpoles forage primarily by night, whereas cane toad tadpoles forage by day (Lever 2001). Thus, the apparent similarity in results of these two studies is surprising. Fraker (2008a) interpreted the strong diurnal response to the lesser importance of diurnal foraging in his study species (and thus, a lowered cost of suppressing feeding activity at that time). This explanation cannot hold for cane toads. Additional work is required to clarify this interspecific difference.

Importantly, the effects of water temperature (Fig. 1a) and time of day (Fig. 1b) will covary because cane toads spawn in shallow ponds exposed to high levels of direct solar radiation (Hagman and Shine 2006; Semeniuk et al. 2007). Water temperatures at 10-cm depth in outdoor ponds near Fogg Dam in October ranged from 22°C in early morning to 38°C by late afternoon; water temperature falls even lower overnight in the middle of the dry season (Hagman and Shine, unpublished data). The effects of diel cycle and water temperature will tend to cancel each other out; for example, water temperatures are low at dawn but tadpole responsiveness is high at this time. The end result of these two influences is likely to be a relative constancy of responsiveness during daylight hours (responsiveness declines during the afternoon, but rising water temperatures will mitigate this effect), but lower responsiveness at night (both because of lowered temperatures and because of the diel cycle in response).

The lack of an effect of tadpole density and the general lack of clutch (and thus, of location-of-origin) effects, are clear-cut null results. The same is true for habituation over the longer timeframe we investigated (Fig. 2a). Such null results are difficult to interpret because there are always more potential reasons why behaviors do not occur than why they do (Gould and Lewontin 1979). It would be interesting to look further at the tadpoles exposed to repeated doses of alarm pheromone at 15-min intervals (Fig. 2b). Why did response levels drop so rapidly after 2 h? This effect could result from tadpole exhaustion, from a shift in response from avoidance to quiescence, or from classical habituation.

Lastly, what do these patterns of response tell us about the feasibility of deploying alarm chemicals in the field to control cane toad populations? Broadly, our results are encouraging, indicating that the pheromone should continue to work effectively day after day throughout the larval phase, regardless of tadpole developmental stage, population density, or feeding rates, and should work over a range of water temperatures typical of breeding ponds in tropical Australia. However, additional research is needed to determine whether or not the alarm pheromone provides a way to reduce cane toad recruitment in nature. For example, we need to know how long the chemical cue persists in nature before it becomes degraded and/or diluted and how long tadpoles continue to respond after being exposed to the cue (Ferrari et al. 2008). Future work could usefully explore the feasibility and effectiveness of deployment of the pheromone in natural water bodies.

Acknowledgments We thank the Australian Research Council for funding, and the members of Team Bufo for help in many ways. In particular, Michelle Gray and Georgia Ward-Fear helped us to clean containers, and Melanie Elphick prepared the figures for this manuscript.

Effects of a *Caenorhabditis elegans* Dauer Pheromone Ascaroside on Physiology and Signal Transduction Pathways

Marco Gallo · Donald L. Riddle

Received: 23 September 2008 / Revised: 17 December 2008 / Accepted: 12 January 2009 / Published online: 4 February 2009

Abstract Daumone is one of the three purified and artificially synthesized components of the *Caenorhabditis elegans* dauer pheromone. It affects the major signal transduction pathways known to discriminate between developmental arrest at the dauer stage and growth to the adult [the transforming growth factor beta (TGF-β) and *daf-2/IGF1R* pathways], just as natural pheromone extracts do. Transcription of *daf-7*/TGF-β is reduced in pre-dauer larvae, and nuclear localization of the DAF-16/FOXO transcription factor is increased in embryos and L1 larvae exposed to synthetic daumone. However, daumone does not require the cilia in the amphidial neurons to produce these effects nor does it require the Gα protein GPA-3 to induce dauer entry, although GPA-3 is required for dauer induction by natural dauer pheromone extracts. Synthetic daumone has physiological effects that have not been observed with natural pheromone. It is toxic at the concentrations required for bioassay and is lethal to mutants with defective cuticles. The molecular and physiological effects of daumone and natural dauer pheromone are only partially overlapping.

Introduction

Development of the free-living soil nematode *Caenorhabditis elegans* includes an embryonic phase, four larval stages (L1–L4), and the adult. Under conditions unfavorable for reproductive growth, i.e., low food supply, high temperature, and/or high population density, *C. elegans* can enter the dauer stage as an alternative to the L3 (Cassada and Russell 1975). Dauer larvae are a non-feeding diapause state that can survive for months by utilizing fat stores for energy. Once environmental conditions improve, they begin to feed, molt to the L4, and then to the adult (Riddle and Albert 1997).

High population density is signaled by the concentration of a constitutively secreted pheromone (Golden and Riddle 1984a). If the ratio of pheromone to food is high during the L1 and L2 stages, the larvae adjust their metabolism to accumulate fat in preparation for a possibly prolonged period without feeding. An accurate environmental assessment (precise threshold) is highly adaptive. An unnecessary developmental arrest substantially delays reproduction, whereas failure to disperse when necessary negatively impacts progeny survival.

The pheromone was shown to induce dauer formation by affecting several signal transduction pathways. Mutations in some of the genes in these pathways lead to constitutive dauer formation (Daf-c), whereas mutations affecting other pathway components impede entry into dauer, a phenotype called dauer-defective (Daf-d; Riddle and Albert 1997). The genes were placed in pathways based on epistatic relationships [reviewed in Riddle and Albert (1997)]. Two parallel signal transduction pathways, the *daf-7*/transforming growth factor beta (TGF-β) pathway and the *daf-2*/insulin-like growth factor 1 receptor (*IGF1R*) pathway, were defined, converging on the DAF-12 nuclear hormone receptor (Snow and Larsen 2000; Jia et al. 2002).

The dauer pheromone was initially identified as a mixture of hydroxylated short-chain fatty acids or bile salts (Golden and Riddle 1984b). Recently, the four major components of this pheromone were purified from extracts and synthesized (Jeong et al. 2005; Butcher et al. 2007, 2008). Biological activity of these structurally related ascarosides (Fig. 1) was demonstrated by measuring entry into the dauer stage on agar plates in the presence of limited food. One of the pheromone components with the trivial name daumone (Jeong et al. 2005) occurs at about one tenth of the concentration of the two major components (Butcher et al. 2007). We used synthetic daumone to compare its modes of action with natural dauer pheromone extracts with the aim of uncovering the physiological effects and the mechanisms by which daumone induces dauer formation.

Methods and Materials

C. elegans Strains Used Wild-type N2, *mIs7[daf-7* p::*gfp*::*daf-7* 3′ UTR *rol-6(su1006)]* (DR 2021), *zIs356[daf-16* p::*daf-16*::*gfp]* (TJ356) (Henderson and Johnson 2001), *gpa-3 (pk35)*, *daf-3(mgDf90)*, *daf-16(mgDf47)*, *daf-8(m85);daf-3 (e1376)*, *daf-12(m20)*, *daf-14(m77);daf-3(e1376)*, and *dpy-14(e188)* were used. Strains were cultured by using standard techniques (Brenner 1974).

Dauer Induction Assays Assays were performed as described by Jeong et al. (2005). In brief, synthetic daumone (KDR Biotech, Seoul, Korea) was dissolved in 95% ethanol. Plates were prepared by adding daumone to NG agar (Brenner 1974) without peptone to a final concentration of 384 μM. A total volume of 3 ml of NG plus daumone was dispensed in each 50-mm diameter plate.

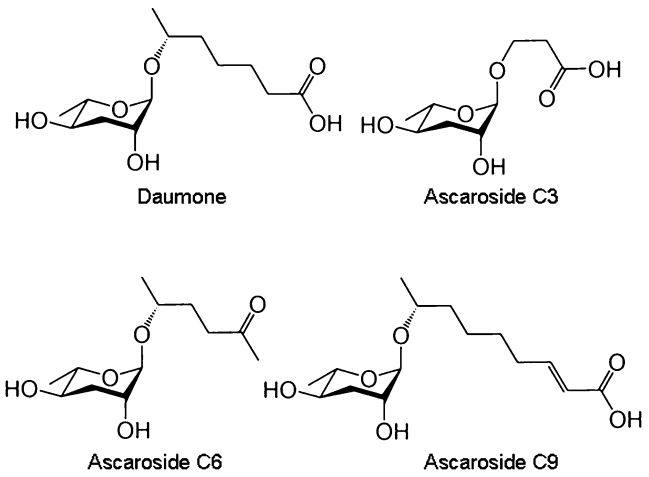

Fig. 1 Structures of the four known components of the dauer pheromone (adapted from Butcher et al. 2008). They are all derivatives of the 3,6-dideoxyhexose ascarilose. Our studies focus on the compound known as daumone

Control plates were prepared by adding 95% ethanol equal to the volume used to deliver daumone to the experimental plates. Heat-killed *Escherichia coli* OP50 (160 μg) were added to the plates and allowed to dry. Five adult worms were placed on each plate and allowed to lay eggs for 5 h before being removed. Plates were then incubated at 25°C for 70–72 h, and dauer formation was scored visually with a stereomicroscope.

Pheromone Plates Pheromone extracts were prepared as described by Golden and Riddle (1984a). Pheromone plates were prepared with pheromone at a final concentration of three times (three times the concentration found in starved liquid culture media) following established protocols (Golden and Riddle 1984b). Control plates were made by adding a volume of M9 buffer equivalent to the volume of pheromone added on the experimental plates.

DAF-16 Nuclear Localization Five *daf-16 p*::*daf-16*::*gfp* (TJ356) adults were placed on daumone or control plates and allowed to lay eggs at 25°C. Nuclear localization was assessed after 14 h by observing green fluorescent protein (GFP) fluorescence at 660× with the aid of a Zeiss Stemi SV 11 Apo stereomicroscope. Embryos or L1 larvae were scored as either having DAF-16 nuclear localization or as intermediate/cytoplasmic localization. *P* values were calculated by using the χ^2 test. Embryonic DAF-16 nuclear localization was similarly assessed on pheromone plates, with the exception that three gravid adults were placed on each plate and allowed to lay 30–50 eggs.

Daumone Toxicity Triton X-100 (Sigma) was used to permeabilize the nematode cuticle. Before seeding plates with OP50, 300 μl of a stock 10% solution of Triton X-100 were added to plates to reach a final concentration of 1% (Rogalski et al. 1990). Control plates were made by adding 300 μl of distilled water instead of detergent. Ten to 15 gravid *dpy-14(e188)* adults were added per plate and incubated at 25°C. Survival was assessed at 16 and 24 h. Statistical analysis was performed with the log-rank test available with the statistical package R.

Results

Daumone Reduces TGF-β Signaling TGF-β signaling promotes reproductive growth, whereas its down-regulation results in dauer formation (Ren et al. 1996). Exposure to dauer pheromone extracts prevents transcription of the TGF-β ligand *daf-7* (Ren et al. 1996), which is solely expressed in the amphid chemosensory neurons ASI. These are a pair of bilaterally symmetrical ciliated neurons that

function to inhibit dauer entry (Bargmann and Horvitz 1991). To test whether daumone possesses similar properties to whole dauer pheromone extracts, we exposed a strain carrying an integrated *daf-7* promoter::GFP fusion (*daf-7* p::*gfp*) to 384 μM daumone. Reporter fluorescence gradually decreased from the L1 to the pre-dauer L2d (Fig. 2c, d) and was completely abrogated in dauer larvae formed in response to daumone.

Although the decreased promoter activity observed in our transgenic larvae recapitulated the effects of whole dauer pheromone extracts (Ren et al. 1996), there was also an obvious difference. About 25% of the larvae treated with daumone expressed the *daf-7* p::*gfp* reporter not only in the ASI neurons but also in another amphid neuron (Fig. 2e). Expression was transient just before dauer formation and was absent in dauer larvae. The cell body of this neuron is just posterior to the midline of the second bulb of the pharynx, a location characteristic of the ciliated amphid neuron ASJ, which is required for exit from the dauer stage (Bargmann and Horvitz 1991). There have been no previous reports of *daf-7* expression in the ASJ neurons.

Daumone Induces DAF-16 Nuclear Localization in Embryos Dauer induction involves down-regulation of *daf-7*/TGF-β and *daf-2/IGF1* signaling. Mutations that disrupt either pathway result in constitutive dauer formation. Insulin/IGF1 signaling inhibits the FOXO transcription factor DAF-16 (Lin et al. 1997). When insulin signaling is reduced, DAF-16 is not phosphorylated by the upstream insulin pathway component AKT-1 and is free to enter the nucleus (Paradis and Ruvkun 1998; Henderson and Johnson 2001) to regulate the transcription of genes involved in dauer formation and adult longevity [reviewed in Jensen et al. (2006)]. If daumone reduces insulin signaling, exposure to daumone should result in the nuclear localization of DAF-16. To test this, we exposed a transgenic line carrying an integrated DAF-16::GFP translational fusion (Henderson and Johnson 2001) to daumone. We scored animals at different developmental stages as having nuclear or cytoplasmic/intermediate DAF-16 localization.

The decision to enter the dauer stage is taken during the L1 and the L2 (Golden and Riddle 1984a), and indeed, nuclear localization appeared to be stronger in daumone-treated L1s (Fig. 3) than in L1s grown on control plates, although this difference did not reach statistical significance (P=0.228). Surprisingly, daumone induced strong DAF-16 nuclear localization in embryos (P<0.001). It did not do so in adults (data not shown). If embryonic DAF-16 nuclear localization is a requirement for dauer formation, it should be elicited by exposure to natural pheromone extracts as well. We treated DAF-16::GFP worms with pheromone extracts at a concentration sufficient to induce 61% dauer formation in N2. However, we observed no difference in embryonic nuclear localization in worms treated with pheromone compared to control (P=0.64).

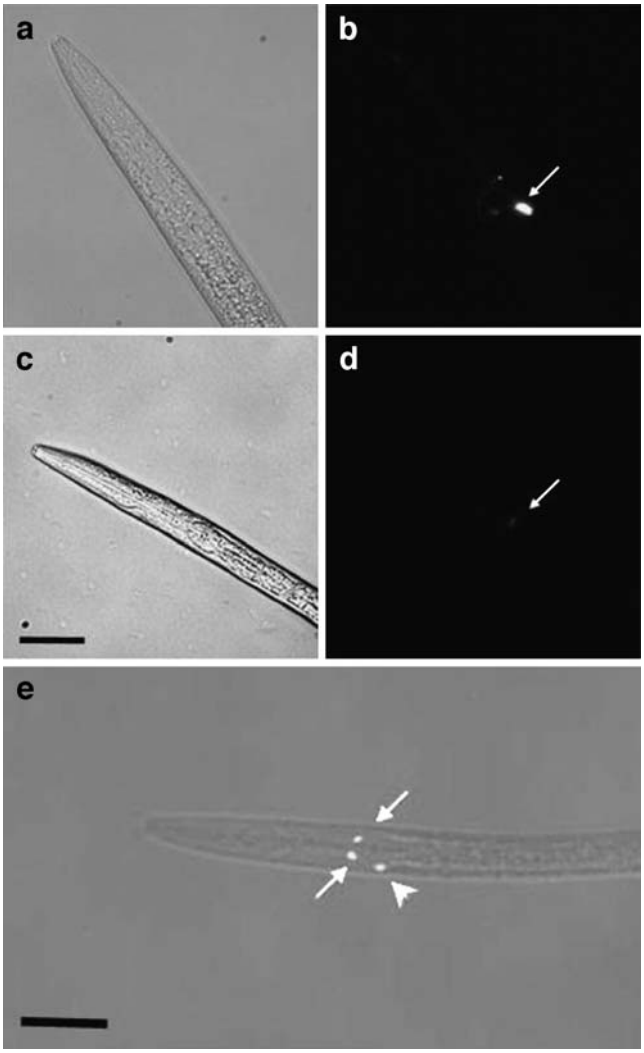

Fig. 2 a–d Daumone decreases expression of *daf-7*, the gene encoding a *Caenorhabditis elegans* TGF-β ligand. Adult hermaphrodites carrying an integrated *daf*-7 p*;;gfp::daf-7* 3′ UTR construct (DR2021) were placed on control or daumone plates and were allowed to lay eggs overnight. After 14-h incubation, larvae were scored for GFP fluorescence with a UV stereomicroscope. **a** DIC and **b** fluorescent image of a control L2 larva. Control larvae showed strong expression of the GFP reporter construct in the ASI neurons. **c** DIC and **d** fluorescent image of a larva hatched in daumone. Larvae exposed to daumone showed little or no GFP reporter expression. **e** Daumone induces expression of *daf-7* in the ASJ neurons. *daf-7* is normally expressed in the ASI neurons (*arrows*). However, ~25% of DR2021 L2d worms treated with daumone expressed *daf-7* in one of the two ASJ neurons (*arrowhead*). The pre-dauer L2d shown is representative of the subpopulation expressing the reporter in ASJ. Scale bars, 50 μm

DAF-16 nuclear localization can be achieved by repression of the insulin pathway or by activation of a stress response pathway parallel to the insulin pathway. This pathway is mediated by the sirtuin SIR-2.1, which binds to DAF-16 and translocates to the nucleus (Henderson and

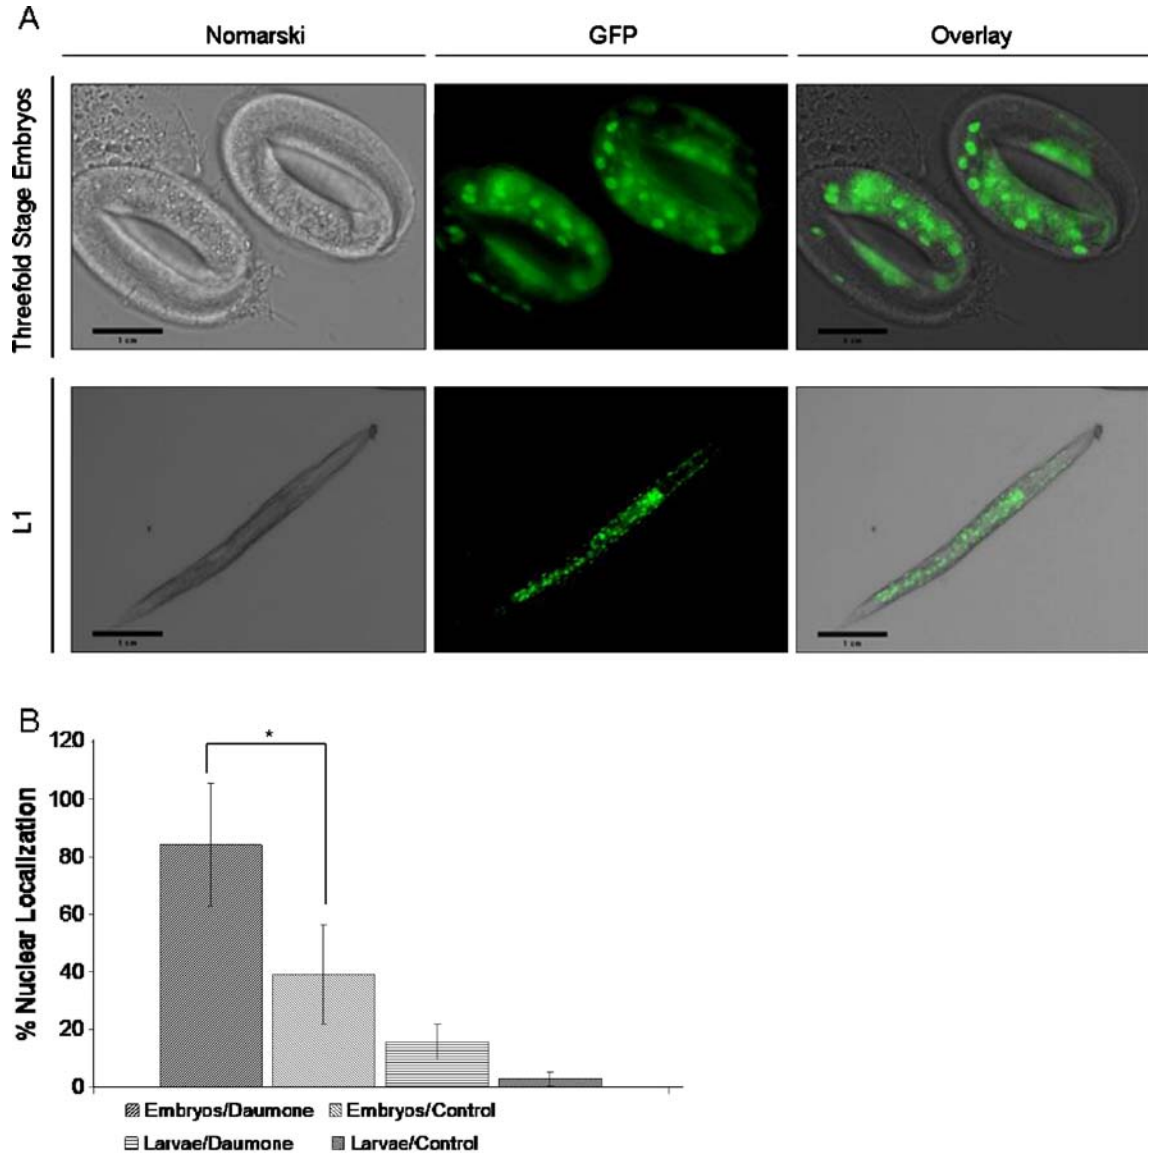

Fig. 3 Daumone induces DAF-16 nuclear localization in embryos. **a** A representative embryo and a representative L1 larva with DAF-16 nuclear localization upon daumone treatment. Strain TJ356 carries an integrated DAF-16::GFP translational fusion construct. **b** Quantification of DAF-16 nuclear localization in embryos and L1s. Animals were described as having nuclear localization if DAF-16 was observed predominantly in the nuclei; otherwise, they were scored as intermediate/cytoplasmic localization. *P* values were calculated with a χ^2 test. *Asterisk* Statistically significant difference. Error bars represent ±standard deviation (SD)

Johnson 2001; Berdichevsky et al. 2006). The DAF-16 nuclear localization in embryos raised the possibility that this was a response to stress (embryos do not enter the dauer stage, and natural pheromone does not induce DAF-16 nuclear localization). The only difference between treatment and control plates was the presence of daumone. Hence, daumone may have toxic effects on *C. elegans* at the concentration used (384 μM; Jeong et al. 2005). Pheromones usually are active in the nanomolar concentration range or a few hundred molecules per square centimeter (Dulac and Torello 2003), much less than the working concentration of daumone required to induce dauer formation in the bioassay (Jeong et al. 2005).

Daumone Toxicity Mutations in the collagen gene *dpy-14* (DumPY) result in a defective cuticle that allows normally excluded substances to leak into mutant worms (Gallo et al. 2006). We used this strain as a sensitized background to perform a daumone resistance assay. To permeabilize the cuticle of these mutants further, we added 1% Triton X-100 to the plates. This concentration of Triton X-100 does not affect animal growth and reproduction (Rogalski et al. 1990). Detergent-treated *dpy-14* adults started dying within 16 h of daumone exposure, as judged by the absence of pharyngeal pumping and lack of response to prodding (Fig. 4). Dpy-14 adults on control plates [where daumone was replaced with 95% ethanol (Jeong et al. 2005)] did not

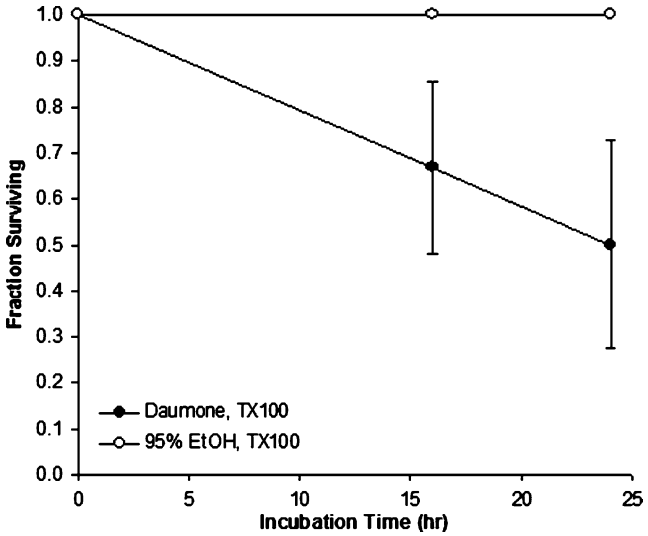

Fig. 4 Daumone is toxic to *dpy-14* mutants with a defective cuticle. This survival assay was performed in duplicate with a total of 18 treated and ten untreated adults. Daumone is lethal to *dpy-14* adults at the concentration used, whereas none of the unexposed mutant adults died. Error bars represent ±standard error of the mean (SE)

die in the first 24 h of daumone treatment. Hence, *dpy-14* adults exposed to daumone had a lower survival rate than controls (P=0.009 by log-rank test). If adults with a Rol-6 (roller) phenotype were placed on daumone plates, they also died or looked sick within a few hours. *rol-6* encodes a cuticular collagen and mutations in this gene result in a cuticle twisted in a right-handed helix (Kramer et al. 1990).

Genes Required for Daumone-Induced Dauer Entry Since the DAF-16 nuclear localization in embryos and L1 larvae could be a response to stress, we wanted to know what pathways might be required for dauer induction with daumone. We employed mutants that down-regulate the *daf-2/IGFR1*-insulin and *daf-7*/TGF-β pathways in dauer induction assays with daumone. The results point to a role for the Smad protein DAF-14 in relaying the daumone signal (Fig. 5). The *C. elegans* TGF-β pathway [reviewed in Riddle and Albert (1997)] includes the DAF-7 ligand, the receptor heterocomplex formed by DAF-1 and DAF-4, and the two receptor Smads (R-Smads) DAF-8 and DAF-14. Activation of these R-Smads results in reproductive growth, whereas mutations that decrease their function result in a Daf-c phenotype. DAF-8 and DAF-14 antagonize the Smad family member DAF-3, which functions with the Sno/Ski family protein, DAF-5, to promote dauer formation. Mutations in DAF-3 and DAF-5 result in a Daf-d phenotype.

The downstream Daf-d mutant *daf-3* suppresses the *daf-8* and *daf-14* Daf-c mutations. Nevertheless, daumone induces dauer formation in such genetic backgrounds (Fig. 5). A failure to respond to daumone indicates that *daf-12* and *daf-14* are required for daumone induction. By contrast, *gpa-3*, *daf-3*, *daf-8*, and *daf-16* are not required. Mutants in *daf*-3 (N=38) or *daf-8; daf-3* double mutants (N=78) responded to 384 μM daumone similar to wild type, forming 50–60% dauer larvae. However, when DAF-14 function was reduced, as in our *daf-14; daf-3* double mutants, dauer formation in response to daumone was severely compromised (5.3%, N=86). This level of dauer formation is actually comparable to that of a *daf-12* (Daf-d) mutant exposed to daumone (6.2% dauer formation, N=103). Our results are, therefore, consistent with genetic data suggesting that the *daf-2/IGF1R* and TGF-β pathways converge on *daf-12* (Riddle and Albert 1997).

One unexpected result was produced by the *gpa-3* (G-protein subunit α) knockout mutant (Fig. 5). GPA-3 is a candidate for relaying the dauer pheromone signal from the pheromone receptors to downstream effectors (Lans et al. 2004), including DAF-11. *gpa-3* and the *daf-11* transmembrane guanylyl cyclase have been shown to interact at the

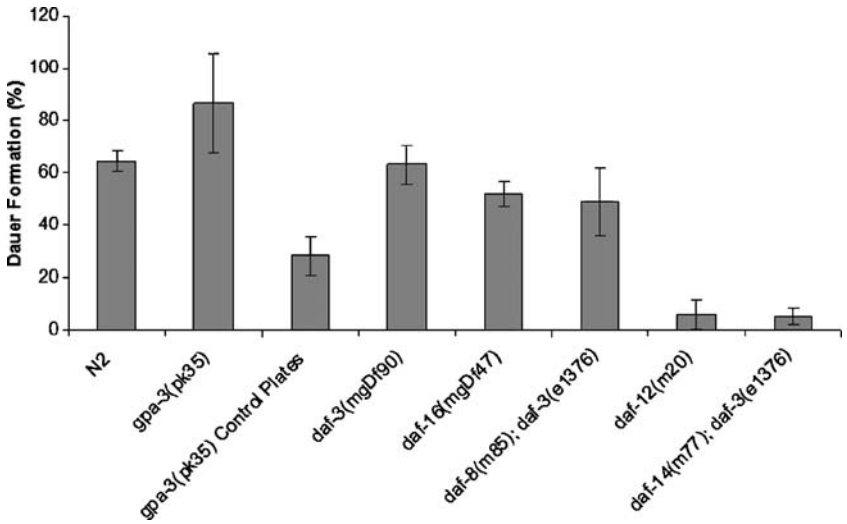

Fig. 5 Response of Daf mutants to daumone. Selected Daf-d mutants in the *daf-2/IGF1R* and TGF-β pathways were used in dauer induction assays with daumone. N2 with daumone treatment and *gpa-3* on daumone assay plates without daumone were used as controls. Bars represent ±standard deviation (SD)

genetic level and have been placed in a pathway both in parallel and partially upstream of the TGF-β pathway (Zwaal et al. 1997; Birnby et al. 2000). *daf-11* mutations result in decreased cyclic guanosine monophosphate (cGMP) levels and constitutive dauer formation (Birnby et al. 2000). cGMP is used as a signaling molecule to modulate many cellular functions through the activation of kinases, other nucleotide cyclases, cyclic nucleotide phosphodiesterases, and cGMP-gated ion channels [reviewed in Goy (1991)].

The *gpa-3(pk35)* knockout strain has a Daf-d phenotype when exposed to pheromone extracts (Zwaal et al. 1997). However, exposure of the Daf-d *gpa-3(pk35)* nulls to daumone resulted in 87% dauer formation (N=60), a significantly higher dauer formation rate than *gpa-3(pk35)* grown on control plates without daumone (28%, N=31). This result suggests that dauer pheromone and daumone induce dauer formation by partially different pathways. The pheromone requires *gpa-3* for dauer induction but daumone does not.

Discussion

This work describes the effects of daumone on *C. elegans* physiology and signal transduction pathways. The optimal concentration for dauer induction assays proposed by Jeong et al. (2005) is about 1,400-fold higher than the concentration of this compound in culture media (Butcher et al., 2007). Butcher et al. (2007) determined the dose–response effect of daumone on dauer formation. From that study and ours, it seems that high concentrations of daumone (384 μM) are required to produce dauer arrest in the absence of the most potent dauer-inducing ascarosides. At this level of exposure, daumone has a lethal effect on animals with permeable cuticles and results in embryonic nuclear localization of DAF-16, suggesting that it may induce dauer formation via a stress response pathway. DAF-16 activity is regulated by insulin signaling via AKT kinases and by a parallel stress response pathway involving SIR-2.1 (Henderson and Johnson 2001; Berdichevsky et al. 2006).

Mutations in *daf-7* result in DAF-16 nuclear localization (Lee et al. 2001), so it is possible that the nuclear localization we observed was due partially to a daumone-induced decrease in *daf-7* gene function. However, DAF-16 nuclear localization in embryos seems to be caused primarily by daumone toxicity. A fluorescent derivative of daumone has been reported to penetrate the egg shell and enter the embryo (Baiga et al. 2008). Our data suggesting that daumone is toxic are in agreement with recent findings of Kim and Paik (2008), who used daumone to induce dauer formation in N2 and to keep them in the dauer stage for increasing lengths of time. They observed that the longer the exposure to daumone, the more severe were the developmental and reproductive defects in post-dauer animals. Such defects were not observed in starvation-induced dauer larvae (Klass and Hirsh 1976).

In spite of its toxic effects, the use of daumone has proven useful for dissecting the functional relationship between the three major ascarosides in the dauer pheromone. Our experiments suggest that daumone does not act on all the canonical pathways for dauer entry. For instance, daumone does not require *gpa-3* to induce dauer entry, although this gene is necessary for dauer induction by natural dauer pheromone extracts (Zwaal et al. 1997). This result suggests that daumone is not sensed by the ciliated neurons, where *gpa-3* is expressed, but instead, it uses an alternative path into the animal. In fact, *daf-10* mutants are Daf-d, but they form 82% dauer larvae at 25°C when exposed to daumone (Jeong et al. 2005). *daf-10* mutants have defective intraflagellar transport and their cilia—rarely formed—are not functional (Qin et al. 2001). *daf-10* does not form dauer larvae when exposed to natural pheromone extracts (Golden and Riddle 1984b). All together, these data suggest that daumone (at the concentration used) does not require the ciliated neurons as does the natural dauer pheromone. Daumone may enter through the cuticle, as this ascaroside is lethal to animals with a permeable cuticle.

Mutations in the FOXO transcription factor *daf-16*, which is the main effector of insulin/IGF1 signaling, do not prevent dauer formation in response to daumone nor do mutations in members of the TGF-β pathway. When *daf-16* is mutated, *daf-3(+)* in the TGF-β pathway may be sufficient for dauer entry in response to daumone. Likewise, when *daf-3* is mutated, *daf-16(+)* may be sufficient to mediate dauer formation. However, DAF-14 is necessary for daumone-mediated dauer entry, suggesting that DAF-14 is required by DAF-16 and DAF-3 to induce dauer formation. When DAF-14 and DAF-3 have reduced function [as in our *daf-14(m77); daf-3(e1376)* double mutant], DAF-16 is not able to induce dauer formation. Interaction between SMAD and FOXO transcription factors has been reported in human cells (Seoane et al. 2004) and was also proposed for DAF-16 and DAF-3 under dauer-inducing conditions in *C. elegans* (Ogg et al. 1997). It is possible that daumone enhances DAF-16/DAF-3 interaction in a DAF-14-dependent manner. The interactions proposed in this paper explain what we observe when animals are treated with daumone and do not necessarily correspond to the pathways normally used for dauer entry.

In summary, daumone, a minor component of the dauer pheromone, needs to be used in synthetic forms at concentrations so high to induce dauer formation that it becomes toxic. It does not fully recapitulate the events that

normally lead to *C. elegans* dauer formation. Our results suggest that dauer formation may be induced partially in response to toxins, in addition to the environmental cues already known (pheromone, food, and high temperatures). The pheromone cue may normally involve the orchestrated action of daumone, the two major ascarosides, and other pheromone components found in the natural dauer pheromone extracts by Butcher et al. (2007) that trigger the complex signaling processes revealed by the genetics. Different ascarosides may activate different sensory receptors, and at physiological concentrations, the behavioral response may result from parallel activities. The chemical composition of the pheromone may contain specific information about environmental status.

Acknowledgments We thank Victor Jensen, Nigel O'Neil, and Donha Park for helpful discussions. The Chlorophyll Catabolite, Pheophorbide *a*, Confers Predation Resistance in a Larval Tortoise Beetle Shield Defense

Fredric V. Vencl · Nélida E. Gómez · Kerstin Ploss · Wilhelm Boland

Received: 28 October 2008 / Revised: 1 December 2008 / Accepted: 4 December 2008 / Published online: 7 January 2009

Abstract Larval insect herbivores feeding externally on leaves are vulnerable to numerous and varied enemies. Larvae of the Neotropical herbivore, *Chelymorpha alternans* (Chrysomelidae:Cassidinae), possess shields made of cast skins and feces, which can be aimed and waved at attacking enemies. Prior work with *C. alternans* feeding on *Merremia umbellata* (Convolvulaceae) showed that shields offered protection from generalist predators, and polar compounds were implicated. This study used a ubiquitous ant predator, *Azteca lacrymosa*, in field bioassays to determine the chemical constitution of the defense. We confirmed that intact shields do protect larvae and that methanol-water leaching significantly reduced shield effectiveness. Liquid chromatography-mass spectrometry (LC-MS) of the methanolic shield extract revealed two peaks at 20.18 min and 21.97 min, both with a molecular ion at *m/z* 593.4, and a strong UV absorption around 409 nm, suggesting a porphyrin-type compound. LC-MS analysis of a commercial standard confirmed pheophorbide *a* (Ph*a*) identity. *C. alternans* shields contained more than 100 μg Ph*a* per shield. Shields leached with methanol-water did not deter ants. Methanol-water-leached shields enhanced with 3 μg of Ph*a* were more deterrent than larvae with solvent-leached shields, while those with 5 μg additional Ph*a* provided slightly less deterrence than larvae with intact shields. Solvent-leached shields with 10 μg added Ph*a* were comparable to intact shields, even though the Ph*a* concentration was less than 10% of its natural concentration. Our findings are the first to assign an ecological role for a chlorophyll catabolite as a deterrent in an insect defense.

Introduction

More so than for agile insect adults, flightless, soft-bodied larvae are exposed to numerous natural enemies as they feed openly on leaf surfaces. Consequently, folivorous larvae suffer the highest mortality rates, frequently approaching 90%, among the respective developmental stages (Gross 1993; Hunter 2000; Zalucki et al. 2002). In response, larvae have evolved an astonishing variety of physical barriers, such as setae, spines, and webs, as well as chemical barriers, such as glandular exudates and fore and aft enteric discharges that function to reduce vulnerability to natural enemies (Whitman et al. 1990; Evans and Schmidt 1991; Ruxton et al. 2004 and references therein). Many of these strategies are supplemented by behaviors that enhance their effectiveness (Gross 1993; Stamp and Casey 1993 and references therein). Among the most bizarre of these characters is fecal retention. Although rare among insects generally (Weiss 2006), fecal retention can be found in a restricted number of leaf beetle (Chrysomelidae) and weevil (Curculionidae) lineages with exophytic larvae. Within the chrysomelids, however, fecal retention is

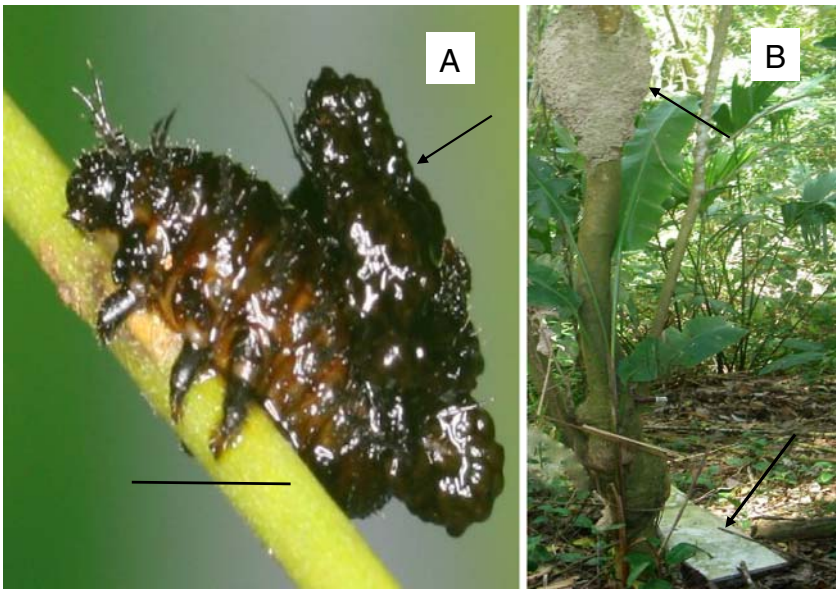

Fig. 1 Larva of **a** *C. alternans* showing the fecal shield (*arrow*) above the larval dorsum (*bar*= 2 mm); **b** the *A. lacrymosa* nest (*upper arrow*) and bioassay arena (*lower arrow*)

common. Nearly 20% of the 35,000 described leaf beetle species have some form of larval fecal retention (Vencl et al. 1999). For example, there are three different approaches to using feces for larval defense in the Chrysomelidae: the unstructured dorsal piles in Criocerinae, the scatoshells in the Camptosomata group, and the elaborate dorsal annexes constructed by the Cassidinae.

Instead of ridding themselves of their digestive wastes, the larvae of tortoise beetles (Cassidinae) have the peculiar habit of voiding feces onto their backs, where it accumulates to form a coating or shield. Shields do not rest passively on the dorsum. They have a solid infrastructure formed by the accumulation of molted skins, which is itself attached to a highly movable, forked caudal process located on the penultimate abdominal segment. Adding to the shield system is a novel, telescoping anus that precisely applies feces to the shield armature (see Vencl et al. 1999; Fig. 1a). Fresh, wet feces may be the most deterrent or repellent part of the elaborate shield structure, and the unusual anal application mechanism maintains the freshest fecal material right at the periphery of the shield where predators are most likely to make initial contact (Vencl, personal observation). Held like parasols above the larvae, shields can be aimed and waved in any direction. Although possibly affording protection against deleterious abiotic factors, tortoise beetle shields have been shown to function as both physical (Eisner et al. 1967; Olmstead and Denno 1993; Eisner and Eisner 2000) and as chemical defenses against natural enemies (Vencl et al. 1999; Müller and Hilker 2004; Gómez et al. 1999; Nogueira-de-Sá and Trigo 2002, 2005).

Larvae of the tortoise beetle, *Chelymorpha alternans*, possess fecal shields that previously have been shown to thwart attacking bugs and ants (Fig. 1a). Although the role of defensive behaviors, such as shield waving and escape, may have contributed to larval survival, the effectiveness of *C. alternans* shields appeared to be due mainly to a chemical component residing in the shield's feces. For example, when larvae lacking recourse to defense behaviors had their shields leached with methanol (MeOH), their capacity to withstand capture by ants was reduced significantly, compared to both larvae with water-leached and larvae with intact shields. This finding indicated that this species relies heavily on MeOH-soluble components to mount an effective defense (Vencl et al. 2005). Although shields in some tortoise beetle species depend on host-derived terpenes, phenolics, alkaloids, or saponins, the shields of other species require fatty acids or phytol to function effectively as defenses (reviewed by Müller and Hilker 2004). However, neither the chemical constitution nor the origin of *C. alternans*' shield chemistry is known.

Here, we investigated how *C. alternans* larvae chemically enhance their remarkable shield structures. We wanted to know what compounds might be responsible for shield effectiveness, whether chemically denuded shields could confer resistance against one of the larva's most important enemies, if larvae were somehow able to sequester repellent or deterrent precursors from their diet, or if they were capable of endogenously synthesizing them. Based on the previous study mentioned above, we focused on the bioactivity of the methanolic extract of *C. alternans* shields, which appeared to be responsible for reduced larval vulnerability to predation.

Materials and Methods

Beetle Collection and Husbandry We collected *C. alternans* larvae from *Merremia umbellata* (Convolvulaceae)

near Gamboa, Colon Province, Republic of Panamá (9°06′ N, 79°41′ W). Larvae were transported to a laboratory at the Smithsonian Tropical Research Institute in Gamboa and maintained at ambient photoperiod and temperature separately in plastic food containers (473 ml) with plastic mesh for aeration and moistened filter paper. Each cup was supplied daily with a fresh, intact *M. umbellata* leaf. Upon reaching the fourth instar, wet and dry weights of larvae and shields (N=34) were taken to the nearest 10^{-4} g. Shields for chemical analysis were harvested and stored without solvent at −32°C. To focus on resistance due to shields alone, we eliminated confounding escape and shield waving behaviors by using freshly killed (by freezing) fourth instar *C. alternans* larvae. Larvae were stored individually in 2 ml glass vials at −2°C for later use in bioassay experiments.

Separation and Identification of Active Compounds in the Shield Extract Liquid chromatography-mass spectrometry (LC-MS) was used to identify the constituents of the methanolic extract. We dissolved 100 mg of shield material in 2 ml MeOH, sonicated it for 5 min, and then centrifuged the sample for 20 min. The supernatant was placed in a gas chromatography (GC) vial and diluted 1:10, of which 10 μl were injected into an Agilent HP 1100 high-performance liquid chromatography (HPLC) equipped with a Lichrosphere RP18, 5 μm column. A water–CH_3CN gradient with a flow rate of 1 ml min^{-1} started at 70:30 CH_3CN/H_2O (*v*/*v*) from 0–30 min to 100% CH_3CN up to 45 min hold at 100% CH_3CN and then 45–45.5 min back to 70:30% CH_3CN/H_2O (*v*/*v*) for 60 min. The sample was analyzed by a Thermo Finnigan LCQ with a positive atmospheric pressure chemical ionization source, in full scan mode with a vaporizer temperature of 450°C, a capillary temperature of 145°C, a sheath gas flow rate of 60 arbitrary units, and an auxiliary gas flow of 15 arbitrary units. The discharge current was 5 eV, the capillary voltage 10 V, and the tube lens offset was 20 V.

Verification of Compound Bioactivity Based on the LC-MS results, a commercial pheophorbide *a* (Ph*a*) standard (Wako 163-11171) was applied to shields to measure repellence or deterrence in field bioassays. One day before a bioassay experiment, larvae were removed from storage and their shields detached by placing fine forceps between the tines of the caudal process and gently lifting the shield away from the larva. Larval bodies were returned to refrigeration at 0°C.

Shields were randomly assigned to either a Ph*a* treatment group, to an intact shield "control" group, or to a solvent control group. The shield groups receiving Ph*a* test solutions were subjected to the following leaching treatment to remove metabolites: 200 ml of MeOH for 45 min with agitation every 5 min, followed by 400 ml of H_2O for 45 min with agitation every 5 min. Shields were dried under a fan for 1 h and then placed individually in 2 ml glass vials. From a 1 mg ml^{-1} methanolic stock solution of pheophorbide *a*, dilutions were made to obtain 1, 3, 5, or 10 μg test dilutions (N=32, 36, 34, and 32 shields, respectively). For example, to apply 1 μg of Ph*a* to a shield, 40 μl of the stock solution was placed in a vial to yield 40 μg, which were then dissolved in 2 ml of MeOH. From this solution, 50 μl (1 μg) were topically applied to each shield. Shields were dried under a fan for 12 h. Each shield was reattached to the caudal process of a larva by using a rapid setting, fumeless, water-insoluble craft glue (DAP®), and allowed to dry 2 h before bioassays began. Shields in the solvent control group (N=41) were leached and dried as per above, and each shield received 50 μl of MeOH. Shields were dried 2 h before bioassays began. Unleached, intact controls (N=32) consisted of only the shield removal and reattachment manipulations described above.

Bioassay Protocol Field bioassays were conducted near Gamboa in September 2007, between 8:30 A.M. and 12:30 P.M. We used a common and aggressively recruiting generalist predator, the ant *Azteca lacrymosa* Forel (Hymenoptera: Formicidae: Dolichoderinae), in the bioassays. Voucher specimens of host, beetle, and ant species are deposited in the herbarium and insect collection of Smithsonian Tropical Research Institute, Panamá.

Bioassay experiments were conducted on a raised, 45×60×2 cm platform that was touching the bole of a tree with an *A. lacrymosa* nest (Fig. 1b). Vines and fallen branches with active ant trails were connected to the platform, and these formed clearly defined avenues across the platform's surface, which varied from four to seven daily. To verify foraging motivation in the ants, the platform was baited with tuna and sugar water 1 h prior to experiments. If baits were removed within the hour, an experiment was conducted with one of the treatments. Each bioassay trial consisted of the presentation of a single shielded larva. With soft forceps, we placed the larva 1 cm from an active foraging trail on the platform. A trial began after the first ant antennated the larva. Each bioassay trial lasted 5 min, or until a larva was captured. A larva was deemed captured when the ants carried it ≥1 cm sideways or backwards, and we recorded this interval as the time from first contact to capture. Individual trials were separated from one another by 3 to 5 min and were conducted along different trails on the platform separated from one another by at least 30 cm. These time delays and variable locations minimized recruitment interactions across assays to insure that different ants were involved in each bioassay trial. Trials of one of the treatment types or of intact larvae were interspersed randomly with trials of the solvent controls.

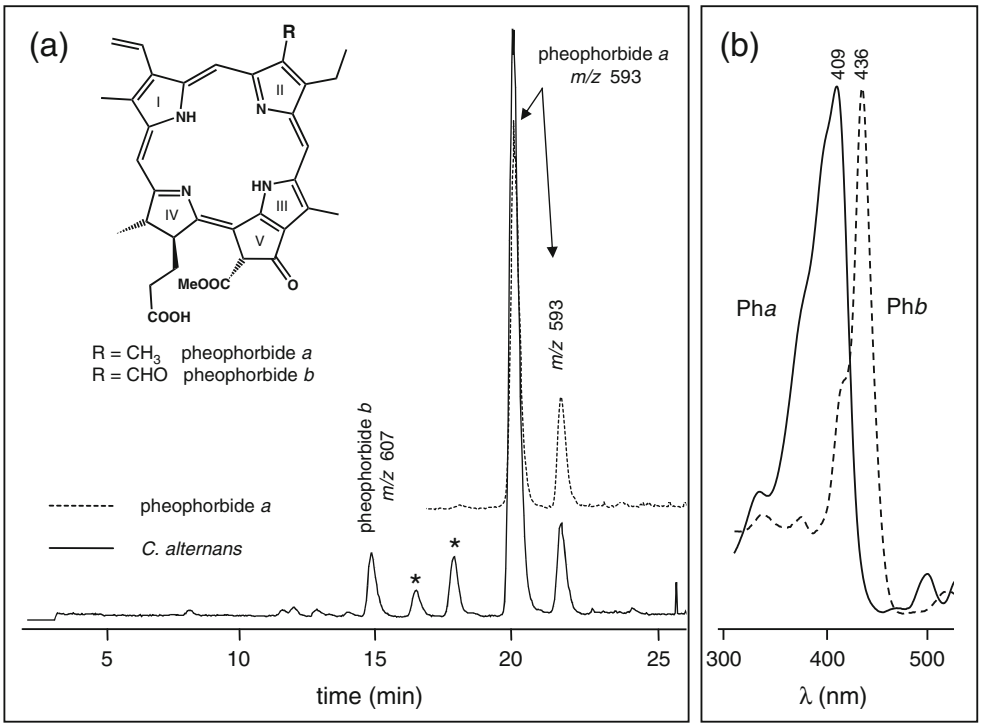

Fig. 2 Chromatographic separation and identification of chlorophyll catabolites from fecal shields of *C. alternans*. **a** LC-MS profile of the methanolic extract of larval shields (*straight line*) and the pheophorbide *a* standard (*dotted line*). The *two peaks* for Ph*a* represent epimeric esters of ring V (Smith et al. 1985), Ph*a* (R = CH_3), Ph*b* (R = CHO), (*asterisks*) unknown compounds. **b** UV spectra of Ph*a* (*straight line*) and Ph*b* (*dotted line*)

Quantification of Pheophorbide a For direct quantification of the components in the methanolic extract, shields (ca. 50 mg) were placed in methanol (2 ml) and sonified for 2 min. Solids were deposited by centrifugation (20 min at 20×*g*) and 10 µl of the supernatant, a clear liquid, were diluted with the tenfold volume of methanol followed by analysis by HPLC-MS without further purification.

To quantify pheophorbide *a* in shields, a calibration curve (peak area vs. concentration) was calculated by using reversed-phase HPLC-MS and the commercial Ph*a* standard at concentrations of 0.01, 0.10, 1.0, and 2.0 µg ml^{-1} MeOH under the same conditions used for the shield samples. The pheophorbide *a* standard gave two peaks, (84:16, see Fig. 2a) corresponding to the stereoisomers in ring V of Ph*a*, whose areas were added together and averaged (y=671,095,720.3552x; R^2=0.9947).

Statistical Analyses We examined larval capture times in the bioassay by using a partial regression failure-time approach, the Cox proportional hazard model (PROC TPHREG; SAS 2004). In contrast to classical methods, such as analysis of variance (ANOVA) that compare either the total number of captures at the end of the experimental time interval or the average capture time among treatment groups, failure-time methods compare the distributions of capture times throughout the entire bioassay period. Times to the occurrence of an event (e.g., capture of a larva by ants) typically do not meet the distributional assumptions required by traditional parametric approaches. In addition, many of the trials ended before a capture event was recorded (i.e., right-censored data), and the ultimate fate of the larva beyond the bioassay interval was unknown. Due to the exclusion of such right-censored events, fail-time approaches are more appropriate than ANOVA or frequency-based methods to detect time-dependant changes in resistance.

Capture functions were compared by using the Wilcoxon's signed ranks test followed by pair-wise multiple comparisons to determine specific differences between treatment groups (Kalbfleisch and Prentice 1980). Significance levels were corrected with the sequential Bonferroni technique (Dunn-Sidák method; Sokal and Rohlf 1995). This method is less conservative than the standard Bonferroni technique but ensures that an appropriate experiment-wise error rate (α=0.05) is maintained. Predation rates were graphed using the life table approach (PROC LIFETEST; SAS 2004).

Results

HPLC-MS of Shield Extract The LC-MS of a methanolic extract from *C. alternans* shields revealed two peaks at 20.18 min (84%) and 21.97 min (16%) both with a molecular ion at *m/z* 593.4 (Fig. 2a). Both peaks had a strong UV absorption around 409 nm accompanied by a smaller absorption at 666 nm (Fig. 2b). These data suggested the presence of a porphyrin-type compound, such as pheophorbide *a* (Ph*a*), the major catabolite of chlorophyll *a* in plants. Injection of authentic Ph*a* generated

the same two peaks at 20.10 min (84%) and 21.89 min (16%) in a similar ratio (Fig. 2a). Thus, on the basis of spectral (MS, UV, ^{1}H and ^{13}C nuclear magnetic resonance; see Smith et al. 1985) and chromatographic coincidence, the two major peaks at *m/z* 593 could be attributed to the chlorophyll catabolite, Ph*a* ($C_{35}H_{36}N_4O_5$).

The two 593 peaks are formed by the separation of the epimeric esters in ring V, which resulted from the facile enolization of the β-keto ester into a conjugated system followed by reprotonation. Due to the presence of a second chiral center in ring III, a mixture of diastereomers is formed that readily separates on the chromatographic column. In addition to the two Ph*a* peaks, we identified a minor signal for pheophorbide *b* (Ph*b*) at 14.79 min. Pheophorbide *b* is characterized by a molecular ion at *m/z* 607 and a long-wave UV maximum at 436 nm, which is due to the extended chromophore with the aldehyde group in ring II (Fig. 2a; R = CHO). The signals at 16.4 min (*m/z* 609) and 17.8 min (*m/z* 625) could not be identified (denoted *; Fig. 2a). These peaks most likely represent other, still unknown chlorophyll catabolites, since their UV spectra also exhibited maxima at 410 and 400 nm, respectively. The natural concentration of Ph*a* in *C. alternans* was determined to be 2.38 μg mg^{-1} of fecal shield. An individual shield had a mean (±SE) dry weight of 64 (±4) mg (*N*=34). The naturally relevant Ph*a* shield concentration was, therefore, estimated to be 152.3±9 μg per intact shield.

Bioassay of Pha-Loaded Shields The regression coefficients derived from the Cox proportional hazard model for shields augmented with 3, 5, and 10 μg concentrations of Ph*a* resisted capture significantly longer than did the solvent-leached controls (Fig. 3; *P*=0.05 after Bonferroni correction for multiple pair-wise comparisons; see "Materials and Methods"). Larvae with shields enhanced with 5 μg Ph*a* withstood capture at a slightly lower but not significantly different rate than did larvae with intact shields (Fig. 3). Capture rates for shields with Ph*a* concentrations of 10 μg did not differ significantly from intact shields (*P*>0.05). Shield concentrations of 1 μg of Ph*a* did not differ from solvent control shields (*P*>0.05).

Most of the ants first coming into contact with a treated larva appeared to hesitate, retreat a short distance with their abdomens raised, and then to re-contact the larvae by antennation or by touching (not biting) with open mandibles. Within the first minute of many bioassay trials (77/166) with intact and Ph*a*-treated larval shields, the first ants to contact a treatment larva either retreated a short distance and began antennal grooming, or they repeatedly ran in circles nearby the larva, only to return briefly without eliciting recruits or seizing the larva. In some trials (17/166), ants making initial contact with a Ph*a*-treated larva withdrew directly and never returned or recruited other ants. All of these behaviors created delays and indicated a reluctance to seize a larva. Such hesitancy contributed to

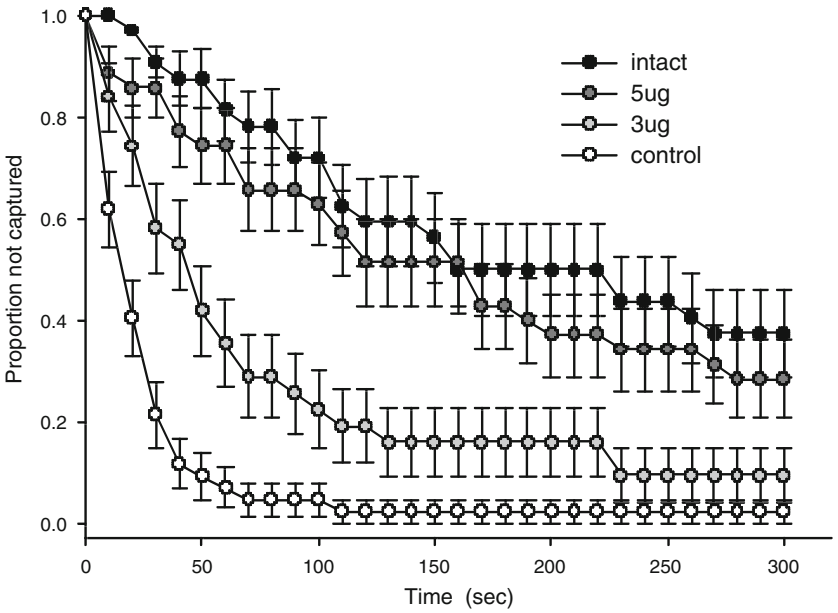

Fig. 3 Survival curves showing capture rates of *C. alternans* larvae with intact, pheophorbide *a*-augmented, or methanol control shields in the *Azteca* ant bioassay. Leached shields were enhanced with either 3 μg/shield (*grey circles*) or 5 μg/shield (*dark grey circles*) concentrations of pheophorbide *a*. Larval controls (*open circles*) had their shields leached (methanol and water), modified with 50 μl of MeOH, and then reattached. Intact shields (*solid circles*) were removed and reattached to larvae without leaching or the addition of any substances. Data from the 1 μg and 10 μg additions of Ph*a* were excluded for the sake of clarity. The former treatment was not different from zero Ph*a*, and the latter treatment did not differ from larvae with intact shields. *Bars* are the standard error of the life table estimate. Samples sizes: 3 μg=36, 5 μg=34, solvent control=41, and intact shields=32

the significantly longer capture times for both the Ph*a* and intact shield treatments. None of these behaviors were observed with the solvent-leached treatments.

Discussion

Our findings demonstrate that the shields of *C. alternans* larvae function mainly as deterrent chemical defenses. Ants avoid larvae only after coming into direct contact with them. On the basis of spectral and structural evidence, we identified actively deterrent compounds that reside in the methanolic extract of *C. alternans* shields as the chlorophyll catabolites, pheophorbide *a*, and pheophorbide *b*. The major metabolite, Ph*a*, with approximately 78% of total chlorophyll catabolites, exhibited significant deterrence against *A. lacrymosa* ants in the field bioassay. Judging from the behavioral responses of *A. lacrymosa*, shields derive their deterrent activity by contact irritancy and then by eliciting disorientation.

Pheophorbide *a* is potent. Deterrence was detected at only 1% or 2% of its natural shield concentration, which is on the order of 100 μg per shield. At 4% of its natural concentration (5 μg), Ph*a* appears to be responsible for over 90% of shield deterrence measured in this type of bioassay against this particular predatory enemy.

The origin of pheophorbide shield derivatives represents a two-step sequestration strategy, consisting of the assimilation and modification of the host plant precursor, chlorophyll, by the insect. Pheophorbide *a* and Ph*b* are most likely produced in the beetle's digestive system from ingested chlorophyll *a* and *b*. Probably no specialized enzymes, besides the ubiquitous lipases and esterases of the gut, are needed to remove the phytol side chain and the central magnesium ion (Kräutler et al. 1997). Pheophorbide *a*, thus, has a unique role in ecology: it is the first time that a chlorophyll degradation product has been assigned an interspecific, non-nutritive defense function, which may have implications for the wider occurrence of chlorophyll degradation products in other defense systems.

Although the vast majority of reports about its activity stem from the mammal literature, Ph*a* appears to have a wide range of activities, including anti-tumor, immunosuppressant, and bio-toxic properties. For example, exposure of human lymphoid leukemia Molt 4B cells to Ph*a* led both to growth inhibition and to the induction of programmed cell death (apoptosis; Hibasami et al. 2000; Chan et al. 2006). Chee et al. (2005) demonstrated that Ph*a* and its derivatives exhibit photocytotoxic activity in human leukemia and oral squamous carcinoma cell lines. As a possible therapeutic, Ph*a* isolated from *Psychotria acuminata* (Rubiaceae) inactivated cell surface receptors and contributed not only to the antitumor effects of photodynamic therapy but also to systematic immuno-suppression (Glinski et al. 1995). As a possible insect toxin, Ph*a* was shown to inhibit cholesterol acyltransferase, an enzyme necessary for the assimilation of the plant sterols that are required by insects to synthesize developmental hormones such as ecdysone (Song et al. 2002). When photosensitized, Ph*a* disrupted mitochondrial electron transport (Kim et al. 2004). Such findings suggest that bioassay experiments conducted in darkness may yield different results. In this connection, it is noteworthy that *C. alternans* larvae feed out of direct sunlight on the abaxial leaf surface. We do not know how the insect protects itself from the effects of Ph*a*. Perhaps the polarity of the molecule, although moderate, contributes to its compartmentalization in the gut, thus insulating it from vulnerable tissues. In favor of this idea is the fact that there is a free carboxyl group that might occur as a salt if the gut pH were alkaline. At least for Lepidoptera, where the foregut is extremely alkaline, with a pH of about 10.5, there are conditions favorable for salt formation (Funke et al. 2008). Future research on events in the gut is required to clarify this question.

Most chemically enhanced shield defenses examined so far rely mainly on host-derived secondary metabolites for their repellence or deterrence (see Müller and Hilker 2004). For instance, the *Cordia*-feeding *Eurypedus nigrosignata* and *Coptocycla leprosa* have potent chemical defenses based on host-derived terpenes (Gómez 1997; Gómez et al. 1999). However, there are a few reports of defenses in larval herbivores attributed to derivatives of co-opted primary compounds, such as chlorophyll or fatty acids. The shields of the *Solanum*-feeding tortoise beetle, *Plagiometriona clavata*, for instance, incorporate both primary host metabolites phytol, hexadecanoic, linolenic and oleic acids, and secondary metabolites like saponins and steroidal alkaloids that mount an effective deterrent defense (Morton and Vencl 1998; Vencl and Morton 1999; Vencl et al. 1999).

By intentionally removing behavior from the defense equation, this study focused on compounds that were separated with LC-MS, and the main peaks detected turned out to be potent in the *Azteca* ant bioassay. Since immobilized larvae with intact shields used in this study were not completely protected from *Azteca* ants—60% were taken within the 5-min bioassay timeframe—there may be more to the *Chelymorpha* defense, namely, (1) other shield chemicals, and (2) evasive behaviors and shield waving. First, from a theoretical standpoint, an herbivore that is threatened by many different enemies should incorporate a variety of different defensive compounds, rather than relying on a single repellent or deterrent, which may have limited efficacy against a broad spectrum of enemies. Even assuming that *Azteca* presently is and has been the major larval enemy, the possibility exists that there are other shield compounds, which may target different

enemies. Interestingly, phytol, a chlorophyll accessory molecule, along with a restricted suite of fatty acids, all of which are demonstrably deterrent (see references above), were detected by GC-MS examination of the hexane extract of *C. alternans*' shields (unpublished data). Future bioassay work will be required to determine if these ancillary compounds add to *C. alternans*' shield defense against *Azteca* or perhaps other enemies as well. Second, a live larva with intact behavior should survive this bioassay significantly better. For instance, a previous study that compared live *Acromis sparsa* and *C. alternans* larvae feeding on the same host (thereby equalizing chemical input to their shields) found that both species were equally resistant to *Azteca* ant predation (Vencl et al. 2005). Compared to *A. sparsa* however, *C. alternans* larvae responded to ant attack with increased defensive behaviors (escape and shield-waving). Moreover, once *C. alternans* larvae were deprived of such behavioral tactics (by freezing), they became significantly more vulnerable to predation compared to their equally immobilized counterparts. The resistance of live *C. alternans*, thus, appears due to higher levels of behavioral defenses. The ability to flee quickly, to tightly grip the substrate, and to reduce their apparency by hiding are important defense tactics for many Cassidinae species as well as for other exophytic larvae, such as those of the Lepidoptera (Stamp and Bowers 1992; Gentry and Dyer 2002; Zalucki et al. 2002). Future avenues of research should assess the importance of chemistry in relation to other defenses to first evaluate their separate contributions and then their possible interactions that may enhance overall survival in a nonlinear fashion.

Over the past 50 years, numerous studies have documented the role sequestered plant secondary metabolites play in herbivorous insect defenses against predators and parasitoids (Whitman et al. 1990; Trigo 2000; Nishida 2002). Given their astonishing diversity in plants, it is surprising that the majority of known defensive phytochemicals utilized by larval herbivores is restricted largely to the derivatives of just three secondary compound classes: phenolics, terpenes, and nitrogen-containing compounds, such as alkaloids and amino acids (Harborne et al. 1999; reviewed by Nishida 2002). This discrepancy may be due partly to an insufficient survey of larval defenses, especially of fore and aft discharges, many of which may rely on the assimilated secondary metabolites, and as demonstrated here, the degradation products of host-derived primary precursors. Erstwhile nutrients like Ph*a*, when activated and positioned strategically, may represent an economical and less dangerous alternative to sequestration of potentially auto-toxic or costly endogenously synthesized defense compounds. The widespread correlation of elaborate morphological annexes, fecal retention behaviors with appropriated host plant chemistry, strongly supports the idea that the recurrence of these traits constitutes an under-recognized, multi-trait integrated phenotype. It is conceivable that such trait assemblages may have been responsible for the astonishing success of the limited number of herbivore lineages whose exophytic larvae feed in the dangerous leaf adaptive precinct.

Acknowledgments We thank N. Rivas, Y. Lakey, and L. Cabilla Rios for laboratory support and technical assistance. An anonymous review and D. Windsor provided many useful insights. Experiments, sample exportation, and specimen collection were done under permits issued by the Authoridad Nacional del Ambiente de Panamá (ANAM). This is contribution #1165 from the graduate program of the Department of Ecology and Evolution at Stony Brook University. This research was supported by the US National Science Foundation IBN #108213 to FVV.

Hyperaccumulators and Herbivores—A Bayesian Meta-Analysis of Feeding Choice Trials

Peter A. Vesk · Suzie M. Reichman

Received: 24 November 2008 / Revised: 30 January 2009 / Accepted: 3 February 2009 / Published online: 26 February 2009

Abstract The leading hypothesis for the evolution of the metal hyperaccumulation trait in plants is as a defense against herbivores. A central piece of evidence expected for this hypothesis is that plants benefit from herbivores being deterred from eating high metal tissues. While many studies have investigated whether or not herbivores are deterred by high metal feeds, there has been no quantitative synthesis of these studies. We performed a Bayesian meta-analysis of 31 feeding choice trials from ten published studies, where invertebrates were offered diets of plant tissue from hyperaccumulating species with high and low metal concentrations. Results of individual trials ranged from distinct preference to distinct aversion for high metal diets. The overall mean effect was for herbivore aversion to high metal diets, whether we used fixed or random effects. However, random effect models were better supported than fixed effect models, indicating there was much real variation between trials. This variation could be attributed partly to each of herbivores, plants, studies, and metals, with herbivores being the greatest source of variation. On average, high metal diets deterred insects but not gastropods, which is supported by other research of metal tolerance and sequestration by gastropods. This suggests that the evolution of hyperaccumulation may have differing selective pressures depending upon the suite of herbivores the plants are naturally exposed to. Future studies should give greater consideration to the selection of herbivores and plants tested.

Introduction

Metal hyperaccumulation, i.e., the ability to accumulate and tolerate large concentrations of metal[1] in aboveground tissues, has been identified in over 415 species of plants across a range of genera, families, and orders worldwide (Baker et al. 2000). Threshold concentrations for the metal hyperaccumulation trait are orders of magnitude higher than the concentrations found in "normal" plant species, e.g., the thresholds for classification as a zinc, nickel, or selenium hyperaccumulator are 10,000, 1,000, or 100 μg g^{-1} metal in the shoots (dry weight), respectively (Baker et al. 2000; Reeves and Baker 2000). Interest in metal hyperaccumulating plants is high within both the research and management communities because of the potential use of hyperaccumulating species in phytoremediation of metal-contaminated sites and the need to conserve the unique and often endangered metalliferous ecosystems in which hyperaccumulating species are found (Whiting et al. 2004).

Boyd and Martens (1992) evaluated early research on hypotheses for the evolution of hyperaccumulator plants and concluded that the herbivory/pathogen-defense hypothesis was the most plausible. Their review stimulated much research that explored the defensive role of hyperaccumulated metals against terrestrial invertebrate herbivores. Boyd's review of 34 studies of the defense hypothesis

[1] Metal hyperaccumulating plants generally are considered to include those that hyperaccumulate metals, such as zinc or copper, and/or metalloids, such as selenium or boron. Throughout this paper, the term metal is used to include both metals and metalloids.

(Boyd 2007) has clarified the categories of evidence needed for demonstration of a selective benefit of hyperaccumulation. There is considerable, but not total, support for the herbivory-defense hypothesis among the hyperaccumulator research-community (e.g., Boyd et al. 2002; Jhee et al. 1999; Pollard 2000; Pollard and Baker 1997). One form of evidence for the herbivory-defense hypothesis is herbivore deterrence in feeding choice trials (Boyd 2007). A number of researchers have investigated the potential of hyperaccumulated metals to protect plants from herbivory via feeding-choice experiments where invertebrate herbivores were offered a choice of leaf tissue (high or low metal concentration) from hyperaccumulator plants, and the feeding preferences were analyzed. Results have varied widely among these, ranging from aversion (e.g., Boyd et al. 2002; Hanson et al. 2004; Martens and Boyd 2002) to preference for a high metal diet (e.g., Boyd and Martens 1999; Hanson et al. 2003; Noret et al. 2005). Findings from choice trials were tabulated, reporting the number that showed a defensive effect (Boyd 2007). This methodology, called vote counting, is limited in its utility for quantitative synthesis (Hedges and Olkin 1980; Bushman 1994). Specifically, Boyd (2007) did not examine the magnitude of the effect and variation therein. By building on Boyd's review (2007), we report here a Bayesian meta-analysis of the published data from feeding-choice trials. Our objective was to investigate quantitatively the following questions: (1) Is there a deterrent effect of high metal concentrations in the leaf tissue of hyperaccumulator plants against herbivory by terrestrial invertebrates? (2) If so, how large is the effect? (3) How does the effect vary among trials? (4) Can the variation be explained?

Methods and Materials

Meta-analysis is a process of quantitative synthesis of results of multiple studies of the same process. By combining results of multiple studies, greater statistical power to examine hypotheses is attained. Moreover, the generality of a model can be examined and effects of covariates determined. We used a Bayesian statistical framework for our analysis for two main reasons. First, we were interested in estimating effect sizes or parameters and confidence in them, rather than the statistical significance of a test of a null hypothesis, as what occurs with classical or frequentist statistical approaches (McCarthy 2007). Second, in many cases, random effect models are more appropriate than fixed effects models (Raudenbush 1994). This is because we expect variation of parameters for biological and logistic reasons, i.e., a range of effect sizes, due to differences in biological interactions that are beyond sampling variation. The technical aspects of performing frequentist random effects meta-analyses are complex, and procedures are neither straightforward nor accepted universally (Raudenbush 1994). By contrast, random effect models, and models with a mixture of fixed and random effects, can easily be constructed and evaluated with Bayesian inference by using Markov Chain Monte Carlo sampling methods (Clark 2005; Link et al. 2002). For an introduction to Bayesian modeling, we suggest Link et al. (2002) and McCarthy (2007).

Our aim here was to compile quantitatively and analyze a data set of invertebrate binary choice feeding trials. We obtained the data set from peer-reviewed publications that reported feeding choice trials of invertebrate herbivores offered control and high metal concentration diets of metal hyperaccumulating plants. We located the publications through personal bibliographies, searches of the online database, Thomson ISI Web of Science (latest search April 2008), and the tabulation provided by a recent review (Boyd 2007). Ten papers were found that fit our criteria for analysis, namely, that means, sample sizes, and precisions (standard errors) for consumption of plant tissue were accessible in the paper. Multiple trials often were reported in a single publication, either as repeat runs or by using different herbivores or plant population combinations. Thus, our data set comprised 31 individual trials (Table 1).

To account for differences in the way trials were conducted (e.g., age and size of herbivores, trial duration) and how response variables were measured (e.g., area vs. mass consumed, absolute vs. relative consumption), we transformed the response data to reflect the proportional change in consumption between control and high metal diets. Because the minimum consumption of a herbivore is zero and because most individuals ate small amounts with a few individuals eating large amounts (i.e., a right skewed distribution), we modeled the data with log-normal distributions. In addition, the skewed data led to standard errors that increased in magnitude with the mean. Hence, we used means and standard errors as presented in the original papers to calculate the parameters for log-normal distributions by using the following formulae (McCarthy 2007):

$$c = \sigma^2/\mu^2 + 1, \tag{1}$$

$$a = 1\mathrm{n}(\mu) - 0.51\mathrm{n}(c), \tag{2}$$

E is the effect size and is positive where control diets were preferred to high metal diet. τ is the precision of the estimated effect size and is the inverse of the variance. See text for details. Trial refers to the trial number in Fig. 1. *G* after the herbivore indicates gastropod, *I* indicates insect

precision (inverse of the variance) of the log-normal. Where data were only presented as graphs, we first scanned the figures and then used the program Datathief (http://www.datathief.org/) to recover mean and standard error values. The effect size (E) of the metal on consumption was then calculated as:

$$E = a_{\text{control}} - a_{\text{metal}} \quad (4).$$

The precision of the effect size was calculated as (assuming independence, so that the variances are additive):

$$\tau = \frac{1}{\left(\frac{1}{t_{\text{metal}}} + \frac{1}{t_{\text{control}}}\right)} \quad (5).$$

In this way, we obtained the basic dataset where the response variable was the effect size, E, and associated precision, τ, for each binary choice trial (Table 1).Note that these effect sizes are not *differences* but *differentials* that reflect how many times more of one diet is consumed than another. Because the effect is on a natural log scale, values for E of 0.5, 1, 2, 3 correspond to eating 1.6, 2.7, 7.4, and 20 times as much of the control diet over the high metal diet; negative values of E imply preference for the high metal diet. τ is the inverse of the variance and, thus, can be converted to a standard error by taking the square root of the inverse. Large values of τ equal small standard errors; e.g., τ =0.5, 1, 5, and 10 yield standard errors of 1.4, 1, 0.45, and 0.32, respectively.

The differentials obtained above were modeled with simple linear models by using Bayesian statistics. Models were fitted by using the Bayesian statistical modeling software WINBUGS 1.4.1 (Lunn et al. 2000), available as freeware from http://www.mrcbsu.cam.ac.uk/bugs/. We began by modeling the differential as a fixed coefficient, such that observed effect sizes were distributed around the grand mean with only random error variance. Next, we modeled the differential as a random coefficient, such that observed effect sizes were random draws from a population of effect sizes for which we inferred the mean and variance. This allowed all trials to have their own effect size, which is drawn from some unknown distribution that we seek to model. Third, we sought to examine the effect of introducing information about covariates as random effects into the models with the differential being a fixed effect or a random effect. Four covariates were included: (1) the publication; (2) the plant species (one of *Brassica juncea*, *Senecio coronatus*, *Stanleya pinnata*, *Streptanthus polygaloides*, *Thlaspi caerulescens*); (3) the herbivore species (see Table 1); and (4) the metal studied (nickel, selenium, or zinc). Finally, we fitted a model with an herbivore type as fixed effect to examine the difference between gastropods and insects.

Although Bayesian inference has the potential to incorporate prior information as expert belief or ancillary data, we chose not to use this, and rather used minimally informative prior distributions for the parameters of interest. All fixed effect coefficients were modeled as being drawn from normal distributions with mean 0.0 and SD 1,000. Random effect coefficients were modeled as normally distributed with mean 0.0 and SDs drawn from a uniform distribution over the interval (0, 100). Three Markov chain Monte Carlo (MCMC) chains with different initial values (−1, 0, 1) were run simultaneously for each model. In all cases, burn-in phases were >1,000 iterations. Standard Bayesian MCMC diagnostics were used to assess convergence, including plots of each of the chain traces, chain autocorrelations, and the Gelman–Rubin statistic (Spiegelhalter et al. 1995; Zuur et al. 2002). Bayesian 95% credible intervals were calculated from the posterior probability density of monitored parameters, in each case by using >50,000 samples. When minimally informative priors are used, as used here, credible intervals are practically equivalent to frequentist confidence intervals calculated with maximum likelihood estimation. The estimates for the effect sizes (E) (and credible intervals) were then converted back to an arithmetic scale by exponentiating, i.e., differential consumption=e^E.

For model selection, the series of models was compared by using the deviance information criterion (DIC) (Spiegelhalter et al. 2002), calculated with WINBUGS. In a given dataset, the model with the lowest DIC is the model that would be most likely to produce a dataset of the same structure as that observed. That is, it is the model that best balances model fit, as measured by the deviance, and model complexity, as measured by the estimated number of parameters in the model. The percentage of deviance explained by a fitted model (similar to R^2) was calculated as the total deviance minus the deviance for the fitted model, divided by the total deviance, using the deviances at the posterior mean of the parameters $\left(\hat{D}\right)$.

Results

The effect sizes (E) modeled for individual trials ranged widely from strong aversion to strong preference (Fig. 1). For the null model, which posits that all measured effect

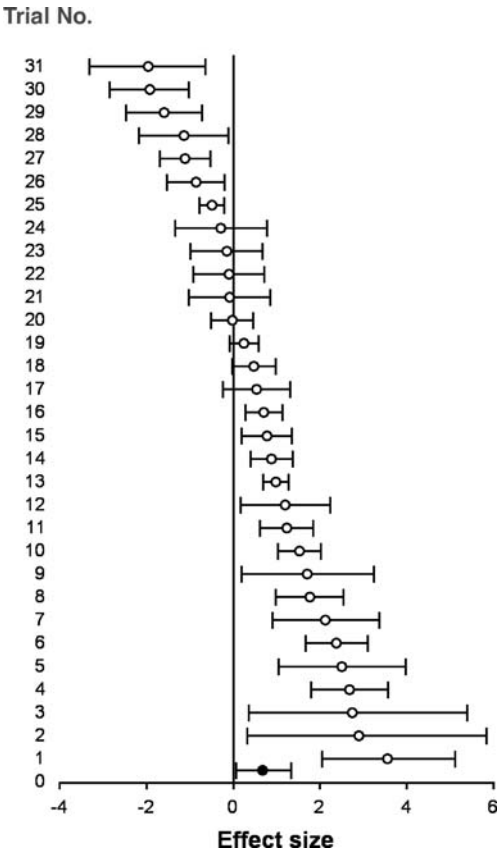

Fig. 1 Effect sizes (with 95% Bayesian credible intervals) of 31 binary choice trials of invertebrate herbivores offered control and high metal concentration plant tissue from a random effects model. Effect size is a natural log scale; positive values indicate aversion to the high metal, and negative ones indicate preference. *Zero* indicates no preference, equal amounts of control and high metal diets are chosen. Individual effect sizes of trials (*open circles*) range widely from strong preference to strong aversion to the metal (see Table 1 for identification of the trial the numbers refer to). The credible interval around the mean effect size (*filled circle, at bottom of graph*) reflects uncertainty about the location of the mean. The distribution of 95% of population effect sizes expected is about twice as wide

sizes should be equal and only vary through sampling error, the mean effect size (and 95% credible interval) was 0.43 (0.32, 0.54). This implies that, on average, invertebrates avoided the high metal plant leaves and ate a mean of 1.54 (1.38–1.72) times as much control diet as high metal diet. However, compared by DIC, the fixed effect model was the poorest of those examined (Table 2). The random effects model had a mean effect size of 0.71 (0.10, 1.36; Fig. 1) corresponding to herbivores eating 2.03 (1.10, 3.89) times as much control diet as high metal diet. The SD of the estimated mean effect was 0.32, but that among trials was fivefold greater, 1.62 (1.19, 2.29), which underscores the relevance of trial-to-trial variation. In other words, the mean effect is larger, but less certain when we account for real variation among trials.

Introduction of covariates improved fixed effect models beyond the null model (see model 11 in Table 2). This is because, for a given level of a covariate, e.g., for the herbivore *Pieris rapae*, the observed effect sizes from different trials were far from equal. In comparison, once the random effect of the trials was included, the addition or removal of other covariates had relatively little influence on model selection (Table 2). Models that included herbivore or plant were better supported than those that included metal or study. There was little evidence for an effect of metal type. The effects for the individual metals all had SDs at least three times as large as the means.

