We noted that during the interactions involving *S. saevissima* or *C. blandus* workers with the application method 1, untreated *C. blandus* workers ran away more frequently in the former than in the latter case (70% *vs*. 36.7%). This can be due to the alkaloids contained in the *S. saevissima* venom that have a repellent function during heterospecific encounters (see Obin and Vander Meer 1985, for *S. invicta*). Indeed, that the alkaloids are not transferred during the reapplication process could explain at least a part of the difference. Also, because aggressive interactions are potential sources of injury or death, ants rather initiate fights when they must defend their nest, territories or food (Roulston et al. 2003). So, in a neutral arena devoid of food

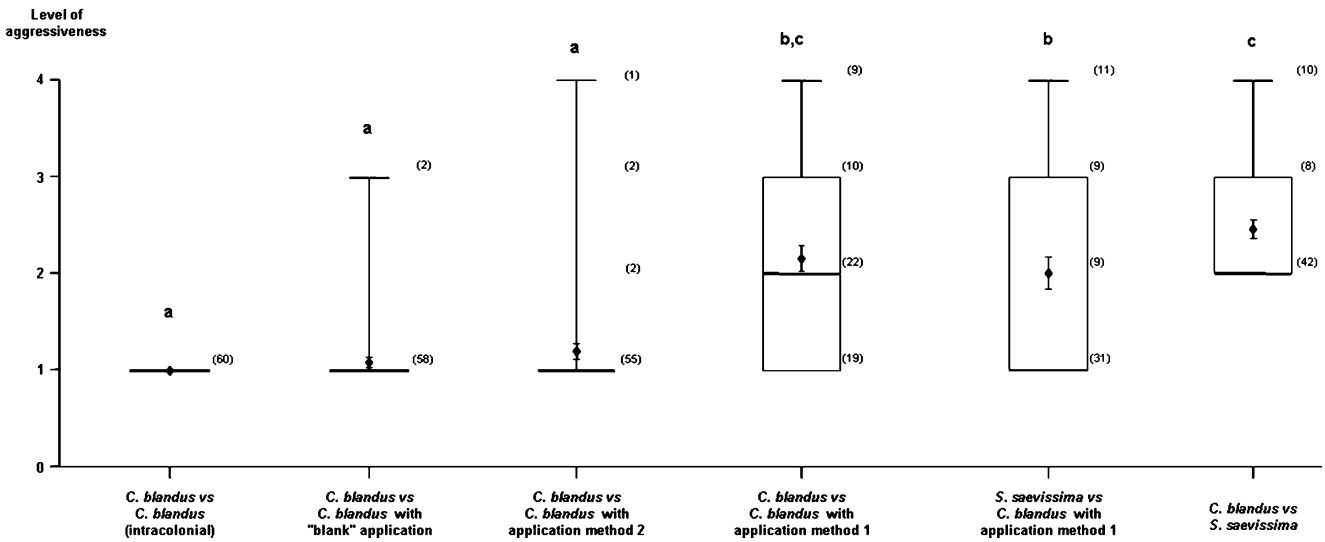

Fig. 2 Box plot and mean ± se of aggressiveness responses observed during the six different types of interactions between *Camponotus blandus* and *Solenopsis saevissima*. Mean (♦). The *box* plots indicate the median (*large horizontal bars*), the 25th and 75th percentiles (*white squares*), and the minimum and maximum values (whiskers). Statistical comparisons were performed by using the Kruskal–Wallis test (H=186.7; df=5; P<0.001) followed by a Dunn's *post hoc* test: different *letters* indicate significant differences (P<0.001). (n) = number of occurrence for each level of aggressiveness

sources, it is in the protagonists' best interest to avoid conflict. The non-aggressive behavior observed during interactions between untreated *C. blandus* workers and *C. blandus* workers with the application method 1 could result from the imperfect distribution of the cuticular compounds on the cuticle of the reapplied workers (Ruther et al. 1998). However, during interactions between untreated *S. saevissima* workers and *C. blandus* workers with the application method 1, reapplied *C. blandus* workers ran away less often than in the previous cases. This could be because its perception of its own "gestalt odor" was altered and partially matched the odor of *S. saevissima* workers. Fresneau (1980) found that this may lead to tolerance of the alien during intraspecific confrontations.

In summary, we have shown that using water-based extracts of cuticular compounds is similar to using hexane-based extracts, and that they can be reapplied onto other individuals through soaking, all while keeping the individuals alive. This method of transferring cuticular compounds might be applicable to other insect-insect or even insect-plant interactions.

Acknowledgments We are grateful to Andrea Dejean for proofreading the manuscript, to Antoine Steven from the *Institut Pasteur de la Guyane* for allowing us the use of a GC-MS, to Felipe Ramon-Portugal for technical assistance, and to the staff of the *Laboratoire Environnement de Petit Saut* for field accommodations. Two anonymous reviewers are thanked for their helpful suggestions, which significantly improved the manuscript. Financial support for this study was provided by the *Programme Amazonie II* of the French *Centre National de la Recherche Scientifique* (*project 2ID*) and the *Programme Convergence 2007–2013, Région Guyane* from the European Community (*project DEGA*).

also is assumed that the level of area marking could inform the ants about their distance from the nest since in central place foragers, the density of exploring nestmates and thereby the density of home-range marks decrease with distance (Devigne and Detrain 2006). Based on the information provided by the level of home-range marking, ants fine tune their recruitment and foraging behavior. By increasing the trail intensity as well as the rate of information transfer on heavily marked areas, scouts reduce the number of foragers mobilized to less frequented areas that are potentially dangerous and promote recruitment and exploitation of food sources to better known sites (Devigne et al. 2004). The nest odor is important when the colony has to emigrate: ants will always prefer to settle in a marked nest than in an unmarked one (e.g., *Lasius niger* (Depickère et al. 2004); *Temnothorax albipennis* (Franks et al. 2007)).

In this paper, we investigated whether area marking in *Lasius niger* ant species originates from cuticular hydrocarbons and to what extent they show the same level of colony specificity as cuticular recognition cues over the ant body. First, we analyzed the cuticular hydrocarbons (CHCs) of forager workers from different localities in France to investigate geographical variations in the cuticular chemical profile of this species. Nestmate recognition in *Lasius* is highly efficient with workers also being able to discriminate nestmates from non-nestmates (Akino and Yamaoka 2005). Therefore, we predicted that the monogynous *L. niger* ant has a well differentiated colonial cuticular profile. Second, we compared the cuticular profiles of head plus thorax vs. legs alone in order to determine whether legs have a secretory role, as hypothesized for Japanese *Lasius* species (Yamaoka and Akino 1994). In this case, thorax and legs would show quite different chemical profiles. In contrast, they would be similar if there is a continuous update of the profile of the individuals due to self-grooming. Third, we analyzed the chemical profile of traces left over inner walls of ant nests, as well as those deposited by the foraging workers over the areas surrounding the nest. We predicted that the inside-nest marking would be colony-specific. Since ants behave similarly over areas that are marked by an alien or by their own colony (Devigne and Detrain 2002), we predicted that, outside the nest, there would be a less clear-cut colonial identity of traces left over the substrate of foraged areas.

Methods and Materials

The Ants The black garden ant, *Lasius niger*, is common in temperate European regions. Colonies were collected in May and June 2007 at three locations: near the cities of Tours (Azay sur Cher, 0° 48′ E, 47° 19′ N, 80 m asl, orchard, colonies T5, T6, and T7) and Pau (Sauvagnon, 0° 22′ W, 43° 25′ N, 187 m, garden, colonies S2 and S3), and in the Alps (M: Morillon, Haute-Savoie, 06° 41′ E, 46° 05′ N, 670 m, on the edge of a torrent, one colony). Within localities, colonies were separated by less than 10 m. All fragments of colonies were queenless and composed of 300 to 500 workers with brood. We checked that the ants were distinct from the close species *L. alienus* and *L. platythorax* by examining their morphological characters as well as their cuticular hydrocarbon profiles which were different (A.L. unpublished).

Colonies were kept in the laboratory (temperature 25°C, natural daylight), in artificial nests composed of two plastic containers (20×20×10 cm) connected by a bridge. The first box contained the nest made with glass tubes half filled with water and covered with black paper. The second container provided a foraging area to the colony, in which twice a week we offered *Tenebrio molitor* larvae and commercial bumblebee solution (Bee Happy®).

Chemical Analyses To study cuticular hydrocarbons, samples consisted of extracts of head plus thorax with the legs. Gaster was eliminated to prevent contamination from Dufour gland. We pooled five workers to get a concentrated sample. To determine a possible secretory role of legs, samples were made of tibias and tarsae from 20 workers. All workers were foragers. Ants were immersed in 200 µl of pentane for 5 min. Samples were removed, and 5 µl of pentane containing 50 ng of eicosane (C20) were added as an internal standard. For analyses, the solvent was evaporated until 10 µl remained. Three µl were injected into a FID gas–chromatograph (VGM250Q system, Perkin-Elmer) with a split/splitless injector and flame ionization detector that used a DB-5 fused silica capillary column. Temperature was kept at 150°C during the initial splitless 2 min, raised from 150°C to 300°C at 5°C/min, and held at 300°C for the last 10 min. The non volatile cuticular lipids were identified with the same GC coupled to a Perkin-Elmer MS operating 70 EV. A series of linear hydrocarbon standards (C20, C22, C24 … to C40) were injected regularly in order to have references. We also injected one cuticular extract into a high temperature column (DB-5HT) to 370°C to check if some hydrocarbons with high molecular weights appeared, as has been found in some ants [see (d'Ettorre and Lenoir 2009)]. As no more hydrocarbons were detected, we subsequently used the normal DB-5 column. The areas of peaks were measured by peak integration with a Perkin Elmer Turbo-Chrome Workstation, and relative proportions were calculated. The quantities of compounds were calculated by using the internal standard areas (ng per head + thorax or per six legs, i.e., one ant).

Chemical compounds deposited on the substrate by the ants were analyzed by using the SPME technique. A polydimethylsiloxane (PDMS) 7 µ (fused silica/SS) fiber

was rubbed on substrate for 5 min. The fiber was desorbed in the GC under the same conditions as for liquid extracts. Three locations were chosen to analyze deposited chemicals marks: inner nest walls, area in front of the nest entrance, and foraging area. For the inside nest marking, we gently pushed the ants outside the nest and rubbed the fiber over the inner walls of the glass tubes. To collect area marking, glass slides were washed completely with a detergent and rinsed several times with hexane. We checked with SPME that the slides were free of any detectable chemical traces. These clean slides were deposited just in front of the nest entrance and in the foraging arena. Since preliminary trials showed that slides in the foraging arena were frequently covered with refuse particles, we put them for at least 2 days on the bridge between the two containers where they were kept clean. It has been shown that the profiles obtained with SPME and classical solvent extraction are qualitatively identical (Sledge et al. 2000; Tentschert et al. 2002), but a precise quantitative analysis shows that the proportions of compounds are slightly different. So, in order to get comparable data for the cuticle and the substrate marking, we also performed a 5 min SPME on the thorax of ants killed in the refrigerator. Moreover, we deposited in five samples a standard of 100 ng of C20 on the fiber to estimate the quantities retrieved by the SPME technique.

Statistics We compared the average relative amounts of different hydrocarbon classes by using a non-parametric Kruskal–Wallis test. To analyze the grouping of samples, we performed discriminant analyses on the peaks present in more than 1% amount followed by post-hoc F tests. We did not transform the data to compensate for their non-independence, since it introduces additional background noise and gives similar results. We also analyzed the distances between groups after discriminant analyses by using the Squared Mahalanobis distances (SMD), and we compared them by using the Kruskal–Wallis non-parametric test. To compare the hydrocarbon quantities we used Mann–Whitney *U* test.

Results

Cuticular Hydrocarbons and Geographical Variations *Lasius niger* workers show a wide spectrum of hydrocarbons from 25 to 39 carbons. These are composed of saturated n-alkanes (3.67%±1.39; mean ± SD, N=46) and corresponding alkenes (1.90%±0.72), large quantities of monomethyl-alkanes (29.70%±4.73), dimethyl-alkanes (58.05% ± 4.58), and trimethyl-alkanes (6.37%±2.64) (Fig. S1 and Table S1). Twenty two peaks are present in more than 1%, the two major peaks are a mixture of methyl-C31 (peak n° 30: 9+11+13+15Me-C31; 11.41%± 3.62) and a mixture of dimethyl-C31 (peak n° 32: 9,11+ 9,13+9,15DiMe-C31; 20.83%±3.77). The total hydrocarbon quantity is estimated at 521±396 ng/head + thorax + legs (N=21).

Discriminant analysis indicates good discrimination among the samples. Among the six colonies, four are well discriminated (T6, T7, S3 and S2, with all P<0.004, *Post-hoc* test F). Colonies M (Morillon) and T5 (Tours 5), however, are not differentiated (P=0.35) (Fig. 1). In the same locality (three colonies from Tours and two colonies from Pau), colonies are clearly differentiated. The Squared Mahalanobis Distances (SMD) are different between the groups (Kruskal–Wallis H(2, N=174)=85.5, P<0.01). The intracolony variation (among individuals) is small (19.89±2.79, mean ± SD, N=35). In contrast, intercolonial SMD between neighboring colonies in the same site is high (1917.14± 939.53, N=34; P<0.001 compared to intracolonial variation). This distance is not higher when we consider two colonies from different locations (for example Tours and Pau): 1666.42±1061.21, N=105 (P=0.46 NS compared to intercolonial variation in the same habitat).

These results indicate that in *L. niger*, there is a colonial chemical identity with colonies that inhabit the same habitat, being well differentiated in distances of a few meters. Additionally, the geographical variation is weak for this species since the SMD distance between the three sites is of the same order of magnitude as those found in the same habitat (one colony from the Alps has the same profile as one from Tours).

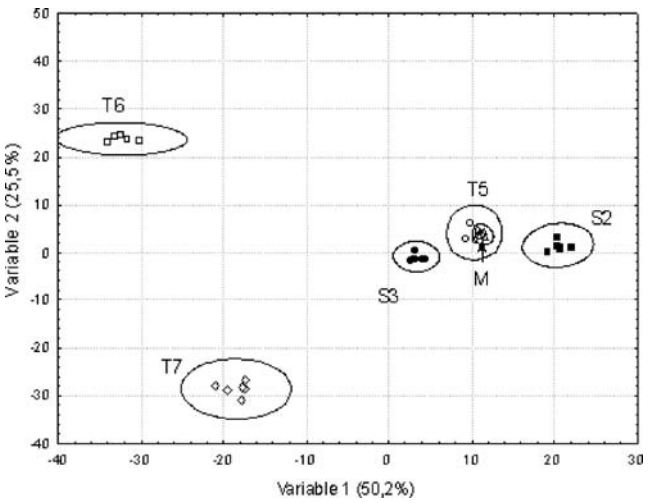

Fig. 1 Discriminant analysis of *Lasius niger* cuticular hydrocarbons. T = Tours (Azay sur Cher, colonies T5, T6, and T7); S = Sauvagnon near Pau (colonies S2 and S3); M = Morillon (Alps). Lambda Wilk< 0.001, F (120, 34)=21.68, P<0.001. *Ellipses* are 95% confidence intervals

Hydrocarbons on the Legs Legs contained the same hydrocarbons as the body cuticle (Table S1): all peaks were present and no new peak appeared. The hydrocarbon quantities were, however, much smaller on the legs (16.4 ng±10.8/worker, N=17, i.e., 3.15% of the thorax plus head cuticle content and less than 3 ng per each tibia + tarsus).

A discriminant analysis of hydrocarbons present on bodies or legs performed on the three colonies confirmed the high segregation among colonies seen in Fig. 1. It also shows that legs bear the colony profile (all P<0.001, F *post-hoc* test; see Fig. S2). By making a new analysis and using as discriminant variables the body part (head + thorax or legs) and the colony, we found that all groups are separated (all P<0.001, F *post-hoc* test) (Fig. 2). A main separation appears on the first axis (76.5% of the variance) among the three colonies. The discrimination is significant but less pronounced between the body cuticles and the legs within the same colony (12.9% of the variance). It indicates that the leg's cuticular profile is slightly different from the body one. It is characterized by an increase of the relative amount of n-alkanes (3.67%±1.39 for cuticle vs. 13.34± 6.69 for legs; H (1, n=63)=34.81, P<0.001), trimethyl-alkanes (6.37%±2.64 vs. 12.74±4.76; H=25.17, P<0.001) and alkenes (1.90%±0.72 vs. 5.73±5.10, H=4.37, P= 0.04). This increase is not due to mono-methyl-alkanes (29.70%±4.73 vs. 29.78±4.65; H=0.54, P=0.82) but to a decrease of dimethyl-alkanes (58.05%±4.58 vs. 38.41± 7.99; h=33.72, P<0.001) (see Table S1). There are no differences between the lengths of hydrocarbon chains: all n-alkanes from C25 to C31 increased and most dimethyl-alkanes decreased.

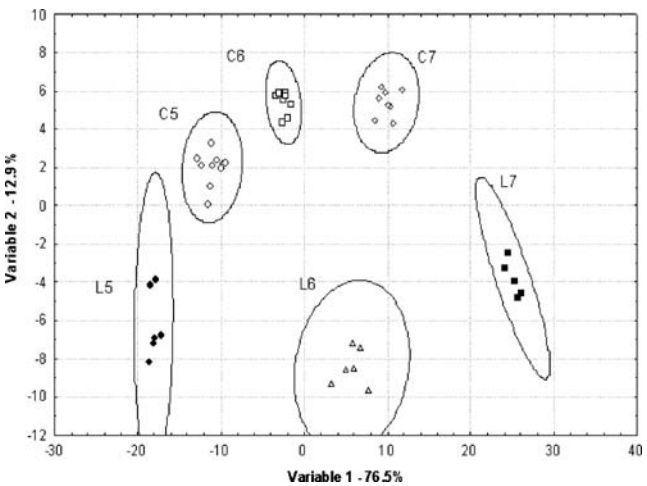

Fig. 2 Discriminant analysis of the hydrocarbons extracted from body cuticle (C) and legs (L) of colonies 5, 6, and 7. Lambda Wilk<0.001, F (130,64)=10.097, P<0.001. *Ellipses* are 95% confidence intervals

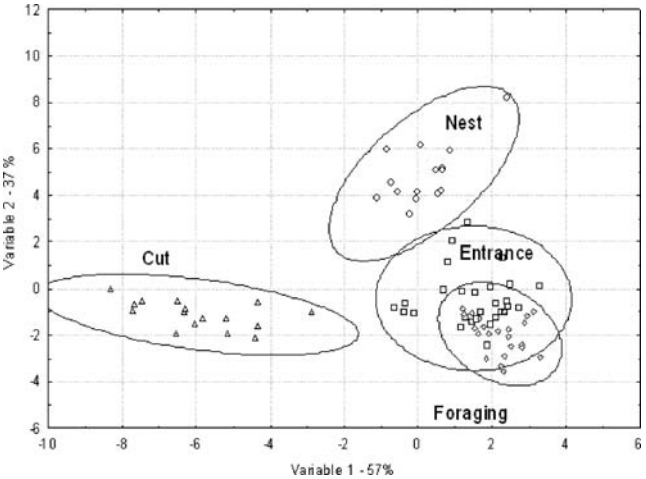

Fig. 3 Discriminant analysis of hydrocarbons obtained by SPME from cuticle (*Cut*), inner walls of the nest (*Nest*), entrance of the nest (*Entrance*) and foraging arena (*Foraging*), independently of the colonies which are not separated. Lambda Wilk 0.008, F (87, 150)= 7.450, P<0.001. *Ellipses* are 95% confidence interval

Hydrocarbons Obtained by SPME SPME and washing of the cuticle gave the same profiles, and the proportions of compounds are similar [Nei index of similarity between the two profiles = 0.96, i.e., comparable to intracolonial variation, see for example (Nowbahari et al. 1990; Lenoir et al. 2001a)]. This means that SPME and washing data can be compared directly.

In a first analysis, we compared the SPME chemical profiles of thorax cuticle, inner walls of the nest, nest entrance area and foraging arena independent of the colony (Fig. 3). The first axis separates the thorax cuticle from the deposited substances, indicating a clear distinction between them. The second axis separates the nest from the entrance and the arena. All groups are statistically different, but 8.5% of the values are not well classified in the foraging and entrance areas with Mahalanobis distances between them being much smaller (8.38 vs. all other distances >33). This indicates a clear separation between the cuticle and the substrate markings. Additionally, the marks left on the inner walls are different from the entrance and the foraging areas, the two latter being not very different. Globally, there is a gradient from the nest to the outside: the relative quantities of n-alkanes increase (from 6.58% to 29.36%), due mainly to a decrease in dimethyl-alkanes and alkenes. The proportions of methyl-alkanes and trimethyl-alkanes do not change (Fig. 4).

The amounts of hydrocarbons retrieved during 5 min of SPME rubbing are variable, but always higher when extracted from the nest walls than from the entrance, or foraging areas: 71.0 ng±80.07, N=15 for the nest, 15.56 ng ±21.45, N=28 for the entrance and 17.12 ng±14.98, N=23 for the foraging area (U Mann–Whitney N/E: P=0.005; N/ F: P=0.02 and E/F: P=0.28). These values are only

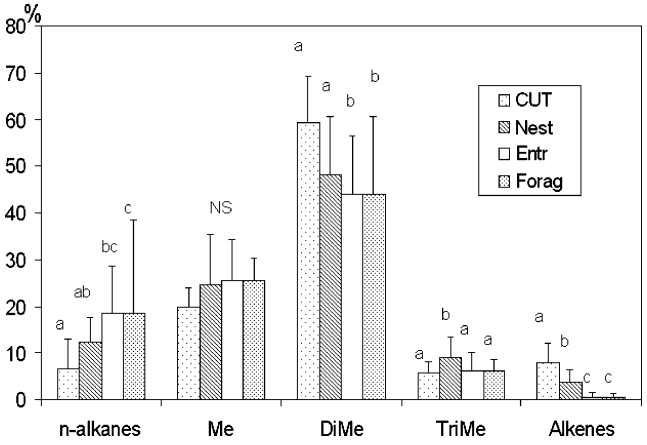

Fig. 4 Relative quantities of hydrocarbon classes present on the thorax cuticle or deposited at different locations (mean ± SD). Different letters indicate significant differences (Kruskal–Wallis test). Me = monomethyl-alkanes, DiMe = dimethyl-alkanes, TriMe = trimethyl-alkanes

comparative, and indicate that the hydrocarbons are more concentrated on the nest walls.

In a second analysis, we performed a discriminant analysis on all the SPME data for the deposited marks: inside-nest walls, entrance, and foraging areas (Fig. 5). The first axis (46.1%) showed discrimination between marking of the nest walls and those laid over areas outside the nest. The distances for inside nest marks were significant between N5/N6 (P=0.004) and N5/N7 (P=0.002) but not between N6 and N7 (P=0.30). This suggests that inside the nest, discrimination is not absolute, and errors are likely to occur. The situation also is complex concerning markings of the nest entrance and foraging arena. Colony 7 is well differentiated from colonies 5 and 6, but there is poor discrimination between its nest entrance and its foraging area (E7 / F7, P=0.04). Colonies 5 and 6 are not at all discriminated (all P>0.05, with a maximum for E6 / F6, P=0.85).

In a third step, considering that methyl branched hydrocarbons could be more important in nestmate recognition [see (Dani et al. 2001) for wasps, reviews by (Hefetz 2007; d'Ettorre and Lenoir 2009), and recent data on some species of *Formica* (Martin et al. 2008a)], we performed a discriminant analysis that used only mono-, di- and trimethyl-branched hydrocarbons. It does not change the results for nest marking: the two colonies 5 and 6 are not discriminated showing a low degree of differentiation for the inside nest marking (data not shown). By contrast, as regards entrance and foraging marks (Fig. 6), a good discrimination appears among the three colonies (only the distance in foraging arenas between colony 5 and 7 is at the significance limit with P=0.05). Nevertheless, the marks do not discriminate the nest entrance from the foraging arena of the same colony. It indicates that outside the nest, considering only the methyl-branched alkanes, the marks are colony-specific but the nest entrance and the foraging arena are not well differentiated under our experimental conditions.

Discussion

Cuticular Profile of Lasius Niger The hydrocarbon profile of *L. niger* workers is composed of a set of linear alkanes and alkenes, and many mono-, di-, and trimethyl-alkanes. The most important peaks are mixtures of monomethyl- and dimethyl-alkanes. Little is known about *L. niger* hydro-

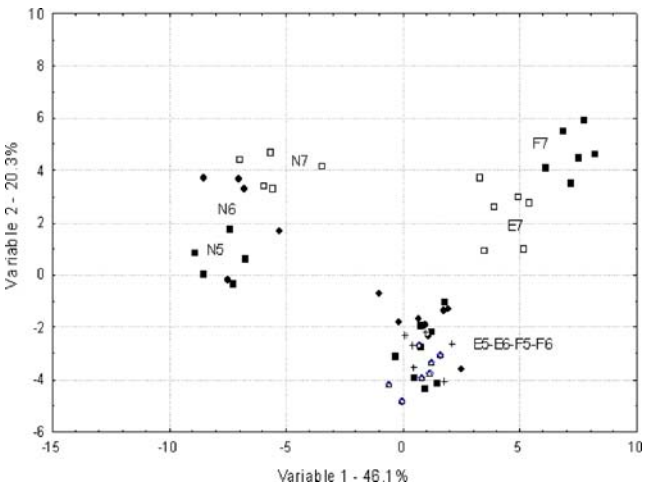

Fig. 5 Discriminant analysis of hydrocarbons obtained by SPME from inner walls of the nest (N), the entrance (E) and foraging arena (F) of colonies 5, 6, and 7. Lambda Wilk<0.001, F (240, 163)=2.92, P<0.001

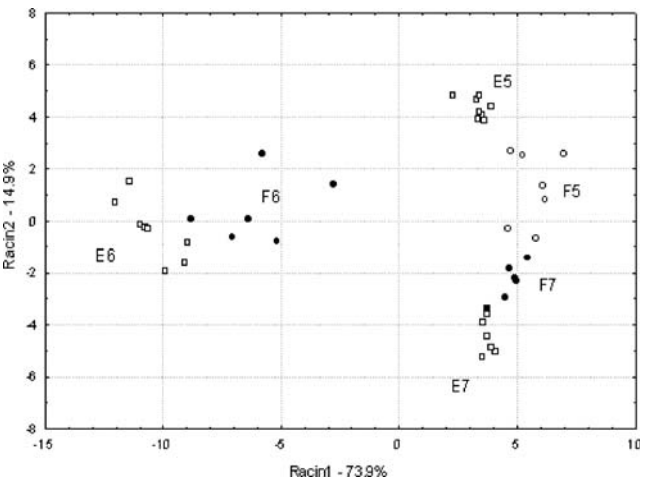

Fig. 6 Discriminant analysis of branched hydrocarbons obtained by SPME from the nest entrance (E) and foraging arena (F) of colonies T5, T6 and T7. Lambda Wilk<0.001, F (115, 73)=2.63, P<0.001. Distances not significantly different (NS): E6/F6 P=0.20; E5/F5 P=0.050; E7/F7 P=0.22 and F7/F5 P=0.23

carbons. Akino and Yamaoka described hydrocarbons of *L. niger* from Japan, which are completely different from European ones, but this species is now considered as a different twin species named *Lasius japonicus* (Akino and Yamaoka 2005). *L. niger* cuticular profiles appear to be stable in various areas in France, and also in Germany (Dinter et al. 2002), Belgium (A.L. unpublished) and Denmark (Dreier and D'Ettorre 2009). It also is the case for the invasive ant *Lasius neglectus*, which keeps the same profile in different locations (Ugelvig et al. 2008). There is no rule concerning the geographical variation of cuticular hydrocarbons in ants. Some species like *Cataglyphis cursor, C. iberica, Camponotus cruentatus*, or *Tetramorium* spp are highly variable (Nowbahari et al. 1990; Dahbi et al. 1996; Steiner et al. 2002; Boulay et al. 2007), while others like *Formica* do not change (Martin et al. 2008b).

Contrasting with the low geographical variation of chemical profiles, *L. niger* shows a strong local colony discrimination, as predicted for a monogynous and a little polyandric species [one to four copulations, see (Van der Have et al. 1988; Boomsma and Van der Have 1998; Aron et al. 2009)]. This seems to be general in monogynous species with independent founding like *Camponotus cruentatus* (Boulay et al. 2007).

The hydrocarbon quantity accounts for 0.1% of the head plus thorax mass, as is usual for ants (Lahav et al. 1998). The legs bear very small quantities of hydrocarbons that are colony specific but that have a slightly different profile from the body with an increase of linear alkanes, and tri - methyl-alkanes and alkenes in smaller proportions . Bagnères and Morgan (1991) also observed an increase in pentacosane (C25) on legs of *Myrmica rubra* queens.

Where do the leg hydrocarbons come from? Among the 20 glands described in ant legs, none seems to be involved in hydrocarbon production (Billen 2008), contrary to what was suggested by (Yamaoka and Akino 1994). Hence, hydrocarbons on the ant legs probably originate from self-grooming, but it is not clear how the difference in the profile can exist.

Are the Nest Walls Marked with Colony Odor? Nests or resting sites of many arthropods are marked and recognized by the owners. Several studies have confirmed such chemically-based nest recognition for solitary living arthropods such as tarantula spiders (Dor et al. 2008) or solitary bees (Guedot et al. 2006), for gregarious insects such as cockroaches (Ame et al. 2004) or triatomines (Lorenzo Figueiras and Lazzari 1998), and for social insects such as bumblebees (Saleh et al. 2007), honeybees (Butler et al. 1969) or ants (e.g., Depickère et al. 2004). In ants, volatile chemicals participate in nest recognition, for example in *Camponotus fellah* or *Pogonomyrmex badius* (see d'Ettorre and Lenoir 2009). Our results show for the first time that the inner walls inside the ant nest are marked with hydrocarbons comparable to those produced by the workers. This explains why many myrmecophiles obtain the colony odor by actively rubbing walls inside the nest (see reviews by Lenoir et al. 2001b; Akino 2008). Tricosane in particular is transmitted to myrmecophiles (Witte et al. 2008) agreeing with our results that show a high amount of linear alkanes inside the nest. Hydrocarbons found on the nest walls probably come from passive contacts with *L. niger* ant bodies. They also may be in the feces (Soroker and Hefetz 2000). Indeed, in the harvester ant *Messor capitatus*, the anal fluids deposited in the nest vicinity contain colony-specific cues that the ants use to recognize their nests from foraging areas (Grasso et al. 2005). We also established that the inside-nest odor is not completely colony-specific; for example, two colonies collected only a few meters apart had non discriminated odors.

The fact that ants have a colony specific cuticular odor and loose partially this specificity on the inside walls could be explained by the passive accumulation of compounds on the nest walls without permanent refreshing of the odor. Additionally, it has been observed that inside the nest, aliens generally are not rejected (Hölldobler and Wilson 1990). We thus hypothesize that the absence of alien rejection may be due not only to a higher threshold of discrimination by inner workers (Hölldobler and Wilson 1990) but also to an inside-nest colonial odor that is largely overlapping between colonies. We suggest that inside the nest, any social parasite will be considered as a fellow nestmate provided it has succeeded in "breaking the fortress" of the nest entrance, as stated by (D'Ettorre and Heinze 2001). This may explain why for instance in *Cardiocondyla elegans*, alate females are transported into alien nests by some workers, and are tolerated as soon as they have passed the nest entrance (Lenoir et al. 2006). Likewise, social parasites have a greater chance of being accepted once they succeed in entering the host nest. Such absence of alien rejection could be due to a saturation of the ant antennae receptors as hypothesized by (Ozaki et al. 2005). Our results show that the concentration of hydrocarbons actually is more important inside the nest than in the colony home-range, probably due to the high frequency of ant body contacts with the nest walls.

Are Nest Entrance and Home-Range Markings Colony Specific? Colony area marking is a widespread phenomenon in ants (see Hölldobler and Wilson 1990) and shows a diversity of glandular origin: postpharyngeal, metapleural, Dufour, cloacal glands, and also feces (Mayade et al. 1993; Cammaerts and Cammaerts 1998, 1999; Wenseleers et al. 2002; Grasso et al. 2005). In all cases, except two *Tetramorium* species (Cammaerts and Cammaerts 2000), area marking is colony-specific.

Our results on *L. niger* confirm previous behavioral results that show that the foraging area is chemically marked (Devigne and Detrain 2002, 2006; Depickère et al. 2004). It also confirms that marks consist of hydrocarbons identical to cuticular ones, as observed by (Yamaoka and Akino 1994). Beside ants, hydrocarbons left on the substrate are perceived by *L. niger* tended aphids and influence their dispersal (Oliver et al. 2007). In our experiments, the absence of active trail-laying behavior by *L. niger* indicates that marks are laid passively by walking ants, thus confirming previous observations (Depickère et al. 2004; Devigne and Detrain 2006). Footprint marks are colony-specific only when we consider the branched hydrocarbons in discriminant analyses. These footprints may act in conjunction with the trail pheromone as it was shown in the Asian species *L. japonicus* (Akino and Yamaoka 2005).

Even though the HC quantities on legs are small (less than 3 ng), the frequency of ants walking over an area may lead to a local density of marks high enough to be perceived by ants. It is well-known that social insects are highly sensitive to extremely low concentrations, for example, *Bombus* foragers rejecting flowers over which HCs doses of 10^{-12} ng/flower were deposited (Goulson et al. 2000). In *L. niger*, the perception of area marking promotes trail recruitment and food exploitation over familiar areas as compared to unexplored ones. The intensity of area marking is relevant for scouts to assess indirectly the colony occupancy at a location as well as the distance from the nest (Devigne and Detrain 2006). It is interesting to note that marks laid over the substrate have more alkanes than the cuticle, an increase in alkanes being also found on legs, which are in contact with the substrate. These higher concentrations of n-alkanes on the substrates may be due partly to differential melting points with branched hydrocarbons evaporating less rapidly than branched ones (Gibbs 1998; Hefetz 2007), and also to the fact that foragers have a larger proportion of straight-chain alkanes as compared to in-nest workers (Bonavita-Cougourdan et al. 1993; Greene and Gordon 2003). In *Formica exsecta* and *Pogonomyrmex barbatus*, this is due to exposure to high temperatures, UV, and low humidity (Wagner et al. 2001; Martin and Drijfhout 2009).

As regards the colony-specificity of area marking, similar chemical profiles are found at the nest entrance and in the foraging arena. This suggests that ants perceive the vicinity of their nest through an increased level of home-range marking rather than through qualitative changes in chemical marks. Volatile compounds also may be used by foragers to locate their nest entrance as has been shown recently on the desert ant *Cataglyphis fortis* (Steck et al. 2009).

Our main conclusion is that ants are faced with various blends of colony odors depending on their location. First, their own cuticular chemical profile varies from the head to the legs. Second, the odors of nestmates vary according to their caste (queen, workers, larvae, and males), their age, or their task performance. This indicates that, during ants' encounters, chemical cues used for nestmate discrimination are more complicated than a single bar-code. Finally, our chemical data confirm previous results that indicate that ants can perceive odors left by nestmates over substrates in their resting and foraging places (Devigne and Detrain 2006). Inside-nest odors are not colony-specific whereas area markings outside the nest are colony-specific, but at a low level. Even though discrimination may occur with branched alkanes, marks left at the nest entrance or on foraged areas are rich in linear alkanes that are considered to be poorly colony-specific.

Moreover, discrimination between colony home-range markings may be difficult to achieve due to the tiny amounts of footprint marks left over the substrate. As a consequence, in *L. niger*, defensive responses occur without a strict territorial marking but rather the ants rely on physical encounters to assess the relative force of opponent neighbors (Czechowski 1984). Area marking being poorly colony specific, rather acts as an indicator of the quality of a location. Conspecific cueing through area marking may influence the choice of a foraging space or of a nest site and thereby may promote a "shared information" strategy in *Lasius niger*. Based on the present work, one hopes that future studies will pay more attention to intracolonial sources of variability in odors, to the environmental influence on odors' colonial specificity, and to the sharing of conspecific chemical cues in insect societies.

Acknowledgments We thank Guy Bourdais for help in ant rearing, Xavier Espadaler and Bernard Seifert for verification of the ant species determination, and two anonymous reviewers for helpful comments. C. Detrain is senior research associate from the Belgian National Fund for Scientific Research. This work was partially supported by a grant from the FRFC (N° 2.4600.09).

colony odor, and these compounds can be homogenized through all members of the colony during trophallaxis and allogrooming. In some ant species, individual ants admix their own CHC with those of nestmates in the postpharyngeal gland (Soroker et al. 1998). Polygynous ant species are expected to bear a gestalt label unique for each colony in a population, although extreme polygyny may limit the creation of unique labels and thereby reduce intercolony variation. The broad range of intracolony odors and lack of a distinct intrinsic colony odor may facilitate formation of unicolonial populations in which colony boundaries are weak or absent, although some odor differences arising from extrinsic factors may still exist (Hölldobler and Wilson 1990).

In the unicolonial, polygynous, and widespread invasive Argentine ant, *Linepithema humile*, CHC play a central role in nestmate recognition (Liang and Silverman 2000; Greene and Gordon 2007; Torres et al. 2007). An inverse relationship between intraspecific aggression and genetic similarity between nests in both native and introduced populations suggests that recognition cues are heritable (Tsutsui et al. 2000). Because prey-derived CHC can radically affect nestmate recognition and worker-worker aggression, it is clear that exogenous, environmentally-derived hydrocarbons also significantly influence the *L. humile* recognition system (Liang et al. 2001; Liang and Silverman 2000). Interestingly, the contribution of environmentally-derived cues to nestmate recognition varies among introduced populations, suggesting that genotypic diversity can affect the expression and perception of components of the *L. humile* recognition system (Buczkowski and Silverman 2006). In addition, *L. humile* colonies from the southeastern U.S. display varying levels of intraspecific aggression and greater genetic diversity than other introduced populations (Buczkowski et al. 2004). They also exhibit a greater range of interactions, varying from highly aggressive and lethal outcomes to colony fusion (Vásquez and Silverman 2008). Colony fusion is expected to affect nestmate discrimination by changing the genetic and phenotypic composition of the fused *L. humile* colony, and thereby offers a possible mechanism for the formation of large networks of interconnected, non-aggressive, multiple-queen nests, a social organization called "supercoloniality".

Supercolony formation in introduced *L. humile* populations may result not only from lower diversity of recognition cues, due to a loss of genetic diversity (Tsutsui et al. 2000), but also from selective mixing of non-nestmates that share higher levels of phenotypic similarity (Giraud et al. 2002). It has been shown that *L. humile* colonies in southeastern U.S. differ in ratios of worker CHC, and that colony fusion at 24 h correlates with similarities of worker CHC profiles (Vásquez and Silverman 2008). Because *L. humile* colonies are extremely polygynous, often containing thousands of queens, and the CHC profile of queens is qualitatively different from that of workers (Liang et al. 2001; de Biseau et al. 2004), we hypothesize that CHC similarity of queens is relevant to colony fusion. Consequently, we would expect a higher frequency of fusion between colony pairs that share greater similarity of their respective queen CHC. The disparate colony odors of workers and queens might together, or independently, guide the outcomes of behavioral interactions between colony pairs, leading to high levels of aggression if the CHC are relatively dissimilar, or to colony fusion if the CHC are relatively more similar. Moreover, fusion of colonies could promote exchanges of CHC within the worker and queen castes, resulting in changes in their respective CHC profiles. Such an exchange could result in blending of colony recognition cues, or the predominance of the chemical profile of one of the colonies. In either case, we suggest that changes in the CHC profile will facilitate colony integration. Therefore, we hypothesize that the chemical similarities of both worker and queen CHC profiles of aggressive *L. humile* colonies determine the probability of colony fusion; as colonies fuse, ants change their CHC profiles to a homogeneous chemical recognition odor. Moreover, behavioral interactions in *L. humile* vary according to the level of CHC similarity among workers (Suarez et al. 2002; Vásquez and Silverman 2008), and also to the degree of worker genetic similarity (Tsutsui et al. 2000; Vásquez and Silverman 2008). Thus, we further hypothesize that the level of genetic similarity between colony pairs also modulates colony fusion; we expect to find a relationship between overall genetic similarity and queen and worker CHC profile similarity between colonies.

To test these hypotheses, we conducted laboratory assays in which we paired experimental *L. humile* colonies, for which we had determined levels of overall genetic similarity and worker and queen CHC profile similarity. We also investigated whether between-colony similarity of the CHC profiles of queens and workers was associated with the frequency of colony fusion at 6 months, and with genetic similarity between colonies. We further compared the CHC profiles of queens and workers from colonies that fused or did not fuse after 6 months, to the profiles of the respective unpaired control colonies (i.e., no intercolony interactions) to determine if changes in worker and queen CHC profiles occurred as a result of fusion.