The best-supported model had random effects of herbivore, plant, and trial (Model 1 in Table 2). According to this model, the mean effect size was 1.41 (−0.40, 3.53), corresponding to 4.1 (0.67, 34.1) times as much control food as high metal food being consumed (Fig. 2). Hence, the uncertainty increased over the model of trial-to-trial variation only, and we cannot be certain that, on average, high metals deter herbivores. Examining the SD of the various random effects revealed important variation among herbivores [SD_h=1.63 (0.52, 3.52)], and among plants [SD_p=1.16, (0.10, 4.63)], and variation between trials was reduced [SD_t=1.06 (0.70, 1.69)] relative to the model with a random trial effect only. The uncertainty about variation among plants was in part because so few hyperaccumulators have been studied. On average, *Stanleya pinnata* and

Table 2 Comparison of models of the effect of high metal concentrations in plant tissue on invertebrate consumption

	Model	DIC	$\widehat{D}$	Explained deviance (%)
1	Trial, herbivore, plant	66.0	11.0	96.9
2	Trial, herbivore, study	66.6	11.7	96.7
3	Trial, herbivore, metal	66.8	12.0	96.6
4	Trial, herbivore	67.7	13.2	96.3
5	Trial, plant	68.0	11.8	96.7

7	Trial, metal	68.6	12.3	96.5
8	Trial, study	68.8	13.4	96.2
9	Trial	69.0	13.0	96.3
10	Herbivore, plant, study	143.5	115.8	67.4
11	Null model, fixed mean effect only	356.9	354.9	0

DIC is deviance information criterion, $\widehat{D}$ is the deviance at the posterior mean of the parameters, Explained deviance reports how much residual deviance after the fitting of a null model (no. 11) is explained by a particular target model. Models with low DIC values are more parsimonious than those with high ones. Models with DIC values that differ by less than about 2 are of equivalent predictive value. All models that included a random effect of trial were more parsimonious than those that did not. Only one such model that lacked an effect of trial is included here for comparison, model 10

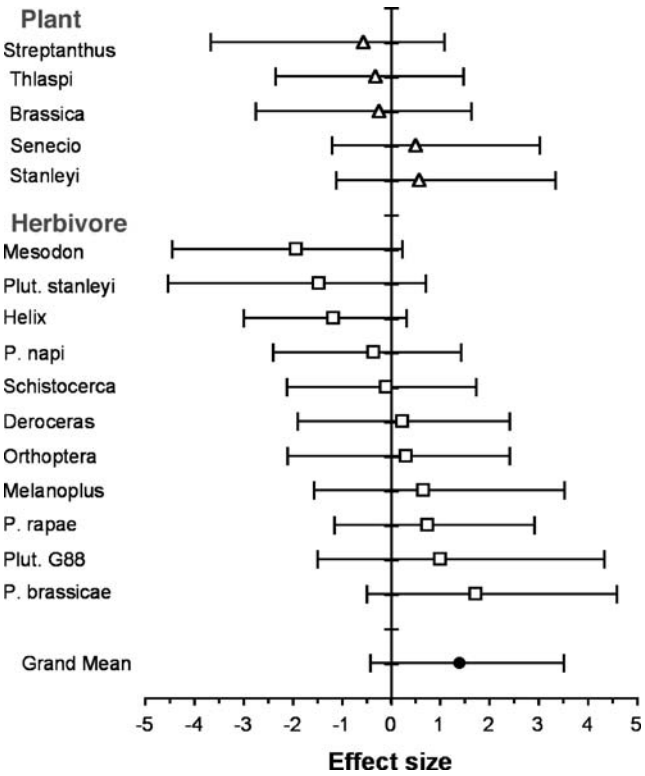

Fig. 2 Plot of the mean (and 95% Bayesian credible intervals) for the effect of plants (*triangles*) and herbivores (*squares*) on differential consumption of control and high metal concentration plant tissue in feeding choice trials. The Grand Mean (*filled circle*) effect is at the bottom of the graph. Zero indicates no preference, equal amounts of control and high metal diets are chosen. The effects of the plants and herbivores are centered on zero and would be added to the Grand Mean. Effect size is a natural log scale; positive values indicate aversion to the high metal, and negative ones indicate preference. Credible intervals here reflect the uncertainty around mean effect sizes. The distribution of 95% population effect sizes expected is about twice as wide

Senecio coronatus tended to evoke greater herbivore deterrence (Fig. 2).

Of the herbivores, the snails, *Mesodon ferrissi* and *Helix aspersa*, were less likely to be deterred by high metal concentrations, thus suggesting a difference in tolerance between gastropods and insects (Fig. 2). Further, the demonstrably Se-tolerant moth, *Plutella xylostella* Stanleyi (Freeman et al. 2006), also was less likely to be deterred by high metal (Se) than other herbivores.

Probing deeper into the herbivore effect, we fitted a model with a fixed effect for herbivore (insect vs. gastropod) as well as random effects for plant and trial (Table 3). This revealed that gastropods were unlikely to be deterred from eating high metal plants; the credible interval around the mean effect for the gastropods included zero, and the mean effect was close to zero (Table 3). By contrast, high metals were likely to deter insects. The contrast between the effects of the herbivores (insects minus gastropods) was 1.84 (0.67, 3.08), which means that the deterrent effect of high metals was on average 6.3 times (1.95, 21.7) greater for insects than for gastropods. Note that the Se-tolerant *Plutella* was included in the insects, yet this did not influence the average deterrence of insects greatly.

Discussion

The meta-analyses revealed three major findings. (1) On average, high metal concentrations in hyperaccumulators deterred herbivory by terrestrial invertebrates. (2) The variation was so great, however, that individual trials revealed results that ranged from distinct metal aversion to distinct metal preference. Some of this variation could be explained by the identity of herbivores, plants, metals, and studies. (3) Herbivores were the greatest source of variation in deterrence, with the suggestion that hyperaccumulation deterred insects but not gastropods.

This work supports an interpretation that metal hyperaccumulation by plants leads to herbivore deterrence, which is a key piece of evidence expected for antiherbivory defense being a reason for the evolution of hyperaccumulation (Boyd 2007). The variability between the effect sizes of individual trials was too great to be considered the result of simple "sampling error". Rather, there is a wide distribution of true effect sizes. It is expected that future studies will report results that range from distinct metal aversion to distinct metal preference, and that some of the range is because there are situations where the true preference is for a high metal diet, rather than just being a result of stochastic sampling variation.

The study identity explained some of the variation in feeding choice. There are a number of possible interpretations of this result. A skeptical interpretation is that experimenters have strong influence on results. A more positive and probable interpretation is that although the herbivore, plant, and metal all influence the effect of high metal on feeding choice, these factors are more similar within studies than between studies. For instance, while three studies compared different herbivores, none compared different plant species. Indeed, one study (Noret et al. 2005) contributed 11 trials, all with the same herbivore and plant species combination. That publication points to a possible "file drawer effect," whereby single or underpowered trials that fail to detect herbivore deterrence are either not submitted for publication or are rejected because they do not match with (unspoken) expectations (Moller and Jennions 2001). The study of Noret et al. (2005) contributed a disproportionate share of trials that indicated preference for high metal diets; perhaps so many trials were needed to convince authors, editors, and reviewers that the findings were not "mistakes." Ecotypic variation within plants and herbivores studied in multiple studies also may contribute to the variation.

Because the distribution of herbivores and plants across studies was limited, uneven, and confounded, the power of

Table 3 Parameter estimates for a model with a fixed effect of insects versus gastropods and random effects for plants and trials

	Mean	SD	2.5% CI	Median	97.5% CI
Insects	1.89	0.72	0.51	1.86	3.42
Insects-Gastropods	1.85	0.61	0.67	1.84	3.08

SD_p	0.97	1.02	0.04	0.72	3.43
SD_t	1.34	0.24	0.94	1.32	1.89

The fixed effect for the herbivore type was modeled such that gastropods were the reference class. This model had a DIC value of 66.6, and $\hat{D} = 11.9$. Insects–gastropods is the contrast between the two classes of herbivore

the analysis to estimate effects of herbivore or plant or metal was limited. Estimates of mean effect sizes for plants and herbivores varied over threefold and 30-fold, respectively, when back-transformed (Fig. 2), but the credible intervals for predictions were broad. The most striking result was that high metal diets did not deter snail herbivory. Our random effect analysis recovered the effect of the evolution of Se-tolerance in a taxon of *Plutella xylostella* (Freeman et al. 2006; compare the two *Plutella* effects in Fig. 2). Yet, high metals deterred the two snail taxa even less than the Se-tolerant *P. xylostella stanleyi*. Indeed, in a study that we could not include in our analysis because we could not extract the relevant statistics, *Helix aspersa* did not distinguish between low and high metal diets of *Arabidopsis halleri* (Huitson and Macnair 2003), thus supporting our results for snails. We note that snails, particularly the species most frequent in our dataset, *Helix aspersa*, have been shown to be tolerant of, and to accumulate, high levels of metals (Coughtrey and Martin 1976, 1977). Snails also regulate free metal concentrations through binding to metallothioneins and calcium phosphate granules (Berger and Dallinger 1989; Howard et al. 1981; Marigomez et al. 2002). If the two snail species, *Mesodon ferrissi* and *Helix aspersa*, and the Se-tolerant *Plutella xylostella* Stanleyi were omitted from the analysis (e.g., in Fig. 2), the effect would be to increase the grand mean deterrent effect and reduce its uncertainty due to these herbivores being the least deterred by metal-rich diets.

Our fixed effect contrast of the gastropods and insects showed that while insects were deterred from eating high metal plants, gastropods were not. This is an important result for better understanding the evolution of hyperaccumulation as a defense. Caution is required because, strictly, the fixed effect analysis cannot be used as a basis for inference about other gastropods and insects, unlike the random effects analysis. The fixed effect also ignores herbivore species variation within those classes of insects and gastropods. This clearly is incorrect; compare the two snails *Helix aspersa* and *Mesodon ferrissi* with the slug *Deroceras caruanae* (Fig. 2). However, visual interpretation of the parameter estimates from the random effect model in Fig. 2 supports the finding that, on average, hyperaccumulation deters insects but not gastropods. Whether this is a general result requires targeted research. Our analyses suggest the evolution of hyperaccumulation may have differing selective pressures that depend upon the suite of herbivores the plants are naturally exposed to. Where gastropods are a large component of potential herbivores, selection for hyperaccumulation as a defense may be diminished.

Explanation for the wide variability in the results may lie in the choice of widespread, generalist herbivores for most herbivory-defense trials on hyperaccumulating plants, including those analyzed here. Herbivores endemic to, or at least occurring in, areas inhabited by hyperaccumulator species may be better able to identify metals in plant tissues and avoid them. Further, with sufficiently long exposure to hyperaccumulators, one might expect the evolution of deterrence and/or detoxification mechanisms in some of these endemic herbivores (e.g., Freeman et al. 2006; Wall and Boyd 2006). We suggest that future researchers pay more attention to the choice of plant–herbivore pairings. Studies that cover multiple plant–herbivore combinations reduce the confounding of studies, plants, and herbivores. Further research also could use the results of this work as priors to be updated with new data using the Bayesian statistical framework (McCarthy and Masters 2007).

Physiological, Nutritional, and Biochemical Bases of Corn Resistance to Foliage-Feeding Fall Armyworm

Yigen Chen · Xinzhi Ni · G. David Buntin

Received: 1 December 2008 / Revised: 20 January 2009 / Accepted: 23 January 2009 / Published online: 17 February 2009

Abstract Three corn (*Zea mays*) germplasm lines [i.e., Ab24E (susceptible control), Mp708 (resistant control), and a locally selected partial inbred line FAW7050 (resistant)] were examined for *Spodoptera frugiperda* (J.E. Smith; Lepidoptera: Noctuidae) resistance. Nutritional [i.e., total protein content, amino acids, glucose, total nonstructural carbohydrates (TNC), protein to TNC (P/C) ratios] and biochemical (i.e., peroxidase and lipoxygenase 3) properties in the seedlings of these corn lines were examined to categorize resistance mechanisms to *S. frugiperda.* Physiological changes in photosynthetic rates also were examined in an attempt to explain nutritional and biochemical dynamics among corn germplasm lines and between insect-infested and noninfested corn plants within a germplasm line. Results indicated that *S. frugiperda* larvae survived better and developed faster in susceptible Ab24E than in resistant FAW7050 or Mp708. The three germplasm lines differed in resistance mechanisms to *S. frugiperda*, and the observed patterns of resistance were probably collective results of the P/C ratio and defensive proteins. That is, the susceptibility of Ab24E to *S. frugiperda* was due to a high P/C ratio and a low level of induced defensive compounds in response to insect herbivory, while the resistance of FAW7050 resulted from elevated defensive proteins following insect herbivory, low P/C ratio, and elevated defensive proteins in Mp708 contributed to its resistance to *S. frugiperda*. The elevated protein amounts in resistant Mp708 and FAW7050 following *S. frugiperda* injury were likely due to greater conversion of photosynthates to defensive proteins following the greater photosynthetic rates in these entries. Greater photosynthetic capacity in Mp708 and FAW7050 also led to higher amino acid and glucose contents in these two lines. Neither amino acid nor lipoxygenase 3 played a critical role in corn resistance to *S. frugiperda*. However, high inducibility of peroxidase may be an indicator of *S. frugiperda* susceptibility as observed elsewhere.

Introduction

Plant nutritional levels and allelochemicals often affect plant suitability and resistance to insect herbivores. Insects that feed on diets or host plants that are high in nitrogen generally have greater growth rates, higher efficiency of conversion of ingested food, and shorter developmental times than when fed on plants with low nitrogen content (Mattson 1980; Woods 1999; Chen et al. 2008). Many herbivorous insects can distinguish qualitatively among host plants or diets and feed and oviposit preferentially on high quality plants (White 1984; Fox et al. 1990; Prudic et al. 2005; Bede et al. 2007; Chen et al. 2008). For instance, larvae and females of beet armyworm, *Spodoptera exigua*, preferred

cotton plants, *Gossypium hirsutum*, with higher nitrogen fertilization for feeding and oviposition, respectively (Chen et al. 2008).

Proteins and amino acids in the diet are the major sources of nitrogen for arthropod growth. Many arthropods have evolved effective strategies to combat the inadequacy of nutrients in their environment (White 1993; Bede et al. 2007). Nutrient balance, in particular, the protein to digestible carbohydrate (P/C) ratio also has been shown to be important for the development of many insects under artificial diet conditions (Simpson and Raubenheimer 1993; Lee et al. 2002; Bede et al. 2007).

Many plants undergo significant biochemical changes following attacks by pathogen and insect herbivores (Hildebrand et al. 1989; Felton et al. 1994; Stout et al. 1994; Bi et al. 1997; Chittoor et al. 1999; Ni et al. 2001; Heng-Moss et al. 2004). For example, increased peroxidase activity in response to pathogen infections was found in rice, *Oryza sativa* L., and cotton, *G. hirsutum* L. (Chittoor et al. 1999). Besides peroxidase, changes in activity triggered by pathogen infection and insect herbivory have been demonstrated in other oxidases and hydrolases such as catalases, polyphenol oxidases, lipoxygenases (linoleate/oxygen 13-oxidoreductase), and esterases (Felton et al. 1994; Duffey and Stout 1996; Ni and Quisenberry 2003). The increases in activity of many of these enzymes are involved in plant resistance by decreasing the nutritive value of host plants (Shukle and Murdock 1983; Felton et al. 1994; Duffey and Stout 1996; Ni et al. 2001; Ni and Quisenberry 2003). For example, corn earworm, *Helicoverpa* zea (Boddie; Lepidoptera: Noctuidae), larval feeding on soybean foliage for 72 h significantly increased lipoxygenase activity compared to undamaged foliage (Felton et al. 1994). The growth of *H. zea* larvae fed on previously damaged leaf tissues was significantly reduced (over 27%) compared to larvae fed on undamaged leaves.

Photosynthesis is a complex, integrated, and dynamic metabolic process that optimizes the use of carbon and nitrogen. It is regulated by the sources (e.g., light and CO_2) and sink (e.g., photo-assimilate, such as sugars; Paul 1981; Paul and Foyer 2001). An understanding of plant photosynthetic capacity may provide insight into dynamic changes of proteins, amino acids, and carbohydrates such as glucose and starch in growing plants.

In this study, we aimed to categorize possible mechanisms of resistance to *Spodoptera frugiperda* from nutritional and biochemical perspectives in three germplasm lines of corn. We examined nutritional components [i.e., total protein content, amino acids, glucose, total nonstructural carbohydrates (TNC), amino acids to TNC ratio] and biochemical (i.e., peroxidases and lipoxygenases) properties of these corn germplasm lines with various degrees of insect resistance in response to *S. frugiperda* injury. Changes in photosynthetic rates and A/Ci and light response curves also were investigated in an attempt to elucidate nutritional and biochemical dynamics among germplasm lines and between insect-damaged and undamaged plants.

Methods and Materials

Corn (*Zea mays*) Plants

Corn plants in the greenhouse were grown in 2-l flower pots filled with sphagnum peat moss (Premier Horticulture Inc., Quakertown, PA, USA) and landscape top soil (Hood Timber Co., Adel, GA, USA) at a ratio of 3:1 as a growing medium. The greenhouse was set at 28±2°C with light/dark (L/D) of 14:10 h. Yardiac vegetable Osmocote slow release fertilizer (N–P–K=14:14:14; Greenville, SC, USA) was mixed with the growing medium according to instructions provided by the manufacturer, and no fertilizer was applied thereafter. Corn plants in the field were grown following agronomic practices for Georgia corn production as described in Ni et al. (2008) on Belflower Research Farm at Tifton, GA, USA. In all greenhouse and field studies, three corn germplasm lines (i.e., Ab24E, Mp708, and FAW7050) were used. Ab24E (Callahan et al. 1992) and Mp708 (Williams et al. 1990) represented the susceptible and resistant controls, respectively. FAW7050 was a partial inbred line derived from FAWCC(C5) (Widstrom et al. 1993) that had been self-pollinated for six generations between 2004 and 2006. Thus, the three entries of the two inbreds (i.e., Ab24E, Mp708) and the partial inbred (i.e., FAW7050) will be referred to as germplasm lines throughout the text.

Fall Armyworm (*S. frugiperda*) Infestation and Development in the Greenhouse

Fall armyworm neonates were obtained from a colony maintained at US Department of Agriculture Agricultural Research Service Crop Protection and Management Research Unit at Tifton, GA, USA. Five neonates were gently placed at the whorl of corn plants by using a camel hair brush when plants were at the six-leaf stage. Control plants without *S. frugiperda* neonates were placed away from the infested plants. Seven days after infestation, surviving *S. frugiperda* larvae were counted and weighed. Larval survival rates were calculated as the number of recovered larvae divided by 5. Larvae were thereafter kept individually on modified Pinto bean diet (Burton 1969) until pupation in an insect rearing room at 28±1°C with L/D= 16:8 h. Pupation of larvae was recorded, and pupal biomass was measured. Ab24E and FAW7050 were replicated six

times, while Mp708 was replicated three times because of limited availability of plants.

S. frugiperda Damage in the Field

To investigate *S. frugiperda* damage under natural conditions, artificial infestation of field-grown corn was conducted. The experimental design was a split plot. The plot was first randomly divided into four main plots, and each main plot has six consecutive rows. Each main plot was further split into three subplots with double rows and randomly assigned to three corn germplasm lines. In each subplot, one of the double rows was infested with 15 *S. frugiperda* neonates when the plants were at the six-leaf stage using the previously described protocol (Davis et al. 1996). The other row was used as uninfested control plants. *S. frugiperda* damage was rated at 7 and 14 days, respectively, after infestation by using a scale of 1–9 according to Davis et al. (1992) and Smith et al. (1994), where 1=no damage or few pinholes, 2=few short holes on several leaves, 3=short holes on several leaves, 4=several leaves with short holes and a few long lesions, 5=several holes with long lesions, 6=several leaves with lesions <2.5 cm, 7=long lesions common on one half of the leaves, 8=long lesions common on one half to two thirds of leaves, and 9=most leaves with long lesions.

Sample Preparation for Protein, Amino Acid, and Carbohydrate Assays

All samples collected for protein, amino acid, and carbohydrate assays were from greenhouse-grown plants. The youngest corn leaves (V7) with leaf collars were collected immediately after removal of *S. frugiperda* larvae and flash frozen in liquid nitrogen. Leaves were transported on ice to the lab and stored at −20°C until the bioassays. The experimental design was a 3 (corn germplasm)×2 (insect-infested and uninfested) factorial design. Six samples from each treatment of Ab24E and FAW7050 were collected, while three samples for each treatment of Mp708 were collected.

Total soluble protein and amino acid extraction followed Bi et al. (2003). Fresh corn leaf tissue was ground in liquid N, weighed, and mixed with 0.1 M ice-cold potassium phosphate buffer (pH 7.0) containing 1% polyvinylpolypyrrolidone in a vortex. The mixture was centrifuged at 10,000×*g* at 4°C for 10 min. The supernatant was used for total protein content determination.

For amino acid and soluble nonstructural carbohydrate (glucose, fructose, and sucrose) extraction, freshly ground leaf tissue was weighed and extracted in 1 ml of 80% ethanol in an 80°C water bath for 8 min. Ethanol extracts were centrifuged at 10,000×*g* at 2°C for 10 min. The supernatant was used for total free amino acid and soluble nonstructural carbohydrate determinations.

Nonsoluble nonstructural carbohydrate (starch) extraction followed Marquis et al. (1997). The pellet after ethanol extraction was dried, weighed, and transferred to test tubes and incubated with 2.5 ml 0.2 M sodium acetate buffer (pH 4.5) in a boiling water bath for 1 h. After cooling to room temperature, 2 ml of acetate buffer and 1 ml of amyloglucosidase (0.5%, *w*/*v*) were added to the mixture, and it was incubated at 55°C overnight. The solution was filtered through Whatman filter papers and diluted as needed. The filtered solution was assayed for glucose content. The starch content was estimated as glucose equivalents.

Protein, Amino Acid, and Carbohydrate Determination

Total protein content was determined with the Bradford protein assay, and amounts were calculated relative to a standard curve established by using bovine serum albumin as a standard. Amino acid content was colorimetrically determined with the cadmium (Cd)–ninhydrin procedure (Doi et al. 1981; Fisher et al. 2001), which is a precise and reliable method for determination of α-amino acids. Plant foliar tissues may contain high NO_3^- (Chen et al. 2008) and NH_4^+. Preliminary experiments indicated that the intervention of these ions with the Cd–ninhydrin method was low, which is consistent with other studies (Doi et al. 1981; Fisher et al. 2001). The working reagent was prepared according to Doi et al. (1981). Briefly, 0.8 g ninhydrin was dissolved in 10 ml acetic acid and 80 ml absolute ethanol (solution 1). One gram of Cd was dissolved in 1 ml deionized water (solution 2). Solution 1 and solution 2 were mixed, forming a stock solution. The working reagent was made by dilution of the stock solution in deionized water with a 1:1.5 ratio. The determination procedure followed Doi et al. (1981) with modification. Fifty microliters of sample supernatant were mixed with 1 ml working reagent in microcentrifuge tubes and heated at 84°C for 10 min. After cooling, the mixture was transferred to a 1.5-ml disposable cuvette with a 1-cm light path (BrandTech Scientific, Inc., Essex, CT, USA). The absorbance was read at 507 nm in the Shimadzu UV Mini-1240 spectrophotometer (Shimadzu Italia, UK) at room temperature against the blank reagent after cooling. The amino acid content was calculated from a standard curve generated by using glycine.

Glucose content was determined following Jones (1979) and the technical bulletin for glucose assay kit (Sigma-Aldrich, St. Louis, MO, USA). The working reagent consisted of 50 mM Tris-HCl buffer (pH 8.0), 5 mM $MgCl_2$, 0.5 mM dithiothreitol, 1.5 mM nicotinamide adenine dinucleotide, 1.0 mM adenosine triphosphate, 2 U ml^{-1} of

hexokinase, and 1 U ml^{-1} of glucose-6-phosphate dehydrogenase. Ten microliters of sample (glucose concentration 0.05–5 mg ml^{-1}) were pipetted into 1-cm path cuvette containing 1.0 ml of working reagent and incubated for 15 min at 31°C. The absorbance at 340 nm was determined in the Shimadzu UV Mini-1240 spectrophotometer at room temperature against deionized water. Absorbance of a sample blank (1.0 ml of water+10 µl sample) and a reagent blank (1.0 ml of working reagent+ 10 µl of water) was subtracted from the glucose absorbance. Fructose and sucrose were determined as by Bi et al. (2001) with some modifications. After original glucose determinations, 2 units of phosphoglucose isomerase were added to the cuvette and reincubated for 15 min at 31°C. Fructose content was calculated as the increase in absorbance at 340 nm from the glucose reading. Then 10 µl of 1% (*w*/*v*) invertase were added to a cuvette and reincubated for 15 min at 37°C. The sucrose content was calculated as the increase in absorbance at 340 nm from the fructose reading. Glucose, fructose, and sucrose contents were calculated from a standard curve generated by using D-glucose as a standard. Total nonstructural carbohydrate was estimated as the sum of glucose and starch because the levels of fructose and sucrose were very low. Protein to TNC ratios (w/w) was calculated with mean molecular weight of TNC (equivalent of glucose) as 180.

Peroxidase and Lipoxygenase 3 Activities

Plant samples prepared for total protein content determination were used to assess peroxidase and lipoxygenase 3 (LOX3) activities. The reaction mixture for peroxidase activity was comprised of 300 µl of 20 mM guaiacol, 250 µl of 0.1 M potassium phosphate buffer (0.1 M, pH 6.0), 240 µl deionized water, and 10 µl plant enzyme extract. The reaction was initiated by adding 200 µl of 0.3% hydrogen peroxide. Peroxidase activity was monitored at 470 nm for 2 min in a Shimadzu UV Mini-1240 spectrophotometer at room temperature (approximately 25°C) after initiation of the reaction against a blank control containing all components of the reaction mixture except the enzyme extract. The activity (micromole per minute per milligram protein) was calculated by using the molar extinction coefficient of 26.6 mM^{-1} cm^{-1} for guaiacol at 470 nm. Peroxidase activity of each plant sample was determined from two subsamples, and the mean of the two subsamples was used for statistical analysis to insure the accuracy of the enzyme activity assays.

Protocol for LOX3 was based on the method developed by Axelrod et al. (1981). The reaction mixture consisted of 2.8 ml of a 0.2-M sodium phosphate (pH 6.5) buffer and 200 µl of a 10-mM sodium linoleate buffer. Reaction was initiated by the addition of plant extracts (varying amounts from 1 to 10 µl depending on ΔA/min). Absorbance was monitored at 234 nm for 2 min in the Shimadzu UV Mini-1240 spectrophotometer at room temperature and converted to micromole product per minute per milligram protein by using a molar extinction coefficient of ketodiene (22 mM^{-1} cm^{-1}).

Photosynthesis Evaluation

Physiological responses of corn seedlings (greenhouse grown) were determined 1 week after *S. frugiperda* infestation. All gas-exchange measurements were made from the youngest fully expanded leaf (V7). Photosynthetic rates were measured with a portable photosynthesis system (model LI-6400, Li-Cor, Lincoln, NE, USA). Leaves were illuminated with a light intensity of 1,500 µmol photons m^{-2} s^{-1} generated by the LI-6400. Three types of photosynthetic-related parameters were determined: a survey photosynthetic measurement (to determine photosynthetic rate of experimental plants measured at 1,500 µmol photons m^{-2} s^{-1} and 400 ppm CO_2), a light response curve (using 0, 20, 50, 100, 200, 500, 1,000, 1,500, and 2,000 µmol photons m^{-2} s^{-1} and at 400 ppm CO_2 concentration), and an A/Ci curve (determines light-independent reactions of photosynthesis; rates measured at 1,500 mmol photons m^{-2} s^{-1} light intensity and at CO_2 concentrations ranging from 400, 300, 200, 100, 0, 400, 400, 600, and 800 ppm). Both light and A/Ci curves were measured by an automated program of the LI-6400 capable of generating the desired light intensities or CO_2 concentrations.

Because leaf chlorophylls are the most important photosynthetic pigments of higher plants and are positively correlated to photosynthetic potential (Curran et al. 1990; Filella et al. 1995; Markwell et al. 1995; Richardson et al. 2002), leaf chlorophyll content was measured by using a Minolta SPAD-502 chlorophyll meter (Konica Minolta Sensing, Inc., Japan). The chlorophyll content under field conditions was measured by using SPAD-502 after damage rating. Four plants (replicates) in each row were used for leaf chlorophyll determination. Chlorophyll content (micromole per square meter) was calculated from a standard curve, chlorophyll (micromole per square meter)=$10^{(M^{\wedge}\ 0.261)}$, where M is the chlorophyll meter reading (Markwell et al. 1995).

Chemicals

All reagents and solvents used in the study were purchased from Fisher Scientific (Pittsburgh, PA, USA) or Sigma-Aldrich (St Louis, MO, USA).

Table 1 Survival and development (mean ± standard error) of *S. frugiperda* larvae after feeding on three corn inbreds for 1 week under greenhouse conditions

Corn germplasm	Survival rate (%)	Larval biomass[b] (g)	Pupal biomass (g)	Developmental time[c] (days)
Ab24E[a]	53.3±6.7a	0.05±0.007a	0.24±0.006a	15.7±0.16b
Mp708[a]	26.7±6.7b	0.02±0.003b	0.26±0.016a	17.2±0.60a
FAW7050[a]	33.3±6.7b	0.02±0.002b	0.25±0.014a	17.6±0.19a

Recovered larvae were reared individually on modified Pinto bean diet. Means followed by different lowercase letters within a column denote significant difference at $\alpha=0.05$

[a] $N=6$ for Ab24E and FAW7050 and $N=3$ for Mp708

[b] Larval biomass at the time of recovery

[c] Time from onset of experiment to pupation in days

Statistical Analyses

S. frugiperda recovery rate, larval and pupal biomass, and the development from onset of experiments to pupation were analyzed with one-way analysis of variance (ANOVA). Recovery rate was arcsin square-root transformed prior to analysis. There were originally six replicates for variety Ab24E and FAW7050 and three replicates for Mp708. Because the only *S. frugiperda* larva recovered in one replicate from variety FAW7050 was accidentally killed, there were only five replicates included in the analyses for larval and pupal biomass and development. Damage rating in the field was analyzed with nonparametric Kruskal–Wallis tests. Photosynthesis data were analyzed by a 3 (corn germplasm)×2 (*S. frugiperda* infested and uninfested) ANOVA. Analyses were separately conducted at different concentrations of CO_2 and light intensity. Total soluble protein, amino acids, glucose, TNC, P/C ratio, peroxidase, and LOX3 activity were analyzed by a 3 (corn inbred)×2 (*S. frugiperda*-infested and uninfested) ANOVA. P/C ratio was square-root transformed before analysis. If the null hypothesis of the overall model was rejected at $\alpha=0.05$, means were further separated by least significant difference or Students' *t* test. All statistical analyses were conducted using the SAS software package (SAS Institute 1999).

Results

Development and Damage of *S. frugiperda* on Corn Germplasm Lines

Development of *S. frugiperda* in the greenhouse trial (Table 1) and damage in the field trial (Table 2) indicated that variety Ab24E was susceptible, while Mp708 and FAW7050 were resistant. More larvae were recovered from variety Ab24E than Mp708 and FAW7050 ($F=3.88$, $df=2, 12$, $P<0.05$). Biomass of *S. frugiperda* larvae feeding on Ab24E for 7 days was significantly greater than those feeding on Mp708 and FAW7050 for the same period of time ($F=14.66$, $df=2, 12$, $P<0.001$). Larvae of *S. frugiperda* took 8–11% less time to develop to the pupal stage after feeding on Ab24E for 7 days than on the other two germplasm lines ($F=16.34$, $df=2, 11$, $P<0.001$). Corn germplasm lines did not affect pupal weight ($F=0.89$, $df=2, 11$, $P=0.44$).

[b] Significant difference between control and damaged treatments of the same corn germplasm at α=0.05

[c] Significant difference between control and damaged treatments of the same corn germplasm at α=0.01

[d] Significant difference between control and damaged treatments of the same corn germplasm at α=0.001

[e] Total nonstructural carbohydrate as sum of glucose and starch (equivalents of glucose)

S. frugiperda injury in the field was significantly affected by corn germplasm lines (7 days after *S. frugiperda* infestation (DAI): X^2=7.03, *df*=2, P<0.05; 14 DAI: X^2=7.63, *df*=2, P<0.05). Damage on Ab24E was consistently greater than damage on Mp708 and FAW7050 (Table 2).

Influence of *S. frugiperda* on Nutritional Properties of Germplasm Lines

The data of protein, amino acid, and nonstructural carbohydrates are summarized in Table 3. Ab24E and FAW7050 had greater constitutive foliar total soluble protein than Mp708 (F=9.42, *df*=2, 12, P<0.01). *S. frugiperda* injury increased total protein content in Mp708 and FAW7050 (F=12.04, *df*=1, 4, P<0.05 for Mp708; F=12.05, *df*=1, 10, P<0.01 for FAW7050) compared with the control plants. Amino acid levels in FAW7050 and Mp708 were greater than Ab24E (F=5.91, *df*=2, 27, P<0.01). Constitutive glucose, starch, and TNC contents did not differ among the three germplasm lines (P>0.05). However, Mp708 and FAW7050 had over 24% higher constitutive glucose than Ab24E. Additionally, *S. frugiperda* damaged leaves of Mp708 and FAW7050 had greater glucose levels than Ab24E (F=9.54, *df*=2, 12, P<0.01). P/C ratios of all three corn lines were greater than 1:1 and were not affected by *S. frugiperda* feeding (F=0.02, *df*=1, 22, P>0.05; Table 3). P/C ratio of Ab24E and FAW7050 was greater than those of Mp708 (F=6.27, *df*=2, 22, P<0.05).

Effect of *S. frugiperda* Infestation on Peroxidase and LOX3 Activities

Constitutive peroxidase activity of Mp708 was higher than Ab24E and FAW7050 (F=10.24, *df*=2, 12, P<0.01; Fig. 1). *S. frugiperda* damage increased peroxidase activity of Ab24E (F=7.19, *df*=1, 10, P<0.05). No significant difference in peroxidase activity was observed among the damaged leaf tissue of the three germplasm lines (F=0.56, *df*=2, 12, P=0.58). *S. frugiperda* damage on leaves decreased LOX3 activity of Mp708 (data not shown; F=18.45, *df*=1, 4, P<0.05). No significant difference in LOX3 activity was detected among germplasm lines.

Photosynthetic Rates of the Corn Germplasm Lines

Because none of the interactions between *S. frugiperda* infestation and germplasm line was significant (all P>0.05), further analysis was performed to examine main effects. Corn germplasm lines significantly (F=7.41, *df*=2, 19, P<0.01) affected photosynthetic rate in the greenhouse, and the rate of *S. frugiperda*-resistant Mp708 was greater

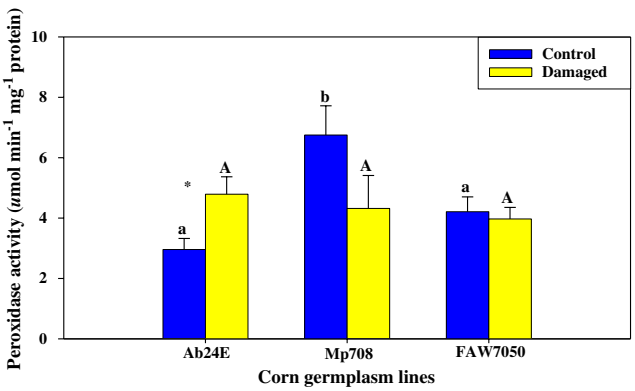

Fig. 1 Peroxidase activity (micromole per minute per milligram protein) of three corn germplasm lines. *Different lowercase letters* (*a–b*) *above bars* denote significant differences among corn germplasm lines of the undamaged (control) plants at α=0.05, whereas *capital letter* (*A*) denotes that no significant difference was detected among the *S. frugiperda*-damaged leaves. *α=0.05 denotes a significant difference between control and *S. frugiperda*-damaged plants of the same germplasm line. N=6 for Ab24E and FAW7050 and N=3 for Mp708

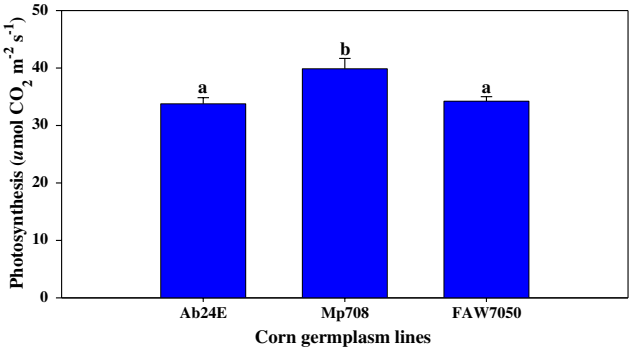

Fig. 2 Photosynthetic rate (micromole CO_2 per square meter per second) of three corn germplasm lines. *Different lowercase letters above bars* denote significant difference at α=0.05. N=6 for Ab24E and FAW7050 and N=3 for Mp708

than either of the other two lines (Fig. 2). However, *S. frugiperda* infestation did not affect photosynthesis using survey measurements (F=0.19, df=1, 19, P=0.67), nor A/Ci curve at each CO_2 concentration (all P>0.05), nor light curve at either of eight light intensities (all P>0.05). Corn germplasm lines had no effects on photosynthetic capacity at any of the light intensities (all P>0.05) under greenhouse conditions. Photosynthetic rates of Mp708 and FAW7050 at CO_2 concentrations of 300, 400, 600, and 800 ppm was greater than that of Ab24E (300 ppm: F=4.28, df=2, 15, P<0.05; 400 ppm: F=8.37, df=2, 51, P<0.001; 600 ppm: F=6.82, df=2, 15, P<0.01; 800 ppm: F=7.26, df=2, 15, P<0.01; Fig. 3). Mp708 and FAW7050 photosynthetic rates were significantly greater than Ab24E when CO_2 levels were greater than 300 ppm.

Leaf chlorophyll of FAW7050 was greater than that of Ab24E and Mp708 (F=20.40, df=2, 90, P<0.001; Table 2), but leaf chlorophyll content was not affected by *S. frugiperda* infestation (F=2.51, df=1, 90, P>0.05). The interaction between *S. frugiperda* infestation and corn germplasm was not significant (F=0.09, df=2, 90, P=0.92).

Discussion

Plant nutritional levels and allelochemicals often affect plant suitability and resistance to herbivory. Amino acids and proteins are two major sources of nitrogen for phytophagous insects, and herbivores provided with added proteins or nitrogen typically develop faster and survive and reproduce better (Mattson 1980; Woods 1999; Lee et al. 2002). Correspondingly, many herbivores have evolved various strategies that maximize the acquisition of amino acids or proteins (White 1993).

FAW7050 and Mp708 had higher levels of amino acids than susceptible Ab24E in the study. *S. frugiperda* development in the greenhouse and damage ratings in the field confirmed that Ab24E was susceptible while FAW7050 and Mp708 were resistant. If amino acid amount were the only determinant in the development of *S. frugiperda*, then larvae growth on FAW7050 and Mp708 would be faster, which is contrary to what was observed. Nutrient balance, in particular, P/C ratio has been suggested as important for development and preference of many insects in the laboratory (Simpson and Raubenheimer 1993; Lee et al. 2002; Bede et al. 2007), and most insects studied, particularly generalist insects, selected artificial diets with a P/C>1 over those with a P/C<1 (Bede et al. 2007). P/C of all three corn germplasm lines in this study were greater than 1:1, and P/C in susceptible Ab24E and resistant FAW7050 were higher than in resistant Mp708. The faster

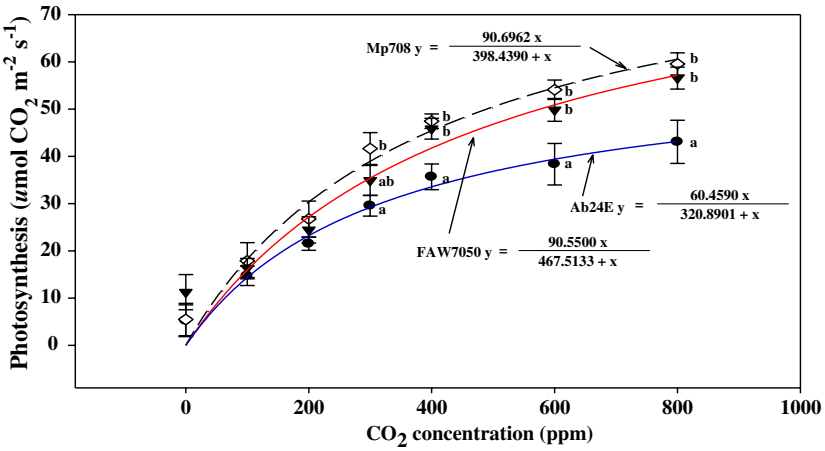

Fig. 3 Photosynthetic rate (micromole CO_2 per square meter per second) of three corn germplasm lines at various CO_2 concentrations using the combined data (N=6 for all CO_2 levels, except 400 ppm with N=18 using the automated program for A/Ci curve). *Different lowercase letters* next to data points of the same CO_2 concentration denote significant difference at α=0.05. The regression equation of photosynthetic rate against CO_2 concentration was nonlinear (*hyperbola): y=ax/(b+x). Regression coefficient (r) values for varieties Ab24E (with filled circle), Mp708 (with empty diamond), and FAW7050 (with filled triangle) were 0.99, 0.99, and 0.98, respectively*

development of *S. frugiperda* in Ab24E and slower growth in Mp708 was consistent with the higher P/C in Ab24E and lower P/C in Mp708, respectively. The slower growth of *S. frugiperda* in FAW7050 that had equally high P/C with Ab24E cannot be explained solely by P/C.

Proteins are another main source of nitrogen, and soluble proteins in plants can be broadly grouped into defensive (e.g., proteinase inhibitors) and nondefensive. Soluble proteins of all three corn inbred lines accounted for less than 1% of total leaf fresh weight, suggesting that arthropods in nature are faced with a shortage of nitrogen (Mattson 1980; White 1993). Susceptible Ab24E had higher constitutive protein levels than the resistant FAW7050 and Mp708, while no difference in total protein content among damaged corn lines was observed. This was because *S. frugiperda* feeding induced protein production in FAW7050 and Mp708, but had little effect in Ab24E. Herbivory induces plant defensive chemicals such as protease inhibitors (Jongsma et al. 1994; Stout et al. 1994, 1998; Lawrence and Koundal 2002), and many of these are detrimental to herbivore fitness (Broadway and Duffey 1988; Ryan 1990; Stout et al. 1998; Leo et al. 2001; Ussuf et al. 2001; Lawrence and Koundal 2002; Zavala et al. 2004). Therefore, the lower survival and slowed development of *S. frugiperda* in resistant FAW7050 and Mp708 might be attributable to elevated plant defensive compounds following herbivory in these two germplasm lines and to a lower P/C in Mp708. The faster growth in susceptible Ab24E was due mainly to higher amounts of constitutive nondefensive proteins and little induction of defensive compounds.

Although many plant oxidative enzymes such as peroxidase and LOX3 are involved in host plant resistance by decreasing the nutritive value of host plants (Shukle and Murdock 1983; Felton et al. 1994; Duffey and Stout 1996; Ni et al. 2001; Ni and Quisenberry 2003), neither peroxidase nor LOX3 was responsible for the lower survival and protracted development of *S. frugiperda* in this study. First, resistant Mp708 had greater peroxidase activity than susceptible Ab24E and resistant FAW7050, and no significant difference in peroxidase activity among damaged corn inbred lines was observed. Second, no significant difference in LOX3 activity among damaged corn germplasm lines was observed. However, the high inducibility of peroxidase might be a good indicator of plant susceptibility as observed in pecan, *Carya illinoinensis* (Wangenh.) K. Koch (Juglandaceae; Chen et al., unpublished data).

Photosynthesis is a complex, integrated, and dynamic process that is regulated by both source (e.g., light and CO_2) and sink (e.g., photosynthates, such as starch; Paul 1981; Paul and Foyer 2001). Because starch levels were not affected in germplasm lines (data not shown) and because light and CO_2 were controlled, the greater photosynthetic rates in resistant Mp708 and FAW7050 (Fig. 3) compared to Ab24E may be intrinsic. The greater rates in FAW7050 and Mp708 were likely due to greater light-independent reactions that assimilate CO_2 and produce carbohydrates. Such difference, in turn, resulted in higher (over 24%) glucose content in Mp708 and FAW7050 than that in Ab24E. Greater photosynthetic rates also led to higher levels of amino acids in these lines. *S. frugiperda* feeding injury led to nearly a twofold increase of glucose levels in Mp708 leaves and more than a twofold increase in FAW7050, compared to their corresponding undamaged controls. However, starch content was not affected. This suggests that *S. frugiperda* feeding damage might have decreased the conversion of glucose to some compounds in these lines, but not to total protein content, as total protein content was elevated in the *S frugiperda*-damaged plants of these lines.

In summary, the three corn germplasm lines differed in their mechanisms of resistance to *S. frugiperda*, and P/C and induced plant defensive compounds (e.g., protease inhibitors) need to be considered to explain resistance mechanisms. Elevated protein amounts in resistant germplasm lines Mp708 and FAW7050 following *S. frugiperda* injury was probably due to greater conversion of photosynthates to defensive compounds.

Disease Status and Population Origin Effects on Floral Scent: Potential Consequences for Oviposition and Fruit Predation in A Complex Interaction Between A Plant, Fungus, and Noctuid Moth

S. Dötterl · A. Jürgens · L. Wolfe · A. Biere

Received: 23 October 2008 / Revised: 20 January 2009 / Accepted: 30 January 2009 / Published online: 25 February 2009

Abstract In the *Silene latifolia–Hadena bicruris* nursery pollination system, the *Hadena* moth is both pollinator and seed predator of its host plant. Floral scent, which differs among *S. latifolia* individuals and populations, is important for adult *Hadena* to locate its host. However, the success of moth larvae is strongly reduced if hosts are infected by the anther smut fungus *Microbotryum violaceum*, a pathogen that is transmitted by flower visitors. There were no qualitative differences between the scent of flowers from healthy and diseased plants. In addition, electroantennographic measurements showed that *Hadena* responded to the same subset of 19 compounds in samples collected from healthy and diseased plants. However, there were significant quantitative differences in scent profiles. Flowers from diseased plants emitted both a lower absolute amount of floral scent and had a different scent pattern, mainly due to their lower absolute amount of lilac aldehyde, whereas their amount of (*E*)-β-ocimene was similar to that in healthy flowers. Dual choice behavioral wind tunnel tests using differently scented flowers confirmed that moths respond to both qualitative and quantitative aspects of floral scent, suggesting that they could use differences in floral scent between healthy and infected plants to discriminate against diseased plants. Population mean fruit predation rates significantly increased with population mean levels of the emission rates of lilac aldehyde per flower, indicating that selection on floral scent compounds may not only be driven by effects on pollinator attraction but also by effects on fruit predation. However, variation in mean emission rates of scent compounds per flower generally could not explain the higher fruit predation in populations originating from the introduced North American range compared to populations native to Europe.

Introduction

In many herbivorous insects, preadult stages have little opportunity to move away from their oviposition site; hence, the mother insect is effectively choosing the diet of her offspring (Mayhew 1997). The oviposition preference–offspring performance hypothesis predicts that oviposition preference should correlate with host suitability for offspring development (Jaenike 1978; Scheirs et al. 2000), as ovipositing on high quality hosts will increase fitness (Awmack and Leather 2002). However, empirical studies have not unequivocally supported this hypothesis (Thompson and Pellmyr 1991; Mayhew 1997, 2001). The quality of a

host plant for herbivores may not only be influenced by the plant itself but also by third parties such as fungi that use the same host plant(s) as the herbivores (Hatcher 1995). Although infection of plants by fungi can have neutral or positive effects on host-plant quality (summarized in Hatcher 1995), it more often has a negative effect on herbivore performance (e.g., Simon and Hilker 2003; Laine 2004). Research on the effects of plant infection by pathogenic fungi on herbivore performance has focused mainly on vegetative plant tissues, whereas little is known about the effects of plant pathogenic fungi on insects that feed on reproductive tissues.

Recently, the anther smut fungus *Microbotryum violaceum* was shown to strongly affect the interaction between *Silene latifolia* and the noctuid moth *Hadena bicruris* (Biere et al. 2002). *Hadena* is not only a pollinator of this species but also lays its eggs within the flowers, where the larvae subsequently feed on developing seeds. This system is one of 14 known nursery pollination systems (Dufaÿ and Anstett 2003; Kato et al. 2003), including the well-studied yucca/yucca moth and fig/fig wasps relationships. *Microbotryum violaceum* sterilizes the plant and produces its spores in the anthers of infected plants, which are transmitted by *Hadena* and other flower visitors. Besides this direct effect on the plant, the fungus may reduce the pollination effectiveness of *Hadena*, which transmits not only pollen but also fungal spores. This negatively affects pollen germination (Marr 1998) and results in infected plants producing sterile flowers.

Infection also affects *Hadena*. First, *Hadena* develops less successfully on diseased than on healthy plants because diseased plant flowers do not produce seeds, and larvae are forced to feed on tissues with lower nutritional quality, resulting in smaller size and lower survival (Biere et al. 2002). Second, larvae on diseased plants suffer a higher predation risk from Hymenopteran parasitoids. This is because the fruit of healthy plants provides protection from parasitoid attack during the stages that caterpillars are concealed within the developing fruit. In diseased plants, ovary development is arrested at an early stage, and caterpillars are not able to gain protection from concealment within fruits (Biere et al. 2002). In natural populations, such larval parasitism may account for 40% of *Hadena* mortality (Elzinga et al. 2007). According to the oviposition preference–offspring performance hypothesis, it can be expected that female moths avoid depositing eggs in diseased flowers, and indeed, oviposition rates have been found to be much higher on flowers of healthy than diseased plants (Biere and Honders 2006). However, the exact cues used by *Hadena* for discriminating between healthy and diseased plants are unknown (Biere and Honders 2006). One of these cues may be floral scent, given that *Hadena* is attracted to flowers by their scent, whereas lilac aldehyde, the most typical compound of *S. latifolia* flowers, has been identified as the most behaviorally attractive compound (Dötterl et al. 2006).

These findings raise the question of whether there is a difference in scent between anther-smut infected and uninfected flowers that could be used by *Hadena* to discriminate between them. Qualitative (presence and absence of compounds), quantitative (absolute amount of single compounds or total scent), and/or semiquantitative (relative/percentage amount of compounds in relation to total amount) differences in scent between pathogen-infected and uninfected plants have been well documented for vegetative plant parts (e.g., Schütz et al. 1999; Cardoza et al. 2002; Rostás et al. 2006; Johne et al. 2008) including "pseudo flowers," which are fungal and fungus-induced vegetative plant structures that mimic flowers by visual floral mimicry, production of nectar rewards, and/or floral fragrances (Roy and Raguso 1997; Raguso and Roy 1998; Kaiser 2006). For vegetative tissue and "pseudo flowers," the most prominent differences in scent have been documented for plants infected by fungi that depend on insects for spore transmission (Roy and Raguso 1997; Raguso and Roy 1998; Naef et al. 2002; Kaiser 2006; Schiestl et al. 2006). In some cases, the changes in scent pattern due to infection have resulted in behavioral changes in phytophagous insects or spore transmitters (e.g., Roy and Raguso 1997; Cardoza et al. 2003; Schiestl et al. 2006; Johne et al. 2008). However, we are not aware of any study that shows the effects of fungal infection on the floral scent of true flowers.

Recently, large qualitative as well as (semi)quantitative differences in floral scent were described among healthy *S. latifolia* populations, i.e., independent of disease status of the plants (Dötterl et al. 2005b, 2007). Furthermore, differences in fruit predation rates by *H. bicruris* among *S. latifolia* populations were observed in a common garden experiment (Wolfe et al. 2004). These findings suggest that population-level fruit predation rates could be explained by among-population variation in floral scent, which could be determined by analyzing population mean fruit predation rates as a function of population mean emission rates of floral scents to which *Hadena* has shown significant antennal responses.

The two main goals in this research were to test whether there is a difference in scent between uninfected and anther-smut-infected flowers that could be used by *Hadena* for discriminating between them and whether differences in fruit predation rates by *H. bicruris* among *S. latifolia* populations could be explained by among-population variation in floral scent. The specific questions are the following: (1) Are there differences in floral scent between flowers of healthy and diseased plants of *S. latifolia*? (2) If the scent differs, is *H. bicruris* able to detect these

differences? (3) Is attraction of the moth affected by scent quantity and composition? (4) Can differences in predation rates among populations be partly explained by differences in floral scent? To answer the first two questions, we compared the volatile profiles of flowers from healthy and diseased plants from a number of populations and measured antennal responses of *H. bicruris* to the emitted compounds. We performed dual-choice behavioral tests on *H. bicruris* to differently scented flowers to address the third question. To answer the fourth question, we tested whether the population mean predation rates by *H. bicruris* measured by Wolfe et al. (2004) on *S. latifolia* plants originating from different North American and European populations that were grown in a common garden are associated with the population specific floral scent spectra emitted by these plants (see Dötterl et al. 2005b, 2007).

Methods and Materials

Plant Material and Fungal Inoculation For experiments on scent differences between healthy and diseased flowers, we used plants from seven different *S. latifolia* populations, two originating from Europe and five from North America (Fig. 1, see also Wolfe et al. 2007). To compare scent profiles of healthy and diseased flowers within populations, we created full-sib families within populations by making crosses between two randomly chosen parents from each population. Twelve seeds of each cross were assigned to a control treatment and 12 to a fungal inoculation treatment group. The 12 seeds from each cross and treatment were germinated by placing them in a 9-cm Petri dish on moist filter paper in a growth cabinet under 16 h 25°C L/8 h 15°C D after inbibing in the dark for 5 d at 4°C. Plants and treatments were part of a larger experiment that addressed the susceptibility of European and North American plants to inoculation (Biere and Verheggen, unpublished data).

Inoculum of *M. violaceum* (Pers.) G. Deml & Oberwinkler was prepared as follows. Diploid teliospore samples were collected from flowers of infected *S. latifolia* plants at Fyfield, Hampshire, UK (51°13′06 N, 1°34′46 E). Spores from individual flowers were plated onto yeast–glucose–agar (YGA) and incubated at 23°C for 5 days. Single spore colonies, containing the haploid meiotic products (sporidia) of both mating types, a1 and a2, were transferred to new YGA plates and incubated as above. The resulting single sporidia colonies were isolated and cultured as above for multiplication. Sporidia of opposite mating type (a1 and a2) can conjugate to form infectious hyphae. The mating type of isolated single sporidia colonies was determined by mixing them with reference sporidia of known mating type on water agar and checking for conjugations after incubation overnight at 15°C. Two sporidial isolates of opposite mating type that originated from different plants were used for inoculation. Inoculation suspensions were made by mixing 10^7 sporidia of each mating type in sterile demineralized water overnight in a rotary shaker at 15°C.

Three days after *S. latifolia* seeds started to germinate, those assigned to the inoculation treatment were inoculated by pipetting 2 ml of the inoculum suspension into a Petri dish, while those assigned to the control treatment received 2 ml of sterile demineralized water (mock inoculation). To increase infection rates in the inoculation treatments, this procedure was repeated 10 days later for each Petri dish using fresh inoculum or control treatments. After 16 days, plant seedlings were transplanted into individual plastic container pots (5-cm diameter and 25-cm depth) containing potting soil and reared in a greenhouse (16 hr L, 21±2°C throughout) for 15 weeks until they were transplanted to an experimental garden at The Netherlands Institute of Ecology (Heteren), where flowering started on May 19, 2005. Successful inoculations are easily assessed by visual inspection of the presence of purple-brown spores instead of creamy pollen in the anthers of male as well as female plants (the latter undergo a fungus-induced morphological sex change).

Insects and Behavioral Tests A *H. bicruris* culture was established by collecting eggs laid in *S. latifolia* flowers in the surroundings of Bayreuth (Germany). Half of the larvae

Fig. 1 Geographic origins of the five North American and two European populations of *Silene latifolia* analyzed. The *digits within the symbols* indicate the number of floral scent samples collected in order to test for differences in scent between healthy plants (*open symbols*) and plants infected by *Microbotryum violaceum* (*solid symbols*)

were reared on freshly collected fruits of *S. latifolia* during all five larval stages, and the others were fed with artificial diet as described by Dötterl et al. (2006). Adults were provided with a sugar solution (30%, same amounts of fructose and glucose corresponding to *S. latifolia* nectar as described by Witt et al. 1999). Two- to 7-day-old flower-inexperienced female and male moths were used for the experiments.

Behavioral tests were conducted in a 160-×75-×75-cm wind tunnel, the same as described by Dötterl et al. (2006). A Fischbach speed controller fan (D340/E1, FDR32, Neunkirchen, Germany) pushed air through the tunnel with an air speed of 0.35 m s^{-1}. Four charcoal filters (145× 457 mm; carbon thickness, 16 mm; Camfil Farr) cleaned the incoming air.

Two dual-choice assays were used to obtain information on the importance of both the total amount of scent and composition of the scent for attracting *Hadena*. In one assay, we compared the attractiveness of two flowers emitting a similar scent (qualitatively and semiquantitatively) but differing in their total amount of scent. In the other test, we compared two flowers that differed in both their quantity of emitted scent and their semiquantitative scent pattern. The flowers chosen represented the most typical chemotypes found in *S. latifolia* (lilac aldehyde vs. phenylacetaldehyde dominated) and the typical quantitative range of scent emission found in this plant (Dötterl et al. 2005b). To eliminate visual stimuli, flowers were presented at the upwind end of the tunnel behind gauze and different metal grids, so that they were invisible to the moths. Single moths were released at the downwind end of the tunnel, and their behavior was observed for at most 5 min. Data were recorded by personal observation for moths flying 'zigzag' to within 5 cm of one of the flowers. Three and four out of 21 individuals used in these two tests, respectively, did not respond at all and were not used for analyses (see Results). The experiments were performed at night with red light illumination (<0.01 μE) 1–3 h after the start of the dark period. The temperature was adjusted to 22–24°C, but the relative humidity was left unchanged.

Volatile Collection Floral scent was collected for three separate purposes: (1) to compare scents between infected and uninfected flowers, (2) to determine the scent of flowers used in behavioral assays, and (3) to obtain scent samples for electrophysiological measurements.

To compare scents between infected and uninfected flowers, we collected floral scent on June 11, 2005 (10–12 P.M.) from 12 healthy and 14 diseased female plants (two to six plants per cross, see Fig. 1, and one flower per plant) by dynamic headspace as described by Dötterl et al. (2005b). One flower per plant was picked, enclosed within a polyester oven bag (10×8 cm; Toppits®, Germany), and 1 min later, scent collection was started. In *S. latifolia*, the volatile emission from cut flowers does not differ from that of flowers still attached to the plant if scent is collected immediately after flower picking (Dötterl, unpublished data).

To determine the composition and amount of scent emitted by the single flowers used in the behavioral tests, each picked flower was sampled two times: immediately after picking the flowers before conducting the biotests and also after the biotests (about 2 h later). Results of these two measurements were used to calculate the mean amount and composition of emitted volatiles during the tests.

In both experiments (infected–uninfected; behavioral assay), volatiles were trapped for 2 min in an adsorbent tube by the use of a membrane pump (G12/01 EB, ASF Thomas, Inc.) with a flow rate of 200 ml min^{-1}. The adsorbent tube was filled with a mixture of 1.5 mg Tenax-TA (mesh 60–80) and 1.5 mg Carbotrap (mesh 20–40). Only young flowers, mostly in their first night of opening, were used for scent collection to avoid confounding effects of ontogenetic changes, e.g., following pollination (Dötterl et al. 2005b; Mühlemann et al. 2006). To distinguish between plant volatiles and ambient contaminants, surrounding air was collected for comparison.

The scent samples used for electrophysiological analyses were six in total and were collected from a subset of the plants used to study effects of fungal infection on floral scent profiles. Four samples were collected from a full-sib cross that originated from one of the European populations (two healthy and two diseased plants), and two samples were collected from a full-sib cross that originated from one of the North American populations (one healthy and one diseased plant). To obtain the samples, a different dynamic headspace method was used. For each sample, floral scent was collected from ten to 40 flowers (the night of June 11 to the morning of June 12). The flowers were enclosed in situ in the same oven bags as used above, but the bag size was larger (30×30 cm). The emitted volatiles were trapped in large adsorbent tubes filled with 15 mg of Tenax-TA 60–80 and 15 mg of Carbotrap 20–40. Volatiles were eluted with 70 μl of acetone (SupraSolv, Merck KgaA, Germany) and stored in a freezer at −80°C for later use in the electrophysiological analyses (see below).

GC-MS Analyses Floral scent samples from the inoculation and behavioral experiments were analyzed on a Varian Saturn 3800 gas chromatograph (GC) fitted with a 1079 injector and a ZB-5 column (5% phenyl polysiloxane; length, 60 m; inner diameter, 0.25 mm; film thickness, 0.25 μm; Phenomenex) and a Varian Saturn 2000 mass spectrometer (MS). The adsorbent tubes were inserted via Varians Chromatoprobe into the GC injector (Amirav and Dagan 1997). The injector split vent was opened (1/20), and the injector was heated at 40°C to flush any air from the system. After 2 min, the split vent

was closed and the injector heated at 200°C min^{-1}, then held at 200°C for 4.2 min, after which the split vent was opened (1/20) and the injector cooled down. Electronic flow control was used to maintain a constant helium carrier gas flow rate (1.8 ml min^{-1}). The GC oven temperature was held for 7 min at 40°C, then increased by 6°C min^{-1} to 260°C, and held for 1 min at this temperature. Mass spectra were taken at 70 eV with a scanning speed of one scan per second from *m/z* 30 to 350.

Analysis of the data was performed using the Saturn Software package 5.2.1. To identify the floral scent compounds of the GC-MS spectra, the NIST 02 and MassFinder 3 databases were used, and identifications were confirmed by comparison of retention times with published data (Adams 1995). Identification of some compounds was also confirmed by comparison of mass spectra and retention times with those of authentic standards. Volatiles emitted from vegetative plant parts were excluded for the analyses. To quantify the amount of each volatile in the blend, known amounts of monoterpenoids, benzenoids, and fatty acid derivatives were injected, and the mean peak area of these compounds was used for quantification.

Electrophysiological Analyses To test whether the antennae of *H. bicruris* can detect (respond to) different compounds present in flowers of healthy and diseased plant individuals, we performed electrophysiological analyses, gas chromatography coupled to electroantennographic detection (GC-EAD). The six scent samples collected for these analyses were tested on four antennae of three different moth individuals; a total of 14 runs were conducted. Each antenna was tested at least on one healthy and one diseased sample of a specific population. Insects were reared from eggs as described above.

Analyses were performed with the GC-EAD system described by Dötterl et al. (2005a). The GC-EAD system consisted of a gas chromatograph (Vega 6000 Series 2, Carlo Erba, Rodano, Italy) equipped with a flame ionization detector (FID) and an EAD setup (heated transfer line, two-channel USB acquisition controller) provided by Syntech (Hilversum, The Netherlands). A volume of 1 µl of an acetone–floral scent sample was injected splitless at 60°C, followed by opening the split vent after 1 min and heating the oven at a rate of 10°C min^{-1} to 200°C. The end temperature was held for 5 min. A ZB-5 column was used for analyses (length, 30 m; inner diameter, 0.32 mm; film thickness, 0.25 µm; Phenomenex). The column was split at the end by the four arm flow splitter GRAPHPACK 3D/2 (Gerstel, Mülheim, Germany) into two pieces of deactivated capillary (length, 50 cm; inner diameter, 0.32 mm) leading to the FID and EAD setup. Makeup gas (He, 16 ml min^{-1}) was introduced through the fourth arm of the splitter. For the EAD, both sides of an excised antenna were plugged into glass micropipette electrodes filled with insect ringer solution (8.0 g l^{-1} NaCl, 0.4 g l^{-1} KCl, 4 g l^{-1} $CaCl_2$), respectively, and connected to silver wires.

To identify the structure of the compounds eliciting signals in the insect antennae, 1 µl of the acetone–floral scent samples was placed into a quartz vial in the injector port of the GC by means of the ChromatoProbe and then analyzed by GC-MS as described above.

Seed Predation in Relation to Floral Scent in Healthy Plants To test whether differences in floral scent profiles between populations were associated with differences in fruit predation by *H. bicruris*, we calculated mean predation rates for female plants from nine European and 12 North American populations using data (collected in 2002) from a previous study performed in the same common garden at The Netherlands Institute of Ecology, Heteren (Wolfe et al. 2004). We also used the mean relative amount of the subset of floral scent compounds to which *H. bicuris* showed a significant response in the electrophysiological analyses (GC-EAD; Dötterl et al. 2006 and the present study) for the same 21 populations but calculated using floral scent (collected in 2003) from a previously published study (Dötterl et al. 2005b). The compounds used were the following: 3-methylbutylaldoxime, (*Z*)-3-hexen-1-ol, benzaldehyde, myrcene, (*Z*)-3-hexenyl acetate, benzylalcohol, (*E*)-ß-ocimene, phenylacetaldehyde, guaiacol, methyl benzoate, 2-phenylethanol, veratrole, lilac aldehyde, benzyl acetate, methyl salicylate, lilac alcohol, benzenepropanol, (*E*)-cinnamaldehyde, (*E*)-cinnamyl alcohol, (*E*)-cinnamyl alcohol acetate, and benzyl benzoate.

Statistical Analyses To test for a difference in the total amount of scent emitted by flowers from healthy and diseased plants, a Mann–Whitney *U* Test was performed using the STATISTICA 7.1 package (StatSoft Inc. 2004).

For detailed analyses of qualitative and quantitative differences in scent composition among samples, we performed analyses of similarities (ANOSIM) using the program package Primer 6.1.6 (Clarke and Warwick 2001; Clarke and Gorley 2006). ANOSIM is a commonly used multivariate procedure roughly analogous to analysis of variance (ANOVA)/multivariate ANOVA that operates directly on a (dis)similarity matrix. It yields a test statistic *R* that is a relative measure of separation between a priori defined groups, based on differences of mean ranks between and within groups. An *R* value of "0" indicates a completely random grouping, whereas a value of "1" indicates that samples within groups are more similar to each other than to any sample from a different group (Clarke and Gorley 2006). Statistical significance of *R* is assessed by random permutations of the grouping vector to obtain an empirical distribution of *R* under the null model.

For analyses of qualitative differences in scent emission, we calculated the qualitative Sørensen index using Primer 6.1.6 to determine pairwise qualitative similarities among samples. Based on this similarity matrix, we performed a two-level nested ANOSIM [factors population and disease status (healthy or diseased) nested within population] to test for qualitative differences in scent between healthy and diseased plants.

For analyses of quantitative differences in scent emission, we calculated the Bray–Curtis quantitative similarity index using Primer 6.1.6 to assess pairwise quantitative similarities between the different samples based on the total amount emitted per compound. Non-metric multidimensional scaling was used (based on the Bray–Curtis similarities) in Primer to ordinate the scent samples of the 12 healthy and 14 diseased samples of the different populations in order to visualize similarities among the individual samples. Analogous to our analyses of qualitative differences, we performed a two-level nested ANOSIM (factors population and disease status nested within population) to test for quantitative differences in scent between healthy and diseased plants based on the Bray–Curtis similarity matrix. In addition, two-way SIMPER was used in Primer to determine the compounds being responsible for quantitative differences in scent that were found between healthy and diseased plants. Mann–Whitney *U* tests were calculated to test for differences in the total amount of the most variable scent compounds between healthy and diseased plants.

In all of the conducted ANOSIM analyses, 10,000 random permutations were run if possible in order to determine the level of significance.

The behavioral dual-choice tests were analyzed using the observed vs. expected frequency chi-square test in STATISTICA.

To test whether differences in floral scent among plants originating from different European and North American populations could explain part of the variation in fruit predation rates among these populations that had been observed in common garden studies, we used generalized linear models (STATISTICA 7.1) with a normal error distribution and an identity link function to test the effects of the continent of origin (class variable), population mean relative amount of the volatile compound (continuous variable), and their interaction on population mean predation rate (number of fruits predated divided by the number of fruits produced by all female plants).

Results

Qualitative Differences in Floral Scent Emission The flowers of both healthy and diseased plants emitted seven benzenoids, six monoterpenoids, three sesquiterpenoids, two phenylpropanoids, and a nitrogen-containing compound (Table 1).

Within populations, healthy and diseased plants emitted the same set of compounds, and there were no significant qualitative differences in scent (ANOSIM: disease status within population, $R=0.22$, $P=0.12$). Qualitative analyses showed that populations differed in the set of compounds that they emitted (ANOSIM: population effect, $R=0.58$, $P<0.01$), although most of the compounds, especially the monoterpenes [e.g., (*E*)-ß-ocimene and lilac derivatives], occurred in all populations and most of the samples. The benzenoid guaiacol was widespread, at least in healthy plants.

(Semi)quantitative Differences in Scent Emission The total amount of emitted scent strongly differed between healthy and diseased plants. The flowers of diseased plants emitted threefold lower amounts of scent than those of healthy plants (*U* test, $Z=2.9$, $P=0.003$).

Interestingly, flowers of diseased and healthy plants emitted not only different total amounts of scent but also different relative amounts of single compounds. The scent of healthy plants was dominated strongly by lilac aldehyde, reaching a median relative amount of 51% (Table 1). The median value of each of the other compounds was less than 10%. In diseased samples, lilac aldehyde also was the main component, contributing a median of 33% to the total scent emitted. However, in these samples, (*E*)-ß-ocimene also reached high relative amounts (median, 25%), and this compound was even the main constituent in some of the samples (maximum, 76%).

Quantitative analyses based on the total amount of individual compounds emitted by single flowers showed significant differences in scent between healthy and diseased plants (ANOSIM: disease status within population: $R=0.55$, $P=0.03$), whereas in this quantitative analysis, differences among populations were not significant (ANOSIM: Population effect, $R=0.20$, $P=0.12$). The disease status effect is visualized in a nonmetric multidimensional scaling plot (Fig. 2), where, in six out of the seven populations, healthy plants have lower mean scores for the dimension plotted along the *X*-axis than diseased plants from the same population. A SIMPER analysis revealed which compounds were responsible for the observed differences: five compounds each contributed at least 5% to the differences, and together they explained 78% of the differences between healthy and diseased plants across the different populations. Lilac aldehyde was most variable and explained 50% of the differences, whereas the contribution of the other four compounds was relatively small (6–9%). The total amount of lilac aldehyde was significantly reduced in diseased plants, and this was also true for arbusculone and a lilac aldehyde degradation

Table 1 Total amount of scent trapped, occurrence and mean relative amount of floral scent compounds found in samples of 12 healthy and 14 diseased flowers (both healthy and diseased samples were collected from seven populations each)

[a] Identification is based on authentic standard compounds

product (Fig. 3). The amount of phenylacetaldehyde and (*E*)-ß-ocimene did not differ between healthy and diseased plants.

Electrophysiological Responses When testing antennal responses of *H. bicruris* to floral scent collected from healthy and diseased plants from different populations, clear signals were elicited in each run. In total, antennae responded to 19 different compounds. Clear responses in the antennae were elicited by (*E*)-ß-ocimene and/or phenylacetaldehyde, 2-phenylethanol, different lilac aldehyde stereoisomers, methyl salicylate, (*E*)-cinnamyl alcohol, and benzyl benzoate (Fig. 4). Some compounds, such as phenylethyl acetate and (*E*)-cinnamyl alcohol, did not occur in all samples and consequently resulted in differences in the antennal responses among populations. Within populations, no consistent differences in antennal responses between healthy and diseased plants were observed, indicating that antennae responded to the same set of compounds in samples collected from healthy and diseased plants.

Behavioral Tests In the first behavioral experiment, we offered two flowers with volatile profiles that were qualitatively similar, and these flowers also emitted compounds in similar relative amounts (both mainly containing isoprenoids, especially lilac aldehyde) but that were quantitatively different (Fig. 5a). The moths were more attracted to flower 2, which emitted a higher amount of volatiles than flower 1 (nine females and seven males vs. one female and one male). In the second experiment, moths were offered a choice between two flowers that, in addition to quantitative differences, represented quite different chemotypes (Fig. 5b). Flower 3 was dominated by

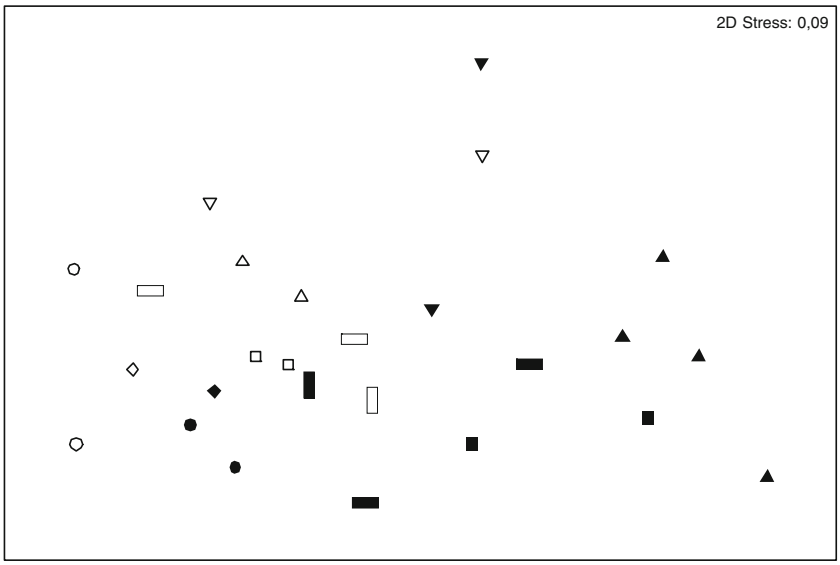

Fig. 2 Multidimensional scaling of the floral scent profile of 12 healthy (*open symbols*) and 14 diseased (*corresponding solid symbols*) flowers from seven different populations of *Silene latifolia* based on Bray–Curtis similarities, which were built on the basis of the total amount of the scent compounds emitted. The origins of the plants used for scent collection is given in Fig. 1

benzenoids, mainly phenylacetaldehyde (only small amounts of lilac aldehyde were emitted); flower 4 was dominated by lilac aldehyde. The moths were attracted equally to both flowers, even though flower 3 emitted about twice the amount of volatiles compared to flower 4 (four females and five males vs. three females and five males).

Associations Between Volatile Compounds and Fruit Predation Of the 21 compounds to which *H. bicruris* showed antennal responses (present study and Dötterl et al. 2006), only lilac aldehyde, which was also the quantitatively most important compounds, could explain a significant part of the variation in fruit predation by this moth among plant populations (Fig. 6a). Plants from North American populations suffered higher fruit predation than plants from European populations [$X^2(1)=11.1$, $P<0.001$] independently of the mean population level of lilac aldehyde. However, within both European and North American populations, predation rate increased with the mean population level of lilac aldehyde [$X^2(1)=3.83$, $P<0.05$, no interaction continent×lilac aldehyde $X^2(1)=0.37$, $P=0.54$]. The amounts of 2-phenylethanol and phenylalcetaldehyde, which are negatively correlated with the amount of lilac aldehyde at the population level, tended to show a negative association with predation rate [$X^2(1)=2.93$ and 2.57, respectively, $P<0.10$; Fig. 6b, c].

Discussion

Healthy vs. Diseased Plants Within the *Silene–Hadena* nursery pollinator system, *H. bicruris* has a strong oviposition preference for healthy over diseased (i.e., anther-smut infected) flowers of *S. latifolia* (Biere and Honders 2006), which is likely an adaptive response (Biere et al. 2002). The data in this study show that there are no qualitative differences (i.e., identity of compounds) in scent emitted by healthy and diseased plants, indicating that both groups of plants emit the same compounds. In the electroantennographic assays, *Hadena* responded to the same compounds in healthy and diseased plants. However, flowers of diseased plants emitted only about one third of the amount emitted by healthy flowers, and there were also differences in the relative (percentage) amount of compounds emitted. Most prominently, the diseased plants had a decreased relative amount of lilac aldehyde and, because the total amount of (*E*)-ß-ocimene was not affected by the disease status of plants, a higher relative amount of (*E*)-ß-ocimene. These differences in scent between healthy and diseased plants may be used by *H. bicruris* to discriminate between them.

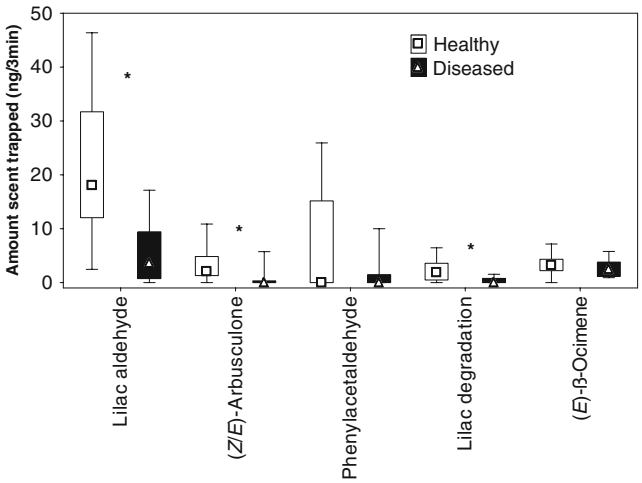

Fig. 3 Amount of *Silene latifolia* floral scent (median, 25%–75%, minimum to maximum) trapped for the compounds being most variable (according to a two-way SIMPER analysis) among healthy and diseased plant individuals across all population groups (*$P<0.01$, *U* test)

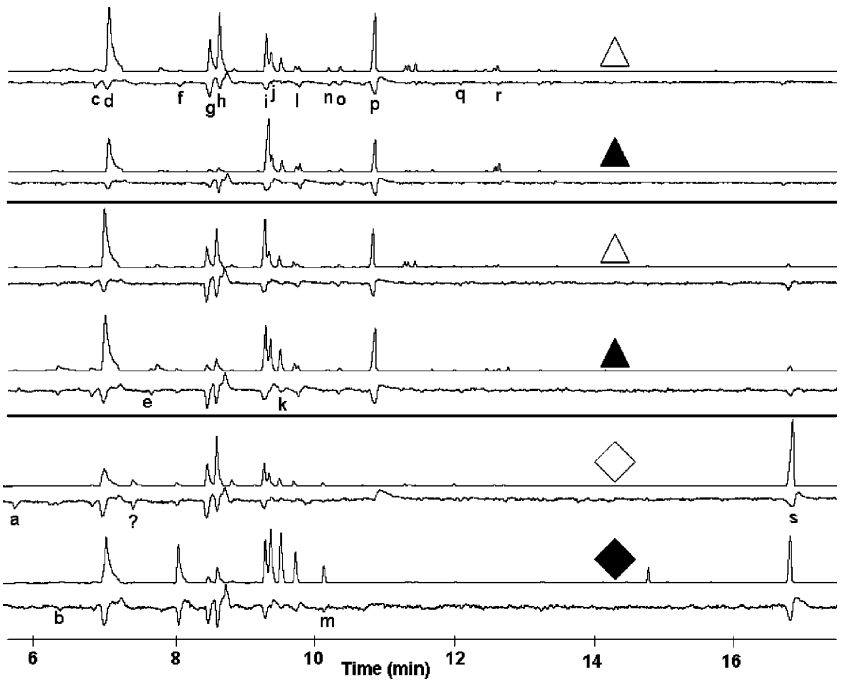

Fig. 4 Antennal responses of *Hadena bicruris* females (*lower lines*) to six different floral scent samples (*upper lines*) of healthy (*open symbols*) and diseased (*solid symbols*) plants of two different populations (see also Fig. 1 for the origin of the plants). *a* Benzaldehyde, *b* (*Z*)-3-hexenyl acetate, *c* benzyl alcohol, *d* (*E*)-ß-ocimene/phenylacetaldehyde, *e* guaiacol, *f* 2-phenylethanol, *g* lilac aldehyde A, *h* lilac aldehyde B+C, *i* methyl salicylate, *j* lilac alcohol A, *k* lilac alcohol B+C, *l* benzenepropanol, *m* phenylethyl acetate, *n* (*Z*)-cinnamyl alcohol, *o* (*E*)-cinnamyl aldehyde, *p* (*E*)-cinnamyl alcohol, *q* benzyl isovalerate, *r* (*E*)-cinnamyl acetate, *s* benzyl benzoate

One possible reason for the different effects of the disease on the total and relative amounts of lilac aldehyde and (*E*)-ß-ocimene is that the biosynthesis of monoterpenes is differentially affected by anther smut infection. Both monoterpenes are synthesized in the plastids via geranyl pyrophosphate (GPP) in the methylerythtritol phosphate pathway (Dudareva and Pichersky 2000). (*E*)-ß-Ocimene is built directly from GPP by an ocimene synthase (Bohlmann et al. 2000), while lilac aldehyde is synthesized via linalool, which is oxidized to 8-hydroxylinalool and 8-oxolinalool (these compounds were not found in the scent samples), and finally cyclized to lilac aldehyde (Kreck et al. 2003). Until now, only linalool synthase, the enzyme converting GPP to linalool has been identified (Pichersky et al. 1994), whereas the other enzymes involved in synthesis of lilac aldehyde via linalool are unknown. Because of differences in synthetic pathways, the anther smut fungus could have affected the steps leading from GPP to lilac aldehyde but not the step from GPP to (*E*)-ß-ocimene.