Methods and Materials

Experimental Colonies and Colony Fusion Assay Argentine ants were collected from five sites in the southeastern USA: Cary (CAR), Chapel Hill (CHH), Research Triangle Park (RTP), and Winston-Salem (FOR) in North Carolina; and

Greenville (COC) in South Carolina. Experimental colonies were established and maintained as previously described (Vásquez and Silverman 2008). Briefly, experimental colonies (5 queens, ca. 100 pieces of brood, 500 workers) were established 1–2 mo after collection in individual Fluon-coated trays (17×25×11 cm), and provided an artificial nest, 25% sucrose solution, artificial diet, and a water source. All queens and 50 workers from each colony were marked with water-based paint (colony 1 = pink; colony 2 = yellow) to observe mixing of individuals and fusion events. Trays were connected through a vinyl tube (12 cm long) that was unblocked after a 24 h acclimation period. Controls consisted of experimental colonies that were not paired to any foreign colony. We recorded total number of workers fighting, and total number of dead workers in each tray for all ten pairwise colony combinations each hour for 6 h, and 24 h after colonies were allowed to interact. Colony pairs were inspected for fusion daily, from day 2 to day 30, and monthly from month 2 to month 6. Fusion was defined as the presence of queens from both colonies and all brood in the same nest (Vásquez and Silverman 2008).

Extraction, Isolation, and Chemical Analysis of Cuticular Hydrocarbons Six months after the colony fusion assay started, we collected queens (4–11) and workers (80–100) from the following colony pairs: CAR-CHH, CAR-COC, CAR-RTP, CHH-FOR, CHH-RTP. Ants were placed individually (queens) or in groups of ten (workers) in glass vials and stored at −20°C for subsequent CHC analysis. Queens were matched to their colony of origin based on the water-based paint mark. We also collected and stored queens (6–10) and workers (60) from each of the five unpaired control colonies. The CHC profiles of queens and workers from unpaired control colonies were analyzed to determine if colonies could be distinguished based on CHC, and to establish any relationship between CHC similarities between colonies and colony fusion at 6 months. We also compared queen and worker CHC profiles from colony pairs with those of their respective unpaired control colonies to determine if changes in CHC occurred after colony fusion. Cuticular lipids of thawed queens and workers were extracted, and CHC purified on silica gel as previously described (Vásquez and Silverman 2008). Capillary gas chromatography (GC) was carried out using an HP5890 gas chromatograph equipped with a DB-5 column (30 m×0.25 mm×0.5 µm film thickness). Extracts were introduced into a split-splitless inlet operated at 300°C in splitless mode (2 min purge) with helium as carrier gas at a linear velocity of 30 cm sec^{-1}. Oven temperature was held at 80°C for 2 min, increased to 270°C at 20°C min^{-1}, then to 310°C at 3°C min^{-1}, and held for 20 min. Individual queen extracts were resuspended in 20 µl hexane and 0.5 µl (0.025 queen equivalents) analyzed; extracts of ten workers were resuspended in 10 µl hexane, and 2 µl (2 worker equivalents) were injected. Peaks were integrated, and their individual percentages of the total CHC peak area calculated; only peaks with a mean percent area across all colonies of ≥1% were used in data analysis. The identity of discriminating peaks was determined by gas chromatography-mass spectrometry (GC-MS) and by comparing their retention times with those of alkane standards (*n*-C23–*n*-C38) (Liang et al. 2001; de Biseau et al. 2004). GC-MS analyses of CHC were performed on an HP6890 GC, equipped with an HP-5MS column (30 m×0.25 mm×0.25 µm film thickness), connected to an HP5973A mass selective detector. The inlet was operated at 300°C in splitless mode with helium as carrier gas at a linear velocity of 45 cm sec^{-1} (2 min purge). Data were recorded in scan mode (25–550 *m/z)* using electron impact ionization.

Genetic Similarity Among Colonies Genetic similarity among colonies used in the fusion assay was assessed by using microsatellite markers. DNA was extracted from 15 workers from each of the experimental colonies (CAR, CHH, COC, FOR, and RTP), and 7–17 queens from CAR, CHH, and RTP, using the DNeasy Tissue Kit (Qiagen, Valencia, CA, USA) and analyzed at eight microsatellite loci: Lhum-11, Lhum-13, Lhum-19, Lhum-28, Lhum-35, Lhum-39 (Krieger and Keller 1999), Lihu-M1 and Lihu-T1 (Tsutsui et al. 2000). PCR reactions were performed as previously described (Buczkowski et al. 2004). Products were separated on 6.5% KB^{Plus} polyacrylamide sequencing gels with a 4300 LI-COR DNA analyzer. Microsatellite alleles were scored using GeneImagIR software (Scanalytics Inc., Billerica, MA, USA). Levels of genetic similarity among colonies were estimated based on the percentage of alleles shared between groups (Tsutsui et al. 2000). Genetic differentiation (F_{ST}) among Argentine ants from different locations was estimated with the program FSTAT v.2.9.3.2 (Goudet 1995).

Statistical Analyses Data analyses were performed with SAS 9.1.3 statistical software (SAS 2004). We performed a stepwise discriminant analysis (stepwise DA) on the transformed quantitative CHC data of control colonies by using PROC STEPDISC to identify variables (GC peaks) that differed significantly between groups of queens or workers. Peak areas were transformed following Aitchison's formula: $Z_{ij}=\ln[Y_{ij}/g(Y_j)]$, where Z_{ij} is the standardized peak area *i* for individual *j*, Y_{ij} is the peak area *i* for individual *j*, and $g(Y_j)$ is the geometric mean of all peaks for individual *j* (Reyment 1989). Only transformed variables that met the assumption of homogeneity of variance (Brown and Forsythe's test) were used in stepwise DA. We then performed a canonical DA on the selected peaks using PROC DISCRIM. Pairwise generalized square distances between group means (cent-

roids) were used as an estimate of the degree of CHC profile differentiation between colonies. To determine changes in queen and worker CHC profiles, of fused and non-fused colonies vs. their respective controls, we first estimated the linear discriminant function coefficients only for unpaired control colonies by using PROC DISCRIM, and then computed the linear discriminant function for fused and non-fused colony pairs using these coefficients.

Spearman rank correlation coefficients were used to determine relationships among percentage of colonies fused at 6 months and genetic similarity vs. queen and worker CHC similarity. The significance of the correlation coefficient was tested by Mantel correlation test in GENEPOP using 10,000 permutations. All means reported are followed by standard errors (SEM).

Results

Colony Fusion Assay The percentage of colony fusion at 6 months varied across *L. humile* colony pairs; all CAR-RTP, CHH-RTP, and COC-FOR replicates fused, none of the CAR-COC, CHH-COC, CHH-FOR, and COC-RTP replicates fused, and 40% of the CAR-FOR and FOR-RTP replicates, and 20% of the CAR-CHH replicates, fused. All queens from one of the paired colonies in replicates that did not fuse were killed. Interestingly, in CHH-FOR, unlike for all other non-fused colony pairs, we observed workers from both colonies mixing in all replicates; all CHH queens were killed by FOR workers.

Chemical Analysis of Cuticular Hydrocarbons: Cuticular Hydrocarbon Patterns of L. humile Unpaired Control Colonies GC and GC-MS analyses of queen and worker CHC showed that chemical profiles differed quantitatively and qualitatively between the castes (Fig. 1). Thirty one CHC peaks for queens and 44 CHC peaks for workers were consistently found in each colony; 21 compounds were common to both castes (Fig. 1). The stepwise DA performed on 25 queen CHC peaks that met the assumption of homogeneity of variance selected nine peaks that distinguished queens from different colonies (*Wilks'* $\lambda<0.01$, $F=13.63$, $df=36, 125.4$, $P<0.001$) (Fig. 2a), and had generalized square distances between colony centroids (i.e., chemical distance) ranging from 7.5 (CAR-RTP) to 123.2 (CAR-COC). All queen peaks that differed among colonies included the same discriminating compounds previously identified in Argentine ant queen adoption assays (Vásquez et al. 2008) as well as nonacosene (xC29:1) and *n*-hentriacontane (*n*-C31). The stepwise DA performed on 34 worker CHC peaks selected 10 peaks that grouped all workers from control colonies according to their colony of

origin (*Wilks'* $\lambda<0.01$, $F=13.54$, $df=40, 62.5$, $P<0.001$) (Fig. 2b), with generalized square distances between colony centroids ranging from 24.8 (CAR-RTP) to 243.2 (CAR-COC). Five of the discriminating worker peaks were identified as 11- and 13-methylheptacosane (11- and 13-MeC27), 3-methylnonacosane (3-MeC29), 11- and 13- and 15-methylhentriacontane (11-, 13-, and 15-MeC31), 5,13,17- and 5,15,19-trimethylpentatriacontane (5,13,17- and 5,15,19-triMeC35), and 5,15- and 5,17-dimethylheptatriacontane (5,15- and 5,17-diMeC37).

Chemical Analysis of Cuticular Hydrocarbons: Cuticular Hydrocarbon Patterns of Fused and Non-fused L. humile Colonies To investigate the effects of colony fusion on queen CHC profiles, we computed discriminant functions for each colony pair by using discriminant function coefficients estimated from nine discriminating peaks derived from the control colonies. The CHC profiles of queens in colony pairs that fused (CAR-CHH, CAR-RTP, and CHH-RTP) occupied a much broader DA space and were spread across the two control groups (Fig. 3), indicating that queens in fused colonies formed a group with higher CHC variability that generally could not be distinguished unequivocally accord-

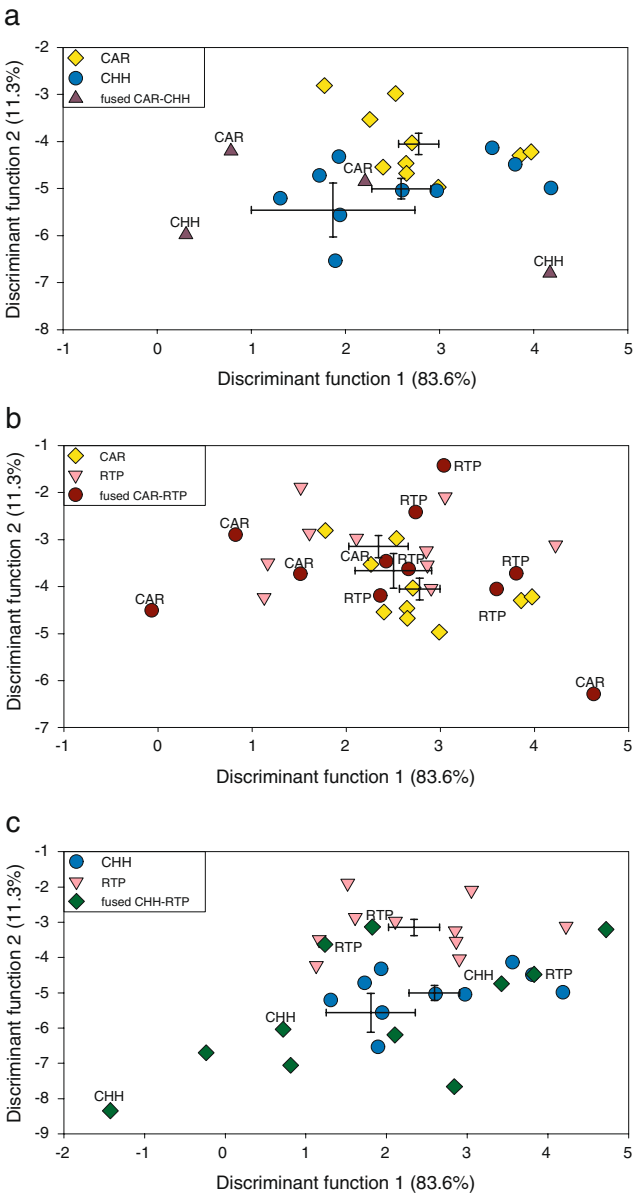

Fig. 3 Linear discriminant functions for cuticular hydrocarbons of *Linepithema humile* queens of fused colony pairs. **a** CAR-CHH (centroid: X=1.87±0.87, Y=−5.46±0.58) and unpaired controls CAR and CHH. **b** CAR-RTP (centroid: X=2.50±0.41, Y=−3.67±0.37) and unpaired controls CAR and RTP. **c** CHH-RTP (centroid: X=1.80±0.55, Y=−5.56±0.55) and unpaired controls CHH and RTP. Functions plotted based on nine variables. Bars represent standard errors for a colony mean (centroid). CAR centroid: X=2.78±0.21, Y=−4.05±0.23; CHH centroid: X=2.59±0.31, Y=−5.01±0.22; RTP centroid: X=2.34±0.32, Y=−3.15±0.24

ing to their colony of origin. This was especially apparent for the CHC profiles of five CAR queens and six RTP queens from CAR-RTP colonies that fused (Fig. 3b). The CHC profiles of two CAR and two CHH queens in fused CAR-CHH colonies made up a group with higher variability than their respective controls, but appeared more similar to CHH control queens (Fig. 3a), suggesting that CAR queens may have acquired CHH hydrocarbons. In the CHH-RTP pairings, six queens of known identity had similar CHC profiles to their controls, CHH and RTP, yet displayed higher CHC variability (Fig. 3c).

In colony pairs that did not fuse (CAR-COC and CHH-FOR), the CHC profiles of queens were more similar to the CHC profile of their respective unpaired control queens, with no overlap with the CHC of the other colony's queens (Fig. 4). In CAR-COC, the CHC profiles of the seven CAR queens and three COC queens examined were more similar to their respective unpaired controls than to those of queens of the other colony, and in CHH-FOR, the CHC profiles of ten queens known to be FOR were similar to those of the FOR control group (Fig. 4b).

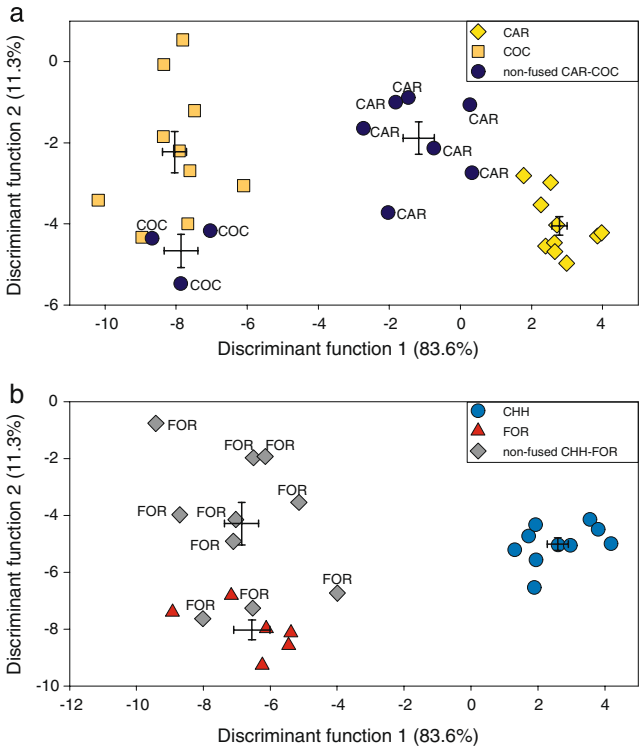

Fig. 4 Linear discriminant functions for cuticular hydrocarbons of *Linepithema humile* queens of non-fused colony pairs. **a** CAR-COC (CAR centroid: X=−1.18±0.44, Y=−1.89±0.40; COC centroid: X=−7.86±0.47, Y=−4.67±0.41) and unpaired controls CAR and COC. **b** CHH-FOR (FOR centroid: X=−6.86±0.51, Y=−4.28±0.75) and unpaired controls CHH and FOR. Functions plotted based on nine variables. *Bars* represent standard errors for a colony mean (centroid). CAR centroid: X=2.78±0.21, Y=−4.05±0.23; CHH centroid: X=2.59±0.31, Y=−5.01±0.22; COC centroid: X=−8.04±0.34, Y=−2.23±0.51; FOR centroid: X=−6.55±0.54, Y=−8.02±0.35

When we plotted worker CHC profiles of each colony pair with profiles of their respective unpaired controls, using ten discriminating peaks, we found that CHC profiles in colony pairs that fused (CAR-CHH, CAR-RTP, and CHH-RTP) occupied a much broader and relatively intermediate DA space between the unpaired control colonies, CAR, CHH, and RTP (Fig. 5). Unlike for the queens, the worker CHC profiles were not scattered throughout the control CHC profiles, probably because each sample consisted of ten randomly sampled workers of unknown colony affiliation. However, we presume that the average CHC profile of workers in fused colonies reflected a homogenized CHC composition of both colonies. In the non-fused CAR-COC pair, samples were taken from replicates that were either CAR or COC, based on colony queen identity, with CHC profiles of workers similar to CHC profiles of the workers of the respective controls (Fig. 6a). However, since CAR-COC workers were not marked, we could not rule out the possibility that these samples may have included workers from both colonies. Interestingly, in CHH-FOR pairings, all CHH queens were killed, but CHH and FOR workers apparently mixed. The CHH-FOR workers had a broad and largely distinctive CHC profile that, for some groups, was more similar to FOR workers than to CHH workers (Fig. 6b).

Genetic Similarity Among Colonies Genetic similarity among colonies (percent alleles shared) in the fusion assay varied across colony pairs, ranging from 35.3% (CHH-COC) to 74.3% (CAR-RTP) (Table 1). The overall genetic differentiation among colonies (F_{ST}) was, on average, 0.201±0.055 with pairings estimates (pairwise F_{ST}) ranging from 0.051±0.015 (CHH-RTP) to 0.431±0.090 (CHH-COC) (Table 1).

Correlations Among Cuticular Hydrocarbon Similarity, Genetic Similarity, and Colony Fusion We found a significant relationship between CHC similarities (i.e., low CHC distance) of queens from control colonies (Table 1) and the frequency of colony fusion at 6 months (*Mantel test* P=0.032) (Fig. 7). A similar relationship was evident between control worker CHC similarities (Table 1) and colony fusion at 6 months (*Mantel test* P=0.050) (Fig. 7). We found a strong relationship between percent alleles shared and queen and worker CHC profile similarity between colonies (*Mantel tests* P=0.007, and P=0.009, respectively) (Fig. 8a). Similarly, we found a relationship between pairwise F_{ST} and queen and worker CHC profile similarity between colonies (*Mantel tests* P=0.023, and P=0.040, respectively) (Fig. 8b). Also, we found a relationship between colony fusion at 6 months and percent alleles shared (*Spearman's* r=0.666, *Mantel test* P=0.042) and pairwise F_{ST} (*Spearman's* r=−0.822, *Mantel test* P=0.009).

Discussion

We demonstrated, for both queens and workers of *L. humile*, that similarity of CHC profiles between unrelated colonies was positively associated with colony fusion, and that the CHC profiles of fused colonies tended to be composed of a blend of CHC from both colonies. Our findings indicate that merging of unrelated *L. humile* colonies can lead to changes in the composition of recognition cues among members of the fused colonies, and possibly to expansion of the recognition template. This likely explains our earlier observation that fused colony pairs directed less aggression toward both source colonies compared to colonies that did not fuse (Vásquez and Silverman 2008). Discrimination abilities are important in structuring *L. humile* societies (Tsutsui et al. 2000; Giraud et al. 2002), and our results suggest that colony fusion can lead to more open colonies that may accept certain non-nestmates, further supporting the idea that expansive colonies in the introduced range of *L. humile* result from mixing or fusion of unrelated colonies.

Linepithema humile workers and queens differ considerably in their CHC profiles; workers have substantial amounts of dimethyl- and trimethylalkanes (diMe- and triMeC33, -C35 and -C37), whereas queens lack (or have very low amounts of) these compounds, but have monomethylalkanes (5-MeC27 to 5-MeC34) and alkenes (C29:1, C31:1, C33:1) as major components (Liang et al. 2001; de

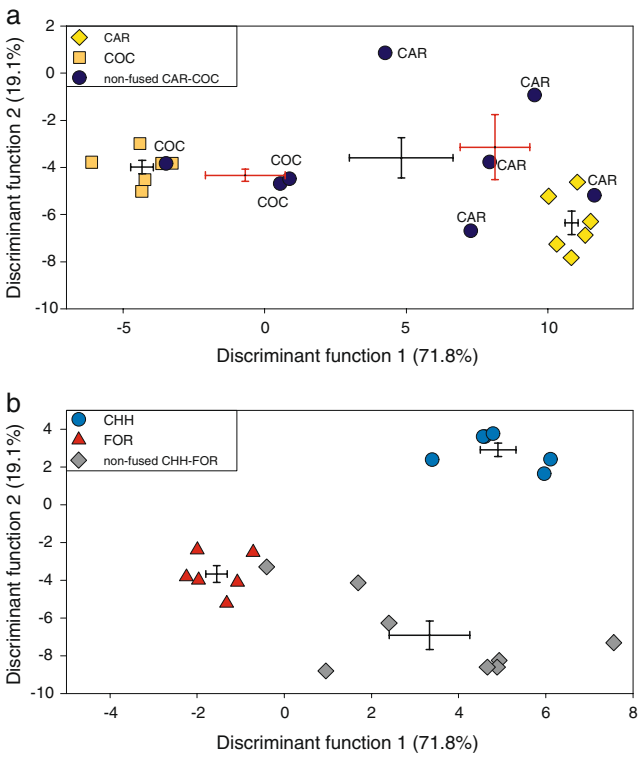

Fig. 6 Linear discriminant functions for cuticular hydrocarbons of *Linepithema humile* workers of non-fused colony pairs. **a** CAR-COC (CAR centroid: X=8.13±1.23, Y=−3.15±1.38; COC centroid: X=−0.69±1.40, Y=−4.33±0.26; or CAR-COC centroid: X=4.82±1.83, Y=−3.59±0.86) and unpaired controls CAR and COC. **b** CHH-FOR (centroid: X=3.34±0.92, Y=−6.90±0.76) and unpaired controls CHH and FOR. Biseau et al. 2004). In this study, we found that quantitative differences of worker and queen CHC profiles reflect colony identity, and that a statistically derived subset of compounds may mediate colony discrimination. Worker CHC supplementation studies (Greene and Gordon 2007; Torres et al. 2007) suggest that a mixture of CHC of different structural classes, with varying ratios across colonies rather than a few compounds from a single structural class, may be used as nestmate recognition cues in *L. humile*. Our findings support this view and, in addition, suggest that alkenes and monomethylalkanes may be important in queen discrimination, while dimethyl- and trimethylalkanes and other unidentified long-chain CHC may be important in worker recognition. Methyl-branched alkanes, *n*-alkanes, and an alkene/*n*-alkane mixture have been shown to be important colony recognition cues in wasps (Dani et al. 1996; Gamboa et al. 1996). In ants, methyl-branched CHC are more colony-specific than *n*-alkanes (Astruc et al. 2001), although

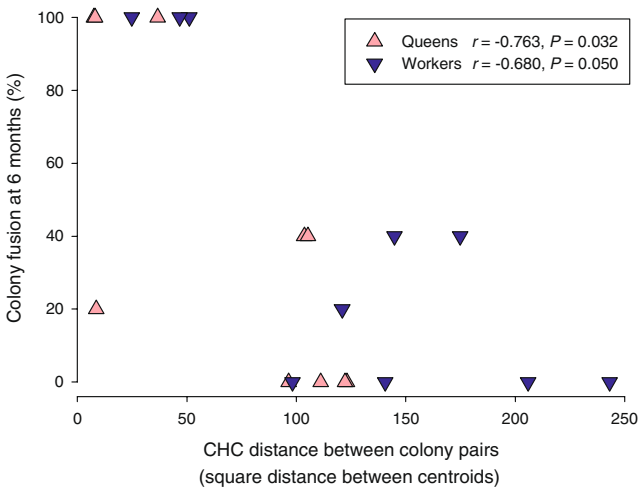

Fig. 7 Relationship (Spearman's *r*) between *Linepithema humile* colony fusion at 6 months and queen and worker cuticular hydrocarbon profile similarity based on nine and ten transformed variables, respectively

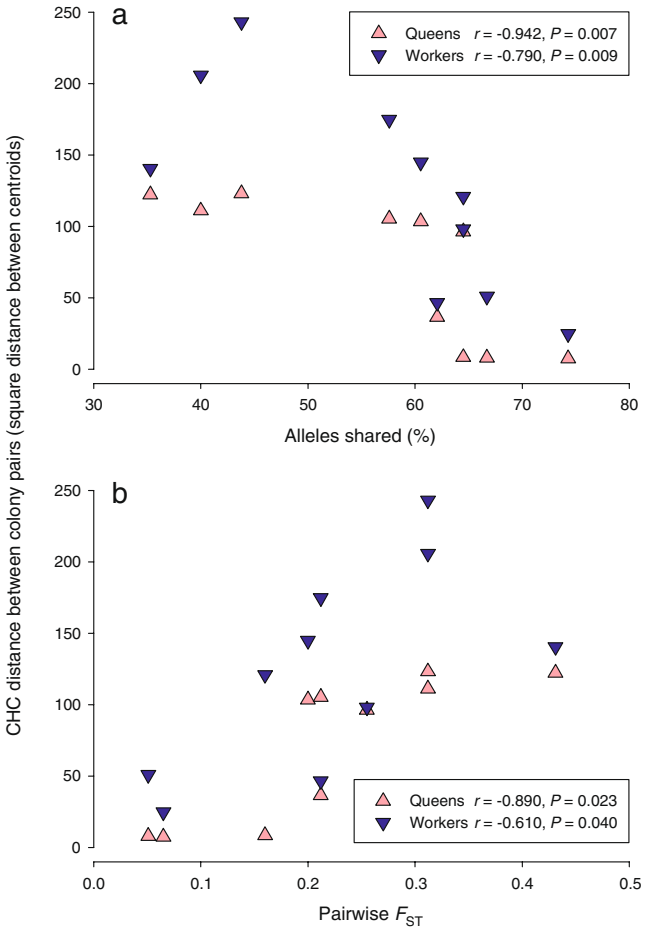

Fig. 8 Relationship (Spearman's *r*) between *Linepithema humile* cuticular hydrocarbon similarity and genetic similarity. **a** Genetic similarity (% alleles shared) between colonies versus queen and worker cuticular hydrocarbon similarity (generalized square distance between colony centroids). **b** Pairwise F_{ST} between colonies versus queen and worker cuticular hydrocarbon similarity (generalized square distance between colony centroids)

dimethylalkanes seem not to be important in nestmate recognition in *Cataglyphis* species (Dahbi et al. 1996). Chemical supplementation studies, testing the various alkanes and alkenes identified in our study, should be conducted to test the behavioral role of these compounds.

The distinct CHC profiles of queens and workers and our statistical identification of different CHC that distinguish queens and workers from different colonies suggest that *L. humile* does not form a unique colony odor distributed among all colony members (castes). Instead, individuals may have either a reproductive or sterile worker odor, that together constitutes a more complex colony template. A similar mechanism of template formation has been suggested for mixed-species groups in which individuals seem to learn and memorize allospecific cues early in adult life (Errard 1994). Two other possibilities are, that individuals bear their own endogenous cues and that these are matched with a learned Gestalt-type template, or that CHC, common to both queens and workers, are used as a single colony recognition template. In *Camponotus vagus*, dimethylalkanes are present across all castes, and are thought to be colony chemical cues, while *n*-alkanes and monomethylalkanes characterize larvae, workers, sexuals, and queens (Bonavita-Cougourdan et al. 1993), and may represent caste-specific cues.

In *L. humile*, genetically-based recognition cues appear to play a major role in nestmate discrimination among genetically diverse populations, whereas environmentally-derived CHC appear to be important in *L. humile* worker recognition in populations with reduced genetic variability (Buczkowski and Silverman 2006). In our study, CHC profiles of workers and queens are likely intrinsic because colonies were exposed to identical environmental conditions, and individuals were sampled 6 months after the start of the experiment. This explains the stronger association we found between worker CHC similarity and colony fusion at 6 months than the one found for colony fusion at 24 h (Vásquez and Silverman 2008). In the latter study, workers may have possessed both exogenous and endogenously-derived CHC. Temporal variation in worker CHC may also explain fusion events that occurred several weeks after interactions started, although factors (e.g., colony phenology, caste ratios, worker age) other than recognition cue phenotypic similarity could also govern the outcome of group interactions. In some colony pairs, CHC profiles between queens were more similar than those between workers, suggesting that workers may not be aggressive toward foreign queens but they may be aggressive toward workers from the foreign colony. Therefore, the outcome of group interactions may not exclusively reflect worker discrimination capability, or individual worker interests, but that of the whole group.

CHC profiles of queens changed after colony fusion, with the CHC profile of queens, as a group, in the fused colony not resembling the CHC profiles of either parent colony or indeed of a hybrid intermediate. Instead, profiles of queens varied across the range of profiles of both source colonies. This, together with the observation that queens could be assigned to their colony of origin based on their CHC profiles in non-fused colony pairs, suggests that by exchanging CHC, queens may match phenotypes in both colonies, thereby forming a broader queen recognition template. The collective worker CHC composition found in fused colony pairs suggests that mixing of worker CHC between colonies may have occurred. Transfer of CHC among individuals of the same colony, among mixed species, and in dulotic and inquiline species, has been well documented (Howard et al. 1980; Soroker et al. 1994). Cue exchange within castes could have occurred through direct body contact, grooming, and trophallaxis, in the same way that interactions with adult workers allow newly eclosed ant workers (callows) to acquire a colony's odor (Vander Meer and Morel 1998), or interactions with heterospecifics result in mixed hydrocarbon profiles in ants (Errard et al. 2006).

Colony fusion between aggressive *L. humile* colonies can also be predicted from the genetic similarity between colonies. This is in line with studies showing that aggression levels between colonies, or populations, of social insects are based on similarity of genetically-based CHC profiles (Dronnet et al. 2006). In *L. humile*, intraspecific aggression is based on levels of genetic similarity (Tsutsui et al. 2000), and is also guided by worker and queen hydrocarbons (Greene and Gordon 2007; Torres et al. 2007; Vásquez et al. 2008). However, the roles of chemical and genetic factors in regulating behavioral interactions among conspecifics have not been tested simultaneously. By combining behavioral, chemical, and genetic approaches, we demonstrated that both genetic and chemical factors play important roles in nestmate recognition and in shaping colony phenotypic composition, thereby offering a potential mechanism for changes in social structure in the introduced range.

While both queen and worker CHC similarity between colonies can guide fusion between genetically distinct *L. humile* colonies, changes in CHC patterns of colonies that had fused suggest homogenization of colony CHC between fused colony pairs, thus explaining reduced aggression toward unpaired control colonies (Vásquez and Silverman 2008) and fused colony cohesion. High aggression between non-fused colony pairs (winning colony) and their respective unpaired controls (defeated colony) after 6 months may be explained by maintenance of the colony chemical signatures. In line with previous studies that found an association between worker CHC similarity and intraspecific aggression in field and laboratory *L. humile* colonies (Liang and Silverman 2000; Suarez et al. 2002; Buczkowski and Silverman 2006), we found that worker and queen CHC

profile similarity is associated with fusion of unrelated colony pairs. Variation in colony genotypic composition, through mixed workers and queens, may lead to the formation of a new colony odor, implying that an updated recognition template must also be learned. It has been proposed that the greater the dissimilarity in CHC profiles between ant species that mix, the lower the aggression toward other ant species, due to a broader template (Errard et al. 2006). Similarly, increased phenotypic cue diversity in fused colonies should result in a much broader template. This may have implications at the population level, since changes in social structure may arise from changes in recognition cue diversity and/or template formation. Therefore, by increasing colony phenotypic diversity, fusion between unrelated colonies may be a proximate mechanism involved in the formation of expansive *L. humile* supercolonies in the introduced range.

et al. 2005). Carboxylic acids also play a crucial role in the behavior of *Ae. aegypti* (Bosch et al. 2000) together with ammonia and lactic acid (Geier et al. 1999). Humans have uniquely high levels of skin-borne lactic acid compared to other mammals and chickens. Therefore, lactic acid may play a critical role in the host-seeking behavior of anthropophilic mosquitoes, which seem to have adapted to utilize this human compound (Dekker et al. 2002). By contrast, ammonia is a typical animal excretory product found on the skin of all vertebrates. Skin bacteria convert human skin lipids into unusual long chain carboxylic acids, whereas long chain carboxylic acids can be converted into volatile carboxylic acids (C2–C14). In addition, short chain carboxylic acids (C2–C5) can be derived from glycerol, amino acids, and lactic acid (James et al. 2004).

Although aliphatic carboxylic acids are involved in the attraction of *An. gambiae s.s.* to humans, the role of the various acids remains elusive. Therefore, we aimed to examine the role of individual aliphatic carboxylic acids using synthetic blends. The carboxylic acids were tested individually (in combination with ammonia + lactic acid), and those that augmented the attractive effect were subsequently tested in combinations, using two different bioassay systems. Both optimization and subtraction experiments were performed in order to examine the contribution of individual carboxylic acids to a multi-component blend.

Methods and Materials

Mosquitoes The colony of *Anopheles gambiae sensu stricto* (hereafter *An. gambiae*) was maintained at Wageningen University, The Netherlands, and originally obtained from Suakoko, Liberia (courtesy Prof. M. Coluzzi, Rome, Italy). The mosquitoes have been cultured in the laboratory since 1988 with blood meals from a human arm twice a week. The mosquito colony was kept in a climate room at 27±1°C, 80±5% RH and a photo-scotophase of 12/12 hL/D. Adult mosquitoes were maintained in 30×30×30 cm gauze cages with access to a 6% glucose solution on filter paper. Larvae were reared on tap water in plastic trays and fed daily with Tetramin® baby fish food (Melle, Germany). Pupae were collected daily and placed into adult cages for emergence.

Olfactometer A dual-port olfactometer, consisting of a flight chamber (1.60 x 0.66×0.43 m) with glass walls and a Luxan top, was used to study the behavioral responses of female mosquitoes to different odor stimuli. Pressurized air was charcoal filtered, humidified, and led through two Perspex mosquito trapping devices connected to two ports (4 cm diam and 28 cm apart) in the flight chamber (flow rate of 20.6±1.4 cm/s). The light from one tungsten light bulb (75 Watt) was filtered and scattered through a screen of yellow cloth hanging ± 1 m above the flight chamber. This resulted in dim light of about 1 Lux in the olfactometer. The experimental room was maintained at 27±1°C and a relative humidity of 61±9% RH. The temperature inside the flight chamber was 27±2.5°C and 64±9% RH. The air flowing out of the ports was maintained above 80% RH and an air temperature of 27.4±1°C.

Odor Stimuli Tested In The Olfactometer To insure a continuous and constant odor concentration for each compound within the odor plumes from start until the end of each experiment, we used air sample bags for ammonia, glass bottles for L-(+)-lactic acid, and 15 aliphatic carboxylic acids (Geier et al. 1999; Bosch et al. 2000).

Ammonia was supplied in a similar way as described in Smallegange et al. (2005). One day before the experiments, 250 µl of a 2.5% aqueous ammonia solution (25% in water; analytical grade, Merck) were injected into an 80 l Teflon air sample bag (SKC Gulf Coast Inc., Houston, TX, USA). Subsequently, the bag was filled with 60 l of warm, humidified, and charcoal filtered pressurized air at least 17 h prior to experiments to allow evaporation of the solution. This procedure resulted in an ammonia concentration of 136 ppm in the bag (Smallegange et al. 2005). During experiments, air pumps (Model 224-PCXR4, SKC Gulf Coast Inc., Houston, TX, USA) were used to lead air from the sample bag, through Teflon tubes (7 mm in diam; Rubber B.V., Hilversum, The Netherlands), and into the trapping devices at a flow of 230 ml/min. The flow of air was regulated by mechanical flow meters (Sho-Rate model GT1355; Brooks Instruments, Veenendaal, The Netherlands), and was mixed with the main air stream at a flow rate of approximately 23.5 l/min.

L-(+)-lactic acid (90% aqueous solution, analytical grade, Purac Bioquimica or 88–92% aqueous solution, Riedel-de Haën) (henceforth termed lactic acid) was mixed with the main air stream by tapping lactic acid vapor (10 ml) from a 250 ml glass bottle (Fisher Scientific B.V., ‘s Hertogenbosch, The Netherlands) with Teflon tubing. The flow rate was regulated to 15 ml/min by flow meters (Gilmont, Fisher Scientific B.V., ‘s Hertogenbosch, The Netherlands), which caused a lactic acid release comparable to that from a human hand (Smith et al. 1970; Geier et al. 1999). Since we applied lactic acid in a different way compared to previous experiments (Smallegange et al. 2005), we verified that it had no additional effect on the response of mosquitoes when added to ammonia.

Fifteen saturated aliphatic carboxylic acids (C2–C16) of the highest purity grade available were used in the experiments: >99% acetic acid (Sigma), 99% propanoic acid

(Sigma), 99% 2-methylpropanoic acid (Sigma), ≥99% 3-methylbutanoic acid (Sigma), >99% butanoic acid (Aldrich), >99% pentanoic acid (Sigma), ≥99% hexanoic acid (Sigma), 98% heptanoic acid (Sigma), ≥ 99% octanoic acid (Sigma), ≥ 97% nonanoic acid (Sigma), >99% decanoic acid (Sigma), ≥99% dodecanoic acid (Sigma), ≥ 98% tridecanoic acid (Sigma), >99% tetradecanoic acid (Sigma), ≥99% hexadecanoic acid (Sigma). Single, pure compounds [10 ml of a liquid compound (C2–C9) or 1 g of a solid compound (C10–C16)] were added to a 250 ml glass bottle (Fisher Scientific B.V., 's Hertogenbosch, The Netherlands). A charcoal-filtered, warm, humidified air stream was passed through the bottle and carried the vaporized compound at the desired flow rate through Teflon tubing and into the main stream through one of the trapping devices. Flow rates were regulated by Gilmont flow meters (Fisher Scientific B.V., 's Hertogenbosch, The Netherlands) at 0.5, 5, 50, and 100 ml/min. The calculated concentrations of the compounds in the air stream of the olfactometer are listed in Table S1 in the online supplement.

When tripartite blends were tested, the three compounds were mixed just before entering the trapping device. When more than one aliphatic carboxylic acid was part of the blend, a Perspex ring with 10 holes was attached upstream of each trapping device to be able to release each odor into the main air stream individually (Fig. 1). Tripartite blends were tested against ammonia alone. During experiments with multi-component blends, the multi-component odor blends were tested against the ammonia + lactic acid blend. Initially, we wanted to examine whether we could increase the attractiveness of ammonia—our best kairomone at that time. For this reason, we used ammonia alone as a control. In addition, we had observed that ammonia + lactic acid + a mixture of 12 carboxylic acids did not attract more mosquitoes than ammonia + lactic acid, but was more attractive than ammonia alone (Smallegange et al. 2005). Once we determined which individual carboxylic acids augmented the attractiveness of ammonia + lactic acid (Table 1), we continued our experiments with ammonia + lactic acid as the control, as we aimed for a better result than was found in Smallegange et al. (2005).

Olfactometer Tests Thirty female mosquitoes, 5–8 d-old, that had not received a blood meal, were randomly collected from their cage 14–18 h before the start of experiments. The mosquitoes were placed into a cylindrical release cage (8-cm diam, 10-cm high) with access to tap water from damp cotton wool placed on top of the cage. Experiments were performed during the last 4 h of the dark period, when *An. gambiae* is normally active (Haddow and Ssenkubuge 1973; Maxwell et al. 1998; Killeen et al. 2006).

In each trial, test compounds were released into the air stream and a group of mosquitoes was set free from a release cage placed at the downwind end of the flight chamber of the olfactometer, 1.60 m from the two ports. Mosquitoes were left in the flight chamber for 15 min. Female mosquitoes that had entered either of the trapping devices were counted at the end of the experiment, after anaesthetization with 100% CO_2. Mosquitoes remaining in the flight chamber were removed with a vacuum cleaner. After use, the trapping devices were washed with soapy water (CLY-MAX Heavy Duty Cleaner, Rogier Bosman Chemie B.V., Heijningen, The Netherlands), rinsed with tap water, and cleaned with cotton wool drenched in 70% ethanol (Merck).