An alternative explanation for the effect of anther smut infection on floral scent is that changes in the total and relative amounts of lilac aldehyde and (*E*)-ß-ocimene are indirect effects of morphological changes that follow fungal infection due to direct interference of infection with steps in the biosynthetic pathway. Within *S. latifolia* flowers, lilac aldehyde is emitted from the anthophore, a column-like structure at the base of the ovary, whereas (*E*)-ß-ocimene is emitted from the petals (Dötterl and Jürgens 2005). In diseased plants, the ovary size is dramatically reduced, whereas petal size is only moderately reduced (Shykoff and Kaltz 1998; Biere and Honders 2006). Therefore, it would

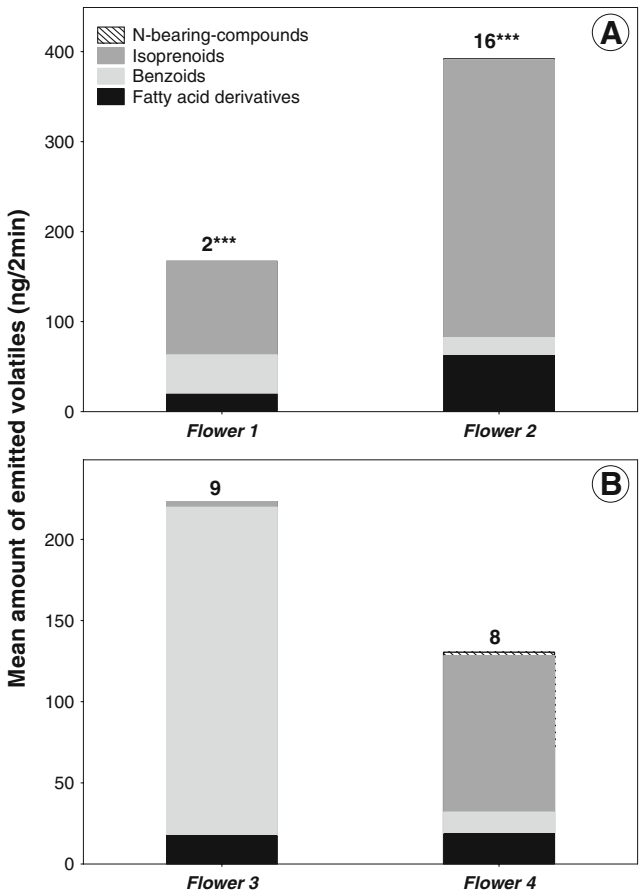

Fig. 5 Attraction of *Hadena bicruris* to different scenting flowers of *Silene latifolia* (*Flowers 1* to *4*). The *numbers above the columns* indicate the number of *H. bicuris* individuals attracted to a particular flower. In total, 21 specimens were tested in choice-test **A** and choice-test **B**, respectively (***$P<0.001$, chi-square test)

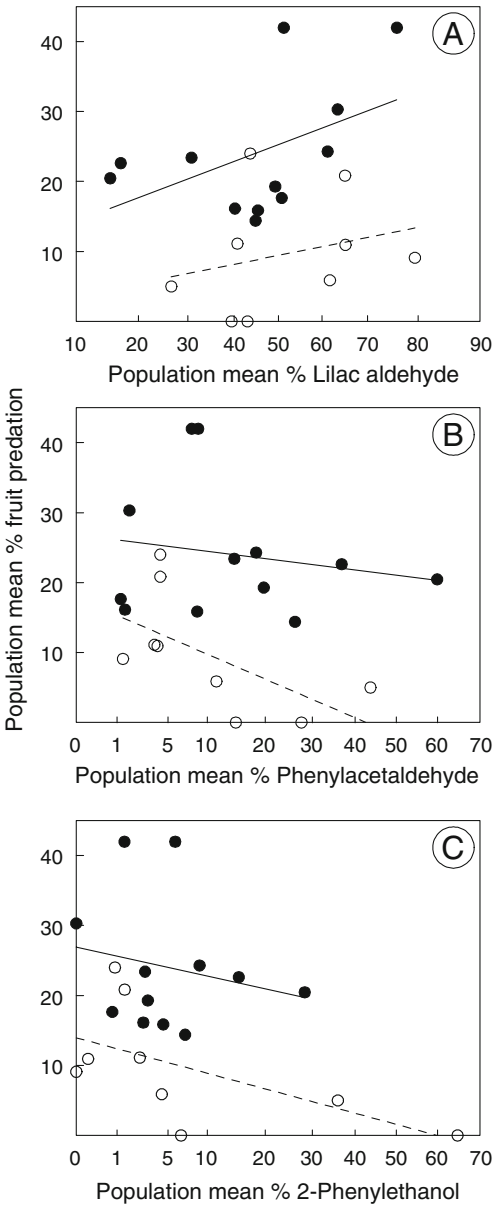

Fig. 6 Population mean fruit predation rate (%) as a function of population mean relative amount of scent volatiles: **A** lilac aldehyde, **B** phenylacetaldehyde, **C** 2-phenylethanol. Populations originating from North America (*closed dots*, *solid regression lines*) and from Europe (*open dots*, *dashed regression lines*) are indicated by different symbols. Note the arcsine-square root scale of the *X*-axes

be interesting to investigate whether the size of the anthophore is correlated with that of the ovary and whether the reduced amount of lilac aldehyde emitted from diseased flowers resulted from stunted development of both the ovary and the anthophore. The relatively small impact of fungal infection on petal size does not affect the levels of (*E*)-ß-ocimene emission.

Lilac aldehyde, as a single compound, features prominently in the *Hadena–Silene* interaction in that it is as attractive to *Hadena* moths as is the total blend of volatiles emitted by *S. latifolia* flowers (Dötterl et al. 2006). This suggests that the reduced predation rate of *H. bicruris* in diseased plants (Biere and Honders 2006) could be due mainly to the reduced total amount of emitted lilac aldehyde. Indeed, the behavioral tests conducted in this study and in previous studies demonstrate that scent quantity (both absolute amount of single compounds, such as lilac aldehyde, and total amount of floral scent) is an important factor in the attraction of *H. bicruris* (Fig. 5, see also Dötterl et al. 2006). Given that lilac aldehyde also is an effective attractant for other visitors/pollinators of *S. latifolia*, such as the generalist noctuid moth *Autographa gamma* (Plepys et al. 2002), diseased plants may be less attractive to flower visitors in general. Indeed, nocturnal flower visitors tend to prefer healthy over diseased plants (Shykoff and Bucheli 1995).

The reduced attractiveness of fungus-infected flowers to flower visitors would seemingly represent an adaptive dichotomy when viewed from both the fungus and the plant's perspective. It would be disadvantageous from the perspective of the fungus *M. violaceum*, which needs pollen vectors to ensure spore transmission, but may be advantageous for *S. latifolia* plants, as it reduces the rate of infection in their offspring (plants usually produce healthy pollen or seeds before becoming infected) or in their healthy kin. However, the lower attractiveness of fungus-infected flowers might have a positive effect on fungus spore dispersal within plant populations if moths that visit infected plants also visit fewer flowers on these plants (since they are less attracted), thereby reducing the waste of spores deposited on other flowers of already infected plants and increasing the number of visits to uninfected individuals. Additional research is needed to investigate the effect of reduced odor emission on the flower visitation patterns of moths. Another possible benefit to the fungus is the change in floral scent, as suggested by the fact that several volatile compounds are fungicidal, including lilac aldehyde (Komaki et al. 2005). Therefore, a decreased emission of lilac aldehyde may, in spite of the decreased visitor attraction, have a positive effect on the fitness of the fungus.

Plant pathogenic fungi, other than *M. violaceum*, that depend on insects for the transmission of their spores/gametes have been reported to affect the scent of their host plants, but mainly through the emission of additional volatiles rather than through a decrease in emission rates. In fungi that infect vegetative plant parts, volatiles emitted by the fungus itself or by infected host plants appear to be involved in attraction of vectors in *Berberis vulgaris* infected by *Puccinia arrhenatheri* (Naef et al. 2002), in *Arabis drummondii* infected by *Puccinia monoica* (Roy and Raguso 1997; Raguso and Roy 1998), and in *Brachypodium* and *Anthoxanthum* grasses infected by *Epichloë*

species (Schiestl et al. 2006). Interestingly, in our analyses of *Silene* flowers, we found no additional fungal or fungal-induced compounds, but this may be due to the location of spore release, i.e., in flowers as compared to vegetative parts. In the *Silene–Microbotryum* interaction, spores are released in the flower, which is already attractive for the spore-transmitting insects that visit the flowers, and no additional fungus-derived scent or modification of flower scent may be required to attract vectors. In the other systems, discussed above, spores are released from vegetative regions (e.g., leaves), which usually have no inherent attractiveness to insects that transmit the spores, and consequently, new volatile compounds are needed to ensure visitation of these plant parts.

Volatile Compounds and Fruit Predation in Healthy Plants The plant *S. latifolia* shows high intraspecific variation in flower scent profiles (Dötterl et al. 2005b, 2007), part of which can be attributed to variation between populations (Dötterl et al. 2007). Most plants and populations are dominated by lilac aldehyde, but in some, the relative amount of lilac aldehyde is low, and the scent is dominated instead by other compounds, such as phenylacetaldehyde (Dötterl et al. 2005b, 2007). Little is known about factors that maintain floral scent variability in *S. latifolia* or the role of different volatile blends in local interactions of *S. latifolia* with its pollinators and fruit predators. However, the data demonstrate that populations that emit lower relative amounts of lilac aldehyde also have lower predation rates by *Hadena* and, therefore, have supposedly lower flower visitation rates, which is supported by our dual-choice behavioral tests demonstrating the importance of lilac aldehyde for the attraction of *Hadena*. Therefore, we hypothesize that differences in predation rates found both among European and North American populations could just be a function of the average amount of lilac aldehyde emitted by the plants in these populations.

Interestingly, floral scent profiles of individual flowers could not explain the generally higher fruit predation rates of plants originating from North America compared to plants from Europe (Wolfe et al. 2004). For any given relative amount of lilac aldehyde, plants from North American populations suffered higher predation rates than those from European populations (Fig. 6a). This observation does not necessarily imply that flower volatiles play no role in intercontinental differences in predation rate. Although absolute and relative amounts of volatile compounds did not show large differences between flowers from North American and European plants at the level of individual flowers (Dötterl et al. 2005b), the number of flowers produced by plants originating from North American populations is about three times higher than that of their European counterparts (Blair and Wolfe 2004; Wolfe et al. 2004). At the whole plant level, North American plants emit larger amounts of flower volatiles than European plants. As scent quantity is important for attraction of *H. bicruris* (Fig. 5; Dötterl et al. 2006), North American plants generally may be more attractive for *Hadena* than plants originating from Europe, resulting in higher predation rates of flowers.

It is tempting to speculate that populations with low relative amounts of lilac aldehydes might occur in areas in which larger suites of alternative pollinators are available, making plants less dependent on *Hadena* for pollination and driving selection for lower amounts of lilac aldehydes to avoid *Hadena* fruit predation. Studies in other nursery pollinator systems indeed have shown that the outcome of co-evolutionary interactions can show extreme geographic variation (Thompson and Cunningham 2002). However, the limited information that is currently available on the interactions between *Silene* and alternative pollinators suggests that other, more generalistic, insect pollinators might use lilac aldehydes as attractants as well, which implies that *S. latifolia* plants with low amounts of lilac aldehyde may not only enjoy lower predation rates but may also suffer lower pollination success. Therefore, more studies that investigate the reproductive success of plants emitting different patterns of flower volatiles are needed to get insight in the adaptive significance of floral scent variability in *S. latifolia*.

The marginally significant negative association we found between fruit predation rate and the relative amounts of phenylacetaldehyde and 2-phenylethanol, two compounds that commonly occur in many floral scent samples of *S. latifolia* (Dötterl et al. 2005b, 2007), may be just an indirect effect mediated by the negative correlation between the relative amounts of these two compounds and the relative amount of lilac aldehyde.

Attraction and Oviposition Although differences in predation/oviposition rate by *H. bicruris* between healthy and diseased plants might, similarly to attraction rates, be explained by differences in floral scent, we do not know whether we should consider floral scent as a cue that elicits the oviposition behavior in *H. bicruris* or not. In other Lepidoptera, oviposition stimuli have been identified to be non-volatile compounds (e.g., Feeny et al. 1988; Haribal and Renwick 1996; Honda et al. 2001). Thus, it seems that generally volatile compounds are used for finding host plants, whereas less- or non-volatile compounds are used for host-plant recognition and for eliciting oviposition behavior (Honda 1995). Chemotactile receptors of the tarsi and the ovipositor are often involved in perception of such oviposition cues.

In *Hadena*, chemotactile receptors may play a role in oviposition, and oviposition cues could be located on the

petal surface of *S. latifolia* flowers. Typically, after *Hadena* is attracted to a flower, it lands on the flower, drinks nectar, and then lays an egg (Brantjes 1976). Therefore, oviposition cues may be located not only on the petals but even inside the flower tube, where they could be perceived by receptors on the proboscis (see also Biere and Honders 2006). The attraction-active lilac aldehyde may play a role in oviposition as well, as this compound is emitted at the base of the gynoecium near the nectaries (Dötterl and Jürgens 2005). However, *H. bicruris* strongly prefers female over male flowers for oviposition, and lilac aldehyde is the dominant compound in the scent of both male and female flowers, with no difference in scent observed (e.g., Dötterl and Jürgens 2005). Thus, other cues must be involved in lieu of, or in addition to, lilac aldehyde.

In summary, the cues used by *H. bicruris* to discriminate between healthy vs. smut-infected plants of *S. latifolia* seem to point to lilac aldehyde in the moth's attraction to the flowers, but the cues used in oviposition need to be identified before we can understand fully the mechanism leading to different oviposition and predation rates in the *Silene–Hadena* interaction.

Detoxification of Gramine by the Cereal Aphid *Sitobion avenae*

Qing-Nian Cai · Ying Han · Ya-Zhong Cao · Yuan Hu · Xin Zhao · Jian-Long Bi

Received: 26 October 2008 / Revised: 13 January 2009 / Accepted: 21 January 2009 / Published online: 18 February 2009

Abstract Secondary metabolites play an important role in host plant resistance to insects, and insects, in turn, may develop mechanisms to counter plant resistance mechanisms. In this study, we investigated the toxicity of gramine to the cereal aphid *Sitobion avenae* and some enzymatic responses of *S. avenae* to this alkaloid. When *S. avenae* fed on an artificial diet containing gramine, mortality occurred in a dose-dependent manner. The LC_{50} of gramine was determined to be 1.248 mM. In response to gramine, *S. avenae* developed increased activities of carboxylesterase and glutathione *S*-transferase, two important detoxification enzymes. The activities of both enzymes were positively correlated with the concentration of dietary gramine. In addition, the activities of peroxidase and polypheolic oxidase, two important oxidoreductase enzymes in *S. avenae*, increased in response to gramine; however, catalase activity decreased when insects were exposed to higher levels of dietary gramine. The potential role of gramine in host plant resistance and *S. avenae* counter-resistance is discussed.

Introduction

Host plant resistance against insects is recognized as an important component of integrated insect pest management (Gao 1994; Schotzko and Bosque-pérez 2000; Li et al. 2001). Plant resistance is attributed largely to secondary metabolites such as phenolics, nonprotein amino acids, and alkaloids, which are documented to be deleterious to insect herbivores (Manuwoto and Scriber 1985; Ciepiela and Sempruch 1999; Wang et al. 2006).

Many alkaloids are strong deterrents to aphids and other herbivores and have been used as botanical insecticides and/or antixenotic chemicals (Luo et al. 1997; Jiang et al. 1999). Gramine, a simple indole alkaloid found in barley and other crop plants, occurs widely in plants of Gramineae and has a wide range of biological activities against insects, mammals, and bacteria (Corcuera 1984, 1993; Züñiga and Corcuera 1986; Leszczynski et al. 1989).

In the plant–insect ecosystem, insect detoxification enzymes (i.e., esterase and glutathione *S*-transferase) and oxidoreductases (i.e., polyphenol oxidase, peroxidase, and catalase) are important antiresistant agents against the secondary metabolites found in their host plants. Their role in overcoming plant resistance has been studied extensively in a number of insect species (Gao et al. 1997; Figueroa et al. 1999; Luo and Zhang 2003). However, little is known about the changes of detoxification enzymes and oxidoreductases in aphids in response to gramine.

The present study was conducted to elucidate some of the biochemical mechanism(s) of gramine in host plant resistance and to determine how the English grain aphid, *Sitobion avenae* (F.), counters this resistance. The specific objectives were (1) to assess the direct toxicity of gramine to *S. avenae* and (2) to determine activities of detoxification enzymes and oxidoreductases in *S. avenae* in response to gramine in its diet.

Methods and Materials

Insects *Sitobion avenae* nymphs and adults were collected from field-grown wheat and maintained on the aphid-susceptible cultivar "Beijing 411," under field conditions. Insects over two generations were used for experiments.

Diet Preparation and Gramine Toxicity To determine gramine toxicity to *S. avenae*, technical-grade gramine was incorporated into an artificial diet containing the following ingredients: 300 mg agrinine, 50 mg cysteine, 200 mg histidine, 200 mg lysine, 100 mg methionine, 100 mg phenylalanine, 100 mg serine, 100 mg tryptophan, 20 mg tyrosine, 10 mg ascorbic acid, 0.1 mg biotin, 50 mg choline chloride, 1.0 mg folic acid, 10 mg *p*-aminobenzoic acid, 10 mg nicotinic acid, 2.5 mg pyridoxine HCl, 2.5 mg thianine HCl, 500 mg K_3PO_4, 200 mg $MgCl_2.6H_2O$, 100 ml distilled water, and 25 g sucrose. The pH was adjusted to 6.0 with K_3PO_4 (Auclair 1965; Kieckhefer and Derr 1967; Chen et al. 2000). Gramine (Kingsley and Keith) was dissolved into the liquid artificial diet to get a range of concentrations (4.0, 2.0, 1.0, 0.5, 0.25, 0.125, and 0.0 mM) for LC_{50} determination.

To assess effect of gramine on *S. avenae* detoxification enzymes and oxidoreductases and to ensure sufficient live aphids for biochemical analyses, technical grade gramine was dissolved in the artificial diet to compose four different concentrations (0.025, 0.05, 0.1, and 0.2 mM) below the LC_{50}. A diet containing no gramine was used as the control.

The second–third instar nymphs of *S. avenae* were fed on the liquid diet held between two layers of Parafilm M® (Auclair 1965). Two layers of stretched Parafilm were placed in a transparent cylindrical Plexiglas tube (height 60 mm and diameter 22 mm) and covered on top with gauze to allow air and humidity exchange. After 72 h of feeding, mortality was determined, and the survivors were collected for analyses of the detoxification enzymes and oxidoreductases.

Detoxification Enzyme Assays Carboxylesterase (CarE) activity was measured according to the method of Ni and Quisenberry (2003), with modification. *Sitobion avenae* (50 mg) were homogenized in 0.02 M potassium phosphate buffer (2 ml; pH 7.0) at 0°C. The homogenate was centrifuged (5,000×*g* at 4°C for 15 min). An aliquot (0.1 ml) of the resulting supernatant was mixed with 0.9 ml of the solution containing a-NA and Fast blue RR salt (10 mg a-NA and 20 mg Fast blue RR salt dissolved in 2 ml acetone, and diluted to 25 ml by adding the above phosphate buffer). The reaction progress was monitored spectrophotometrically at 405 nm.

Glutathione *S*-transferase (GST) was measured according to Ni and Quisenberry (2003). Frozen *S. avenae* (50 mg) were homogenized in 0.1 M Tris–HCl buffer (2 ml; pH 8.0) at 0°C. The homogenate was centrifuged (10,000×*g* at 4°C for 15 min). The assay mixture contained the resulting supernatant (0.1 ml), the above described Tris–HCl buffer (1.4 ml), and reduced glutathione (40 mM; 50 μl). After a preincubation (5 min at 25°C), CDNB (30 mM; 60 μl) was added. Change in absorbance was monitored at 340 nm.

Oxidoreductase Assays Aphids (50 mg) from each sample were ground in liquid nitrogen and then homogenized in 1 M ice-cold potassium phosphate buffer (1 ml) containing 1% polyvinylpyrrolidone and 1% Triton X-100 at pH 7.0. The homogenate was centrifuged (10,000×*g* at 4°C for 15 min), and the supernatant was used for analyses of the following three oxidoreductases.

Peroxidase (POD) activity was measured using the method of Hildebrand et al. (1986) and Hori et al. (1997). Enzyme extract (20 μl) was mixed with the substrate containing hydrogen peroxide (30%; 10 μl), guaiacol (18 mM; 300 μl), and hydroxyethylpiperazine ethanesulfonic acid (HEPES) buffer in deionized water (200 mM; pH 7.0; 100 μl). POD activity was estimated from the increase in A_{470}. The measurement was repeated three times.

Polyphenol oxidase (PPO) activity was determined following the method of Hori et al. (1997). Enzyme extract (20 μl) was mixed with a solution containing 1.6% catechol in HEPES buffer (500 μl), 200 mM HEPES (pH 6.0; 100 μl), and deionized water (380 μl). PPO activity was estimated from the increase in A_{470}. The analysis was repeated three times.

Catalase (CAT) activity was determined as described by Hildebrand et al. (1986) with minor modification. Enzyme extract (20 μl) was mixed with a solution containing hydrogen peroxide (75 mM; 100 μl), HEPES (200 mM; pH 8.0; 100 μl), and deionized water (780 μl). CAT activity was estimated from the increase in A_{240}. The analysis was repeated three times.

Total protein content was determined by the Bradford method (Bradford 1976). Absorbance of the reaction mixture was read at 595 nm with a spectrophotometer, and protein content was determined from a standard curve established using known quantities of bovine serum albumin (from Sigma Chemical) and the protein assay reagent.

Statistical Analysis Toxicity of gramine to *S. avenae* was subjected to probit analysis using the PriProbit Program V1.6.3 (Sakuma 1998). Analysis of variance was used to analyze the activity data from GST, CarE, POD, PPO, and CAT assays in *S. avenae*. Means were separated by the least significant difference test (α=0.05) (SPSS 11.0).

Correlation between enzymatic activities and gramine concentrations was determined by correlation test (α= 0.05) (SPSS 11.0).

Results

Gramine Toxicity Gramine killed *S. avenae* when the insect was fed with the artificial diet containing higher concentrations of the alkaloid (Fig. 1). After 72 h of feeding, *S. avenae* mortality followed in a dosage-dependent manner. The LC_{50} was determined to be 1.248 mM (range 0.947–1.743 mM).

Effect of Gramine Enzyme Activity Total protein content of *S. avenae* varied after the aphids fed on the artificial diet containing gramine at various concentrations (Fig. 2). With the exception of aphids that fed on 0.025 mM gramine, higher levels of total protein were found in all treatments compared to the control (df=4, 10, F=275.34, P<0.001).

GST activity in *S. avenae* was influenced by artificial diets containing different amounts of gramine (df=4, 10, F=58.66, P<0.001) (Fig. 3 GST). GST activity was significantly greater in *S. avenae* that fed on the diet containing 0.05, 0.1, and 0.2 mM of gramine than on the control diet. A positive correlation was observed between gramine concentration in diet and GST activity in *S. avenae* (N=5; r=0.940; P=0.009).

CarE activity in *S. avenae* was also affected by the increased gramine in the diet (df=4, 10, F=150.16, P<0.001) (Fig. 3 CarE). Gramine concentration was positively correlated with CarE activity in *S. avenae* (N=5; r=0.889; P=0.022).

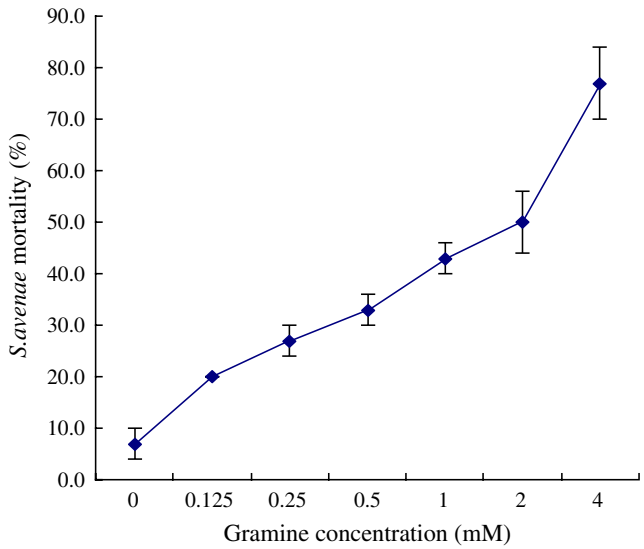

Fig. 1 Effect of gramine on the mortality of *S. avenae* at 72 h after treatment

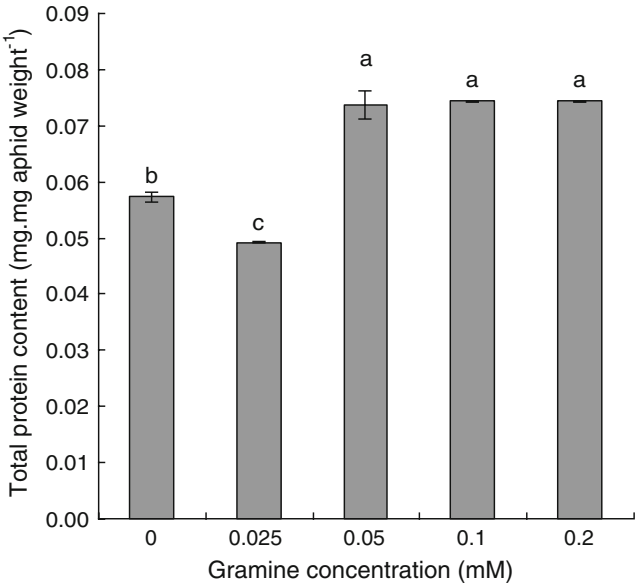

Fig. 2 Effect of different gramine concentrations on total protein content (mean ± SE) of *S. avenae*. *Bars with different letters* are significantly different (P<0.05)

POD and PPO activities were greater in *S. avenae* that fed on the artificial diet containing gramine than those on the control diet (df=4, 10; F_{POD}=113.20, F_{PPO}=57.74, P< 0.001) (Fig. 4 POD, PPO). Activities of both enzymes appeared to peak in *S. avenae* that fed on the diet containing 0.025 mM gramine. Then, enzymatic activities gradually increased with increased gramine (between 0.05 and 0.2 mM). PPO activity was positively correlated with dietary gramine levels (N=5; r=0.903; P=0.018). However, the correlation between POD activity and dietary gramine concentration was weak (N=5; r=0.800; P=0.052).

With the exception of 0.025 mM gramine treatment, CAT activity in *S. avenae* was suppressed by higher gramine concentration (between 0.05 and 0.2 mM) (df=4, 10; F=160.10; P<0.001) (Fig. 4 CAT). The correlation between dietary gramine concentration and CAT activity was not significant (N=5; r=−0.629; P=0.128).

Discussion

Many plant alkaloids are toxic to insects and are major resources of biological insecticides (Corcuera 1984; Jiang et al. 1999). Gramine has been considered as a deterrent and/or toxicant to many herbivorous insects such as *Schizaphis graminum*, *Rhopalosiphum padi*, *S. avenae*, and *Locusta migratoria* (Corcuera 1984; Zúñiga and Corcuera 1986; Leszczynski et al. 1989; Kanehisa et al. 1990; Rustamani et al. 1992; Moharramipour et al. 1997; Ishikawa and Kanke 2000; Wang et al. 2006). This study

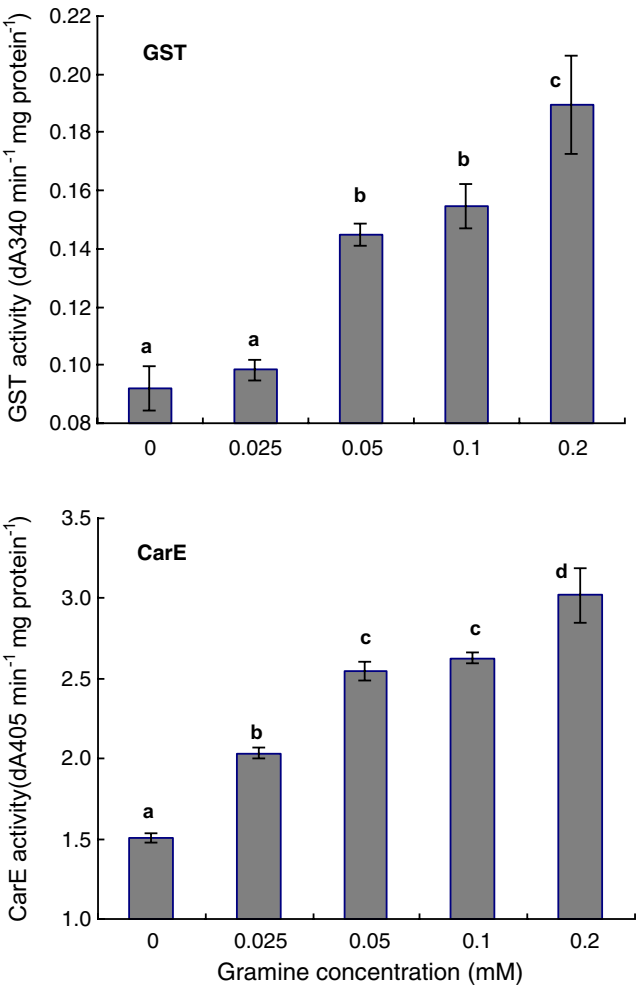

Fig. 3 Effect of gramine on activities (mean ± SE) of glutathione *S*-transferase (*GST*) and carboxylesterase (*CarE*) in *S. avenae*. Enzyme activities with *different letters* are significantly different ($P<0.05$)

showed that *S. avenae* mortality caused by exposure to dietary gramine was dosage-dependent with a defined LC_{50}, providing further evidence that gramine is active in plant resistance against aphids.

Detoxification enzymes (i.e., CarE and GST) play an important role in insect counter-resistance to plant secondary metabolites. The activity of these insects is closely related to the level of secondary metablites in host plants. CarE activity varies significantly among the populations of *Aphis gossypii* collected from different cotton varieties (Gao 1992; Jiang and Guo 1996). A higher CarE activity was observed in *R. padi* from resistant wheat varieties compared to susceptible varieties (Chen et al. 1997; Cai et al. 2004). Previous studies showed that alkaloids have been used as insecticides to regulate esterase activity in *Lipaphis erysimi* (Katenbach) and *Plutella xylostella* (L.) (Luo et al. 1997). The indole alkaloid gramine used in this study increased CarE activity in *S. avenae*, and the increase was positively correlated with dietary gramine concentrations, suggesting that CarE is involved with gramine detoxification.

GSTs (EC 2.5.1.18) constitute a group of enzymes that are involved in the detoxification of endogenous or

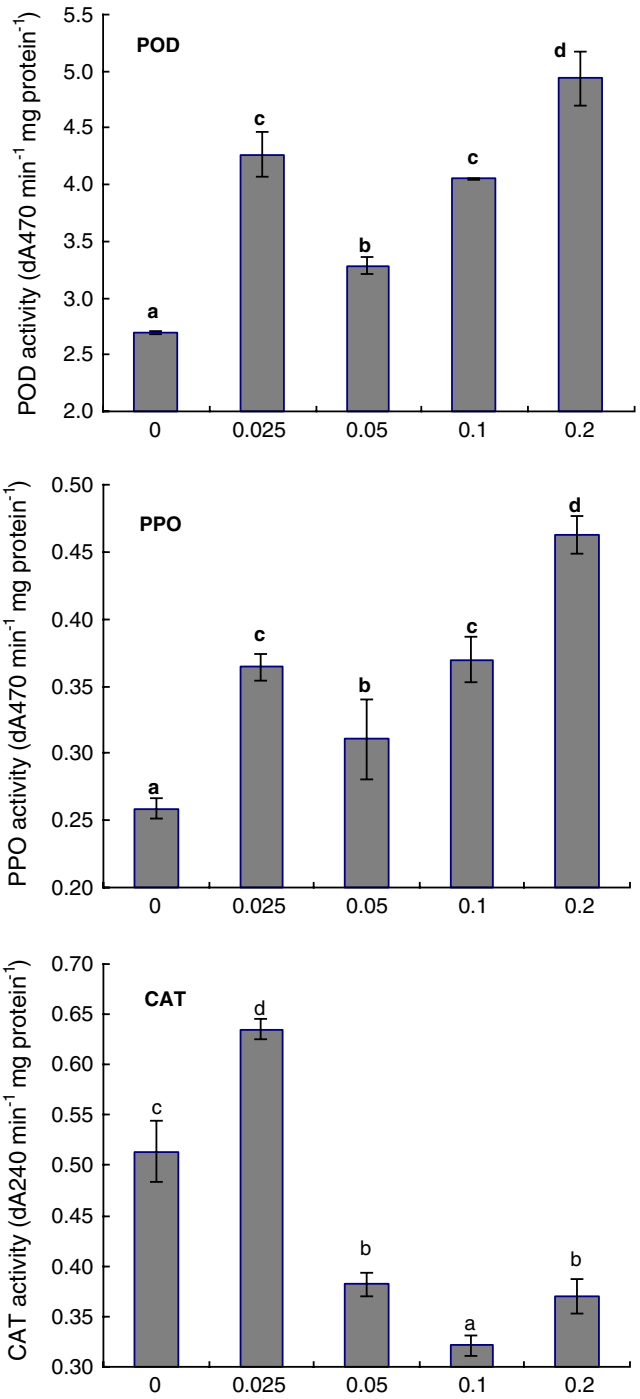

Fig. 4 Effect of gramine on activities (mean ± SE) of peroxidase (*POD*), polyphenol oxidase (*PPO*), and catalase (*CAT*) in *S. avenae*. Enzyme activities with *different letters* are significantly different ($P<0.05$)

exogenous toxic compounds (Vos and van Bladeren 1990). Increased level of GSTs in insects has been associated with resistance to a variety of insecticides (Foumier et al. 1992). Leszczynski et al. (1993) reported that GST activity was higher in *S. avenae* that fed on resistant wheat cultivars with high concentrations of phenolic compounds than those that fed on the susceptible ones. In this study, increased GST activity in aphids was observed when they fed on diets containing higher gramine concentrations, and enzyme activity was positively correlated with gramine concentration (Fig. 3). These results indicate that GSTs play a positive role in aphid antiresistance against allelochemicals (e.g., phenolics and gramine) in cereals.

POD and PPO are oxidoreductases, and in phytophagous insects, they may be able to counter plant resistance by reducing plant phenolics and their derivatives (Urbanska and Leszczynski 1992; Leszczynski et al. 1993). Phenolic compounds are involved in the resistance of cereal against aphids (Leszczynski et al. 1985, 1996). When aphids fed on a diet containing different concentrations of gramine, significantly different activities of POD and PPO were detected among the concentrations, and the gramine concentrations were correlated strongly with PPO activity in aphids but weakly with POD activity (Fig. 4). These results suggest that both POD and PPO in aphids are involved in gramine metabolism.

CAT is the classical enzyme in aerobic organisms that catalyzes the decomposition of hydrogen peroxide. This enzyme occurs in the midgut of *S. avenae* (Felton and Duffey 1991; Urbańska 2007). Many plant phenolics enhance the enzymatic activity in *S. avenae* (Figueroa et al. 1999; Loayza-Muro et al. 2000; Lukasik 2007). Interestingly, the opposite was observed in the present study, as *S. avenae* CAT activity was strongly reduced by higher gramine concentrations. However, significant correlations were not found between the activity and gramine concentration. This suggests that *S. avenae* CAT may be dissimilarly modified by the different cereal allelochemicals, i.e., alkaloids vs. phenolics.

In summary, gramine is considered to be an important secondary metablite in host plant resistance. This study showed that dietary gramine was toxic to *S. avenae*. In response to gramine, *S. avenae* enhanced CarE and GST activities, as well as PPO and POD activities, thus possibly countering the resistance.

Do Caterpillars Secrete "Oral Secretions"?

Michelle Peiffer · Gary W. Felton

Received: 3 September 2008 / Revised: 5 December 2008 / Accepted: 18 January 2009 / Published online: 17 February 2009

Abstract The oral secretions or regurgitant of caterpillars contain potent elicitors of plant induced responses. These elicitors are recognized by host plants to differentiate between simple mechanical injury and the presence of herbivores. In some cases, this level of recognition is highly specific. Despite the in-depth chemical characterization of these elicitors, little is known about the amounts delivered in regurgitant during feeding. In this study, we use a fluorescent dye to label regurgitant in order to visualize caterpillar regurgitation during feeding. The procedure is highly sensitive and allows us to visualize nanoliter amounts of regurgitant. We examined the propensity of larval *Helicoverpa zea*, *Heliothis virescens*, *Spodoptera exigua*, *Spodoptera frugiperda*, and *Manduca sexta* to regurgitate on various host plants. These species were selected because they have been among the most intensely studied in terms of elicitors. Our results indicate that most larvae did not regurgitate following a brief feeding bout (~10 min) during which they ate ca. 0.40 cm^2 of leaf. When larvae did regurgitate, it was typically less than 10 nl. This is several orders of magnitude less than is typically used in most studies on oral secretions. The frequency of regurgitation appears to vary depending upon the host plant. Larval *H. zea* are less likely to regurgitate when feeding on tomato leaves compared to corn mid-whorl tissue. Our results have importance in understanding the role of oral secretions in plant recognition of herbivory. Because caterpillars did not routinely regurgitate during feeding, it is likely that they avoid the elicitation of some plant defensive responses during most feeding bouts.

Introduction

The specificity of plant responses to herbivores is determined, in part, by the particular feeding style of the herbivore (Rodriguez-Saona et al. 2005) and by the presence of herbivore-derived elicitors or herbivore-associated-molecular-patterns (HAMPs) found in their secretions (Korth and Thompson 2006; Fatouros et al. 2008; Felton 2008; Felton and Tumlinson 2008; Mithöfer and Boland 2008). Lepidopteran secretions, which may contact the plant, include not only regurgitant from the insect gut but also saliva produced by the labial and mandibular salivary glands and feces (Felton 2008). Most of the HAMPSs that have been identified are found in the regurgitant or oral secretions (OS) of lepidopteran larvae and can elicit both direct and indirect defenses. These lepidopteran HAMPs include β-glucosidase (Mattiacci et al. 1995), fatty acid-conjugates (e.g., volicitin; Alborn et al. 1997; Voelckel and Baldwin 2004), and the inceptins (Schmelz et al. 2006) found in OS. HAMPs may trigger biosynthesis of wound hormones including jasmonic acid, the release of volatile emissions, and the induction of defense genes (Felton and Tumlinson 2008; Mithöfer and Boland 2008).

Another factor contributing to the specificity of plant responses to herbivores is that the activity of elicitors may be context specific. For example, the activity of elicitors such as volicitin or inceptins is host-plant specific (Schmelz

et al. 2006, 2007). The transcriptome responses of two Solanaceous plants, *Nicotiana attenuata* and *Solanum nigrum*, to herbivory by *Manduca sexta* were strikingly different, although the fatty acid conjugates in OS of the caterpillar are not affected by diet (Schmidt et al. 2005). These data suggest that the elicitors are differentially active in the two host plants. Another plausible explanation for these differential responses is that although the composition of the elicitors in OS is not altered by host plant, there may be differences in the amount of OS applied to each host plant during feeding.

How the caterpillar applies these elicitors to the plant and in what amounts is much less understood. Volicitin found in the OS of caterpillars such as *Spodoptera exigua* has been well characterized and shown to induce volatile production in maize (Alborn et al. 1997). In an elegant study, radiolabeled volicitin was identified in the caterpillar regurgitant and recovered from corn leaves after feeding by *S. exigua* (Truitt and Pare 2004). The researchers estimated that 100 pmol of volicitin in 4.2 μl of regurgitant was transferred to the leaf over a 9-h period; although the authors noted that the secreted volicitin may arise from a mixture of fluids from the gut and salivary glands. Additionally, it is not clear if the volicitin originated solely from OS or also could have been deposited in fecal excrement.

Our laboratory has investigated the effect of host plant variation on the rate of salivary secretions in the noctuid *Helicoverpa zea*. We used antibodies targeted to specific components of caterpillar saliva to investigate this question. One of the active components in caterpillar saliva is the enzyme glucose oxidase (GOX; Eichenseer et al. 1999; Musser et al. 2002). Glucose oxidase, visualized on leaf tissue prints by using immunolabeling, is secreted at the feeding site and randomly across the leaf by larval *H. zea* (Peiffer and Felton 2005). GOX can be recovered from leaves fed on by larvae and then quantified by using the antibody. Larvae secrete microgram amounts of saliva depending upon the host plant (Peiffer and Felton 2005). Differences in rates of GOX secretion may partially explain the variation in responses of host plants to caterpillar salivation that we have observed (unpublished data).

Some researchers, however, have questioned the role oral secretions play in the specificity of plant responses and, instead, have argued that the physical damage inflicted by herbivores has not been adequately mimicked by investigators. In studies where oral secretions or saliva are tested, the mechanically wounded control treatment typically involves a single wounding event performed with a razor blade, pattern wheel, scissors, or other mechanical device (Alborn et al. 1997; Halitschke et al. 2001; Gomez et al. 2005; Schmelz et al. 2007; Wu et al. 2007). It has been consistently observed that a single wounding event may not adequately mimic the continuous or semicontinuous feeding by an herbivore (Mithöfer et al. 2005). A "mechanical" caterpillar (named MecWorm) was designed to test the effect of continuous feeding on the volatile emissions in lima bean leaves (Mithöfer et al. 2005; Arimura et al. 2008). Their experiments indicated that volatile emissions produced by MecWorm damage qualitatively resemble that produced by herbivore feeding (Mithöfer et al. 2005; Arimura et al. 2007), suggesting that OS are not required for volatiles released by caterpillar feeding.

Despite a fairly robust literature on caterpillar OS, no one has explicitly documented lepidopteran regurgitation on leaves during feeding. Regurgitant used in most studies is collected by squeezing the larva or even by applying an electrical shock. However, in certain caterpillar species, regurgitation is typically a defensive response to predators (Grant 2006; Brown et al. 2007). Thus, our objective was to determine the extent to which caterpillars may regurgitate during feeding. In this paper, we used a fluorescent dye to label the regurgitant, thereby allowing us to visualize and quantify regurgitant at the feeding site.

Material and Methods

Insects and Plants *H. zea*, *Heliothis virescens*, and *M. sexta* eggs were purchased from the North Carolina State University Insectary; *S. exigua* were kindly supplied by Jim Tumlinson, Penn State University; *S. frugiperda* were kindly supplied by Dawn Luthe, Penn State University. All caterpillars were reared on a wheat germ and casein-based artificial diet (Chippendale 1970) with ingredients purchased from BIOSERV (Frenchtown, NJ, USA). Insects were kept at 27°C, with a 16-h photoperiod.

Plants used were: tomato *Solanum lycopersicum* (cv Betterboy); corn *Zea mays* (cv B73); squash *Cucurbita pepo* (cv Dixie); and bean *Phaseolus vulgaris* (cv Bush Blue Lake 274). Before beginning the fluorescence experiments, we observed tomato leaves with the confocal microscope over a range of wavelengths. This preliminary scan indicated that leaves have minimal autofluorescence at 488 nm. Therefore, Alexa 488 was determined to be an appropriate dye to work with.

Effect of Alexa 488 on H. zea Larval Growth To determine the effect of Alexa 488 on caterpillar growth, 10 μg Alexa Fluor 488 carboxylic acid esters (Invitrogen, Carlsbad CA, USA) were dissolved in a small amount of water and then pipetted onto 1.0 g artificial diet. Fourth instar *H. zea* were allowed to feed for 3 day, then relative growth rates were calculated and compared to larvae feeding on diet without Alexa.

Sample Preparation and Observation of Feeding Sites by Confocal Microscopy To make regurgitant fluorescent, 10 μg Alexa Fluor 488 in 100 μl water were pipetted onto 0.5 g of artificial diet. Newly molted fifth instars were allowed to feed overnight on the spiked diet. Control caterpillars were fed diet to which 100 μl of water were added. By morning, the entire piece of diet had been consumed, and caterpillars were placed on leaves. After 10 min, caterpillars were removed, and the feeding site on the leaf excised and pressed between a glass slide and a coverslip and secured with tape. If caterpillars were allowed to feed longer, the ingested leaf material pushed the fluorescent diet through the gut, and the regurgitant became less fluorescent. Therefore, leaves were examined after only a single feeding bout in order to increase the chance of observing regurgitation.

To collect *H. zea* saliva, ice-chilled larva were immobilized in a metal hair clip and observed with a dissecting microscope. As the larva returned to room temperature, labial saliva was collected via capillary action into a gel loading pipet tip (VWR, West Chester, PA, USA) containing 3 μl water. Saliva and water were then expelled onto a glass coverslip and allowed to dry before observation. Ventral eversible gland (VEG) secretions were collected from the gland in noctuids in the same manner as saliva. Caterpillars were placed on parafilm and gently squeezed until they regurgitated. The regurgitant was collected, and 3 μl were placed on a coverslip and allowed to dry.

Leaves and coverslips containing secretions were observed with an Olympus FV1000 Laser Scanning Confocal Microscope (Olympus, America Inc., Melville, NY, USA) with an excitation of 488 nm. For each leaf, three visual fields were imaged at ×10 and relative intensity of fluorescence measured with FV10-ASW version 1.6. ANOVA using Fisher's separation of means was used to determine if the relative intensity of leaves were different from control leaves. Saliva and VEG secretions were imaged at a ×20 magnification.

Dilution Series and Standard Curve To determine the lowest amount of regurgitant detectable, regurgitant was collected from four larvae that had eaten Alexa 488 spiked diet. The regurgitant was diluted in water and 0.2 μl applied to detached leaves and allowed to dry. The leaves were mounted and observed as previously described. Relative intensity of fluorescence was plotted against amount of regurgitant applied to create a standard curve. This curve was used to estimate the amount of regurgitant caterpillars secreted onto the leaf.

Effect of Alexa Source Additional experiments were done to determine if *H. zea* would regurgitate differently if allowed to feed longer on plants, or if Alexa was acquired by feeding on spiked leaves rather than diet. To acclimate *H. zea* to tomato leaves, third instar *H. zea* were caged on intact 4-week-old tomato seedlings and allowed to feed. When larva molted to fifth instar, they were removed from plants and placed in cups with leaves spiked with Alexa 488. To spike the leaves, cut petioles were placed in 100 μl of solution containing 10 μg Alexa 488. When leaves had taken up the entire solution, they were fed to *H. zea*. After *H. zea* consumed the entire spiked leaf, they were placed on fresh leaves for 10 min, and leaf samples and secretions were prepared as previously described. The experiment was repeated with corn, except third instars were fed on detached corn leaves.

Effect of Spinneret Ablation on Regurgitation To determine if ablating the spinneret would effect regurgitation, before feeding on diet spiked with Alexa 488, *H. zea* caterpillars were ablated as previously described (Peiffer and Felton 2005). Ablation of the spinneret is a procedure routinely used to determine the role of labial gland saliva on induced defenses.

Results

Effect of Alexa 488 on H. zea Growth No differences were observed in relative growth rates of *H. zea*-fed Alexa-spiked diet vs. normal diet. *H. zea*-fed spiked diet had a relative growth rate of 0.5216 mg gained/day/mg larva, while those fed normal diet had a relative growth rate of 0.5284 mg gained/day/mg larva (F=0.34, P=0.562). This suggests that Alexa 488 has no obvious, deleterious effects on *H. zea* at the concentrations used.

Distribution of Fluorescence in Caterpillar Secretions After caterpillars had fed overnight on diet spiked with Alexa 488, we determined that their labial saliva and, in the case of the noctuid species, their VEG secretions were not fluorescent. No fluorescence was observed in the saliva of any *H. zea* tested (Fig. 1). The saliva of all eight *H. virescens* larvae observed lacked detectable fluorescence. Likewise, all eight *H. zea* and eight *H. virescens* lacked fluorescence in the VEG secretions. *M. sexta*, *S. frugiperda*, and *S. exigua* have comparatively short spinnerets, making it nearly impossible to collect saliva directly or to be assured that regurgitant is free of saliva. Thus, saliva was not specifically tested for these species. However, we were able to collect VEG secretions from ten *S. frugiperda* and nine *S. exigua*, and all lacked detectable fluorescence.

In all experiments, regurgitant, collected after the caterpillars ate spiked diet, was highly fluorescent (Table 1). Feces, from caterpillar-fed spiked diet, were also highly fluorescent (Fig. 1).

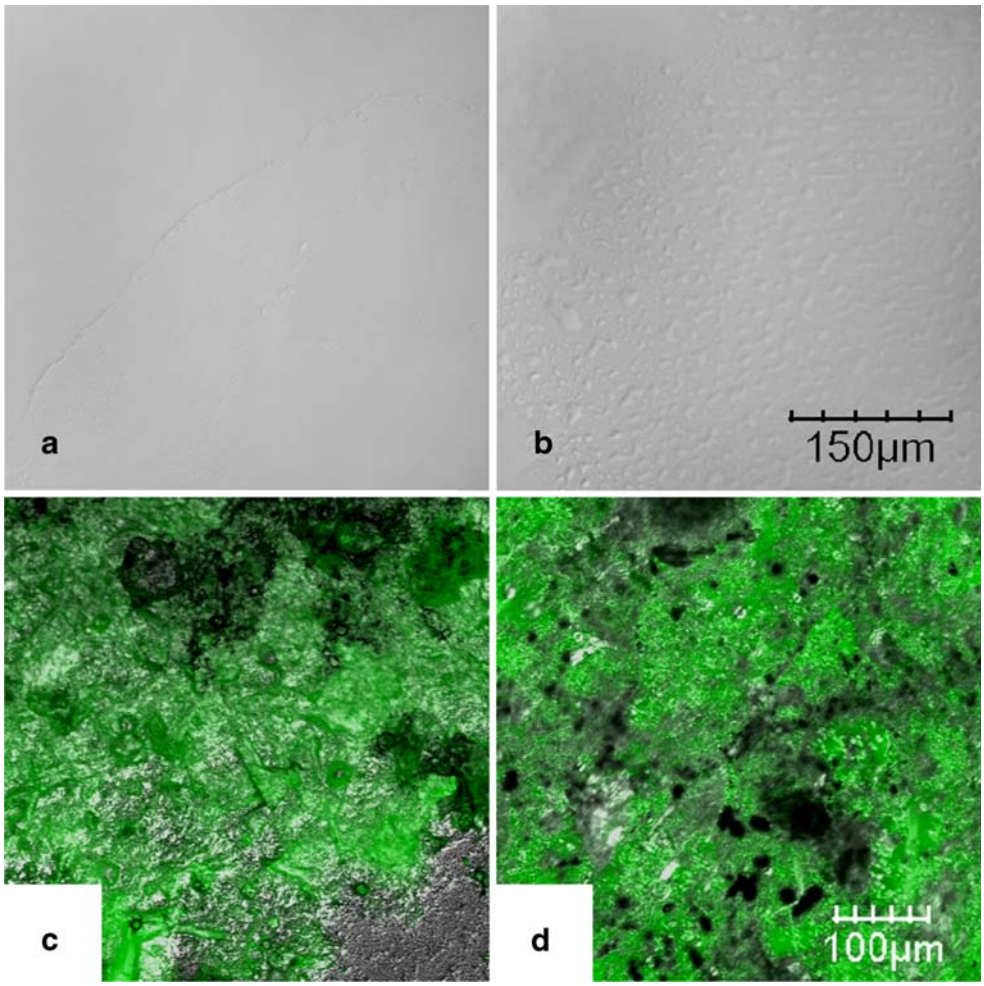

Fig. 1 Distribution of fluorescence in Helicoverpa zea oral secretions and feces after eating 0.5 g diet spiked with Alexa 488. **a** saliva, **b** VEG secretions, **c** regurgitant, **d** feces

Effect of Host Plant on Regurgitation in H. zea When *H. zea* larvae were placed on tomato leaves after feeding on spiked diet, they ate on average 0.12 cm^2 (SE=0.02) of leaf material before being removed. Fluorescence was detected on only one of 20 leaves (Fig. 2). Nineteen of the leaves lacked any fluorescence along the eaten edges or anywhere else on the leaf. The estimated average amount of regurgitant on this leaf was 0.32 nl (SE=0.12; Table 2).

H. zea ate on average 0.13 cm^2 (SE=0.07) of bean leaves, and regurgitant was visually detected on only one of five bean leaves (Table 2). *H. zea* ate 0.21 cm^2 (SE=0.11) of squash leaves, and regurgitant was detected on one of five leaves. When *H. zea* fed on corn leaves, they ate on average 0.26 cm^2 (SE=0.05) of leaf, and low levels of regurgitant were detected in five of eight leaves (Table 2). When *H. zea* were ablated before being fed spiked diet, they ate 0.31 cm^2 (SE=0.06), and regurgitant was detected on only one of six tomato leaves (Table 3).

Standard Curve for Regurgitant Applied to Leaf When serial dilutions of regurgitant were applied to leaves, the relative intensity of fluorescence and the amount of regurgitant applied were found to have a linear relationship (Fig. 2). From this standard curve, we estimated the amount of regurgitant on leaves with visually detected fluorescence.

Effect of Alexa Source on H. zea When *H. zea* were allowed to feed on leaves and then acquire Alexa from spiked leaves, they ate on average 0.22 cm^2/leaf (SE=0.09),

Table 1 Relative intensities of regurgitant from larvae fed diet spiked with Alexa 488 or fed control diet

Caterpillar species	Alexa 488 Diet	Control Diet
Helicoverpa zea	150.97	3.61
Heliothis virescens	192.51	13.62
Manduca sexta	55.29	14.27
Spodoptera exigua	22.72	1.19
Spodoptera frugiperda	86.05	0.10

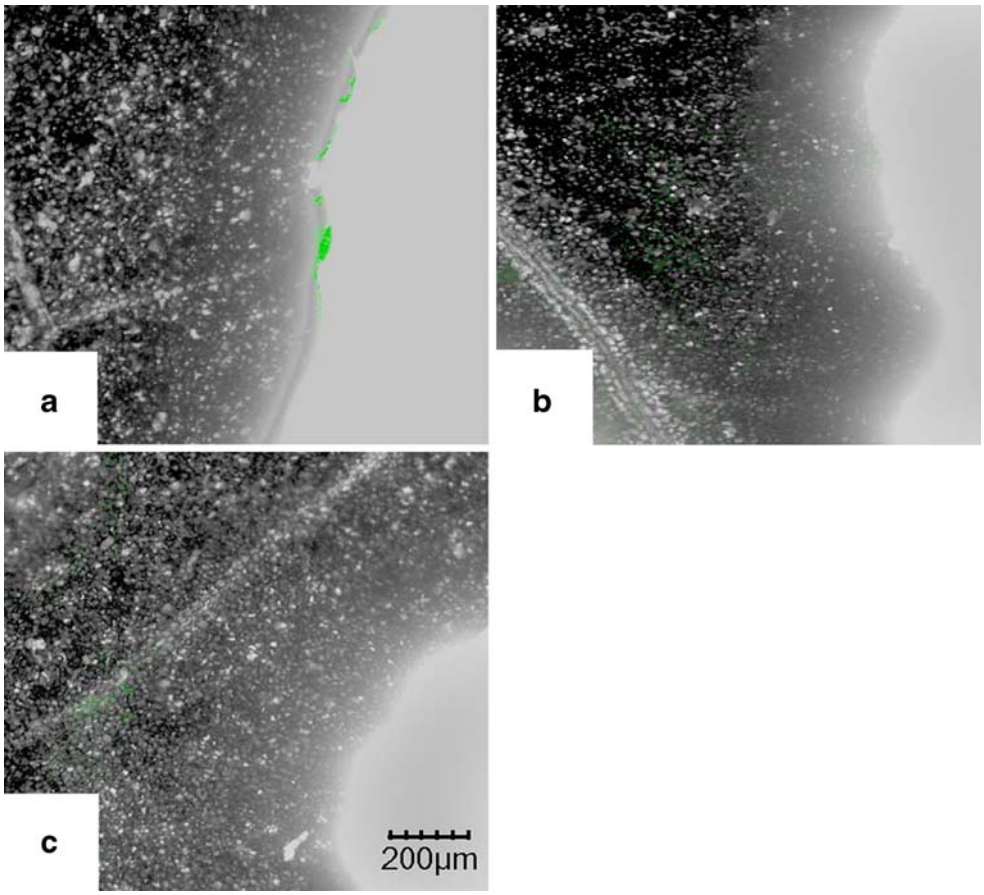

Fig. 2 Visual detection of fluorescent regurgitant from *Helicoverpa zea* after eating diet spiked with Alexa 488. **a** Tomato leaves with fluorescent regurgitant along the feeding site. **b** Leaf which *H. zea* fed upon but no regurgitant was detected. **c** Leaf fed upon by *H. zea* fed control diet

and fluorescence was not detected on any of the seven tomato leaves examined (Table 2). *H. zea* from corn ate 0.36 cm^2 (SE=0.10) of the corn leaf. Fluorescence was detected on only one of ten corn leaves after acquiring Alexa from corn leaves (Table 2).

H. virescens on Tomato Leaves H. virescens caterpillars had slightly higher rates of regurgitation, after eating 0.20 cm^2 (SE=0.02) leaf. When 14 tomato leaves were examined after being fed upon by caterpillars that had eaten spiked diet, fluorescence was detected on five (Table 3). A standard curve was generated from *H. virescens* regurgitant, and the average amount of regurgitant on the leaves was calculated to be 4.8 nl (SE=1.82).

Other Caterpillar Species When *M. sexta* larva were allowed to feed on diet spiked with Alexa 488, then tomato leaves, they ate on average 0.3 cm^2 (SE=0.10) of leaf material, and the collected regurgitant was highly fluorescent. However, fluorescence was not detected on any of 15 leaves following feeding (Table 3). This suggests that *M. sexta* do not typically regurgitate during feeding on tomato.

Table 2 Detection of *Helicoverpa zea* regurgitant on different host plants

Alexa source	Host plant	# Fluorescent/total # observed	Estimated amount of regurgitant (nl) mean ± SE
Diet	Tomato	1/20	0.32[a]
Diet	Bean	1/5	0.31[a]
Diet	Squash	1/5	0.27[a]
Diet	Corn	5/8	0.55±0.10
Tomato leaves	Tomato	0/7	0.00
Corn leaves	Corn	1/10	1.49[a]

[a] Result from one observation

Table 3 Detection of regurgitant on plants after feeding by caterpillars spiked with Alexa 488

Caterpillar species	Plant	# Fluorescent/total # observed	Estimated amount of regurgitant (nl) mean ± SE
Helicoverpa zea (ablated)	Tomato	1/6	0.07[a]
Heliothis virescens	Tomato	5/14	4.80±1.82
Manduca sexta	Tomato	0/15	0
Spodoptera exigua	Corn	3/9	0.90±0.34
Spodoptera frugiperda	Corn	2/10	1.20±0.49

[a] Result from one observation

Regurgitation on corn leaves was detected on three of nine leaves fed on by *S. exigua*, which ate 0.36 cm^2 (SE= 0.04) per leaf (Table 3). *S. exigua* regurgitant diluted and manually applied to corn leaves also gave a linear standard curve. From this curve, we determined that the three *S. exigua* that had visually detectable fluorescence had 1.6, 0.5, and 0.6 nl of regurgitant (Table 3).

S. frugiperda ate on average 0.32 cm^2 (SE=0.03) per leaf and two of ten *S. frugiperda* regurgitated on the corn leaves (Table 3). By using the standard curve generated from *S. exigua* data, the two *S. frugiperda* were calculated to each have secreted 1.4 and 1.0 nl of regurgitant.

Application of 20 μl Regurgitant Researchers studying the effects of regurgitant on plants typically apply 20 μl of regurgitant to wounded leaves. When we applied 20 μl fluorescent regurgitant to leaves, the fluorescence was obvious and bright. Relative fluorescence could not be measured because the detector was saturated at the settings normally used for the feeding experiments, and the area covered by fluorescence was too large to fit in a visual field (Fig. 3).

To determine if wounding of the plant tissue caused quenching or interference with the fluorescence detection, regurgitant was diluted 1:5 with water, and 20 μl were applied after wounding with a pattern wheel. Fluorescence was spread over the wounded surface and again very bright, coating not only the wound sites but also the entire leaf and trichomes (Fig. 4).

Discussion

Plants can discriminate herbivory from mechanical damage by either recognizing specific components (HAMPs) in the oral secretions of the herbivore and/or by the unique patterns of physical injury incurred during feeding (Howe and Jander 2008; Mithöfer and Boland 2008). Our laboratory has approached this problem by developing surgical techniques to prevent caterpillars from releasing saliva either by ablation of the spinneret (the secretory structure for labial gland saliva) or by surgically removing the labial glands (Musser et al. 2002, 2006). These techniques have demonstrated that saliva plays a key role in the suppression of inducible defenses in several caterpillar-host plant models (Musser et al. 2002, 2005; Bede et al. 2006; Delphia et al. 2006; Weech et al. 2008). The MecWorm was designed to more accurately mimic the continuous physical injury incurred during caterpillar feeding. MecWorm "feeding" produced volatile emissions qualitatively similar to actual caterpillar feeding on lima bean plants (Mithöfer et al. 2005). However, not all plant species respond to MecWorm treatment with a similar emission profile as the herbivore-induced suite (Maffei et al. 2007). This indicates that HAMPs may not be active in all plant species, and/or HAMPs may not be released by herbivores on all plant species. Nevertheless, there is strong evidence that certain HAMPs such as volicitin are important components in plant recognition of herbivores. Not only is volicitin secreted on maize leaves by *S. exigua* larvae (Truitt and Pare 2004) and activates specific indirect defenses (Alborn et al. 1997), but there is evidence for a putative volicitin receptor on the plasma membrane in maize (Truitt et al. 2004).

Because HAMPs have been identified in lepidopteron regurgitant, it has been assumed that as caterpillars feed, they regurgitate onto the wound site, thereby exposing the plant to the HAMPs. However, in order to better understand how plants recognize herbivores, it is necessary to determine whether regurgitant or OS are typically secreted during feeding bouts and if there is variation in the secretion depending upon a particular host plant species used by the herbivore. In the majority of studies on OS in caterpillars, researchers have routinely applied 10–20 μl of OS to leaves mechanically wounded without regard to the actual amounts that may be secreted. Our data indicate that regurgitation during feeding does not occur with every feeding bout, and when it does occur, caterpillars regurgitate in nanoliter amounts.

We used Alexa 488, which is a highly fluorescent and very stable dye, to visualize and quantify regurgitation. Caterpillars placed on diet spiked with Alexa 488 have highly fluorescent

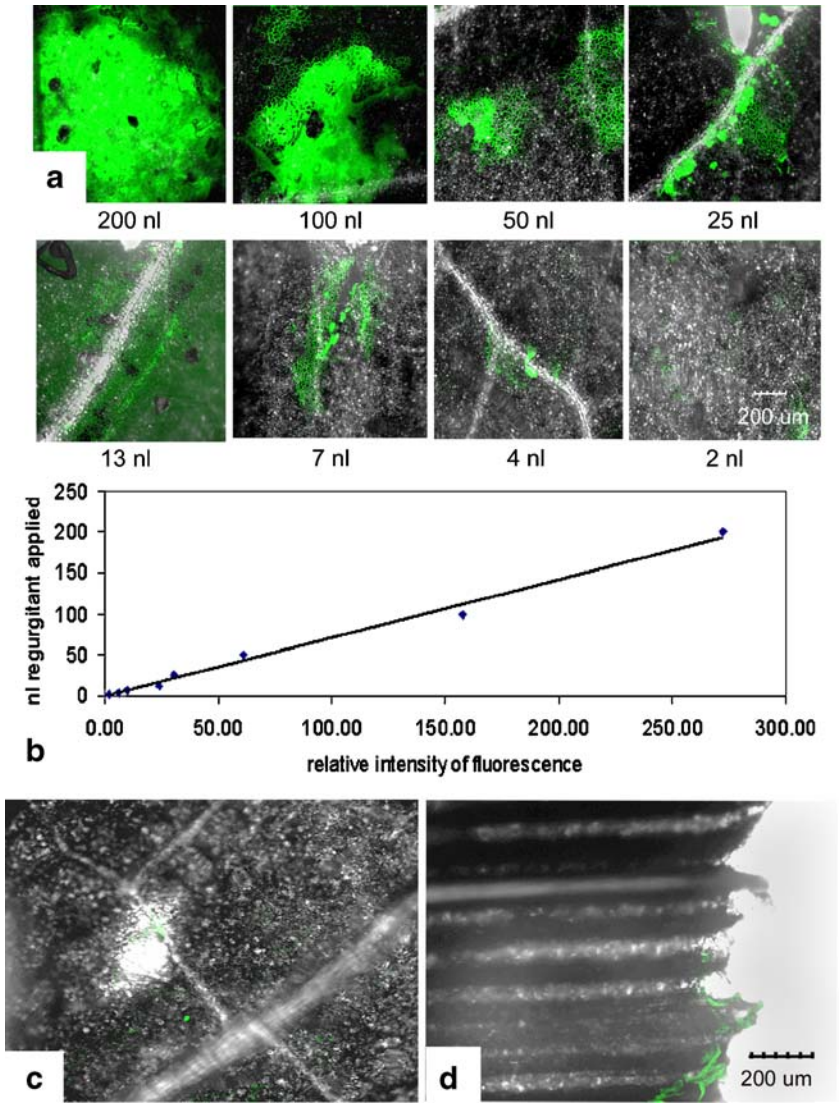

Fig. 3 Dilution series of regurgitant collected from *Helicoverpa zea* fed diet spiked with Alexa 488. **a** Regurgitant was diluted in water then 0.2 µl applied to tomato leaves; *numbers* represent the actual amount of regurgitant in the application. **b** The relative intensity increases exponentially with increasing amounts of regurgitant. R^2=0.992. Equation for the linear curve is y=0.7128x. **c** *H. zea* regurgitant at the feeding site of squash leaf from the linear curve the amount of regurgitant was calculated to be 0.27 nl. **d** *H. zea* regurgitant at the feeding site of corn leaf; from the linear curve, the amount of regurgitant was calculated to be 1.02 nl

regurgitant 24 h after being placed on the diet. Caterpillars were transferred to leaves and appeared to feed normally and, if agitated by the researcher, regurgitated easily. We were unable to detect any fluorescence in the caterpillar saliva or in the secretions of the ventral eversible gland of noctuid larvae, another secretory organ in this group of insects (Felton 2008). Thus, this technique specifically labels oral secretions or regurgitant in these species. By manually collecting regurgitant and applying it to leaves, we detected as little as 4 nl of regurgitant. Even with this sensitivity, however, only a fraction of the caterpillars left detectable regurgitant at the feeding site. Of those that did regurgitate, the amount was calculated to be ca. 0.5 to 5.0 nl per feeding bout. This is 4,000 to 40,000 times less than the 20 µl typically applied to plants. It is possible that some of the regurgitant is reingested during feeding, such that caterpillars are "eating their evidence" (Schittko et al. 2000). Although this cannot be ruled out by our methodology or that used by others (Truitt and Pare 2004), we suggest it would be unlikely that caterpillars would selectively regurgitate on foliage that was ingested and yet leave the feeding margins largely free of regurgitant. In the case of labial saliva, although some is reingested during feeding, substantial amounts of salivary glucose oxidase (microgram quantities) are left on feeding margins and also dropped on other portions of the leaf (Peiffer and Felton 2005).

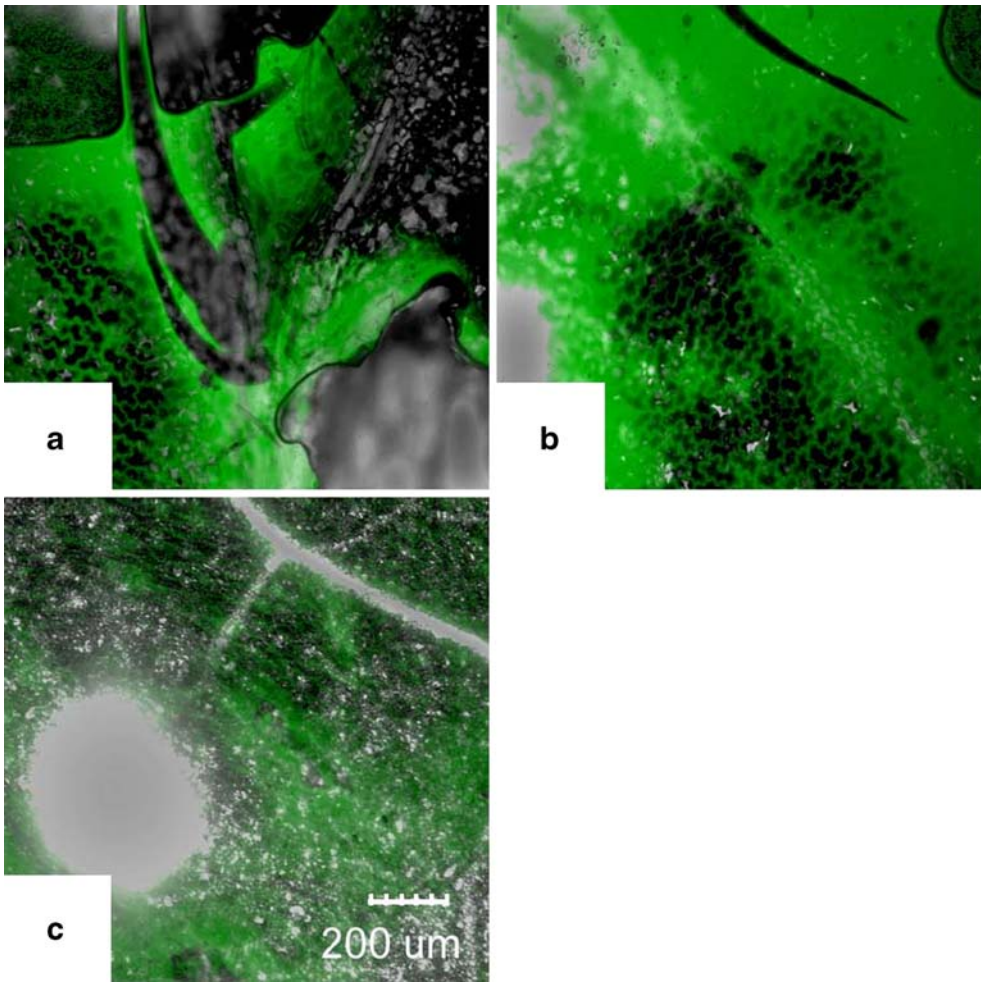

Fig. 4 Regurgitant from caterpillars fed diet spiked with Alexa 488 was collected and manually applied to tomato leaves after wounding with pattern wheel; **a** 1 μl of regurgitant from *Helicoverpa zea*. **b** 3 μl regurgitant from *H. zea*. **c** Regurgitant from *Manduca. sexta*, diluted 1:5, then 20 ul applied

Our data indicate that there are differences among caterpillar species in their predisposition to regurgitate during feeding. These differences may provide insight into how plants can differentiate feeding between related herbivore species, despite the species possessing similar elicitor profiles (De Moraes et al. 1998). The factors responsible for these differences in regurgitation during feeding are unknown, but differences in the propensity of caterpillar species to regurgitate in response to the threat of predation have been linked to the relative size of the fore- and midguts (Grant 2006). Those species with comparatively larger foreguts and smaller midguts are more prone to defensive regurgitation (Grant 2006). It should be noted that all of the caterpillar species used in our study have comparatively small foreguts (personal observations); thus, we do not know if there is also a similar constraint of gut structure and propensity to regurgitate during feeding, but this warrants further examination.

The propensity to regurgitate varied depending upon the host plant of the caterpillar. For instance, larval *H. zea* were far more likely to regurgitate when feeding on corn compared to other hosts such as tomato. The particular host factors that contribute to these differences are unknown but could be due to an array of factors associated with a particular host including water content, leaf toughness, nutritional status, and/or presence of specific toxins. Alternatively, it would be important to determine if caterpillars are able to specifically minimize regurgitation in order to prevent the elicitation of host defenses.

To date, few studies have included a dose-response analysis of OS when determining effects on induced plant responses. There have been an inexplicable number of studies that have used an identical quantity of OS for testing without regard to the species or stage of insect used. The fluorescent method developed here for specifically labeling OS provides the means to better estimate the actual amounts of OS that are released during feeding. Our results indicate that OS are not released during every caterpillar feeding bout, and they suggest that some herbivores may minimize their display of elicitors during feeding.

Acknowledgments The support of the USDA NRI is greatly appreciated (2005-35607-15242 and 2007-35302-18218 awarded to G.W.F.). Statistical advice by Torrence Gill was helpful. All confocal (or digital) microscopy was done at the Cytometry Facility, University Park (Huck Institutes of the Life Sciences, Penn State University). This project is funded, in part, under a grant with the Pennsylvania Department of Health using Tobacco Settlement Funds. The Department specifically disclaims responsibility for any analyses, interpretations, or conclusions.

Abstract The sex pheromone of *Phyllophaga* (*Phytalus*) *georgiana* was characterized as valine methyl ester, tentatively the L-enantiomer. This is the first sex pheromone identified from the *Phyllophaga* subgenus *Phytalus*. The pheromone was extracted from female glands, the active component isolated by coupled gas chromatography–electroantennogram detection analysis, characterized by mass spectrometry, and shown to be active in field tests. The seasonal flight pattern was determined for *P. georgiana* as well as for three other species, *P. anxia* (both northern and southern genitalic forms), *P. gracilis*, and *P. postrema*. The latter three species were captured in traps baited with L-isoleucine methyl ester.

Introduction

The scarab beetle, *Phyllophaga* (*Phytalus*) *georgiana*, is distributed along the east coast of the United States from New Jersey to South Carolina, Georgia, Alabama, and Mississippi (Harpootlian 2001; Robbins et al. 2006). It is one of eight US species in the *Phyllophaga* subgenus *Phytalus*. The remaining *Phytalus* species (ca. 90) are distributed from Mexico, through Central America, to Brazil, Uruguay, and Paraguay (Evans and Smith 2007).

The larvae of *P. georgiana* are root-feeding pests of cranberries in New Jersey (Koppenhöfer et al. 2008). When the larvae were originally discovered feeding in the roots of cranberries, the species could not be identified because character differences in the larvae have yet to be described, although this is currently underway. To identify the species, ca. 50 larvae were reared to adulthood. The resulting adults were all identified as *P. georgiana.* We used these adults for the isolation and identification of the pheromone.

Materials and Methods

Pheromone Collections Larvae were dug from a bog in southern New Jersey and kept individually, in 30-ml plastic cups in a 3:1 mixture of greenhouse sand and screened peat moss raised to 12% moisture (*w*/*w*), in a controlled environment room, at 25°C for the 16-h photophase and

20°C for the 8-h scotophase. After eclosion, adult females were placed in observation cages to observe calling [abdominal pheromone gland everted (Leal et al. 1993; Nojima et al. 2003b)] during the scotophase. Once a female was observed calling, it was removed from the cage and its pheromone gland everted by applying gentle pressure to the abdomen. The gland was excised with scissors and extracted for 20 min in 200 μl of dichloromethane. After this, the gland was removed from the solvent and the extract was concentrated under a nitrogen stream to a volume of ca. 20 μl. Samples were stored at −80°C until analyzed.

Gas Chromatograph–Electroantennogram Detection Analysis Extracts of single glands were analyzed with a coupled gas chromatograph–electroantennogram detector (GC–EAD) system. A Hewlett Packard 5890 series II gas chromatograph, equipped with either a non-polar SPB-1 capillary column (30 m×0.25 mm ID, 0.25 μm film thickness; Supelco, Bellefonte, PA, USA) or a polar EC-WAX Econo-cap capillary column (30×0.25 mm ID, 0.25 μm film thickness; Alltech, Deerfield, IL, USA), was used for the GC–EAD analyses. The carrier gas was N_2 at a head pressure of 138 kPa (flow rate, 2.0 ml min^{-1}). Injections were made in the splitless mode (split valve opened at 1 min). The temperature program was 40°C for 5 min, then 15°C min^{-1} to 250°C. Injector, EAD outlet, and FID detector temperatures were 260°C. The column effluent was combined with N_2 make-up gas (30 ml min^{-1}) and split 1:1, between the flame ionization detector (FID) and EAD by using a TCD capillary column adapter (Agilent Technology, Wilmington, DE, USA), two deactivated capillary columns (non-polar, 0.25 mm ID, Alltech) of equal length as transfer lines, and a universal capillary Y connector (Alltech). The TCD adapter and the Y connector were connected with a short length of deactivated wide-bore capillary column (0.53 mm ID) and a stainless steel reducing union (3.2 mm OD to 1.6 mm OD). The end of the column was fixed to the TCD adapter with a regular column nut so that the column was extended to the inside of the wide-bore column to facilitate column changes.

An extra FID port of the GC was modified and used for the EAD outlet. The transfer line passed through the heating block and was protected and insulated with a short length of glass-lined stainless steel tube (1.6 mm OD× 0.3 mm ID, Alltech) and a larger diameter stainless steel tube. The transfer line terminated in a humidified, filtered air stream, which was refrigerated by a modified condenser flushed with ice-cold water. The air stream carried the column effluent over the beetle antennal preparation (Robbins et al. 2003). The output signal from the antenna was amplified by a customized single-step high-input impedance DC amplifier. The resulting signal was recorded on an HP 3390A integrator synchronized with the GC integrator. These methods were adapted from Zhang et al. (1997) and Nojima et al. (2003a). Gland extracts from ten virgin females were analyzed using antennae from five different males.

Chemical Analysis Gas chromatography–mass spectrometry (GC–MS) analysis was performed on a Shimadzu QP 5050A equipped with a non-polar DB-1ms capillary column (30 m×0.25 mm ID, 0.25 μm film thickness; J & W Scientific, Folsom, CA, USA) or a polar EC-WAX Econo-Cap capillary column (30 m×0.25 mm ID, 0.25 μm film thickness; Alltech), under the same conditions as those in the GC–EAD analyses, except helium was the carrier gas at 1.0 ml min^{-1}. The EAD-active compound was tentatively identified by comparing its mass spectrum to those of compounds in the NIST mass spectral library. Confirmation of the identification was made by comparing GC retention times (on the two columns) and mass spectrum of the beetle-produced product with those of the authentic sample.

Chemicals L-Valine and L-isoleucine methyl esters were supplied by Dr. A.C. Oehlschlager of ChemTica Internacional S.A. (San Jose, Costa Rica).

The D-valine methyl ester was obtained as a hydrochloric acid salt (Aldrich). Dissolving the salt in an aqueous alkali solution and extracting the mixture with three portions of diethyl ether generated the amino acid methyl ester. The ether extracts were combined, washed with brine, dried over sodium sulfate, and concentrated *in vacuo*. The resulting methyl ester was used without further purification.

Preparation and Field Evaluation of Synthetic Lures Lures were formulated by dissolving the neat compounds in hexane at 20 μg/μl and dispensing appropriate amounts in rubber septa (Thomas Scientific, Swedesboro, NJ, USA); the solvent was allowed to evaporate in a fume hood. Lures were deployed in the field in lab-constructed cross-vane traps (Robbins et al. 2006).

Six treatments were tested: L-valine methyl ester at 1, 2, and 4 mg; 4 mg L-isoleucine methyl ester; L-valine and L-isoleucine methyl esters at 4 mg each; and a control with hexane applied to the septum. L-Isoleucine methyl ester was included in this field trial because we suspected that it could function as a behavioral antagonist to *P. georgiana* when combined with L-valine methyl ester. Four replicates of the six treatments were deployed May 19, 2003, around the cranberry bog from which the *P. georgiana* larvae were sampled. The traps were placed about 15 m apart, with the bottom of the trap about 0.5 m from the ground. Traps were checked 18 times between May 19 and September 3. Traps were placed randomly at first placement and were re-randomized every other time they were checked. Lures were replaced every 4 weeks.

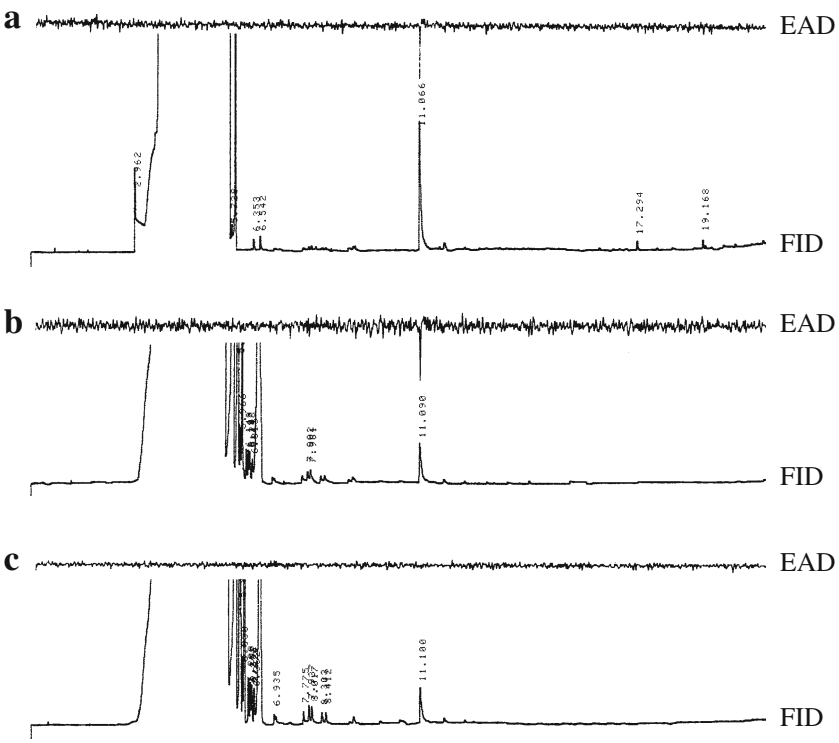

Fig. 1 Simultaneous electroantennogram (EAD)–flame ionization detection (FID) traces illustrating male *Phyllophaga georgiana* antennal responses to **a** extract of the pheromone gland of a female *P. georgiana*; **b** 10 ng of L-valine methyl ester; **c** 10 ng of D-valine methyl ester

On May 22, 2008, four traps were deployed at each of four cranberry bogs in southern New Jersey to confirm flight phenology for the beetle. Each trap was baited with a septum that contained 4 mg of L-valine methyl ester. The traps were placed at least 100 m apart, with the bottom about 0.5 m from the ground. Traps were checked 15 times between May 29 and September 10, and lures were replaced every 4 weeks. Traps were randomized at first placement and re-randomized every other time they were checked.

Captured males were identified to species according to Luginbill and Painter (1953) and Harpootlian (2001).

Statistics The *P. georgiana* trap catch data were tested for homogeneity of variance using Levene's test and then log-transformed ($x+1$). Data were analyzed using a one-way ANOVA, $P<0.05$. Fisher's LSD test was used for post hoc comparisons.