The operator wore surgical gloves (Romed®, powderfree vinyl) to avoid contamination of the equipment with human volatiles. Each trial started with new mosquitoes and clean trapping devices. An experiment testing a particular blend was repeated at least 6 times on different days. The sequence of test odors was randomized on the same day and between days. Test stimuli were alternated between

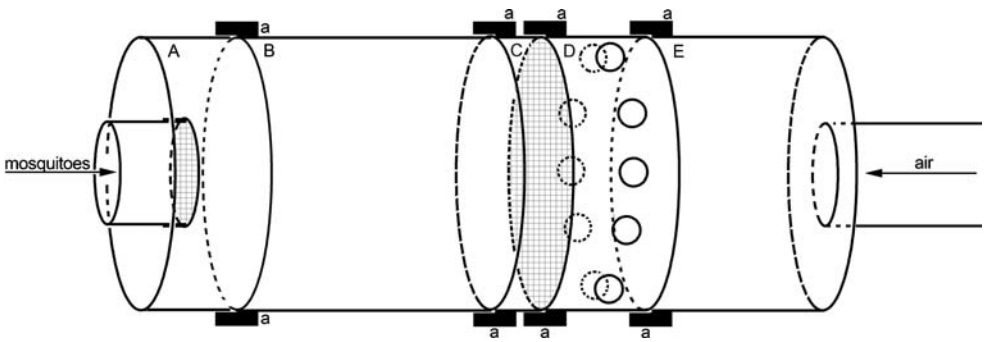

Fig. 1 An olfactometer trapping device is composed of three parts: *A*: part with baffle where mosquitoes enter the device; *B*: middle part device; *C*: distal end sealed with metal gauze to prevent mosquito crossing. A Perspex ring (*D*) with 10 holes for separate odor delivery. The end of the tube running from the glass bottle with an odor was inserted through one of the holes. Charcoal filtered, warm, humidified, pressurized air is led into the trapping device through *E* (a: schematic representation of the couplings between the various parts, made to fit smoothly on each other to prevent air loss)

Table 1 Effect of adding an individual carboxylic acid, at four flow rates (ml/min), to ammonia + lactic acid tested against ammonia alone in the dual-choice olfactometer. A: significantly more mosquitoes in the trapping device baited with the tripartite blend compared to the trapping device baited with ammonia (χ^2-test, $P<0.05$). R: significantly fewer mosquitoes in the trapping device baited with the tripartite blend compared to the trapping device baited with ammonia (χ^2-test, $P<0.05$). Calculated concentrations of the compounds in the odor plume are given in the online supplement (Table S1).

n.t. not tested

right and left ports in different replicates to rule out any positional effects. Experiments in which only clean air was fed into the olfactometer through both ports were done to test the symmetry of the trapping system.

Trapping Experiments in Screen Cage To assess the performance of some of the blends as a lure, we conducted laboratory experiments with volatile baited MM-X traps in a textile screen cage (233×250×330 cm; Howitec Netting BV, Bolsward, The Netherlands) inside a climate-controlled room (22.7±1.1°C and 52.4±7.4% RH). Two Mosquito Magnet-X (MM-X) traps (American Biophysics Corp., U.S.A.) (Kline 1999) were placed inside the cage at 2 m distance from each other.

Initially, a 9-compound blend (blend A) was tested. To compose this blend, 500 µl of a liquid pure compound or 500 mg of a solid compound (tetradecanoic acid) were put into individual low density polyethylene sachets (LDPE; 6×6 cm; Audion Elektro, The Netherlands; Torr et al. 1997) with a thickness of 0.1 mm (ammonia, lactic acid, heptanoic, octanoic, and tetradecanoic acid) or in a closed LDPE tube (32×14 mm, Kartell, 3.5 ml; Fisher Emergo, The Netherlands) within an LDPE sachet with a thickness of 0.2 mm (this delivery method was used for the 4 most volatile aliphatic carboxylic acids (i.e., propanoic, butanoic, 3-methylbutanoic, and pentanoic acids) to reduce their release to a higher extent than would have been possible with a sachet only). Only ammonia was diluted with distilled water (to 2.5%). The sachets were applied inside the central, black tube of the MM-X traps using odorless tape (3M™ Double Coated Tape 400). Air flow was created by a fan on top of this tube taking the headspace of the test blend downwards and outside the MM-X trap. Second, a tripartite blend was tested (blend B). Since we calculated that the release rates of the aliphatic carboxylic acids in blend A were at least two times higher than calculated for the multi-component blends tested in the optimization and subtraction olfactometer experiments, the 3 LDPE sachets (each with a thickness of 0.1 mm) containing the separate components of blend B were made as small as possible (2.5×2.5 cm) to reduce evaporation (Torr et al. 1997). One hundred µl of a liquid pure compound (ammonia, lactic acid) or 50 mg of a solid compound (tetradecanoic acid) were put into individual LDPE sachets. The amount of a compound within a sachet does not affect the evaporation rate of the compound through the LDPE material, whereas the surface of a LDPE sachet does (Torr et al. 1997). When blend B was applied, ammonia was not diluted (25.0%). Both blend A and B were tested against a blend of ammonia + lactic acid. Evaporation rates of the compounds were measured by weighing the LDPE sachets before and after experiments (see Table S1 in the online supplement).

Fifty female mosquitoes, 5–8 d-old, which had not received a blood meal, were randomly collected 14–18 h before the start of experiments. They were placed into a cylindrical release cage (diam 8 cm, height 17.5 cm) with access to tap water from damp cotton wool placed on top of the cage. The mosquitoes were set free from the release cage in the center of the screen cage. After 4 h, the MM-X traps were closed and transferred into a freezer to kill the mosquitoes. These experiments were performed during the last 4 h of the dark period. Each two-choice test was repeated either 4 or 6 times, alternating the position of each treatment every experimental day. Surgical gloves were worn to avoid contamination of equipment with human volatiles. Experiments with unbaited traps in the MM-X setup were done 6 times to test the symmetry of the trapping system.

Statistical Analysis For each two-choice assay, a Chi-square test was used to analyze whether the total number (i.e., sum of all replicates; a comparison of data collected on different days revealed no heterogeneity) of mosquitoes trapped in the treatment trapping device (of either olfactometer or MM-X trap) and the total number that was trapped in the control trapping device (of olfactometer or MM-X trap) differed from a 1:1 distribution. Effects were considered to be significant at $P<0.05$. The number of female mosquitoes caught in both trapping devices divided by the number of mosquitoes that flew out of the release cage is expressed as the trap entry response (TER).

Results

Initial Experiments The combined results of all dual-choice olfactometer experiments with clean air from both ports together show that equal numbers of mosquitoes were caught in both trapping devices (*Chi-square test, df*=1, $P=0.16$). This is proof that the olfactometer was symmetrical and that no positional bias interfered. Even when no volatile source was present, small numbers of mosquitoes flew into the trapping device. However, the TER was low (5.9%, $N=853$).

The combination of ammonia (136 ppm) + lactic acid (15 ml/min) caught mosquitoes in numbers similar to those caught by ammonia alone ($P=0.14$, $N=324$, TER=28.4%). Based on these results and the synergism between ammonia, lactic acid, and a blend of carboxylic acids that we reported previously (Smallegange et al. 2005), we decided to test single carboxylic acids by adding them to the blend of ammonia + lactic acid and examine the effect of this synthetic tripartite blend on the response of *An. gambiae* compared to the effect of ammonia alone.

Individual Aliphatic Carboxylic Acids First, 15 aliphatic carboxylic acids were tested in the dual-choice olfactometer at four different release rates, for their ability to increase the attractiveness of the blend of ammonia + lactic acid compared to ammonia alone. Seven of the carboxylic acids had no effect at any of the four concentrations (Table 1), namely acetic, 2-methylpropanoic, nonanoic, decanoic, dodecanoic, tridecanoic, and hexadecanoic acids (C2, 2mC3, C9, C10, C12, C13, and C16). Depending on the release rate applied, hexanoic acid had either no effect or significantly decreased the number of mosquitoes flying into trapping devices baited with the tripartite blend compared to those flying into the trapping devices baited with ammonia only (P=0.003 at the lowest concentration tested).

Adding propanoic, butanoic, 3-methylbutanoic, pentanoic, heptanoic, octanoic, or tetradecanoic acids (C3, C4, 3mC4, C5, C7, C8, and C14) to the ammonia + lactic acid blend resulted in an increase in the number of mosquitoes flying into the trapping device at one or more of the tested concentrations. The tripartite blend was more attractive than ammonia when butanoic, 3-methylbutanoic, pentanoic, heptanoic, or octanoic acids were part of the blend at either the lowest (flow rate 0.5 ml/min, C4, 3MC4 and C7, P<0.05), the second highest (50 ml/min, C8, P<0.001) or highest concentration (100 ml/min, C5, P=0.01). The second lowest and the highest concentrations of propanoic acid (5 and 100 ml/min) enhanced the attraction of ammonia + lactic acid ($P\leq$ 0.001). All four concentrations of tetradecanoic acid increased the attraction to ammonia + lactic acid compared with the attraction to ammonia alone (P<0.05). At the lowest concentration (0.5 ml/min), heptanoic acid increased the attractiveness of ammonia in combination with lactic acid (P=0.03). However, fewer mosquitoes were caught at the two intermediate heptanoic acid concentrations (5 and 50 ml/min) added to ammonia + lactic acid (P=0.005 and 0.007, respectively).

Optimization Of A Multi-Component Blend Based on previous odor blend experiments, a blend of ammonia + lactic acid and the 7 aliphatic carboxylic acids (C3, C4, 3mC4, C5, C7, C8, and C14) was prepared. This blend enhanced the attractiveness of ammonia when combined in a tripartite blend with lactic acid. Dual-choice olfactometer experiments were performed in which the concentrations of the 7 aliphatic carboxylic acids within this blend were varied in order to examine their effectiveness as mosquito attractants. In total, odor blends were tested in 6 different compositions in which the release rates varied between blends (see Table 2). Two of these experimental blends (blend 1 and blend 4) elicited significantly stronger attractions to the blend of 9 compounds (i.e., the 'complex blend') than to ammonia + lactic acid only (the 'control blend') (Table 2, P<0.001). The other blends were equally attractive as the control blend (Table 2, P>0.05).

Subtraction Experiments Blend 4, containing all 7 of the aliphatic carboxylic acids [each applied at the lowest dose (0.5 ml/min)], was selected for subtraction experiments. The blend minus one of the 7 acids was tested against the control blend (ammonia + lactic acid) to determine the contribution of each individual carboxylic acid on the attractiveness of the complex blend.

Removal of 3-methylbutanoic acid from the complex blend increased the blend attractiveness significantly (Table 3, P=0.01). When tetradecanoic acid was removed, the test blend attracted fewer mosquitoes into the trapping device than the control blend (P=0.02). Elimination of

Table 2 Optimization experiments with carboxylic acids in the dual-choice olfactometer. The left part of the table shows the flow rates for each individual aliphatic carboxylic acid within an odor blend consisting of nine components (ammonia + lactic acid + seven carboxylic acids). The total numbers of mosquitoes caught in the trapping device baited with the test blend (T) and in the trapping device baited with the control blend (C) are given. Also the result of the χ^2-test, total number of mosquitoes released (N) and trap entry response (TER) are given for each blend

Blend	Flow rate (ml/min)							T	C	χ^2-test	N	TER
	C3	3mC4	C4	C5	C7	C8	C14					
1	100	0.5	0.5	100	0.5	50	50	56	25	P<0.001 A	715	11.3%
2	50	0.5	100	0.5	0.5	100	100	3	2	P=0.65	169	3.0%
3	0.5	0.5	0.5	0.5	0.5	5	100	9	10	P=0.82	174	10.9%
4	0.5	0.5	0.5	0.5	0.5	0.5	0.5	30	9	P<0.001 A	548	7.1%
5	0.06	0.06	0.06	0.06	0.06	0.06	0.06	9	16	P=0.80	171	8.8%
6	5	0.5	0.5	5	0.5	5	5	13	5	P=0.06	146	12.3%

A: significantly more mosquitoes in the trapping device baited with the complex blend compared to the trapping device baited with ammonia + lactic acid (χ^2-test, P<0.05).

Table 3 Subtraction experiments performed in the dual-choice olfactometer. The total numbers of mosquitoes caught in the trapping device baited with the test blend (T) and in the trapping device baited with the control blend (C) are given. Also the result of the χ^2-test, total number of mosquitoes released (N) and trap entry response (TER) are given for each blend

Blend	T	C	χ^2-test	N	TER
Blend 4	15	15	P=1.000	338	8.9%
Blend 4 -C3	2	7	P=0.10	171	5.3%
Blend 4 -C4	7	10	P=0.47	164	10.4%
Blend 4 -3mC4	13	3	P=0.01 A	165	9.7%
Blend 4 -C5	1	6	P=0.06	171	4.1%
Blend 4 -C7	12	12	P=1.000	171	14.0%
Blend 4 -C8	9	6	P=0.44	160	9.4%
Blend 4 -C14	4	14	P=0.02 R	165	10.9%

A: significantly more mosquitoes in the trapping device baited with the complex blend compared to the trapping device baited with ammonia + lactic acid (χ^2-test, $P<0.05$).

R: significantly fewer mosquitoes in trapping device baited with complex blend compared to trapping device baited with ammonia + lactic acid (χ^2-test, $P<0.05$)

pentanoic acid may have reduced the attractiveness of the complex blend (P=0.06), but this effect was only marginally significant. Removal of the other four aliphatic carboxylic acids had no significant effect.

Effect of 3-Methylbutanoic Acid Based on the previous results, the effect of 3-methylbutanoic acid was examined by using a blend of ammonia + lactic acid + tetradecanoic acid (shown to have an important role within the complex blend, Table 3) and also propanoic and pentanoic acid (P-value in subtraction experiments $\leq$ 0.10, Table 3). In this series of experiments, blend 4 again was significantly more attractive than the control blend (ammonia+lactic acid) (Table 4, P=0.02). A blend of ammonia + lactic + propanoic + pentanoic + tetradecanoic acids was as attractive as the control (P=0.56). Adding 3-methylbutanoic acid to the latter blend at a flow rate of 0.5 ml/min did not alter the attractiveness, whereas reducing the flow rate to 0.05 ml/min increased attractiveness close to a marginally significant level (P=0.06).

Trapping Experiments Dual-choice experiments were conducted with MM-X traps baited with either a blend of ammonia + lactic acid + tetradecanoic acid or a blend of ammonia + lactic acid + the 7 carboxylic acids. These two blends were tested against the control blend containing ammonia + lactic acid. Traps baited with the tripartite blend and the 9-component blend trapped significantly more mosquitoes than traps baited with the control blend (Table 5, $P<0.001$). The two traps together caught 44.0% and 53.3% of the released mosquitoes (N=298 and 199, respectively). Two unbaited MM-X traps together caught 35.2% of the mosquitoes that left the release cage (N=585). These experiments without odor baits demonstrated that the system was symmetrical (P=0.40).

Discussion

Our results show that aliphatic carboxylic acids with defined chain lengths (C3–C8 and C14) enhance the attractiveness of ammonia to *An. gambiae* mosquitoes in a dose-dependent manner when applied in a tripartite blend with lactic acid. These compounds are likely to serve as kairomones in the host-seeking behavior of *An. gambiae*. As several of these compounds also affect the host-seeking behavior of other mosquito species—e.g., *Ae. aegypti* (Bosch et al. 2000) and *Culex quinquefasciatus* Say, another mosquito species that acts as a vector of human disease (Allan et al. 2006; Puri et al. 2006), our findings lend further credence to the kairomonal role of aliphatic carboxylic acids present on the human skin for anthropophilic mosquitoes.

Individual Aliphatic Carboxylic Acids The carboxylic acids that enhanced the attractiveness of the blend of ammonia and lactic acid to *An. gambiae* all occur in human skin

Table 4 Effect of adding four carboxylic acids in different combinations to ammonia + lactic acid tested against ammonia + lactic acid in the dual-choice olfactometer. The total numbers of mosquitoes caught in the trapping device baited with the test blend (T) and in the trapping device baited with the control blend (C) are given. Also the result of the χ^2-test, total number of mosquitoes released (N) and trap entry response (TER) are given for each blend

Blend	T	C	χ^2-test	N	TER
Blend 4	29	14	P=0.02 A	258	16.7%
ammonia + lactic acid + C3 + C5 + C14	15	12	P=0.56	346	7.8%
ammonia + lactic acid + C3 + $3mC4_{(0.5)}$ + C5 + C14	11	12	P=0.83	84	27.4%
ammonia + lactic acid + C3 + $3mC4_{(0.05)}$ + C5 + C14	22	11	P=0.06	261	12.6%

$3mC4_{(0.5)}$ and $3mC4_{(0.05)}$: 3-methylbutanoic acid applied at an air flow of 0.5 or 0.05 ml/min passing through the glass bottle containing this compound. All other aliphatic carboxylic acids were applied at a flow rate of 0.5 ml/min. A: significantly more mosquitoes in the trapping device baited with the complex blend compared to the trapping device baited with ammonia + lactic acid (χ^2-test, $P<0.05$).

Table 5 Blends tested in dual-choice screen cage experiments with MM-X traps. A MM-X trap was baited with one of the 2 test blends (T); the other MM-X trap was baited with ammonia and lactic acid (C). The total numbers of mosquitoes caught in the trap baited with the test blend (T) and in the trap baited with the control blend (C) are given. Also the result of the χ^2-test, total number of mosquitoes released (N) and trap entry response (TER) are given for each blend

Blend	T	C	χ^2-test	N	TER
A. ammonia + lactic acid + 7 carboxylic acids	85	21	$P<0.001$ A	199	53.3%
B. ammonia + lactic acid + tetradecanoic acid	87	44	$P<0.001$ A	298	44.0%

A: significantly more mosquitoes in the trapping device baited with the test blend compared to the trapping device baited with the control blend (χ^2-test, $P<0.05$). The release rate of each compound applied in LDPE sachets are given in the online supplement (Table S1).

emanations (Bernier et al. 2000; Healy and Copland 2000; Curran et al. 2005; Penn et al. 2007; Gallagher et al. 2008). Our results suggest that only few of these carboxylic acids, depending on their chain length and concentration, contribute to the attractiveness of *An. gambiae* to humans. Both attractive and repellent compounds might be involved in the differential host preference of this mosquito species (Qiu et al. 2004, 2006a). We have documented here that aliphatic carboxylic acids can act in both ways depending on concentration and molecular structure.

Knols et al. (1997) reported that 12 of the 15 acids tested also in this study comprised an attractive synthetic blend. However, the same blend was repellent to *An. gambiae* in a later study, but when combined with ammonia + lactic acid, produced an attractive blend in a synergistic fashion (Smallegange et al. 2005). Acetic acid levels in fresh sweat were higher than in incubated human sweat, the latter being more attractive to *An. gambiae* (Meijerink et al. 2000). Propanoic and hexanoic acids were detected in fresh sweat, but not incubated sweat. Levels of butanoic acid were similar in fresh and incubated sweat. 3-Methylbutanoic acid does occur in incubated human sweat, but in small amounts. We found that propanoic, butanoic, and 3-methylbutanoic acid affect the host-seeking response of *An. gambiae*.

At the lowest dose, heptanoic acid increased the attractiveness of ammonia + lactic acid, whereas fewer mosquitoes were attracted to the two intermediate doses (Table 1). This confirms that not only the molecular structure of the odor, but also its dosage determines whether an odor acts as an attractant or a repellent (Vale and Hall 1985). Heptanoic, nonanoic, and tridecanoic acids, the latter two inactive in this study, were not present in the 12 carboxylic acid-containing synthetic mixture used as attractant by Knols et al. (1997) and which had a synergistic effect in combination with ammonia and lactic acid (Smallegange et al. 2005).

A tripartite blend of ammonia + lactic + and hexanoic acid was found to have a synergistic effect in Y-tube olfactometer tests with *An. gambiae* (Smallegange et al. 2002). Olfactory neurons tuned to aliphatic carboxylic acids were found to innervate antennal sensilla trichodea in *An. gambiae* (Meijerink et al. 2000; Qiu et al. 2006b). Antennal grooved peg sensilla contain neurons sensitive to pentanoic and hexanoic acids. Hexanoic acid also elicited electrophysiological responses from olfactory neurons in trichoid sensilla (Qiu et al. 2006b). Carboxylic acids eliciting an electrophysiological response, but not showing a behavioral effect in this study, may be involved in other behaviors of this mosquito species.

C1–3, C5–8, and C13–18 carboxylic acids enhance the attractiveness of lactic acid to *Ae. aegypti* (Bosch et al. 2000). Several carboxylic acids (C2–18) attract high numbers of female *Cx. quinquefasciatus* in Y-tube olfactometer experiments or induce landing responses when tested individually (Allan et al. 2006; Puri et al. 2006). Bosch et al. (2000) found that hexanoic acid augmented the attractiveness of lactic acid to *Ae. aegypti*. A blend of ammonia, lactic acid, and hexanoic acid is now commercially available (BioGents, Germany; Kröckel et al. 2006) and shown to have potential as an attractant for *Ae. aegypti* (Kröckel et al. 2006; Williams et al. 2006a, b, c). However, in the present study with *An. gambiae,* none of the hexanoic acid doses enhanced attractiveness. In fact, repellency occurred at the lowest dose (Table 1). Attempts to reduce the hexanoic acid concentration from a glass bottle (0.05 ml/min and lower) did not have any effect on the attractiveness of the combination of ammonia, lactic acid, and hexanoic acid compared to ammonia alone. Also, flow rates of 25 ml/min and 230 ml/min had no effect (data not shown). When 8 doses of hexanoic acid were applied to a sand-blasted glass slide (see Smallegange et al. 2005), no attraction was found (in combination with ammonia and lactic acid against ammonia and solvents (diethyl ether; Merck, ≥99.8%) to dilute hexanoic acid (Sigma, ≥99%), and ethanol (Merck, ≥99.8%) to dilute L(+)-lactic acid (sodium salt, Sigma, 98%) (data not shown). Therefore, we conclude that hexanoic acid is not important to *An. gambiae* in attracting host-seeking females from a distance.

Several carboxylic acids showed neither an attractive nor a repellent effect toward *An. gambiae* females at any of the concentrations tested. We do not know the actual concentra-

tion of the acids encountered by mosquitoes in our bioassays or when engaged in host-seeking at varying distances from the host under typical host-seeking conditions. It is possible that the acids were tested at concentrations (see Table S1 in the online supplement) outside of the range that naturally occur in the volatile blends released by humans. Further study of the absolute concentration of human-produced volatiles in the odor plume is required to clarify the role of single carboxylic acids as kairomones for blood feeding insects.

Optimization Experiments Both the optimization and the trapping experiments with the odor blends consisting of nine compounds showed that the blend containing ammonia, lactic acid, and the 7 carboxylic acids enhanced the effect of ammonia in the first experiment, and is attractive to *An. gambiae*. However, the concentration and/or the ratio of carboxylic acids, are crucial factors as can be concluded from the optimization experiments (Table 2). Apparently, the flow rates of the carboxylic acids in blend 5 were too low to induce an effect. When comparing blend 1, 2, and 4, it is likely that the flow rates of butanoic, octanoic, and/or tetradecanoic acid in blend 2 were too high. It is surprising that blend 3 showed no effect. This suggests that the flow rate of tetradecanoic acid was too high, although this seems to contradict the results obtained with this carboxylic acid in the first experiment. It may be that the highest concentration at which tetradecanoic acid is attractive depends on the presence of other carboxylic acids.

Subtraction Experiments And The Effect Of 3-Methylbutanoic Acid Blend 4 was no longer more attractive than the control blend when we initiated the series of subtraction experiments (Table 3), unlike the results presented in Table 2. However, the subtraction experiments are valid, since the effect of eliminating an individual aliphatic carboxylic acid on the attractiveness of the complex blend is clear. In addition, blend 4 was attractive in a series of olfactometer experiments conducted after the subtraction studies (Table 4). Moreover, MM-X traps baited with this blend attracted 4 times more mosquitoes than the control blend in a larger set-up (Table 5). Therefore, we conclude that blend 4 is attractive to *An. gambiae* and that the blend components jointly affect host-seeking behavior.

Individual removal of propanoic, butanoic, pentanoic, heptanoic, or octanoic acid had no effect on the attractiveness of the complex blend suggesting that these 5 carboxylic acids do not play a significant role in the attractiveness of the complex blend and might be exchanged by one another.

Elimination of tetradecanoic acid made the complex blend less attractive than the control blend, whereas the complex blend without 3-methylbutanoic acid was significantly more attractive than the control blend. This suggests that 3-methylbutanoic acid has a repellent or inhibitory effect. On the other hand, a low dose of 3-methylbutanoic acid (0.05 ml/min) also appeared to have a positive effect (although not quite significant) compared with the blend of 5 compounds (Table 4). The effect of 3-methylbutanoic acid seems to depend on the dose of this compound and the other carboxylic acids in the blend (see also Table 1). However, strictly adhering to the significance level of 5%, none of the blends with either 3 or 4 aliphatic carboxylic acids mentioned in Table 4 had the same effect as blend 4 (P=0.02). In other words, these four aliphatic carboxylic acids cannot replace the 7 aliphatic carboxylic acids in blend 4 to enhance the attractiveness of ammonia + lactic acid. Apparently (taking all results together), interactions between aliphatic carboxylic acids in odor blends affect the "active" composition of the blend, which we cannot fully elucidate based on our results. Combining the subtraction results with the result of the first experiment where tetradecanoic acid increased the attractiveness of ammonia when lactic acid was present at all flow rates, suggests that it is an important component in behaviorally significant odor blends for *An. gambiae*. This aliphatic carboxylic acid was also found to be more abundant (almost twice as much) in the odor profiles of two people that were more attractive to *An. gambiae* than two people with lower amounts of tetradecanoic acid. In addition, tetradecanoic acid was a major constituent in the odor profiles of these four people as determined by sampling skin residues on small glass beads (Qiu et al. 2006a). The residues were desorbed by placing the beads into a thermal desorption unit combined with a cryo-focussing system and then analyzed by GC-MS (A.M. Galimard, personal communication).

Trapping Experiments The trapping experiments showed that a complex blend of 9 compounds is more attractive than the control blend (ammonia + lactic acid), which is in agreement with the results of the olfactometer assays. A catch rate of about 42.7% of the mosquitoes released by the MM-X trap baited with the complex blend compared to 17.6% per trap in experiments with two unbaited traps is a promising finding. Semi-field and field experiments should be conducted to reveal the potential of this blend as a bait for wild mosquitoes in Africa. The MM-X trap baited with the tripartite blend also caught more mosquitoes than the MM-X trap baited with the bipartite blend, suggesting that despite its low volatility, tetradecanoic acid increases the attractiveness of ammonia and lactic acid in two different assays.

Comparisons of the release rates that were calculated based on physicochemical parameters and the gravimetrically determined evaporation rates (Table S1 in the online supplement) of compounds applied in the olfactometer and in the MM-X traps, respectively, seem to show differences

in the concentrations applied in the two bioassays. However, it is hard to estimate the exact concentrations encountered by mosquitoes, considering the differences between the two bioassays (e.g., sizes of the experimental arenas in which experiments have been conducted and the release methods used for the test compounds).

The tripartite blend caught about 29.2% of the total number of mosquitoes released into the experimental room. When the attractiveness of the 9-component blend is compared statistically with the tripartite blend, a significant difference is not found [P=0.73; GLM (binomial, link in logit); calculated for the ratio of (treatment)/(treatment + control); mean 0.60±0.39 (9-component blend) and 0.66± 0.11 (tripartite blend)]. Thus, the trapping experiments show, in addition to olfactometer data, that tetradecanoic acid in combination with ammonia and lactic acid may be used as a reliable basic blend to which other candidate kairomones for *An. gambiae* can be added. Although semi-field and field experiments have to be conducted to see how well this tripartite blend performs under African conditions, it seems likely that the blend efficacy can be improved by adjusting the concentrations of each compound and by addition of compounds other than aliphatic carboxylic acids (R.C. Smallegange, unpublished data).

In summation, our results demonstrate that several aliphatic carboxylic acids elicit a significant odor-mediated behavioral preference in the malaria mosquito *An. gambiae*. They also enhance the attractive effectiveness of the ammonia and lactic acid mixture. Tetradecanoic acid emerges as a crucial compound and is attractive over a broad concentration range. In contrast, 3-methylbutanoic acid reduced the trap entry response when present in a blend of ammonia, lactic acid and seven carboxylic acids. The inhibitory effect was much less when the dose was reduced and applied in a blend with 6 compounds. The behavioral effect of 3-methylbutanoic acid needs to be further examined. A remarkable species-specific difference was revealed when hexanoic acid was found to act as an inhibitor or to be ineffective, whereas in the anthropophilic *Ae. aegypti* it is an important kairomone. Semi-field and field studies are needed to confirm that the qualitative and quantitative composition of attractive blends for *An. gambiae* reported here can be successfully employed in trapping strategies under field conditions.

Acknowledgements We thank Dr. F. Griepink (Plant Research International, Wageningen University and Research Centre, Wageningen, The Netherlands) and the professors Dr. D. Hall and Dr. S. Torr (Natural Resources Institute, University of Greenwich, Chatham Maritime, UK) for their advice on the use of LDPE sachets and for the materials provided. We are also thankful to F. van Aggelen, A. Gidding, and L. Koopman (Laboratory of Entomology, Wageningen University, Wageningen, The Netherlands) for rearing the mosquitoes. Dr. M. Posthumus (Laboratory of Organic Chemistry, Natural Products Chemistry Group, Wageningen University, Wageningen, The Netherlands) is acknowledged for providing estimations of vapor pressures for various test compounds. We also thank G. Leenders (PSG Facility Services, Wageningen University and Research Centre, Wageningen, The Netherlands) for making adjustments to the olfactometer and trapping devices and Dr. H Smid (Laboratory of Entomology, Wageningen University, Wageningen, The Netherlands) for drawing Fig. 1. This study was financed by the Technology Foundation of The Netherlands Organisation for Scientific Research (STW-NWO, grant WBI.4834) and in part by a grant from the Foundation for the National Institutes of Health (NIH) through the Grand Challenges in Global Health Initiative (GCGH#121).

Insects use a combination of visual and chemical cues to locate their host plants (Bernays and Chapman 1994), and plant volatiles play an important role (Bruce et al. 2005). There is evidence that *H. hampei* uses both visual (Morallo-Rejesus and Baldos 1980; Mathieu et al. 2001) and olfactory stimuli (Giordanengo et al. 1993; Mendoza-Mora 1991; Mathieu et al., 2001). However, to date, no studies have established which volatiles are responsible for attraction of *H. hampei*, possibly because the small size of the antennae makes electrophysiological recordings a challenge. The ripeness/physiological maturity of berries of coffee determine the level of attraction and colonization by the beetle (Baker 1999). Studies conducted so far have demonstrated that female insects prefer (ripe) or black (overripe) berries over green ones (Giordanengo et al. 1993; Mendoza-Mora 1991; Baker 1999; Mendesil et al. 2005). The volatile composition of coffee berries at different stages of ripeness has been reported (Mathieu et al. 1996, 1998; Warthen et al. 1997; Ortiz et al. 2004), but no electrophysiological studies of responses to coffee volatiles have been conducted previously with *H. hampei*, and the semiochemicals used in host location have not yet been defined. Identification of the volatile compounds used for host recognition may contribute to novel and sustainable pest management strategies, for example by using baited traps. To address this, the objective of the present study was to identify volatiles released by coffee berries that elicit electrophysiological responses from *H. hampei* antennae, and to investigate behavioral responses to these semiochemicals in an olfactometer.

Methods and Materials

Insects The culture of coffee berry borer used in the laboratory experiments was established with field collected insects from Ethiopia. They were maintained under controlled conditions (21°C, 75% RH, 12:12 h L:D) and reared in the laboratory on artificial media as described by Brun et al. (1993).

Chemicals Authentic samples of methylcyclohexane, nonane, ethylbenzene, (*R*)-limonene, (*S*)-limonene, and octen-3-ol were purchased from Sigma Aldrich (Gillingham, UK; all≥96% purity). 3-Ethyl-4-methylpentanol was provided by Prof J. Millar, Department of Entomology, University of California.

Collection of Volatiles Coffea arabica (Rubiaceae) berries were collected in Ethiopia (local coffee type, from garden coffee near Jimma town). Berries at green, ripe, and dry stages (500 g) were enclosed separately in a glass vessel (20 cm length, 6 cm diam). Air entering the vessel was drawn through a charcoal filter. Air was pumped out at 400 ml min^{-1} through a Porapak Q adsorbent tube (Alltech associates, Lancashire, UK) in a 5 mm diam glass tube (Alltech associates, Carnforth, Lancashire, UK; 50 mg Porapak Q in 5 mm diam glass tube). All connections were made with PTFE tubing (Alltech associates, Lancashire, UK) with brass ferules and fittings (North London Valve, London, UK) and sealed with PTFE tape (Gibbs & Dandy, Luton, UK). Berries were entrained for 3 d, and the Porapak Q filter was eluted with 0.5 ml of redistilled diethyl ether, providing a solution that contained the isolated volatile compounds. Samples were stored in the freezer (−22°C) until used for the experiments.

Gas Chromatography Analysis Volatiles were analyzed on a Hewlett-Packard 6890 GC equipped with a cold on-column injector and a flame ionization detector (FID) fitted with two columns of different polarity: a non-polar HP-1 bonded-phase fused silica capillary column (50 m× 0.32 mm i.d., film thickness 0.52 µm) and a polar DB-wax column (50 m × 0.32 mm i.d., film thickness 0.82 µm). The oven was maintained at 30°C for 1 min and then programmed at 5°C min^{-1} to 150°C followed by 10°C min^{-1} to 230°C. The carrier gas was hydrogen. Chiral GC analyses were conducted by using an HP5890 GC (Agilent Technologies, UK) equipped with a cool on-column injector and a FID, fitted with a β-cyclodextrin chiral capillary column (30 m × 0.25 mm i.d., 0.25 µm film thickness; 140 kPa head pressure). The GC oven was maintained at 50°C for 1 min, and then raised by 2°C min^{-1} to 150°C where it was held for 30 min. The carrier gas was hydrogen.

Coupled Gas Chromatography-Electroantennography (GC-EAG) Electroantennogram (EAG) recordings were made by using Ag-AgCl glass microelectrodes filled with Ringer solution (7.55 g l^{-1} sodium chloride, 0.64 g l^{-1} potassium chloride, 0.22 g l^{-1} calcium chloride, 1.73 g l^{-1} magnesium chloride, 0.86 g l^{-1} sodium bicarbonate, 0.61 g l^{-1} sodium orthophosphate). The head of an adult female *H. hampei* was separated from the body with a microscalpel and laid upside-down on double-sided sticky tape, then secured with a water-based erasing fluid (Tippex, BIRO BIC Ltd.) placed around the base of the head and allowed to dry. The antennae were brought forward and secured in a similar way. The indifferent electrode, from which the tip had been removed, was placed within the head capsule. The recording electrode was inserted into the tip of one antenna. The coupled GC-EAG system, in which the effluent from the GC column is simultaneously directed to the antennal preparation and the GC detector, has been described previously (Wadhams 1982). The stimulus was delivered into a purified and humidified airstream (1 l/min) flowing continuously over the preparation. Separation of the

volatiles was achieved with a Hewlett-Packard 6890 GC equipped with a cold on-column injector and a flame ionization detector (FID). The column was HP-1 (50 m× 0.32-mm i.d.). The oven temperature was maintained at 30°C for 2 min, and then programmed at 5°C min^{-1} to 100°C and then at 10°C min^{-1} to 250°C. The carrier gas was hydrogen. EAG signals were passed through a high-impedance amplifier (UN-06; Syntech, the Netherlands), and simultaneous recordings of the EAG and FID responses were obtained with specialized software (EAD version 2.3; Syntech, the Netherlands). Six coupled runs were completed. Only FID peaks that corresponded to an EAG peak in three or more replicates were considered to be electrophysiologically active.

Coupled Gas Chromatography-Mass Spectrometry (GC-MS) Identification of electrophysio-logically active FID peaks was achieved by GC-MS. One µl of the air entrainment sample was injected onto a capillary GC column (50 m×0.32 mm i.d. HP1) directly coupled to a mass spectrometer (Thermo-Finnigan, MAT95, Bremen, Germany). Ionization was achieved by electron impact at 70 eV, 250°C. The oven temperature was maintained at 30°C for 5 min, and then programmed at 5°C min^{-1} to 250°C. Tentative identifications of electrophysiologically active FID peaks were made by comparison of spectra with those of authentic samples in a database (NIST 2005). Tentative identification by GC-MS were confirmed by co-injection of the air entrainment sample with authentic standards on both HP-1 and DB-WAX columns, with peak enhancement indicating co-elution. Quantification of identified compounds was achieved by injecting authentic standards at three known concentrations onto the HP 1 GC column and recording the peak area. Each standard was injected three times, and a calibration curve was plotted for each compound, and used to determine quantities of each compounds in the air entrainment sample.

Olfactometer Bioassay Behavioral assays were done by using a Perspex four-arm olfactometer (Pettersson 1970). It was illuminated from above by diffuse uniform lighting (23 µmol $m^{-2}s^{-1}$) and maintained at 23°C. The bottom of the apparatus was lined with filter paper (Whatman No 1), and air was drawn through the four arms towards the center at 240 ml min^{-1} (flow rate through each individual arm was 60 ml min^{-1}). Single female *H. hampei* (1 – 3 wk-old, assumed mated as obtained from a mixed culture) were introduced into the central chamber, and the time spent and number of entries into each arm was recorded using specialist software (OLFA, Udine, Italy) over a 16-min period. The apparatus was rotated a quarter of a turn every 2 min to eliminate any directional bias. If the insect remained motionless continuously for 2 min, it was considered inactive, and the replicate was repeated by using a new insect. After each experiment, all glassware was washed thoroughly with Teepol detergents, rinsed with acetone and then with distilled water and baked in an oven for at least 2 h. Perpex components were washed with Teepol solution, rinsed with 80% ethanol solution, and then with distilled water and left to air dry.

Initially, responses to headspace samples collected from green, ripe, and dry stages of *C. arabica* berries were tested. Ten µl of headspace sample were applied to a filter paper strip, and the solvent was allowed to evaporate for 30 s. The filter paper was placed at the end of the treated side arm. The three control arms were similarly treated with redistilled solvent (diethyl ether) (10 µl) on filter paper. The sample that elicited the strongest behavioral response was selected for GC-EAG analysis, and electrophysiologically active synthetic compounds then were used as treatments in subsequent bioassays. Responses to individual compounds were tested by using 10 µl of 100 ng $µl^{-1}$ solutions formulated in redistilled hexane in the treated arm and 10 µl of redistilled hexane in the control arm. Compounds that elicited a positive behavioral response were formulated as a synthetic blend (in redistilled hexane) that comprised all the active compounds in the same concentration and ratio as in the entrainment sample they were identified from, and the response to 10 µl aliquots of this blend was tested. For each series of replicates, the mean time spent in and number of entries into treated and control arms were compared using a paired *t*-test (GenStat) after checking that data were normally distributed. A choice test also was conducted in which there were two treated arms and two control arms (Webster et al. 2008). Thus the response to the synthetic blend and the natural headspace sample it was based on were directly compared.

Results

Behavioral Responses of H. hampei to Headspace Samples In the olfactometer bioassay, female *H. hampei* spent more time in the region of the olfactometer where ripe and dry stage fruit volatiles were used as an odor source compared to control regions ($P<0.01$). However, the insects showed no significant response to odor from green stage *C. arabica* berries (Fig. 1). The entrainment sample of dry berries that gave the strongest response in the bioassay ($P=0.005$) was selected for use in coupled GC-EAG recordings.

Identification of Electrophysiologically Active Compounds in Air Entrainment Sample Coupled GC-EAG revealed 6 electrophysiologically active compounds in the headspace sample. By using coupled GC-MS and GC peak enhance-

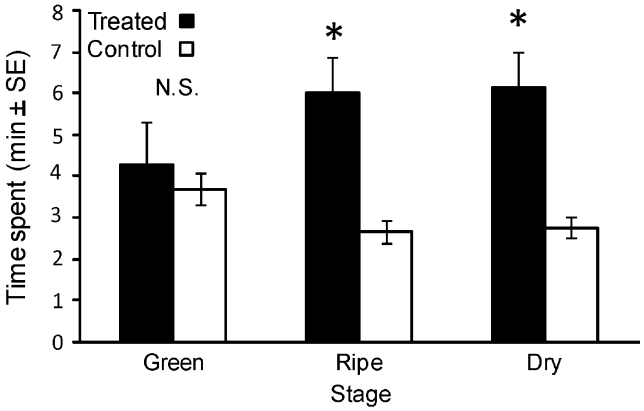

Fig. 1 Behavioral responses of female coffee berry borer, *Hypothenemus hampei* to green, ripe and dry stage of *Coffea arabica* berries in four-arm olfactometer (N=8) (*=P<0.01)

ment on two GC columns of different polarity, these 6 compounds were identified as methylcyclohexane, ethylbenzene, nonane, 1-octen-3-ol, limonene, and 3-ethyl-4-methylpentanol. The quantities and ratio of these compounds are listed in Table 1. Chiral GC analyses indicated that the main enantiomer of limonene was (*R*)-limonene, although a trace of (*S*)-limonene also was present. Quantities of 1-octen-3-ol were too small in the natural sample to resolve the enantiomer. For 3-ethyl-4-methylpentanol, a racemic synthetic sample gave two peaks eluting at 23.03 and 23.36 min, whereas the natural sample of *C. arabica* berry volatiles only gave one peak eluting at 23.06 min. The earlier eluting peak was enhanced in a co-injection of natural and synthetic samples. The (*R*)-enantiomer is known to elute before the (*S*)- enantiomer on a ß-cyclodextrin column (Greenberg et al. 2007), and thus the compound present was (*R*)-3-ethyl-4-methylpentanol.