Results and Discussion

Pheromone Identification GC–EAD analysis, using both non-polar and polar columns, of gland extracts of female *P. georgiana* showed one consistent EAD-active compound (Fig. 1a). The mass spectrum of this compound matched that of L-valine methyl ester. GC retention times (on the two columns) compared with those of an authentic sample also confirmed the identification (Fig. 1b). The opposite enantiomer, D-valine methyl ester, did not elicit an EAD response from antennae of male beetles (Fig. 1c). A chiral column was not available at the time of analysis; therefore, we cannot be certain of the chirality of the valine methyl ester. However, based on the relative EAD activities (and field tests; see below), we tentatively assume the L-enantiomer to be the pheromone compound.

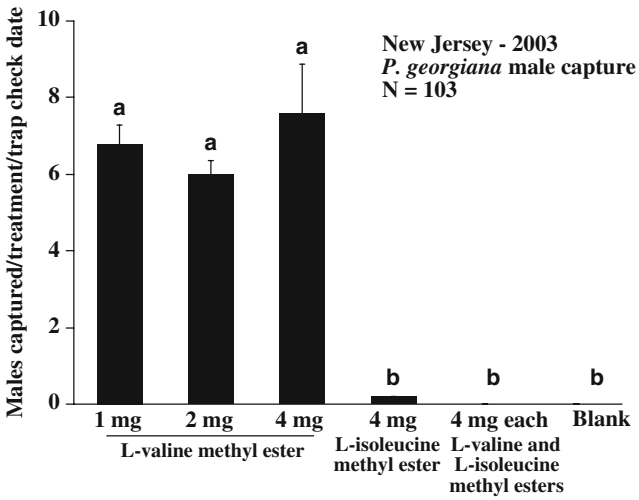

Fig. 2 Average capture/treatment/trap check (mean±SE) of male *Phyllophaga georgiana* in traps baited with various doses of L-valine methyl ester, L-isoleucine methyl ester, and a blend of L-valine/L-isoleucine methyl esters, at Chatsworth, NJ in 2003. *Bars with the same letter* are not significantly different ($P<0.05$, Fisher's LSD test)

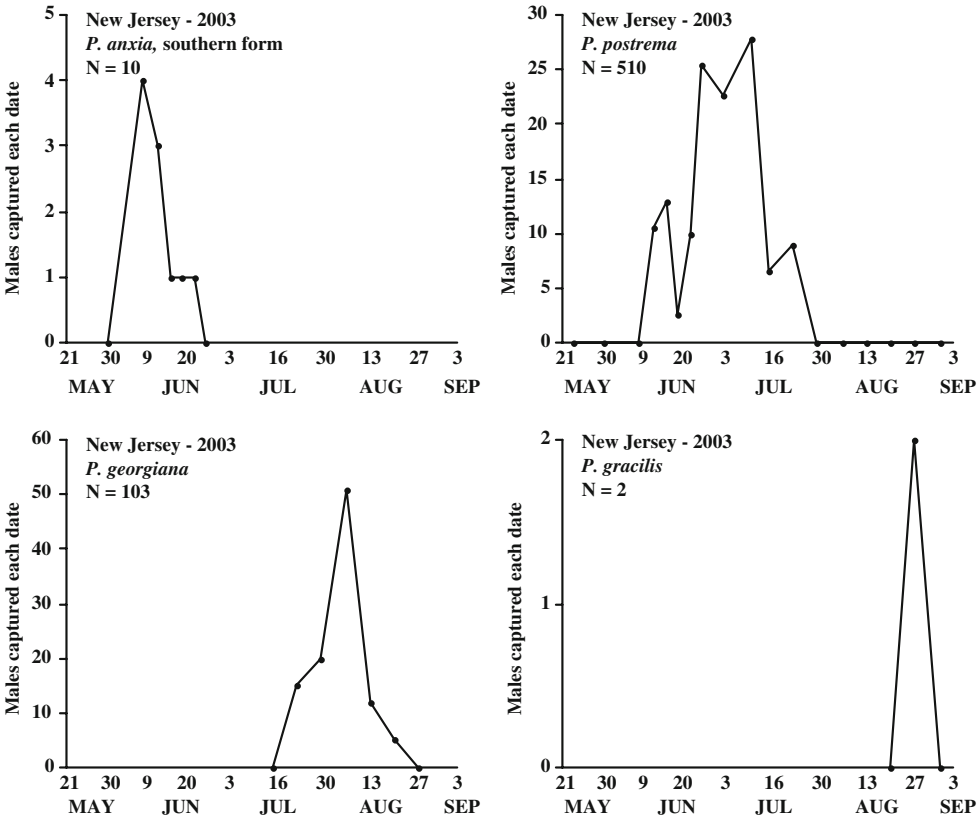

Fig. 3 Seasonal flight patterns and numbers of males of four species of *Phyllophaga* caught in pheromone-baited traps near Chatsworth, NJ in 2003

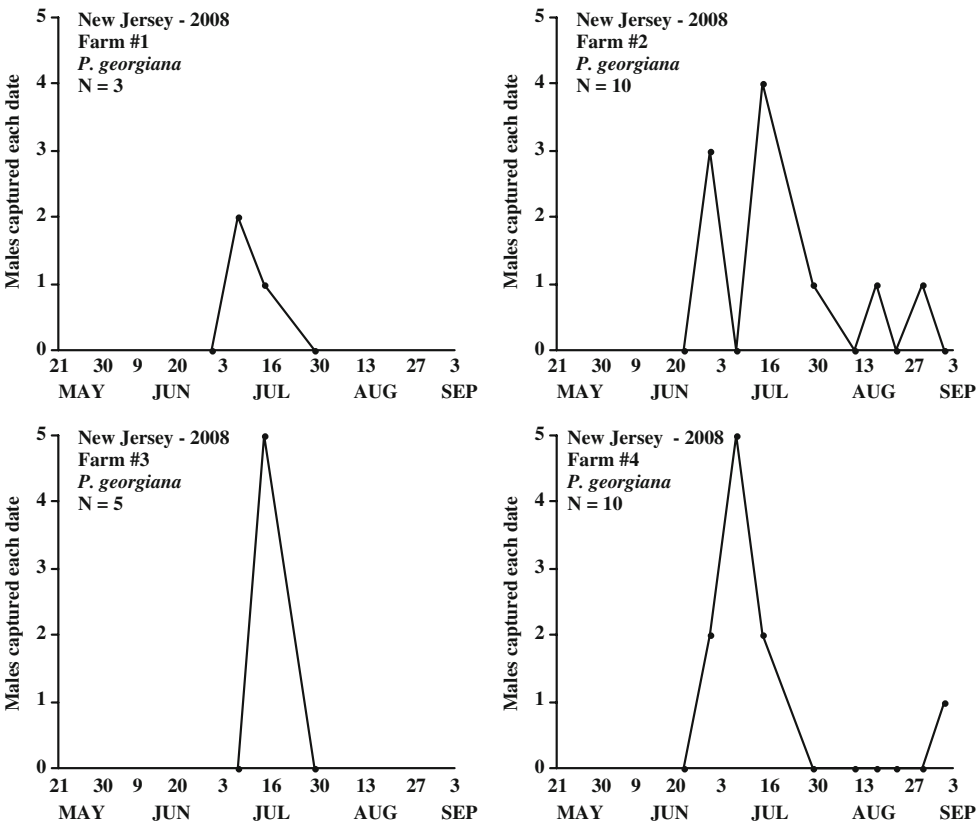

Fig. 4 Seasonal flight patterns and numbers of males of *Phyllophaga georgiana* captured in pheromone-baited traps at four farms near Chatsworth, NJ in 2008

Field Evaluation of Synthetic Lures One-way ANOVA indicated significant differences in *P. georgiana* male captures among the six treatments tested ($F_{5,24}$=7.70; $P<$ 0.001, Fig. 2). Fisher's LSD test in a post hoc comparison showed no significant differences among mean catches of the traps baited with 1, 2, or 4 mg of L-valine methyl ester. However, catches of males in traps baited with any of the three dosages of L-valine methyl ester were significantly greater than catches in traps baited with 4 mg L-isoleucine methyl ester-baited trap, 4 mg each of L-valine and L-isoleucine methyl esters, or the hexane control. A single *P. georgiana* male was captured in a trap baited with 4 mg of L-isoleucine methyl ester, and no males were captured in traps baited with 4 mg each of the methyl esters of L-valine and L-isoleucine, thus indicating that L-isoleucine methyl ester acts as a behavioral antagonist.

Our tentative identification of L-valine methyl ester as the sex pheromone of *P. georgiana* is consistent with previous observations in Tifton, GA in 2000 (Robbins et al. 2006). In that study, two male *P. georgiana* were captured in a trap baited with 4 mg of L-valine methyl ester on two dates in July 2000. The other seven traps at the Tifton location were baited with lures containing varying amounts of L-isoleucine methyl ester, from 10% to 100%, and no *P. georgiana* were captured in those traps.

Seasonal Flight Patterns for Species Captured Figure 3 illustrates the seasonal flight patterns and numbers of individuals of the four *Phyllophaga* species captured during the 2003 season. In general, the flight dates and male response to pheromone blends of the species observed in this test corroborate the results reported by Robbins et al. (2006).

Of the ten male *P. anxia* captured in traps baited with L-isoleucine methyl ester, eight were of the southern genitalic form and two were of the northern genitalic form [see Luginbill and Painter (1953) and Woodruff and Beck (1989)]. The southern forms were found on June 9 (four males), June 13 (3), and June 17 (1). The northern forms were found on dates following the flight of the southern forms, namely June 20 (1) and June 24 (1). Further studies may reveal whether the apparent asynchronous flights of the two L-isoleucine methyl ester-responding genitalic forms observed here are consistent over geography and years as well as whether interbreeding occurs in areas of sympatry. See Robbins et al. (2008) for more information regarding pheromone races of the northern and southern genitalic forms of *P. anxia*.

Of the 510 *P. postrema* captured between mid-June and mid-July, 506 were captured in traps baited with L-isoleucine methyl ester, and four were captured in traps baited with the blend of L-valine and L-isoleucine methyl esters. The two *P. gracilis* were captured on August 27 in traps baited with L-isoleucine methyl ester.

To date, there have been no studies on the life cycle of *P. georgiana*. However, the fact that the flight does not begin until mid-July suggests that this species probably pupates in the spring, unlike *P. anxia*, which pupates and emerges in the hibernaculum in the fall; the teneral adult remaining underground until the following May or June when the flights begin (Lim et al. 1980). The *P. georgiana* seasonal flight patterns observed at the four locations where traps were placed during the 2008 season (Fig. 4) were similar to the pattern observed in 2003 (Fig. 3).

Other species in the genus *Phyllophaga* (*s. str.*) also have been observed responding to L-valine methyl ester, including *P. anxia* (northern genitalic form, L-valine methyl ester pheromone morph), *P. congrua*, *P. crenulata*, *P. hirtiventris*, *P. inversa*, *P. latifrons*, *P. marginalis*, and *P. vehemens* (Robbins et al. 2006). Eberhard (1993) reported *Phyllophaga* males following pheromone upwind to non-conspecific females, landing on the female briefly, and then leaving. Further work should investigate the reproductive isolation of sympatric *Phyllophaga* species that respond to L-valine methyl ester.

Sex Pheromones and Reproductive Isolation of Three Species in Genus *Adoxophyes*

Chang Yeol Yang · Kyeung Sik Han · Kyung Saeng Boo

Received: 9 September 2008 / Revised: 29 December 2008 / Accepted: 18 January 2009 / Published online: 17 February 2009

Abstract We tested differences in female pheromone production and male response in three species of the genus *Adoxophyes* in Korea. Females of all three species produced mixtures of (*Z*)-9-tetradecenyl acetate (*Z*9–14:OAc) and (*Z*)-11-tetradecenyl acetate (*Z*11–14:OAc) as major components but in quite different ratios. The ratio of *Z*9–14:OAc and *Z*11–14:OAc in pheromone gland extracts was estimated to be ca. 100:200 for *Adoxophyes honmai*, 100:25 for *Adoxophyes orana*, and 100:4,000 for *Adoxophyes* sp. Field tests showed that males of each species were preferentially attracted to the two-component blends of *Z*9–14:OAc and *Z*11–14:OAc mimicking the blends found in pheromone gland extracts of conspecific females. The effects of minor components identified in gland extracts on trap catches varied with species. Addition of 10-methyldodecyl acetate (10me-12:OAc) or (*E*)-11-tetradecenyl acetate (*E*11–14:OAc) to the binary blend of *Z*9–14:OAc and *Z*11–14:OAc significantly increased captures of *A. honmai* males, whereas *E*11–14:OAc exhibited a strongly antagonistic effect on catches of *Adoxophyes* sp. males. Moreover, (*Z*)-9-tetradecen-1-ol (*Z*9–14:OH) or (*Z*)-11-tetradecen-1-ol (*Z*11–14:OH) added to the binary blends increased attraction of male *A. orana* but not *A. honmai* and *Adoxophyes* sp. males, suggesting that these minor components, in addition to the relative ratios of the two major components, play an important role in reproductive isolation between *Adoxophyes* species in the southern and midwestern Korea where these species occur sympatrically.

Introduction

Several species in the genus *Adoxophyes* (Lepidoptera: Tortricidae) are economically important pests of fruit and tea trees in Asia and Europe (Tamaki et al. 1971a; Meijer et al. 1971; Kou et al. 1990). In the past, it was believed that *Adoxophyes orana* is the only species found in Korea (Shin et al. 1994), but field trapping revealed that there is considerable variability in male response to pheromone blends among different geographical populations of *Adoxophyes* spp. (Han 2002; Yang et al. 2005). These findings prompted us to study the taxonomic status of Korean *Adoxophyes* populations by using mitochondrial gene sequences, and we found three distinct species, *Adoxophyes honmai*, *A. orana*, and *Adoxophyes* sp. (Park et al. 2008). Larvae are difficult to differentiate, but adults of the different species are distinguishable by wing patterns and male genitalia (Han 2002; Byun, personal communication).

Adoxophyes species often share host plants (Han 2002; Yang et al. 2005) and have some seasonal overlap in Korea (Choi 2002; Yang 2002). Furthermore, the diel periodicity of pheromonal emission also overlaps, with females of all

three species calling at the end of the scotophase and beginning of the photophase (Sato and Tamaki 1977; Den Otter and Klijnstra 1983; Han 2002). Therefore, differences in these parameters appear insufficient to maintain reproductive isolation among these species. Males of *Adoxophyes* species, however, are rarely attracted to heterospecific females in fields (Yang, unpublished), suggesting that species-specific blends of pheromone components may be responsible for reproductive isolation between sympatric species (Roelofs and Brown 1982; Löfstedt et al. 1991). Thus, the principal objectives of this study were to identify the sex pheromones of three *Adoxophyes* species and to determine the role of the pheromones as prezygotic reproductive isolating mechanisms between sympatric congeners in Korea.

Methods and Materials

Insects

Larvae of *Adoxophyes* spp. were collected from pear orchards in Naju, Cheonan, and Namyangju, Korea during June and July of 2006. The larvae were reared individually on artificial diet (Bio-serv, Frenchtown, NJ, USA) in transparent plastic Petri dishes (1.5 cm high and 5.5 cm diameter) and maintained at 23°C under a 16:8-h ratio of light to dark photoperiod. Pupae were separated by sex and kept individually in plastic bottles (7 cm high and 2.5 cm diameter). After eclosion, moths were identified based on forewing color patterns (Han 2002) and then provided with a cotton pad soaked with a 5% (*w*/*v*) sucrose solution as food.

Chemicals

Synthetic dodecenyl acetate (12:OAc), tridecyl acetate (13:OAc), (*Z*)-9-dodecenyl acetate (*Z*9–12:OAc), 10-methyldodecyl acetate (10me-12:OAc), tetradecyl acetate (14:OAc), *Z*9–14:OAc, *E*11–14:OAc, *Z*11–14:OAc, (*Z*)-11-hexadecenyl acetate (*Z*11–16:OAc), (*Z*)-9-tetradecen-1-ol (*Z*9–14:OH), (*Z*)-11-tetradecen-1-ol (*Z*11–14:OH), and octadecanal (18:Ald) were purchased from Pherobank (Wageningen, The Netherlands). Isomeric purity of these compounds exceeded 99%.

Gland Extraction

Pheromone gland extracts were taken from 2- to 3-day-old females at the end of the scotophase, during their calling periods (Den Otter and Klijnstra 1983; Han 2002). The pheromone gland of each female was extruded by applying gentle pressure to the abdomen, excised with fine forceps, and individually extracted in 10 μl hexane containing 10 ng of 13:OAc as an internal standard in a 0.3-ml conical vial (Wheaton, Millville, NJ, USA) for 30 min at room temperature. The supernatant was transferred into another vial and stored at −80°C until analysis.

Chemical Analysis

Pheromone gland extracts were analyzed on an Agilent 6890N GC equipped with a split/splitless injector and a flame ionization detector. Samples were run on DB-5 and DB-Wax columns (30 m×0.25 mm ID, 0.25 μm film thickness, J&W Scientific, Folsom, CA, USA) in the splitless mode. Injector and detector temperature were 250°C. Helium was used as carrier gas (1 ml/min). The gas chromatograph (GC) oven temperature was programmed from 80°C (1 min hold) to 220°C at 5°C/min and held for 10 min. Components in pheromone gland extracts were identified by comparison of retention times with those of authentic standards on two different columns. The quantity of each component was estimated by comparing its GC peak area with that of the internal standard.

Gas chromatography–mass spectrometry (MS) analyses of the crude extract of pheromone glands were performed on an Agilent 6890N GC interfaced to an Agilent 5973 mass-selective detector. Samples were analyzed on the DB-Wax column (30 m×0.25 mm ID, 0.25 μm film thickness) with the temperature program described above. The ionization voltage was 70 eV. The ion source temperature was 230°C. Components in gland extracts were tentatively identified by comparison of their mass spectra with the mass spectra library (Wiley-NIST, Hoboken, NJ, USA), and identifications were confirmed by comparison of retention times and mass spectra with those of authentic standards.

Field Experiments

Field experiments were conducted in pear orchards at Naju, Cheonan, and Namyangju, respectively, during May–July of 2007. Sticky Delta traps (Green Agro Tech, Korea) baited with rubber septa (Aldrich Chemical Co., Milwaukee, WI, USA) impregnated with test chemicals in hexane were hung on branches 1–1.5 m above ground level. All field tests employed a complete randomized block design with five replicate blocks. The distance between traps within a block was at least 15 m. Twice a week, moths were counted, removed, and identified to species by using wing venation and then verified by examination of the genitalia.

Experiment 1 investigated the attraction of *A. honmai*, *A. orana*, and *Adoxophyes* sp. males to the two major components *Z*9–14:OAc and *Z*11–14:OAc singly and in binary blends. Experiment 2 was conducted to test the individual effects of the nine minor components identified

in female gland extracts; 12:OAc, *Z*9–12:OAc, 10me-12:OAc, 14:OAc, *E*11–14:OAc, *Z*9–14:OH, *Z*11–14:OH, *Z*11–16:OAc, and 18:Ald as possible synergists or antagonists, by using standard baits of the two major components. The standard baits used for *A. honmai*, *A. orana*, and *Adoxophyes* sp. were 1 mg of 35:65, 80:20, and 3:97 mixtures of *Z*9–14:OAc and *Z*11–14:OAc, respectively. Trap catch data (x) were transformed to log (x+1) and submitted to one-way analysis of variance. Means were compared by Tukey's test at α=0.05 (SAS Institute Inc. 2004).

Distribution of *Adoxophyes* Species

We sampled larvae of *Adoxophyes* spp. from pear orchards at eight different sites in Korea during June–August of 2007 and 2008 and reared them on artificial diet. After eclosion, female moths were assigned to three species according to their wing characters and subsequently verified by examination of the sex pheromones. Individuals were classified as *A. honmai*, *A. orana*, and *Adoxophyes* sp. when *Z*9–14:OAc and *Z*11–14:OAc in pheromone gland extracts were present in a ca. 100:200, 100:25, and 100:4,000 ratios, respectively. In all cases, the pheromone blend of individual glands supported the initial species identification based on adult morphological characters.

Results

Chemical Analysis

GC and GC–MS analyses of pheromone gland extracts showed that *Z*11–14:OAc is the major component of *A. honmai* and *Adoxophyes* sp., whereas *Z*9–14:OAc is the most abundant component in the pheromone blend of *A. orana* (Fig. 1). The ratios of *Z*9–14:OAc and *Z*11–14:OAc in pheromone blends were 100:209, 100:25, and 100:3,810 for *A. honmai*, *A. orana*, and *Adoxophyes* sp., respectively. In addition to these two major components, three acetate esters (12:OAc, 14:OAc, and *E*11–14:OAc), *Z*11–14:OH, and 18:Ald, as well as nonadecane, heneicosane, and tricosane, were detected in gland extracts of all species (Table 1). Small amounts of *Z*9–14:OH and *Z*11–16:OAc were detected in *A. honmai* and *A. orana*, while *Z*9–12:OAc and 10me-12:OAc were present only in *A. honmai*.

Field Experiments

Traps baited with *Z*9–14:OAc or *Z*11–14:OAc alone caught no *Adoxophyes* males. Responses of males to various blends of *Z*9–14:OAc and *Z*11–14:OAc differed markedly among species. Male *A. honmai* were equally attracted

30:70 to 80:20 ratios of *Z*9–14:OAc and *Z*11–14:OAc (Fig. 2a), while *A. orana* males were preferentially attracted to ratios from 50:50 to 90:10 (Fig. 2b). In contrast, *Adoxophyes* sp. males were most attracted to traps baited with *Z*11–14:OAc as a major component (Fig. 2c). Regression analysis indicated a positive linear relationship between trap catch of male *A. orana* and *Z*9–14:OAc concentration for binary blends (r^2=0.75, P<0.05), while a negative relationship was observed with *Adoxophyes* sp. (r^2=0.86, P<0.01).

The effects of minor component of gland extracts on field trap catches varied significantly among species. Specifically 10me-12:OAc and *E*11–14:OAc showed a strong synergistic effect with the 35:65 mixture of *Z*9–14:OAc and *Z*11–14:OAc for *A. honmai* (Fig. 3a), while the capture of male *A. orana* increased when the two alcohols,

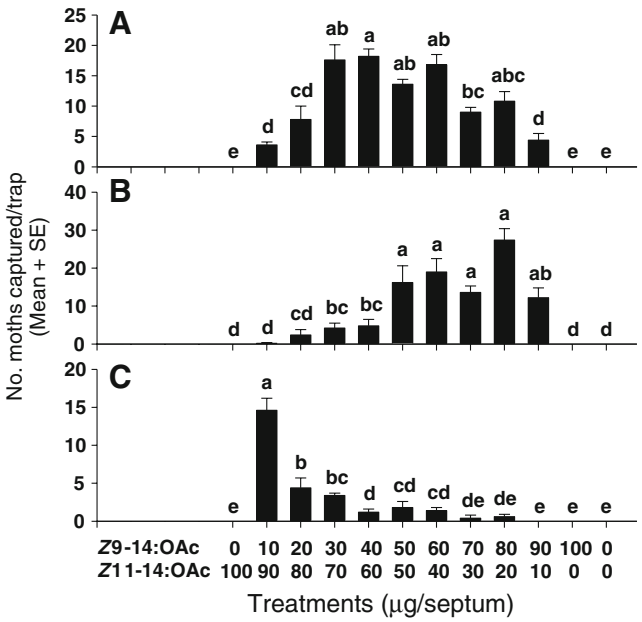

Fig. 2 Number of *A. honmai* (**a**; Naju, May 11–18, 2007), *A. orana* (**b**; Cheonan, May 17–24, 2007), and *Adoxophyes* sp. (**c**; Namyangju, May 18–25, 2007) males captured in traps baited with lures containing different ratios of *Z*9–14:OAc and *Z*11–14:OAc at pear orchards in Korea. *Bars with the same letter* are not significantly different (Tukey's test: P>0.05)

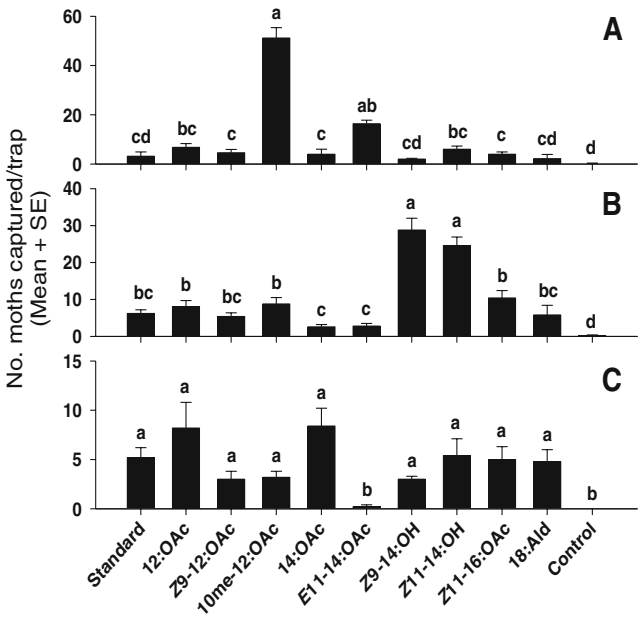

Fig. 3 The effect of adding 5% of different minor components to standard baits with 1 mg/septum of *Z*9–14:OAc and *Z*11–14:OAc on captures of male *A. honmai* (**a**; Naju, June 22–29, 2007), *A. orana* (**b**; Cheonan, July 12–19, 2007), and *Adoxophyes* sp. (**c**; Namyangju, July 13–20, 2007) at pear orchards in Korea. *Bars with the same letter* are not significantly different (Tukey's test: P>0.05)

*Z*9–14:OH and *Z*11–14:OH, were added to the 80:20 mixture of *Z*9–14:OAc and *Z*11–14:OAc (Fig. 3b). In the case of *Adoxophyes* sp., the only significant effect of minor components was the strong inhibitory effect of adding *E*11–14:OAc to a 3:97 ratio of the primary binary blend (Fig. 3c).

Distribution of *Adoxophyes* Species

It is evident from the pheromone gland analyses of females collected as larvae from different sites that there is considerable difference in the geographic distribution of the three species (Table 2).

Discussion

The analyses of glands extracts indicate that all three *Adoxophyes* species have *Z*9–14:OAc and *Z*11–14:OAc as major components, but in markedly different ratios. Males were preferentially attracted to the blend found in pheromone gland extracts of their conspecific females, but males of *A. honmai* and *A. orana* both responded to a broad range of ratios of *Z*9–14:OAc and *Z*11–14:OAc. These findings suggest that while difference in the relative composition of two major pheromone components is a component in the reproductive isolation of the sympatric *Adoxophyes* species, this is not sufficient to provide species-specific communication channels. However, our data suggest that two minor components, 10me-12:OAc and *E*11–14:OAc, play a role in isolating *A. honmai* and *Adoxophyes* sp. where they occur sympatrically in the southern part (Ulju, Jinju) of Korea.

A. orana also produces *Z*9–14:OH and *Z*11–14:OH. Their presence in the lure increases trap catch and our results support the idea that these two alcohols, as well as the relative ratios of the two major components, contribute to the maintenance of premating reproductive isolation between sympatric populations of *A. orana* and *Adoxophyes* sp. in the midwestern part (Ansung, Cheonan) of Korea. In our study, we found no evidence that *A. honmai* and *A. orana* occur sympatrically in Korea, but if they do, the differences in the ratios of major components and synergistic pheromone compounds, such as 10me-12:OAc and *Z*9–14:OH, may prevent cross-attraction between them.

Even though *E*11–14:OAc is present at low levels in the pheromone glands of *A. orana* and *Adoxophyes* sp., the addition of this compound to standard baits significantly decreased attraction for conspecific males. The antagonistic effect of minor compounds found in gland extracts of conspecific females has been reported for other moths (McElfresh and Millar 1999; Wu et al. 1999). However, it is not known whether *E*11–14:OAc is actually released from the female glands during calling. Further research is required to compare the attractiveness of pheromone blends actually emitted with those found in female gland extracts of these two species. Similarly, the roles of *Z*9–12:OAc and *Z*11–16:OAc, present in small amounts in gland extracts of some *Adoxophyes* species, need to be elucidated. Do they function as antagonists to sympatric moth species, or are they just by-products of the pheromone biosynthesis? Additionally, the influence of several components present simultaneously within blends on male trap catch also needs to be investigated.

Female pheromone glands from Japanese females of *A. honmai* contain *Z*9–14:OAc and *Z*11–14:OAc as major components at 67:33 (Tamaki et al. 1971a) or 73:27 (Noguchi et al. 1985) ratios, with two behaviorally important minor components, 10me-12:OAc and *E*11–14:OAc, at 4–5% and 2–3% of the two major components, respectively (Tamaki et al. 1979; Noguchi et al. 1985). These ratios are markedly different from those observed in this study (see Table 1), providing evidence of pheromonal variation in geographic populations of *A. honmai*. Interestingly, the observed ratio of the two major pheromone components in Korean *A. honmai* feeding on tea tree as well as on fruit trees (Han 2002) is similar to that reported

Table 2 The relative proportion of three *Adoxophyes* species collected from pear orchards at eight different sites in Korea

from an *Adoxophyes* sp. from tea gardens in Taiwan (Kou et al. 1990), again supporting the idea of geographic variability in the pheromones within the genus.

The pheromone glands of *A. orana* females in Switzerland (Guerin et al. 1986) and females from different populations of *A. orana fasciata* in Japan (Tamaki et al. 1971b; Sugie et al. 1984; Noguchi et al. 1985) have similar ratios (77:23 to 88:12) of the two major components. Furthermore, pheromone traps baited with lures with similar ratios are effective in capturing males at all sites (Tamaki et al. 1971b; Meijer et al. 1971; Sugie et al. 1984; Guerin et al. 1986), thus supporting the idea that populations of *A. orana* and/or *A. orana fasciata* in Asia and Europe use similar blends of the major pheromone components. The addition of *Z*9–14:OH or *Z*11–14:OH to the binary blend of *Z*9–14:OAc and *Z*11–14:OAc significantly increased captures of *A. orana* males in Europe (Guerin et al. 1986), and a similar pattern was noted in our field trials in Korea (Fig. 3). However, while these minor components are present in pheromone gland extracts of *A. orana fasciata* (Noguchi et al. 1985), their addition to lures does not enhance trap efficiency in Japan (Sugie et al. 1984). Thus, the pheromone characteristics of Korean population of *A. orana* are identical to those of European population of *A. orana*, but different from those reported for Japanese *A. orana fasciata*.

Our field results show that *Adoxophyes* sp. is the dominant species of *Adoxophyes* in Korea. This species has a 3:97 blend of *Z*9–14:OAc and *Z*11–14:OAc, a ratio that has not been reported from any *Adoxophyes* species in Japan, Taiwan, or Europe. A 1:9 ratio of *Z*9–14:OAc and *Z*11–14:OAc captured *Adoxophyes privatana* males in Vietnam (Hai et al. 2002), so the Korean *Adoxophyes* sp. may be *A. privatana*, although nothing is known about the pheromone gland content of this species. Additional research that examines different *Adoxophyes* species around the world is necessary to clarify the composition of sex pheromones of different species within this genus. Parallel morphological and molecular studies should also be carried out to clarify the phylogenetic relationships and to understand the evolution of pheromone communication in this genus.

Acknowledgments The authors thank Prof. Soowon Cho and Dr. Bong Kyu Byun for identification of *Adoxophyes* species and two anonymous reviewers and Jeremy McNeil for invaluable comments. We also acknowledge the assistance of Tae Hyun Kyung with field trials.

Sex Pheromone of the Bud Borer *Epinotia aporema*: Chemical Identification and Male Behavioral Response

Paula Altesor · Carmen Rossini · Paulo H.G. Zarbin · Andrés González

Received: 3 October 2008 / Revised: 30 December 2008 / Accepted: 30 January 2009 / Published online: 5 March 2009

Abstract *Epinotia aporema* (Walsingham) is a Neotropical pest of legumes in southern South America. Its importance has increased during the last decade owing to the significant growth of soybean production in the region. Monitoring of *E. aporema* is difficult due to the cryptic behavior of the larvae, and hence, chemical control is carried out preventively. We analyzed the female-produced sex pheromone so as to develop monitoring traps and explore pheromone-based control methods. We analyzed pheromone gland extracts by combined chromatographic, spectrometric, and electrophysiological methods. Based on the comparison of retention indices, mass spectra, and electroantennogram (EAD) activity of the insect-produced compounds with those of synthetic standards, we identified two EAD-active compounds, (*Z*,*Z*)-7,9-dodecadienol and (*Z*,*Z*)-7,9-dodecadienyl acetate (15:1 ratio), as sex pheromone components of *E. aporema*. We also studied the behavior of males in wind tunnel tests using virgin females and different combinations of synthetic standards (15:1, 1:1, and 1:0 alcohol/acetate) as stimuli. A significantly greater percentage of males reached the chemical source with the 15:1 synthetic mixture than with any of the other treatments, indicating that these two compounds are pheromone components.

Introduction

Soybean production in southern South America has increased dramatically in recent years. In Uruguay, for example, the planted area has expanded 30-fold during the period 2000–2007, causing a tenfold increase in the use of insecticides such as endosulfan and chlorpyrifos (Ferrari 2007). During the same period, the area of soybean production in Brazil grew to almost 60%, reaching more than 22 million hectares (Conab 2007).

Epinotia aporema (Walsingham, 1914) (Lepidoptera: Tortricidae) is a stem and bud borer that has become a major pest of legumes in Uruguay, Argentina, Chile, and southern Brazil (Iede and Foerster 1982; Sanchez et al. 1997; Pereyra and Sanchez 1998; Alzugaray et al. 1999). *E. aporema* originates from Costa Rica, but is now widely distributed throughout South America. The insect has five to six generations per year, mostly concentrated between November and April (Bentancourt and Scatoni 2006).

The economic importance of *E. aporema* is restricted to the south of its distribution due to the year-round availability of hosts (soybean, alfalfa, lotus, peas, flax, red clover) (Biezanko et al. 1957; Morey 1972; Bentancourt and Scatoni 1995; Alzugaray and Ribeiro 2000). In soybean, the larvae feed on vegetative plant parts, affecting the normal growth of the plant. In other legumes, larval feeding can severely affect the flower and prevent production of seeds, an important commodity in some forage

legumes (alfalfa, lotus) (Bentancourt and Scatoni 1995; Alzugaray and Ribeiro 2000).

E. aporema populations are monitored by direct observation of the larvae, a highly inefficient method with poor predictive capacity, and chemical control is, therefore, used in a prophylactic way. In order to develop a monitoring tool for the insect, we studied its sex pheromone. In this study, we report the characterization of the sex pheromone of *E. aporema* as a 15:1 mixture of (*Z*,*Z*)-7,9-dodecadienol and (*Z*,*Z*)-7,9-dodecadienyl acetate (hereafter referred to as Z7,Z9-12:OH and Z7,Z9-12:Ac, respectively).

Methods and Materials

Insects *E. aporema* adults were obtained from a laboratory population kept in an incubator, under a 14:10-h (L/D) photoregime, 21–23°C, and 60–70% relative humidity. The larvae were raised on an artificial diet based on bean homogenate and agar, either in glass tubes or in plastic cups. Virgin adults were obtained by separating male and female pupae.

Gland Extractions Female pheromone glands were dissected between the fifth and seventh hours of the scotophase. Virgin females (2–6 days old) were placed individually in glass tubes (10 cm length, 8 cm diameter; gauze-closed) during the photophase. Following the scotophase, calling females were removed from the vials, killed, and their glands exposed and excised with forceps. The glands of 83 females were accumulated in a 0.2-mL conical vial that was stored at −15°C. Pooled glands were extracted with 100 μL of distilled hexane for 20 min at ambient temperature, and the extract concentrated under a stream of N_2.

Chemical and Gas Chromatography–Electroantennogram Detection Analyses Gas chromatography–electroantennogram detection (GC-EAD) analyses were carried out using an HP 5890 Series II Gas Chromatograph adapted for simultaneous flame ionization (FID)/EAD detection. The column effluent was split with a fused silica outlet splitter (Alltech) with an extra make-up flow of N_2 (30 mL min^{-1}) added before the splitter. The column directing the flow to the EAD left the oven upwards into a condenser inner tube (1 cm diameter) where a stream of charcoal-filtered and humidified air (flow 300 mL min^{-1}) transported the volatile chemicals to the antennal preparation. The water in the condenser was kept cold by a circulating chiller. The antenna was located 1 cm downstream from the column exit and was held between antenna holders (Syntech, Hilversum, The Netherlands) with electrically conductive gel. The holders were in turn connected to a preamplifying probe (10X, Syntech), and the EAD response was further amplified with a high-impedance amplifier (Syntech). The analog signal was finally fed back to the GC motherboard for digitization and processing.

The GC-EAD was equipped with an Elite-WAX or an Elite-5 column (Perkin Elmer) (30 m×0.25 mm i.d., 0.25 μm film thickness), operated with a constant carrier gas flow of 2 mL min^{-1} (H_2). The temperature program for both columns was 70°C (kept for 1 min) to 250°C at 7°C min^{-1}. Injection was splitless with injector and detector temperatures of 220°C and 250°C, respectively.

GC–mass spectrometry (MS) analyses were carried out on a QP-2010 Shimadzu GC-MS, equipped with an AT™-WAX MS column (Alltech) (30 m×0.25 mm, 0.25 μm), operated with a constant carrier flow of 1 mL min^{-1} (He) and splitless injection. The initial temperature was 70°C (held 1 min), then increased to 250°C at 8°C min^{-1}. The injector temperature was 220°C, and the interface temperature was 250°C.

Retention indices (RIs) of the EAD-active components were determined by using the GC-EAD system by coinjecting a hexane solution of *n*-alkanes (even-numbered C8–C24, plus C19, 100 ppm each) with the gland extracts. RIs were calculated as defined for programmed temperature analysis (arithmetic index in Adams 2007).

Synthetic standards of the acetates were kindly provided by Tetsu Ando (Tokyo University of Agriculture and Technology) and Christer Löfstedt (Lund University). The alcohol standards were obtained by hydrolysis of the corresponding acetates (10% NaOH in ethanol, 100°C, 1 h).

Wind Tunnel Experiments The responses of males to virgin calling females and mixtures of synthetic standards were evaluated. The wind tunnel consisted of a cylindrical acrylic glass tube (150 cm length; 40 cm diameter) with a controlled suction pump, activated charcoal filters, and a metal screen to laminate the airflow (0.3 m s^{-1}, measured with a Testo 490 anemometer). Environmental conditions during wind tunnel tests were 20–25°C and 50–70% relative humidity. Dimmed red light was used for the observations. Males used in the experiments came from the laboratory colony. Four hours before testing, 1- to 5-day-old virgin males were placed in individual glass tubes (8 cm length, 4.5 cm diameter) with gauze enclosing both ends.

The stimuli (virgin females or pheromone septa) were hung at the tunnel entrance, centered, and inside a glass tube (10 cm length, 8 cm diameter; gauze-enclosed for the females). For the virgin female test, five females (2–5 days old) were placed in the tunnel 4 h before the experiments; for each male tested, at least one of the females was observed calling throughout the test period. Z7,Z9-12:OH and Z7,Z9-12:Ac (at mixtures of 15:1, 1:1, and 1:0 alcohol/acetate) were loaded (in 10 μL hexane) onto red rubber sleeve septa with a total dose of 1.6 μg per septum. Control septa were loaded

with 10 μL hexane. Septa were changed every day of the test with totals of ten males tested to each pheromone blend and 28 to the virgin females.

The tests were run between the third and seventh hours of the scotophase. Each tube containing a male was hung at the end of the tunnel, centered, and left closed for 1 min to allow the pheromone plume to reach the male. The gauze was then removed from both ends of the tube, and the behavior of the male was recorded continuously for 10 min. The behavioral elements observed were the time to initiate flight, response to the pheromone (including flying within the plume and/or wing fluttering), and reaching the odor source. Behavioral data were analyzed using analysis of variance and Dunnett's pairwise comparisons for the time of flight initiation [transformed to log (X+1)], and chi-square 2×2 contingency tables to compare the proportions of males arriving at the source and responding to the pheromone.

Results and Discussion

Chemical and GC-EAD Analysis Hexane extracts of pheromone glands [one female equivalent injected in 1 μL] elicited two consistent EAD responses from the male antennae. Only one of the EAD-active compounds was observed as a faint FID peak, while the other was only observed in the EAD trace (Fig. 1a; EAD responses shown with injection of synthetic compounds in Fig. 1b). Coinjection of the gland extracts and a mixture of *n*-alkanes in the GC-EAD system allowed us to calculate the RIs of both EAD-active compounds in the gland extract (2,076 and 2,155 on an Elite-WAX column; 1,529 and 1,664 on Elite-5). In addition, the GC-EAD analyses on both GC phases showed that the two EAD-active compounds inverted their relative elution order with the major compound eluting second on Elite-WAX (RI=2159) and first on Elite-5 (RI=1529). This inversion and the 135-unit difference in the RIs on Elite-5 suggested the presence of an alcohol/acetate pair in the mixture with alcohol as the major component. Moreover, the RI on both GC phases was around the region of RIs known for conjugated dodecadienyl alcohols (e.g., Δ5,Δ7: range 1,511–1,537 on DB5; 2,161–2,197 on DB-wax) and acetates (e.g., Δ5,Δ7: ranges 1,636–1,666 on DB5; 2,063–2,108 on DB-wax) (El-Sayed 2008). Previously, a 1:1 mixture of Z7,Z9-12:Ac and Z7,Z9-12:OH had been identified in the female gland of a European congener, *E. tedella* (Priesner et al. 1989), which prompted us to compare our pheromone extract with synthetic standards of these compounds. The standards were injected as a 100-ppm mixture in the GC-EAD system, giving strong EAD responses from *E. aporema* male antennae with identical retention times to the compounds in female extract that elicited the EAD signals (Fig. 1b).

GC-MS analysis of a concentrated (ten female equivalents per microliter) female gland extract revealed the presence of two peaks with identical retention times and mass spectra to those of Z7,Z9-12:Ac and Z7,Z9-12:OH standards (Fig. 2). The alcohol (both natural and synthetic) showed a clear M^+ peak (*m*/*z* 182) with a loss of 18 mass units and a weak fragment at *m*/*z* 31, both typical of primary alcohols. Both spectra showed the characteristic ions of aliphatic dienes (*m*/*z* 67, 82, and 96) and high abundance of the M^+ ion which, along with the long retention time on Elite-WAX (96 RI units larger than a

Runs were performed consecutively on an AT-WAX column, using identical temperature programs and splitless injection

nonconjugated dodecadienyl alcohol; El-Sayed 2008), indicated a conjugated dienyl system (Fig. 2b, c) (Ando et al. 2004). The natural and synthetic acetates showed almost identical spectra (Fig. 2d, e). The fragments characteristic of aliphatic dienes were also present with an additional fragment at *m*/*z* 43 (CH_3CO^+) and a molecular ion at *m*/*z* 224 in the synthetic sample. The absence of the molecular ion in the spectrum of the natural acetate is attributed to the low amount of the compound in the sample. The total ion chromatogram of gland extracts showed that the alcohol and the acetate were present in a 15:1 ratio.

A second set of comparative GC-MS analyses was performed with the pheromone gland extract and mixtures of geometric isomers of 7,9-dodecadienol and 7,9-dodecadienyl acetate. The retention time of the natural 7,9-dodecadienol matched that of synthetic Z7,Z9-12:OH (see Supplementary Figure S1), while the retention time of the natural Z7,Z9-12:Ac (Fig. 2d) matched that of synthetic Z7,Z9-12:Ac. There was an unknown compound in the gland extract that eluted at the same time as the E7, E9-12:Ac, but its mass spectrum (not shown) indicated that it was not a 7,9-12:Ac isomer.

These two compounds are produced by the European congener, *E. tedella*, in a 1:1 ratio (Priesner et al. 1989). In fact, most genera within the tribe Eucosmini (subfamily: Olethreutinae) include species that are attracted to Δ7 and/or Δ9 dodecenyl/dodecadienyl alcohols and acetates (El-Sayed 2008). Therefore, this Neotropical tortricid produces compounds closely related chemically to its closest relatives.

Wind Tunnel Experiments The time for male flight initiation ranged between a few seconds up to 3 min. The shortest time corresponded to the responses to virgin females, which was significantly shorter than the flight initiation time to the control. The tests with the synthetic pheromone blends resulted in intermediate flight initiation times, which were not significantly different from times to either virgin females or the control (Fig. 3a). In terms of response to the pheromone (including flying within the plume and/or wing fluttering), the synthetic pheromone blend with the same proportion as found in the female glands (15:1), the pure alcohol (1:0), and virgin females elicited the greatest responses with 70%, 60%, and 50% of males, respectively, responding to these treatments. However, only the 15:1 synthetic blend elicited a significantly greater percentage of males to respond than did the control and 1:1 (i.e., high proportion of acetate) treatments (Fig. 3b).

With respect to the arrival at the pheromone source, the 15:1 synthetic blend was the most attractive with 60% of males arriving at the septum within 10 min. In most cases, males arrived, left, and flew back to the source several times. The percentage of males arriving at the source for this treatment was significantly greater than for all other treatments. Less than 15% of males arrived at the calling females or the septa loaded with other blends, and no males arrived at the control septa (Fig. 3c).

Although the 15:1 proportion of the two pheromone components in the gland extracts may not reflect the actual proportion emitted by the female, the synthetic treatment with this ratio elicited the strongest responses from males, even at the low dose at which it was tested (1.6 μg). Although males responded to the alcohol-only treatment, indicating that this compound is probably crucial for male responses, the lower rates of males arriving at the source (compared to the 15:1 blend) indicates that the acetate is also an important component of the blend. The relatively low responses (arriving, especially) of males to the virgin females may be due either to an atypical or discontinuous pheromone emission because of the stressful conditions of the wind tunnel tests or simply to the low amount of pheromone females emit compared to that from the septa.

Pheromone-based monitoring of *E. aporema* could become an important tool for the integrated management of this pest in soybean crops in southern South America.

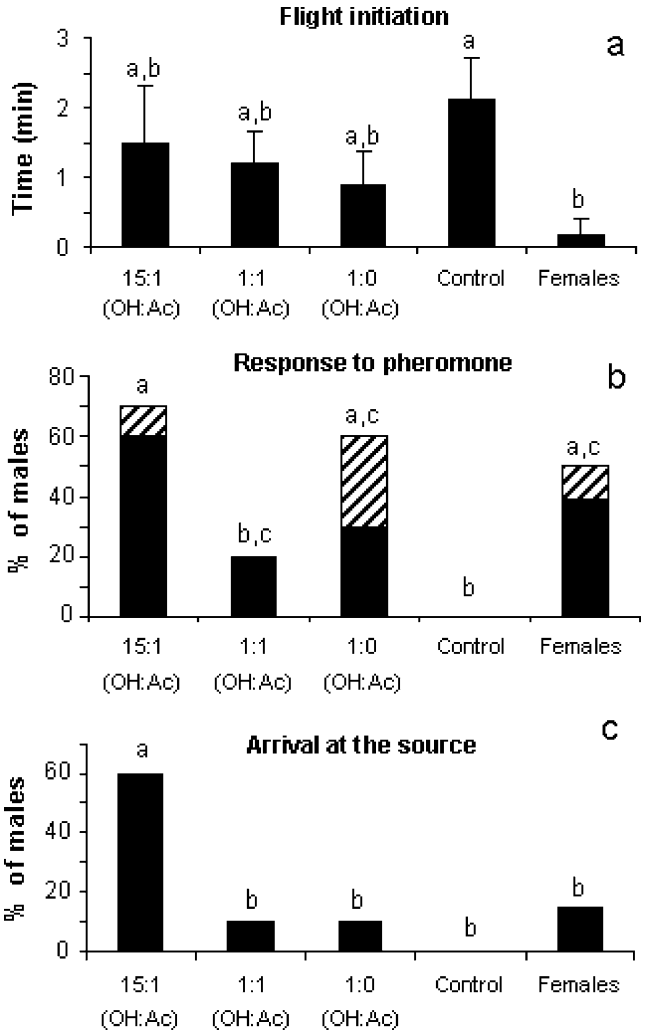

Fig. 3 Behavioral responses of *E. aporema* males to various treatments including virgin calling females and rubber septa loaded with different blends of (*Z*,*Z*)-7,9-dodecadienyl acetate (*Ac*) and (*Z*,*Z*)-7,9-dodecadienol (*OH*). **a** Time for flight initiation (mean minutes±SEM). **b** Percentage of males responding to the pheromone (*solid bars* flight within the plume, *striped bars* wing fluttering only). **c** Percentage of males arriving at the pheromone source. *Different letters above treatments* indicate significant differences at $P<0.05$

Control of this pest is complicated by the fact that the larvae are inside buds. Hence, monitoring of adults could be used to schedule insecticide applications more precisely, when larvae are exposed. The deficiency of a monitoring system not only results in overuse of insecticide, but also hinders the development of alternative control measures, such as use of insect hormone mimics or biological control. These alternatives need to be used within a specific time window during larval development, which is only possible after accurate detection of adult flight. Moreover, insecticides for the control of *E. aporema* are usually employed early in the growing season, causing a decline in populations of natural enemies that would otherwise control later-appearing noctuid moths. This, in turn, results in more

insecticides being applied later in the season; a trend that, combined with the expansion of soybean production, is threatening the sustainability of soybean and neighboring agroecosystems. To evaluate the potential of pheromone-based monitoring of *E. aporema*, field tests with various blends and pheromone doses are planned for the upcoming austral summer season.

Acknowledgements Financial support was provided by the Instituto Nacional de Investigación Agropecuaria of Uruguay, CONICYT, the Lindbergh Foundation, and IFS-OPCW to AG, and CNPq to PHG. The authors also wish to thank Tetsu Ando and Christer Löfstedt who kindly provided the pheromone standards and Jan Bergmann for the useful comments on the manuscript.

Fine Tuning of Social Integration by Two Myrmecophiles of the Ponerine Army Ant, *Leptogenys distinguenda*

Volker Witte · Susanne Foitzik · Rosli Hashim · Ulrich Maschwitz · Stefan Schulz

Received: 8 July 2008 / Revised: 16 January 2009 / Accepted: 2 February 2009 / Published online: 21 February 2009

Abstract Myrmecophiles are animals that live in close association with ants and that frequently develop elaborate mechanisms to infiltrate their well-defended host societies. We compare the social integration strategies of two myrmecophilic species, the spider, *Gamasomorpha maschwitzi*, and the newly described silverfish, *Malayatelura ponerophila* gen. n. sp. n., into colonies of the ponerine army ant, *Leptogenys distinguenda* (Emery) (Hymenoptera: Formicidae). Both symbionts use chemical mimicry through adoption of host cuticular hydrocarbons. Exchange experiments between *L. distinguenda* and an undetermined *Leptogenys* species demonstrate that reduced aggression toward alien ants and increased social acceptance occurred with individuals of higher chemical similarity in their cuticular hydrocarbon profiles. We found striking differences in chemical and behavioral strategies between the two myrmecophiles. Spider cuticular hydrocarbon profiles were chemically less similar to the host than silverfish profiles were. Nevertheless, spiders received significantly fewer attacks from host ants and survived longer in laboratory colonies, whereas silverfish were treated with high aggression and were killed more frequently. When discovered and confronted by the host, silverfish tended to escape and were chased aggressively, whereas spiders remained in contact with the confronting host ant until aggression ceased. Thus, spiders relied less on chemical mimicry but were nevertheless accepted more frequently by the host on the basis of behavioral mechanisms. These findings give insights into the fine tuning of social integration mechanisms and show the significance of qualitative differences among strategies.

Introduction

Ant societies may function as small ecosystems for various other animals (Hölldobler and Wilson 1990). Especially large ant colonies offer ecological niches free of enemies and rich in food resources for organisms that have managed to intrude into the host's social system. Although such symbionts frequently partake in host resources, the term symbiosis originally did not imply a particular positive or negative interaction between the partners (Goff 1982).

Symbionts that live in close association with ants are also frequently referred to as myrmecophiles. To attain social integration, myrmecophiles apply adaptive strategies of appeasing or deterring the host or of circumventing the nest recognition system (Lenoir et al. 2001). Specifically with migratory ants, myrmecophiles require additional mechanisms of maintaining contact with their mobile hosts. Although many army ants impose such challenges by being highly migratory, forming only temporary nests (bivouacs) that are shifted frequently, they exhibit an extraordinarily diverse fauna of myrmecophiles (Gotwald 1995). This is probably due to the large colonies that offer numerous ecological niches and to the availability of considerable amounts of high-quality food that is retrieved during regular and highly efficient raiding activities. The Southeast Asian ponerine, *Leptogenys distinguenda* (Emery) (Hymenoptera: Formicidae), which reaches colony sizes of more than 50,000 workers and exhibits army ant behavior (Maschwitz et al. 1989), is also inhabited by numerous myrmecophiles, including beetles, phorid flies, springtails, silverfish, woodlice, spiders, and snails (Witte 2001; Witte et al. 2008). By depleting colony resources or by direct predation on the host, myrmecophiles might exert fitness costs on their host (Kistner 1982), and under these circumstances, selection may have occurred such that the host now displays counterstrategies to minimize the costs of symbionts. In this study, we analyzed the specific interactions for two selected myrmecophiles and their host, *L. distinguenda*, in order to identify potential host countermeasures that would reduce symbiont pressure. We compared the integration levels of the oonopid spider, *Gamasomorpha maschwitzi* (Wunderlich 1994), and the newly described silverfish, *Malayatelura ponerophila* gen. n. sp. n. (Mendes et al., unpublished). Both of these symbionts occur in most *L. distinguenda* colonies, and since they consume some of the host's resources, they are costly for the host (Witte et al. 2008). In this study, we compared the chemical and behavioral integration strategies of these two morphologically and systematically different symbiont species.

Chemical cues are known to play a major role in social insect recognition mechanisms; social insects generally use characteristic hydrocarbon profiles on the cuticle to recognize nestmates (Reese 1982; Vender Meer et al. 1982; Howard and Blomquist 2005; Hefetz 2007). These surface chemicals are transferred constantly among nestmates, passively by physical contact and actively by grooming and trophallaxis (Soroker et al. 1995). Myrmecophiles have been found to mimic the chemical profiles of their hosts either by biosynthesis of cuticular hydrocarbons or by acquiring the host chemical profiles passively (Dettner and Liepert 1994). The term "chemical mimicry" is used in this paper according to the original definition of the term "mimicry," as one organism's resemblance to another organism's properties (Vane-Wright 1976). Since chemical profiles of ant colonies may change considerably over time (Hölldobler and Wilson 1990), intruders must be able to update their profiles constantly in order to avoid detection. We hypothesize that myrmecophiles will fail to match host profiles if they do not continuously renew their chemical cues. At some point, profiles will diverge to such an extent that hosts can detect, expel, or even kill myrmecophiles. Once a certain state of mismatch in recognition cues has been reached, it must become increasingly difficult to approach host workers and to update the chemical profiles for organisms relying on passive chemical mimicry. By negative feedback, this process might even lead to complete social rejection, which would be fatal for obligate symbionts. Hence, symbionts might pay high costs for the exploitation of their host. We show in this study that considerable differences exist in the social acceptance of two common symbionts and that their social integration is a well-balanced and potentially fragile system.

Methods and Materials

We used a fourfold approach to study the behavioral and chemical integration of the myrmecophiles into the colony of their host: (1) studies of behavioral interactions between host ants and myrmecophiles in two colonies, which included their native myrmecophiles, but were reduced in size to enable laboratory observations; (2) studies of recognition and aggression between colonies with different cuticular hydrocarbon profiles; (3) identification of cuticular hydrocarbons in free-living host colonies based on the samples of highest concentrations; and (4) analyses of chemical similarities between hosts and myrmecophiles based on a large dataset of relative quantities of the principal cuticular hydrocarbon components from six free-living colonies.

Behavioral Observations We studied the host ant *L. distinguenda* in a well-recovered secondary, dipterocarp, lowland rainforest ecosystem at the Field Studies Centre of the University Malaya in Ulu Gombak, Malaysia (03°19.4796′ N, 101°45.1630′ E; elevation, 228.8 m). Studies were carried out for a total of 9 weeks, 3 weeks each in March and September 2006 and another 3 weeks in March 2007. Host colonies were located during their activity phase at night by retracing raiding columns to the nest sites. Nest sites were numbered, marked with tape, and checked every 30 min between 9:00 P.M. and 3:00 A.M. for ongoing activities. Army ants shift their nest sites frequently, carrying all larvae and pupae in a continuous column to a new location (migration). With *L. distinguenda*, such migrations last several hours. When a colony was found emigrating, *G. maschwitzi* and *M. ponerophila* were collected with aspirators directly from the emigration column. Adult and young teneral adult host

workers (also known as callows), larvae, and pupae also were collected to assemble simplified observation nests for behavioral studies (two colonies) and for exchange experiments (two additional colonies) at the field station (see below). Six additional collections, again from different free-living host colonies, were subjected to cuticular hydrocarbon extraction and chemical analyses (see below). To permit investigation of potential influences of nest composition on the interactions between the host and each symbiont, laboratory colonies were assembled with a different demographic composition. Worker numbers ranged from 83 to 140, callows from 3 to 34, larvae from 15 to 28, and pupae from 9 to 53. Ant colonies were housed in clear plastic containers (1×14×20 cm) with a 1-cm wide entrance, shaded with cartridge covers, and placed upside down on a moistened plaster floor in an arena (9×25×32 cm). Arenas were covered with plastic lids when no observations were carried out, and the side walls were treated with paraffin oil to prevent escape of the ants. These nests were for behavioral studies only, so the paraffin treatment did not affect our chemical analysis.

Interactions among spiders, silverfish, and host ants were monitored during nightly observation sessions of defined length, on average, 12 sessions of 5 min per night. Observation times of the four laboratory nests summed up to more than 38 hours and included 20 spiders and 41 silverfish. Observations were carried out both before and after feeding. Each day before the observation sessions, total numbers of all nest inhabitants were counted. For statistical analysis, the behaviors observed between the host and the spider and between the host and the silverfish were standardized in a behavioral index (F_r). This was necessary to compare laboratory nests of different composition, considering that the odds of interactions are influenced by the number of potentially interacting individuals and the observation time. The index (F_r) standardizes the frequency of a particular behavioral pattern between the objects A and B relative to the number of individuals in the focal groups (A and B) and observation time with $F_r = [F_o/(N_A \times N_B \times t)]$, where F_o is the observed frequency, N_A is the number of animals in group A, N_B is the number of animals in group B, and t is the observation time. Behavioral indices were evaluated with nonparametric statistical methods (Wilcoxon-matched pairs test, Mann–Whitney U test, and Kruskal–Wallis test). Furthermore, the data were standardized to 100% for each symbiont species to compare the overall proportions of behavioral patterns.

To study the dependency of social acceptance on colony-specific chemical cues, reciprocal exchange experiments were carried out between two *L. distinguenda* laboratory colonies, including 40 host ants, ten spiders, and three silverfish. Unfortunately, spiders and silverfish could be exchanged only in smaller numbers due to their overall rarity, their low social acceptance, and particularly the mortality of silverfish from aggressive behavior by the host. Twenty ants of a closely related (undescribed) *Leptogenys* species also were tested as a control. This species resembled *L. distinguenda* morphologically and showed similar behavior, including army ant mass raiding. Specimens of this species were deposited at the Ludwig-Maximilians Universität (LMU, Munich, Germany). For intercolonial exchanges, individuals from one colony were captured by using a padded aspirator and introduced carefully into a different observation colony without causing disturbance. All interactions were monitored for the following 10 min and forward jerking toward an introduced animal; chasing, mandible grabbing, snapping, biting, or stinging were all classified as "aggression." All kinds of direct physical contact between two focal objects were considered as "contact." In addition to these behavioral observations, cuticular hydrocarbons were extracted as described below from the experimental colonies as well as the control species.

Chemical Analyses We examined the cuticular hydrocarbon profiles of the *Leptogenys* colonies that were used for laboratory exchange experiments to correlate observed aggression levels directly with chemical similarities/dissimilarities. In addition, chemical analyses were conducted with six *L. distinguenda* field colonies including their spider and silverfish symbionts to unravel the chemical resemblance between symbionts and their hosts in natural colonies.

Cuticular hydrocarbons were extracted by placing individual insects (or spiders) in 2-ml vials with polytetrafluoroethylene septa and treated for 5 min with 200 μl of pentane (HPLC grade, Sigma-Aldrich). The crude extracts containing both polar and non-polar components were analyzed at the LMU by coupled gas chromatography and mass spectrometry (GC-MS) on an Agilent Technologies 6890N GC and 5975 MSD (70 eV, EI) equipped with a Restek Rxi-5MS column (30 m length, 0.25 mm i.d., 0.25-μm film thickness). Injections were performed in the pulsed splitless mode over 1.0 min at 280°C, including an initial pressure pulse of 16 psi for 0.5 min, followed by automatic flow control at 1.0 ml/min with helium as the carrier gas. The oven program began isothermally at 120°C for 2 min, then increased at 25°C/min until 200°C was reached, followed by a temperature ramp of 4°C/min until the final temperature of 300°C was reached. The transfer line was held constantly at 310°C. A range of 50–500 amu was scanned after an initial solvent delay of 3.8 min.

Identification of Compounds In the most concentrated extracts, individual compounds, mostly hydrocarbons, were identified by their mass spectra, their retention indices, and comparison with library spectra (Wiley7N). As far as possible, concentrations were evaluated semiquantitatively according to the relative contribution of each peak to the total peak area of the sample. Structures of saturated unbranched and branched hydrocarbons were assigned according to well-

established procedures (Carlson et al. 1998; Schulz 2001). Double-bond positions in alkenes and alkadienes were identified by derivatization of the crude extract with dimethyldisulfide (DMDS; Francis and Veland 1981; Vincenti et al. 1987; Carlson et al. 1989; Schulz and Nishida 1996). The resulting adducts allowed assignment of the (*E*)-or (*Z*)-configuration only in cases when both diastereomers were present in the extract. Because of the completely stereoselective reaction of DMDS, the adduct derived from the (*Z*)-compound eluted before the (*E*)-adduct on apolar gas chromatographic phases (Leonhardt and Devilbiss 1985). Double-bond positions in tri-, tetra-, and pentanes were identified tentatively by analysis of mass spectra and rationalization of fragmentation patterns according to known reference compounds. The general appearance of the mass spectra points to a homoconjugated arrangement of double bonds (Blumer et al. 1970; Youngblood et al. 1971; Karunen 1974; Steiger et al. 2007). The mass spectra of these compounds show the characteristic fragments a, a′, and b, which, together with the molecular mass, allow assignment of double bonds (Fig. 1). The spectra are shown in the Supplementary material (S1).

Chemoinformatics Characteristic cuticular hydrocarbons for "within-nest groups" of animals (workers, callows, larvae, pupae, spiders, or silverfish of a particular host colony) were identified and compared for potential similarities with multivariate statistical methods. To consider a GC peak characteristic for a particular within-nest group, at least 50% of the samples belonging to this group had to show the corresponding GC peak. Peaks had to be characteristic for at least one group; otherwise, they were considered not consistent and excluded from analysis. Consistency of 50% of the samples within one group is a rather conservative restriction and therefore minimizes the risk of excluding meaningful chemicals from analysis. Contaminants were excluded, and only hydrocarbons of 21 C-atoms or more were included in the statistical evaluation, since these are considered typical insect cuticular hydrocarbons (Carlson et al. 1998). Absolute peak area of these substances was fourth root transformed, and each peak analyzed in a sample was standardized by dividing its area by the transformed area of the maximum peak in the sample to evaluate relative proportions of compounds only. We used this procedure because we had no a priori hypothesis about the composition of profiles between host and symbionts, and standardization by maximum peak area appears most appropriate for comparing profiles containing different numbers of peaks. Non-parametric statistical procedures robust to data type and distribution (Clarke 1999) were applied by using the Primer 6 software package (Primer-E Ltd.). Bray–Curtis distances were calculated, which were then subjected to the following statistical procedures. A similarity percentage (SIMPER) procedure was used to calculate relative contributions of each compound to the similarity of a within-nest group. Non-metric multidimensional scaling (NMDS) was applied to visualize chemical distances. These were analyzed further by hierarchical cluster analysis (CA), with group average cluster mode, and the results were combined with the NMDS plots to visualize similar groups of samples. A priori hypotheses about differences between sample groups were tested for significance by the analysis of similarities (ANOSIM).

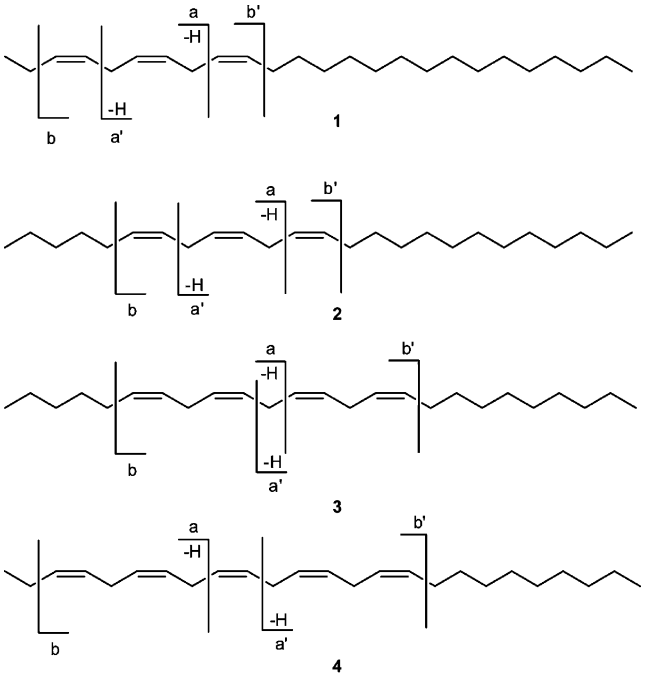

Fig. 1 Characteristic fragments for the identification of homoconjugated polyenes. Ions of the general formula $[C_nH_{2n-4}]^+$.are preferentially formed (*a*, *a′*), resulting in intense even-numbered ions. Less abundant were ions resulting from other characteristic cleavages next to the polyene system, such as cleaving off the shorter alkyl chain (*b*) or cleavage in the distal end of the polyene system resulting in less abundant ions (*b′*), often not more intense than other ions of the same ion series. For example, by this method, 3,6,9-pentacosatriene (*1*, *a*=108, *a′*=290, *b*=317=M-29) can be readily differentiated from 6,9,12-pentacosatriene (*2*, *a*=150, *a′*=248, *b*=275=M-71). Similarly, 6,9,12,15-pentacosatetraene (*3*, *a*=150, *a′*=206, *b*=273=M-71) can be differentiated from the 3,6,9,12-isomer (*a*=108, *a′*=248, *b*=315=M-29). Finally, the spectrum of 3,6,9,12,15-pentacosapentaene (*4*, *a*=108, *a′*=206, *b*=313=M-29) was identical to the published spectrum of the all-*Z* isomer (Leal et al. 2005), also showing an identical retention index. With the exception of 1, all tri-, tetra-, or pentenes were present in trace amounts only (Table 2). Not all trace components could be detected in samples from spiders and silverfish because they usually contained much less material, making identification of trace compounds difficult

Results

We collected myrmecophiles from ten different *L. distinguenda* colonies and recorded a median of three spiders

(range, 1–13) and 14 silverfish (range, 3–47). This difference in abundance is significant (P=0.008, exact Wilcoxon matched-pair test, N=10 each). It is important to note that emigrations could not always be sampled from the very beginning so that higher total numbers of myrmecophiles are possible and even likely. Nevertheless, silverfish are found typically in the earlier emigration phases and spiders in later phases, so that the number of silverfish was likely underestimated relative to the number of spiders. Consequently, sampling error should not affect the observed difference in abundances. On three emigrations, larval packets carried by worker ants were collected, which contained silverfish larvae (size, 1.0–1.2 mm) hidden between host larvae, as well as silverfish subadults (size, <4 mm) attached to the outside of the packets. This suggests that the entire life cycle of this myrmecophile takes place within the host colonies.

Behavioral Integration Surprisingly, we observed considerable differences in survival rates of the myrmecophiles in our laboratory colonies, which contradict the naturally observed abundances. Within the first 6 days of observation, 92–100% of the spiders survived (N=20), which was similar to host worker survival of 80–100%. In contrast, silverfish (N=41) disappeared almost completely within these 6 days (0–30% survival), and this loss was attributed to increased host aggression. In all laboratory nests, aggression increased toward silverfish, and active killings of myrmecophiles were frequently observed (Fig. 2). Thus, the observed mortality of silverfish was not a result of inappropriate laboratory handling, but rather a consequence of host aggression (see below). We observed significantly more attacks toward silverfish than spiders (P<0.001, U= 5211.5, Mann–Whitney U test, N=54).

Overall, the two myrmecophile species showed strongly dissimilar behavioral patterns (P<0.001, X^2 test, Table 1). Spiders interacted more with adult ants (P<0.001, Mann-Whitney U test, U=3132.0, N_{SP}=271, N_{SF}=147), whereas silverfish interacted more frequently with callow adults (P= 0.001, U=2,265.5, Mann–Whitney U test, N_{SP}=174, N_{SF}=72). Silverfish were frequently observed moving their body surface directly over the cuticle of adult and callow worker ants. This type of close physical contact to the host may be a mechanism that obtains host cuticular chemicals (Lenoir et al. 1997, 2001). This characteristic behavior of silverfish was more frequent during interaction with callow adult workers than with adult ants (P<0.001, U=4,842.9, Mann–Whitney U test; N=31). In accordance with this observation, aggression toward myrmecophiles (N=87) was never initiated by callows but instead by older workers. Contact between silverfish and worker ants occurred most frequently when the silverfish were below the ants (Table 1) and when the ants were occupied with other tasks such as feeding or brood care. Spiders, in contrast, were typically observed crawling on top of adult workers or callows and actively maintained contact by following worker ants through the nest (Table 1). From the on-top position, spiders had permanent physical contact and frequently moved their legs actively over the cuticle of the host (N> 20). Both myrmecophiles spent significant time in areas where ants were actively feeding and also were observed directly in contact with food (Table 1). The rare occasions when myrmecophiles directly contacted food with their mouthparts (Fig. 3) lasted only a few seconds each.

Aggressive interactions were regularly observed between spiders; however, these interactions did not result in injury or fatality. On encounter, one spider typically displaced another individual after a short period of leg-struggling. Spiders occasionally constructed small, flat webs (0.5–1 cm diameter) inside the ant nests, but prey capture was never observed with these webs. Passing host ants also frequently damaged these webs; therefore, they were of short durability and might serve purposes other than foraging.

In exchange experiments (see "Methods and Materials"), *L. distinguenda* recognized conspecifics from other colonies as alien; however, they were treated with low aggression (Fig. 4a). In addition to inspection behavior, which included intense bouts of antennation (N=330), dominance behavior was displayed, which included upright positioning of the resident ant, mandible grabbing and

Fig. 2 Myrmecophiles are attacked and killed by host *Leptogenys distinguenda* ants. *Left* Myrmecophilic spider, *Gamasomorpha maschwitzi*; *right* myrmecophilic silverfish, *Malayatelura ponerophila*

Table 1 Relative proportions of typical behaviors observed for spiders, *Gamasomorpha maschwitzi*, and silverfish, *Malayatelura ponerophila*, in two *Leptogenys distinguenda* laboratory colonies

Behavior	Spider	Silverfish
At larvae	9.7	3.0
At pupae	10.1	0.7
On callows (contact)	11.8	35.0
On adults (contact)	9.2	2.8
Rubbing on callows	0.0	5.6
Rubbing on adults	0.0	1.0
Following adults	19.1	0.8
Below adults (contact)	0.9	12.8
Attacked by adults	1.7	2.5
Groomed by adults	1.2	0.0
At food	33.0	33.5
Feeding	3.2	2.5
Total	100.0	100.0

holding down of the subdominant, and antennal boxing (N=13). These interactions ceased within 5 min so that introduced workers could finally move undisturbed and were adopted into the alien colony. In contrast, allospecific ants (*Leptogenys* sp.) were treated aggressively (Kruskal–Wallis test, P<0.001, N=128). Resident *L. distinguenda* workers displayed defensive and aggressive behavior, including bouts of forward jerking (N=214) and biting (N=165). Allospecific workers were found dead, although this happened long after the 10-min observation period had ended. In contrast, and similar to conspecific workers, introduced myrmecophiles from other *L. distinguenda* colonies were treated with lower aggression (Fig. 4a). Both myrmecophilic species sought direct physical contact with resident ants, possibly thus obtaining chemical signatures (Fig. 4b, Kruskal–Wallis test, P<0.001, N=82). However, behavioral responses to host aggression differed considerably between the two myrmecophilic species, which explains observed differences in contact frequencies. Spiders remained stationary, tolerated ant dominance behavior, and tried to maintain host contact (N=58). Silverfish, in contrast, attempted to escape when encountered, a behavior that provoked aggressive chases and attacks by ant workers, similar to the response to introduced allospecifics (N=8). If resident ants were able to capture an alien silverfish, it was subsequently killed. Thus, the survival of transferred silverfish was zero (N=3), whereas eight of ten spiders were finally accepted.

Chemical Integration We identified 109 different cuticular hydrocarbons among the host and two myrmecophiles (Table 2). Many of the substances occurred in low amounts, so that only characteristic principal compounds were included in the multivariate analysis (see "Methods and Materials"). The analysis showed, however, that spiders and silverfish did not carry any compounds that were uniquely different from those on the host ants (Table 2). Furthermore, the presence or absence of cuticular hydrocarbons on the myrmecophiles depended on their concentrations on the host ants. Only compounds that occurred as traces on the host were found significantly less frequently on the myrmecophiles than expected under the hypothesis of a total match of compounds (P<0.001, chi-square goodness of fit test, N=75) (see Supplementary material, Table S2). All compounds that occurred at >0.1% of total peak area were not found less frequently than expected (P>0.545, chi-square goodness of fit test, N=119, 27, and 12, respectively).

The hydrocarbon profiles from workers of three different *L. distinguenda* laboratory colonies showed weak (Fig. 5), but significant, colony-specific structure (ANOSIM, pairwise R values ranged between 0.23 and 0.67, overall P< 0.002). Hydrocarbon differences were more pronounced between colonies of *L. distinguenda* and *Leptogenys* sp. (ANOSIM, R>0.94, P<0.001; Fig. 5). Further quantification is shown in the Supplementary material (Table S3).

The hydrocarbon profiles of myrmecophilic spiders and silverfish from six field colonies resembled the patterns from their host to a high degree; however, colony-specific matching was not observed. This might be due in part to the small sample sizes of the myrmecophiles. More likely and

Fig. 3 Myrmecophile contact with food lasts only a few seconds. *Left* Myrmecophilic spider *Gamasomorpha maschwitzi* gets brief access to a prey item from the top. *Right* myrmecophilic silverfish *Malayatelura ponerophila* participates from the top at larval feeding

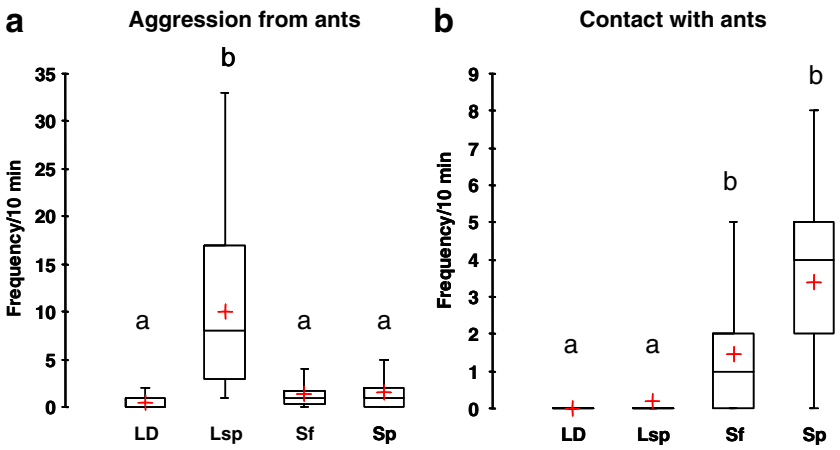

Fig. 4 Differences in aggressive behavior directed by and contact received by *Leptogenys distinguenda* workers during 10-min observation periods relative to conspecific workers (*LD*), allospecific workers (*Lsp*), and myrmecophilic silverfish (*Sf*) or spiders (*Sp*). **a** Aggression of resident ants toward introduced animals. **b** Physical contact initiated by introduced animals to resident ants. The *plus symbol* indicates mean values. *Different letters* denote significant differences according to a Kruskal–Wallis test, $P<0.001$

consistent with the results above, *L. distinguenda* intercolonial differences are too weak to be detected through their myrmecophilic fauna. Instead of showing colony-specific structure, the profiles of within-nest groups were distinct across all *L. distinguenda* colonies ($R=0.376$, $P<0.001$, two-way nested ANOSIM, within-nest groups nested in colony groups). Thus, we further compared chemical similarities among workers, callow adults, larvae, pupae, as well as myrmecophilic spiders and silverfish of field colonies and found a high chemical resemblance of the two myrmecophile profiles with callow and adult host profiles (Fig. 6). Nine cuticular hydrocarbons accounted for more than 98% of the similarity within each of these groups, despite being present in different proportions (see results of SIMPER analysis in the tabular insert of Fig. 6).

Both myrmecophiles were chemically more similar to adult and callow adult host ants than to host ant larvae and pupae, which typically lack most cuticular hydrocarbons (Fig. 7). Based on hierarchical CA, 98% of adults, 97% of callow adults, 84% of silverfish, and 57% of spiders were arranged in a 70% similarity group, whereas only 38% of the larvae and none of the pupae were sorted into the same group. Instead, all pupae, most larvae, and the remaining samples were spread in six separated groups. On a higher similarity level of 80%, there were still 88% of adults and callows, as well as 57% of silverfish, and 21% of spiders sorted into one group. A second group contained few host ants (6% of workers and 9% of callows) and a considerable number of spiders (36%) and silverfish (19%). An ANOSIM revealed more details, which cannot be observed directly in Fig. 7. Spiders were less similar to both callows ($R=0.54$) and adults ($R=0.58$), whereas silverfish showed higher resemblance to callows ($R=0.12$) and adult host ants ($R=0.22$) ($P<0.002$ for all pairs, ANOSIM). Thus, in the six field colonies, silverfish were chemically more similar to their hosts than were spiders, whether we performed the ANOSIM on selected cuticular hydrocarbon groups only (i.e., unsaturated or saturated) or on the most abundant hydrocarbons.

Discussion

Social Integration Strategies of Myrmecophiles If mimicry is regarded as the resemblance of the properties of a model organism (Dettner and Liepert 1994), our results demonstrate chemical integration by mimicry of host cuticular hydrocarbon patterns for both myrmecophilic species. To the best of our knowledge, this is the first report of chemical mimicry in silverfish. A well-known example of chemical mimicry in spiders is with *Cosmophasis bitaeniata*, which feeds on larvae of the weaver ant, *Oecophylla smaragdina*, and acquires a colony-specific chemical signature (Allan et al. 2002; Elgar and Allan 2004, 2006). Nonetheless, social integration of most myrmecophilous spiders remains poorly studied, even though myrmecophily is not uncommon among spiders (Cushing 1997). Our study supports the notion that a passive mechanism of chemical mimicry through maintenance of physical contact (Lenoir et al. 1997, 2001) was used by both myrmecophiles. Specifically, a passive transfer of chemicals predicts a match of major host compounds with only host compounds of low concentrations falling below the detection threshold on the myrmecophiles. Furthermore, it appears evolutionarily unlikely that spiders and silverfish experienced all mutations to biosynthesize all or most of these specific *Leptogenys* host compounds (Dettner and Liepert 1994). A system of passive chemical mimicry by adoption of nest odor requires a constant renewal of the myrmecophile cuticular hydrocarbon profile, and such efforts were apparent in their behavior. In both species, over 40% of all monitored behaviors were species-specific attempts to get in close contact with host ants. Direct physical contact with legs (spiders) or body surface (silverfish) was observed frequently. Nevertheless, our chemical analysis of free-living colonies demonstrated considerable variation in the chemical profiles within each group of myrmecophiles, suggesting different success in maintaining mimicry among individuals. Chemical dissimilarity even reached

[a] Relative abundances of individual components within samples are denoted by the following abbreviations: *xxx* >10%, *xx* 1–10%, *x* 0.1–1%, and *tr* <0.1% of the total peak area. Location of double bonds of monoenes obtained by analysis of DMDS-derivatized samples are indicated in the appropriate entries. Usually three alkene peaks are observed, but peak assignments could not be made. In the less concentrated samples of spider and silverfish, the location of the double bond in the alkenes was only possible for major components. Typeface refers to the relative proportion within an entry (*bold* major isomer, *italics* minor isomer). *Numbers* indicate double bond positions. *Un* unknown position of double bonds, *nd* not detected. Compounds used in multivariate statistical analyses are rendered in bold italics.

such a high degree that several individuals were not grouped together with their host ants by CA. Such significant deviations from the host colony odor could provide sufficient recognition cues for the myrmecophile to be detected and rejected, which also explains the observed killings of myrmecophiles in our laboratory colonies.

In native colonies, silverfish resembled host profiles better than spiders, no matter which class of cuticular hydrocarbons the analysis was based on. This finding suggests that silverfish should thrive well in free-living host colonies, and in fact, they were found in high numbers. In stark contrast to this, silverfish showed strikingly high mortality rates in our laboratory colonies. This could be attributed only to the altered nest structure of our observation nests. Full-sized *L. distinguenda* colonies show a different and distinct nest structure (Witte 2001). Adult workers occupy peripheral areas of the nest, whereas large piles of pupae and dense aggregations of callow adults with larvae in their mandibles are found in the center. Silverfish prefer these central regions, where they find enough space to hide between brood, and to update their chemical profiles from defenseless callows without disturbance. Furthermore, they are able to hide their offspring in the larval clumps that are located in these central nest regions. Brood and callows were not arranged in such distinct spatial structure in our small laboratory colonies, so that silverfish were probably unable to find their natural niche. Encounters with aggressive mature workers were frequent, which constantly disturbed the silverfish and probably hindered the updating of their cuticular hydrocarbon profiles by physical contact. Consequently, they were detected, attacked, and finally killed. Mortality due to worker aggression was also observed in myrmecophilous silverfish associated with ecitonine army ants (Rettenmeyer 1963). In contrast to silverfish, most of the spiders were accepted in our *L. distinguenda* laboratory colonies probably due to their behaviorally different integration strategy, which depended less on the nest structure and interactions with defenseless callows. Continuous contacts with callow and adult host ants and frequent rubbing of their filigree legs over the host cuticle while resting directly on their bodies facilitated a constant update of the chemical signature. Spider cuticular profiles were presumably more stable under laboratory conditions, and these myrmecophiles were better suited to remain socially accepted.

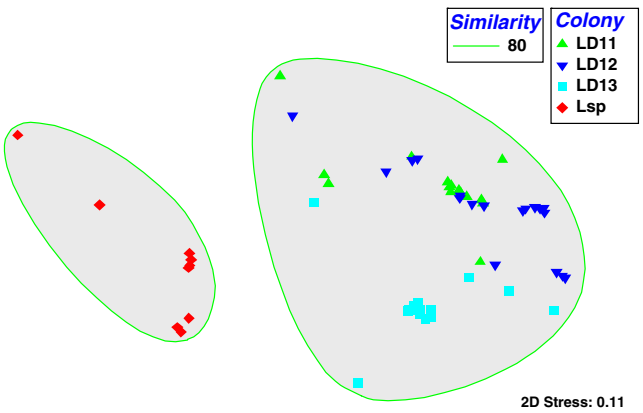

Fig. 5 Non-metric multidimensional scaling (NMDS) plot visualizing chemical similarities of three *Leptogenys distinguenda* colonies (*LD11*, *LD12*, and *LD13*) and one closely related *Leptogenys* sp. colony (*Lsp*) as an outgroup. Hierarchical cluster analysis also demonstrated the similarity among groups at the 80% level. N_{LD11}=15, N_{LD12}=18, N_{LD13}=17, and N_{Lsp}=9

Countermeasures by the Host Even if amplified by our laboratory conditions due to an artificial change in nest structure, the possibility of recognition and aggressive rejection of myrmecophiles is an important finding. This demonstrates that the host ant *L. distinguenda* is able to detect and regulate its symbiont fauna to a certain extent. Myrmecophiles live under the potential risk of being detected, expelled, or even killed. Accordingly, active host regulation can explain, on the one hand, the overall limited numbers of myrmecophiles within *L. distinguenda* colonies and, on the other hand, the large variation in myrmecophile abundances. Due to colony-specific circumstances and species-specific integration mechanisms, it might be temporarily more or less challenging for myrmecophiles to exploit a host colony. Although field conditions were

Total ion chromatograms of (from *top* to *bottom*) callow (*Ca*), adult worker (*Ad*), myrmecophilic silverfish (*Sf*), and myrmecophilic spider (*Sp*). Principal compounds are numbered: *1* 9-tricosene, *2* tricosane, *3* tetracosane, *4* 6,9-pentacosadiene, *5* 9-pentacosene, *6* 7-pentacosene and 3,6,9-pentacosatriene, *7* pentacosane, *8* 9- and 11-methylpentacosane, *9* 9-heptacosene and 6,9-heptacosadiene, *10* 7-heptacosene and 3,6,9-heptacosatriene; *11* 9-nonacosene and 6,9-nonacosadiene; *12* 7-nonacosene and 3,6,9-nonacosatriene. The *table insert* shows relative contributions of the nine principal compounds to the similarity of within-nest group chemical profiles according to a similarity percentage (SIMPER) procedure (see text for details)

different from laboratory conditions, nest demography also varies in free-living *L. distinguenda* colonies. We suggest that silverfish can also experience integration difficulties under natural conditions (e.g., after demographic changes due to resource shortages, in small colony propagules after nest fission, or simply if a silverfish fails to locate callow adult aggregations in a larger colony or a widely spread nest arrangement). The considerable variation of silverfish abundance (three to 47 individuals) is in accord with this assumption. Although exploitation of colony resources by symbionts can be tolerated when they occur in low numbers, cost of symbionts to the colony increases if they occur in higher abundances. Consequently, there should be selection on the host for symbiont recognition and rejection mechanisms. The question remains to be explained why silverfish occur regularly in higher numbers than spiders in natural *L distinguenda* colonies. We hypothesize that the reproductive rate of silverfish mainly is responsible, because, in contrast to spiders, we repeatedly detected juvenile silverfish. Furthermore, spiders might encounter stronger intraspecific competition as they frequently showed intraspecific aggressive interactions.

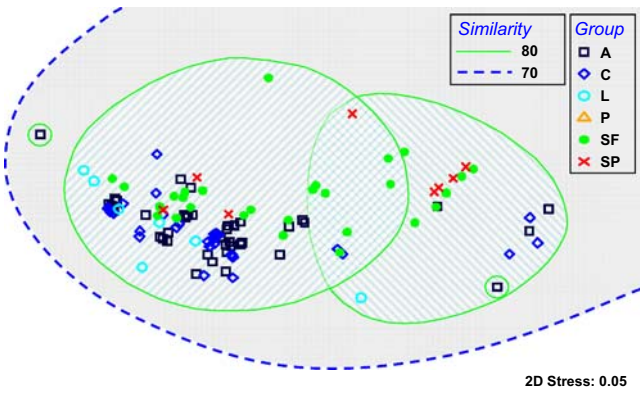

Fig. 7 Non-metric multidimensional scaling (NMDS) plot visualizing chemical similarity of 49 adults (*A*), 32 callow adults (*C*), 21 larvae (*L*), 11 pupae (*P*), 37 myrmecophilic silverfish (*SF*), and 14 myrmecophilic spiders (*SP*) from six different *Leptogenys distinguenda* colonies (=164 samples). In the hierarchical cluster analysis, the 70% similarity group contained 77% of all samples (=126 samples). Pupae (*P*) data points are out of range of the shown frame

Nestmate Recognition and Aggression Somewhat surprisingly and atypically for ants, nestmate recognition appeared to be developed weakly in *L. distinguenda,* which contradicts an effective symbiont recognition system. Both variation in cuticular hydrocarbon profiles between different colonies and the level of inter-colonial aggression were surprisingly low in *L. distinguenda*. This phenomenon might be explained by the mode of reproduction in this species. Winged males disperse to enter alien colonies for mating, whereas queens are wingless. Similar to our

exchange experiments with conspecifics, male intrusion into alien colonies elicits initial aggression that ceases over time so that males are finally able to enter (Witte, personal observation). Furthermore, males show similar profiles to workers (Witte, unpublished data), and this suggests a trade off in chemical discrimination and aggressive behavior in *L. distinguenda*. Cuticular hydrocarbon profiles might be just sufficiently different to recognize aliens and to maintain colony integrity but not so different to elicit high aggression levels, which in turn would complicate the intrusion and acceptance of males. Nevertheless, social integrity is guaranteed, as our analysis confirmed that chemical differences were greater between different *Leptogenys* species, accompanied by elevated aggression. In addition to chemical recognition and rejection, there are other lines of defense against social parasites, such as the extraordinarily high migration frequency of *L. distinguenda* (Maschwitz et al. 1989) that places additional adaptive challenges on the symbiont fauna. However, both spiders and silverfish appear well-adapted in this respect, as they are able to follow host emigration trails independently and without obvious difficulties (Witte et al. 2008). Thus, the mechanisms based on chemical recognition and rejection that we described in this paper appear to be of particular importance concerning the regulation of these myrmecophile species.

Nestmate and Task Cues are Influenced and Encoded Differently within Ant Cuticular Hydrocarbon Profiles

Stephen J. Martin · Falko P. Drijfhout

Received: 25 November 2008 / Revised: 19 February 2009 / Accepted: 20 February 2009 / Published online: 5 March 2009

Abstract Insect cuticular hydrocarbons (CHCs) are primarily antidesiccation agents, but they also play crucial roles in intra- and interspecific communication, especially among social Hymenoptera. The complex CHC profiles of social insects have often been compared among individuals, kin, nestmates, colonies, and species. In the ant *Formica exsecta*, only the (*Z*)-9-alkene part of the CHC profile encodes the nestmate signal. Here, we showed that the other major part of the CHC profile with *n*-alkane components is influenced strongly by the task a worker performs (foraging vs nonforaging). This part of the profile is independent of the nestmate signal. Therefore, the CHC profile of *F. exsecta* workers is composed of two independent parts: a colony-specific (*Z*)-9-alkene profile under genetic influence and an environmentally influenced task-related *n*-alkane profile. The dissociating of the CHC profile into two or more independent parts has implications for the analysis and interpretation of past and future CHC studies.

Introduction

The cuticle of all life stages of insects is covered with a thin epicuticular layer of wax. In the vast majority of species, this layer is dominated by hydrocarbons, which are environmentally stable (Lockey 1988; Gibbs and Crockett 1998; Martin et al. 2009). Hundreds of different insect cuticular hydrocarbons (CHCs) have now been described, and a major challenge in chemical ecology is to understand their various roles. The principal role of CHCs is the control of the transcuticular water flux, thereby preventing wetting, dehydration, and the penetration of microorganisms. CHCs account for about 0.1% of the total mass of a typical insect, but their presence can reduce the insect's permeability to water by up to 1,300% (Edney 1977). Structurally, the best hydrocarbons to perform this task are saturated straight-chained linear *n*-alkanes that dominate the CHC profile of nearly all insects (Blomquist and Dillwith 1985; Lockey 1988). However, many other more complex CHCs are present and, together with *n*-alkanes, are believed to play important roles as semiochemicals in insect communication (Howard and Blomquist 2005).

The complexity of CHC profiles has led to the widespread use of multivariate statistical methods, techniques that reduce data dimensionality and so confound rather than separate out the various signals (Martin and Drijfhout 2009). By using these methods, researchers have suggested that the variation in CHC profiles is associated with recognition cues at the individual (e.g., D'Ettorre and Heinze 2005), kin (e.g., Arnold et al. 1996), patriline (Boomsma et al. 2003), nestmate (e.g., Nielsen et al. 1999; Wagner et al. 2000; Liu et al. 2001; Kaib et al. 2002), and species level (e.g., Lockey and Metcalfe 1988; Neems and Butlin 1995; Dapporto 2007). Furthermore, correlations have been found between changes in the CHC profiles and

caste (e.g., Ayasse et al. 1999; Tentschert et al. 2002), dominance (e.g., Ayasse et al. 1995; Heinze et al. 2002; Monnin et al. 2002), task (Greene and Gordon 2003), and fertility (e.g., Liebig et al. 2000). All these studies have assumed that the profile perceived by the insect and that produced by the gas chromatography (GC)–mass spectrometry (MS) are congruent. However, it is becoming apparent that this is not the case. For example, honeybees learn and discriminate some hydrocarbons well (alkenes) and others poorly (*n*-alkanes) (Châline et al. 2005). This explains why honeybees were attacked when their alkene profile was changed but were ignored when their *n*-alkane profile was altered (Dani et al. 2005), even though the honeybee profile was dominated by *n*-alkanes (Arnold et al. 1996; Dani et al. 2005).

To make progress in recognition studies, it is essential that we detect those components of the CHC profile relevant for communication. In the seed-eating desert harvester ant (*Pogonomyrmex barbatus*), the cuticles of foragers and patrollers have higher amounts of *n*-alkanes than the cuticles of nonforagers (Wagner et al. 1998), and the proportion of *n*-alkanes increased when individuals were exposed to high temperatures and low relative humidity (Wagner et al. 2001). This indicates that *n*-alkane production is influenced by environmental conditions.

The ant *Formica exsecta* is an ideal model species because it has a simple CHC profile dominated (>90%) by an *n*-alkane and a (*Z*)-9-alkene homologous series (Martin et al. 2008a). We have shown previously that the (*Z*)-9-alkenes encode nestmate recognition in this species, whereas the proportions of *n*-alkanes among nestmates could be highly variable (Martin et al. 2008a, b). This phenomenon also occurs in other *Formica* species (*Formica lemani*, *Formica candida*) that have CHC profiles similar to *F. exsecta* (author's unpublished data). We investigated in five species of Formicinae ants whether the variability in *n*-alkanes is due to foragers that possess higher amounts of *n*-alkanes than nonforagers. We also studied in *F. exsecta* whether the *n*-alkane and colony-specific (*Z*)-9-alkene parts of the profile are independent.

Methods and Materials

Study Species During May 2008, we collected 10 foragers and 10 nonforagers from nine different *F. exsecta* colonies within 30 km of the Tvärminne zoological station at Hanko, southern Finland. Foragers were collected individually at a distance between 1 and 2 m from the nest mound. Care was taken not to disturb the mound until the foragers had been collected. Nonforagers were then collected by quickly removing nesting material from as deep within the mound as possible. Nest material was placed into a container and 10 ants were collected. It is impossible to guarantee that only nonforagers were collected, but collecting ants from deep inside the mound decreases the chance of collecting foragers. The presence of a small proportion of foragers in the nonforaging group will lead to an underestimation of the actual differences.

To investigate the generality of forager vs nonforager differences, we extended the study to include four other ant species: *Formica pratensis*, Finland; *Formica lugubris*, UK; *F. lemani*, UK; and *Lasius niger*, UK. All UK samples were collected in the Peak District (Derbyshire) during June 2008 by using the same collection method, i.e., collecting 10 foragers and 10 nonforagers, but only one colony per species was studied as we wished to establish whether a trend similar to that found in *F. exsecta* exists, rather than to conduct a full-scale study.

Chemical Analysis All individuals were killed after collection by storing in a freezer at −20°C. Each ant was placed into a glass insert with 30 μl (50 μl for *F. pratensis* and *F. lugubris*) of high-performance liquid chromatography-grade hexane. After 30 min, the hexane had evaporated. The ant was removed, and the dried extract was stored at 5°C. Immediately prior to analysis, 30 μl of hexane containing an internal standard (5 ng/μl of C_{20}) was added to the extract. The sample was analyzed on an HP 6890 GC (equipped with an HP-5MS column; length: 30 m; ID: 0.25 mm; film thickness: 0.25 μm) connected to an HP5973 MSD (quadrupole mass spectrometer with 70-eV electron impact ionization). Samples were injected in the splitless mode, and the oven was programmed from 70°C to 200°C at 40°C/min, and then from 200°C to 320°C at 25°C/min, and held for 2 min at 320°C. Helium was used as carrier gas at a constant flow rate of 1.0 ml min^{-1}. Wood ants of the *Formica rufa* group have CHC profiles that contain compounds not detected by standard columns (Akino 2006). Therefore, we ran the *F. pratensis* and *F. lugubris* samples on a SGE Forte HT5 GC capillary column (length: 30 m, inner diameter: 0.22 mm, and 0.1 μm film thickness) with the oven programmed to start at 50°C (1-min hold) with a first ramp of 40°C/min up to 280°C, then a 20°C/min ramp to 420°C with a 2-min hold. All compounds were characterized by using standard MS databases, diagnostic ions, and Kovats indices. Authentic standards of alkanes and alkenes were either purchased or synthesized at Keele University. The double-bond positions of the alkenes have been previously determined by dimethyl disulfide derivatization (Martin et al. 2008b).

Head Width Measurements Since large ants will have more CHCs relative to small ants, we investigated whether morphological size differences occurred among colonies and between foragers and nonforagers. These data enabled us to relate CHC quantities to body size. We compared the

head width of the 10 workers from each group (foragers vs nonforagers) in each colony. After the CHC had been extracted, each ant's head was removed and placed onto a microscope slide. Head width was measured with a Leica light binocular microscope at a magnification of 80× with a graticule.

Statistical Analysis The amounts of *n*-alkanes and alkenes extracted from each ant were determined by using the peak area of an internal standard (C_{20}) as the reference. For statistical analysis, the data were log-transformed in order to meet the assumption of equal variances (homogeneity of variance) before conducting two-way independent analyses of variance for the *F. exsecta* ants (factor 1: *n*-alkanes/alkenes; factor 2: colonies). Then, each *F. exsecta* colony was analyzed separately by using an independent *t* test to compare the chemical differences between quantities of *n*-alkanes and alkenes detected in extracts of foragers and nonforagers. The *t* test was conducted because the amount of CHCs extracted was highly correlated to head width (see results), and head width between *F. exsecta* colonies was highly variable (Fig. 1). Furthermore, across all individuals,

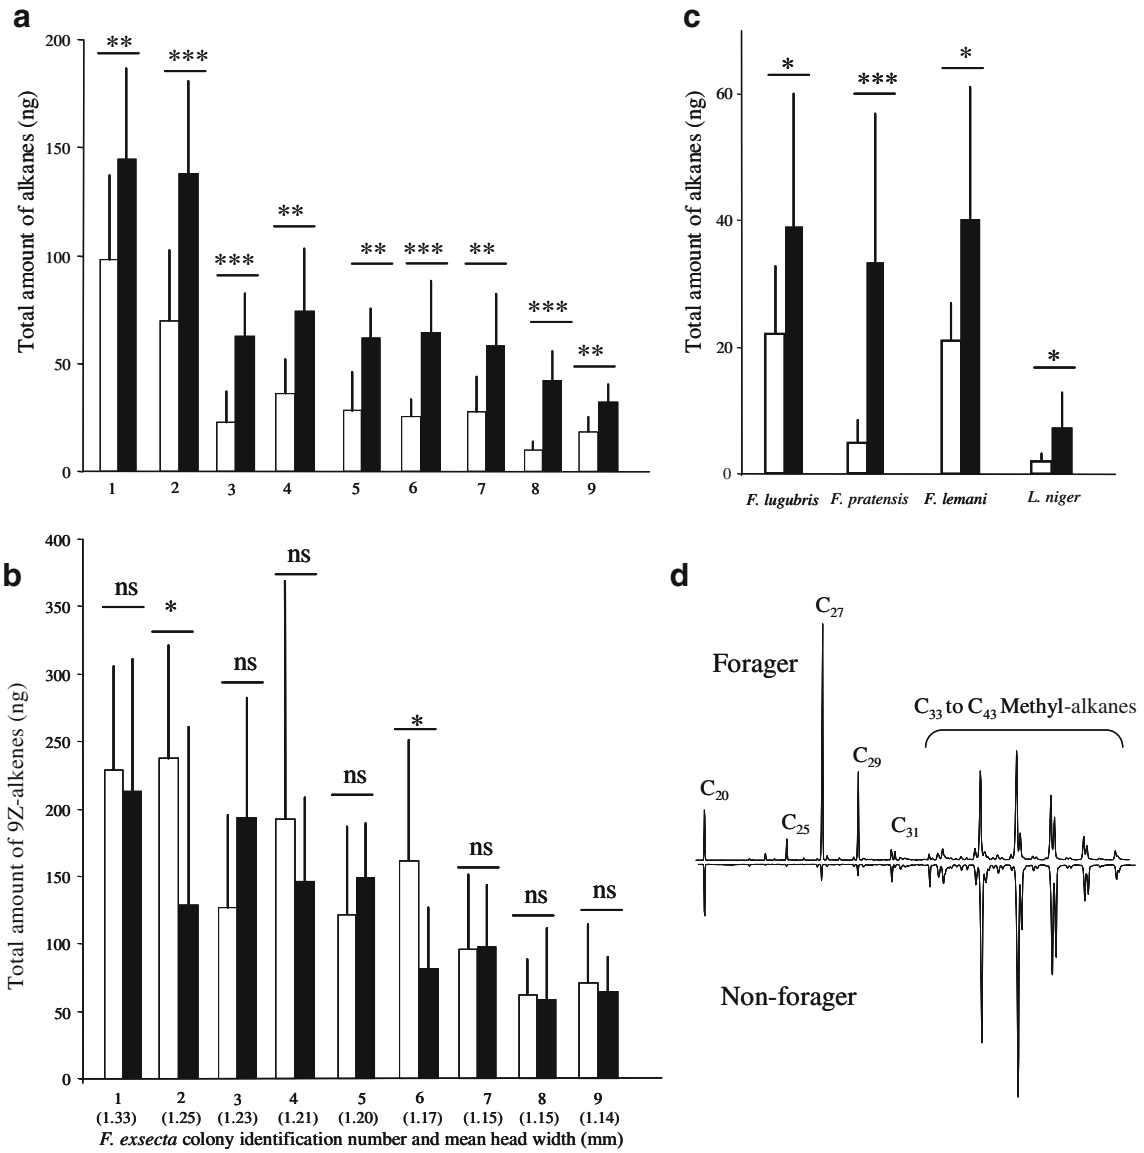

Fig. 1 Comparison of amounts (ng; means + SD) of **a** *n*-alkanes, **b** alkenes between nonforagers (*clear bars*, $N=10$) and foragers (*filled bars*, $N=10$) of nine different *F. exsecta* colonies. The numbering of colonies is ordered by decreasing worker head widths, which are given in parentheses. **c** The amounts of *n*-alkanes (ng; means + SD) in nonforagers (*clear bars*, $N=10$) and foragers (*filled bars*, $N=10$) in three additional *Formica* species and *L. niger*. **d** Part of typical total ion current chromatograms with *n*-alkanes (C_{25}–C_{31}) and C_{33}–C_{43} methyl alkanes from cuticular extracts of a *F. pratensis* forager and nonforager; C_{20} is the internal standard. $^*P<0.05$, $^{**}P<0.01$, $^{***}P<0.001$ was determined by independent *t* tests

the amounts (ng) of *n*-alkanes and alkenes in *F. exsecta* were poorly correlated (R^2=0.18, N=180). That indicates that the production of one is largely independent of the other. The correlations between amounts of CHCs (ng) and mean head width (mm) among the nine colonies were calculated in SPSS v. 14 by using Pearson's correlation coefficient. As each of the four other ant species studied were represented by a single colony, these were also analyzed individually with an independent *t* test to compare quantities of CHC in foragers and nonforagers. As in *F. exsecta*, the amounts of *n*-alkanes were poorly correlated to nonalkane CHC in the profiles of the four additional species (*F. lugubris* R^2=0.12, *F. pratensis* R^2=0.01, *F. lemani* R^2=0.19, *L. niger* R^2=0.22).

To illustrate how calculating CHC proportions influences the way we perceive CHC data, we first calculated the proportions in the usual way, i.e., the proportion of each individual CHC is based on the total amount of *all* CHCs in the profile. Then, we calculated the proportion in a new, more biologically realistic way since it separates out rather than combines potential cues: that is, the proportion of each individual CHC is calculated by using the total amount of CHCs belonging only to the *same homologous series*. The following formula provides an example for this method of evaluation:

$$C_{25}=\frac{C_{25}}{\sum n-\text{alkanes}}\ \text{rather than}$$

$$C_{25}=\frac{C_{25}}{\sum n-\text{alkanes}+\sum \text{alkanes}+\sum \text{methyls}\ldots}$$

Results

In each of the nine *F. exsecta* colonies, the amount of *n*-alkanes extracted from foraging ants was consistently greater than that from nonforaging ants (Fig. 1a). This difference was highly significant ($F_{1,157}$=164.8, P<0.001). However, there was no corresponding difference ($F_{1,\ 157}$= 2.8, P=0.095) in the amount of alkenes on foragers and nonforagers (Fig. 1b). The amounts of both *n*-alkanes and alkenes differed significantly between colonies (*n*-alkanes $F_{8,157}$=2203, P<0.001; alkenes $F_{\ 8,157}$=13, P<0.001) and were highly correlated with head width (see below). Across the nine *F. exsecta* colonies, foragers (N=90) had, on average, 2.3 times the amount of *n*-alkanes of that found on nonforagers (N=90).

A significantly (t always >2.2, df=18, P always <0.04) higher amount of *n*-alkanes on foraging vs nonforaging ants also was found in the additional four species investigated (Fig. 1c), indicating that this is a widespread phenomenon, at least among the Formicinae ants. In *F. pratensis*, the putative nestmate/species recognition compounds, i.e., methylated alkanes (Akino 2006), were well separated from the lighter *n*-alkanes that were not present at chain lengths greater than C_{33} (Fig. 1d).

Worker size among the nine *F. exsecta* colonies differed significantly ($F_{1,160}$=11.4, P<0.001), although the within-colony variation in head width was similar in each colony, i.e., the *SD* ranged from 0.04 to 0.09 with a mean of 0.07 mm. The amount of CHC (ng) extracted and worker head width correlated significantly across the nine colonies [Pearson's correlation, R=0.94, P (one-tailed)<0.001, N=9]. This explains the large intercolony variation in the amounts of *n*-alkanes (Fig. 1a) and alkenes (Fig. 1b). Head widths did not differ significantly ($F_{1,160}$=1.3, P=0.26) between foragers (mean=1.22±0.09 mm, N=90) and nonforagers (mean=1.21±0.10 mm, N=90) across all colonies, or when each colony was analyzed separately (t tests, P always >0.05).

Discussion

Here, we demonstrated that the *n*-alkane, but not the (*Z*)-9-alkene, components of the CHC profile of *F. exsecta* workers varied depending on task, i.e., foraging vs nonforaging. Across all *F. exsecta* colonies, and in single colonies of *F. lemani*, *F. lugubris*, *F. pratensis*, and *L. niger*, the amounts of *n*-alkanes on the cuticles of foragers were consistently greater than on the cuticles of individuals taken from inside the colony (Fig. 1a). Nevertheless, some individual exceptions from this rule were detected; the nonforaging groups occasionally contained some individuals with forager-typical *n*-alkane amounts. These individuals were not removed from the analysis of the nonforaging groups.

Alkanes are structurally the best hydrocarbons to function as desiccation resistance and waterproofing compounds (Blomquist and Dillwith 1985). Foragers, which are exposed to greater fluctuations in temperature and humidity, have increased amounts of protective *n*-alkanes, as has been shown in the ant *P. barbatus* (Wagner et al. 1998, 2001). These studies indicate that changes in the amount of *n*-alkanes were a direct response to environmental conditions, rather than age-related. In *F. exsecta*, workers emerge during a 1-month period in summer and survive for about a year (as determined by mark-recapture records, Emma Vitikainen, personal communication). Therefore, irrespective of task, all workers in a nest are of similar age. Furthermore, no size polymorphism related to foraging was found in *F. exsecta*. Thus, the increased amount of *n*-alkanes is associated with the task of foraging and is not age- or size-related.

Pogonomyrmex barbatus showed task-specific CHC profiles (Wagner et al. 1998). Foragers and patrollers were richer (≈5%) in *n*-alkanes than nest maintenance workers. The CHCs regulate the number of foragers (Greene and Gordon 2003), suggesting that *n*-alkanes mediate intraspecific communication in this species. This finding is supported by other studies of the intraspecific role of CHCs in ants (e.g., *F. japonica* Akino et al. 2004; *Linephithema humile* and *Aphaenogaster cockerelli* Greene and Gordon 2007; *F. exsecta* Martin et al. 2008a). Such studies have shown behavioral differences of ants towards glass beads treated with *n*-alkanes and *n*-alkane-free beads. However, these studies also detected that behavioral responses to other groups of hydrocarbons, e.g., alkenes, were even stronger than those to *n*-alkanes. This is consistent with the observations of Châline et al. (2005), who demonstrated that honeybees only poorly learned to discriminate between various *n*-alkanes when compared with alkenes of similar chain length. Therefore, ants may have to rely on large-scale differences in the amounts of *n*-alkanes to determine the task of an individual, whereas an increased sensitivity to alkenes allows small changes in alkene ratios to be used in nestmate recognition (Martin et al. 2008a).

Awareness of the proportion of foragers within a colony is information crucial for efficient colony organization (Holldöbler and Wilson 1990; Seeley 1995). Therefore,

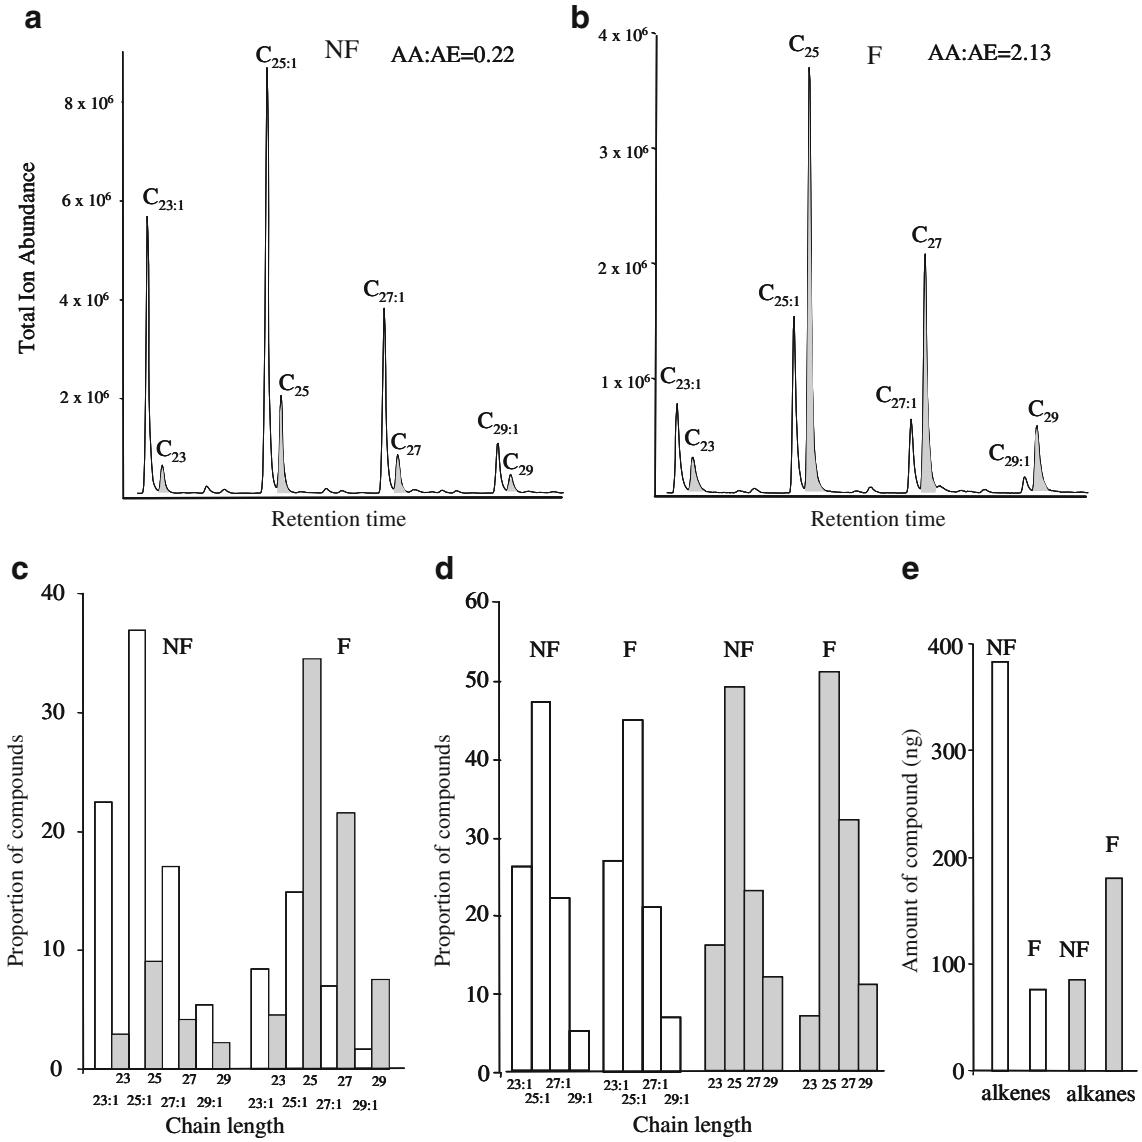

Fig. 2 A CHC profile of **a** a nonforager (*NF*) and **b** a forager (*F*) of the same colony (no. 2) that have very different *n*-alkane (*AA*)/alkene (*AE*) ratios. **c** The same nonforager and forager profiles remain distinct after normal standardization (i.e., proportions are calculated from total peak area). **d** However, when the proportions of each compound are calculated from the total peak area of those compounds belonging only to the same homologous series, the alkene proportions become stable despite **e** the two nestmates possessing very different amounts of alkenes. Throughout, *n*-alkanes (C_n) are shown as *gray peaks* or *bars*, whereas alkenes ($C_{n:1}$) are either *white peaks* or *bars*

the increased amounts of *n*-alkanes that help to protect foragers may have been co-opted in some species (e.g., *P. barbatus*) as a cue used by the colony thus modulating forager numbers (Greene and Gordon 2003). In this study, we showed that morphologically similar individuals can possess different chemical profiles, depending on their task. Pharaoh ants have morphologically identical ants that perform different behavioral tasks, e.g., "path finding"; such ants have chemically distinct profiles (Jackson et al. 2007). As the conveyance of information by chemical cues is a common mode of communication among insects, we expect many more of these "chemotypes" to exist, especially among social insects that possess a diverse array of chemical signals.

The presence of different proportions of two or more chemotypes within a sample has implications for the interpretation of results. It means that the CHC profiles can look very different among nestmates (Fig. 2a–c). The clear differences in amounts of *n*-alkanes between foragers and nonforagers allowed us to estimate the proportion of foragers sampled from the mound surface in ten *F. exsecta* colonies previously sampled (Martin et al. 2008a), and this ranged widely from 10% to 70%. This variation may be due to colony disturbance during ant collection since, once the colony is disturbed, many ants appear suddenly on the mound's surface. However, it means that the ratio of chemotypes within a sample can be highly variable (Fig. 2a,b), and this may generate misleading results (Martin and Drijfhout 2009). However, such variability (Fig. 2a–c) either disappears (alkenes) or is reduced greatly (*n*-alkanes) when the two groups of compounds are dissociated and then analyzed separately (Fig. 2d) or when ants are grouped correctly into foragers and nonforagers from the same nest. As expected for a nestmate signal, the colony-specific alkene ratio of two nestmates remained consistent irrespective of task [e.g., forager vs nonforager (Fig. 2d)], despite large differences in the amount of alkenes produced by each individual (Fig. 2a,b,e). Furthermore, intracolony variability in the alkene ratio is always lower than that of alkanes (Martin et al. 2008b), and there is only poor or no correlation between the total amounts of alkenes vs *n*-alkanes (this study) or between alkenes and *n*-alkanes of the same chain-length (Martin and Drijfhout 2009). This suggests that, for *F. exsecta* chemical communication, it is the distribution (ratios) of alkenes of different chain lengths (ratio of $C_{23:1}$ to $C_{25:1}$, $C_{25:1}$ to $C_{27:1}$, etc.) and not the total amount of alkenes that is important, whereas the opposite appears to be the case for the *n*-alkanes. Furthermore, Yamaoka (1990) found that, when a *Formica* sp. No. 5 (*Formica hayashi*) colony was made queen-less, the CHC profile of individual workers became highly variable. This increase in CHC variability was restricted, however, to the *n*-alkanes, whereas the amount of alkenes remained stable, thus maintaining the colony-specific profile. All these results suggest that the alkene chain length ratios remain stable among nestmates, whereas the *n*-alkanes are more labile, and as such, cannot be involved in nestmate, kin, or patriline recognition as has been suggested for honeybees (Arnold et al. 1996) and ants (Boomsma et al. 2003).

The fundamental functional differences and roles between *n*-alkanes (water-proofing) and alkenes (recognition signal) may help explain the consistent discrepancies found between the CHC profile and the profile within the postpharyngeal gland (PPG). The PPG is an exocrine gland unique to ants and is believed to be involved in pheromone communication (Soroker et al. 1995). In previous studies (Bagnères and Morgan 1991; Soroker et al. 1995; Akino et al. 2004), the proportions of *n*-alkanes were consistently higher on the cuticle than in the PPG gland. We suggest that *n*-alkanes also may be secreted directly onto the cuticle via various subepithelial glands known to exist in ants (Gobin et al. 2003), whereas compounds used in nestmate recognition, e.g., alkenes, may be sequestered and exchanged via the PPG.

In summary, the CHC profile of *F. exsecta* is composed of two distinct groups of components: an *n*-alkane part that varies among individuals depending on task, and a (*Z*)-9-alkene nestmate signal that remains stable across all colony members (Martin et al. 2008a). The task-driven profile changes associated with foraging are influenced by the environment, whereas nestmate- and species-recognition cues are genetically influenced since they remain stable irrespective of the environment changes either at a local [e.g., forager vs nonforagers (this study)] or geographical scale (Martin et al. 2008c). Thus, the CHC profile of *F. exsecta* is composed of both genetically (alkenes) and environmentally (*n*-alkanes) driven components.

How Reliable is the Analysis of Complex Cuticular Hydrocarbon Profiles by Multivariate Statistical Methods?

Stephen J. Martin · Falko P. Drijfhout

Received: 24 July 2008 / Revised: 08 December 2008 / Accepted: 12 February 2009 / Published online: 5 March 2009

Abstract Numerous recent studies have correlated cuticular hydrocarbon profiles with a wide range of behaviors, particularly in social insects. These findings are wholly or partly based on multivariate statistical methods such as discriminate analysis (DA) or principal component analysis (PCA). However, these methods often provide limited insight into the biological processes that generate the small differences usually detected. This may be a consequence of variability in the system due to inadequate sample sizes and the assumption that all compounds are independent. A fundamental problem is that these methods combine rather than separate the effects of signal components. By using cuticular hydrocarbon data from previous social insect studies, we showed that: (1) in 13 species of *Formica* ants and seven species of *Vespa* hornets, at least one group of hydrocarbons in each species was highly ($r^2>0.8$) correlated, indicating that all compounds are not independent; (2) DA was better at group separation that PCA; (3) the relationships between colonies (chemical distance) were unstable and sensitive to variability in the system; and (4) minor compounds had a disproportionately large effect on the analysis. All these factors, along with sample size, need to be considered in the future analysis of complex chemical profiles.

Introduction

During the past 15 years, there has been an explosion of studies correlating cuticular and glandular chemical profiles with a wide range of behaviors across a broad range of species. Social insects (ants, bees, termites, and wasps) in particular have been shown to possess complex chemical profiles correlated with complex behaviors, and these have been the focus of numerous studies (see reviews by Lenoir et al. 2001; Howard and Blomquist 2005). Due to the widespread availability of gas chromatography (GC) and GC-mass spectrometry (MS) machines, the vast majority of these studies have focused on cuticular hydrocarbons (CHC). CHC occur on the external surfaces of all insects (Lockey 1988) and have been implicated in recognition at various levels of organization mediating many key behaviors, such as aggression and altruism among species, nestmates, and kin. The majority of these findings have been based on multivariate statistical methods such as discriminate (DA) (e.g., Dapporto 2007) or principal component analysis (PCA) (e.g., Steiner et al. 2007). More novel methods that use genetic algorithms (Lavine et al. 2003), self-organizing maps (Steiner et al. 2002), and neural networks (Bagnéres et al. 1998) have been used with varying degrees of success.

CHC profiles often consist of 20–100 individual compounds, and this high degree of data dimensionality makes it difficult to interpret the relationships among compounds and differences among individuals or colonies without reducing data to fewer dimensions. This is compounded by the fact that, with the exception of sex pheromones, very

few compounds or profile components have been identified that have been linked directly with the observed behavior, e.g., nest-mate discrimination (Akino et al. 2004; Martin et al. 2008a). Furthermore, many signals used for species, colony, kin, fertility, or task recognition appear to be encoded by using the same shared components of the CHC profile (Denis et al. 2007). This makes isolation of the various signal components difficult, and we are only just starting to understand how these various signals are encoded (Martin et al. 2008a, b, c).

The advantage of multivariate statistical methods is that highly complex data sets are reduced to a single data point, which can be visualized in relation to other data points and interpreted by the investigator in light of the observed behavior. This is a powerful feature of these methods because they can detect small differences among groups, which are particularly useful for chemical ecologists studying the complex CHC patterns of social insects. However, these methods often have provided limited insight into the biological processes that generate the differences. Most often, isolated compounds subsequently have failed to produce the expected behavioral response when bioassayed (G. Jones and T. Monnin, personal communication). The central problem is that multivariate statistical methods combine rather than separate out the effects of signal components, which can produce unstable results. As recognition signals in ants, and probably many other insects, are known to consist of several compounds, those ratios are stable at a certain level, e.g., colony (Akino et al. 2004; Martin et al. 2008a, b) or species (Martin et al. 2008c). DA then is a good method to demonstrate group differences. However, this may be appropriate only if other types of variation that originate from other signals or extraneous sources are eliminated, since the strength of DA and PCA can also be the weakness. That is, the results of DA/PCA reflect *all* the variation in the system, and it is becoming more apparent (Greene and Gordon 2003; Martin et al. 2008a) that various signals are encoded only in part, rather than all, of the profile.

In almost all studies, each peak (compound) in a profile is treated as an independent variable. Normally, the number of samples per group must exceed the number of variables (predictors or peaks). This basic statistical rule is overlooked routinely by both investigators and reviewers. In fact, when using multiple regression methods, the ratio of observations to independent variables should not fall below five (Bartlett et al. 2001), with ten observations to each independent variable being optimal (Halinski and Feldt 1970; Miller and Kunce 1973). This is especially critical when using continuous data, like that generated in CHC studies. It is common that ratios lower than one are used, and so there is a risk of overfitting, meaning that results cannot be generalized (Hair et al. 1995). The same ratio considerations apply to PCA, since an increase in sample size decreases the level at which an item loading on a factor becomes significant. Therefore, an analysis should not be done with less than 100 observations (Hair et al. 1995).

It is often the case that prior knowledge of the data classification is known (e.g., colony type), and in those cases, DA should be preferred over PCA, as this method guarantees the optimal separation among the clusters. Indeed, where the data are prestructured, the principal components are evidently known. In fact, PCA does not consider the cluster structure at all, and there is no guarantee that the resulting projection will separate clusters (Sanguinetti 2008).

In general, each of the compounds found in a CHC profile is assumed to be unrelated to other compounds. However, it has long been known (Lockey 1988), but overlooked, that the majority of CHC (alkanes, alkenes, and monomethylalkanes) belong to homologous series in which the chain length increases by two carbons (e.g., C_{25}, C_{27}, C_{29}). The positions of double bonds or methyl groups are also known to remain constant (e.g., $3MeC_{25}$, $3MeC_{27}$, $3MeC_{29}$). There is, thus, a strong probability that compounds within these homologous series may be correlated, as they share common biosynthetic pathways (Morgan 2004). This leads to multicollinearity problems and unstable results if multivariate methods are used (Field 2005).

The aim of this study was to use data from previous social insect studies to investigate: (1) if high levels of correlation among compounds within the CHC profiles exist and (2) how changing the variability of the signals both within a group and among groups affects the resulting DA and PCA analysis, by using a two-signal model based on the ant *Formica exsecta*. The nest-mate signal in two closely related species of ants *Formica japonica* (Akino et al. 2004) and *F. exsecta* (Martin et al. 2008a) is based on the unique colony distribution of (Z)-9-alkenes. Both these species have a simple CHC profile that consists of a single homologous alkane and alkene series. Intracolony variation in the amount of alkanes is variable since foragers have higher amounts of alkanes than nonforagers (Martin and Drijfhout 2009). This means that the two-signal model is realistic; (3) the effect of minor compounds on the DA analysis of actual *F. exsecta* data to test how well the known colony-specific compounds are correctly identified in the structure matrix.

Methods and Materials

Relationship among Compounds From 2005 to 2007, large CHC data sets have been amassed for 13 species of *Formica* ants predominantly from Finland (565 individuals) (Martin et al. 2008c) and from seven species of Japanese

hornets (*Vespa*) (142 individuals) (Martin et al. 2008d). For each species (Table 1), at least 15 individuals from three different colonies were analyzed. The data for each individual exists in three forms: (1) the relative amounts of each compound reported as the number of ions contained beneath the peak, (2) the proportion (%) of each compound with respect to the total amount ions detected from those individual, and (3) the transformed proportions from using the method of Reyment (1989) and Aitchison (1986):

$$Zi,j = \mathrm{Ln}[Yi,j/g(Yj)]$$

where Yi,j is the area of peak i for the individual j, $g(Yj)$ is the geometric mean of the areas of all peaks for individual j, and Zi,j is the transformed area of peak i for individual j. These three data blocks were arranged in Microsoft® Excel spreadsheets so that correlations among compounds could be compared across individuals from the same colony or species by plotting the values on a scatter graph and using the linear trend line function to calculate the r^2 value. We compared the predominant compounds that occurred within each species.

Table 1 Correlations (r^2) between relative amounts of two consecutive hydrocarbons within a homologous series from *Formica* ants and *Vespa* hornets

Compound	r^2	Species
Alkanes		
C_{21} to C_{25}	>0.84	*F. cinerea*
C_{23} to C_{31}	>0.91	*F. aquilonia*
C_{25} to C_{31}	>0.97	*F. lugubris*
C_{23} to C_{33}	>0.90	*F. polyctena*
C_{23} to C_{33}	>0.88	*F. pratensis*
C_{23} to C_{29}	>0.80	*F. candida*
C_{27} to C_{33}	>0.92	*F. uralensis*
C_{27} to C_{33}	>0.93	*F. truncorum*
C_{23} to C_{27}	>0.90	*F. fusca*
C_{25} to C_{31}	>0.98	*V. mandarina*
C_{21} to C_{25}	>0.84	*V. dybowskii*
C_{27} to C_{33}	>0.89	*V. ducalis*
C_{25} to C_{27}	>0.88	*V. simillima*
Alkenes		
$C_{23:1}$ to $C_{31:1}$	>0.94	*F. candida*
$C_{23:1}$ to $C_{29:1}$	>0.91	*F. lemani*
$C_{23:1}$ to $C_{29:1}$	>0.95	*F. exsecta*
$C_{27:1}$ to $C_{31:1}$	>0.82	*F. lugubris*
$C_{25:1}$ to $C_{27:1}$	>0.92	*F. sanguinea*
$C_{27:1}$ to $C_{29:1}$	>0.98	*V. simillima*
$C_{27:2}$ to $C_{29:2}$	>0.98	*F. candida*
Mono-methyl alkanes		
3-Me C_{23} to C_{29}	>0.91	*V. crabro*
3-Me C_{27} to C_{29}	>0.98	*V. affinis*
3-Me C_{23} to C_{25}	>0.90	*F. fusca*
3-Me C_{23} to C_{29}	>0.94	*F. lemani*
7-Me C_{21} to C_{25}	>0.87	*F. cinerea*
9,11,13-Me C_{23} to C_{31}	>0.83	*F. sanguinea*
9,11,13-Me C_{25} to C_{35}	>0.93	*F. aquilonia*
9,11,13-Me C_{23} to C_{29}	>0.90	*V. simillima*
13-Me C_{26} to C_{30}	>0.81	*F. rufa*
Di-methyl alkanes		
7,15 diMe C_{21} to C_{25}	>0.88	*F. cinerea*
11,15 diMe C_{27} to C_{29}	>0.98	*V. analis*
10,18 diMe C_{30} to C_{34}	>0.93	*F. aquilonia*

For example, C_{21} to C_{25} indicates that C_{21} vs. C_{23} and C_{23} vs. C_{25} both had r^2 values greater than 0.84.

Two-Signal Model We modeled a two- (nest-mate and task) signal system based on the ant *F. exsecta*. We constructed five groups (colonies), each of which contained 10 individuals (ants) that had a profile composed of two independent signals (S_1=nest-mate and S_2=task). Each signal was composed of four variables (compounds), whose ratios can be correlated (constant within a group) or not correlated (highly variable). During the simulation, five unique group profiles (distributions) were used. An example of how two different groups with the least and most amount of intragroup signal variation were constructed is shown in Fig. 1. When the intra- or intercolony signal was constant, we added a small (<3%) amount of variation to the proportion of each compound because multivariate statistical analysis is obviously not possible if no variation in the data exists.

For each model run, we constructed 50 individual (ant) profiles that were grouped into their five respective groups (colonies). For each individual, the values of the eight compounds that make up the two signals were combined, and the proportion of each compound was recalculated since proportions are always calculated by using all peaks present. These data were geomean-log transformed and analyzed by using both discriminant analysis (DA) function in SPSS v.14 and principal components and classification analysis (PCA) function in Statistica v. 6, the first and second factors plotted. The DA used a grouping variable where all independents were entered together with a within-group covariance matrix. The PCA analysis was based on correlations and variances computed as $SS/(N-1)$, and no grouping variable was used. Different combinations of within-group (large vs. small) and between-group variation in the signals were investigated. Additionally, it is known that the relationship between two different signals does not always remain constant across all members of a group (Martin et al. 2008a), so we also measured the effect on the DA and PCA analysis when the ratios of the two signals

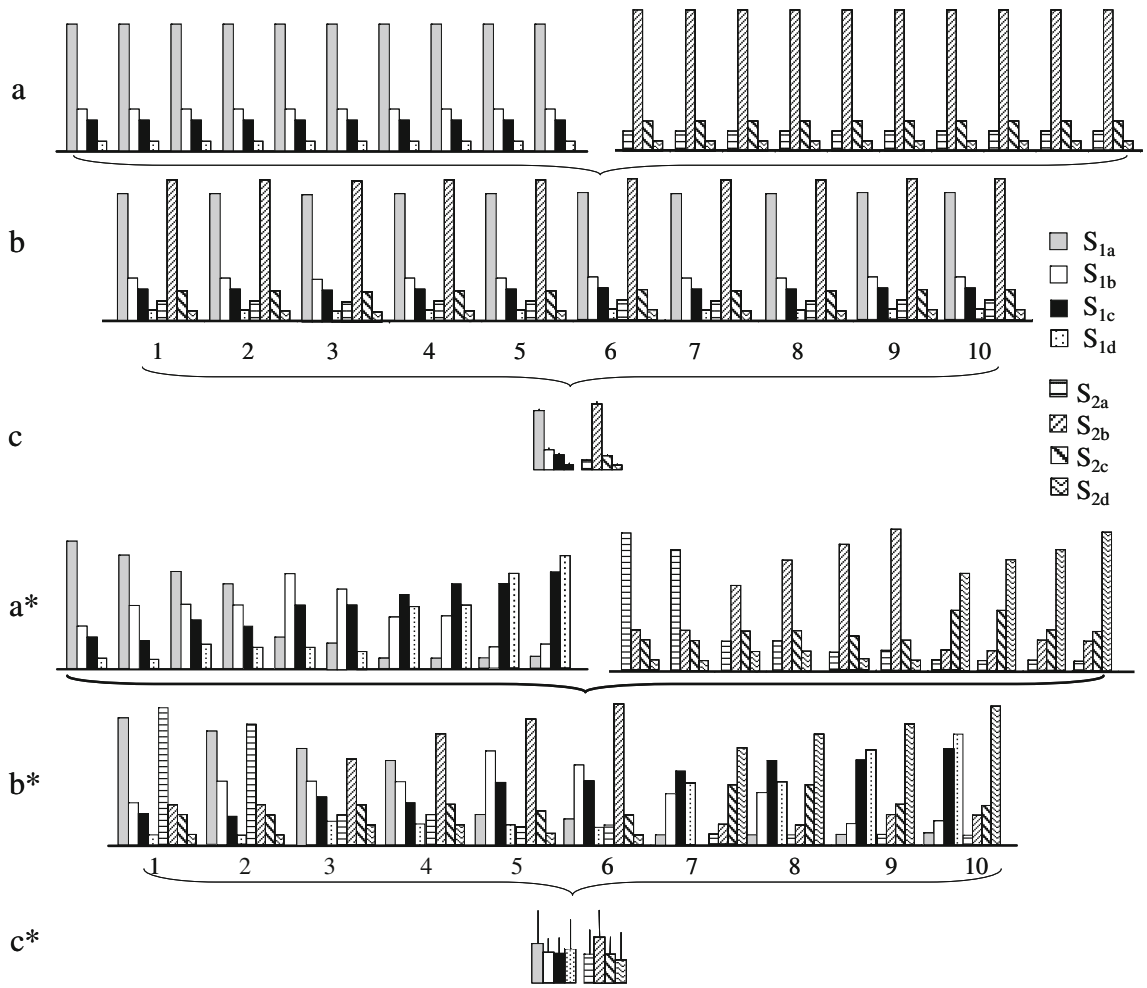

Fig. 1 The composition of two groups in which the two signals are either constant (**c**) or highly variable (**c***). Each group member (**b**–**b***) has a profile containing two signals S_1 and S_2 (**a**–**a***) that are in turn composed of four compounds ($S_{1a–d}$, $S_{2a–d}$). Each group (**c**) is composed of 10 individuals that have a similar (**a**, **b**, **c**) or different (**a***, **b***, **c***) profiles. The four compounds of each signal will be highly correlated in (**c**) and not correlated in (**c***)

(S_1 and S_2) remained constant (1:1) or varied (1:0.3–3) within each group. This is extraneous variation since it is totally dependant on the composition of the group sampled and arises from sampling morphologically identical individuals that represent different chemo-types. For example, individuals engaged in some task or with a specific physiological state may have part of a profile that is chemically distinct (Jackson et al. 2007).

Effects of Minor Compounds By using real data from five *F. exsecta* colonies that were analyzed in the same way as above, we compared the DA results when eight major CHC were analyzed, with results when six minor components were added. We then artificially reduced within-group variation in the minor compounds from c. 10% to c. 3% and investigated the effect on group separation under different conditions. We also investigated the structure matrices to see how well known key compounds were identified.

Results

Relationship among Compounds In all 13 species of *Formica* ants and seven species of *Vespa* hornets, at least one group of compounds within a homologous series were highly (r^2>0.8) correlated. Furthermore, these high correlations could occur in any type of homologous series (Table 1). Correlations may sometimes extend across homologous series among compounds with the same chain length, but this feature of the CHC profile is highly variable (Table 2).

The relative amounts of $C_{23:1}$ and $C_{25:1}$ in five different *F. exsecta* colonies was always highly correlated. This correlation persisted when the amounts were converted into proportions after the values were geomean-log transformed (Table 3).

Two-Signal Model In most simulations, both DA and PCA successfully separated out the five colonies, although, as

Table 2 Correlation (r^2) between major compounds with the same chain length but belonging to different homologous series in seven different species of *Formica* ants from Finland and one UK population

The highly correlated values are given in bold.

expected, group differences were consistently better resolved by DA (Fig. 2). DA was able to clearly separate the five groups even when the group differences were small (Fig. 2b), although resolution is lost when extraneous variation was introduced (i.e., between the two signals). However, both methods were unable to distinguish between two or one group-specific signals (compare Fig. 2a and c) or show whether the differences between the group signals were large or small (compare Fig. 2a and b). The entire removal of one of the signals (S_1 or S_2) produced a similar but not identical result, as shown in Fig. 2a–c. As the total amount of signal variation increased, the DA factor scales generally decreased, but not in a consistent way. Also, the relationships among colonies (chemical distance) were unstable as they changed depending on the amount of real or extraneous variability in the system and the method used. For example, the chemical distance between groups 1 and 4 is small when analyzed by DA but large when analyzed by PCA (Fig. 2a).

Effects of Minor Compounds The DA separated out the five different colonies only when major compounds (Fig. 3a) or when all compounds (major and minor) were used (Fig. 3b). However, when the within-colony variation of only the minor compounds was reduced, better separation was obtained (Fig. 3c). When the between-colony variation in all compounds was reduced to <3% for all compounds, no separation occurred (Fig. 3d). The addition of natural levels of variation in only the six minor compounds, however, resulted in colony separation (Fig. 3e). This effect illustrates the power of minor compounds on the analysis. This is supported by the structure matrix data that consistently fail to correctly identify the major alkenes that are known to encode (Martin et al. 2008a) the nest-mate recognition system in this species.

Discussion

We have shown that DA and, to a lesser extent, PCA are good at separating group differences, even when these differences are small (see Fig. 2b). However, they provide limited information about the actual number of signals present. For example, the results are indistinguishable whether one or two distinct signals are present (compare Fig. 2a and c).

Our investigation of *Formica* ant and *Vespa* hornet data illustrates that multicollinearity is a common property of CHC profiles, and it indicates that this is probably a widespread phenomenon. This suggests that compounds share common biosynthetic pathways, particularly in the case of by-products that are likely to be closely linked to the main product. Importantly, where compounds are highly correlated ($r^2>0.8$) within a colony, population, or species, that series of compounds can be treated as a single variable. This approach greatly reduces the data dimensionality of the profile and helps focus in on key compounds, or more correctly, related groups of compounds. It also reduces the requisite number of predictors, meaning that fewer samples are needed. However, the number of samples still must exceed the number of predictors by at least a ratio of five to one (Halinski and Feldt 1970; Miller and Kunce 1973; Bartlett et al. 2001) unless evidence is provided to the contrary. In the future, studies need to be conducted on species where sample size is not a limiting factor, which, in

Table 3 The correlation (r^2) between $C_{23:1}$ and $C_{25:1}$ from five *F. exsecta* colonies where 10 workers were analyzed from each colony

Proportions	0.93	0.93	0.88	0.97	0.91
Transformed proportions	0.99	0.95	0.90	0.98	0.94

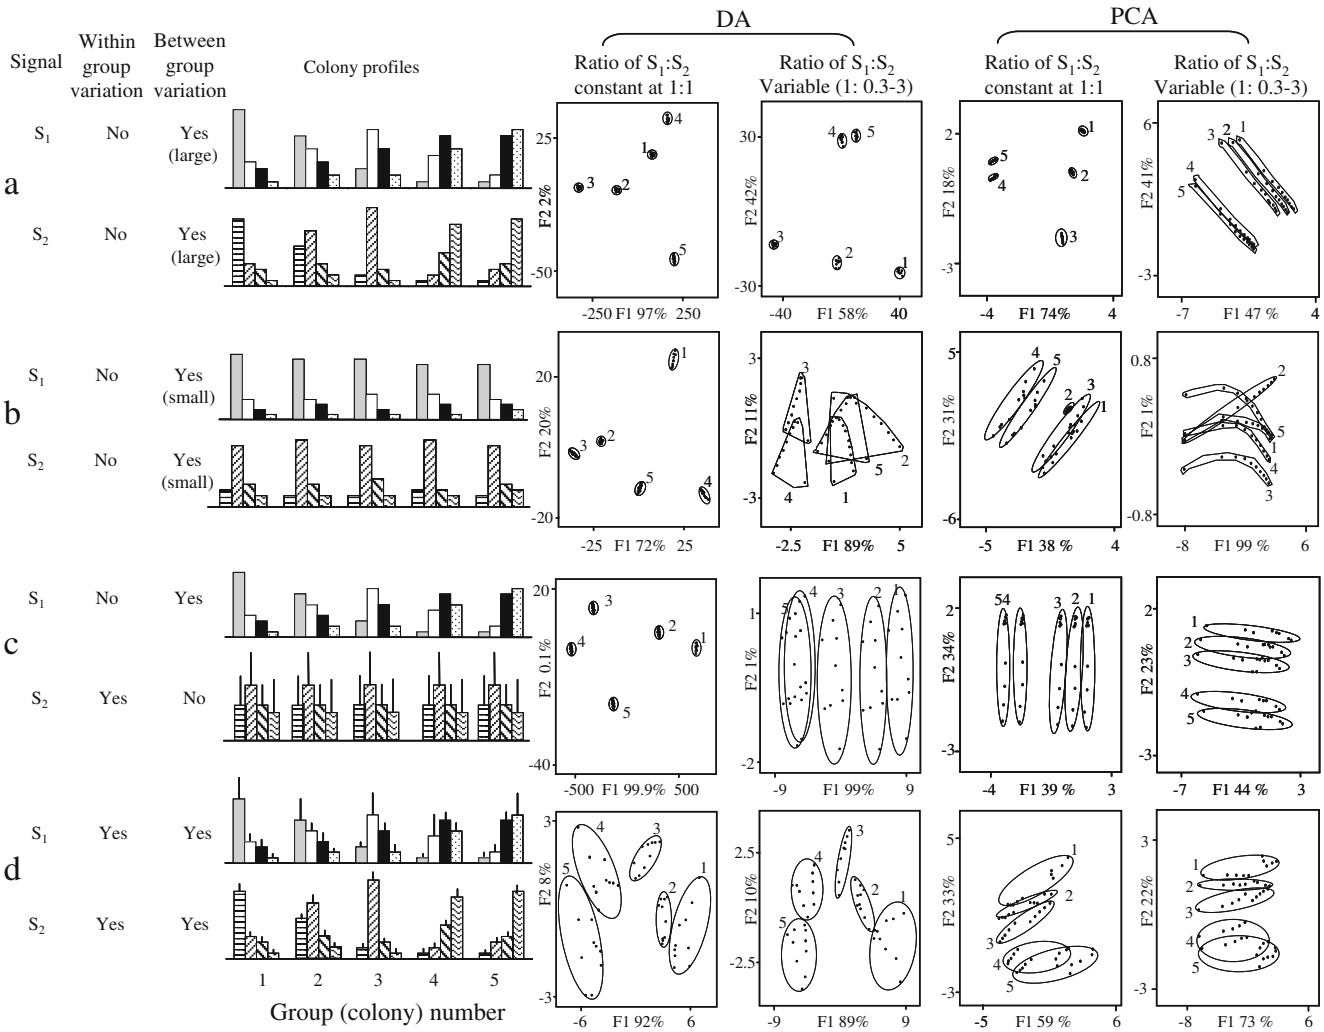

Fig. 2 Effect of varying the amount and type of variation of two signals on the results produced by DA and PCA. For each simulation (**a**–**d**), the histograms illustrate the five group signals, with the *error bars* representing the SD. Only error bars are shown were the error is >3%. The resulting combined plots obtained by DA and PCA are shown when the ratio of the signals (S_1:S_2) was both variable and constant. All 10 data points for each group are enclosed within a *line*

the case of many social insect species, should not be a problem. The downside of multicollinearity is that it violates the equal intraclass covariance assumption that underpins DA and PCA (Sanguinetti 2008), thus making the results of multivariate statistical methods unstable and sensitive to small changes. Thus, PCA/DA is sensitive to small changes, especially background noise. As we have shown, the addition of minor compounds, and their variation (Fig. 3) or variation between signals (Fig. 2), alters both the scale and the intergroup relationships, thus making interpretation of the results unstable. Furthermore, researchers also must be aware that increased collinearity among compounds raises the chances of encountering type II error, and the transformation of the data does not remove this multicollinearity problem (Table 3).

When compounds cannot be integrated, due to their absence or because they lie below the instrument detection limit, then a small nominal value must be used during the data transformation since a geomean cannot be calculated if zeros are present (Steiner et al. 2007). Therefore, potential qualitative differences are not reflected in the analysis, and these transformed nominal values will reduce the amount of variation among minor compounds and possibly increase the chemical distance between existing groups (see Fig. 3). Chemical distances among groups are highly unstable as they are sensitive to the amount of variation in the system and even the method used (Fig. 2a). They are only really robust when only one known signal is being analyzed.

These potential problems should be considered before employing multivariate statistical methods that are often systematically used. Only by separating out the various signals can the signals contained within the CHC profile be decoded. It is becoming apparent that different species use different methods to encode recognition signals

Fig. 3 The effect of minor compounds on the analysis is illustrated using real data from five *F. exsecta* colonies. **a** Uses only the eight major compounds; **b** uses both the eight major and six minor components, i.e., with values <2%, which vary naturally; **c** uses the same compounds as **b**, but the within-group variation of the six minor compounds is reduced; **d** between-colony variation is low in all compounds, whereas in **e**, between-colony variation is present only in the minor compounds. Each *panel* illustrates the actual alkane and alkene colony profiles, the resulting DA, and the structure matrix, which gives the pooled within-groups correlations between discriminating variables and standardized canonical discriminant functions. The major compounds known to be used in nest-mate recognition in this species (Martin et al. 2008a) are shown in *bold*. *Asterisks* mark the largest absolute correlation between each compound and any discriminant function

(Martin et al. 2008b). Currently, there is no suitable method that will easily reveal these mechanisms, and this includes DA because it produces no reliable information about the composition of the signal (Fig. 3). Study of the various parts of the profile is more biologically relevant since different groups of hydrocarbons are perceived differently, e.g., alkanes vs. alkenes (Chaline et al. 2005; Dani et al. 2005). This means that the profile perceived by the insect and that produced by the GC-MS are not congruent. Simple regression analysis has begun to reveal

(Martin et al. 2008b) that apparently complex CHC profiles are in fact a mixture of correlated and non-correlated compounds. The study of their relationships across many individuals and the use of methods such as electroantennagrams are starting to help us decode the signals contained within these profiles.

Milieu-Dependent Pro- and Antioxidant Activity of Juglone May Explain Linear and Nonlinear Effects on Seedling Development

V. Chobot · F. Hadacek

Received: 3 December 2008 / Revised: 27 January 2009 / Accepted: 10 February 2009 / Published online: 5 March 2009

Abstract Juglone, 5-hydroxy-1,4-naphthoquinone, is known for its wide range of biological activities. It has been suggested that juglone's excellent redox cycling properties contribute to this reputation. Many biological activities are nonlinear with low concentrations exerting stimulating effects, whereas only higher concentrations cause inhibition. Here, we corroborate studies on the nematode *Caenorhabditis elegans* that point out hormetic effects by showing that juglone may cause a nonlinear effect on postgerminative shoot and root growth of *Sinapis alba*. This effect was only significantly visible, however, when seedlings were stressed with methanol. Classic and modified versions of the deoxyribose assay were applied successfully to characterize antioxidative (purposeful generation of hydroxyl radicals) and prooxidative (no purposeful generation of hydroxyl radicals) activities. Variants of the assay with and without the addition of the iron chelator EDTA showed that the antioxidant activity is independent on chelation of iron ions by juglone; by contrast, the strength of the prooxidative activity depended on the chelation of iron ions by juglone. The hormetic effects of lower concentrations on germination of *Sinapis alba*, thus, may be caused by the antioxidant activities of this compound, which are especially effective when the test organism is subjected to higher oxidative challenge. The present study suggests that pronounced prooxidative activities, which are considerably accelerated by chelation of iron ions, may contribute to the toxic effects of juglone at higher concentrations.

Introduction

Although the need for greater use of modern technology and additional research on allelopathic mechanisms has been articulated (Romeo 2000), this area remains somewhat neglected relative to traditional phytotoxicity experiments. A few recent studies include those on: juglone effects on root plasma membrane H^+ ATPase activity and root water uptake (Hejl and Koster 2004); the use of polydimethylsiloxane materials to quantify levels of the photosynthesis inhibitor sorgoleone in the rhizosphere of sorghum plants (Weidenhamer 2005); the critical evaluation of the contribution of (±)-catechin to invasion success of spotted knapweed (Blair et al. 2005, 2006); degradation of soluble phenolics by ectomycorrhizal fungi, thus controlling species interactions in black spruce stands (Zeng and Mallik 2006); selective phytotoxicity of L-DOPA because of differential polyphenol oxidase activity in barnyard grass and lettuce, thus mediating reactive oxygen species and/or free radical species (Hachinohe and Matsumoto 2007); and differential gene expression in rice under low nitrogen due to stronger activation of genes that function in synthesis of allelochemicals (Song et al. 2008).

Often, we do not pay much attention to studies carried out many decades ago, simply because, compared to current standards, the methodologies have dramatically changed. Hans Molisch is generally regarded as the person coining

the term allelopathy. In his experiments, he used the odor of apple peels, mainly comprised of ethylene, as a model system to explore effects of volatile emissions on the development of a range of plant species. He reported the results in his famous booklet "Der Einfluß der Pflanze auf die andere, Allelopathie" (the effect of one plant on another, allelopathy); there also exists an English translation (Molisch 2002). Molisch's observations contain some fundamental insights, which are still under discussion today. In the summary, Molisch notes: "If seedlings are only exposed to the gas emitted by apples a relatively short time, then it becomes evident, that not an inhibition of longitudinal growth occurs but a very pronounced stimulation. Exposure to apple odor for one to five hours caused an unambiguous stimulation, whereas 24 hours caused a slight inhibition that became more pronounced with ongoing exposure". He also provides an interpretation: "Here, the often observed rule is confirmed that poisons and irritating compounds are harmful in higher concentrations, but stimulate in diluted form". The last sentence is especially notable, because Molisch (1937) already acknowledges a nonlinear mode of action for allelochemicals. In many instances, the response of living organisms to abiotic or biotic effectors is nonlinear, i.e., at low dosages the response is opposite to that of high ones; high doses inhibit growth and low doses stimulate growth. The latter phenomenon is also known by the term hormesis (Calabrese et al. 2007). Although it has been known for a long time, it has been largely ignored because nobody could explain it (Stebbing, 1982). Allelopathic studies that address the phenomenon of hormesis are infrequent, and then the phenomenon is addressed usually only peripherally (Romagni et al. 2000; Belz 2008). However, it has been focused on recently in ecological modeling of allelopathy (Sinkkonen 2007). In their recent survey of hormesis in plant biology, Calabrese and Blain (2009) note that allelopathy is a rapidly developing area in plant chemical biology in which hormetic responses of chemical exudates from plant roots are to be considered.

Juglone, 5-hydroxy-1,4-naphthoquinone, is classified as a strong redox cycler with high potential to react with oxygen and its reactive species. Thereby, it interferes with vital cell processes such as photosynthesis, respiration, cell division, and membrane transport (Bertin et al. 2003; Tomilov et al. 2006). Among others, one of the noted harmful effects is the alleged role in the allelopathy of walnut trees (Jose 2002). In an attempt to optimize simple tube assay procedures, thus allowing us to explore the potential redox reactions of allelochemicals, modified variants of the deoxyribose assay were used. This assay was developed as a simple screening method for hydroxyl radical scavengers (Aruoma et al. 1987; Halliwell et al. 1987). The recognized function of juglone as a redox cycler distinguishes this allelochemical as a suitable model for exploring the combined applicability of simple tube assays with biological assays to obtain further insights about the milieu-dependent reactivity of candidate molecules. In this study, the effects of juglone on seedling development of *Sinapis alba* served as the biological assay. In consideration of the proposed role of reactive oxygen species (ROS) in the mode of action of juglone, we used an agar- and filter paper-based growth assay to simulate low and high level of oxidative stress caused by variable additions of methanol (0.2 and 10%, *v/v*, respectively) to the medium. We expected to detect nonlinear effects (hormesis) at higher methanol levels. Hormetic abilities previously have been reported for effects of juglone on the genetic model nematode *Caenorhabditis elegans*; these effects became especially evident when *C. elegans* was pretreated with low dosages of heat, hyperbaric oxygen, or even juglone itself, and then subjected to subsequent stresses of the original or one of the other stressors (Cypser and Johnson 2002).

Materials and Methods

Chemicals All chemicals were obtained from Sigma Aldrich Inc. (St. Louis, MO, USA) unless otherwise stated; water had Milli-Q quality.

Antioxidative Assays Procedures followed those described by Halliwell et al. (1987) and Aruoma (1994) for the deoxyribose assay. Juglone (Fluka, Buchs, Switzerland) was dissolved in an aqueous KH_2PO_4/KOH buffer solution (50 mM, pH 7.4) to yield final concentrations of 2–500 µM. To 125 µl of this solution, 25 µl of a 10.4 mM 2-deoxy-D-ribose solution in the same buffer system and 50 µl of an aqueous solution of $FeCl_3$ (50 µM) were added. In one series of the assay, those 50 µl contained 52 µM EDTA in buffer, and in the other series, only buffer was added. To start the Fenton reaction, various reactants dissolved in the above mentioned buffer systems or in water were added: 25 µl 10.0 mM aqueous solution of H_2O_2 and 25 µl 1.0 mM ascorbic acid in buffer. Standard 1.5 ml sample vials (La-Pha-Pack, Werner Reifferscheidt GmbH, Langerwehe, Germany) were used as reaction vials. The mixture was vortexed and incubated at 27°C for 60 min. Thereafter, 10 µl of 2.5% ethanolic butylated hydroxytoluene solution followed by 250 µl of 1.0% 2-thiobarbituric acid dissolved in 3% trichloroacetic acid were added to each vial to detect malonyldialdehyde, the decomposition product of 2-deoxy-D-ribose caused by the attack of hydroxyl radicals. The vials were vortexed and heated in a water bath at 85°C for 30 min. The reaction was stopped by transferring the vials into an ice water bath for 3 min. To extract the reaction product of malonyldialdehyde

and thiobarbituric acid, 600 µl of *n*-butanol was added and the mixture was rigorously vortexed. The butanol layers of the vials, each 350 µl, were pipetted into flat-bottomed 96-well plates (Greiner, Kremsmünster, Austria), and the absorbance was determined with a microplate reader (Tecan Infinite M200, Männedorf, Switzerland) at 532 nm. Assays were performed in triplicate. Reaction mixtures lacking the test compound served as negative controls. Blank was reactive mixture without 2-deoxy-D-ribose.

Prooxidative Assays This modification of the deoxyribose assay was carried out without the addition of H_2O_2 and ascorbic acid. Reactions of juglone depended strongly on the dissolving of oxygen into the liquid. Thus, scoring was performed after 16 h.

Postgermination Growth Assays (Low Stress Scenario) Seeds of *S. alba* L. were obtained from B and T World Seeds (Paguignan, France) and surface sterilized (1 min in 70% EtOH). Petri dishes (9 cm diam, Greiner Bio-One, Kremsmünster, Austria) were prepared with solidified Murashige and Skoog (MS) basal medium and spiked with a methanolic solution of juglone to provide concentrations of 6–200 µg ml^{-1} juglone in the agar medium. Controls were spiked with methanol alone (0.2% *v*/*v*). Surface-sterilized seeds were transferred to the agar medium with sterilized forceps. Petri dishes were incubated at 25±2°C in dark. After 5 days, control and treated seedlings were photographed with an Olympus D500 digital camera equipped with a 35 mm macro lens (Olympus Corporation, Tokyo, Japan). Image analysis was carried out for shoots and roots separately using Image J 1.36b (Wayne Rasband, NH, USA). Means of the pixel counts of the control seedlings were determined as 100% growth.

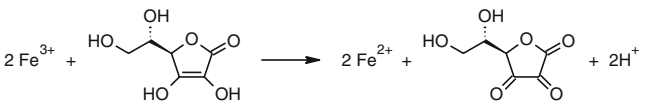
Postgermination Growth Assays (High Stress Scenario) Filter paper disks (Schleicher and Schuell 520 B 1/2, 60 mm diam) were moistened with 1 ml of a 10% methanolic aqueous solution containing the test compound in concentrations of 6–200 µg ml^{-1}. The moistened filter papers were placed in 9-cm Petri dishes. Surface-sterilized seeds were transferred to the filter paper with sterile forceps. Petri dishes were kept sealed for 48 h; then, the sealing tape was removed and the methanol was allowed to evaporate. Water was added to replenish the liquid and to keep the filter paper moistened. Scoring was performed as previously described. The assay was performed in dark at 25°C and scoring was performed after 5 days.

Statistics Statgraphics Plus 5.0 (Statistical Graphics Corp., Rockville, MD, USA) was used for statistics. Mann–Whitney rank test and analyses of variance (ANOVA) with Duncan's multiple range tests were performed at a confidence level of 95%.

Results and Discussion

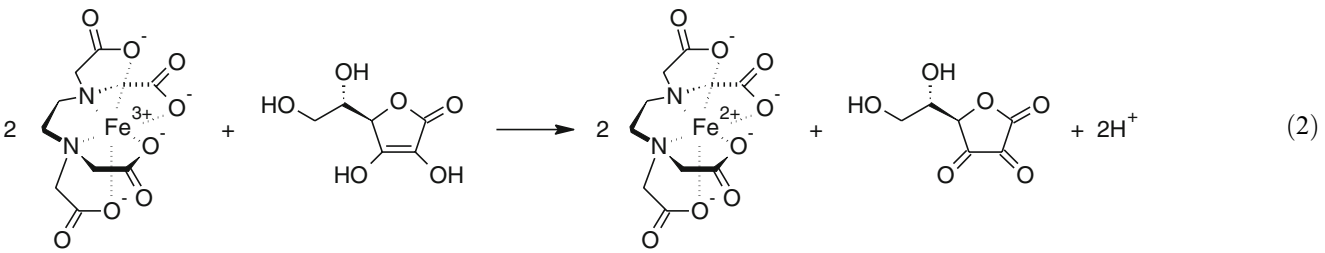
In the following text, we illustrate a number of reactions that aim to support our interpretation of the results obtained from the deoxyribose decomposition assays including one and two electron transfers. We stress that these reactions represent only a selection of possible ones, the majority of which probably are running simultaneously and reversibly. They are aimed at providing evidence that possible reactions exist that support the assay results.

Juglone proved to be a strong scavenger of hydroxyl radicals ($^{\bullet}OH$) in the deoxyribose assay (Fig. 1a). In this setup, ascorbic acid reduces iron (III) to iron (II). Ascorbic acid is oxidized to dehydroascorbic acid (1).



(1)

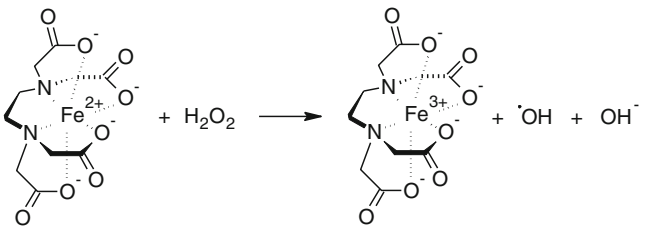
The same assay also was performed with the addition of EDTA, which efficiently chelates the iron ions but does not prevent iron from participating in further redox reactions. Consequently, ascorbic acid also reduced the EDTA-complexed iron (2).



(2)

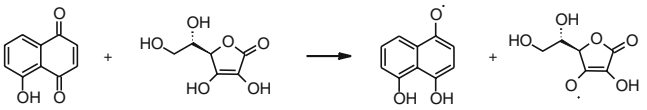
In our setup of the assay, the antioxidant activity was comparable to the variant without EDTA (Fig. 1a). This implies that chelation of iron by juglone does not affect its antioxidant activity. The reduced iron (Fe^{2+}), both in its free form (3) and as complex (4), reacts with hydrogen peroxide in the Fenton reaction and generates hydroxyl radicals, which are strong enough to decompose 2-deoxy-D-ribose to malonyldialdehyde (Aruoma et al. 1987; Aruoma 1994).

(3)

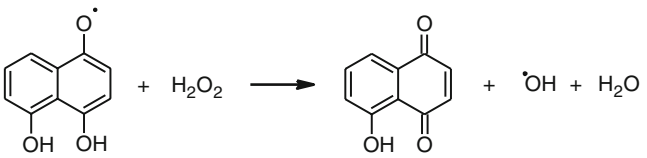


(4)

The hydroxyl radical also may arise by one electron transfers between the semiquinone of reduced juglone and hydrogen peroxide (5, 6).

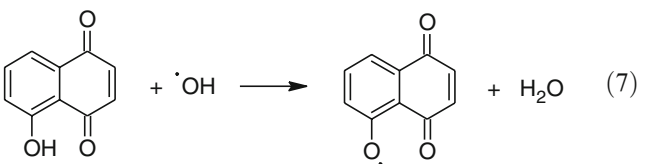


(5)



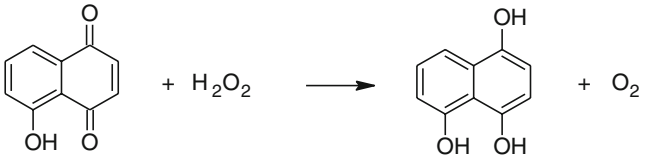
(6)

The fundamental reaction of the antioxidant activity of juglone is most likely the reduction of hydroxyl radicals to water (7).



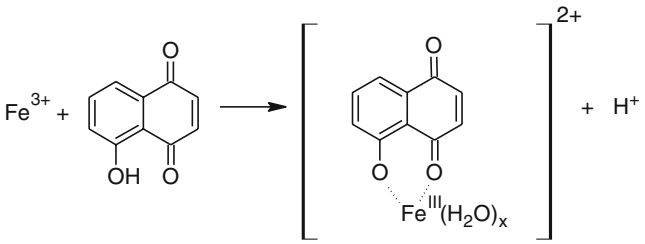
(7)

Alternatively, juglone may oxidize hydrogen peroxide to oxygen and thereby get reduced to trihydroxynaphthalene (8). The latter compound may be a more powerful reducing agent than juglone itself.



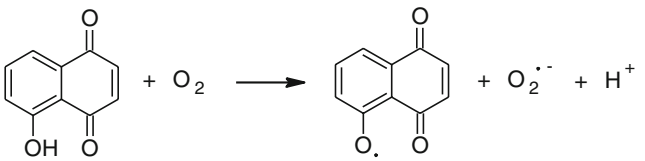
(8)

These reactions are possible at a more or less neutral pH (the pH of the aqueous buffer was adjusted to 7.4, thus resembling the milieu in the cytosol); at a lower pH, such as in the vacuole, they are less likely to work. In neutral milieu, juglone also may chelate iron ions (the chelation is both possible for iron (III) and iron (II) ions; the former are illustrated [9]). However, for antioxidant activity, chelation of iron ions by juglone did not affect the efficacy of the reaction.



(9)

In an attempt to obtain a tube assay that also facilitates the detection of prooxidative effects, the deoxyribose assay was modified. In this variant, hydrogen peroxide and ascorbic acid were not added. The duration of the assay was increased to 16 h to facilitate detection of reactions with oxygen dissolved in the aqueous buffer. Juglone showed a pronounced prooxidative effect as expected (Fig. 1b). Again, two setups were performed, one with addition of EDTA, the other without. However, the prooxidative activity of juglone was much more pronounced if EDTA was not added. This difference merits attention. Due to the absence of low concentration of free radicals, molecular oxygen is reduced to superoxide by juglone (10).