Amounts of Electrophysiologically Active Compounds in Samples from Different Growth Stages GC analysis of samples collected from green stage berries indicated that few volatiles were emitted at this phenological stage. Out of the electrophysiologically active compounds, only methylcyclohexane was detected. More volatiles were emitted at the ripe stage (Table 2), with methylcyclohexane and (*R*)-3-ethyl-4-methylpentanol being released in maximum amounts. At the dry stage, there was a decrease in release of methylcyclohexane and (*R*)-3-ethyl-4-methylpentanol, and ethylbenzene, nonane, octen-3-ol, and (*R*)-limonene formed a greater proportion of the volatile blend (Table 2).

Behavioral Responses of H. hampei to Synthetic Compound Of the six electrophysiologically active compounds, four elicited attraction when presented individually in the olfactometer. Female *H. hampei* showed significant responses to 3-ethyl-4-methylpentanol (P=0.005), nonane (P=0.021), methylcyclohexane (P = 0.029), and ethylbenzene (P=0.042) (Fig. 2). There was no significant response to (*R*)-limonene and octen-3-ol. When 3-ethyl-4-methylpentanol, nonane, methylcyclohexane, and ethylbenzene were combined in a 4-component synthetic blend, in the same concentration and ratio as the natural headspace sample, they elicited a highly significant response (P< 0.001) (Fig. 2). A choice test between this 4-component blend and the natural headspace sample showed that there was no significant difference in time spent (P= 0.229). The mean time (± S.E.) in the area where insects were exposed to the synthetic blend was 3.20 (± 0.77) min, while it was 3.63 (± 0.20) min in the area where they were exposed to the natural sample of volatiles.

Discussion

Female coffee berry borer were attracted to ripe and dry stage *C. arabica* berry volatiles in the olfactometer bioassay (P<0.01) (Fig. 1), whereas volatiles collected from green immature berries were not significantly attractive. There were clear differences in volatile blends released at the different phenological stages (Table 2), especially at the green stage where all but one of the electrophysiologically active compounds were not detected, thus explaining the lack of a behavioral response to green stage headspace samples. This agrees with previous reports of the preference of this insect for ripe and over ripe *C. arabica* berries

Table 1 Electrophysiologically active compounds identified in *Coffea arabica* berry volatiles

Compound no.	Compound name	Retention Index (polar)	Concentration[a] (ng µl^{-1})	Ratio[a]
1	methylcyclohexane	752	33.9	9.1
2	ethylbenzene	852	10.3	2.8
3	nonane	902	3.7	1.0
4	1-octen-3-ol	951	5.0	1.3
5	(*R*)-3-ethyl-4-methyl pentanol	1010	40.3	10.8
6	(*R*)-limonene	1023	53.0	14.2

[a] Concentration and ratio as in the sample of dry stage berry volatiles that elicited the greatest response in olfactometer bioassays

(Mendoza-Mora 1991; Giordanengo et al. 1993; Mendesil et al. 2005). The small size of the insect meant that electrophysiological studies with the antennae reported here were somewhat challenging. Nevertheless, six electrophysiologically active compounds were identified in a headspace sample of dry (over ripe) *C. arabica* berries. Of these, methylcyclohexane, ethylbenzene, nonane, and 3-ethyl-4-methylpentanol were significantly attractive when presented individually in the olfactometer bioassay. A blend of these four key compounds, in the same concentration and ratio as in the headspace sample they were identified from, elicited highly significant attraction of *H. hampei* ($P < 0.001$), suggesting that the identified volatile compounds are used in host location by *H. hampei*. (*R*)-Limonene and octen-3-ol were not significantly attractive when presented alone, and were not crucial for the response observed to the headspace sample, as the 4-component synthetic blend not containing them was as attractive as the natural headspace sample in a choice test.

Two of the four compounds identified in this study as attractants for *H. hampei* have been reported previously: Ortiz et al. (2004) found nonane and 3-ethyl-4-methylpentanol in headspace analyses of *C. arabica* berries. However, methylcyclohexane and ethylbenzene have not been reported previously. Methylcyclohexane has been found in the essential oil of *Laportea aestuans* (Olufunke et al. 2008). Ethylbenzene is in a range of plants including *Limonium bicolor* (Wei and Wang 2006), poplar bark (Zhao et al. 2002), olives (Scarpati et al. 1993), Malabar nightshade (Kameoka et al. 1991), and *Cucurbita* flowers (Granero et al. 2004). Nonane is in an even wider range of plants other than *C. arabica*. 3-Ethyl-4-methylpentanol is a more unusual compound, and could perhaps be used to distinguish *C. arabica* from non-host material, as it is less widely occurring. However, even this compound is not unique to *C. Arabica*, as it has been reported as a component of French bean (*Phaseolus vulgaris*) volatiles (Barra et al. 2007) and as a trace compound in wine aroma (Genovés et al. 2005; Zhang et al. 2007). It also has a different function in a different ecological context as a sex pheromone of the ant *Polyergus breviceps* (Greenberg et al. 2007). Other compounds emitted in significant quantities, but not found to be electrophysio-

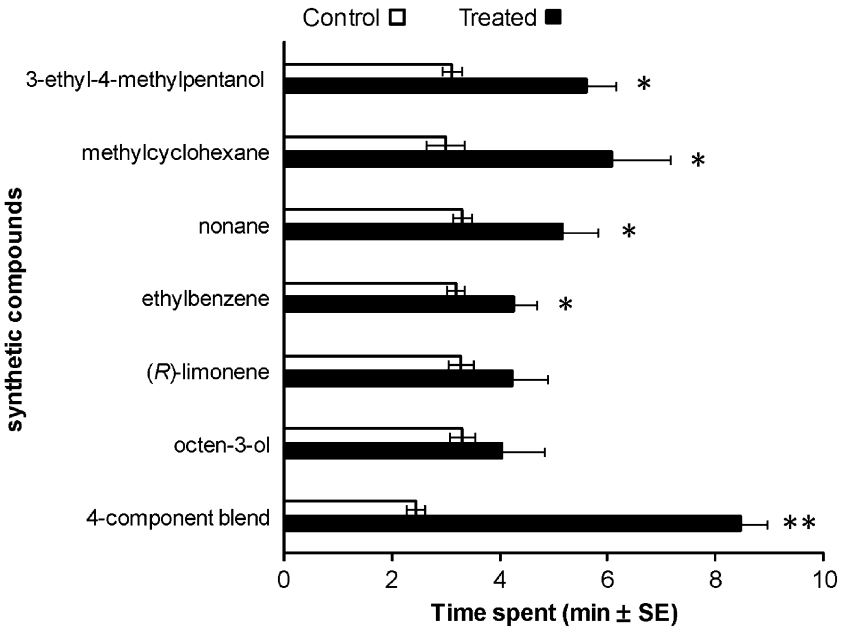

Fig. 2 Behavioral responses of female coffee berry borer, *Hypothenemus hampei* to electrophysiologically active synthetic compounds (100 ng on filter paper) and a four-component blend of synthetic compounds in four-arm olfactometer (N=8) (*=P<0.05; **=P<0.001)

logically active, were hexanal, 1-hexanol, 2-heptanone, 2-heptanone, 2-heptanol, isobutyl butyrate, linalool, and methyl salicylate, and they have been previously identified in coffee berries (e.g., Mathieu et al. 1998).

As the attractants identified here are not specific to *C. arabica*, it is unlikely that a single volatile compound is used for host recognition by *H. hampei*. We suspect that *H. hampei* uses a blend of compounds for host recognition because the response in the olfactometer to a 4-component blend of volatiles that comprised methylcyclohexane, ethylbenzene, nonane, and 3-ethyl-4-methylpentanol in the natural ratio elicited considerably stronger attraction than any of these compounds presented individually (Fig. 2). Use of a blend can enable host recognition by host specific ratios of ubiquitous rather than host-specific volatile compounds (Visser 1986; Bruce et al. 2005). Further studies are required to elucidate fully the role of ratios in host location by *H. hampei* and to define parameters of the minimum component blend required for attraction in the field. Furthermore, to study whether there are any herbivore induced volatiles emitted from *C. arabica* fruits, as in the case with other insect species (Dicke 1994; Karban and Baldwin 1997; Jönsson and Anderson 1999), would add a valuable dimension to the work. Most importantly, field trials should be carried out to assess the potential for use of the semiochemicals identified here in integrated pest management of the coffee berry borer. Baited traps could be useful for monitoring pest abundance (including for quarantine) or even in mass trapping as female insects were attracted to the semiochemicals in the olfactometer.

Acknowledgements Rothamsted receives grant-aided support from the Biotechnology and Biological Sciences Research Council (BBSRC) of the United Kingdom. This work was supported by a Rothamsted International fellowship awarded to Esayas Mendesil. We would like to thank Jocelyn Millar for kindly providing a sample of 3-ethyl-4-methylpentanol.

expression of other genes, and interfering with apoptosis (Eaton and Gallagher 1994; McLean and Dutton 1995; Neal 1995; Guengerich et al. 1998). Economic losses due to aflatoxin contamination are estimated at millions of dollars in the U.S. each year. To minimize the harmful effects of aflatoxins, strict regulations have been established in the US. While crops and finished food products that contain aflatoxins above 20 ppb are not allowed for human consumption, the limitation is set at 5 ppb for milk (Cleveland et al. 2003; Williams et al. 2004). Two other fungi, *Aspergillus ochraceus* and *Penicillium verrucosum,* primarily produce ochratoxins. Ochratoxin A (OTA) interferes with immune system function (Neal 1995) and also may be carcinogenic. Because of these properties, commodities contaminated with high concentrations of mycotoxins (e.g., 20 ppb for aflatoxins) are blocked from sale both in the U.S. and overseas (Park and Troxell 2002; Bayman and Baker 2006). Without appropriate monitoring measures, mycotoxin-contaminated food has had serious impacts on human health in many areas, especially in developing countries in Asia and Africa (Williams et al. 2004).

The level of tolerance to mycotoxins in insects varies from several ppb to several ppm and is both species- and sex-specific (Gudauskas et al. 1967; Chinnici et al. 1976; Llewellyn and Chinnici 1978; Chinnici and Llewellyn 1979; Zeng et al. 2006). *Drosophila melanogaster* larvae, which feed naturally on fermenting fruits, exhibit significantly altered development on diets containing low AFB1 concentrations (i.e., less than 1 ppm); larvae feeding on higher concentrations will die (Kirk et al. 1971; Chinnici et al. 1976; Llewellyn and Chinnici 1978; Chinnici and Llewellyn 1979). The corn earworm, *Helicoverpa zea* (CEW), another species that encounters mycotoxin-releasing fungi in damaged plants (Widstrom et al. 1976; Widstrom 1979; Archer and Bynum 1994), also is tolerant of aflatoxins. Low concentrations of AFB1 in the diet of 1st instars (less than 100 ng/g) can affect development, causing delayed pupation and reduced pupal weight; higher concentrations of AFB1 (200 ng/g) are lethal (Zeng et al. 2006).

The toxicity of aflatoxins to insects depends on their metabolism as mediated by cytochrome P450 monooxygenases (P450s, Phase I detoxification enzymes) into bioactive products. One of the most toxic of these is the AFB1-*exo*-epoxide, which is derived from AFB1. The bioactivated metabolite of AFB1, exo-8,9-epoxide (AFBO), can bind directly to proteins and DNA and cause cell death (Eaton and Gallagher 1994; McLean and Dutton 1995; Guengerich et al. 1998; Suriawinata and Xu 2004). Glutathione-S-transferases (GSTs, Phase II detoxification enzymes) conjugate glutathione to the lipophilic products of P450-mediated metabolites that are more readily excreted (Hayes et al. 2005). In rodent livers, susceptibility to AFB1 is inversely associated with GST activity toward AFBO (Lotlikar et al. 1984; Monroe and Eaton 1988; Buetler et al. 1992; Johnson et al. 1997). Another biotransformation of AFB1 is its direct reduction by NADPH-dependent aflatoxin B1 aldehyde reductases (AFAR) to form aflatoxicol (AFL). However, this product is converted rapidly back to AFB1 by dehydrogenases (Eaton and Gallagher 1994). Alternative biotransformation pathways that generate detoxified metabolites, such as aflatoxicol, aflatoxin M1, and aflatoxin B2a, and that do not generate bioactivated epoxidized metabolites also exist in NOW and contribute to the high aflatoxin tolerance of this species (Lee and Campbell 2000). Characterization of similar biotransformation pathways in CEW indicate that at least one P450 in this species, specifically CYP321A1, is capable of converting AFB1 into polar metabolites, with the demethylated product aflatoxin P1 (AFP1) as the principal metabolite (Niu et al. 2008).

Given the existence of alternative biotransformation pathways in both NOW and CEW, we initiated a series of studies to compare toxicity and tolerance of mycotoxins in these two species. Because NOW is associated regularly with fungus-contaminated hostplant tissue, we hypothesized that its level of tolerance to both aflatoxins and ochratoxins should exceed that of CEW, which only occasionally encounters fungal contamination inasmuch as it feeds on fruits before they fall to the ground.

Methods and Materials

Chemicals Piperonyl butoxide (PBO) was purchased from Tokyo Kassie Kogyo (Tokyo, Japan). Aflatoxins B1, G1, and ochratoxin A were purchased from Sigma Chemicals (St. Louis, MO, USA). Analytical grade dimethyl sulfoxide (DMSO) was obtained from Fisher Scientific (Pittsburgh, PA, USA). All chemicals were stored at −20°C and dissolved in DMSO to make stock solutions.

Insects Laboratory colonies of *H. zea* (originating from specimens collected in Champaign County, IL, USA), and *A. transitella* (originating on almond trees in Fresno, CA, USA that have been maintained in culture for the past 25 years by the Commodity Protection and Quality Unit, USDA/ARS, Parlier, CA, USA) were kept in an insectary at UIUC at 28±4°C with 16-h/8-h L/D cycle. *H. zea* larvae were reared individually from egg hatch in 5 oz (142 g) plastic cups containing approximately 5 g control or supplemented diet. *A. transitella* larvae were mass-reared until pupation in 500 ml plastic containers containing 200 g of wheat bran diet (Tebbets et al. 1978).

Bioassays AFB1 and OTA s*tock* solutions were prepared in DMSO and stored at −20°C for up to 2 months. Diets containing AFB1 (1, 5, 10, 20, 50, and 100 μg/g) were made from AFB1 stock solutions (1, 100, or 500 μl of 1 mg/ml in 0.5% DMSO) and incorporated into 100 g of diet to make 1 or 5 μg/g of AFB1 diet; 50, 100, 250 and 500 μl of 20 mg/ml of AFB1 stock solution were added to 100 g of the diet to make 10, 20, 50 and 100 μg/g of AFB1 diets in 0.5% DMSO. For low concentrations of AFB1 diets (i.e., 20, 40, 60, 80, 100, 120, or 140 ng/g), AFB1 stock solution in 0.2% DMSO (20, 40, 60, 80, 100,120, 140 μl of 100 μg/ml) was added to 100 g of diet. OTA stock solutions (50 or 250 μl of 2 mg/ml in 0.25% DMSO) were incorporated into 100 g of the OTA–containing diet to make 1 or 5 μg/g of the OTA diet; in addition, OTA (50, 100, or 250 μl of 20 mg/ml in 0.25% DMSO) was added to 100 g of the diet to make 10, 20, or 50 μg/g of the OTA diet. Pilot experiments determined that concentrations of DMSO up to 0.5% of the diet do not affect development or survivorship in either NOW or CEW.

To assess the toxicity of AFB1 to NOW, six concentrations of AFB1 (1, 5, 10, 20, 50, and 100 μg/g) diets were prepared. NOW neonates (20 newly hatched 1st instars) were placed individually into 142-g plastic cups that contained 0.5 g unamended diet or supplemented diet prepared with a final concentration of 0.5% DMSO. Two higher concentrations of AFB1-containing diets (50 and 100 μg/g) were fed to 20 ultimate instars (5th) with 0.5% DMSO as control. Larvae were monitored until pupation, and final pupal weights were measured within 48 h after the final larval molt. Each set of bioassays was replicated three times.

Similarly, OTA toxicity to NOW larvae was tested with a variety of OTA-containing diets (1, 5, 10, 20, or 50 μg/g OTA at a final concentration in 0.25% DMSO); 1st instars (20) in each group were treated. On the 12th day, the proportion of dead larvae was recorded, and each larva was weighed on the 14th day. The pupation rate was measured within 48 h of pupation. To test the toxicity of OTA to CEW, 1st instars were exposed to diets containing 1 or 5 μg/g OTA in DMSO (0.25%) and control diet. The survivorship of larvae at 12 days post-hatch on diets and frequency of 5th instars at 12 days post-hatch were recorded.

To compare the effects of AFB1 on the development of NOW and CEW, 1st instar CEW larvae were fed artificial diets containing 0.2% DMSO and 10, 20, 40, 60, 80, 100, 120, or 140 ng/g AFB1, while 1st instar *A. transitella* were fed with artificial diets containing 0.5% DMSO, 1, 5, or 10 μg/g AFB1. For each species, the numbers of larvae reaching the 2nd instar were recorded within 48 h.

Midgut Protein Preparations To obtain sufficient larval midgut tissue, guts were dissected from ultimate instars (at least 100) that had molted within the previous 12 h. Midgut dissections were performed in 0.1 M phosphate buffer and on ice. The midguts were frozen in liquid nitrogen and stored at −80°C until use. For each midgut preparation of ultimate instars, frozen midguts (approx. 40) were ground in a mortar in the presence of liquid nitrogen. The resulting material was transferred into a Eppendorf tube (1.5 ml), suspended in phosphate buffer (1.5 ml; 0.1 M; pH 7.4), EDTA (1 mM), PMSF (0.5 mM), DTT (0.1 mM), and 20% glycerol; the mixture was shaken gently for 5 s. These midgut homogenates were centrifuged (10,000 rpm; 10 min) in an Eppendorf centrifuge at 4°C. The cleared supernatant was transferred into a new 1.5 ml Eppendorf tube for immediate use, or frozen in liquid nitrogen and stored at −80°C for up to 6 months. Protein concentrations for the cleared lysates were determined by using the Bio-Rad protein assay (Bio-Rad Laboratories, Hercules, CA, USA).

In Vitro Metabolism Assays For all assays, the frozen cleared lysates were taken from the −80°C freezer and thawed on ice (approx. 30 min) before the metabolism assays were initiated. AFB1 and OTA metabolism assays were carried out as described previously in Lee and Campbell (2000) with only slight modification. Stock solutions of AFB1 or OTA at 10 μg/g were prepared in DMSO. Each 250-μl reaction contained AFB1 (1 μl) or OTA stock (10 μg/μl), reduced glutathione (5 mM), protein (1 mg/g), sodium phosphate buffer (0.1 mmol/l; pH 7.4), and EDTA (1 mM). Reactions were initiated with the addition of 50 μl of 3 mM NADPH. After a 60-min incubation period (at 30°C with shaking), 1 ml of ice-cold methanol containing 10 μM AFG1 (internal standard) was added to terminate reactions. The reaction mixtures were centrifuged (10,000 g for 10 min) in an Eppendorf centrifuge, and each supernatant was analyzed by high-pressure liquid chromatography (HPLC). All reactions were run in triplicate and repeated at least twice. To trap the AFB1-*exo*-epoxide metabolite, mouse liver cytosol (10 μl, 50 mg/ml) was added into reactions containing NOW crude proteins. Reactions were stopped after incubation (30°C for 1 h) and analyzed (10 μl) by HPLC.

AFB1 and its metabolites were separated by HPLC using a reverse-phase Supercosil LC-18 column (250×4.6 mm), a flow rate of 1 ml/min, and were detected at 362 nm with photodiode array UV detector (Waters Novapak). A ternary solvent system consisting of water/methanol/acetonitrile (60:20:20) was used to separate AFG1 (eluted at 10.6 min) and AFB1 (eluted at 14.6 min). Separation of OTA was achieved with an acetic acid/methanol/acetonitrile (1/49/49) solvent system, at a flow rate of 1 ml, and monitoring at 333 nm. OTA eluted at 10.4 min.

Statistics All data were analyzed by using a one-way ANOVA with a post-hoc Tukey test at a significance level of $P<0.05$.