(10)

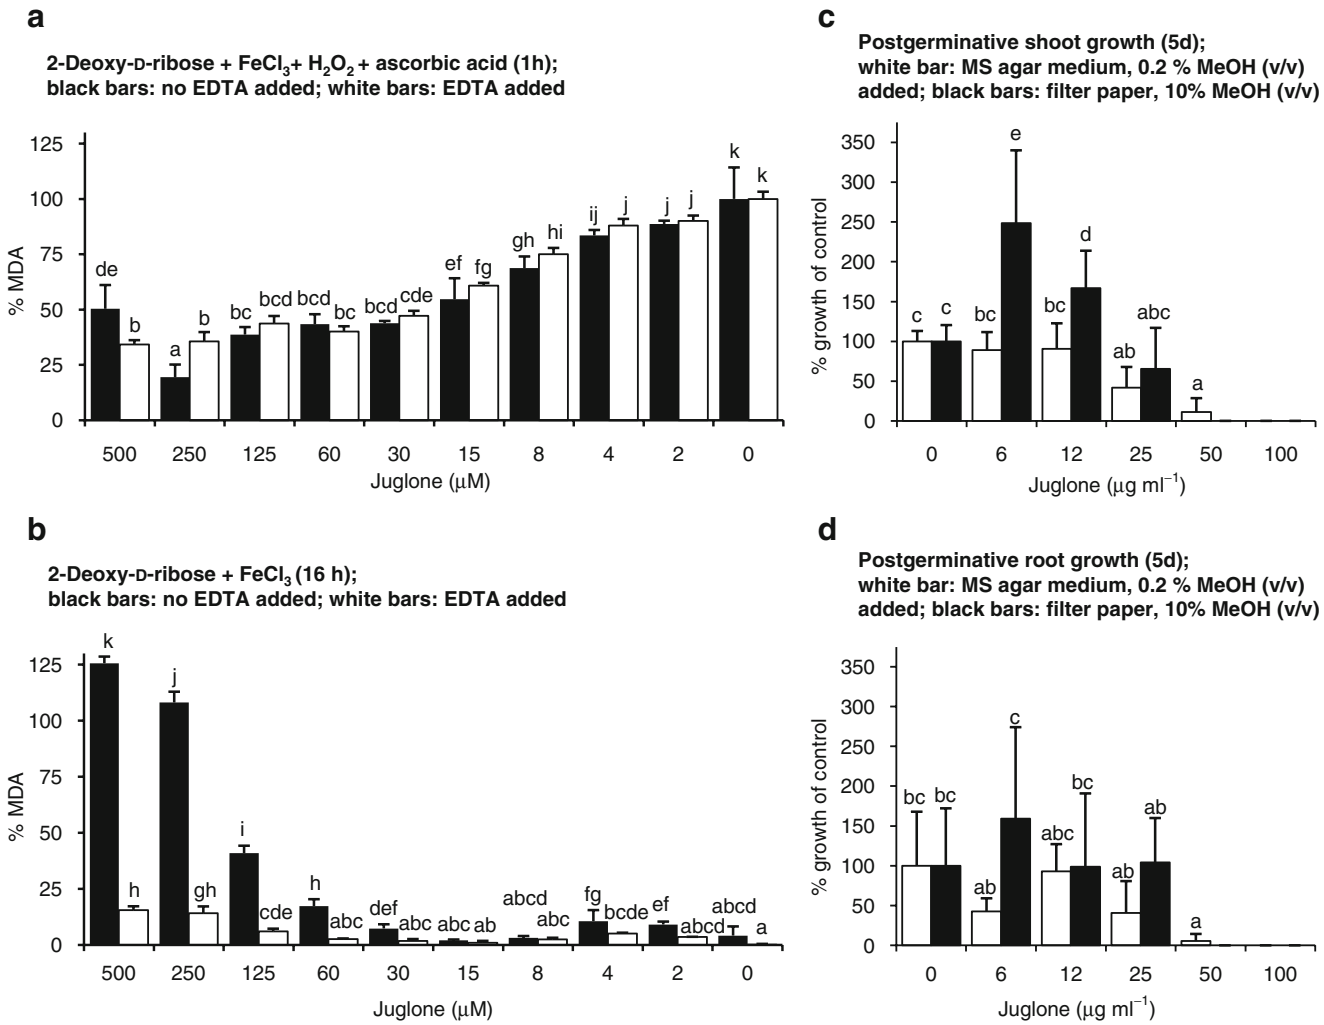


Fig. 1 **a** Antioxidative activity of juglone, quantified in % malonyldialdehyde, an oxidative decomposition product of 2-deoxy-D-ribose; *bars*, means; *error bars*, standard deviation; *N*=3, letters indicate different levels of significance (95% probability, Duncan's multiple range test). **b** Prooxidative activity of juglone; for specific information, see antioxidant activity; scale of 100% MDA scale is the same as in (**a**). **c** Postgerminative shoot growth, quantitative biological assay; *bars*, means; *error bars*, standard deviation; *N*=5; *letters* indicate different levels of significance (95% probability, Duncan's multiple range test). **d** Postgerminative root growth; for specific information, see shoot growth

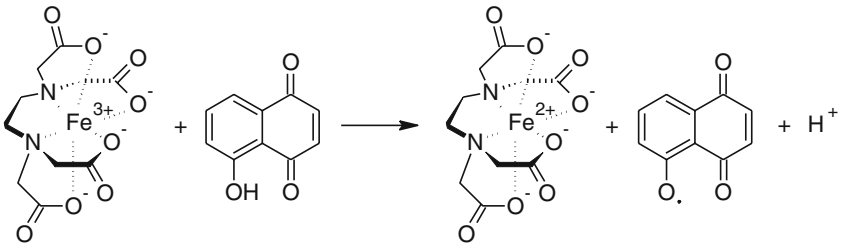
Superoxide can react with itself (dismutation of superoxide, [11]).

$$2\,O_2^{\bullet -} + 2\,H^+ \longrightarrow H_2O_2 + O_2 \qquad (11)$$

Superoxide may also directly react with the formed hydrogen peroxide generating hydroxyl radicals conditional to the presence of iron (12).

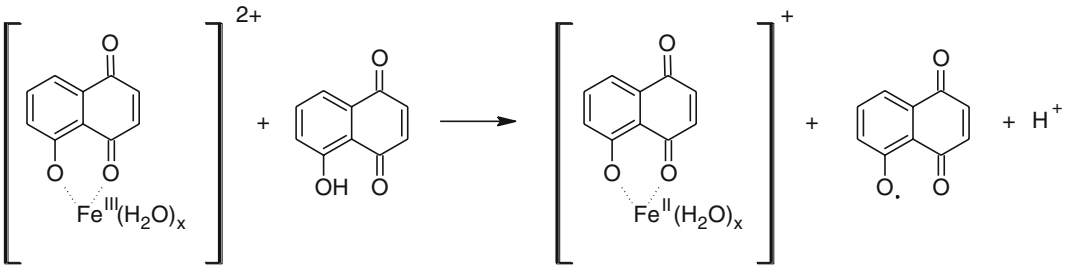
$$O_2^{\bullet -} + H_2O_2 \xrightarrow{Fe^{3+}} O_2 + {}^{\bullet}OH + OH^- \qquad (12)$$

The results suggest that chelation of iron by different molecules affects the electrochemical potential required for reduction of iron (III) (Miller et al. 1990). If EDTA is added, juglone reduces the EDTA complex of iron (III) (13).



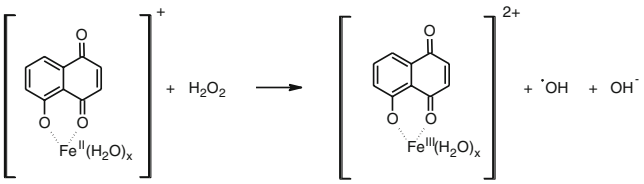
(13)

If no EDTA is added, then iron (III) is chelated by juglone and—as suggested by the pronounced activity visible at higher concentrations tested—reduced to iron (II) in the complex (14).



(14)

For the juglone–iron (III) complex, the required energy for the reduction seems to be considerably lower. As a consequence, more juglone-chelated iron (II) is available for the generation of hydroxyl radicals in a Fenton type reaction (15) than EDTA-chelated iron (II) in the other setup.



(15)

Within the tested range of concentrations, the prooxidative effect was linear. It is possible that the nonlinearity in the antioxidant setup, where no EDTA was added, may be caused by the reactions leading to the prooxidative effect as described above.

By starting from the notion that juglone is an efficient redox cycler, we wanted to explore if juglone might cause nonlinear effects in biological assays, hormesis—a process whereby test organisms exposed to low levels of stress or toxins become relatively more resistant to subsequent challenges. In the present case, we expected low levels of juglone to ameliorate the stress caused by higher methanol concentrations. In vivo oxidation of methanol may generate superoxide, thus causing toxic effects in living organisms. The addition of methanol to aqueous solutions may not only be employed to improve dispersion of lipophilic compounds in aqueous media—as is good laboratory practice—but also to increase stress for the tested organism. Thus, to create a low- and high-stress setup of the postgermination growth assay, *S. alba* was germinated on MS agar medium (<0.2% MeOH) and on filter paper assay (10% MeOH). The results are illustrated by Fig. 1c and d. Shoot size of the seedlings exposed to higher methanol concentration was nearly half the size of seedlings exposed to the low methanol concentration (P=0.005, Mann–Whitney rank test). Figure 1c and d illustrate the postgerminative growth dynamics as % in relation to the control; thus, the inhibitory effect of the higher methanol concentration is not evident, as both means of the control denote 100%.

Root development was not significantly affected by the various methanol concentrations (P=0.689, Mann–Whitney rank test). At lower methanol concentrations (<0.2%), increasing concentrations of juglone inhibited postgermination growth of *S. alba* seedlings clearly affecting the shoot and less evidently the root; 100 μg ml^{-1} completely inhibited germination. The concentration of the solution of juglone in the agar was about 575 μM. At the same concentration range, the deoxyribose degradation assay suggests that juglone may cause a pronounced prooxidative effect when levels of free radicals are low (Fig. 1b). In the filter paper assay (the initial concentration of methanol was around 10%), germination was inhibited at 50 μg ml^{-1} (287 μM). Although, at 6 μg ml^{-1} (34 μM), a significant stimulatory effect was visible (Fig. 1c). This stimulation of lower juglone concentrations was especially visible in the shoot development, which similarly was more affected by higher methanol concentrations. The roots were less affected and, accordingly, were less stimulated by lower juglone concentrations. At the low concentrations where the stimulatory and thus hormetic effect was visible (±30 μM), the deoxyribose degradation assay suggests that juglone may efficiently scavenge present hydroxyl radicals. This also reflects a mitigating effect on the stress when the seeds were exposed to high methanol concentrations.

Cypser and Johnson (2002) observed a similar hormetic effect of juglone in gerontological studies that used the nematode *C. elegans* as a test organism. In that study, pretreatment with the toxin juglone mitigated oxygen stress. Conversely, preceding oxygen stress also mitigated stress caused by the application of juglone. These authors concluded that low levels of initial oxidative stress

obviously mitigate effects of subsequent stressors that cause oxidative stress. Here, we demonstrated that juglone can scavenge hydroxyl radicals generated by Fenton type reactions during oxidative stress in a chemical assay. In our biological assay, a hormetic effect was visible only when seeds of *S. alba* were stressed with 10% methanol in the solution. The results suggest that the hormetic effect of a redox cycling compound (in this regard, juglone represents an efficient example) may be caused by scavenging ROS such as the hydroxyl radical.

Juglone is a potent bioactive compound. Can this compound, however, serve as an effective chemical defense, for example, in the case of allelopathy of the walnut tree? This question is difficult to answer, as it is difficult to develop one ideal assay to measure pro- and antioxidative activities (Halliwell and Gutteridge 1995). Hormetic activity may be determined not only by structural characteristics and concentration, but also—as our results suggest—be facilitated by the milieu in the tissues of the targeted organism. The results presented here provide ideas for explaining hormesis caused by juglone. Evolution may favor such potent redox cyclers. Gene expression studies in *Arabidopsis thaliana* and rice have shown that juglone (Mylona et al. 2007), herbicides such as paraquat and glyphosate (Ahsan et al. 2008), and even hormones such as abscisic acid (Guan et al. 2000), may by generating ROS provoke similar effects in the expression patterns of antioxidant genes. This suggests that common stress-related motifs in the promoters of these genes should be present (Mylona et al. 2007). Studies that assess the effect of allelochemicals on cell cycling (Sanchez-Moreiras et al. 2008) should increase our understanding of allelopathy.

Acknowledgements V.C. and the research carried out in this study were supported by a Lise Meitner fellowship of the Austrian Science Fund (FWF M920-B03).

Ontogenetic Variation in the Chemical Defenses of Cane Toads (*Bufo marinus*): Toxin Profiles and Effects on Predators

Received: 30 October 2008 / Accepted: 11 February 2009 / Published online: 5 March 2009

Abstract We conducted a quantitative and qualitative chemical analysis of cane toad bufadienolides—the cardioactive steroids that are believed to be the principal cane toad toxins. We found complex shifts in toxin composition through toad ontogeny: (1) eggs contain at least 28 dominant bufadienolides, 17 of which are not detected in any other ontogenetic stage; (2) tadpoles present a simpler chemical profile with two to eight dominant bufadienolides; and (3) toxin diversity decreases during tadpole life but increases again after metamorphosis (larger metamorph/juvenile toads display five major bufadienolides). Total bufadienolide concentrations are highest in eggs (2.64±0.56 μmol/mg), decreasing during tadpole life stages (0.084±0.060 μmol/mg) before rising again after metamorphosis (2.35±0.45 μmol/mg). These variations in total bufadienolide levels correlate with toxicity to Australian frog species. For example, consumption of cane toad eggs killed tadpoles of two Australian frog species (*Limnodynastes convexiusculus* and *Litoria rothii*), whereas no tadpoles died after consuming late-stage cane toad tadpoles or small metamorphs. The high toxicity of toad eggs reflects components in the egg itself, not the surrounding jelly coat. Our results suggest a dramatic ontogenetic shift in the danger that toads pose to native predators, reflecting rapid changes in the types and amounts of toxins during toad development.

Introduction

Understanding the pathways by which introduced species modify the ecosystems they invade is a central challenge for conservation biology; unless we understand those effects, we are unlikely to mitigate them. However, the challenge is a daunting one because of the diverse array of mechanisms involved in the ecological impact of invasive species. Some introduced species act as predators, some as competitors, and others as parasites (Sandlund et al. 1999; Mack et al. 2000; Mooney and Cleland 2001; Schlaepfer et al. 2002). Another category of impact involves toxic invaders, species that imperil native species via exposure to toxins lethal to the native taxa. If an invading species belongs to a phylogenetic lineage not represented in the fauna of the invaded area, it may possess toxins to which native predators are naïve and, hence, are unable to tolerate. For example, Australia has no endemic bufonids ("toads"), and the invasion of South American cane toads (*Bufo marinus*; see Frost et al. 2006; Pramuk 2006; Pramuk et al. 2008 for alternative generic allocations) has killed a diverse array of Australian predators (including crocodiles, marsupials, snakes, lizards, and anurans) through poisoning when they attempt to eat the toxic invader (Burnett 1997; Doody et al. 2006; Griffiths and McKay 2007; Crossland et al. 2008; Letnic et al. 2008).

Although conventional wisdom (including publications for the general public from government departments and museums) asserts that all life history stages of cane toads are highly toxic to predators, this generalization is not supported by empirical evidence. Although it is more than a

century since Phisalix (1903, 1922) reported that toxicity of bufonid larvae (*Bufo bufo*) decreased with increasing tadpole stage, few empirical data are available on the toxicity of bufadienolides from cane toads (Lever 2001). This lack of empirical support for the conventional wisdom motivated the present study.

To our knowledge, there have been no previous analyses of the chemical composition of bufonid toxins as a function of ontogeny. The most direct evidence of shifts in toxicity comes from studying the effects of toad eggs and larvae on predators. Crossland and Alford (1998) reported no apparent ontogenetic change in toxicity of cane toads (for example, both eggs and hatchlings of toads were toxic to frog tadpoles but not to crayfish), but their experiments were not designed to focus specifically on ontogenetic shifts. In a more detailed study, Crossland (1998) reported that belostomatid water bugs experienced higher mortality rates from consuming late-stage toad tadpoles than from eating earlier-stage conspecifics. Ontogenetic changes in palatability of toad tadpoles also hint at underlying toxicity (presumably, predators detect and avoid toxins). Several authors have reported that the palatability of toad tadpoles differs among developmental stages (see review by Gunzburger and Travis 2005). For example, Heyer et al. (1975) personally tasted small and large tadpoles of *B. marinus* and reported that larger tadpoles were less palatable. Similarly, Lawler and Hero (1997) found that palatability of cane toad tadpoles to fish (barramundi, *Lates calcarifer*) decreased during ontogeny.

In adult toads, toxins are localized largely in parotid glands, where they can be expressed as a secretion during a predatory event. At the molecular level, the toxic chemicals in cane toad parotid secretions are attributed to steroids known as bufadienolides (Lever 2001). Bufadienolides are not unique to toads and are known to exert a cardiotoxic effect by inhibiting membrane-bound heart tissue Na^+/K^+ adenosine triphosphatase (ATPase; Steyn and van Heerden 1998). The potency and selectivity of toxicity vary among different bufadienolides and with different isoforms of Na^+/K^+ ATPase in different tissues and animal species (e.g., Akimova et al. 2005; Keenan et al. 2005). Given this variability in sensitivity to cane toad bufadienolides, it is impossible to establish a single definitive bioassay—biochemical-, cell-, or animal-based—that measures absolute toxicity. To generate ecologically relevant measures of "overall toxicity," we need detailed analysis not only of the toxin components within each ontogenetic stage but also of their relative toxicity to predators. The latter measures could be obtained in a standard Na^+/K^+ ATPase bioassay, but this is not definitive. A more ecologically relevant assay would be based on actual measures on the predator species of concern (in the case of cane toads in Australia, this would involve taxa such as varanid lizards, crocodiles, and quolls), but this becomes prohibitive (on both logistical and ethical grounds) when each species requires its own optimized assay. Rather than this, we used a chemical approach to assess likely levels of toxicity by measuring the presence and composition of the different bufadienolides. Australian cane toad parotid secretions are dominated by several major bufadienolides (some of which have not been reported previously from parotid secretions), with >90 additional, as yet unidentified, bufadienolides occurring at low concentrations (Hayes and Capon, unpublished). Although many of these minor cane toad bufadienolides are present at concentrations <0.1% of that of the major bufadienolides, bufadienolide potency against Na^+/K^+ ATPase can span several orders of magnitude (e.g., Wallick and Schwartz 1988).

These observations highlight the importance of establishing sensitive analytical methods capable of detecting and quantifying the full complement of cane toad bufadienolides, whether from secretions or whole animals and across all life history stages. The relative toxicity of cane toad eggs, tadpoles, and metamorphs bears directly on the ecological impact of this invasive species. For example, the toxicity of eggs and tadpoles determines the risk of poisoning to aquatic fauna (e.g., fishes, native tadpoles), whereas the toxicity of metamorph toads determines the risks faced by predators that forage for small prey at the margins of breeding ponds (such as adult frogs, small snakes, and waterbirds). Because alternative toxins are likely to be differentially toxic to different types of predators (e.g., vertebrates vs. invertebrates: Crossland and Alford 1998), we also need to document toxin identities. Hence, understanding the distribution of toxin types and contents during toad ontogeny can provide a useful background for interpreting the ecological impact of this invasive anuran. To clarify these issues, we measured toxin content of eggs, larvae, and postmetamorphic toads, and we also monitored mortality of predators exposed to these life history stages.

Methods and Materials

Collection, Preparation, and Chemical Analysis of Samples We obtained four clutches of eggs from captive toads collected in the Townsville region of Queensland (two pairs) and the Adelaide River floodplain of the Northern Territory (two pairs). Spawning was induced by subcutaneous injections of 0.5–0.75 ml of leuprorelin acetate (Lucrin, Abbott Australasia) diluted in amphibian ringers' solution to a concentration of 0.25 mg/ml. Soon after oviposition, we collected fertilized eggs, some of which were frozen and stored at −80°C. After hatching, tadpoles were kept in water conditioned with aquaria water ager at a

pH of 7.5. We fed tadpoles with boiled lettuce *ad libitum* (twice a week) and changed the water weekly.

A subset of tadpoles were euthanized at Gosner (1960) development stages 21, 25, and 44/45 and then stored frozen at −80°C. Tadpoles from each of the four clutches were left to complete metamorphosis, at which time some were frozen (snout–urostyle length [=SUL] 6.0–9.0 mm, mean=8.0 mm; mass=20.2–90.0 mg, mean=48.9 mg), and the remainder were kept separately by clutch in 54-l containers (45×40×30 cm) on a substrate of moist sand and water, with shelter items for refuge. The enclosures were illuminated by fluorescent tubes (photoperiod 12:12 h L/D cycle), with 75% relative humidity, and ambient temperature at 32°C. The toads were fed live crickets *ad libitum*. We cleaned the enclosures weekly and changed the water daily. After 60 days postmetamorphosis, toad metamorphs/juveniles (SUL 14.0–34.0 mm, mean=24.2 mm; mass 0.51–3.59 g, mean=1.73 g) from each of the four clutches were euthanized and stored frozen at −80°C.

To identify and quantify specific bufadienolides, tissue samples from each life history stage from each clutch (N=8) were homogenized (IKA T10 Basic Ultra Turrax with S10N-5G dispersion tool) in water (1 ml). Each homogenate was made up to equal volumes of water and *n*-butanol, and phases were left to separate at 4°C overnight. Samples were filtered with filter aid (Celite), divided into water and *n*-butanol fractions, and evaporated to dryness *in vacuo* at 40°C. The mass of each fraction was determined, and *n*-butanol fractions were diluted to a final concentration of 2 mg/ml with methanol. High-performance liquid chromatography (HPLC) was performed with an Agilent 1100 Series Separations Module equipped with an Agilent 1100 Series diode array detector (DAD) and running ChemStation Rev. B0201SR1 software. We performed electrospray ionization mass spectrometry (MS) using an Agilent 1100 Series Separations Module equipped with an Agilent 1100 Series liquid chromatograph/mass selective detector. HPLC gradient conditions were as follows: 1-ml/min gradient elution from 90% H_2O/MeCN (0.01% trifluoroacetic acid, TFA) to 50% H_2O/MeCN (0.01% TFA) over 20 min, then to MeCN (0.01% TFA) over 5 min, followed by a 5-min flush with MeCN. The HPLC-DAD-MS gradient was identical to above except for the use of 0.05% HCOOH as a modifier in the place of TFA, in order to minimize ion suppression in the negative mode. The column used for both gradients was a Phenomenex Onyx Monolithic C_{18} 100×4.6-mm column.

We inferred the presence of bufadienolides by examination of the UV-Vis spectrum of each peak, with the α-pyrone ring having a distinctive absorption maximum at 297 nm. For those components where the molecular weight could be ascertained, we assigned tentative identity to several of the detected components, based on this molecular weight, the characteristic UV-Vis spectra, comparison of retention time to bufadienolides from adult cane toad parotid secretion [purified and characterized by HPLC-DAD and ^{1}H and ^{13}C nuclear magnetic resonance (Hayes and Capon, unpublished)], and previous reports from this and related toad species (Akizawa et al. 1994; Matsukawa et al. 1994; Steyn and van Heerden 1998).

Bioassay of Toad Palatability and Toxicity We obtained eggs from cane toads collected on the Adelaide River floodplain of the Northern Territory and raised them through to metamorphosis in large outdoor enclosures. To quantify toxicity of eggs, tadpoles, and metamorphs to native predators, we needed a predator that might encounter and consume all stages in the toad's early life history (eggs, larvae, and metamorphs). Tadpoles of native frogs were chosen as predators because field studies show that these animals frequently consume toad eggs and often die as a result (Crossland et al. 2008). Although frog tadpoles rarely kill live toad tadpoles or metamorphs, they readily consume dead tadpoles and metamorphs (Crossland and Alford 1998; Crossland and Azevedo-Ramos 1999; M. Crossland personal observation). Egg clutches of two frog species (*Limnodynastes convexiusculus* and *Litoria rothii*) were collected from the Adelaide River floodplain and raised in large outdoor enclosures. To quantify the level of risk posed by toads at different life history stages, we placed ten eggs, a dead tadpole, or a dead metamorph toad together with a native tadpole (*L. convexiusculus* Gosner stages 25 to 37; snout–vent length [=SVL] 7.21–20.70 mm; *L. rothii* Gosner stages 27 to 38; SVL 9.36–27.32 mm) in a 1-l plastic container. We used toad tadpoles at three developmental stages: early stage (Gosner stages 25 to 28; SVL 4.7–6.2 mm, mean=5.0 mm), midstage (Gosner stages 30 to 35; SVL 7.7–9.0 mm, mean=8.5 mm), and late stage (Gosner stages 40 to 42; SVL 13.2–14.6, mean=13.9 mm). Two size classes of metamorph toads were tested: (1) 10.9–12.9 mm SUL (mean=12.1 mm) and 0.11–0.18 g (mean=0.15 g) and (2) 16.0–19.4 mm SUL (mean=17.4 mm) and 0.38–0.77 g (mean=0.48 g). Depending on availability, we ran either 20 or 40 native tadpoles as experimental animals plus the same number of controls (run concurrently, kept individually in identical containers, but without the toad stimulus). After 24 h, we quantified consumption of toads and scored whether the native tadpole was alive or dead and, if alive, whether it was overtly affected by exposure to toad material (impaired swimming ability).

As in other anuran species, eggs of cane toads consist of an ovum surrounded by a jelly coat. The jelly coat consists of several layers, each of which may have specific biological functions (e.g., Duellman and Trueb 1986). Thus, the rapid decline in toxicity from toad eggs to toad

tadpoles (see below) might reflect, at least partly, high concentrations of toxin in the jelly coat (Gunzburger and Travis 2005). To test this hypothesis, we carefully separated eggs from their jelly coats and exposed tadpoles of three frog species (N=20 per treatment for *Litoria caerulea*, *Litoria nasuta*; N=10 per treatment for *Opisthodon ornatus*) to the jelly coat material, plus appropriate controls (ten intact toad eggs per container; and no egg material per container). All tadpoles were in individual containers, as before.

Results

Toxin Profiles Figure 1 compares chromatograms of the *n*-BuOH extracts of each ontogenetic stage and reveals differences among toxin profiles of different ontogenetic stages of the cane toad. Six of the bufadienolides found in these stages were characterized by HPLC-DAD-MS, and their percentage occurrence in each stage is shown (Table 1). The unique UV spectrum of the bufadienolides allowed their assignment to this class of compound, even if a complete chemical identity was not obtainable, and in this case the number of additional bufadienolides is given (Table 1). The number of bufadienolide peaks found uniquely in each ontogenetic stage is also given (Table 1).

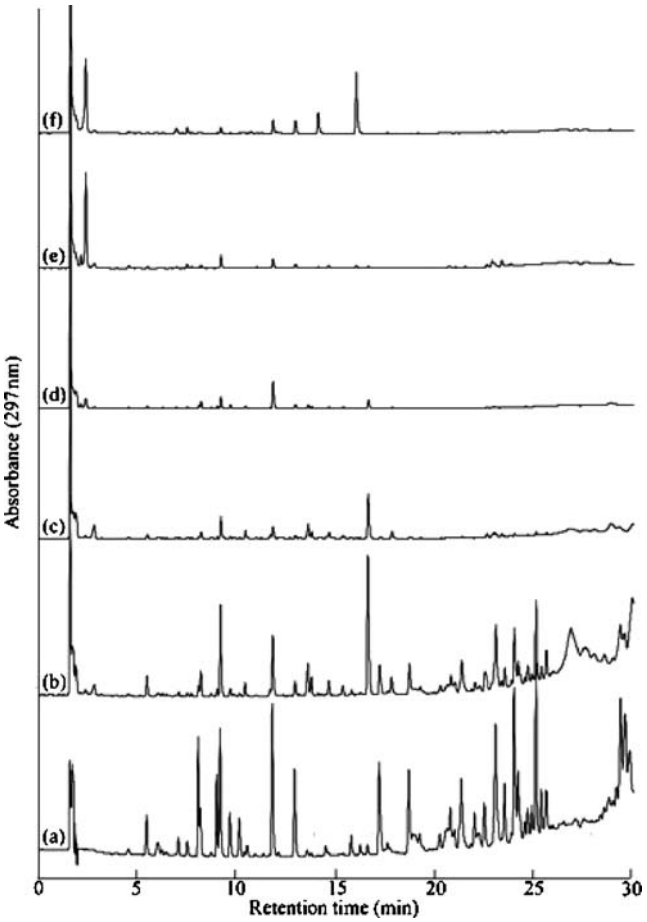

Fig. 1 Stack plot of sample HPLC chromatograms of *n*-BuOH extract from each studied ontogenetic stage of cane toads, analyzed at 297 nm. Stage of each plot is indicated: (*a*) eggs, (*b*) stage 21, (*c*) stage 25, (*d*) stage 44/45, (*e*) small metamorph, (*f*) large metamorph/juvenile. Gradient: 100% H_2O for 5 min, gradient to 25% MeOH over 5 min, isocratic for 10 min, then gradient to 100% MeOH over 5 min, using Phenomenex Onyx Monolithic C_{18} column (100×4.6 mm)

Analyses across different ontogenetic stages showed that the total number of bufadienolide peaks varied with stage ($F_{5,\ 48}$=25.16, P<0.001; Fig. 2a), as did the mean amount of bufadienolide (in micromole per milligram of extract; $F_{5,\ 48}$=5.462, P<0.001; Fig. 2b). Multiple comparisons determined with Tukey test are displayed in Fig. 2. In each case, the eggs had the highest values, both in number of peaks and in amount of bufadienolide. In the case of peak numbers, there was no significant difference between the number of bufadienolide peaks in all tadpole and early postmetamorphic stages, except for another significant drop at stage 25 (Fig. 2a). Stage 25 was the only stage to have a significantly reduced amount of bufadienolide (Fig. 2b), although a trend is apparent whereby eggs and larger metamorphs/juveniles had the most bufadienolide, with a reduction during the larval stage and immediately post-metamorphosis.

Bioassay of Toad Palatability and Toxicity In both predator species that we tested, palatability and toxicity of cane toads decreased dramatically through ontogeny (Figs. 3 and 4). Controls did not exhibit any mortality or abnormal behavior over the course of trials, in any experiment. Palatability of toads declined gradually through early toad ontogeny for *L. convexiusculus* tadpoles but remained high before an abrupt decline in *L. rothii* tadpoles (Fig. 3). Consumption of toad eggs was invariably fatal to frog tadpoles in our trials (one to ten eggs eaten), whereas feeding on late-stage larvae or metamorphs (including complete consumption) did not kill any test animals. The proportion of tadpoles adversely affected by toad consumption declined rapidly; early-stage toad tadpoles posed a significant danger whereas late-stage toad tadpoles and smaller metamorphs did not (Fig. 4). Sublethal toxic effects did not become apparent again until tadpoles fed on larger metamorphs (*L. convexiusculus* only; Fig. 4). The lack of mortality after exposure to larger metamorphs (Fig. 4) presumably reflects their low palatability to both tadpole species (especially *L. rothii*: Fig. 3) and, thus, says little about their actual toxicity. Contingency table tests show that the ontogenetic stage of the toad strongly influenced the probability that a predator would survive toad consumption, in both species of native frog (*L. convexiusculus*, χ^2=76.96, df=3, P<0.001; *L. rothii*, χ^2=99.07, df=5, P<0.001). Similarly, the probability of surviving after encoun-

Table 1 Percentage occurrence and tentative identity of bufadienolides from each life history stage of cane toads examined

Tentative identity	Percent occurrence by ontogenetic stage					
	Eggs	Stage 21	Stage 25	Stage 44/45	Meta	Juv
Arenobufagin	75	75	25	89	100	100
Hellebrigenin	75	63	–	33	50	–
Telocinobufagin	75	75	–	89	100	100
Marinobufagin	75	50	–	33	88	100
Bufalin	–	–	–	–	–	100
Resibufagenin	38	–	38	89	–	100
Number of additional bufadienolides	23	7	1	8	7	–
Number of unique bufadienolides	17	1	–	–	1	1

The final two rows show the number of additional unidentified bufadienolides from each stage and the number of unique bufadienolides found in each stage that were not detected in any other stage. "–" means below detectable levels. The "Meta" column refers to small metamorphs (<13 mm SUL) and the "Juv" column refers to a mixture of larger metamorphs and juveniles (i.e., >16 mm SUL). Mean amounts of each component shown in Table S1 in Supplementary Data

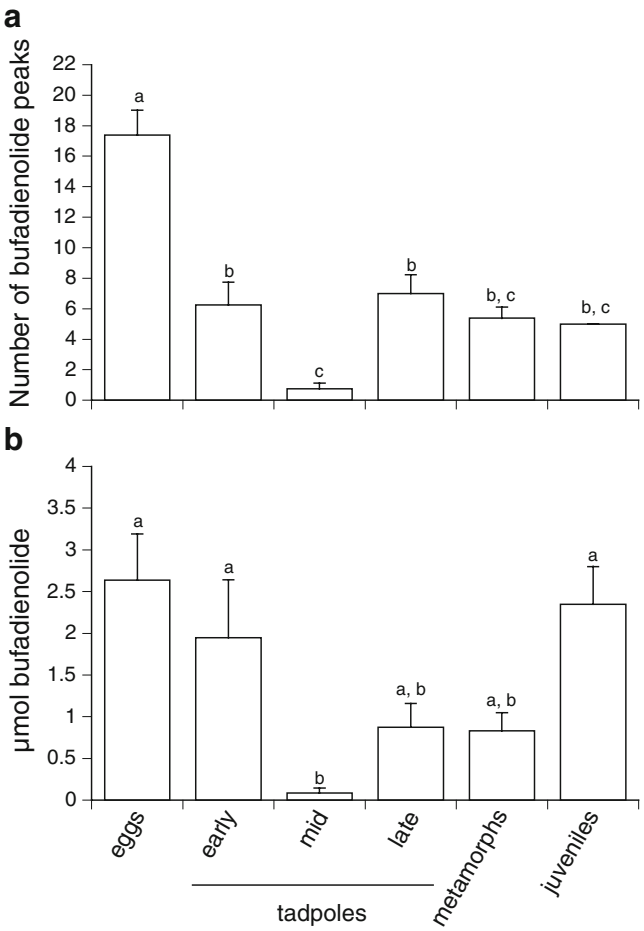

Fig. 2 Changes in the bufadienolide content and diversity across ontogenetic stage: **a** mean number of bufadienolide peaks detected and **b** total amount of bufadienolide (μmol). All data shown as mean± SEM. The "metamorph" category refers to small metamorphs (<13 mm SUL), whereas the "juveniles" category refers to metamorphs >16 mm SUL. Differing *small letters above bars* indicate statistical significance at $P<0.001$

tering (but not necessarily eating) toads differed strongly among toad age classes (*L. convexiusculus*, $\chi^2=108.35$, $df=5$, $P<0.001$; *L. rothii*, $\chi^2=116.42$, $df=5$, $P<0.001$).

Trials to identify the location of the toxin (ovum vs. jelly coat) also yielded clear patterns. All tadpoles placed with jelly coat (or controls with no egg materials) survived and exhibited normal behavior. All tadpoles in the jelly coat trials consumed the jelly that was offered. Intact eggs posed a greater danger. For *L. caerulea*, 13 of 20 tadpoles placed with intact eggs died, after consuming 0.5 to two embryos. Another three tadpoles ate one to two embryos and survived; the remainder did not eat during the trials. The *L. nasuta* and *O. ornatus* tadpoles placed with toad eggs consumed 0.5 to six eggs each, and all died.

Discussion

Both the total amount of toxin and its composition (relative proportions of different bufadienolides) change considerably through the course of toad ontogeny (Fig. 1, Table 1). Notably, newly laid toad eggs contained high levels of bufadienolides, whereas midstage tadpoles exhibited lower amounts, and all stages after the egg show a decreased diversity of toxins (Fig. 2). In the absence of detailed information on the toxicity of each type of bufadienolide to each type of potential predator, we cannot translate data on bufadienolide content directly into a measure of the danger posed to a predator.

Nevertheless, our data on toxicity of early-stage toads to native predators (frog tadpoles) fit well with the results of our chemical analyses, especially regarding diversity of the toxins. Toad eggs were invariably deadly to frog tadpoles, but the risk of poisoning fell rapidly through toad larval

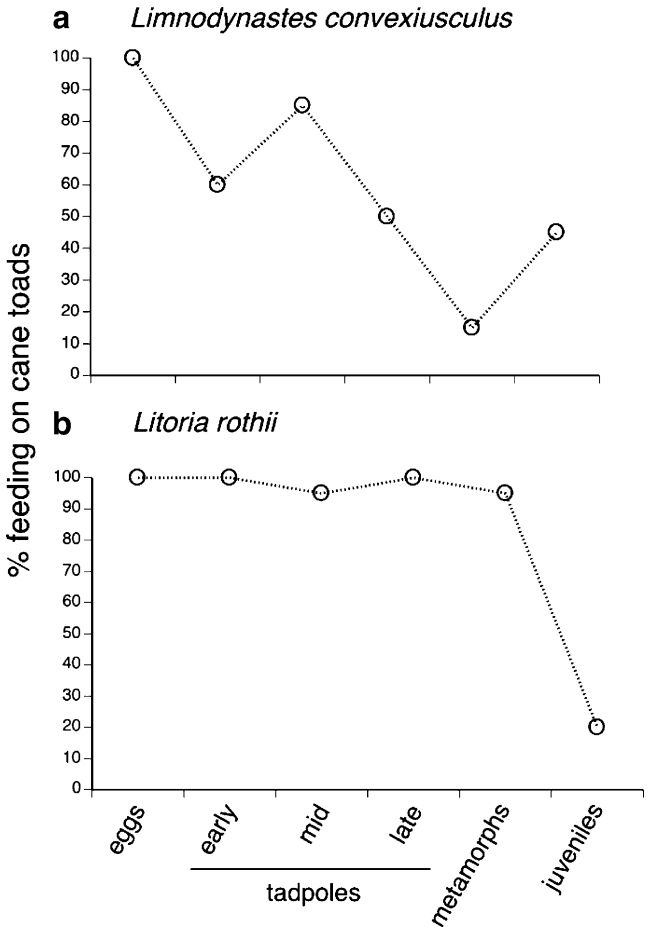

Fig. 3 Ontogenetic shifts in the palatability of early life history stages of cane toads (*B. marinus*) to tadpoles of two Australian frog species, *L. convexiusculus* and *L. rothii*. Captive tadpoles were exposed to eggs, tadpoles, and metamorphs of cane toads. We define palatability based on the proportion of predators that attempted to consume toad tadpoles. The "metamorph" category refers to small metamorphs (<13 mm SUL), whereas the "juveniles" category refers to metamorphs >16 mm SUL

life, was minimal for frog tadpoles encountering late-stage toad tadpoles or small toad metamorphs, and became evident again when feeding on larger metamorphs (Fig. 4). A similar general pattern of unpalatability declining from earlier to later stages during anuran early ontogeny seems to be widespread in amphibians (Gunzburger and Travis 2005) including bufonids (Brodie et al. 1978; Brodie and Formanowicz 1987). Thus, although intuition suggests that larger toad tadpoles should contain more toxins (Heyer et al. 1975) and some previous experiments have shown exactly that shift in either palatability (Lawler and Hero 1997) or toxicity (Crossland 1998), our study shows a decreasing toxicity through development for toads consumed by frog tadpoles.

The chemical analyses similarly reveal large and rapid ontogenetic shifts in toxin content (both concentration and diversity) during the cane toad's early life history. High concentrations of bufadienolides in the ovary of reproducing female toads and high toxicity of toad eggs have been reported by several authorities (e.g., Licht 1968; Lever 2001). Experiments in which we separated the egg into their two main components localize the toxin clearly to the ovum, not the jelly coat. The jelly coat may have multiple biological functions including facilitation of fertilization and protection against physical injury, fungal infection, thermoregulation, and embryo hydration (see review by Duellman and Trueb 1986). Larger firmer egg capsules deterred predation by fishes (Grubb 1972); and removal of the egg capsule or jelly coat increased vulnerability to predation (Licht 1968; Werschkul and Christensen 1977; Jennings and Schaefer 1978; Ward and Sexton 1981). However, these studies could not assess whether protection

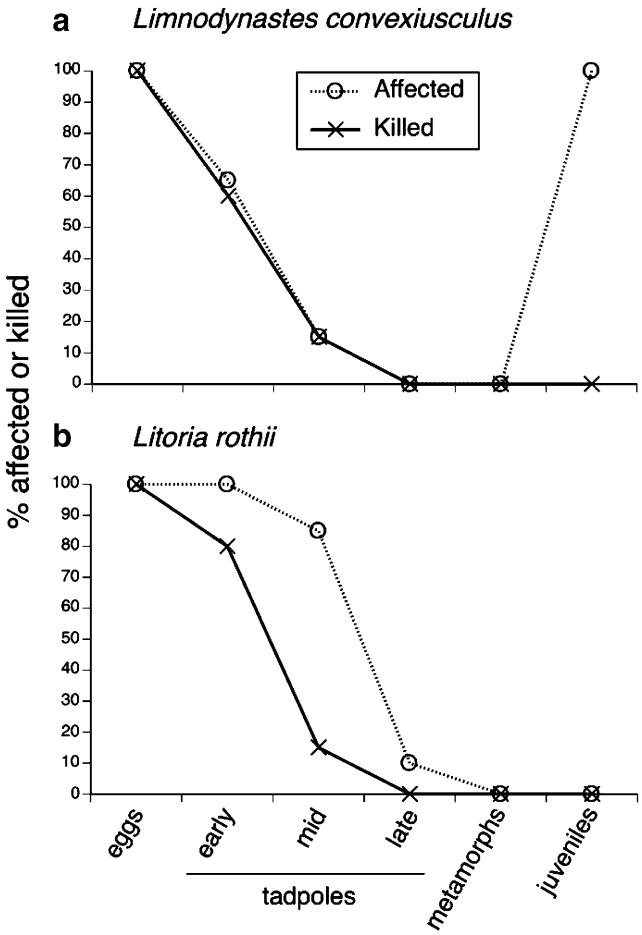

Fig. 4 Ontogenetic shifts in the toxicity of early life history stages of cane toads (*B. marinus*) to tadpoles of two Australian frog species, *L. convexiusculus* and *L. rothii*. Captive tadpoles were exposed to eggs, tadpoles, and metamorphs of cane toads. Control tadpoles all survived, so data for these groups are not shown. The "metamorph" category refers to small metamorphs (<13 mm SUL), whereas the "juveniles" category refers to metamorphs >16 mm SUL

was gained from chemical or physical properties of the jelly coat, and we are not aware of any experimental demonstration that identifies the location of toxins in amphibian eggs (albeit, we note that Phisalix [1922] concluded that "the toxic components of *Bufo* eggs appear to be in the ovarian egg, and the jelly coat gives added protection"). Our results implicate the ovum and not the jelly coat as the source of toxins in cane toads.

Ontogenetic shifts in toxicity may have major ecological consequences (Hanifin et al. 2004); for example, the danger posed by cane toads to native predators shifts dramatically through toad ontogeny. In the case of the frog species that we studied, the risk level changed from almost certainly fatal (ingestion of eggs) to minimal risk (ingestion of late-stage larvae and small metamorphs), before increasing again for larger metamorphs. The broad conservatism in physiological determinants of vulnerability to bufadienolides among vertebrates suggests that other vertebrate predators will exhibit similar patterns of vulnerability. For the minority of predator species with high tolerance to these toxins, no life history stage of the cane toad will be threatening (Peterson and Blaustein 1992; Lever 2001). In a country like Australia, however, which lacks native bufonids, many predators have low resistance to the cane toad's toxins (Lever 2001; Phillips et al. 2003). For most of this latter group, we predict that toad eggs will be more toxic than either tadpoles or small metamorphs. The stage of postmetamorphic life when the young toads begin to produce their own toxins may vary among *Bufo* species: for example, Brodie et al. (1978) reported high levels of unpalatability for *Bufo americanus* within 24 h after metamorphosis.

Patterns of vulnerability may also differ for other types of predators. The physiological pathways by which arthropods are affected by bufadienolides differ considerably from those of vertebrates. Insect Na^+/K^+ ATPase lacks the binding site for cardenolides (Okimura et al. 2002) and thus presumably the site for binding of bufadienolides, and these toxins will not have the same effect on insect predators. A recent review of literature concluded that, overall, insect predators are less likely to find amphibian eggs unpalatable than are vertebrate predators (Gunzburger and Travis 2005). Many invertebrates are unaffected by cane toad toxins (e.g., crustaceans, odonates, nepids, dytiscids), but others are vulnerable (e.g., snails—Crossland and Alford 1998). Intriguingly, Crossland (1998) reported that late-stage cane toad tadpoles were more toxic to belostomatid water bugs than were early-stage tadpoles: the reverse of the pattern was documented in the present study. This toxicity is presumably related to some other unidentified toxin or toxins rather than to bufadienolides (that are decreased in diversity at this stage). Further work to test this hypothesis would be of interest, and interspecific variation may be considerable. For example, newly hatched toad (*B. americanus*) larvae are less palatable to invertebrate predators than midstage or late-stage tadpoles (Brodie et al. 1978; Brodie and Formanowicz 1987).

Given the invariably fatal outcomes from ingesting toad eggs (Fig. 4), why do frog tadpoles attack these dangerous meals? This situation may reflect the lack of evolutionary contact between frog species in our Australian study area with the invasive cane toad (that arrived only 2 years before the experiments were conducted). Even in species that have evolved with toads, selection to avoid eggs may be weak if the eggs typically are laid in places and at times where they would rarely be encountered by frog tadpoles. In Gunzburger and Travis' (2005) review, *Bufo* eggs, hatchlings, and tadpoles were rejected as prey in only 20% of trials—most of which dealt with predators sympatric with bufonids over evolutionary timescales. None of the studies reviewed by Gunzburger and Travis reported avoidance of bufonid eggs by heterospecific tadpoles.

Further, what do our results tell us about the ecological impact of cane toads in Australia and the kinds of methods that we might use to mitigate that impact? The degree of risk to a predator will depend upon the toxin content in toads (which may vary geographically and among individuals: Daly et al. 2008) as well as upon the life history stage of cane toads that the predator attempts to consume. As is well known, adult cane toads are highly toxic (our analysis of adult toad parotid glands reveals five dominant and ~100 minor bufadienolides: R. A. Hayes and R. J. Capon unpublished data), but the situation is more complex with earlier life history stages. A vertebrate predator will be at greater risk if it attempts to consume toad eggs rather than toad tadpoles. Fortunately, the egg stage (typically 1–2 days' duration) is briefer than the tadpole stage (38 days on average in the field: Alford et al. 1995) and, thus, poses a danger for a briefer period. The reluctance of native tadpoles to attack live toad tadpoles (Crossland and Alford 1998; M. Crossland and R. Shine unpublished data) reduces further the vulnerability of frog tadpoles to toad larvae. Not surprisingly, most cases of mortality of frog tadpoles following toad breeding occur immediately postspawning and are due to predation on toad eggs rather than larvae (Crossland et al. 2008). The low toxin levels of small metamorph toads also reduce predator vulnerability; even small native predators that ingest these tiny anurans are at less risk than if they had consumed eggs or larger metamorphs. The defensive toxins reach their minimum around metamorphosis, at the same time as the transition from aquatic to terrestrial life reduces the toad's locomotor ability (Arnold and Wassersug 1978). In combination, metamorphosis is likely to be a critical time in the toad's life history, when both of its usual defenses (fleeing from danger and poisoning predators) are ineffective. The toad's

small body size at metamorphosis and high ratio of surface area to volume add further risk through high rates of desiccation (Cohen and Alford 1993; Child et al. 2008). The end result is that attempts to control populations of this invasive anuran may usefully target the vulnerable and relatively undefended metamorphs, although density-dependent population processes may weaken the effectiveness of this strategy (Cohen and Alford 1993; Alford et al. 1995).

Many methods have been proposed to reduce population densities of cane toads in Australia (Shine et al. 2006). Because these proposals differ in the life history stage targeted for control, the ontogenetic shift in toxicity in toads means that these methods also will differ in their probable effects on native fauna. For example, control of toad populations by introducing sterile males (Mahony and Clulow 2006) would result in eggs remaining in water bodies until they decomposed, prolonging the egg stage and thus increasing the risks of fatal encounter for local native aquatic fauna. In contrast, controlling cane toads by genetic manipulations that kill toad tadpoles prior to metamorphosis (Pallister et al. 2006) would not affect the egg stage but instead would increase the numbers of dead tadpoles. Because frog tadpoles in this system are scavengers rather than predators of live anuran larvae, the dead toad tadpoles would pose a greater toxic risk to native tadpoles than would live toad larvae. However, if mortality is delayed until shortly before metamorphosis, toxin levels (and thus danger to native tadpoles) will be low. Nonetheless, late-stage toad tadpoles are highly toxic to some invertebrate predators (Crossland 1998) and this method of toad control might impose collateral damage on aquatic invertebrates. Reducing toad populations by increasing rates of metamorph mortality (e.g., via parasites—Kelehear 2007) may have less effect on native predators (or at least, vertebrate predators). Understanding ontogenetic shifts in toxin content and hence in predator vulnerability may help in predicting the ecological impacts of alternative approaches to toad control.

Acknowledgements We thank the Australian Research Council, Queensland State Government, and Invasive Animals Cooperative Research Center for funding and David Nelson for assistance with bioassay experiments. Procedures involving live animals were approved by the University of Sydney Animal Care and Ethics Committee.

Individual Discrimination by Odors in Sibling Prairie Voles (*Microtus ochrogaster*)

Zuleyma Tang-Martínez · Andrea Bixler

Received: 18 September 2008 / Revised: 12 January 2009 / Accepted: 31 March 2009 / Published online: 17 April 2009

Abstract The habituation–discrimination paradigm has been used widely to demonstrate that animals can detect individually distinctive odors of unfamiliar conspecifics. By using a modification of the habituation–discrimination technique, Todrank et al. (Anim Behav 55:377–386, 1998) found that golden hamsters discriminate between the individual odors of their own familiar brothers but cannot discriminate between the odors of two siblings that are unrelated and unfamiliar to the subject. This suggested that previous evidence showing that animals could discriminate between the odors of individuals actually may have demonstrated the ability to discriminate between genetically unrelated conspecifics (i.e., members of different families). To test this possibility, we conducted habituation–discrimination experiments with prairie voles, *Microtus ochrogaster*. Voles were tested under three conditions: subject and both targets were unrelated and unfamiliar; subject and both targets were brothers and familiar; subject was unrelated and unfamiliar to targets, but targets were brothers. In all cases, voles discriminated between the two individual odors. Thus, prairie voles can discriminate individual differences between the odors of brothers and they do not have to have previous experience with the conspecifics in order for discrimination to occur. The theoretical importance of these results is discussed.

Introduction

In many vertebrate species, chemical communication plays a role in social recognition (e.g., Brown 1979; Zenuto et al. 2004; Fernandez-Vargas et al. 2008). Individually distinctive odors particularly have been well studied in rodents and are believed to serve multiple functions that can be critically important to social dynamics (Halpin 1980, 1986).

The chemical composition of chemosensory social signals has been studied in only a few species of rodents. Most signals appear to be composed of a mix of compounds. However, there is sufficient interindividual variation in the relative proportion of the compounds to code for individually distinctive chemosensory cues (Singer et al. 1997; Weidong et al. 1999).

The habituation–discrimination paradigm (Schultze-Westrum 1969; Halpin 1974) has been used widely to investigate the occurrence of individually distinctive odors and the ability of conspecifics to discriminate such individual differences. With this paradigm, it has been demonstrated repeatedly that in rodents and other taxa, subjects reliably distinguish among the odors of conspecifics. A variant technique (often referred to as "habituation–dishabituation") also has been commonly used (Todrank et al. 1998, 1999).

The habituation–discrimination paradigm has two components. During the habituation phase, the subject is presented with the odor of one conspecific (odor A) until the subject habituates to this odor. During the subsequent discrimination phase, the subject is simultaneously presented with odor A and odor from a second conspecific (odor B).

The time spent investigating odors B and A is compared. The assumption is that if the subject cannot distinguish a difference, then it should spend equal time investigating each. If, however, the subject can detect a difference between the odors, then it should spend significantly more time investigating the novel odor B.

Todrank et al. (1998), used habituation–dishabituation to study golden hamsters, *Mesocricetus auratus*. The rationale and mechanisms of this technique are identical to those of habituation–discrimination, but subjects are habituated by a series of brief exposures to odor A and are then presented with odor B. The time spent investigating odor B then is compared to the time spent investigating odor A during the last habituation exposure. Todrank et al. (1998) found that golden hamsters discriminate among the individual odors of their own familiar brothers but cannot discriminate between the odors of two siblings that are unrelated and unfamiliar to the subject. They concluded that the odors of genetically related individuals (i.e., siblings) are so similar that subjects without prior social experience with the odor donors are unable to discriminate between them.

Prior to Todrank et al. (1998), all studies that used these two paradigms had tested odors from conspecifics that were genetically unrelated to one another and both unrelated and unfamiliar to the subject. For example, tests with both of these methodologies demonstrated that golden hamsters discriminate between the odors of unrelated and unfamiliar conspecifics (Johnston et al. 1993; Tang-Martínez et al. 1993).

The results of Todrank et al. (1998) raised an interesting but troubling possibility that in all previous studies that used the two techniques, subjects had been able to distinguish between the odors of two conspecifics only because the two targets were genetically unrelated (i.e., they came from different families). Therefore, one interpretation would be that subjects in previous studies were discriminating between family-related cues rather than between individual ones. If this were the case, siblings might be producing such similar "family odors" that a difference could not be detected by the subject in the absence of previous social familiarity (Todrank et al. 1999).

Such a conclusion opens to question a large body of literature on individually distinctive odors and their putative functions. If animals, in fact, cannot distinguish between the odors of siblings, we need to reevaluate the role of individual odors in social group dynamics and in important evolutionary processes such as kin selection, reciprocal altruism, and mate choice. This possibility makes it imperative that the Todrank et al. (1998) experiments be replicated by using other species and methodologies.

We examined this question by using prairie voles (*Microtus ochrogaster*). Prairie voles are highly social, biparental, monogamous rodents that often live in extended family groups and may remain in contact with siblings even after dispersal (Getz et al. 1993, 1994; Getz and Carter 1996). Newman and Halpin (1988) previously demonstrated that *M. ochrogaster* can discriminate between the odors of two unrelated and unfamiliar conspecifics.

In this study, we hypothesized that prairie voles would be able to distinguish odor differences even between siblings and that the results obtained by Todrank et al. (1998) may not be generalized to all rodents. We now report that male prairie vole can, in fact, discriminate between the odors of (a) their own brothers and (b) two brothers that are unrelated to the subject and with whom he has had no prior experience. This study does not address kin recognition per se or its mechanisms. These questions already have been investigated in prairie voles by using cross-fostering techniques (Gavish et al. 1984; Paz y Miño and Tang-Martínez 1999).

Methods

General Subjects and odor donors came from the vole colony of the University of Missouri-St. Louis. The colony was maintained on a 12:12 h L/D cycle with food (5001 Rodent Diet by Lab Diet) and water provided ad libitum. Voles were weaned at 21 days of age and housed with their siblings in plastic cages (20×23×45 cm) with wood shavings (Aspen Shavings by NEPCO) and paperchip (Cellu-Dri by Shepherd Specialty Papers). All subjects and odor donors were males, at least 40 days old, sexually naïve, and had not been used in other experiments.

Experiments were performed in a room separate from the housing area and conducted during the light phase of the cycle. Each odor donor was single-housed in a plastic cage (15×20×26 cm) with wood shavings for 3 days prior to the trial. Between tests, petri dishes and terraria were washed thoroughly with soap and hot water and rinsed with ethanol. Investigators washed their hands between tests and used latex gloves (American Health Products) to handle Petri dishes and terraria.

We followed the habituation–discrimination method (Halpin 1974; Newman and Halpin 1988). For each trial, the subject was introduced into an empty glass terrarium (30×50×25 cm) and allowed a 5-min acclimation period. During this time, we filled polycarbonate petri dishes (9.5 cm diam) with bedding from cages of the odor donors, taking only dry bedding from throughout the cage. Petri dishes had approximately 60 1-mm holes drilled in both the top and bottom of the dish to allow the subject to smell the contents. Two dishes were filled from the cage of one donor (A) and one dish was filled from the cage of the other donor (B) at the same time.

Following the 5-min acclimation, one Petri dish from donor A was taped to the inside of the terrarium, approximately 5 cm above the floor and in the center of the back wall. For 5 min, we used a stopwatch to record the number of

seconds that the subject spent investigating the dish. Investigation was recorded only when the subject was sniffing within 1 cm of the top surface of the dish. Chewing, climbing, or leaning against the dish were not counted as investigation. After this 5-min period, the subject was left in the terrarium with the same dish of bedding for 50 min; we then recorded investigation for another 5 min. These two 5-min periods, and the 50 min in between, constitute a 1-h habituation period. Habituation was inferred if the subject spent less time investigating the dish during the last 5 min as compared to the first 5 min.

At the end of the 1-h habituation period, the dish used during habituation was removed. Immediately, two new dishes, one containing bedding from odor donor A and the other from odor donor B, were introduced and taped at opposite ends of the terrarium, approximately 5 cm above the floor, with one dish in the center of each side wall. The position (i.e., side of the terrarium) in which dishes containing odors A and B were placed was random across trials. A fresh dish from donor A was used during this phase to control for the possibility that the subject's own odors or markings (e.g., from chewing the dish) would affect the subject's responses. However, since this dish had been prepared at the same time as the original dish from odor donor A and the dish from odor donor B, the two odors used during discrimination were of equal "freshness."

The discrimination phase lasted 10 min, and the time spent investigating each dish was recorded on separate stopwatches. All experiments were performed blind: the dishes used during the discrimination phase were labeled on the bottom prior to the start of the habituation period, the labels were covered, and the dishes shuffled; labels were not rechecked until the end of the discrimination phase. Additionally, in some trials, the position of dishes was assigned by an assistant. Thus, the experimenter was never aware which dish contained odor A or odor B until the trials had been completed and all data had been collected.

The positions of the dishes were changed from the back wall of the terrarium during the habituation phase to the two side walls during the discrimination phase to control for any habituation that might have occurred to the location of the odor source. Thus, during the discrimination phase, both odors were in a novel location, and any differential responses to the two odors by the subject must have been due to perceived differences in the odors rather than to their location.

Experiment 1: (All Unrelated) Our objective was to verify a previous finding (Newman and Halpin 1988) that male voles can discriminate between the odors of two conspecifics. The subject was unrelated to, and inexperienced with, the odor donors, which were also unrelated to one another.

Subjects were 16 males from 16 litters born to 13 breeding pairs (in only two cases did two subjects, used in different tests, come from the same litter). Odor donors were 36 males from 33 litters born to 20 breeding pairs. In three cases, two odor donors came from the same litter but they always were used in different trials; no odor donor was ever paired with the same subject or odor donor in more than one trial. No animal was used as a subject in more than one trial, and no subject was used as an odor donor in other trials.

Experiment 2: (All Related) Here, we tested the ability of the subject to discriminate between the odors of two brothers from his own litter (i.e., subject and odor donors were siblings and socially familiar with one another). Voles were housed together until the odor donors were separated into individual cages 3 days before the trial, as described above.

Subjects were 16 males from 16 litters born to 13 different breeding pairs; odor donors were two brothers of the subject. No animal was used as a subject in more than one trial nor were any subjects used as odor donors in other trials.

Experiment 3: (Odor Donors Related) Odor donors in this experiment were brothers, but they were not related to the subject and he had no prior experience with them. Thus, we tested whether the subject could discriminate between the odors of two animals that were related to each other to the same degree as the odor donors in the second experiment, but who were not related or familiar to the subject.

Subjects were 13 males from 12 litters born to nine different breeding pairs. The odor donors were 13 pairs of brothers from seven breeding pairs. No animal was used as a subject in more than one trial nor were any subjects used as odor donors in other trials.

Statistical Analyses Habituation was determined by comparing time spent investigating odor A during the first and last 5 min of the habituation phase. Since habituation should cause a decrease in investigation over time, these data were analyzed with one-tailed *Wilcoxon signed rank tests* for matched pairs (Siegel 1956).

The results of the discrimination phase were analyzed by comparing time spent investigating the familiar odor (A) and novel odor (B). Since habituation to odor A predicted that more time should be spent investigating odor B (if the two odors are different), one-tailed *Wilcoxon signed rank tests* for matched pairs were used to compare differences. The critical level of significance was set at $P<0.05$.

All aspects of the experimental design were approved by the IACUC of the University of Missouri-St. Louis and conform to USA laws.

Results

In all experiments, the subjects demonstrated habituation to the odor presented during the habituation phase by

decreasing the amount of investigation (given in seconds± S. E.) from the first 5 min to the last 5 min of the habituation period (Experiment 1: N=16, T=3, P<0.005; means=49.7±8.3 vs. 19.4±7.9. Experiment 2: N=16, T=0, P<0.005; means=39.9±6.9 vs. 1.0±0.5. Experiment 3: N=13, T=13, P=0.01; means=42.1±6.0 vs. 21.2±5.1).

In Experiment 1 (All Unrelated), subjects spent more time (given in seconds±S. E.) investigating the novel odor as compared to the odor to which they had habituated (N=16, T=23, P<0.01; mean for A=32.3±4.9, mean for B=50.0± 7.8; 13 of the 16 subjects spent more time investigating the novel odor B). This indicates that the subjects were able to distinguish between the odors of individuals who were unrelated to each other and to the subjects.

In Experiment 2 (All Related), the subjects spent more time investigating the second odor as compared to the odor to which they had become habituated (N=16, T=30, P<0.025; mean for A=27.6±4.9, mean for B=34.8±5.0; despite some overlap of standard error bars, 12 of the 16 subjects spent more time investigating the novel odor B). In other words, subjects were able to distinguish between the odors of their own two familiar brothers, although there was a smaller difference in mean time spent sniffing the two odors as compared to the mean differences in the other two experiments.

In Experiment 3 (Odor Donors Related), the subjects also were able to distinguish between the two odors (N=13, T= 17, P<0.025; mean for A=28.7±5.6, mean for B=44.7±3.5; 10 of 13 subjects spent more time investigating the novel odor B), and more time was spent investigating the novel odor as compared to the habituated odor.

Discussion

We found that subjects discriminated between odor donors that were unrelated to each other and between donors that were familiar brothers of the subject. However, while Todrank et al. (1998) reported that golden hamsters could not distinguish between the odors of brothers that were neither related nor familiar to the subject, we found that prairie voles can make this discrimination. Even if brothers share similar odors because of their genetic relatedness (odor–genes covariance sensu Todrank and Heth 2003), prairie voles discriminate individual differences in these odors. Our findings also confirm that the results of previous studies, on a variety of species (e.g., Halpin 1974, 1980, 1986; Newman and Halpin 1988; Johnston et al. 1993; Tang-Martínez et al. 1993), demonstrated true individual odor discrimination rather than just discrimination of family-related differences.

The methodological differences between the habituation–discrimination protocol used in this experiment and the habituation–dishabituation technique used by Todrank et al. (1998) may be responsible for our different results. Both techniques are used commonly and are considered sufficiently powerful to reveal the existence of individual odors in most situations. However, based on our results, we propose that when the odors of individuals are likely to be extremely similar because of kinship (as in the case of siblings), the habituation–discrimination method may be more sensitive and should be explored before concluding that individually distinctive odors either do not exist or cannot be discriminated by subjects.

This conclusion is buttressed by the results of Jonhston and Peng (2000) on the role of the vomeronasal organ in the ability of golden hamsters to detect individual differences in conspecific odors. After conducting experiments in which the novel odor (B) was presented by itself during the test phase, and others in which odors A and B were presented together, they concluded that simultaneous presentation enhances the subjects' ability to discriminate. Unpublished studies from our laboratory, comparing the two methods, also support this conclusion.

The habituation–discrimination technique is likely to be more sensitive for two reasons. First, the habituation period consists of one long exposure to the odor of the first individual rather than to small numbers of brief repeated exposures. The longer exposure may result in more robust learning and habituation by the subject. Secondly, the simultaneous presentation of the habituated and novel odors allows the subjects to compare directly the two odors rather than having to rely only on the memory of the habituated odor (Jonhston and Peng 2000).

The social ecology of voles and hamsters also may explain the differences between our results and those of Todrank et al. (1998). Specifically, high levels of sociality can be expected to affect the abilities of animals to make fine discriminations among conspecific cues. Golden hamsters are solitary and highly aggressive (Lawlor 1963; Payne and Swanson 1970). In contrast, prairie voles are highly social and often live in extended family groups (Getz et al. 1993, 1994; Getz and Carter 1996). Accordingly, selection likely favored prairie voles that were able to make fine odor discriminations among relatives, an ability that may allow them also to perceive subtle individual differences in the odor cues of other conspecifics. For solitary golden hamsters, it is unlikely that there was strong selection for the ability to discriminate such small differences in conspecific cues. We suggest that the results obtained with golden hamsters (Todrank et al. 1998) cannot be generalized to social species that have complex social organizations.

Differences in the genetic history of the two test populations undoubtedly are also important. All golden hamsters used in laboratories in the USA are descended from one male and two females collected in the field in

1930 (Adler 1948; Bunnel et al. 1977). Thus, laboratory hamsters are highly inbred and genetically similar to one another. By contrast, the vole colony used in our experiments was created from more than 20 voles trapped in the field. To avoid excessive inbreeding, new animals (also field-trapped) were added to the lab population approximately every 2 years. Given that odor differences are correlated with genetic differences (i.e., "odor-genes covariance": Todrank and Heth 2003), the odors of sibling voles certainly are more individually distinctive than the odors of sibling golden hamsters from laboratory colonies. As a result, voles apparently do not need to have prior experience with the distinctive odors of closely related conspecifics before they can distinguish them.

The results of Todrank et al. (1998) are particularly important because they demonstrate that extremely close genetic relatedness may impact the ability of animals to distinguish individual odors of conspecifics. Our data indicate that species or populations with different social, ecological, and/or genetic characteristics also may differ in their ability to perceive subtle differences in odors. Moreover, when differences in individual odors become more tenuous (e.g., when two individuals are closely related genetically), animals should have more difficulty discriminating between these odors. By modifying experimental paradigms to facilitate learning or comparison of conspecific odors (e.g., as in habituation–discrimination), we increase the probability that subjects will be able to distinguish even between the odors of close genetic relatives.

Acknowledgments We thank Ailien Britt and Melissa Walker for helping with the experiments, and David A. Chisholm for modifying the petri dishes. We are grateful to Manuel Leal, Josephine Todrank, and Giora Heth for valuable discussions and insights over the years. Support for this project was provided by grants from the University of Missouri Research Board and the National Science Foundation (NSF IBN 9728767) to ZTM.

Altered Olfactory Receptor Neuron Responsiveness Is Correlated with a Shift in Behavioral Response in an Evolved Colony of the Cabbage Looper Moth, *Trichoplusia ni*

Michael J. Domingue · Kenneth F. Haynes · Julie L. Todd · Thomas C. Baker

Received: 5 December 2008 / Revised: 26 March 2009 / Accepted: 27 March 2009 / Published online: 24 April 2009

Abstract There is little understanding of how sex pheromone blends might change during speciation events. For the cabbage looper, *Trichoplusia ni*, there is a mutant laboratory strain that has exhibited characteristics of a shift to a new pheromone blend. Mutant females produce a blend that is significantly different from wild-type females in having a much higher proportion of a minor pheromone component and lower quantity of the major component. Males in this colony have changed over the years to become more broadly tuned and fly upwind equally well to both the wild-type and mutant female pheromone blends. They also exhibit reduced overall sensitivity to pheromone, flying upwind to either blend at a lower success rate than is typical when wild-type males respond to the wild-type blend. Using single-cell recordings, we examined the olfactory receptor neurons (ORNs) of males from evolved and wild-type colonies for evidence of changes in response characteristics that might explain the above-described behavioral evolution. We found that in evolved-colony males the ORNs tuned to the major sex pheromone component exhibited a somewhat lower responsiveness to that compound than the ORNs of wild-type males. In addition, the minor pheromone component, emitted at excessively high rates by mutant females, elicited a drastically reduced ORN responsiveness in evolved-colony males compared to wild-type males. This alteration in ORN responsiveness may be responsible for allowing evolved males to tolerate the excessive amounts of the minor pheromone component in the mutant female blend, which would normally antagonize the upwind flight of unevolved males. Thus, peripheral olfactory alterations have occurred in *T. ni* males that are correlated with the evolution of the more broadly tuned, but less sensitive, behavioral response profile.

Introduction

The nature of pheromonal changes related to speciation has been speculated upon frequently (Phelan 1992; Baker 2002, 2008; Symonds and Elgar 2004; Symonds and Wertheim 2005). It has been particularly difficult to pinpoint what initial mutations to olfactory systems might occur that provide the raw material upon which selection could operate. According to the "asymmetric tracking" hypothesis (Phelan 1992), the nonlimiting sex (usually males) that experiences stronger selection will more strongly track changes that occur in the limiting sex (usually females). For systems in which females emit sex pheromones, this asymmetry manifests itself in high between-individual variation in emitted pheromone blend composition, while

males have high within-individual variation in behavioral response profiles to these blends that bracket the pheromone composition of most females in the population (Löfstedt 1990). Therefore, shifts in female pheromone blends might initially require that males in the population broaden their response profiles to include mutant female pheromone blends as well as the wild-type female blends.

Pheromone olfactory pathways logically can be inferred as playing a key role in allowing broad pheromone blend responsiveness of males in this first stage of the asymmetric tracking process. Indeed, olfactory receptor neuron (ORN) tuning profiles have been implicated in the broader responsiveness of "rare" males in *Ostrinia nubilalis* and *Ostrinia furnacalis* that fly upwind equally well to the quite different pheromone blends emitted by females of these two species (Roelofs et al. 2002; Linn et al. 2003, 2007; Domingue et al. 2007a, b).

A system that is particularly well suited for exploring the olfactory changes possibly involved in broader behavioral response related to speciation is the sex pheromone behavior of the cabbage looper moth, *Trichoplusia ni*. This species uses (*Z*)-7-dodecenyl acetate (Z7-12:OAc) as its major pheromone component along with five minor pheromone components (Bjostad et al. 1984; Linn et al. 1984). In 1990, a mutant female phenotype, caused by a single gene mutation, was reported to produce a 1:2 ratio of the minor pheromone component (*Z*)-9-tetradecenyl acetate (Z9-14:OAc) to Z7-12:OAc compared to the normal wild-type proportion of 1:100 (Haynes and Hunt 1990). An "evolved" colony then was developed in which all females displayed this inherited mutant trait, which is controlled by a major autosomal gene (Haynes and Hunt 1990).

Initially, males from this mutant female colony were like wild-type males, in that they were more likely to fly upwind to and reach the source of the wild-type female pheromone blend than they were to the mutant female blend. Then, between generations 10 and 25, males from the evolved colony began to fly to the mutant female blend more frequently while retaining the same upwind flight success rate in response to the wild-type female blend. The success rate of upwind flight and source contact by males from the evolved colony in response to either the mutant or the wild-type blend became equal at generation 37, e.g., after approximately 3 years (Liu and Haynes 1994; Haynes 1997).

In an early attempt to see whether the ORNs of evolved-colony and wild-type males differed in their abundance or response profiles, recordings were performed on male sensilla from generations 14–17 (Todd et al. 1992). Most sensilla (type I) were found to house a larger-spike-size ORN responding primarily to Z7-12:OAc, with sometimes a lower-frequency response to (*Z*)-7-tetradecenyl acetate (Z7-14:OAc) and a smaller-spike-size ORN responding to (*Z*)-7-dodecen-1-ol (Z7-12:OH). There were also sensilla (type II) in which one ORN responded strongly to Z9-14:OAc. There was a rare sensillum type (type III) housing one ORN primarily tuned to another minor pheromone component, Z7-14:OAc. The degree to which behavioral evolution of the males had begun at this point is not clear, and physiologically tested males also were not behaviorally characterized. There were no obvious differences in the relative proportions of sensillum types in the two colonies. However, the firing frequencies on ORNs responsive to Z9-14:OAc appeared to be lower in evolved-colony vs. wild-type males. If the tendency to respond behaviorally to pheromone blends with greater proportions of Z9-14:OAc had begun at this point, a lower responsiveness to Z9-14:OAc could have facilitated such a response, assuming that the relative firing ratios of type I and type II ORNs influence behavior. In the ensuing 2 years, the evolved-colony males clearly began to exhibit the broad behavioral tuning consistent with the asymmetric tracking model (Phelan 1992). A behavioral tendency to fly successfully upwind to mutant- and wild-type female pheromone blends had become fixed in the population (Liu and Haynes 1994; Haynes 1997).

We checked the ORNs of these evolved-colony males vs. wild-type males in 1996 (Todd et al., previously unpublished) and again more thoroughly in 2007 in order to refine our knowledge about what, if any, changes in the peripheral receptor tuning profiles may have occurred that could explain the behavioral evolution. Recently, it was reported (Hemmann et al. 2008) that the more broadly behaviorally receptive males from the evolved colony also are less sensitive in response to either pheromone blend than wild-type males are to the wild-type blend. Thus, higher doses of either blend are required before evolved-colony males fly upwind. Here, we also examined whether changes in the responsiveness of the ORNs might have occurred that are consistent with this reduced behavioral sensitivity.

Methods and Materials

Electrophysiological sampling of wild-type and evolved-colony males has occurred on separate occasions at three historical points, in generations 14–17 (1990, see Todd et al. 1992), in generations 86–90 (1996), and finally in about the 220th generation (2007). At the different time points, experiments were performed by different analysts by using slightly different methodologies. The methodology used in 1990 has been described previously (Todd et al. 1992). It was not until the recent 2007 experiments that we developed and performed a highly replicated and well-controlled experimental protocol to compare the relevant characteristics of the ORNs responsive to Z9-14:OAc and

Z7-12:OAc in wild-type and evolved-colony males. Thus, we primarily describe the methodology for this most recent experiment, noting how the previous experiments differed.

Insects The wild-type and evolved colonies were originally derived from a colony collected in Riverside, CA, USA (Haynes and Hunt 1990). Both colonies were used in the 1990 physiology experiments. In 1996 and 2007, the same evolved colony was used, but the wild-type colony of *T. ni* derived from a colony maintained at the US Department of Agriculture-Agricultural Research Service Insect Attractants, Behavior, and Basic Biology Research Laboratory in Gainesville, FL, USA (Hemmann et al. 2008). Colonies were reared on a pinto-bean-based diet (Shorey and Hale 1965), at ambient room temperature, humidity, and light conditions. Male pupae of each colony were shipped from Kentucky to California (1990), Iowa (1996), or Pennsylvania (2007) for physiological analysis.

For the 2007 experiment, the source of the evolved-colony and wild-type males was withheld from the physiological analyst until the experiment was completed. Pupae and emerging adults were incubated at 25°C, in plastic containers with a Petri dish full of cotton saturated with sugar water at a 16:8 h L:D photoperiod. Different containers were used to separate males emerging within each day, such that we could ensure that all males sampled were between 2 and 7 days old when analyzed.

Single-Cell Electrophysiology ORN responses were recorded from trichoid sensilla by using the cut sensillum technique (Kaissling 1974; van der Pers and den Otter 1978). Individual antennae were excised from the head and placed in a saline-filled recording electrode including a silver wire. When possible, recordings were made from both antennae of an insect. Each antenna was positioned with a micromanipulator such that a single trichoid sensillum rested on the tip of a vertically positioned tungsten knife. A second horizontally oriented glass knife, controlled with another micromanipulator, was used to cut the sensillum tip. The cut sensillum then was contacted and surrounded by a saline-filled glass micropipette containing a silver recording electrode.

A stream of purified humidified air blew continuously over the antenna (10 ml/s) through a 25-cm-long glass tube (8-mm inner diameter (ID)), the end of which was placed 2 cm from the antenna. A 50-ms air pulse at a 40-ml/s flow rate was injected through the odor cartridge and into the airstream by using a stimulus flow-controller device (SFC-2, Syntech). Linear flow through the air-stream was ~0.3 m/s. The AC signal from the recording electrode passed through a built-in amplifier (DAM50, World Precision Instruments, Sarasota, FL, USA) and recorded with a computer. An external loudspeaker coupled with computer software (Syntech Autospike v.32; Syntech, Hilversum, The Netherlands) allowed visual and auditory monitoring of neural activity as it was recorded. In the 1996 and 2007 experiments, we observed little spontaneous background activity, typically less than one spike per second (Fig. 1). To measure spike frequency, Syntech software was used to count the number of spikes occurring within 300 ms of the first appearance of a spike. If there were less than two spikes within a second of a puff, the response was considered negative.

ORN Classes in 1990 and 1996 A random search protocol for sampling the sensilla was performed at the first two time points in 1990 and 1996. In 2007, a different analyst knew more about the spatial distribution of sensillum types, which

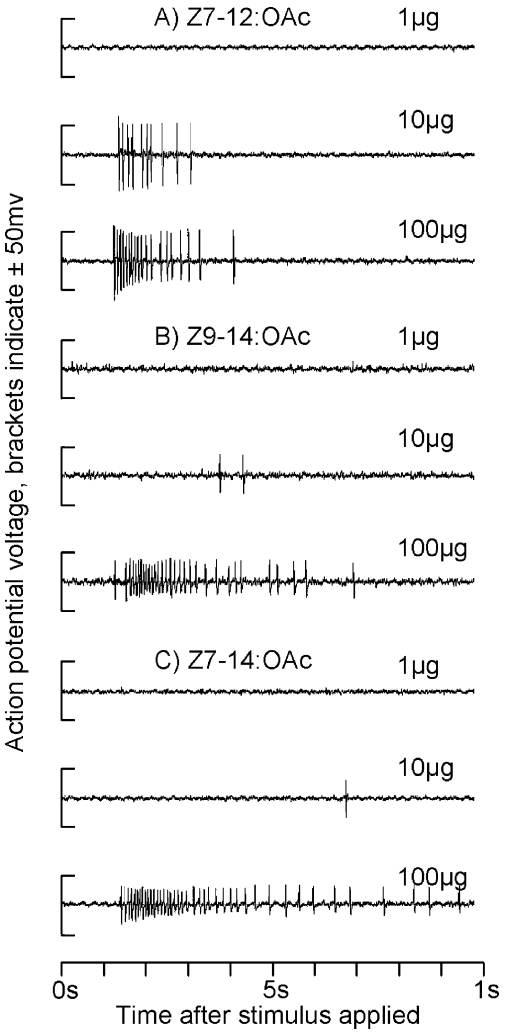

Fig. 1 Dose–response series (0.1-µg dose excluded) from ORNs housed within the three sensillum types commonly observed in *Trichoplusia ni*. The compounds inducing responses in these ORNs include Z7-12:OAc (*A*), Z9-14:OAc (*B*), and Z7-14:OAc (*C*), respectively. This series were obtained from different sensilla of the same male

precluded the same random sampling scheme (see Grant et al. 1998). The 1996 experiment followed the previously described protocol for the 1990 study (Todd et al. 1992). Compounds screened included Z7-12:OAc, Z7-12:OH, Z7-14:OAc, Z9-14:OAc, 12:OAc, 11–12:OAc, and Z5-12:OAc. Sensillum types were assigned based on responses to Z7-12:OAc and Z7-12:OH (type I), Z9-14:OAc (type II), and Z7-14:OAc (type III). The other minor pheromone components usually only weakly stimulate ORNs sensitive to these other compounds. In all colonies, there also have been <5% sensilla with ORNs broadly tuned to many compounds, which are not considered in our analyses. Thus, our current approach reduces the potential number of sensillum types compared to what was delineated in the 1990 study (Todd et al. 1992).

Comparisons of the relative proportion of sensilla belonging to each of the three sensillum types in the evolved and wild-type colonies in 1990 and 1996 were made by using logistic regression including *colony* (evolved vs. wild-type) and *year* (1990 vs. 1996) as factors that might explain the frequency of sensillum types observed. PROC LOGISTIC in SAS (version 9.3) was use to perform this analysis.

Dose–Response Relationships Dose–response relationships were investigated in 1996 and more thoroughly in 2007. In both cases, we made pheromone cartridges from dilutions of Z7-12:OAc, Z9-14:OAc, and Z7-14:OAc in high-performance liquid chromatography (HPLC)-grade hexane. For each concentration (0.01, 0.1, 1, or 10 μg/μl), 10 μl was pipetted onto a 0.5 × 2.0-cm^2 filter paper strip held in a 15-cm-long Pasteur pipette odor cartridge. The filter paper loadings thus were 0.1, 1, 10, or 100 μg, a range that includes the 10-μg dose used successfully previously with the cut-tip method (Todd et al. 1992). The same cartridges were used for all recordings over an approximately 1-month period within a given year.

After a single stimulation with one such cartridge, there was at least a 30-s delay before further testing. For a typical sensillum, we began by administering the three compounds at the lowest concentration in random order. We then continued at each successively higher concentration by using the same order of compounds. When it became clear which sensillum type we had encountered, we usually completed the dose–response curve for the relevant compound only. For verification of the sensillum type, the other two compounds were puffed at the highest concentration at the end of the experiment. This protocol was also important to prevent biases in the pretest exposure of these compounds to other sensilla because we usually sampled multiple sensilla per antenna.

A total of 25 type I sensilla and 12 type II sensilla were sampled from wild-type males in 1996. During this same period, 12 type I sensilla and four type II sensilla were sampled from evolved-colony males. In the 2007 experiment, sensilla sampled included 149 type I, 36 type II, and 62 type III from wild-type males. We also sampled 88 type I, 33 type II, and 11 type III sensilla from evolved-colony males in 2007.

Additional precautions were employed for the 2007 experiment. The larger sample in 2007 allowed a more thorough exploration of statistical differences between the ORN characteristics of ORNs tuned to Z7-12:OAc vs. Z9-14:OAc in the populations, which might be relevant to their behavioral differences. By using the pattern of the distribution of sensillum types described by Grant et al. (1998), sampling was focused on the medial portion of the antenna where sensilla housing ORNs responsive to Z7-12:OAc and Z9-14:OAc should be found with high frequency. At the beginning of the experiment, sensilla were sampled randomly from this region. Sensilla were encountered with ORNs responsive to Z9-14:OAc much less frequently than those for Z7-12:OAc, and, thus, antennae were sampled as many times as possible in order to ensure that Z9-14:OAc-responsive ORNs were encountered at least once per moth. As the experiment proceeded, the analyst developed the ability to visually distinguish the sensillum types. To maintain an unbiased approach, pairs of ORNs responsive to Z7-12:OAc or Z9-14:OAc were sampled per antennae in random order, before sampling sensilla likely to have ORNs responsive to Z7-14:OAc. Thus, throughout the experiment, we ensured that the order of sampling of sensilla with ORNs responsive to Z7-12:OAc vs. Z9-14:OAc remained random. Also, sampling from the two colonies, coded only by number, was regularly alternated as much as possible, with approximately equal proportions of the moths sampled from the two colonies over each of the 3 weeks of the experiment.

To analyze the data, spike frequency dose–response curves were calculated for mutant vs. wild-type males in the 1996 and 2007 populations. Further hypotheses were tested concerning the response characteristics of Z7-12:OAc and Z9-14:OAc in the 2007 experiment. First, the maximum spike frequencies obtained within each dose series were compared for the ORNs responsive to Z7-12:OAc and Z9-14:OAc in wild-type vs. evolved-colony males. Usually, the greatest response was elicited at 100 μg, but sometimes there was a slight decline at 100 μg after a stronger response at 10 μg. Data were log-transformed to ensure that the distributions were normal and of homogeneous variance. Analysis of variance (ANOVA) was performed, using *ORN type*, *colony*, and *ORN type*×*colony* as factors. The analysis was performed such that per individual rather than per sensillum differences were considered. Thus, the latter two factors were nested within the individual sampled from (*Moth*).

The other hypothesis of interest was whether there were any differences between the colonies with respect to the threshold for responses to Z9-14:OAc and Z7-12:OAc. For this purpose, the minimum concentration eliciting responses to Z9-14:OAc or Z7-12:OAc was noted for all the relevant ORNs. Possible shifts in the threshold response doses were assessed by logistic regression, assuming a cumulative logit model, using the SAS procedure GENMOD. Contrasts were evaluated by comparing the distributions of thresholds of wild-type to evolved-colony males for ORNs in type I or type II sensilla. The interaction effect between *colony* and *ORN type* also was evaluated. It also must be considered that the unbalanced sampling of varying numbers of sensilla across males might bias the results. Thus, rather than using all sensilla without considering such subsampling, we weighed each observation proportionally to the number of sensilla sampled for that moth.

Cartridge Emissions and ORN Spike Frequencies in Type I and Type II Sensilla Compounds emitted from odor cartridges were collected as they were issued from the pipette tip in 25-cm-long glass collection tubes (3-mm ID). The tip of an odor cartridge containing the filter paper strip dosed with one of the pheromone components was inserted into a collection tube, and the connection was sealed with Teflon tape. The collection tube was placed in a container (20 cm long × 3-cm ID) filled with dry ice. The odor cartridge was connected to the flow controller that generated 20-ms puffs of air with the flow set at 15 ml/s through the cartridge. Collection tubes were washed with 30 µl of HPLC-grade hexane containing (*Z*)-10-pentadecenyl acetate (50 pg/µl) as an internal standard. Collected amounts were analyzed by using gas chromatography–mass spectrometry (GC–MS) in selective ion mode. Collected amounts were calculated as mean picogram per puff and corrected for differences in relative abundance of the selected ions relative to the internal standard. Trap breakthrough was checked and confirmed negative for all odor cartridges at the highest dose level by analyzing collected material in a second, in-series-connected, glass collection tube.

Collection protocol was as follows: Z7-12:OAc was collected by using 512 pulses for each dose. Collection of Z9-14:OAc was performed with 4,096 pulses of each dose. Collections were analyzed by using a 30-m DB-1 capillary column. All collection tubes were stored at −20°C prior to analyses by GC–MS.

For the 1996 and 2007 ORN data, ORN firing frequencies were plotted in response to emitted amounts of Z7-12:OAc and Z9-14:OAc from the cartridges. We interpolated the Z7-12:OAc to Z9-14:OAc ORN relative firing ratios in response to emitted amounts of Z7-12:OAc and Z9-14:OAc that had been measured from mutant and wild-type females (Haynes and Hunt 1990) in order to relate the peripheral olfactory input experienced by evolved-colony and wild-type males to their upwind flight behavior when exposed to the evolved-colony and wild-type pheromone blends (Liu and Haynes 1994; Hemmann et al. 2008).

Results

Compared to males in the wild-type colony, the ORNs of evolved-colony males exhibited lower mean spike frequencies in response to Z9-14:OAc and Z7-12:OAc at all concentrations in both 1996 and 2007 (Figs. 2 (A, B) and 3 (A, B)). However, the reduction in spike frequency was much greater for the evolved-colony male ORN response to Z9-14:OAc vs. that to Z7-12:OAc. Lower responsiveness of the Z9-14:OAc ORN in evolved-colony vs. wild-type males had been observed in the 1990 populations, although dose–response curves were not collected and sample sizes were smaller than in 2007 (Todd et al. 1992). In contrast, the 2007 spike frequencies in wild-type vs. evolved-colony males responsive to Z7-14:OAc appeared similar at all odorant doses (Fig. 3 (C)).

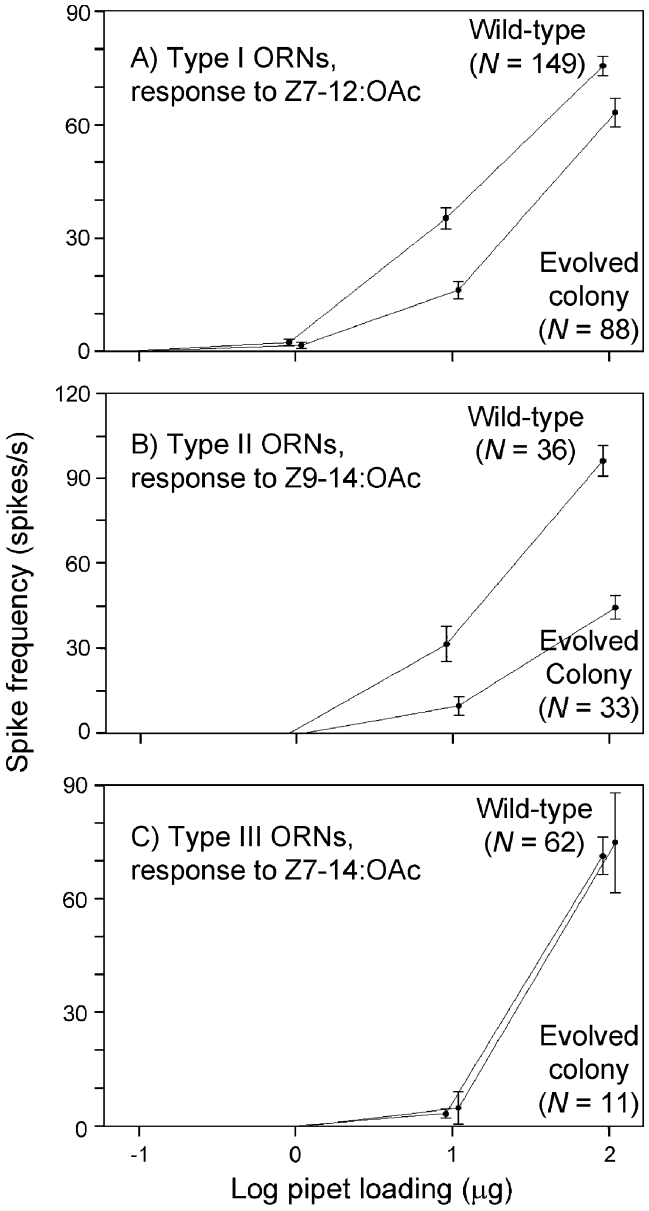

Fig. 3 Dose–response relationships for ORNs of type I (*A*), type II (*B*), and type III (*C*) sensilla to their respective ligands Z7-12:OAc, Z9-14:OAc, and Z7-14:OAc (mean spike frequency+SE). Means reflect pooled data from all individuals in which ORNs were sampled in 2007 (about 220 generations after the colony was initiated)

There were relatively fewer type II vs. type I sensilla located in the random search for evolved-colony vs. wild-type males as indicated by the corresponding significant regression coefficient (Tables 1 and 2). There was no similarly statistically significant relationship between the frequencies of type III vs. type I sensilla with respect to the *colony* effect (Table 2). However, it is also relevant to note that in 2007 we became able to locate any of these three sensillum types based on their consistent location and morphology. After achieving this capability, we could not detect any differences in the frequencies of these sensillum types. In the regression model presented in Table 2, only the *colony* effect is shown. Models also were considered where *year* and *colony*×*year* interactions were considered. In a full model that used all three factors, the model did not converge when the iterative method for obtaining maximum likelihood estimates of the parameters was performed. Models were also considered where either *year* or *colony-by-year* interactions were removed, which in both cases did not exhibit such a lack of convergence. Regardless of the model selected, *colony* was the only effect that was ever significant. Thus, we present the simplest model containing only this effect.

The pattern observed for differences in ORN response characteristics between wild-type and evolved-colony males in the dose–response curves is further reinforced by statistical analysis of the maximum spike frequencies for the Z9-14:OAc- and Z7-12:OAc-responsive neurons in wild-type and evolved-colony males from 2007. The average maximum spike frequency in response to Z9-14:OAc was greater than that for Z7-12:OAc in wild-type males (Fig. 4). This measurement was lower for both compounds in evolved-colony males. However, the reduced maximum spike frequency in evolved-colony males was much greater for responses to Z9-14:OAc than for those to Z7-12:OAc, thus resulting in lower response levels to Z9-14:OAc. The interaction effect indicative of this observation is statistically significant (Table 3).

There were significant differences in the distribution of observed threshold of responses for the evolved-colony and wild-type populations of ORNs for both type I and type II sensilla (Table 4). In both cases, more ORNs have a higher threshold of response to Z7-12:OAc or Z9-14:OAc in evolved-colony male vs. wild-type male sensilla. There was

Table 1 Proportion of sensilla of each ORN type

Sensillum type	Wild-type colony		Evolved colony	
	1990	1996	1990	1996
I (Z7-12:OAc)	77/112 (69%)	58/80 (72%)	83/96 (87%)	51/55 (95%)
II (Z9-14:OAc)	26/112 (23%)	12/80 (15%)	10/96 (10%)	4/55 (7%)
III (Z7-14:OAc)	3/112 (3%)	6/80 (7%)	3/96 (3%)	0/55 (0%)

The colonies were sampled in 1990 (gens. 14–17) AND 1996 (gens. 86–90)

no significant interaction effect between population and sensillum type in this analysis.

The amounts emitted per puff from the odor cartridges for a given filter paper loading conformed to previous measurements involving pheromone components that differed in chain length by two carbons (Cossé et al. 1998). The amount per puff of Z9-14:OAc emitted was approximately ten times lower than that of Z7-12:OAc at 1-, 10-, and 100-µg loading, respectively (Fig. 5).

Emitted amounts from cartridges were used not only for calculating ORN response thresholds (Table 4) but also for comparing the Z7-12:OAc to Z9-14:OAc ORN spike frequency ratios of evolved-colony compared to wild-type males in response to the mutant- and wild-type-female-emitted blends (Fig. 6). Amounts of Z7-12:OAc and Z9-14:OAc emitted by wild-type and mutant females (Hunt and Haynes 1990) fell between the emitted cartridge amounts for the 1996 and 2007 ORN data, as shown in Fig. 6 for our 2007 recordings only.

In both 1996 and 2007, wild-type males that, as a group, exhibited good upwind flight in response to their wild-type female pheromone blend (Liu and Haynes 1994; Hemmann et al. 2008) had a slightly greater than 1:1 Z7-12:OAc to Z9-14:OAc ORN firing ratio in response to this blend (Table 5). Similarly, evolved-colony males that had evolved the ability to fly upwind successfully in response to either the mutant or wild-type female blends exhibited ratios of firing of Z7-12:OAc to Z9-14:OAc ORNs that were approximately 1:1 or 3:1, respectively (Table 5). In contrast, in both years, wild-type males challenged to fly upwind in response to the mutant female blend exhibited poor upwind flight (Liu and Haynes 1994; Hemmann et al. 2008). It is of interest that the ORN firing ratio of this group of males in response to the mutant blend was the only one in which the Z7-12:OAc-tuned ORN's contribution to the ratio was only one half that of the Z9-14:OAc-tuned ORN (a 1:2 firing ratio; Table 5).

Discussion

Three aspects of ORNs responsive to Z9-14:OAc and Z7-12:OAc on male *T. ni* antennae were examined that could be relevant to the historical broadening of the behavioral response of evolved-colony males. This response now includes upwind flight to both the unusual pheromone blend produced by mutant females as well as the blend emitted by wild-type females (Haynes and Hunt 1990; Liu and Haynes 1994). These aspects include: (1) the relative abundance of each sensillum type; (2) the response threshold of each ORN within each type of sensillum; and (3) the spike frequencies exhibited by these ORNs in response to a given stimulus. Of these factors, all showed some statistically significant differences between evolved-colony and wild-type populations.

The most obvious difference we observed was the severe reduction in firing frequency of evolved-colony male exhibited by ORNs tuned to Z9-14:OAc (Figs. 2, 3, and 4, Table 3). Evolved-colony males also exhibited significantly reduced sensitivity and firing frequency of the ORN tuned to Z7-12:OAc compared to this type of ORN in wild-type males. However, there was a much greater reduction in responsiveness of the Z9-14:OAc-tuned ORN, underscored by the statistically significant interaction comparing alterations to ORN responsiveness in type I (Z7-12:OAc) vs. type II (Z9-14:OAc) sensilla in evolved-colony vs. wild-type males in 2007 (Fig. 4, Table 3). While the studies of evolved-colony and wild-type males in 1990 (Todd et al. 1992) and 1996 were not replicated and controlled well enough to demonstrate a similar statistically significant

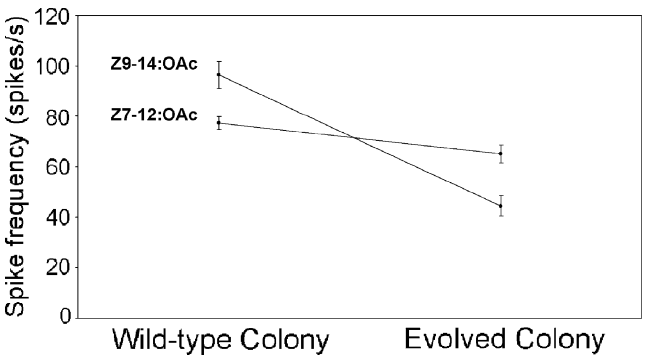

Fig. 4 Average of the maximum ORN response within each dosage series (mean spike frequency+SE) to Z7-12:OAc and Z9-14:OAc in the wild-type and mutant colonies. Means are weighted using per individual variation

effect, the trend also can be observed in the 1996 data (Fig. 2) and in 1990 (Todd et al. 1992). In the 1990 study, the ORN spike frequency in type I sensilla screened for response to Z7-12:OAc was lower in evolved-colony than in wild-type males by about 25% (134.6/s vs. 98.8/s). At the same time, a screening of type II ORN response to Z9-14:OAc showed a spike frequency in mutant male ORNs that was about 50% lower in evolved-colony than in wild-type males (142.3/s vs. 72.7/s).

It appears that there has been the evolution of a highly significant dampening of ORN responsiveness to Z9-14:OAc in males from the mutant colony. Thus, a behavioral response to a greater proportion of Z9-14:OAc in the female blend of mutant females is correlated with a diminished physiological response to that same component by the males. This alteration seems to have helped place the ratio of Z7-12:OAc to Z9-14:OAc peripheral inputs within a range acceptable to integrative centers in the brain. Therefore, a simple selective attenuation of a peripheral response to one component may explain the behavioral response.

However, a reduction in sensitivity of the Z9-14:OAc ORN pathway cannot also explain how evolved-colony males have simultaneously retained their ability to fly successfully upwind in response to the wild-type pheromone blend. The Z7-12:OAc to Z9-14:OAc spike frequency ratios in wild-type ORNs exposed to the wild-type female blend range from 1.13:1 to 1.41:1, whereas the ratios of evolved-colony male ORNs flying upwind to wild-type or mutant blends were somewhat lower or higher than this range, respectively. In evolved-colony males exposed to the wild-type blend, the ratio of spiking activity would be more heavily skewed (3:1) toward the Z7-12:OAc ORN than in wild-type males exposed to this same blend. Thus, ORN spike frequency ratios, which are somewhat higher (3:1 for evolved-colony male ORNs to the wild-type blend) or lower (0.83:1 or 1.05:1 for evolved-colony male ORNs to the mutant blend) than the ratio range shown above for the wild-type male ORNs to the wild-type blend, are at least adequate for upwind flight. The poorest upwind flight and source contact was exhibited by wild-type males in response to the mutant blend, and this ratio was low (1:2) and dominated by the activity of the Z9-14:OAc ORN, apparently making it out of the normally acceptable range to promote flight.

It is difficult to reconstruct precisely the sequence of olfactory changes that occurred at the inception of the evolved colony along with the evolution of behavioral responsiveness to both the mutant and wild-type pheromone blends. Many critical tests that would have been

Table 4 Threshold of responses in type I and type II sensilla from 2007

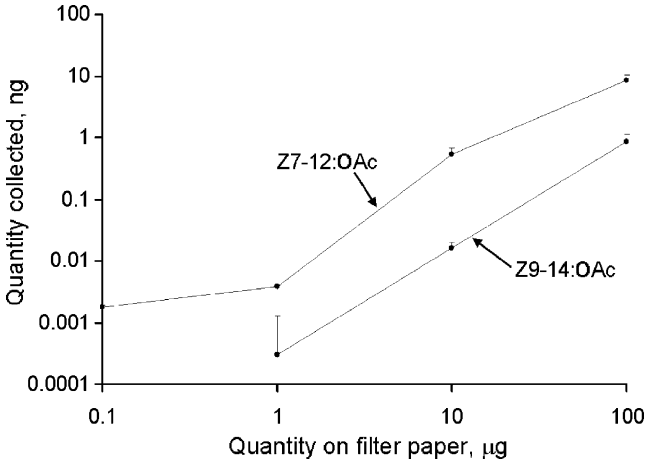

Fig. 5 Relationship between the dosage applied to filter papers in the odor cartridges and the amounts emitted from the cartridges per single puff (mean+SE). Sample sizes vary for each concentration ($N = 2$ for Z7-12:OAc at 1 µg, $N = 3$ for Z7-12:OAc at 0.1 µg, and Z9-14:OAc at 1 µg and 10 µg, $N = 4$ for Z7-12:OAc at 10 µg and 100 µg, and Z9-14:OAc at 100 µg)

useful in the earliest generations did not become apparent until later on. Despite such inherent difficulties, a reasonable historical scenario is beginning to emerge.

At the initiation of the evolved colony line, male ORNs from the first few generations were not sampled to provide a baseline reading of ORN firing frequency ratios. However, because males were randomly selected from the wild-type population to mate with mutant females to initiate the mutant colony, it is reasonable to assume that the ORN firing ratios in response to different pheromone blends did not differ initially between the two colonies, and this is consistent with behavioral observation at the time. A new pattern of behavioral responsiveness to the mutant female blend by males began to evolve between 10 and 25 generations after the colony was founded (Liu and Haynes 1994). Males from this colony have exhibited a shift from an approximately 1:2 Z7-12:OAc to Z9-14:OAc ORN firing ratio in response to the mutant pheromone blend to a 1:1 ratio in response to this mutant blend. Concomitantly, a ratio of nearly 3:1 of Z7-12:OAc to Z9-14:OAc ORN firing in response to the wild-type blend was established as a result of this shift in ORN responsiveness. This ratio likewise is coincident with the retention of adequate levels of upwind flight by evolved-colony males to the wild-type female blend. Although we can provide only strong statistically confirmation of this physiological alteration from more recently employed experiments, it is likely to have occurred by 1990 (generations 14–17), when limited sampling pointed to this trend (Todd et al. 1992).

We caution that it is not clear if the physiological alteration is a direct cause of the behavioral evolution of the mutant colony population or is one in addition to other potentially important factors. These physiological assays of earlier generations had sample-size limitations and were not experimentally linked to behavioral observations, while neither trait was likely to be fixed in the population. Further experimental inquiries into the degree of genetic linkage between the mutant behavior, the ORN firing ratio alteration observed here, and perhaps yet unknown factors are still possible and could contribute to understanding how this novel behavior evolved. It also would be interesting to investigate the potential linkage of the female pheromone and male ORN and behavioral response traits. With these caveats, the current focus on peripheral ORN response shifts do not preclude the role of olfactory alterations such as changes in antennal lobe interneuron response profiles or the central nervous system olfactory integration of the incoming ORN activity.

Nevertheless, profound shifts in pheromone behavioral response profiles have been shown to have occurred in other species such as the E and Z strains of *O. nubilalis* due to alterations of the ORNs alone (Kárpáti et al. 2008). In that case, behavioral blend preferences are correlated with shifts in the primary afferents' tuning profiles, with

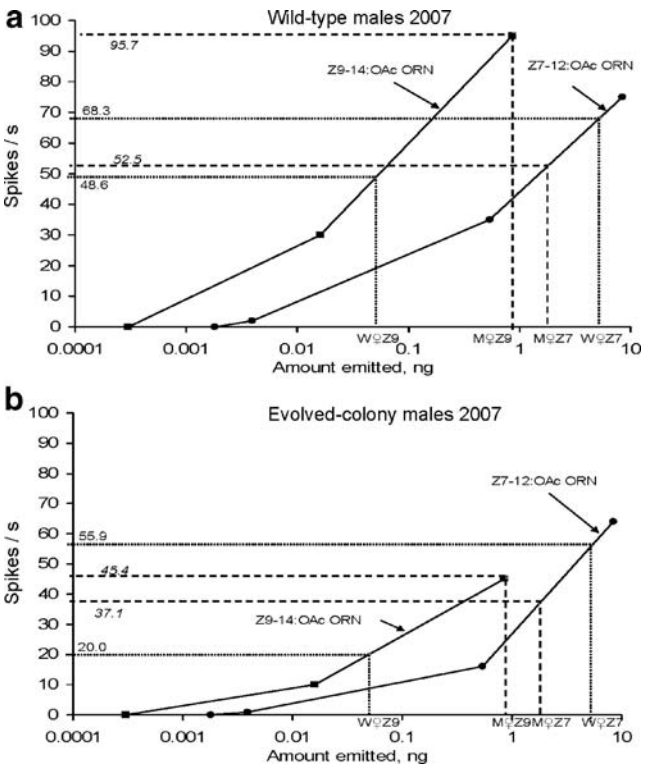

Fig. 6 Dose–response curves for the Z7-12:OAc- and Z9-14:OAc-tuned ORNs in **a** wild-type and **b** evolved-colony males using the amounts emitted from the odor cartridges. Interpolations were made to construct the firing frequencies of the ORNs in response to the amounts of Z7-12:OAc and Z9-14:OAc emitted by wild-type and mutant females in their blends (Haynes and Hunt 1990). The interpolated ratios of Z7-12:OAc/Z9-14:OAc ORNs are shown in Table 5. *Dashed line* shows mutant female emission rate. *Dotted line* shows wild-type emission rate

Table 5 Z7-12:OAc/Z9-14:OAc ORN spike frequency ratios and flight performance

2007[a]			
Wild-type males			
Wild-type female blend	69:49 spikes per second	(1.41:1)	Good flight
Mutant female blend	53:96 spikes per second	(0.55:1)	Poor flight
Evolved-colony males			
Wild-type female blend	56:20 spikes per second	(2.80:1)	Adequate flight
Mutant female blend	38:46 spikes per second	(0.83:1)	Adequate flight
1996			
Wild-type males			
Wild-type female blend	72:64 spikes per second	(1.13:1)	Good flight
Mutant female blend	54:109 spikes per second	(0.49:1)	Poor flight
Evolved-colony males			
Wild-type female blend	56:20 spikes per second	(2.80:1)	Adequate flight
Mutant female blend	39:37 spikes per second	(1.05:1)	Adequate flight

[a] See Fig. 6 for derivation of ratios

no changes in glomerular wiring (Kárpáti et al. 2008). Furthermore, the ORN alteration documented here for *T. ni* is similar in many respects with others observed that involve unusual behavioral variants of the corn borer species *O. nubilalis* and *O. furnacalis* that included broadened behavioral receptivity, characterized by upwind flight to conspecific and heterospecific pheromone blends. These rare behavioral phenotypes had correlated alterations to their ORNs, which were likely to impact relative ORN firing rates (Domingue et al. 2007a, b), as we observed here for *T. ni*. Together, the results of such studies support the generality of the "balanced olfactory antagonism" (Baker 2008) model for insect olfactory systems. In this model, there is said to be a set point for a behaviorally optimal balanced ratio of neuronal activity along mutually antagonistic odorant-specific olfactory pathways. The model predicts that a previously narrow range of pheromone component blend ratios can be expanded to include a wider range after alterations in olfactory activity occur, often at the ORN level. Differential changes in the sensitivities of differently tuned ORN classes may allow previously unacceptable pheromone blend ratios to evoke ratios of firing that fall within the acceptable balanced range (Baker 2008).

In both the *T. ni* and *Ostrinia* study systems, reductions rather than increases in ORN responsiveness appear to be the critical factors that promote flight to rare or mutant pheromone blends in laboratory populations. More specifically, these significant reductions in responsiveness tend to occur on ORNs associated with the minor pheromone components as described here for *T. ni* (also, *O. nubilalis* Domingue et al. 2007b) or with heterospecific behavioral antagonists (*O. furnacalis*, Domingue et al. 2007a). After such alterations have occurred, compounds that were previously antagonistic at low proportions in the pheromone blend can become acceptable and even promote flight at higher ratios.

The molecular basis for the observed reductions in ORN responsiveness in the rare *T. ni* males is speculative given the current level of knowledge of the functionality and expression of odorant receptors (ORs) and other factors influencing signal transduction in this species. Possible explanations might include, but are not limited to, changes to the conformations of ORs or reductions in the numbers of normal ORs expressed on the dendrites. Interestingly, if it were not for the severe decline in responsiveness of the Z9-14:OAc-tuned ORNs, the evolved males' slight reduction in responsiveness of the Z7-12:OAc-tuned ORNs alone may have actually created a less optimal ORN firing ratio for upwind flight to the mutant blend.

As described above, evolved-colony *T. ni* males are equally likely to fly upwind to mutant or wild-type blends, but respond positively to the wild-type blend less often than wild-type males do (Hemmann et al. 2008). It has been previously determined that this particular shift in behavioral response patterns can cause assortative mating between members of the two strains under certain rearing conditions (Zhu et al. 1997). It is thus possible that the physiological alteration described here represents a neuroethological cause of reproductive isolation, which involves a tradeoff between the breadth and sensitivity of the pheromone response.

Formidable challenges remain for explaining how the final stages of a speciation event could occur after the initial stages of reproductive isolation evolve because of an olfactory alteration of the particular types uncovered in the laboratories. How could the novel broadly tuned pheromone response system characteristic of the intermediate behavioral state further evolve into another highly sensitive and narrowly tuned system typical of most closely related species or races found in nature (Kárpáti et al. 2008), where reproductive isolation from the parent population is strong? Perhaps certain saltational events, such as radical changes in OR conformation, the

substitution of different ORs on dendrites, or reorganization of aspects of the central nervous system will be more likely to be adaptive when most males of a population are already in a broadly tuned state similar to that currently in existence for the evolved *T. ni* colony. After such a saltational event, it may become possible for selective pressures again to allow increases in the specificity and sensitivity of the pheromone system in a manner that continues to facilitate reproductive isolation from the parent population.

Acknowledgments Andy Myrick of Penn State University assisted in the statistical calculations. Bonnie Chastain and Shelby Stamper of the University of Kentucky maintained insect colonies.

Mechanism and Behavioral Context of Male Sex Pheromone Release in *Nasonia vitripennis*

Sven Steiner · Joachim Ruther

Received: 28 January 2009 / Revised: 27 March 2009 / Accepted: 29 March 2009 / Published online: 24 April 2009

Abstract Males of the parasitic wasp *Nasonia vitripennis* (Hymenoptera: Pteromalidae) attract virgin females by releasing a sex pheromone composed of (4*R*,5*R*)- and (4*R*,5*S*)-5-hydroxy-4-decanolide (HDL). The pheromone is biosynthesized in the rectal vesicle of males. In the present study, we investigated the mechanism and behavioral context of pheromone release, and determined the range of activity and the longevity of the chemical signal. Our data show that the sex pheromone of *N. vitripennis* is substrate-borne and is deposited on surfaces by dabbing movements of the abdominal tip, a behavior previously described in *N. vitripennis* males as 'abdomen dipping'. Chemical markings deposited by a single male were highly attractive to virgin females. Chemical analyses revealed the presence of HDL in surface washings of marked areas, and HDL amounts correlated with male marking activity. Pheromone deposition occurred spontaneously without any additional cues being present, but marking intensity increased greatly after copulation or after a single contact with a virgin female. In contrast, marking intensity was not influenced by the presence of host puparia. Male pheromone deposits were perceived by females in a still-air olfactometer at distances of up to 4.5 cm and remained attractive for at least 2 h. The function of the substrate-borne sex pheromone is discussed with respect to the mating system of *N. vitripennis*.

Introduction

Parasitic Hymenoptera play an important regulative role in agricultural and natural ecosystems (Godfray and Cook 1997; Keeling et al. 2004). Interest in pheromone chemistry of this large and biologically diverse group is increasing, particularly because of the practical value of using natural enemies of insect pests. Sexual communication in parasitic wasps has long been assumed to be mediated mainly by female-derived pheromones that function either in attraction of males over long distances or in male courtship behavior at close range (Quicke 1997; Kainoh 1999; Ayasse et al. 2001; Steiner et al. 2005, 2006). Recent studies have revealed that, depending on the mating system, males also can be the sex that releases pheromones, thus enabling mate attraction and arrestment, respectively (Consoli et al. 2002; Ruther et al. 2007, 2008).

Nasonia vitripennis (Walker) (Hymneoptera: Pteromalidae) is a cosmopolitan ectoparasitoid that develops gregariously in pupae of cyclorrhaphous flies (Whiting 1967). The species occurs naturally in nests of hole-breeding birds and carcasses and has been a model organism for the study of parasitic wasp biology for more than four decades (Beukeboom and Desplan 2003; Shuker et al. 2003). Recent studies have demonstrated the existence of a male-derived sex pheromone in *N. vitripennis* that is highly attractive to virgin but not mated females. It is composed of a mixture of (4*R*,5*R*)- and (4*R*,5*S*)-5-hydroxy-4-decanolides (HDL) (Ruther et al. 2007). Attractiveness of HDL is synergized by the trace component 4-methylquinazoline (4-MeQ), which co-occurs with HDL in the male abdomen but is not attractive as a single compound (Ruther et al. 2008). Histological and selective chemical analyses of different abdominal tissues have revealed that HDL is synthesized in the male rectal papillae and is secreted to the

rectal vesicle (Abdel-latief et al. 2008). However, the mode and behavioral context of pheromone release, as well as the range of activity and longevity of the chemical signal, is not well understood. Previous studies on *N. vitripennis* reported that males display dabbing movements of their abdominal tips, thereby depositing fluid drops as continuous streaks (Barras 1969; van den Assem et al. 1980). This behavior, termed "abdomen dipping", is shown by males particularly after mating. Since *N. vitripennis* males are territorial, abdomen dipping has been suggested as serving as a chemical marking of male residence areas (van den Assem et al. 1980). However, these observations are anecdotal, and the exact function of the behavior remains unknown.

In this study, we tested the hypothesis that *N. vitripennis* males show abdomen dipping and deposit the sex pheromone, and we investigated the behavioral context in which this behavior is shown. For this purpose, we performed behavioral bioassays and chemical analyses to study whether: (a) male markings are attractive to virgin females, (b) the main pheromone component HDL can be detected on marked substrates, (c) HDL amounts in surface extracts correlate with the intensity of male marking behavior, and (d) the intensity of male marking behavior is influenced by previous mating, mere contact with females, or the presence of host puparia. The influence of host puparia was tested because, in many insects, pheromone calling is elicited by oviposition substrates or volatile chemicals associated with these resources (Landolt and Phillips 1997). Finally, we narrowed the range of activity and the longevity of male markings. The results are discussed with respect to the biology and the mating system of *N. vitripennis*.

Methods and Materials

Insects and General Methods Parasitic wasps were reared on pupae of the green bottle fly *Lucilia caesar* (Diptera: Calliphoridae) at 25°C, 60% relative humidity, and a photoperiod of 16:8 h (L/D) (for details, see Ruther et al. 2007). To obtain virgin parasitoids of both sexes, pupae were excised from host puparia 1–2 days before eclosion and kept individually in 1.5 ml microcentrifuge tubes (Brand GmbH, Wertheim, Germany) until emergence. The females that were used to test the attractiveness of male deposits were virgin and between 2 and 3 days old. The males that were used to investigate characteristics of the marking behavior were 2 days old and of comparable size. Size was determined by measuring the head width of fully melanised pupae under a stereo microscope with the help of a measuring eyepiece. Only pupae with a medium head width (660 to 700 μm) were used for the experiments. Mated males were obtained by keeping a single virgin female together with a virgin male in a microcentrifuge tube until mating was observed. One hour before testing, parasitoids were placed into the bioassay room to allow acclimatization to experimental conditions. Frequency of male abdomen dipping was observed under a stereomicroscope. Behavioral parameters in all experiments were recorded with the computer software The Observer 3.0 (Noldus Information Technology, Wageningen, The Netherlands). All experiments were conducted at room temperature (20–22°C). Parasitoids were used only once.

Experiment 1: Attractiveness of Male Markings Attractiveness of male markings to virgin females was examined by using a static four-cavity olfactometer. This was made of acrylic glass and consisted of a round walking arena (9-cm diameter, 8-mm thick) equipped with four symmetrically arranged spherical cavities (1-cm diameter, 4-mm deep), a low rim (2-mm high), and a glass plate to cover the arena. Single males were mated, transferred to one of the cavities (test cavity), and allowed to deposit chemical markings on the surface for 3 min. Males that did not show the characteristic abdomen dipping movements during this time were excluded from the experiment. The other three cavities remained empty and were used as controls. After males were removed, virgin females were released individually into the center of the four-cavity olfactometer, and the time they spent in test and control cavities was recorded for 5 min (N=20).

Experiment 2: Chemical Analyses of Marked Substrates - Single males of equal size were placed into a bioassay arena (1-cm diameter, 4-mm high) immediately after a copulation, and the frequency of abdomen dipping was recorded for 3 min. Subsequently, males were removed, and the surface of the arena was rinsed with 50 μl dichloromethane containing 5 ng/μl methyl undecanoate (Sigma-Aldrich, Deisenhofen, Germany) as an internal standard. The bioassay arena was made of polytetrafluoroethylene (Teflon) to minimize contamination of the extracts. Aliquots (1 μl) were analyzed by coupled gas chromatography–mass spectrometry (GC-MS) on a Fisons 8060 GC (Fisons Instruments, Mainz-Kastel, Germany) equipped with a 30 m×0.32 mm DB-5 ms capillary column (film thickness, 0.25 μm; J & W Scientific, Folsom, CA, USA) and linked to a Fisons MD800 quadrupole MS running in the electron impact (EI) mode at 70·eV. Helium (1 ml/min) was used as carrier gas. Initial oven temperature was 80°C, increased at 5°C/min to a final temperature of 280°C, and then held for 30 min. Total HDL amounts in the extracts were determined by relating peak areas to the internal standard and to the frequency of abdomen dipping displayed by the respective male (Ruther et al. 2007; N=15).

Experiment 3: Behavioral Context of Abdomen Dipping To study the behavioral context of abdomen dipping, individual males were placed into an observation chamber made of glass (3-cm diameter, 12-mm high), and the frequency of abdomen dipping was determined for 5 min under the following conditions: (a) without any additional cue (control), (b) in the presence of three unparasitized host puparia, (c) immediately after males had a single copulation with a virgin female, and (d) immediately after males had a single contact with a virgin female but were not allowed to copulate (N=15 for each condition).

Experiment 4: Longevity of Pheromone Markings To estimate the time period in which male pheromone deposits remain attractive to virgin females, we used a linear still-air olfactometer that consisted of an angular acrylic tube (14×1×1 cm) that was divided into 4-cm test and control zones at either end and with a 6-cm neutral zone in the center (Ruther et al. 2008). Microcentrifuge tubes were attached to both ends and separated from the main olfactometer arena by gauze (mesh, 0.5 mm). The tube that was connected to the test zone contained pheromone deposits released by single freshly mated males for 10 min. The tube connected to the control zone remained untreated. Volatiles were allowed to diffuse from the tubes into the olfactometer for 5 min, thus enabling the formation of an odor gradient. Subsequently, virgin females were released individually into the neutral zone, and the time parasitoids spent in test and control zone was recorded for 5 min. Odor sources were exchanged after two females had been tested. Attractiveness of the pheromone deposits was tested 0, 1, 2, and 3 h after males had deposited the pheromone (N=15). Between pheromone deposition and bioassay, microcentrifuge tubes were stored at room temperature without cover.

Experiment 5: Range of Activity of Pheromone Markings The purpose of this experiment was to estimate the distance from which *N. vitripennis* females are able to locate the pheromone source. The test was performed in a transparent polyethylene still-air Y-olfactometer (5-mm inner diameter) that consisted of a 4-cm stem and two arms of variable length (3-, 4.5-, or 6-cm distance to the branching point). Two removable polyethylene chambers (1-cm long, 4-mm inner diameter) containing pheromone deposits of a single male (test chamber, see experiment 4) or untreated (control chamber) were connected to the ends of both arms. The olfactometer was fixed vertically on a white cardboard (30×30 cm) and illuminated from above (2,050 lx). Volatiles were allowed to diffuse into the arms of the Y-tube for 5 min. Subsequently, *N. vitripennis* females were introduced individually into the olfactometer via the stem and allowed to choose one of the two arms within 3 min. Final choice was recorded when females walked at least 3 cm into one of the two arms. Females that did not make a choice within the 3 min were assumed to be unmotivated and thus were excluded from statistical analyses. Pheromone sources were renewed after every 10 min, and the olfactometer was cleaned with ethanol and demineralized water. To avoid biased results due to possible side preferences, positions of test and control chambers were exchanged regularly (N=36 for each distance).

Statistical Analyses Statistical analyses were performed by using Statistica 4.5 scientific software (StatSoft, Tulsa, OK, USA). Data in text and figures are presented as mean ± SE. The residence times that female parasitoids spent in experiment 1 in test and control cavities of the olfactometer were analyzed by a Friedman analysis of variance, followed by a Wilcoxon–Wilcox test for multiple comparisons. A Pearson correlation was done in experiment 2 to analyze the relationship between HDL amounts and the frequency of male abdomen dipping. The frequency of abdomen dipping displayed by males in experiment 3 in different situations was analyzed by a Kruskal–Wallis H test, followed by multiple Bonferroni-corrected Mann–Whitney U tests for individual comparisons. The residence time females spent in experiment 4 in the test and control zone of the linear still-air olfactometer was analyzed by a Wilcoxon matched-pairs test. Female preferences for test and control arm of the Y-olfactometer in experiment 5 were analyzed by a one-tailed binominal test.

Results

Attractiveness of Pheromone Markings (Experiment 1) Virgin females spent significantly more time in the test field that contained the male markings than in the empty control fields of the four-cavity olfactometer (Fig. 1).

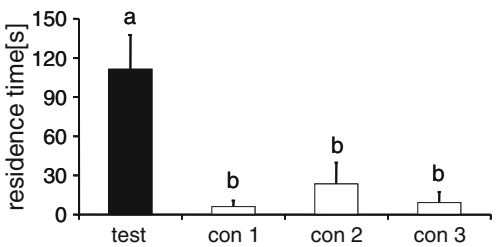

Fig. 1 Mean residence time (±SE) of virgin *Nasonia vitripennis* females in a static four-cavity olfactometer during a 5-min observation period. The test cavity contained pheromone markings deposited by a mated male for 3 min; the control cavities (con 1–3) remained untreated. *Bars with different lower case letters* are significantly different at P<0.001 (analyzed by Friedman analysis of variance, followed by Wilcoxon–Wilcox tests for multiple comparisons; N=20)

Chemical Analyses of Marked Substrates (Experiment 2) Following copulation, 80% of *N. vitripennis* males displayed abdomen dipping. The main pheromone components (4*R*,5*R*)- and (4*R*,5*S*)-HDL were detected in dichloromethane extracts of the marked substrates. During the 3-min observation period, they dipped on average 13.5±2.8 times on the substrate, thereby depositing 23.3± 5.3 ng HDL. There was a positive correlation between the frequency of abdomen dipping and the amount of total HDL determined in the surface extracts (r=0.790; t=4.649; P<0.001; N=15; Fig. 2).

Behavioral Context of Abdomen Dipping (Experiment 3) Males showed the marking behavior in all situations tested, albeit not with the same intensity (Fig. 3). They performed abdomen dipping at a very low level when additional cues were missing (5.9±2.4) or in the presence of host puparia (6.0±2.1). However, the frequency of abdomen dipping increased greatly after copulation (36.2±3.6) and even after a single contact with a virgin female (25.7±4.3).

Longevity of Pheromone Markings (Experiment 4) Females were strongly attracted to male pheromone markings 0, 1, and 2 h after pheromone deposition, and they spent significantly more time in the test zone than in the control zone of the linear olfactometer (Fig. 4). Three hours after pheromone deposition, however, females no longer responded to the markings (P=0.14).

Range of Activity of Pheromone Markings (Experiment 5) Females preferred the test arm over the control arm of the Y-olfactometer when the pheromone source was presented at distances of 3 and 4.5 cm from branching point (Fig. 5). At a distance of 6 cm, however, they did not distinguish between test and control arm (P=0.12).

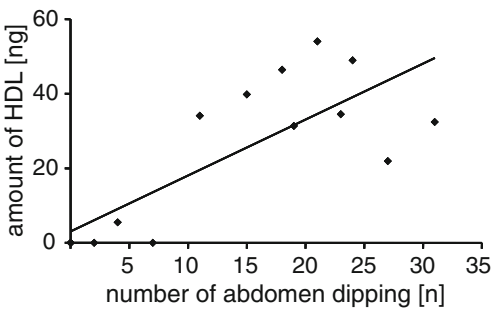

Fig. 2 Relationship between the frequency of abdomen dipping performed by *Nasonia vitripennis* males immediately after copulation during a 3-min observation period and the total amount of HDL extracted from the marked substrate (analyzed by a Pearson correlation; N=15)

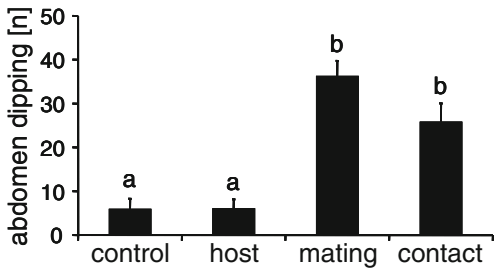

Fig. 3 Frequency of abdomen dipping by *Nasonia vitripennis* males under the following conditions: (1) without any additional cue (control), (2) in presence of host puparia, (3) immediately after mating, and (4) immediately after contact with a virgin female. *Bars with different lower case letters* are significantly different at P<0.05 (analyzed by a Kruskal–Wallis H test, followed by multiple Bonferroni-corrected Mann–Whitney U tests for multiple comparisons; each N=15)

Discussion

The study demonstrates that *N. vitripennis* males deposit their sex pheromone by the typical abdomen dipping behavior. Areas marked by a single male were strongly attractive to virgin females in the olfactometer bioassays, and GC-MS analyses revealed the presence of the major pheromone components (4*R*,5*R*)- and (4*R*,5*S*)-HDL in surface extracts. Total HDL amounts determined in these extracts correlated with the frequency of abdomen dipping displayed by individual males. The synergizing trace component 4-MeQ was not detectable in the surface washings by the applied GC-MS protocol, but the presence of this extremely odorous compound (Ruther et al. 2008) was indicated unambiguously by the characteristic medicinal odor of the marked substrates.

Pheromone production or sequestration in the rectum and release via the anal orifice is not unparalleled in

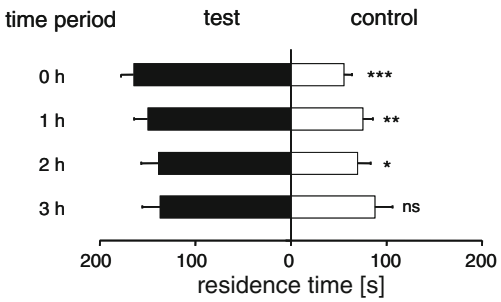

Fig. 4 Mean residence time (±SE) of virgin *Nasonia vitripennis* females in the test and control zone of a linear still-air olfactometer 0, 1, 2, and 3 h after pheromone deposition. Tubes connected to the test zone contained pheromone markings deposited for 10 min by a single male immediately after copulation; tubes of the control zone were untreated. *Asterisks* indicate significant differences (*P<0.05, **P< 0.01, ***P<0.001); *ns* not significant (analyzed by Wilcoxon matched-pairs test; each N=15)

The test arm of the Y-tube contained pheromone markings deposited for 10 min by a single male immediately after copulation; the control arm was untreated. *Asterisks* indicate significant differences (***$P<0.001$); *ns* not significant (analyzed by one-tailed binominal test; $N=36$)

insects. Males of many tephritid fruit flies use rectal pheromones to attract females (Fletcher and Kitching 1995; Khoo and Tan 2005). However, pheromone release in these insects is airborne and often supported by morphological adaptations. The melon fly *Dacus cucurbitae*, for instance, has evolved a spray mechanism by which pheromone droplets are transferred from the anus to the wings by the hind legs and subsequently are spread by wing vibration (Kuba and Sokei 1988). Substrate-borne release of rectal pheromones for recruitment purposes is known from many ant species of the taxon Formicinae (Übler et al. 1995). As in *Nasonia*, the bioactive chemicals are released via the anus by dipping movements of the abdomen (Hölldobler and Wilson 1990).

Other aculeate hymenopterans also use substrate-borne pheromones in the context of sexual communication. In bumblebees, for example, males mark spots along their patrol routes with labial gland secretions that are attractive to females (Ayasse et al. 2001). Males of the European beewolf, *Philanthus triangulum* F. (Hymenoptera, Crabronidae), attract females by marking territories with a sex pheromone secreted by the postpharyngeal gland (Kroiss et al. 2006). The use of substrate-borne sex pheromones also is documented for parasitic Hymenoptera. Females of the solitary parasitoid *Aphelinus asychis* Walker deposit a pheromone on the ground, and males follow the trail to the source by intensive antennal searching on the marked areas. However, the chemical identity and the production site of the pheromone is unknown (Fauvergue et al. 1995). A similar mate finding mechanism also has been suggested for *Ascogaster reticulatus* Watanabe (Kamano et al. 1989), *Trichogramma brassicae* Bezdenko (Pompanon et al. 1997), and *Aphytis melinus* DeBach (Bernal and Luck 2007). In contrast to the present study, however, substrate-borne sex pheromones in these parasitoids were female-derived.

The release of sex pheromones by male insects is sometimes associated with the presence of resources crucial for female reproduction (Wyatt 2003). Males of the papaya fruit fly, *Toxotrypana curvicauda*, for example, display distinct pheromone calling on the fruits used by females for oviposition (Landolt et al. 1992). In this way, responding females are rewarded with both copulation and oviposition substrate at the same site. Our results do not support such a mechanism in *N. vitripennis*, since males did not enhance the frequency of abdomen dipping in the presence of host puparia. A decisive parameter for the release of marking behavior, however, is the presence of females. Although males also showed marking behavior spontaneously and in the absence of additional cues, they clearly increased their marking activities shortly after copulation and even after mere contact with a virgin female. This suggests that males have to economize the pheromone and release higher amounts particularly when the chance is high that pheromone calling will result in mating. The mating system of *N. vitripennis* is characterized by local mate competition (Werren 1983; Shuker et al. 2005). Flightless males that emerge before females will typically mate with those emerging in rapid succession from the same host or host patch (van den Assem 1986). Hence, the presence of one virgin female indicates that others are in the vicinity, and pheromone release is likely to pay off.

Our results on the range of activity and the longevity of the chemical signal are in agreement with the *N. vitripennis* mating system. The data show that male markings attract virgin females only over relatively short distances. Pheromone molecules reach the females only by diffusion, and dispersion by wind plays a negligible role (which can be assumed in natural habitats like nests of hole-breeding birds). Thus, the male-derived sex pheromone has a range of activity of approximately 5 cm and is unlikely to assist in mate finding over longer distances. Since mating in *N. vitripennis* occurs exclusively at the site of emergence, chemically mediated long range attraction, as known particularly from solitary parasitoids (Godfray 1994), should be of no importance in this species. Male pheromone markings remained attractive for at least 2 h. Therefore, to avoid waste of resources and to make the pheromone markings a reliable signal, males should be faithful to the site of pheromone release. Indeed, it has been reported that *N. vitripennis* males sometimes stay for days at the site they have marked after copulation (van den Assem et al. 1980). However, in a previous study, males were not arrested by (4*R*,5*R*)- and (4*R*,5*S*)-HDL, the main components of their sex pheromone (Ruther et al. 2007). This suggests that other components of the abdominal secretion are involved.

Male-Produced Aggregation Pheromone of the Lesser Mealworm Beetle, *Alphitobius diaperinus*

Robert J. Bartelt · Bruce W. Zilkowski · Allard A. Cossé · C. Dayton Steelman · Narinderpal Singh

Received: 30 October 2008 / Revised: 6 February 2009 / Accepted: 23 February 2009 / Published online: 1 April 2009

Abstract The lesser mealworm beetle, *Alphitobius diaperinus* (Panzer), is a widespread serious pest in poultry production facilities and is difficult to control by conventional means. Although pheromone-based tools have become useful in the management of other beetle pests, no pheromone was known for *A. diaperinus*, and this study sought to develop basic pheromone information. Volatiles were collected in the laboratory from groups of male and female *A. diaperinus* maintained on poultry food (chick starter mash). Gas chromatographic–mass spectrometric analysis of volatiles collected from feeding males and females revealed five male-specific compounds that were identified as (*R*)-(+)-limonene, (*E*)-β-ocimene, (*S*)-(+)-linalool, (*R*)-(+)-daucene, and 2-nonanone. Emission of these began 1–2 weeks after adult emergence and could continue for at least 1 year, ceasing and resuming in response to changes in food availability and quality and other factors. No female-specific compounds were discovered. A synthetic blend of the five male compounds was attractive to both sexes in poultry production facilities in Illinois and Arkansas, indicating that the blend functions as an aggregation pheromone, but it is not yet known whether all five compounds are required for activity. A new pitfall trap is described for field use.

Introduction

The lesser mealworm, *Alphitobius diaperinus* (Panzer) (Coleoptera: Tenebrionidae), also known as the darkling beetle or litter beetle, is a small (5–6 mm), shiny, black beetle species with a cosmopolitan distribution. This species has become an important insect pest of commercially raised poultry. Both adults and larvae are scavengers (Leschen and Steelman 1988), consuming chicken feed, feces, and dead birds and sometimes attacking living birds (Legner and Olton 1970; Pfeiffer and Axtell 1980). This insect harbors numerous avian pathogens (De las Casas et al. 1972, 1976) including *Salmonella typhimurium* (De las Casas et al. 1968; McAllister et al. 1994), *Escherichia coli* (McAllister et al. 1996), infectious bursal disease virus (McAllister et al. 1995), and *Campylobacter* (Strother et al. 2005). In addition, larvae and newly emerged adults damage poultry facility insulation as they tunnel to and from pupation sites, leading to increased heating and cooling costs (Ichinose et al. 1980; Safrit and Axtell 1984). Finally, attraction of dispersing beetles to outdoor lighting at night has led to heavy infestations in homes and businesses and, sometimes, to litigation (Gall 1980).

The lesser mealworm is difficult to control. Long-term dependence upon organic insecticides has resulted in the development of resistance. Loss of insecticide efficacy has been reported at poultry production facilities in many countries, including the USA (Wakefield and Cogan 1991;

Cogan et al. 1996; Lambkin 2005; Lambkin and Rice 2006; Steelman 2009). There is little current effort to develop new insecticides for the lesser mealworm.

Pheromones and other semiochemicals may offer alternative pest management strategies, but basic information on the chemical ecology of *A. diaperinus* is essentially lacking. There has been considerable research on semiochemicals in other Tenebrionidae, however. Defensive compounds have been described in over 100 tenebrionid species and consist primarily of quinones and 1-alkenes (Tschinkel 1975a). Cuticular hydrocarbons have been studied in tenebrionids (e.g., Lockey 1984 and references therein); these non-volatile compounds tend to occur in species-specific mixtures and likely have close-range behavioral importance. Volatile pheromones are also known. Six *Tribolium* species, some of which are serious grain pests, have male-produced aggregation pheromones (reviewed by Plarre and Vanderwel 1999), and the aldehyde, (4*R*,8*R*)-4,8-dimethyldecanal, is a major component (Suzuki and Mori 1983). One of these species, *Tribolium castaneum* (Herbst), was also found to have a female-produced pheromone, (*Z*)-2-nonenyl propionate, to which only males respond (Rangaswamy and Sasikala 1991). *Tenebrio molitor* L. has both a female-specific compound, (*R*)-4-methyl-1-nonanol (Tanaka et al. 1986), and a male-specific compound, (*Z*)-3-dodecenyl acetate (Bryning et al. 2005); both of these affect the behavior of the opposite sex. The broad-horned flour beetle, *Gnatocerus cornutus* (F.), has a male-produced aggregation pheromone, (1*S*,4*R*,5*R*)-(+)-α-acoradiene (Tebayashi et al. 1998; Tashiro et al. 2004), but no female-produced pheromone is known in this species. In *Parastizopus transgariepinus* Koch, 1-tridecene appears to function both as a component of the defensive secretion and as a male-produced sex pheromone (Geiselhardt et al. 2008). The chemical ecology of tenebrionids is complex, both biologically and chemically, and the literature provided little concrete guidance for this project.

Quinone defensive compounds have been found in *A. diaperinus* (Tseng et al. 1971). In a doctoral thesis, Falomo (1986) presented evidence for the existence of pheromones from both males and females. Her behavioral conclusions were based on laboratory pitfall bioassays. The research proceeded to the point of chromatographic purifications and examination of extracts by gas chromatography, but no chemical identifications were made.

Our study of *A. diaperinus* chemical ecology was begun to follow up on this earlier basic research. The initial approach was to compare volatiles from feeding males and females. Male-specific compounds were detected and fully characterized, but no female-specific compounds were found. Then, by using commercially available and synthetic chemicals, trapping experiments at poultry production facilities demonstrated attractiveness of the male-specific blend.

Methods and Materials

Beetles and Rearing Adult *A. diaperinus* were obtained from a commercial turkey production facility near Delavan, Tazewell County, IL, USA. The beetles were subsequently reared at NCAUR in Peoria, IL essentially by using the method of Falomo (1986). Briefly, rearing containers had a layer of wood shavings or fine vermiculite with pieces of corrugated cardboard on top, which served as pupation sites and hiding places for adults and larvae. Food for both adults and larvae was finely ground chick starter mash ("DuMor" brand, Tractor Supply Co., Brentwood, TN, USA). Water was provided, either by moistened sponges or by water-filled 5-ml vials, which were plugged with cotton dental wick and laid on their sides in the containers. The containers were misted with water every 1–3 days. Rearing containers were kept in an incubator with a temperature of 30°C, a humidity of 80–90%, and a 16:8-h (L/D) photoperiod. Periodically, young larvae were obtained by sifting rearing materials through various screens and then were transferred to new containers. Sifting also aided the recovery of pupae and prepupal larvae. Pupae were separated by sex under a microscope by using the differences in abdominal appendages described by Barké and Davis (1967). Newly emerged males and females were placed in groups by age (age range within groups was 1 week). These beetles were used for volatile collections.

Volatile Collections Erlenmeyer flasks (250 ml, with female 24/40 ground glass joints) were used as volatile collectors. Each flask was capped with a glass inlet/outlet adapter having a male 24/40 joint (catalog no. 5175, Ace Glass, Vineland, NJ, USA). Finely ground chick starter mash (approximately 5 g) was placed on the bottom of the flask and covered with a layer of vermiculite (approximately 2 cm). Water was provided by a vial with a cotton wick, as described above. Three or four cardboard squares (2×2 cm) gave additional shelter to beetles. Conditions in the volatile collectors mimicked those for successful rearing, but wood shavings were avoided because the abundant volatiles from these made the search for beetle compounds more difficult.

Adult beetles of a single sex and similar age, usually 50 in number, were added to the flask. Filters packed with Super-Q porous polymer (Cossé et al. 2002) were attached with short pieces of Teflon™ tubing to the inlet and outlet. Air was drawn through the flasks at 250–300 ml/min by a gentle vacuum connected to the outlet filter. The inlet filter served to clean incoming air, while the volatiles emitted within the flask were trapped on the outlet filter. Volatiles were recovered by rinsing filters with methylene chloride (500 μl) at intervals of 2–4 days. Temperature in the

incubator was 27°C, humidity was approximately 50%, and photoperiod was 16:8-h L/D.

During the course of the 2-year study, 20 groups of unmated males and 16 groups of unmated females were established and monitored in this way. Overall, 458 collections were made from males and 276 from females. In addition, 32 collections were made from identically prepared flasks, but without beetles. Two groups each of males and females were monitored continuously for 12 months. Each volatile collection was analyzed by gas chromatography (GC) or coupled GC mass spectrometry (GC-MS). A large number of collections were needed to detect consistent male/female differences and to distinguish them from spurious GC peaks due to occasional microbial growth or other unintended volatile sources. Selected collections were combined for further chemical analysis.

Chemical Instrumentation An HP 5890 gas chromatograph (Hewlett Packard, Palo Alto, CA, USA) was used for the GC–flame ionization detector (GC-FID) analyses. This instrument was equipped with a flame ionization detector, cool-on-column inlet, autosampler, and a DB-5MS column (30-m length, 0.25-mm i.d., 1.0-μm film thickness; J&W Scientific, Folsom, CA, USA) and was interfaced to an HP ChemStation data system. A 20-cm retention gap of deactivated fused silica, 0.53-mm i.d., was attached to the head of the column with a press-fit glass connector to allow injections with a standard syringe. Carrier gas was helium, with inlet pressure set to 140 kPa. Oven temperature program began at 50°C for 1 min, increased at 10°C/min to 250°C, and then remained at 250°C for 3 min. Injections were made in oven-track mode (inlet temperature was always 3°C warmer than oven temperature), and detector temperature was 250°C.

For GC-MS, a 5973 mass-selective detector was interfaced to a 6890 gas chromatograph (Agilent, Santa Clara, CA, USA). For most analyses, the column was a DB-1 (30 m, 0.25-mm i.d., 1.0-μm film thickness, J&W). Carrier gas was helium and the inlet pressure was 42 kPa. The split/splitless inlet was used in splitless mode and the temperature was 200°C. Transfer line temperature was 200°C. The usual temperature program was as above for GC. Electron impact spectra were acquired at 70 eV. The Wiley mass spectral library, with 275,000 spectra, was installed on the data system.

For analysis of the enantiomers of the semiochemicals, GC-MS was performed with a Beta Dex 325 column (30 m, 0.25-mm i.d., 0.25-μm film thickness, Supelco, Bellefonte, PA, USA). Oven temperature always started at 50°C for 1 min, followed by increase at 30°C/min to the final temperature. For limonene, linalool, and daucene, the final temperatures were 90°C, 100°C, and 110°C, respectively. In each run, we verified that the GC peaks had the expected mass spectra.

Nuclear magnetic resonance (NMR) spectra were acquired on an Avance 500-MHz instrument (Bruker, Billerica, MA, USA). Samples were dissolved in $CDCl_3$ or C_6D_6. Experiments provided ^1H, ^{13}C, DEPT-135, COSY, HSQC, HMBC, and NOESY spectra. Further details are given with results.

High-performance liquid chromatography (HPLC) was conducted by using a Waters 515 pump, a Waters R401 refractive index detector, and a 25×0.46-cm i.d. silica column (Adsorbosphere Silica 5 μm, Alltech, Deerfield, IL, USA) treated with silver nitrate as described by Heath and Sonnet (1980) for separation of unsaturated compounds. Solvent was 1% 1-hexene in hexane.

Carrot Seed Extract Whole carrot seed was obtained from a local garden store, and an extract was prepared by first pulverizing the seed (78 g) in a Waring blender and then soaking the resulting meal in hexane overnight. Filtering and solvent removal under vacuum gave an oil (8 g) from which components were purified by column chromatography.

Liquid Chromatography on Open Column Volatile collections from beetles, carrot seed extract, and various synthetic products and intermediates were purified on open columns of silica gel (for separations by polarity) or silica gel containing 25% silver nitrate (for bulk separation of unsaturated hydrocarbons). In either case, solvents were various mixtures of ethyl ether and hexane. Further details are given with results.

Hydrogenation Catalytic hydrogenation of beetle- and carrot-derived compounds was conducted over 10% palladium on carbon by bubbling hydrogen gas through a methylene chloride solution for approximately 10 min, at which time no further change was observed by GC-MS.

Chemicals The following standards (Fig. 1) were acquired from Aldrich Chemical Co., Milwaukee, WI, USA: (*R*)-(+)- and (*S*)-(−)-limonene, racemic and (*R*)-(−)-linalool, and 2-nonanone. "Ocimene" [a mixture of isomers, primarily (*E*)-β-ocimene (71%) and the (*Z*)-isomer (19%), based on our analysis] came from International Flavors and Fragrances, New York, NY, USA. Synthetic reagents were also purchased from Aldrich.

(*E*)-β-ocimene was obtained from the commercial mixture in 98% purity by column chromatography on silver-nitrated treated silica (the *E* isomer was the last compound to elute; solvent was 2.5% ether in hexane). The identity of this compound was confirmed by NMR analysis (Table 1) with assignments of ^1H and ^{13}C shifts based on

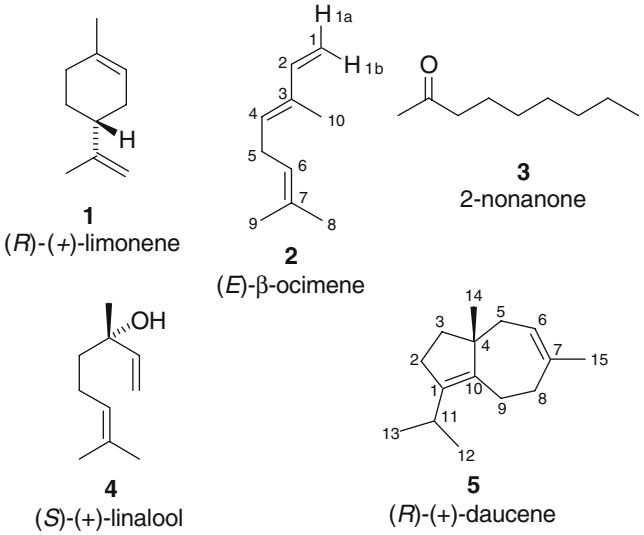

Fig. 1 Structures of key beetle-derived compounds. Position numbers for **2** and **5** correspond to Table 1 where NMR shifts are given. In (*E*)-β-Ocimene (**2**), NOESY correlations were observed between methyl 10 and olefinic proton 1b and between methyl 10 and methylene 5, but not between methyl 10 and olefinic proton 4 (the last correlation was not expected for the *E* isomer, but would occur with the *Z* isomer)

^{1}H, ^{13}C, DEPT-135, COSY, HSQC, and HMBC spectra (position numbering defined in Fig. 1). Configuration of the tri-substituted double bond between carbons 3 and 4 was confirmed to be *E* by the NOESY (nuclear Overhauser) experiment (see Fig. 1).

(*S*)-(+)-Linalool was prepared by converting the commercial (*R*)-(−)-isomer (89% e.e.) to the 4-methoxybenzoate ester, with inversion of the asymmetric center (Mukaiyama et al. 2003), followed by recovery of the alcohol by reducing the ester with diisobutylaluminum hydride (March 1985; product 79% e.e; purity by GC-FID, 98%, after column chromatography).

Racemic daucene was synthesized by the method of Naegeli and Kaiser (1972) as a standard for enantioselective GC. The initial sample of (*R*)-(+)-daucene was obtained by direct extraction from carrot seed and purification on silica gel (hexane) and $AgNO_3$-HPLC (1% 1-hexene in hexane). A richer source of (*R*)-(+)-daucene was carotol, the main constituent of carrot seed oil. This alcohol was purified on silica gel (25% ether in hexane) and dehydrated to daucene using thionyl chloride in pyridine, as described by Levisalles and Rudler (1967). After chromatography on silica gel coated with silver nitrate (elution with 2.5% ether in hexane), the (*R*)-(+)-daucene was 98% pure. No (*S*)-enantiomer was detected.

Lures for Traps Red rubber septa (11 mm, Wheaton, Millville, NJ, USA) were first cleaned by Soxhlet extraction in methylene chloride and dried. A solution of the five synthetic components (amounts as in Table 2) was then applied to each (100 μg total, in 10 μl hexane), followed by 300 μl methylene chloride, which was allowed to soak in. The two commercial components, 2-nonanone and (*R*)-(+)-limonene (>99% pure, by GC), were used as

[a] Based on regression analysis of volatile amounts collected in laboratory, ± standard error of fitted value

received; the other three components, (*E*)-β-ocimene, (*S*)-(+)-linalool, and *R*)-(+)-daucene, were prepared as described above. Loaded septa were stored in a tightly closed bottle in the freezer until used for experiments.

Emission characteristics of three of the septa were measured in the laboratory at 27°C. Each was placed in a glass tube through which air was drawn (250 ml/min), and emitted volatiles were captured on Super-Q porous polymer (Bartelt et al. 2006). Samples were collected every 2 h for the first 8 h and then after 1 and 2 days. Amounts were determined by GC-FID and used to calculate emission rate per hour. The rate data were transformed to logarithms, and a linear regression model was fitted to describe the release behavior of each compound.

Pitfall Traps A trap was designed for field studies (Fig. 2). The trap base was a 20-cm^2, 5-mm-thick piece of plywood with a 5-cm circular hole in the center. A threaded metal canning ring (7-cm diameter; Ball Inc., Muncie, IN, USA) was attached, concentric to the hole, with three flat-head, machine screws, size 6–32 by 1.25 cm (0.5 in.), and hex nuts. Holes were predrilled, spaced equally around the canning ring. The trap top was a 10-cm^2, 5-mm-thick piece of plywood. Three holes drilled through the top aligned with the machine screws protruding through the trap base. The ends of these screws served as pegs to keep the trap top centered above the 5-cm hole, and the hex nuts served as separators between the trap top and base. Trap assembly was completed by screwing a jar into the canning ring. Jar size was either 240 ml (8 oz) or 120 ml (4 oz; Ball, Inc.).

The traps, intended to capture beetles moving about on top of poultry house litter, were set into place firmly so that the trap base was slightly below the surface of the litter. The trap tops were added to take advantage of a beetle behavior observed in the laboratory, i.e., that they often crawl into narrow spaces and beneath objects. Beetles entered the traps readily through the gap between the top and base (Fig. 2). During trap development, traps were first used without the tops, but beetles appeared reluctant to enter the center hole and trap catches were low, leading to modification into the final design.

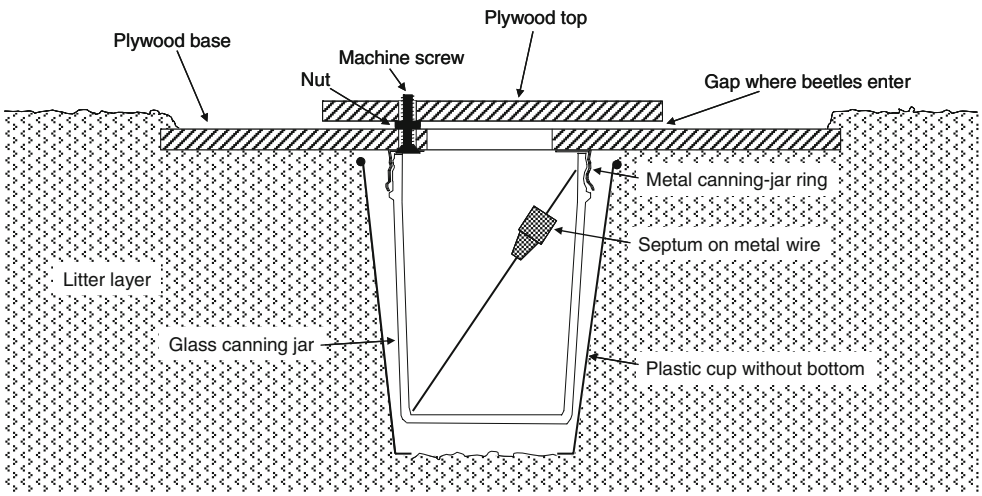

Fig. 2 Diagrammatic cross-section of trap in place during experiment. This cross-section shows one of the three screws that attach the canning ring to the trap base. See text for further description

In the Illinois field study, the wood-shaving litter was too dense for the trap simply to be twisted down into position, yet the surrounding litter quickly caved in if a hole were dug with a trowel to receive the trap jar (240-ml size). Thus, a 475-ml (16 oz) plastic cup, with the bottom removed, was first twisted down into the litter layer, with the assistance of a bulb-planting tool if resistant material was encountered. With the cup installed, the litter inside was scooped out and then the trap was seated onto the litter surface (Fig. 2). In Arkansas, the litter was loose enough so that the traps could be easily twisted into place, but the layer was relatively thin, so that the smaller 120-ml jars had to be used. Trap parts were cleaned with water and detergent and then air-dried between experiments.

Field Tests in Illinois Tests were conducted in a commercial turkey production building 10 km east of Delavan, Tazewell County, which was known to have an infestation of *A. diaperinus*. The experiments were conducted on 4 days, June 20, 24, 26, and 30, 2008, after the turkeys in the building had been moved out, but before insecticide treatment of the installation for beetles. Traps were set into the litter underneath a line of automatic feeders (for convenience, the feeders had been raised out of the way). Trap spacing was 1.5–2 m, and treatment positions within blocks (each containing two or four traps, depending on experiment) were randomized. Experiments were set out between 2:00 and 4:00 P.M. and were checked the following morning, between 8:00 and 10:00 A.M.

Experiment 1 had a paired design, and the two treatments were pheromone septa and controls. Pheromone septa were impaled on a wire (straightened paper clip) and set into the jar (Fig. 2). Thirty-four replications were acquired over the 4 days and included the nine comparisons of pheromone vs. control from experiment 2 (below). Random samples of 50 beetles from pheromone traps and 50 from controls were dissected to determine sex.

Experiment 2 had a 2^2 factorial design. The factors, pheromone, and turkey manure, were tested in the four possible combinations. A casual observation during the first 2 days of tests was that beetles aggregated around clumps of manure in the building, and this material was therefore tested as a trap treatment. Clumps of aged turkey manure were collected and, in the laboratory, were broken up and mixed thoroughly. For use in traps, the manure was wetted and 15 ml was placed in a 30-ml plastic cup, covered with fine cloth mesh secured with a rubber band to prevent entry by responding beetles. Pheromone septa were impaled on wires as above, and the cups and septa were placed in the trap jars according to the experiment plan. There were nine replications of this experiment over the final two test days.

Field Test in Arkansas The Arkansas field test was conducted August 20–23, 2008 in an infested broiler production house located 15 km west of Fayetteville, Washington County. The building was 14 m wide and 99 m long with the long axis orientated east to west and was managed to produce 6- or 8-week-old broiler chickens, but it did not contain birds at the start of the study. Two automatic feeder lines ran the length of the house, 2 m out from the wall. The floor of the house was covered with pine wood-shaving litter approximately 8 cm deep. Plastic trays containing chick feed were present; these measured 56×34 cm and were used instead of automatic feeders for newly hatched chicks during the first 10 days of a production cycle. The trays were in three parallel lines beneath each automatic feeder line, and tray spacing was 2 m, within or between lines. Beetles were abundant under the trays. The beetle traps were placed parallel to the feeder lines and between two rows of the chick feeding trays. Trap spacing was approximately 1 m. Blocks 1 and 2 were on the north side of the house and blocks 3 and 4 on the south side. Each block consisted of 12 traps, six with pheromone-treated septa and six with untreated (control) septa, which were randomly assigned within the block. Trapping was conducted over three consecutive days.

The house temperature was 28°C when the traps were initially placed and baited in the afternoon. The beetles were collected from the traps after 24 h and trap baits were replaced. Then, the house temperature was raised to 34°C (the rearing temperature of the young birds) with propane heaters. After the second 24-h period, trapped beetles were again removed and baits replaced. At this time, the chicks were released into the facility, and once again, beetles were collected from the traps after 24 h. Thus, the beetle response to the treated septa was monitored for 1 and 2 days prior to chick introduction and for 1 day afterward, and the time period of the study included a defined temperature change. Trapped beetles were transported back to the laboratory for counting.

Statistical Analysis of Field Experiment Data Trap catch data were subjected to analysis of variance after transformation by $\log(X+1)$ to stabilize variance. Linear contrasts were used in the factorial experiment to assess factor effects and their interaction. Pairwise comparison of means was by the least significant difference method ($\alpha=0.05$).

Results

Male-Specific Compounds GC and GC-MS analysis of volatile collections revealed that males feeding on chick

starter mash usually emitted five compounds that were essentially absent from females (Fig. 3). Compounds **1**–**4** were tentatively identified by a computer library search of their mass spectra (Fig. 4) as limonene, (*E*)-β-ocimene, 2-nonanone, and linalool, respectively. The identifications were confirmed by matching GC retentions and mass spectra with authentic standards, except that this analysis gave no information about the stereochemistry of **1** and **4**.

The female peak marked with a dagger in Fig. 3 had the same mass spectrum as **1** (limonene) from males, but it was later shown to be the opposite enantiomer and likely originated from the diet (see below). The compound marked with a double dagger in Fig. 3 had essentially the same GC retention as **4** (linalool), but had a different mass spectrum; this impurity was also present in many male and food-only collections and closely matched nonanal in the mass spectral library. Compound **3** (2-nonanone) was also found occasionally from females in minor amounts (i.e., <10% of the amounts in comparable male collections). It was not visible in the female sample in Fig. 3.

In contrast, no library match was found for compound **5** (mass spectrum in Fig. 4). The compound eluted from silica gel with hexane, suggesting it was not oxygenated. The apparent molecular weight (204) would correspond to the molecular formula, $C_{15}H_{24}$, likely a sesquiterpene hydrocarbon, and indicated the presence of four double-bond/ring equivalents. Serendipitously, a compound with exactly the same mass spectrum and GC retention was encountered from carrot seed oil during work on another project. Hydrogenation of both samples over palladium increased the molecular weight to 208 and generated identical GC peaks (apparently four products with nearly identical mass spectra), indicating that two double bonds were reduced and that asymmetric centers were created. The final molecular weight of 208 implied that two rings were present in **5**. An example mass spectrum of the hydrogenation products is given in Fig. 4.

The minute amount of **5** obtainable from *A. diaperinus* would not readily allow structure analysis by NMR, but the carrot seed extract supplied enough of the compound so that key NMR experiments could be run (^{1}H, COSY, HSQC, and HMBC). Deuterobenzene was used as the solvent because some sesquiterpene hydrocarbons are labile in the more commonly used, but somewhat acidic, $CDCl_3$. The compound was concluded from the spectra to be daucene (**5** in Fig. 1, but with unknown stereochemistry). Daucene was first isolated from carrots (Pigulevskii and Kovaleva 1961). Having the likely structure, we searched the literature for confirming structural and spectral information and for sources of standards for enantioselective GC. Thus, racemic daucene was synthesized and (*R*)-(+)-daucene was prepared by dehydrating carotol. Daucene from both sources was identical to the beetle and carrot compounds by non-enantioselective GC-FID and GC-MS. The literature indicated that daucene was stable in $CDCl_3$, and the NMR spectra were obtained in this solvent for the daucene sample derived from carotol for better comparison to published information. Assign-

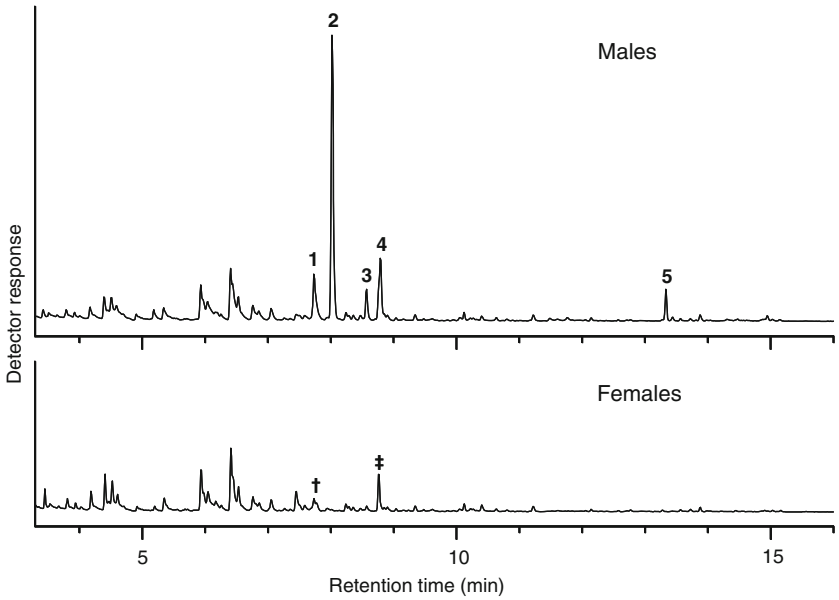

Fig. 3 Gas chromatograms of male- and female-derived volatile collections. Both chromatograms are in the same scale. Consistently encountered male-specific peaks are numbered. Peak **2** for males represents about 40 ng injected (corresponding to about 100 ng emitted per male per day in the collection flask). The peak marked with a *dagger* in the female sample has the same mass spectrum as **1**, but we concluded that it was the opposite enantiomer (see text); the peak marked with a *double dagger* has nearly the same retention time as **4**, but had an entirely different mass spectrum

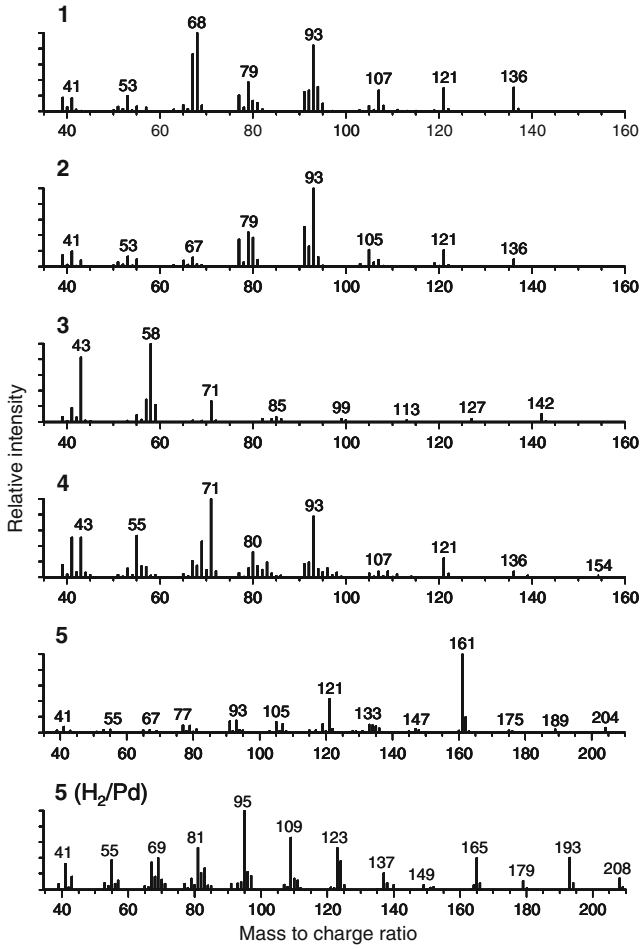

Fig. 4 Mass spectra of the five male-specific components and the hydrogenation product of **5**

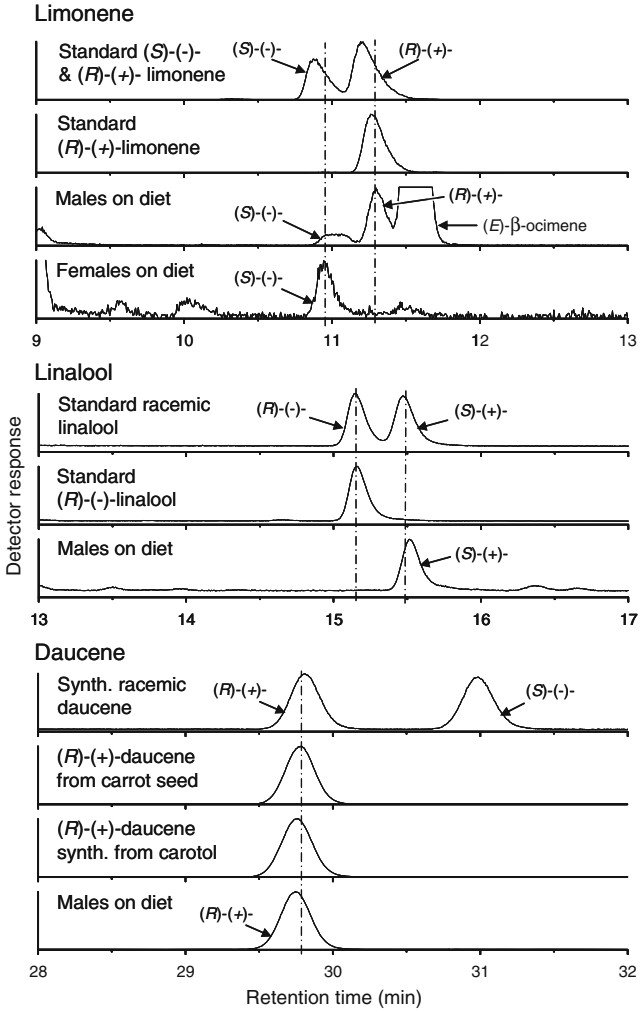

Fig. 5 Enantioselective GC analysis of beetle-derived and standard compounds

ments of resonances to structure positions are given in Table 1 (numbering as in Fig. 1). The NMR data closely matched those of Park and Little (2008), the most complete published analysis that we found.

Enantioselective GC-MS Limonene (**1**), linalool (**4**), and daucene (**5**) each have one asymmetric center, and enantioselective GC-MS was used to determine the enantiomeric composition of the natural product produced by *A. diaperinus*. The Beta-Dex 325 column was capable of separating the enantiomers of all three compounds (Fig. 5). For limonene, the (*R*)-(+)-standard was the later-eluting enantiomer, and this matched the major limonene peak from male *A. diaperinus*. However, the (*S*)-(−)-enantiomer was also detected in samples from males, females, and diet in minor amounts. We conclude that (*R*)-(+)-limonene is male-specific but that a relatively small amount of (*S*)-(−)-limonene occurs in the diet. For linalool, the commercial (*R*)-(−) standard was the earlier-eluting enantiomer, but the male-specific compound was the later-eluting one. Thus, male *A. diaperinus* emit (*S*)-(+)-linalool. The enantiomer of daucene extracted directly from carrot seed and from dehydration of carotol, reported to be (*R*)-(+)- in both cases (Levisalles and Rudler 1967; Yamasaki 1972), was the earlier GC peak, and the enantiomer from *A. diaperinus* aligned with these. Thus, males of *A. diaperinus* emit (*R*)-(+)-daucene.

Emission of Male-Specific Compounds: Biological Results Compounds **1**–**5** eventually were detected from all 20 of the monitored groups of males, but not from females [except for the opposite enantiomer of **1** (limonene) and occasional relatively minor amounts of **3** (2-nonanone), as discussed above]. Anecdotally, high production of **1**–**5** usually coincided with males walking about rapidly on the surface of the vermiculite in the collector flasks and exhibiting mating attempts toward one another. Based on 41 GC collections in which **1**–**5** stood out well above background and were easily integrated, the proportions of the compounds were fairly stable and (*E*)-β-ocimene was always the most abundant (Table 3). The compounds were

Table 3 Proportions of components in male emissions [normalized to 100 for (*E*)-β-ocimene, *N*=41]

Compound	Relative amount ± SD	Minimum, maximum
(*R*)-(+)-Limonene	16.1±2.9	11.0, 23.3
(*E*)-β-Ocimene	100	–
2-Nonanone	6.7±3.0	3.4, 21.3
(*S*)-(+)-Linalool	18.2±6.8	8.6, 40.0
(*R*)-(+)-Daucene	16.3±5.6	6.4, 28.9

A typical absolute emission rate for (*E*)-β-ocimene was 35 ng per male per day and the maximum was 120 ng per male per day

first detected 1–2 weeks after males emerged from pupae. In the groups of males monitored for 12 months, emission rate varied dramatically over time (Fig. 6). Amounts of **1**–**5** inevitably declined as food in the flask was used up or became moldy, but transferring the beetles to a clean flask with fresh food always led to a surge in the amount emitted. The conditions that reduced production of **1**–**5** did not necessarily kill the beetles, and 15 of the original 50 in the example group (Fig. 6) were still alive at the end of 1 year. Overall mean emission rate of (*E*)-β-ocimene during that period was 35±28 (SD) nanograms per day per male (*N*=108). Component proportions appeared similar to those in Table 3 throughout regardless of absolute amount.

Emission Properties of Pheromone Lures It was possible to prepare septum lures that matched the emission profile of male beetles fairly closely (Table 2), but the high volatility of the components and their considerable range of molecular weights were disadvantageous. In the laboratory evaluation, the overall emission rate decreased to 24% of the original rate after just 1 day. The proportions of components changed considerably during 1 day but generally stayed within the range measured from the beetles. Therefore, lures were used for only 1 day in field experiments and then discarded.

Field Tests in Illinois Experiment 1 demonstrated a significant treatment (pheromone) effect, and overall, the pheromone-baited traps captured 3.6 times more beetles than the controls (Table 4). Fourteen of the 68 trap catches exceeded 1,000, reflecting the large beetle population in the facility and demonstrating that beetles would enter the traps readily. Both sexes were captured in this experiment: 60 of the dissected individuals were females and 40 were males. The ratio was consistent between the pheromone treatment (31 females and 19 males) and controls (29 females and 21 males); Pearson's chi-square statistic for the two-by-two contingency table was 0.17 (1 *df*, *P*=0.68).

In experiment 2, there was also a significant treatment effect, and the partitioned effects for both the pheromone and the manure were significant, although the pheromone effect was stronger (Table 4). Given the large amount of manure that was present in the building, it seems remarkable that attraction to it could be demonstrated in the experiment. No synergism between these treatments was evident.

Field Test in Arkansas The synthetic pheromone was significantly attractive in the Arkansas experiment (Table 5).

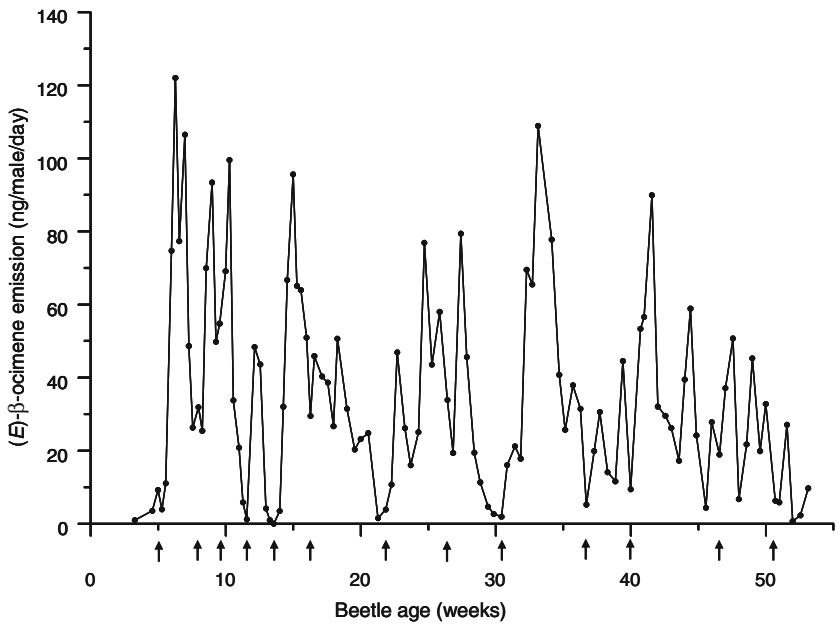

Fig. 6 Pheromone emission from one group of beetles over time, with the major component, (*E*)-β-ocimene, as the indicator. *Arrows* indicate timing of transfer to clean flasks with fresh diet

Table 4 Summary of field experiments conducted at a commercial turkey production facility near Delavan, IL, during June 20–30, 2008

Treatment	Log(X+1) scale	Untransformed
Experiment 1: Attractiveness of pheromone (paired design)		
Means (N=34)		
Control	1.80 b	61.7
Pheromone	2.35 a	222.1
Treatment effect: $F_{1,33}$=22.58 (P<0.001)		
Experiment 2: Attractiveness of pheromone and manure and combination (2×2 factorial design)		
Means (N=9)		
Control	2.4766 b	299
Pheromone	3.0248 a	1,058
Manure	2.9182 a	827
Pheromone + manure	3.1391 a	1,377
Overall treatment effect: $F_{3,24}$=8.52 (P<0.001)		
Partition of treatment effect into contrasts:		
Pheromone vs. no pheromone: $F_{1,24}$=15.0 (P<0.001)		
Manure vs. no manure: $F_{1,24}$=7.84 (P=0.01)		
Interaction: $F_{1,24}$=2.72 (P=0.11)		

Statistical analysis was on log (X+1) transformed data. Within an experiment, means followed by the same letter are not significantly different (LSD, α=0.05)

Overall, the pheromone-baited traps caught 3.3 times more beetles than controls. Captures decreased about 30-fold after the chicks were introduced (days 1 and 2 vs. day 3), for unknown reasons. Nevertheless, the factor difference between the pheromone and controls was stable among the days (treatment-by-day interaction was not significant). The statistical analysis revealed differences in total capture among the experimental blocks, indicating that

Table 5 Field experiment conducted at a broiler production facility near Fayetteville, AR, Aug 20–23, 2008[a]

Treatment	log(X+1) scale	Untransformed
Single day means (N=24)		
Day 1		
Control	2.7271 b	532
Pheromone	3.1096 a	1,287
Day 2		
Control	2.6723 b	469
Pheromone	3.2533 a	1,791
Day 3		
Control	1.1611 b	13.5
Pheromone	1.7553 a	55.9
Overall means (N=72)		
Control	2.1869 b	153
Pheromone	2.7061 a	507
ANOVA summary		
Treatment: $F_{1,129}$=33.2 (P<0.001)		
Day: $F_{2,129}$=120 (P<0.001)		
Treatment × day interaction: $F_{2,129}$=0.58 (P=0.56)		
Block: $F_{3,129}$=6.72 (P<0.001)		
Block × day interaction: $F_{6,129}$=5.23 (P<0.001)		
All interactions involving both treatment and block were not significant and were combined into residual error.		

Experiment had a randomized complete block design, with six traps for each treatment within each of four blocks, replicated on 3 days. Analysis was on log(X+1) transformed data. Within a day, or for overall means, values followed by the same letter are not significantly different (LSD, α=0.05)

the beetle population was not distributed uniformly throughout the house, and the significant interaction between blocks and days suggested that beetle distribution changed somewhat over time. Importantly, though, no interactions involving blocks and treatments were significant, indicating a consistent pheromone effect over space as well as time.

Discussion

Pheromone of A. diaperinus Based on the emission of male-specific compounds and attraction to these in traps, we conclude that *A. diaperinus* males produce an aggregation pheromone to which both sexes respond. While the blend of compounds **1**–**5** was attractive in field experiments, it is still unknown whether all five are actually required for activity. The true pheromone may be some subset of **1**–**5**, and further research is needed to address this issue. Additional research should also investigate attractants in turkey manure and other materials in the beetle habitat and test more thoroughly for synergistic interactions with **1**–**5**. It is unknown if any of the compounds **1**–**5** corresponds to the male-specific GC peak reported by Falomo (1986).

Our data suggest that the terpenoid components from *A. diaperinus* (**1**, **2**, **4**, and **5**) are synthesized by the males rather than being sequestered from food because these chemicals were not detected in the absence of males [only the opposite, (*S*)-(−)-enantiomer of limonene (**1**) was found in volatiles from females or from the beetle diet]. Traces of 2-nonanone (**3**) were sometimes detected from the food, and sequestration of this ketone by males is conceivable. However, the rather stable proportions of components in male volatiles (Table 3), despite considerable variability in absolute amounts (Fig. 6), suggest a concerted biosynthetic system that includes **3** and that keeps the ratios of all emitted volatiles fairly consistent.

Related Compounds in Other Tenebrionids None of compounds **1**–**5** was previously reported as a pheromone component in the Tenebrionidae. However, straight-chain ketones of other sizes than **3** (Tschinkel 1975b; Gnanasunderam et al. 1985) and terpenoids other than **2**, **4**, and **5** (Gnanasunderam et al. 1981; Geiselhardt et al. 2006) occur in tenebrionid defensive secretions. Limonene (**1**) has been reported in defensive secretions, but it was either the (*S*)-(−)-enantiomer (Geiselhardt et al. 2006) or its configuration was not determined (Gnanasunderam et al. 1981). In contrast to the aggregation pheromone of *A. diaperinus*, defensive secretions are released in direct response to disturbance and by both sexes. The defensive quinones of *A. diaperinus* were occasionally detected in minor amounts in volatile collections, but the emission of compounds **1**–**5** did not correlate with these, was not a result of disturbance, and was essentially sex-specific. At this point, the pheromone system of *A. diaperinus* appears most like that of *G. cornutus* (Tebayashi et al. 1998; Tashiro et al. 2004) in that only a male-produced aggregation pheromone has been detected so far and that the predominant chemicals are terpenoid.

Occurrence of **1**–**4** *in Other Insects* All of the identified compounds are well known from plants, but four of them also are known to occur in other insects and have even been reported as pheromone components. For example, (*E*)-β-ocimene and linalool (configuration not determined) are present in the hairpencil secretions of male danaid butterflies and likely have a pheromonal function (Komae et al. 1982). (*E*)-β-Ocimene occurs in the Dufour's glands of *Labidus* spp. army ants (Keegans et al. 1993). (*S*)-(+)-Linalool is part of the sex pheromone emitted by male cabbage looper moths (Heath et al. 1992). 2-Nonanone is a component of the pheromone blend emitted by female caddisflies (Löfstedt et al. 2008). Limonene and linalool are present in the defensive secretions of various true bugs (Aldrich 1988). Limonene is part of the alarm pheromone of termites (Lindström et al. 1990), is found in the mandibular glands of ants (Lloyd et al. 1989), and occurs in volatile emissions from cherry fruit flies (Raptopoulos et al. 1995). We are unaware of any previous reports of compound **5** in insects.

Practical Uses It is clear that traps in poultry buildings can capture large numbers of *A. diaperinus*, but it remains to be determined whether the pheromone can become a practical tool in managing these beetles. Trapping strategies with attractants would have to take into account factors such as the presence or absence of birds (Table 5) and the clumped but rapidly changing distribution of beetles (Strother and Steelman 2001). One positive aspect is that all five of the identified components should be readily obtainable in quantities that would allow large-scale practical use.

Acknowledgments Karl Vermillion, NCAUR, acquired the NMR spectra and generously gave advice on interpretation. We are indebted to David and George Sinn, Delavan, IL for permitting us to work at their farm and for adjusting their schedule to allow the experiments to be conducted. Jill R. Bartelt kindly translated the article by Levisalles and Rudler (1967). The mention of trade names or commercial products in this article is solely for the purpose of providing specific information and does not imply recommendation or endorsement by the US Department of Agriculture.

Ethanol and (−)-α-Pinene: Attractant Kairomones for Bark and Ambrosia Beetles in the Southeastern US

Daniel R. Miller · Robert J. Rabaglia

Received: 22 September 2008 / Revised: 10 February 2009 / Accepted: 4 March 2009 / Published online: 19 March 2009

Abstract In 2002–2004, we examined the flight responses of 49 species of native and exotic bark and ambrosia beetles (Coleoptera: Scolytidae and Platypodidae) to traps baited with ethanol and/or (−)-α-pinene in the southeastern US. Eight field trials were conducted in mature pine stands in Alabama, Florida, Georgia, North Carolina, and South Carolina. Funnel traps baited with ethanol lures (release rate, about 0.6 g/day at 25–28°C) were attractive to ten species of ambrosia beetles (*Ambrosiodmus tachygraphus*, *Anisandrus sayi*, *Dryoxylon onoharaensum*, *Monarthrum mali*, *Xyleborinus saxesenii*, *Xyleborus affinis*, *Xyleborus ferrugineus*, *Xylosandrus compactus*, *Xylosandrus crassiusculus*, and *Xylosandrus germanus*) and two species of bark beetles (*Cryptocarenus heveae* and *Hypothenemus* sp.). Traps baited with (−)-α-pinene lures (release rate, 2–6 g/day at 25–28°C) were attractive to five bark beetle species (*Dendroctonus terebrans*, *Hylastes porculus*, *Hylastes salebrosus*, *Hylastes tenuis*, and *Ips grandicollis*) and one platypodid ambrosia beetle species (*Myoplatypus flavicornis*). Ethanol enhanced responses of some species (*Xyleborus pubescens*, *H. porculus*, *H. salebrosus*, *H. tenuis*, and *Pityophthorus cariniceps*) to traps baited with (−)-α-pinene in some locations. (−)-α-Pinene interrupted the response of some ambrosia beetle species to traps baited with ethanol, but only the response of *D. onoharaensum* was interrupted consistently at most locations. Of 23 species of ambrosia beetles captured in our field trials, nine were exotic and accounted for 70–97% of total catches of ambrosia beetles. Our results provide support for the continued use of separate traps baited with ethanol alone and ethanol with (−)-α-pinene to detect and monitor common bark and ambrosia beetles from the southeastern region of the US.

Introduction

Non-native bark and ambrosia beetles (Coleoptera: Scolytidae) are regularly introduced into countries via the movement of solid wood packing materials (pallets, crating, and dunnage) used in international shipments. In New Zealand, >73% of 1,505 interception records of 103 species of bark and ambrosia beetles during 1950–2000 were associated with solid wood packing material (Brockerhoff et al. 2006). Allen and Humble (2002) reared 1,549 beetles from 29 spruce bolts (*Picea abies* L.) used as dunnage to ship granite from Norway to Canada in 1998; 95% were Scolytidae. In the US, 73% of scolytid interceptions at ports of entry from 1985 to 2000 were associated with solid wood packing material (Haack 2001).

Detection and eradication of invading species are one of three strategies that are essential in countering impacts of invasive species in the forests of the US (Chornesky et al. 2005). Direct examination of shipments for the presence of bark and ambrosia beetles is problematic, as adult and larval beetles generally are hidden within bark or wood

tissues (Allen and Humble 2002). Early detection of species that have been missed by such examinations and have attempted to escape to neighboring forest habitats is essential to successful management or eradication (Chornesky et al. 2005). One common tactic used to detect bark and wood-boring beetles employs flight traps baited with lures releasing various semiochemicals, particularly ethanol and α-pinene (Haack 2006; Liu and Dai 2006; Lee et al. 2007). In the US, national programs such as the Cooperative Agricultural Pest Survey (CAPS) and the Early Detection and Rapid Response program (EDRR) employ funnel traps baited with lures releasing ethanol or ethanol and (−)-α-pinene to capture a broad array of subcortical beetles (USDA APHIS 2007; Rabaglia et al. 2008).

In Europe, ethanol is attractive to many species of bark and ambrosia beetles such as *Anisandrus* (*Xyleborus*) *dispar* (Fabricius), *Hylastes cunicularius* Erichson, *Hylastes brunneus* Erichson, *Hylastes opacus* Erichson, *Hylurgops palliatus* (Gyllenhal), *Hylesinus* (*Leperisinus) varius* (Fabricius), *Tomicus piniperda* L., and *Trypodendron lineatum* (Olivier) (Bauer and Vité 1975; Kohnle 1985; Schroeder 1988; Schroeder and Lindelöw 1989). In British Columbia, ethanol is attractive to *T. lineatum* (Moeck 1970) and acts in synergy with the pheromone of two other species of ambrosia beetles, *Gnathotrichus sulcatus* (LeConte) and *Gnathotrichus retusus* (LeConte) (Borden et al. 1980). Kelsey and Joseph (2001) found that the bark beetle *Scolytus unispinosus* LeConte was attracted to ethanol produced by stressed branches of Douglas fir, *Pseudotsuga menziesii* (Mirb.). In the US, ethanol is attractive to *A. dispar*, *Monarthrum mali* (Fitch), *Pseudopityophthorus minutissimus* (Zimmermann), and *Xyleborinus saxesenii* (Ratzeburg) (Montgomery and Wargo 1983; Dunn and Potter 1991).

Similarly, α-pinene, a monoterpene commonly found in pine trees (Mirov 1961; Smith 2000), is attractive to various species of bark beetles such as *Hylastes nigrinus* (Mannerheim), *Ips grandicollis* (Eichhoff), *Ips typographus* L., and *T. piniperda* (Rudinsky et al. 1971; Schroeder and Eidmann 1987; Witcosky et al. 1987; Schroeder 1988; Erbilgin and Raffa 2000). The combination of ethanol and α-pinene is attractive to bark and ambrosia beetles such as *Dendroctonus valens* LeConte, *Dryocoetes autographus* (Ratzeburg), *G. retusus*, *G. sulcatus*, *H. palliatus* (Gyll.), *Hylastes porculus* Erichson, *T. lineatum*, and *T. piniperda* (Borden et al. 1981; Schroeder 1988; Chénier and Philogène 1989; Schroeder and Lindelöw 1989; Erbilgin et al. 2001).

However, data on the attractiveness of such lures to bark and ambrosia beetles are limited to a small portion of known species (<1% of nearly 6,000 species; Seybold et al. 2006). Specifically lacking are response data for species common to the southeastern US. Attraction of *I. grandicollis* to small loblolly pine logs in the southeastern US was enhanced with the application of pinenes and turpentine directly onto the bark (Anderson 1977). In the northern portion of its range (Wisconsin and southern Ontario), monoterpenes including α-pinene affected trap captures of *I. grandicollis* (Chénier and Philogène 1989; Erbilgin and Raffa 2000). In Florida, the combination of ethanol and turpentine was attractive to *Dendroctonus terebrans* (Olivier), *Hylastes salebrosus* Eichhoff, and *Xyleborus pubescens* Zimmermann, whereas *Xyleborus affinis* Wood was attracted to ethanol but not turpentine (Fatzinger 1985; Fatzinger et al. 1987; Phillips et al. 1988; Phillips 1990). The use of turpentine in these studies is a concern, as the monoterpene composition of turpentine can vary widely depending on species and location of conifers used in production (Mirov 1961; Smith 2000). The main constituent of the turpentine used in at least one of the Florida studies was α-pinene (Phillips et al. 1988).

A second concern is that α-pinene may interrupt attraction of some ambrosia beetles to ethanol. In southwestern British Columbia (Canada), α-pinene seems to interrupt catches of *A. dispar*, *X. saxesenii*, *Xyleborinus alni* (Niisima), *Xyleborus pfeili* (Ratzeburg), and *Xylosandrus germanus* (Blandford) (L. Humble, unpublished data). Schroeder and Lindelöw (1989) found that α-pinene interrupted catches of *A. dispar* to ethanol-baited traps in Sweden. In Europe, Lindelöw et al. (1993) found that α-pinene interrupted the attraction of *H. cunicularius*, *H. opacus*, and *D. autographus* to a blend of ethanol and turpentine. For this reason, most operational detection programs for ambrosia beetles use traps baited solely with ethanol in addition to traps baited with ethanol and α-pinene or α-pinene alone to avoid the risk of species evading detection.

Our objective was to assess the attraction of bark and ambrosia beetles (common to pine forests of the southeastern US) to standard commercially available ethanol and (−)-α-pinene lures used with funnel traps. We wanted to determine: (1) the species that are attracted to traps baited with these compounds in southern pine forests and (2) if traps baited with the combination of the two lures were as effective as, if not better than, traps baited solely with one lure. We monitored the responses of 49 species of common bark and ambrosia beetles to traps baited with ethanol and/or (−)-α-pinene in southeastern US (Tables 1 and 2). Our data on Buprestidae, Cerambycidae, Curculionidae, and Elateridae were published previously (Miller 2006). Our goal is to provide operational guidelines for the use of semiochemical-based trapping systems in monitoring populations of beetles in the southeastern US, as well as in suppression and detection programs in countries where these species may not be native.

Methods and Materials

Experimental Design Methods and materials were reported previously in Miller (2006). The same experimental design

Expt.	Location	Tree species	Trapping dates
1	Ocala NF near Salt Springs, FL	*P. palustris* Miller	26 February–26 May 2002
2	Osceola NF near Lake City, FL	*P. palustris* and *P. elliottii* Engelmann	25 February–25 May 2002
3	Oconee NF near Juliette, GA	*P. taeda* L.	12 June–8 August 2002
4	Blue Valley EF near Highlands, NC	*P. strobus* L.	20 June–20 August 2002
5	Bankhead NF near Grayson, AL	*P. taeda* and *T. canadensis* (L.)	28 April–10 July 2003
6	Nantahala NF near Murphy, NC	*P. strobus* and *P. echinata* Miller	1 May–14 August 2003
7	Sumter NF near Union, SC	*P. taeda*	15 April–16 July 2003
8	Apalachicola NF near Tallahassee, FL	*P. palustris* and *P. elliottii*	30 March–16 June 2004

was employed in mature pine stands on each of seven National Forests (NF) and one Experimental Forest (EF) in the southeastern US, resulting in eight experiments (Table 1). In each experiment, four treatments were randomly assigned to four eight-unit funnel traps [Phero Tech (now Contech) Inc., Delta, British Columbia, Canada] within each of eight replicate blocks (N=8) as follows: (1) unbaited control; (2) ethanol alone; (3) α-pinene alone; and (4) ethanol (+)-α-pinene. Traps were spaced 10–15 m apart within blocks; replicate blocks were spaced 15–500 m apart. Phero Tech Inc. supplied sealed ultra-high-release (UHR) plastic pouches containing either ethanol (150 ml) or α-pinene (200 ml; chemical purities >95%). The enantiomeric purity of α-pinene was >95%-(−). The release rate of ethanol from its UHR pouch was 0.6 g/day at 25–28°C (determined by weight loss). (−)-α-Pinene was released at 2–6 g/day from its UHR pouch at 25–28°C (determined by weight loss). Each trap was suspended between trees by rope such that the bottom of the trap was 0.2–0.5 m above ground level. Collection cups contained 150–200 ml of pink propylene glycol solution (Peak RV and Marine Antifreeze, Old World Industries Inc., Northbrook, IL, USA) as a killing and preservation agent. Voucher specimens were deposited in the Entomology Collection, Museum of Natural History, University of Georgia (Athens, GA, USA).

Statistical Analyses Trap catch data were analyzed with the SYSTAT (ver. 11.00.01) and the SigmaStat (ver. 3.01) statistical packages (SYSTAT Software Inc., Point Richmond, CA, USA) for locations where sufficient numbers ($N \geq 50$) were captured for individual species. Trap catch data were transformed by $\ln(Y+1)$ to remove heteroscedasticity (Pepper et al. 1997). In each experiment, trap catch data were subjected to analysis of variance (ANOVA) by using the following model components: (1) replicate; (2) ethanol; (3) α-pinene; and (4) ethanol × α-pinene. In cases with one treatment lacking variation (due to lack of any beetle captures), the data were subjected to ANOVA by using the following model components: (1) replicate and (2) treatment. In all experiments with three to four non-zero treatment means, the Holm–Sidak multiple-comparison procedure (Glantz 2005) was used to compare means within a location for each species when there was a significant treatment effect (α=0.05). In cases with two treatments lacking variation (due to lack of any beetle captures), the means of catches associated with the two remaining treatments were analyzed by two-tailed t tests.

Results

Ambrosia Beetles A total of 28,521 ambrosia beetles were captured from all eight locations in 2002–2004, ranging from 972 to 10,683 per location (Table 2). Of 23 species captured in our trapping studies, nine are established non-native exotic species and accounted for 69.7–96.6% of total ambrosia beetle catches. The most common non-native species were *X. saxesenii*, *Xylosandrus crassiusculus* (Motschulsky), and *Dryoxylon onoharaensum* (Murayama), whereas the most common native species were *X. affinis*, *Xyleborus ferrugineus* (Fabricius), and *X. pubescens*. Generally, ethanol had an attractive effect on most ambrosia beetles with (−)-α-pinene playing a minor role (Table 3).

The exotic ambrosia beetle *X. saxesenii* was captured at all eight locations with a total catch of 13,671 (accounting for 48% of total ambrosia beetle catches; Fig. 1). Ethanol had a significant effect on trap catches of *X. saxesenii* (Table 3). At all locations, traps baited with ethanol [with or without the addition of (−)-α-pinene] caught more *X. saxesenii* than unbaited control traps. At most locations, (−)-α-pinene had no effect on catches of *X. saxesenii* (Table 3). However, catches of *X. saxesenii* in traps baited with ethanol were interrupted by (−)-α-pinene in Florida (Ocala NF) and North Carolina (Nantahala NF; Fig. 1e, f).

Catches of the exotic ambrosia beetles *Xylosandrus compactus* (Eichhoff), *X. crassiusculus*, and *X. germanus*

Grand total	3,936	9,442	2,439	3,984	2,730	3,708	4,214	12,970

All species are Scolytidae (Coleoptera) except *Euplatypus compositus* and *M. flavicornis*, which are in the Platypodidae

[a] Exotic species

totaled 4,725 beetles (17% of total ambrosia beetle catches) with *X. crassiusculus* being the most common (Fig. 2). Ethanol had a significant effect on trap catches of all three species (Table 3). In five locations, catches of *X. crassiusculus* in traps baited with ethanol [with or without the addition of (−)-α-pinene] were greater than those in unbaited control traps (Fig. 2a–e). The same was true for *X. compactus* in Florida (Apalachicola NF; Fig. 2f) and *X. germanus* in North Carolina (Blue Valley EF; Fig. 2g). There was no effect of (−)-α-pinene on any of these three species (Table 3, Fig. 2).

An interruptive effect of (−)-α-pinene on the attraction of ambrosia beetles to ethanol-baited traps was apparent with two native species, *Ambrosiodmus tachygraphus* Zimmermann, *Anisandrus* (*Xyleborus*) *sayi* (Hopkins), and an exotic species, *D. onoharaensum* (Table 3, Fig. 3). All three species were attracted to traps baited with ethanol. In North Carolina (Nantahala NF), catches of *A. tachygraphus* in traps baited with ethanol alone were significantly greater than those in unbaited controls, whereas catches in traps baited with ethanol and (−)-α-pinene were not different from those in control traps (Fig. 3a). No beetles were captured in traps baited solely with (−)-α-pinene. In North Carolina (Nantahala NF), catches of *A. sayi* in traps baited with ethanol and (−)-α-pinene were significantly less than those in traps baited solely with ethanol (Fig. 3b). No beetles were caught in control traps or traps baited solely with (−)-α-pinene. In five of six locations, catches of *D. onoharaensum* in traps baited with ethanol and (−)-α-pinene were significantly less than those in traps baited solely with ethanol (Fig. 3c, e–h). We caught a total of 6,571 *D. onoharaensum* across the six locations (23% of total ambrosia beetle catches; Fig. 3c–h).

Lastly, ethanol and (−)-α-pinene significantly affected catches of five common native species of ambrosia beetles (Table 3, Figs. 4 and 5), although results were inconsistent between locations. Catches of *X. affinis*, *X. pubescens*, and *X. ferrugineus* totaled 2,458 beetles (9% of total ambrosia beetle catches). Traps baited with ethanol were attractive to *X. affinis* and *X. ferrugineus* in three and five locations, respectively (Figs. 4a–c and 5a–e), whereas *X. pubescens* were attracted to ethanol-baited traps in only one of four locations (Fig. 4g). Traps baited with (−)-α-pinene alone were attractive to *X. pubescens* in Florida (Osceola NF) with (−)-α-pinene enhancing catches of beetles in ethanol-baited traps (Fig. 4f). *X. ferrugineus* were attracted to traps baited with (−)-α-pinene in two locations in Florida (Fig. 5b, c) but interrupted by (−)-α-pinene in Alabama (Fig. 5a). (−)-α-Pinene had no effect on *X. affinis* at four locations (Fig. 4a–c). *M. mali* was attracted to traps baited with ethanol (Fig. 5f), whereas the platypodid *Myoplatypus flavicornis* (Fabricius) was attracted to traps baited with (−)-α-pinene (Fig. 5g). As with the other species for which numbers were too low for analyses ($N<50$) at some locations (Table 2), the low numbers of *M. mali* or *M. flavicornis* in traps at the other locations may have been a consequence of low population numbers or a lack of attraction at these localities.

Bark Beetles A total of 14,902 bark beetles were captured from all eight locations in 2002–2004, ranging from 713 to 2,914 per location (Table 2). Of 26 species captured in our trapping studies, only *Scolytus multistriatus* (Marsham) is a non-native species. The most common bark beetles were *D. terebrans*, *H. porculus*, *H. salebrosus*, *Hylastes tenuis* Eichhoff, and *I. grandicollis*. In contrast to ambrosia beetles, (−)-α-pinene had an effect on most bark beetle species with ethanol playing a minor role (Table 4). *Cryptocarenus heveae* (Hagedorn) and a *Hypothenemus* Westwood sp. were the only two species of bark beetles that

were attracted to ethanol-baited traps with no effect from (−)-α-pinene (Fig. 6a, b).

A total of 2,616 black turpentine beetles *D. terebrans* were captured across six locations (18% of total bark beetle catches; Fig. 6c–h). Catches of *D. terebrans* were significantly affected by (−)-α-pinene with little, if any, effect of ethanol (Table 4). At all locations, traps baited with (−)-α-pinene (with or without the addition of ethanol) caught more *D. terebrans* than unbaited control traps. However, in Florida (Ocala NF), catches of *D. terebrans* in traps baited with (−)-α-pinene were enhanced by the addition of ethanol (Fig. 6e); there was no effect of ethanol at the other locations (Fig. 6a–d, f).

The eastern five-spined ips, *I. grandicollis*, was captured at all eight locations with a total catch of 5,833 beetles (39% of total bark beetle catches; Fig. 7). As with *D. terebrans*, catches of *I. grandicollis* were significantly affected by (−)-α-pinene at all locations with inconsistent effects of ethanol among locations (Table 4). At all locations, traps baited with (−)-α-pinene (with or without the addition of ethanol) caught more *I. grandicollis* than blank control traps. The addition of ethanol to traps baited with (−)-α-pinene enhanced catches of *I. grandicollis* in Alabama (Fig. 7a) but interrupted catches in Florida (Ocala NF; Fig. 7e). There was no effect of ethanol at the other locations (Fig. 7b–d, f, g).

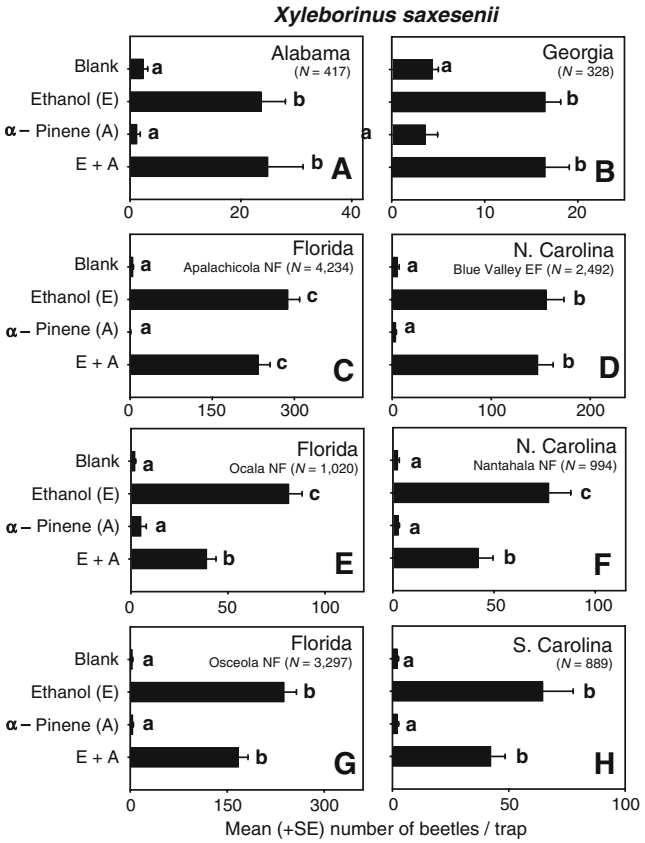

Fig. 1 **a**–**h** Effects of ethanol and (−)-α-pinene on trap catches of *X. saxesenii* (Scolytidae) in the southeastern US. Means followed by the same *letter* are not significantly different (α=0.05, Holm–Sidak multiple comparison)

Catches of *H. porculus*, *H. salebrosus*, and *H. tenuis* totaled 5,678 (38% of total bark beetle catches) with *H. tenuis* the most common (Figs. 8, 9, and 10a–f). (−)-α-Pinene had a significant effect on all three species (Table 4). At all locations, traps baited with (−)-α-pinene (with or without the addition of ethanol) caught more *H. porculus* and *H. tenuis* than blank control traps (Figs. 8 and 9). The effect of ethanol on catches of *H. porculus* and *H. tenuis* was inconsistent among locations (Table 4). Ethanol enhanced catches of *H. tenuis* to traps baited with (−)-α-pinene in Florida (Apalachicola NF; Fig. 8c) but not at the other five locations (Fig. 8a, b, d–f). Similarly, catches of *H. porculus* in traps baited with (−)-α-pinene were enhanced by the addition of ethanol in Georgia and North Carolina (Blue Valley EF; Fig. 9c, e) but not at the other three locations (Fig. 9a, b, d).

The effects of ethanol and (−)-α-pinene on catches of *H. salebrosus* were fairly consistent among six locations (Table 4). At all six locations, catches of *H. salebrosus* were highest in traps baited with both ethanol and (−)-α-pinene (Fig. 10). At four of six locations, traps baited with (−)-α-pinene caught more *H. salebrosus* than control traps (Fig. 10a–c, f). In South Carolina, traps baited with ethanol were more attractive than control traps (Fig. 10f). Similarly, catches of *Pityophthorus cariniceps* LeConte were highest in traps baited with ethanol and (−)-α-pinene (Fig. 10g).

Discussion

In addressing our first objective, we found that traps baited with ethanol and/or (−)-α-pinene were attractive to 20 species of common bark and ambrosia beetles in the southeastern US, including five exotic species of ambrosia beetles. In southern pine forests, traps baited with (−)-α-pinene were attractive to the bark beetles, *D. terebrans*, *I. grandicollis*, *H. tenuis*, *H. porculus*, and *H. salebrosus* (Figs. 6, 7, 8, 9, and 10) and the platypodid ambrosia beetle *M. flavicornis* (Fig. 5g). In some locations, traps baited with (−)-α-pinene were attractive to the ambrosia beetles, *X. ferrugineus* (Fig. 5b, c) and *X. pubescens* (Fig. 4f).

Our results with *D. terebrans* are consistent with previous tests that employed turpentine (Fatzinger et al.

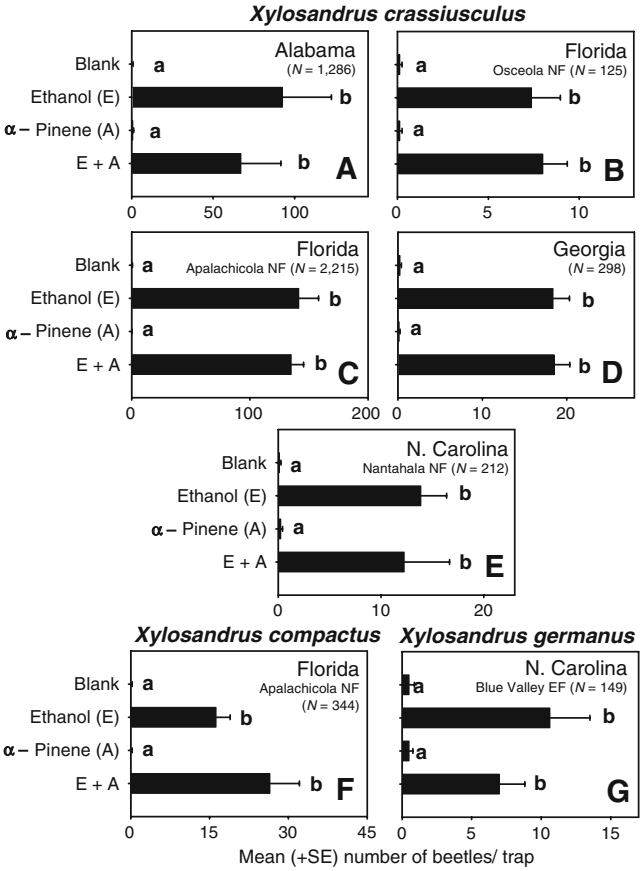

Fig. 2 Effects of ethanol and (−)-α-pinene on trap catches of *X. crassiusculus* (**a**–**e**), *X. compactus* (**f**), and *X. germanus* (**g**; Scolytidae) in the southeastern US. Means followed by the same *letter* are not significantly different (α=0.05, Holm–Sidak multiple comparison)

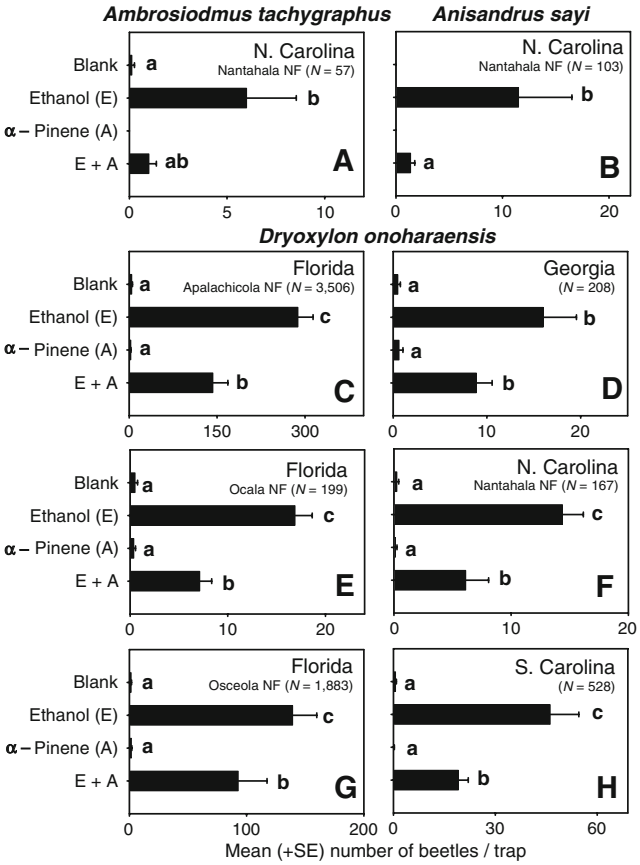

Fig. 3 Effects of ethanol and (−)-α-pinene on trap catches of *A. tachygraphus* (**a**), *A. sayi* (**b**), and *D. onoharaensum* (**c**–**h**; Scolytidae) in the southeastern US. Means followed by the same *letter* are not significantly different (α=0.05, Holm–Sidak multiple comparison) for three to four treatments (**a** and **c**–**h**) or by *t* test for two treatments (**b**). Treatments without a *letter* had zero catches

1987; Phillips et al. 1988). We specifically identify (−)-α-pinene as one of the active components for *D. terebrans*. Previously, Anderson (1977) found that α-pinene, technical pinene, and turpentine increased the attractiveness of loblolly pine logs to *I. grandicollis*. In Ontario, Chénier and Philogène (1989) captured more *I. grandicollis* in traps baited with lures that included α-pinene (total catch was only 25 beetles over six treatments). In Wisconsin, Erbilgin and Raffa (2000) found that *I. grandicollis* were attracted to traps baited with (−)-α-pinene. We know of no prior data on the specific attraction of *H. tenuis*, *H. porculus*, *H. salebrosus*, *X. ferrugineus*, and *X. pubescens* to α-pinene.

Attraction of bark beetles to monoterpenes is a fairly common phenomenon, especially in combination with pheromones (Seybold et al. 2006). Monoterpenes are common constituents of the air within forested stands, changing constantly due to various environmental and anthropogenic factors (Seybold et al. 2006). Compounds such as α-pinene are abundant in the resin of coniferous trees, particularly pine species (Smith 2000), providing important defenses against invasion by insects and diseases (Franceschi et al. 2005; Seybold et al. 2006). Leakage of monoterpenes into the environment around trees may occur through the outer bark and foliage of healthy trees, perhaps increasingly so from physically damaged trees or from trees weakened by factors such as drought or disease, which may indicate suitable breeding opportunities for bark and ambrosia beetles (Byers 1989; Franceschi et al. 2005; Raffa et al. 2005; Seybold et al. 2006). In addition, trees under attack by bark beetles release monoterpenes through the flow of resin and from the frass produced by boring beetles, thereby providing further attractiveness to other beetles (Seybold et al. 2006).

There are hundreds of volatile compounds in tree resins, and it is likely that bark beetles are attracted to monoterpenes other than α-pinene within this "dynamic aerial sea of monoterpenes" (Seybold et al. 2006). In felled loblolly pine, α-pinene is the dominant monoterpene in tree resin with four additional monoterpenes (myrcene, camphene, limonene, and β-pinene) present at levels of >5%

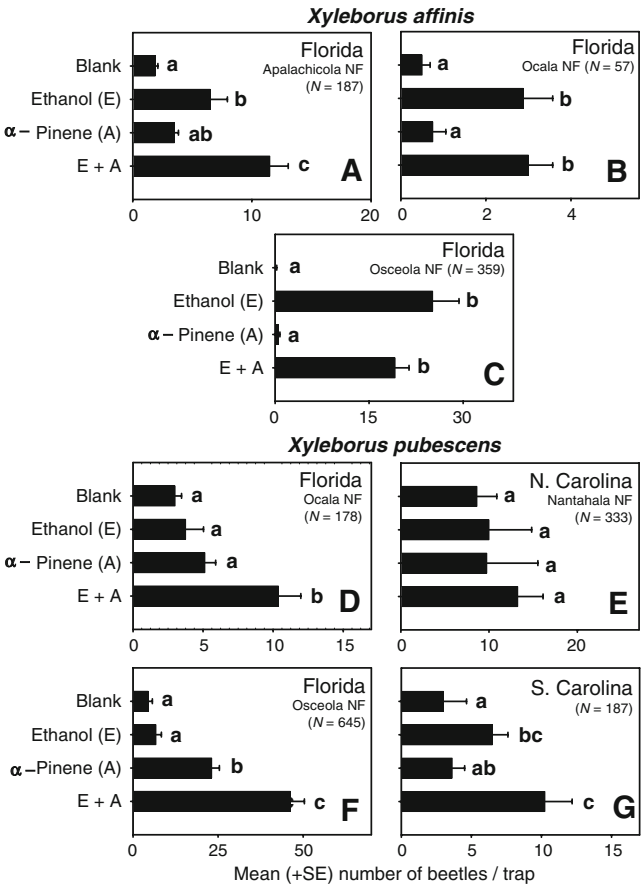

Fig. 4 Effects of ethanol and (−)-α-pinene on trap catches of *X. affinis* (**a**–**c**) and *X. pubescens* (**d**–**g**; Scolytidae) in the southeastern US. Means followed by the same *letter* are not significantly different (α=0.05, Holm–Sidak multiple comparison)

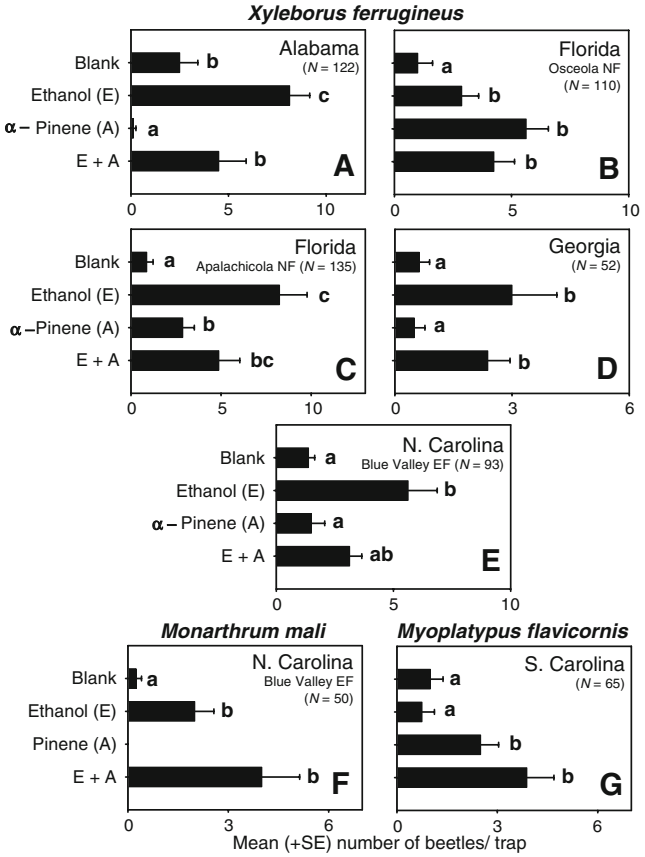

Fig. 5 Effects of ethanol and (−)-α-pinene on trap catches of *X. ferrugineus* (**a**–**e**), *M. mali* (**f**; Scolytidae), and *M. flavicornis* (**g**; Platypodidae) in the southeastern US. Means followed by the same *letter* are not significantly different (α=0.05, Holm–Sidak multiple comparison) for three to four treatments. Treatments without a *letter* had zero catches

(Werner 1972). In addition to α-pinene, *I. grandicollis* responded to myrcene, camphene, and limonene in walking bioassays (Werner 1972).

The issue of enantiomeric composition of α-pinene may be important as well (Seybold et al. 2006). We used (−)-α-pinene in our studies. Enantiomeric composition of α-pinene in pine trees can vary widely among pine species (Mirov 1961), although the relationship between enantiomeric composition and bark beetle responses may not be clear (Seybold et al. 2006). In California, Hobson et al. (1993) found that (+)-α-pinene was attractive to *D. valens* with attraction to (+)-α-pinene interrupted by (−)-α-pinene. (+)-α-Pinene is predominant in species such as *Pinus flexilis* James, *Pinus lambertiana* Dougl., and *Pinus resinosa* Ait., whereas (−)-α-pinene is the most common enantiomer in species such as *Pinus monticola* Dougl., *Pinus coulteri* D. Don, and *Pinus contorta* Dougl. ex Loud. (Mirov 1961), all of which occur within the range of *D. valens* and can be used as host material by *D. valens* (Furniss and Carolin 1977).

In another finding relevant to our first objective, traps baited with ethanol were attractive to the ambrosia beetles, *A. tachygraphus*, *A. sayi*, *D. onoharaensum*, *M. mali*, *X. saxesenii*, *X. affinis*, *X. ferrugineus*, *X. pubescens*, *X. crassiusculus*, *X. compactus*, and *X. germanus* (Figs. 1, 2, 3, 4, and 5), and the bark beetles, *C. heveae* and *Hypothenemus* sp. (Fig. 6a, b). Previously, Klimetzek et al. (1986) found that *X. saxesenii* was attracted to ethanol released at rates >1 mg/h whereas Phillips et al. (1988) found that *X. affinis*, but not *X. pubescens*, were attracted to traps baited solely with ethanol. Montgomery and Wargo (1983) state that ethanol was attractive to *M. mali* and *X. saxesenii* in oak forests in Connecticut (USA), although data were not presented. In southern California, *X. saxesenii* is attracted to ethanol-baited traps (Flint et al. 2007).

We know of no other prior data on the ethanol-based attraction of the ambrosia beetle species caught in our study. Yet, ethanol-baited traps are commonly (and successfully) used to assess temporal and spatial patterns of ambrosia beetles as well as in detection programs like CAPS and EDRR. For example, Roling and Kearby (1975) used ethanol-baited window traps to successfully monitor the seasonal flight patterns of *A. sayi*, *M. mali, X. saxesenii*, and *X. ferrugineus* in stands of oak in Missouri (US). Although no data are presented, they noted that previous attempts without ethanol were unsuccessful. Similarly, Markalas and Kalapanida (1997) used ethanol-baited traps to monitor flight periods of *X. saxesenii* in an oak forest in Greece. Ethanol-baited traps are used to monitor the flight activity of ambrosia beetles such *X. saxesenii*, *X. crassiusculus*, and *X. germanus* in horticultural tree nurseries prior to initiating an insecticide control program (Oliver and Mannion 2001; Bambara et al. 2008). Coyle et al. (2005) used ethanol-baited funnel traps to monitor flight activity of 28 species of bark and ambrosia beetles in stands of cottonwoods in South Carolina. Our data simply add evidential weight to the experiences of professionals in support of ethanol-baited traps for ambrosia beetles.

The attraction of ambrosia beetles to ethanol is likely related to their preference for woody material that has aged for a sufficient period of time for anaerobic respiration to generate ethanol within the tissues (Graham 1968; Cade et al. 1970; Moeck 1970; Lindelöw et al. 1993). Kelsey (1994) found that the ambrosia beetles *G. retusus* and *T. lineatum* preferred Douglas fir logs, *P. menziesii* (Mirb.) Franco, that had been felled in November of the previous year over logs that had been felled in January or March of the current year; ethanol concentrations were highest in logs felled in November of the previous year.

Hypoxia conditions arising in stressed trees also can lead to the production of ethanol and subsequent attack by bark and ambrosia beetles. Gara et al. (1993) found that lodgepole pines infected with heartwood decay fungi

Table 4 Significance levels for ANOVAs on effects of ethanol and (−)-α-pinene on bark beetle trap catches in the southeastern US

emitted ethanol at rates higher than uninfected trees. Ethanol concentrations are higher in the roots and root collars of Douglas fir and ponderosa pine infected with root disease than in healthy uninfected trees (Kelsey and Joseph 1998; Kelsey et al. 1998). Ethanol production in Douglas fir branches increases with water stress, resulting in attacks by the Douglas fir engraver, *S. unispinosus* LeConte, in Oregon (Kelsey and Joseph 2001). Ethanol production and landing preferences by bark and wood-boring beetles in ponderosa pine are correlated strongly with stress from crown scorch caused by wildfires (Kelsey and Joseph 2003).

In answer to our second objective, we found that the binary combination of ethanol and (−)-α-pinene was preferred by *H. salebrosus* and *P. cariniceps* (Fig. 10). Previously, Phillips (1990) found that *H. salebrosus* preferred the combination of turpentine with ethanol to turpentine alone. However, the benefit of adding ethanol to (−)-α-pinene-baited traps was inconsistent for several other species among locations. The binary combination was preferred by *D. terebrans* at only one of six locations (Fig. 6e), *X. affinis* at one of three locations (Fig. 4a), *X. pubescens* at two of four locations (Fig. 4d, f), *I. grandicollis* at one of eight locations (Fig. 7a), *H. tenuis* at one of six locations (Fig. 8c), and *H. porculus* at two of five locations (Fig. 9c, e). Fatzinger et al. (1987) and Phillips et al. (1988) found that *D. terebrans* and *X. pubescens* in Florida preferred the binary combination of ethanol and turpentine, whereas *X. affinis* was unaffected by the addition of turpentine to ethanol-baited traps. In southern California, Flint et al. (2007) found that *H. tenuis* preferred traps baited with ethanol and (−)-α-pinene over those baited with either ethanol or (−)-α-pinene alone. We know of no other prior data on the specific attraction of these species to the combination of ethanol and (−)-α-pinene.

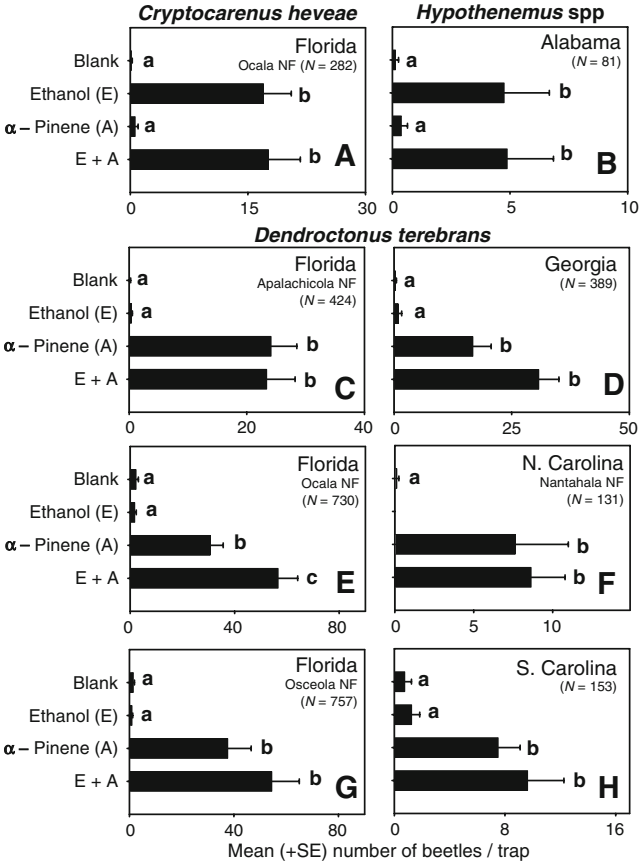

Fig. 6 Effects of ethanol and (−)-α-pinene on trap catches of *C. heveae* (**a**), *Hypothenemus* sp. (**b**), and *D. terebrans* (**c**–**h**; Scolytidae) in the southeastern US. Means followed by the same *letter* are not significantly different (α=0.05, Holm–Sidak multiple comparison)

In contrast, (–)-α-pinene had an interruptive effect on the responses of some species of ambrosia beetles to traps baited with ethanol. Catches of the ambrosia beetles *A. sayi* and *D. onoharaensum* to ethanol-baited traps were reduced by the addition of (−)-α-pinene (Fig. 3b–h). The exotic ambrosia beetle *D. onoharaensum* was one of the most common species in our trapping studies (Table 1). In two of eight locations, (−)-α-pinene had an interruptive effect on the attraction of *X. saxesenii* to ethanol (Fig. 1e–f). In British Columbia (Canada), α-pinene interrupted catches of *X. saxesenii* in ethanol-baited traps (L. Humble, unpublished data). However, Flint et al. (2007) found that (−)-α-pinene had no interruptive effect on catches of *X. saxesenii* to ethanol-baited traps in southern California, similar to our results with *X. saxesenii* in six of eight locations (Fig. 1a–d, g, h). With the exception of *I. grandicollis* at the Ocala NF (Florida; Fig. 7e), ethanol did not interrupt the response of bark beetles to traps baited with (−)-α-pinene. Catches of *I. grandicollis* at the seven other locations were not interrupted by ethanol (Fig. 7a–d, f–h).

Preferences for various combinations of ethanol and (−)-α-pinene may reflect conditions found in suitable hosts. In damaged or severed trees, the emissions of monoterpenes are likely high initially, decreasing over time with effects of desiccation and oxidation. In contrast, ethanol emissions are likely low initially, increasing over time as a consequence of anaerobic respiration (Kelsey 1994). Preferences of some species to ethanol with no apparent effect of (−)-α-pinene may relate to broad host ranges that include hardwood tree species; in fact, some ambrosia beetle species may be more common in hardwood species (Jordal et al. 2001).

We are unable to explain the variation among locations in responses of some species to baited traps. Although the same experimental design was employed at all locations, it is possible that the power was lower at some locations than others, particularly for species with low total catches. In some locations, sample size may have been insufficient to detect significant differences where such differences truly existed. It is possible that background or competing sources of ethanol and/or (−)-α-pinene may have differed significantly among locations. In some areas, emissions from baits

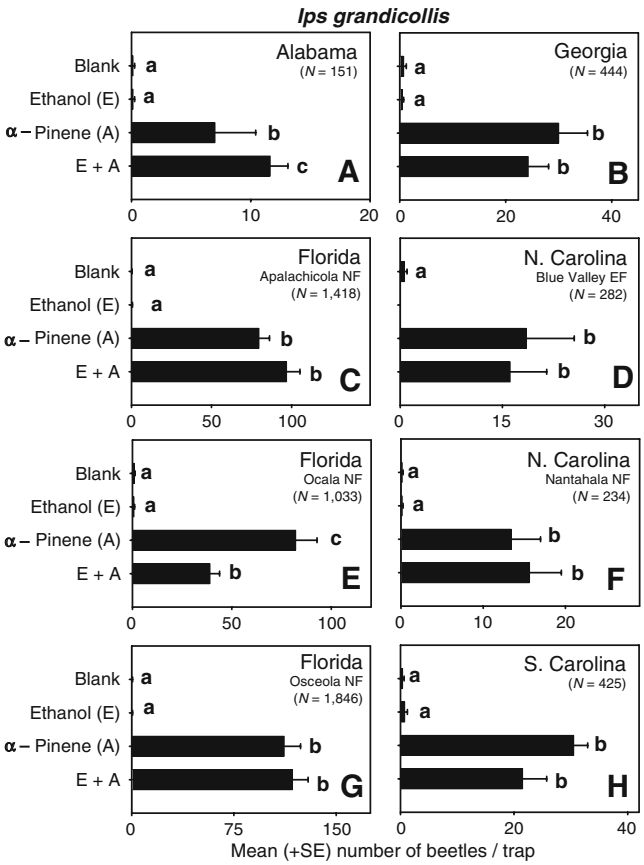

Fig. 7 **a**–**h** Effects of ethanol and (−)-α-pinene on trap catches of *I. grandicollis* (Scolytidae) in the southeastern US. Means followed by the same *letter* are not significantly different (α=0.05, Holm–Sidak multiple comparison)

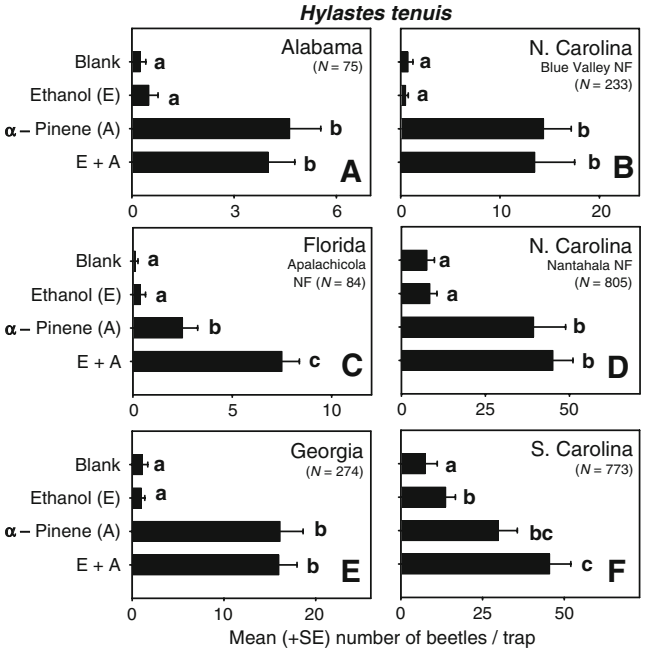

Fig. 8 **a**–**f** Effects of ethanol and (−)-α-pinene on trap catches of *H. tenuis* (Scolytidae) in the southeastern US. Means followed by the same *letter* are not significantly different (α=0.05, Holm–Sidak multiple comparison)

might have been overwhelmed by background levels of ethanol and/or (−)-α-pinene. In other areas, these emissions might have been dampened directly by vegetation. In addition to variation in trapping dates and primary pine

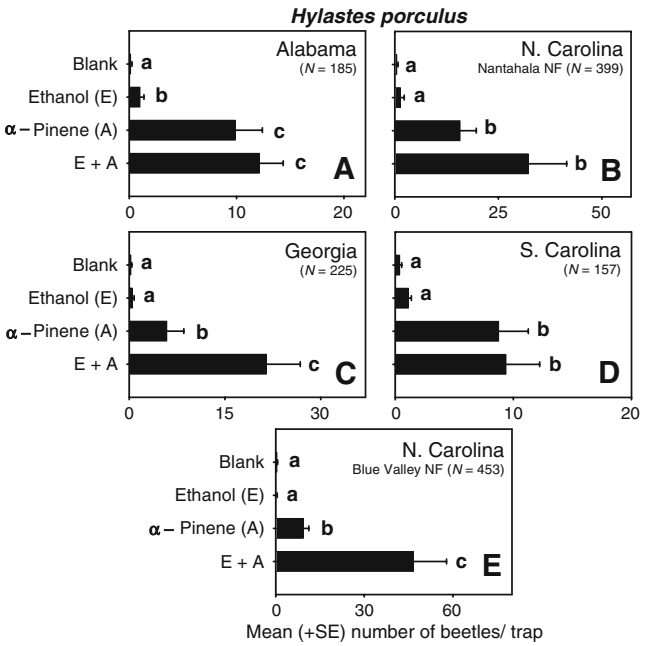

Fig. 9 **a**–**e** Effects of ethanol and (−)-α-pinene on trap catches of *H. porculus* (Scolytidae) in the southeastern US. Means followed by the same *letter* are not significantly different (α=0.05, Holm–Sidak multiple comparison)

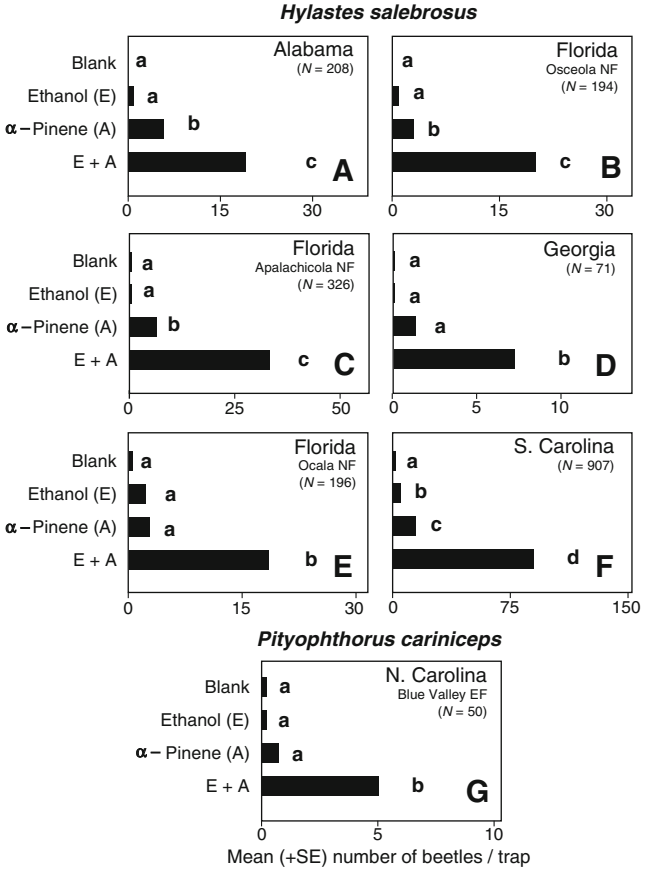

Fig. 10 Effects of ethanol and (−)-α-pinene on trap catches of *H. salebrosus* (**a**–**f**) and *P. cariniceps* (**g**; Scolytidae) in the southeastern US. Means followed by the same *letter* are not significantly different (α=0.05, Holm–Sidak multiple comparison)

species (Table 1), the eight study sites used in our study likely differed in many aspects including host composition, damage type, understory vegetation, and climate regimes. Unfortunately, we have no detailed information over an adequate sample size of locations to evaluate or explain this type of variation. Suffice it to say that our results suggest that variation in responses can be expected in an operational program as well.

In summary, we provide evidence to support the continued use of traps baited with ethanol and/or (−)-α-pinene in detection and monitoring programs for bark and wood-boring beetles. Moreover, the interruptive effect of (−)-α-pinene does necessitate the use of a separate trap baited solely with ethanol. Serendipitous to our stated objectives, we found a significant and disturbing pattern in the relative abundance of exotic species. Exotic non-native species of ambrosia beetles were consistently dominant in total trap catches of ambrosia beetles throughout our study area, accounting for 69.7–93.4% in North Carolina, 90.6% in Georgia, 82.9% in South Carolina, 90.0% in Alabama, and 75.1–96.6% in Florida.

The abundance of non-native ambrosia beetles in trap catches likely reflects their relative abundance in forested areas of the South. Previously in South Carolina and Tennessee, Coyle et al. (2005) and Oliver and Mannion (2001) found that the percentage of exotic beetles in ethanol-baited baited traps was 88% and 74%, respectively. Ambrosia beetles generally play an important role in initiating the decomposition cycle (Lindgren 1990). Yet, little is known of the impacts of exotic ambrosia beetles on forest ecology in southern forests, particularly with respect to decomposition of woody material and carbon sequestration. Moreover, the generalist host requirements and the incestuous nature of xyleborine ambrosia beetles suggest that new invasions and expansion of existing invasions are likely (Jordal et al. 2001; Hulcr et al. 2007), all without known consequences.

Acknowledgments We thank R. G. Kelsey, Assoc. Editor S. J. Seybold, B. T. Sullivan, and two anonymous referees for reviews of the manuscript; C. M. Crowe, C. Asaro, D. Johnson, and R. Brantley for field and laboratory assistance; D. E. Bright for identifications of *Pityophthorus* species; and the staffs at the Apalachicola, Bankhead, Nantahala, Ocala, Oconee, Osceola, and Sumter National Forests and Blue Valley Experimental Forest for assistance and permission to conduct these studies on their respective lands. The use of trade names and identification of firms or corporations does not constitute an official endorsement or approval by the US Government of any product or service to the exclusion of others that may be suitable. Funding for this research was provided by the USDA Forest Service. The USDA is an equal-opportunity provider and employer.

Optimization of a Phenylacetaldehyde-Based Attractant for Common Green Lacewings (*Chrysoperla carnea s.l.*)

Miklós Tóth · Ferenc Szentkirályi · József Vuts · Agostino Letardi · Maria Rosaria Tabilio · Gunnhild Jaastad · Geir K. Knudsen

Received: 15 August 2008 / Revised: 25 February 2009 / Accepted: 5 March 2009 / Published online: 31 March 2009

Abstract In field trapping tests, the catch of *Chrysoperla carnea sensu lato* (Neuroptera: Chrysopidae) increased when acetic acid was added to lures with phenylacetaldehyde. The addition of methyl salicylate to the binary mixture of phenylacetaldehyde plus acetic acid increased catches even further. The ternary blend proved to be more attractive than β-caryophyllene, 2-phenylethanol, or 3-methyl eugenol (compounds previously described as attractants for chrysopids) on their own, and no influence on catches was recorded when these compounds were added as fourth components to the ternary blend. There were minimal changes in activity when (*E*)-cinnamaldehyde or methyl anthranylate (both evoking large responses from female or male antennae of *C. carnea* in this study) were added, although both compounds showed significant attraction on their own when compared to unbaited traps. In subtractive field bioassays with the ternary mixture, it appeared that the presence of either phenylacetaldehyde or methyl salicylate was important, whereas acetic acid was less so in the ternary mixture. The ternary blend attracted both female and male lacewings at sites in southern, central, and northern Europe. Possible applications of a synthetic attractant for lacewings are discussed.

Introduction

The common green lacewing, *Chrysoperla carnea sensu lato* (Neuroptera: Chrysopidae), is one of the most important lacewing species used in biological control. Adults of some genera and all lacewing larvae feed on pest aphids, scales, caterpillars, and other pests of many crops (McEwen et al. 2001). A synthetic attractant for green lacewings might be useful for monitoring lacewing abundance or manipulating lacewing population densities (for a review, see Szentkirályi 2002).

Lacewings of different genera (*Chrysopa* sp. and *Peyerimhoffina* sp.) are highly attracted to semiochemicals that lacewings produce themselves (Hooper et al. 2002). In *Chrysopa oculata* Say, a semiochemical apparently secreted by elliptical epidermal glands found only on the male abdominal sternites (Zhang et al. 2004) is a powerful aggregation pheromone (Chauhan et al. 2007). Although specific pheromones have yet to be found for lacewings in the genus *Chrysoperla*, several chemicals occurring in the

scent of several flowers attract *Chrysoperla* and other lacewings. 3-Methyl eugenol (Suda and Cunningham 1970; Umeya and Hirao 1975), methyl salicylate (Molleman et al. 1997; James 2003, 2006; James and Price 2004), β-caryophyllene (Flint et al. 1979), and 2-phenylethanol (Zhu et al. 1999, 2005) have all been reported to attract *C. carnea* or some other species of Chrysopidae in the field. Recently, we also discovered that phenylacetaldehyde was attractive to *C. carnea* in field tests in Hungary and Italy (Tóth et al. 2006). The objective of the present study was to optimize multicomponent attractant blends with phenylacetaldehyde as the core component. We investigated new, optimized attractant combinations and searched for synergists by using electroanntennographic and field screening techniques and by utilizing data from other synthetic lacewing attractants known from literature. In addition, the most attractive combination of volatiles was tested for its attractivity in several areas in Europe.

Methods and Materials

Electroantennograms Insects for electroantennogram (EAG) analyses were collected from the edge of an oak forest at Julianna major (Budapest, Hungary). To present the stimuli to the antenna during EAG studies, a stainless steel tube (Teflon-coated inside) with a constant humidified airflow of ca. 0.7 l/min was set up. An antenna was freshly amputated at the base from a live lacewing and mounted between two glass capillaries containing 0.1 N KCl solution. The mounted antenna was placed at ca. 3 mm distance from the out-coming airflow. One of the electrodes was grounded, while the other was connected to a high impedance DC amplifier (IDAC-232, Syntech, Hilversum, The Netherlands). Test compounds (10 μg each) were administered in hexane solution onto a 10×10 mm piece of filter paper inside a Pasteur pipette. Stimuli consisted of pushing 1 ml of air through the Pasteur pipette into the airstream flowing towards the antenna. Response amplitudes were normalized against the means of responses to phenethyl alcohol (eliciting medium high responses from antennae), which was tested before and after the test compounds. Stimuli were administered at ca. 20–30 s intervals.

Trap Types For field studies conducted in Hungary, we used standard CSALOMON® VARL+ funnel traps (www.julia-nki.hu/traps) produced by the Plant Protection Institute, HAS (Budapest, Hungary). This trap type was developed originally for capturing moths (Tóth et al. 2000; Subchev et al. 2003) but later proved to be suitable for the green lacewing (Tóth et al. 2006). The trap consists of an opaque plastic funnel (top opening outer diameter, 13 cm; funnel hole diameter, 3 cm; height of funnel, 16 cm), with a 20×20 cm flat plastic roof. The trap also has a round transparent plastic collection container (ca. 1 l capacity) attached to the bottom funnel by a rubber band. The bait was suspended from the middle of the roof and positioned slightly above the level of the upper edge of the large funnel opening. A small piece (1×1 cm) of household anti-moth strip (Chemotox®, Sara Lee, Temana Intl. Ltd, Slough, UK; active ingredient 15% dichlorvos) was placed in the collection container to kill the captured insects.

For trials conducted in Italy, we used sticky delta traps (the standard CSALOMON® RAG traps produced by Plant Protection Institute, HAS, Budapest, Hungary; Szöcs 1993; Tóth and Szöcs 1993; www.julia-nki.hu/traps). In Norway, we used delta traps with sticky bottoms produced by PheroNet AB, Lund, Sweden.

Baits All synthetic compounds (>95% chemical purity as per the manufacturer) were obtained from Sigma-Aldrich Kft. (Budapest, Hungary). For preparing the baits, compounds were loaded onto a 1-cm piece of dental roll (Celluron®, Paul Hartmann AG, Heidenheim, Germany), which was put into a polyethylene bag (ca. 1.0×1.5 cm) made of 0.02 mm linear polyethylene foil (FS471-072, Phoenixplast BT, Pécs, Hungary). Loaded dose of single compounds was kept at 100 mg each, unless otherwise stated in the respective experiments. The dispensers were heat sealed and attached to 8×1 cm plastic handles for easy handling when assembling the traps. Dispensers were wrapped singly in pieces of aluminum foil and stored at −18°C until used. In the field, baits were changed at 2 to 3-week intervals, as previous experience showed that they do not lose their attractiveness during this period (Tóth et al. 2006)

Field Tests Field comparison tests were conducted routinely by using the methods applied in similar studies on pheromones and attractants (e.g., Roelofs and Cardé 1977; Arn et al. 1986). Trapping experiments were conducted in fruit orchards. Green lacewings are frequently seen flying at 1.5–2.0 m in the crown of trees, thus traps were suspended in the trees at a height of 1.5–1.7 m above ground. One trap of each treatment was incorporated into a block so that individual treatments were 5–8 m apart (according to the distance between trees at the respective sites). Blocks were situated 15–20 m apart. Unless otherwise stated, five blocks of traps were applied in an experiment, and traps were inspected twice weekly. In Hungary, field tests were conducted at Halásztelek, in a sour cherry orchard, and at Érd-Elviramajor, in a cherry orchard (both sites situated in Pest county). In Italy, field tests were conducted in an apricot orchard near Rotondella (southern Italy), and in Norway, traps were placed in sweet cherry orchards in two

different areas in Ås (southeastern Norway) and Ullensvang (western Norway).

Experimental Details

Experiments 1A and 1B The objective of these preliminary tests was to study the influence of acetic acid added to phenylacetaldehyde. These tests were originally aimed at catching noctuid moths (Lepidoptera: Noctuidae). Treatments included traps baited with phenylacetaldehyde on its own [a well-known moth attractant (e.g., Creighton et al. 1973; Cantelo and Jacobson 1979)], or phenylacetaldehyde plus acetic acid (1:1). In the treatment containing both compounds in experiment 1A, acetic acid and phenylacetaldehyde were loaded into separate dispensers (so in this case, traps with this treatment contained two dispensers), whereas in experiment 1B, the two compounds were loaded into a single dispenser. Both tests were conducted at Halásztelek; experiment 1A was carried out from 9 May to 10 June, 2003, whereas experiment 1B was carried out from 10 June to 23 September, 2003. There were five blocks in the former and six blocks in the latter.

Experiment 2 The objective was to study the optimal ratio of acetic acid added to phenylacetaldehyde. Treatments included traps baited with phenylacetaldehyde or acetic acid alone, and their binary mixtures in 10:1, 1:1, and 1:10 ratios. The test was conducted at Halásztelek from 11 August to 24 August, 2003.

Experiment 3 In this test, we studied the activity of methyl salicylate or β-caryophyllene alone or in addition with the optimal blend of phenylacetaldehyde and acetic acid. Treatments included methyl salicylate or β-caryophyllene alone, the binary mixture of phenylacetaldehyde and acetic acid (1:1), ternary mixtures of phenyalcetaldehyde, acetic acid, and β-caryophyllene or methyl salicylate, and unbaited traps. The test was conducted at Érd-Elviramajor from 14 June to 23 July, 2004.

Experiment 4 This test was designed to study the influence of varying doses of methyl salicylate added to the optimal phenylacetaldehyde + acetic acid blend. Traps baited with methyl salicylate on its own, the binary phenylacetaldehyde + acetic acid blend, and ternary mixtures of phenylacetaldehyde + acetic acid + methyl salicylate (1:1:1, 10:10:1, 1:1:10) and unbaited controls were set out. An extra treatment which contained the phenylacetaldehyde + acetic acid blend plus methylsalicylate in separate dispensers was also tested. The test was conducted at Érd-Elviramajor from 23 July to 13 October, 2004.

Experiment 5 This test was aimed at comparing efficacy of the phenylacetaldehyde + acetic acid + methyl salicylate ternary blend with that of the known lacewing attractants 2-phenylethanol and 3-methyl eugenol. The test consisted of the treatments 2-phenylethanol and 3-methyl eugenol on their own, the ternary phenylacetaldehyde + acetic acid + methyl salicylate blend, and unbaited traps. The test was conducted at Érd-Elviramajor from 4 to 19 July, 2005.

Experiment 6 The objective was to study the influence of 2-phenylethanol and 3-methyl eugenol when added to the ternary phenylacetaldehyde + acetic acid + methyl salicylate blend. Treatments included the ternary phenylacetaldehyde + acetic acid + methyl salicylate mixture (1:1:1), quaternary blends of these compounds with 2-phenylethanol or 3-methyl eugenol added (1:1:1:1), a blend of all five compounds together (1:1:1:1:1), and unbaited traps. The test was conducted at Érd-Elviramajor from 19 July to 16 August, 2005.

Experiment 7 In this test, we studied the activity of cinnamaldehyde and methyl anthranylate, both compounds with high EAG activity. Traps with (*E*)-cinnamaldehyde or methyl anthranylate on their own were compared to traps with the ternary phenylacetaldehyde + acetic acid + methyl salicylate mixture, the quaternary blends containing (*E*)-cinnamaldehyde or methyl anthranylate as fourth components, and unbaited traps. The test was conducted at Halásztelek from 1 June to 13 July, 2007.

Experiments 8 and 9 The objective of these tests was to compare the relative importance of the single components in the ternary blend of phenylacetaldehyde, acetic acid, and methyl salicylate. In both experiments, treatments included phenylacetaldehyde on its own, its binary combinations with acetic acid or methyl salicylate (1:1), and the ternary combination (1:1:1). Experiment 9 also included unbaited traps. The tests were conducted at Érd-Elviramajor from 16 August to 12 September, 2005 (experiment 8) and at Halásztelek from 13 July to 21 August, 2007 (experiment 9).

Activity of the Optimized Attractant in Different European Regions Apart from the comparison tests performed in Hungary (central Europe), the optimized ternary attractant of phenylacetaldehyde + acetic acid + methyl salicylate (1:1:1) also was tested at sites in southern Europe (Italy) and in northern Europe (Norway). The purpose of these tests was to confirm attraction of *C. carnea* in these regions.

It Italy, five traps with bait dispensers and five unbaited control traps were checked for adult *C. carnea* weekly between 14th April and 27th July.

In Ullensvang (western Norway), ten traps with bait dispensers and ten unbaited control traps were checked for

adult *C. carnea* four times between 16th May and 15th June. From 16th June until 12th September 3, traps with bait dispensers and five control traps were checked for adults 12 times. Further, these traps were checked for *C. carnea* eggs twice between 16th May and 15th June (ten baited traps and ten control traps) and 12 times between 16th June and 12th September (five baited traps and five control traps). In Søråsjordet, Ås (southeastern Norway), five traps with bait dispensers and one unbaited control trap were checked ten times for both adults and eggs between 29th May and 8th August. A second field in this area, Norderåshagen, had seven traps and one control trap and was checked five times from 29th May until 13th June.