Results

Aflatoxin B1 And Ochratoxin A Toxicity to NOW Larvae *Amyelois transitella* larvae tolerated high dietary levels of AFB1, with concentrations of 1, 5, 10, and 20 μg/g AFB1 having no apparent toxic effect on 1st instars (Table 1). In diets containing 10 and 20 μg/g AFB1, pupation rates were 77% and 78%, respectively. These did not differ significantly from pupation rates on control DMSO diet, and there was no significant difference in pupal weights between diets containing 10 and 20 μg/g AFB1 and control diets. On the diet containing 50 μg/g AFB1, larval development was delayed and only 55% of the larvae successfully pupated, a rate significantly lower than the rate with the control diet ($P<0.05$). At the extremely high AFB1 concentration of 100 μg/g, development of 1st instar *A. transitella* was severely inhibited; however, 30% of the treated larvae survived for at least 3 weeks. Exposure of later stage larvae to diets containing varying concentrations of AFB1 showed that their tolerance to AFB1 increased with developmental stage; ultimate instars tolerated 100 μg/g AFB1 with no significant decreases in pupation rate compared to control larvae fed diets containing 0.5% DMSO (Table 2).

Similarly, *A. transitella* 1st instars also were tolerant of OTA, with concentrations less than 10 μg/g having no detectable toxic effect (Table 3). At higher OTA concentrations (20 μg/g), there were no significant differences in mortality rates or larval weight after 14 days. Compared with control larvae fed diets with 0.25% DMSO, *A. transitella* fed with the highest concentration of OTA (50 μg/g) experienced slight effects on development, as evidenced by lower larval weights; larval weights after 14 days were significantly lower than those fed control diet ($P=0.047$). The highest concentration of OTA (50 μg/g) did not lower the pupation rate (Table 3).

Comparison of OTA and AFB1 Toxicity of to CEW and NOW The toxicity of AFB1 in *A. transitella* and *H. zea* was measured to compare the effect of AFB1 on 1st instars. The LC_{50} for AFB1 *A. transitella* (defined as the concentration preventing 50% of newly hatched larvae from molting to 2nd instar within 48 h) is 100 times greater for than for *H. zea* (Fig. 1). After 48 h, 60 ng/g AFB1 allowed 50% of 1st instar *H. zea* to develop into 2nd instars, while 10 μg/g AFB1 allowed 80% of 1st instar *A. transitella* to develop to 2nd instars—a greater than 100-fold difference in tolerance.

Table 1 Pupation rate and pupal weight of *Amyelois transitella* larvae after exposure to different concentrations of aflatoxin B1 (in 0.5% DMSO) at 1st instar. Values for pupation rate are means ± SE from 20 1st instar caterpillars/treatment with 3 experimental replicates for each. Values for pupal weight are representative of one of the 3 series of replicates and are means with SE

Concentration (μg/g)	Pupation rate (%)	Pupal weight (mg)
0.5% DMSO	85±6	43±2
1	90±5	44±2
5	85±6	45±2
10	77±9	45±2
20	78±2	44±3
50	55±10[a]	40±5
100	0	0

[a] Indicates that the mean value of this group is significantly different from that of the control group (0.5% DMSO) ($P<0.05$)

Table 2 Toxicity of aflatoxin B1 to ultimate (5th) instar *Amyelois transitella.* Values for pupation rate are means ± SE from 20 ultimate instars/treatment with 3 experimental replicates for each. Values for larval and pupal weight are representative of 1 of the 3 series of replicates and are means with SE. The data were evaluated with one-way analysis of variance (ANOVA), and no differences were found in the means of pupation rate or pupal weight among the groups

Concentration (μg/g)	Pupation rate (%)	Pupal weight (mg)
plain diet	97±6	41±4
0.5% DMSO	98±3	38±3
50	92±10	38±4
100	93±3	39±4

Table 3 Toxicity of ochratoxin A to 1st instar larvae of *Amyelois transitella.* Values for survival rate are means ± SE from 3 replicate bioassays. Values for larval and pupal weight are representative of one of the three series of replicates and are means with SE.

Concentration	Survival rate on day 12 (%)	Larval weight on day 14 (mg)	Pupation rate (%)
Plain diet	90±10	38±2	90±7
0.25%	85±5	36±2	75±4
1	80±10	32±9	80±7
5	85±5	33±3	83±5
10	85±10	35±5	75±4
20	90±5	33±2	78±2
50	80±5	26±6[a]	75±4

[a] Indicates that the mean value of this group is significantly different from that of the control group (0.5% DMSO) ($P<0.05$)

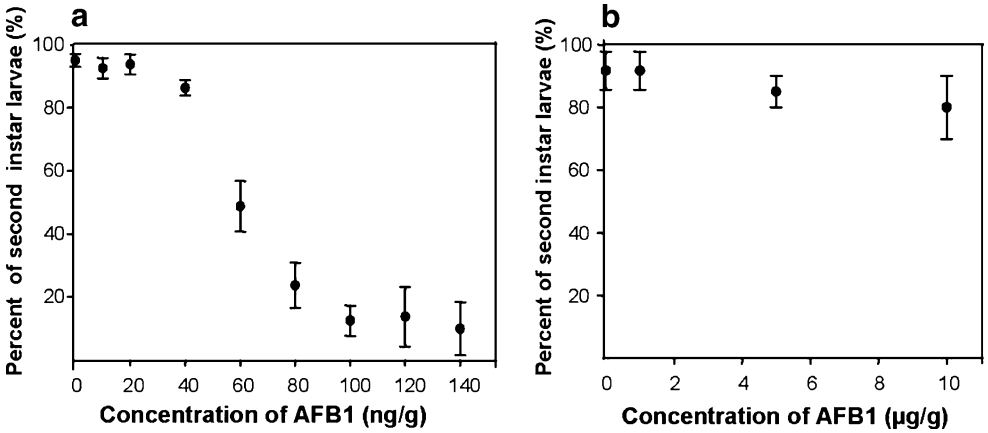

Fig. 1 Developmental effects of AFB1 on 1st instar *Helicoverpa zea* and *Amyelois transitella*. **a** Percentage of *H. zea* larvae molting to 2nd instar after 48 h on diets containing increasing concentrations of AFB1 and a final concentration of 0.2% DMSO. **b** Percentage of *A. transitella* larvae molting to 2nd instar after 48 h on diets containing increasing concentrations of AFB1 and a final concentration of 0.5% DMSO

Comparisons of the toxicity of OTA to *A. transitella* and *H. zea* also revealed considerably greater resistance to OTA in *A. transitella*. Development of 1st instar *A. transitella* was not affected by concentrations as high as 1 and 5 µg/g OTA. These concentrations significantly inhibited the development of 1st instar *H. zea* compared with control larvae, with 10% or no 5th instars appearing after 10 days on 1 or 5 µg/g OTA-supplemented diets, and 40% 5th instars appearing on the 0.25% DMSO control diet (P= 0.032 or 0.015, respectively) (Fig. 2).

NOW Metabolism of AFB1 and OTA To investigate the ability of *A. transitella* to metabolize AFB1, *in vitro* metabolism experiments were conducted with cleared midgut lysates quantified based on total protein. In reactions initiated with NADPH (as outlined in Methods and Materials), two polar metabolites of AFB1 (Met1 with R_t=7.8 min and Met2 with R_t=8.0 min) were readily detected by HPLC analysis (data not shown). Compared with *H. zea* midgut lysates, *A. transitella* midgut lysates have higher turnover rates (32±4 pmol/min/mg total protein vs. 0 pmol/min/mg total protein). In contrast, CEW midguts show no activity toward AFB1 unless induced by prior exposure to coumarin and xanthotoxin (Niu et al. 2008).

In an attempt to trap reactive AFBO intermediates, mouse liver cytosol was added to some *in vitro* reactions, but no additional metabolite peaks were detected (data not shown). This finding is consistent with the suggestion that AFB1 is detoxified, and not bioactivated, as the result of hydroxylation by midgut proteins. Comparable reactions with OTA showed no OTA metabolism by *A. transitella* or *H. zea* lysates either at the level of substrate disappearance or metabolite production. The methods used in this analysis may have been insufficiently sensitive to detect metabolism; alternatively, both of these species may rely on detoxification in tissues other than midgut, or non-enzymatic means, to counter the toxic effects of this compound.

Discussion

Zeng et al. (2006) and Niu et al. (2008) studied the toxicity and metabolism of AFB1 by *H. zea*, a lepidopteran with tolerance to a broad range of phytochemicals but only limited tolerance to aflatoxins even though it occasionally encounters aflatoxin-releasing fungi. In contrast, *A. transitella*, a herbivore that specifically locates and feeds on unharvested fruits, is tolerant of extremely high concentrations of mycotoxins in its diet. Our studies indicate that *A. transitella*, although a hostplant generalist, may well be highly specialized for mycotoxin detoxification. Indeed, recent studies indicate that NOW grows better on fungus-contaminated hostplant tissue and in fact may consume fungal tissue as well (Palumbo et al. 2008; personal observations).

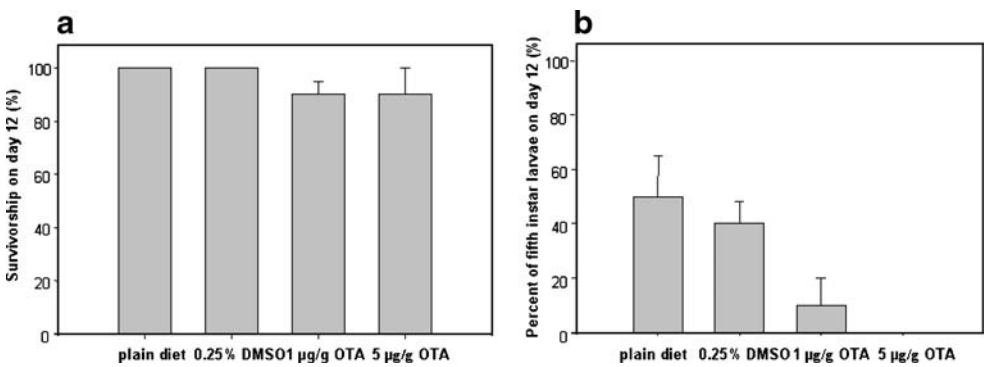

Fig. 2 Toxicity of OTA to 1st instar larvae of *Helicoverpa zea*. **a** Survivorship of larvae 12 days post-hatch on diets containing increasing concentrations of OTA and a final concentration of 0.25% DMSO. **b** Frequency of 5th instar larvae 12 days post-hatch on diets containing 0.25% DMSO, 1 µg/g OTA, or 5 µg/g OTA

In this study, we demonstrated the extremely high tolerance of *A. transitella* to concentrations of AFB1 and OTA and showed that this tolerance exceeds that of other mycotoxin-associated species such as *H. zea*. The concentrations analyzed did not kill *A. transitella* when administered at early developmental stages and caused only marginal sublethal effects. Comparisons of the toxicological effects in *A. transitella* and *H. zea* demonstrated that *A. transitella* larvae are 100 times more tolerant of AFB1 than *H. zea* and also are significantly more resistant to OTA. The ecological consequences of this tolerance are apparent in the high survival rates of *A. transitella* larvae in the mycotoxin-contaminated environments that it exploits as a scavenger. The interaction between NOW and *Aspergillus* species might be mutualistic in that the fungus may contribute to maintaining a micro-environment that optimizes caterpillar growth and development, and the caterpillar may promote the dispersal and establishment of the fungus by causing damage that allows fungal spores to gain access to fruits (Weis 1982). *Aspergillus* species can be cultured from adults, and the levels are high in adults emerging from *Aspergillus*-infested substrate (JS, unpublished data).

Aflatoxin tolerance might be explained by an excess detoxification capacity that generates nontoxic metabolites. Both Lee and Campbell (2000) and this study demonstrated that bioactivated metabolites are not produced in the reactions of NOW proteins. Because AFBO production increases toxicity 100-fold compared to its parent compound (AFB1) (Eaton and Gallagher 1994; McLean and Dutton 1995; Guengerich et al. 1998; Suriawinata and Xu 2004), absence of AFBO production by NOW might be a key feature of AFB1 tolerance. In contrast with AFB1, there are no reports of insect detoxification of OTA. Although we failed to detect metabolites of OTA produced by midgut proteins of either *H. zea* or *A. transitella*, bioactivation is involved in its genotoxicity to other organisms (Manderville 2005; Schaut et al. 2008), and the absence of major pathways that produce bioactivated metabolites also may reflect adaptation of these insects to the presence of this mycotoxin in their diet.

Acknowledgments We thank Dr. Rensen Zeng and Dr. Zhimou Wen for advice and assistance in the design, execution, and analysis of bioassays. Also, we thank Allen Lawrance for assistance with colony maintenance. This project was funded by a grant from the Almond Board of California (ABC-C6480).

mitochondria, which resulted in production of two new isoprenoids and enhanced attraction of carnivorous predatory mites (*Phytoseiulus persimilis*) (Kappers et al., 2005). We have set out to modify the glucosinolate profile in *A. thaliana* in order to study tritrophic interactions between the plant, an insect pest (*Brevicoryne brassicae*) and its natural enemy, the braconid endoparasitoid (*Diaeretiella rapae*). Cruciferous plants (Brassicaceae) characteristically accumulate glucosinolates, a group of amino acid-derived secondary metabolites consisting of a β-thioglucose moiety, a sulfonated oxime, and a variable side chain. Together with endogenous myrosinase (β-thioglucoside glucohydrolase, 3.2.1.147) glucosinolates serve a central role in defense against herbivores and pathogens (Wink, 1988; Jander et al., 2001; Kliebenstein et al., 2005a, b). Tissue damage brings together myrosinase and glucosinolates, which are otherwise spatially separated (Kelly et al., 1998) yielding a variety of toxic hydrolysis products (Fig. 1), such as isothiocyanates, epithionitriles, thiocyanates, and nitriles (Bones and Rossiter, 1996, 2006; Halkier and Gershenzon, 2006).

The myrosinase-glucosinolate system is an effective defense against many generalist insect herbivores. However, specialist crucifer-feeding insects have evolved counter adaptive biochemical mechanisms to overcome this defense. This is achieved, in the larvae of the cabbage white butterfly, *Pieris rapae* (Wittstock et al., 2004), and the diamondback moth, *Plutella xylostella* (Ratzka et al., 2002), through different types of detoxification mechanisms. Other insect herbivores, including larvae of the turnip sawfly, *Athalia rosae* (Muller et al., 2001), the harlequin bug, *Murcantia histrionica* (Aliabadi et al., 2002), as well as the cabbage aphid, *Brevicoryne brassicae*, and the turnip aphid, *Lipaphis pseudobrassicae* (= *L. erysimi*) (Bridges et al., 2002; Kazana et al., 2007) appear to tolerate glucosinolates, and actually sequester these compounds from their host plants. Sequestration of glucosinolates provides these insects with a defense against potential natural enemies. In the two species of aphid, a myrosinase, distinct from plant myrosinase, has evolved, resulting in a defense that mimics that of their host plants, with the production of isothiocyanates following tissue damage (Jones et al., 2001, 2002; Bridges et al., 2002; Husebye et al., 2005). Isothiocyanates provide both a direct, toxic, defense against potential natural enemies (Francis et al., 2001), and an indirect defense by synergizing the response of aphids to the alarm pheromone, *E*-β-farnesene (Dawson et al., 1987). Despite this defense, both *B. brassicae* and *L. pseudobrassicae* are subject to attack by a range of natural enemies, such as insect parasitoids, which also apparently are adapted to toxic glucosinolate hydrolysis products (Bridges et al., 2002).

Exploitation of the cruciferous plants' myrosinase-glucosinolate defense by *B. brassicae* is not restricted to glucosinolate accumulation. Volatile cues, in the form of isothiocyanates are also utilized by the aphid in host-plant location (Nottingham et al., 1991). Similarly, several studies have shown that the braconid wasp, *D. rapae*, a solitary endoparasitoid of aphids that feed on crucifers, is able to exploit glucosinolate hydrolysis products as olfactory cues in host foraging behavior. These olfactometry studies recorded positive behavioral responses of female parasitoids to several species of *Brassica* experimentally infested with aphids, including cabbage (*Brassica oleracea*) (Reed et al., 1995), turnip (*Brassica rapa* var *rapifera*) (Blande et al., 2007), and collard (*Brassica oleracea*) (Read et al., 1970), as well as the model crucifer *A. thaliana* (Girling et al., 2006). Additional olfactometry experiments, using glucosinolate hydrolysis products in place of aphid infested plants identified isothiocyanates as important signaling chemicals (Read et al., 1970; Reed et al., 1995; Vaughn et al., 1996; Bradburne and Mithen, 2000; Blande et al., 2007). Air entrainments further confirmed that higher levels of isothiocyanates were produced by aphid infested turnip plants compared with uninfested plants, and the ability of *D. rapae* females to discriminate between these two odor sources (Blande et al., 2007). Interestingly, parasitoids were not able to discriminate between plants infested with the specialist *L. pseudobrassicae* or the generalist *Myzus persicae*, despite the fact that once the aphid host is located, *D. rapae* attacks the crucifer-specialist at a greater rate than the generalist (Blande et al., 2004).

Tritrophic interactions are inherently complex, and the impact of specific compounds is often difficult to discern (Burow et al., 2006; Barker et al., 2007). Plants that differ in their glucosinolate or glucosinolate hydrolysis profile may also differ in other ways, such as the presence of other deterrents, stimulants, or synergists, leaf morphology, or nutritional content (Nielsen et al., 2001). These concerns may be addressed partly through the use of pure compounds and artificial diets, although this approach is less successful in defenses where toxic compounds are formed

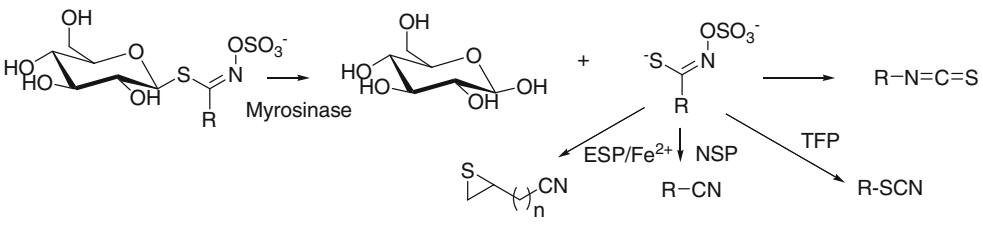

Fig. 1 Glucosinolate hydrolysis pathway. ESP: epithiospecifier protein; TFP: thiocyanate forming protein; NSP: nitrile-specifier protein

from inactive precursors, such as in the myrosinase-glucosinolate system (Wittstock et al., 2003).

The genetic characterization of model plants such as *A. thaliana* offers a potentially powerful tool with which to assess the importance of specific compounds in both bitrophic and tritrophic interactions. This approach has been applied to investigate the indirect roles of signaling pathways (Mewis et al., 2006) and a novel calmodulin-binding protein (Levy et al., 2005) on insect herbivory through their impacts on glucosinolate levels, while other studies have looked at the effects of elevated glucosinolate levels (Nielsen et al., 2001). A number of studies have focused on glucosinolate hydrolysis and the impact of epithiospecifier protein (ESP) (Jander et al., 2001; Lambrix et al., 2001; Burow et al., 2006) and the associated epithiospecifier modifier1 (ESM1) (Zhang et al., 2006). Other studies have focused on the functional significance of the myrosinase part of this defense (Barth and Jander, 2006).

There have been few studies looking at the impact of modifying the glucosinolate profile by transgenic methodology on plant-herbivore interaction, although recently the effect of overexpressing the dioxygenase AOP2 in Col-0 on a generalist pest was determined (Hansen et al., 2008). Variation in methionine-derived aliphatic glucosinolate side-chain modification in *A. thaliana* is controlled by the *GS-AOP* locus, which has three alleles that produce methylsulfinylalkyl (*GS*-null), alkenyl (*GS-ALK*), or hydroxyalkyl (*GS-OHP*) side-chains (Kliebenstein et al., 2001b, 2005a). The functional alleles code for 2-oxoglutarate-dependent dioxygenases that determine the nature of the aliphatic glucosinolate profile by converting the methylsulfinylalkyl functionality to alkenylglucosinolates (AtAOP2) or to hydroxyalkylglucosinolates (AtAOP3). The Columbia (Col) ecotype, however, does not possess a functional *GS-AOP*, and consequently accumulates 4-methylsulfinylbutylglucosinolate. Thus, by overexpressing a 2-oxoglutarate dependant dioxygenase in Col-5, it is possible to switch the plant from a methylsulfinylalkylglucosinolate producer to one with alkenylglucosinolates (Fig. 2). Here, we present responses of the crucifer specialist, *B. brassicae* and its natural enemy, *D. rapae*, to wild-type Col-5 plants and to Col-5 plants transformed with a functional *AtAOP2* ortholog from *Brassica nigra* (*BniGSL-ALK*). We also compare the response of the parasitoid to the *A. thaliana* ecotype Ru-0, which produces 2-propenylisothiocyanate.

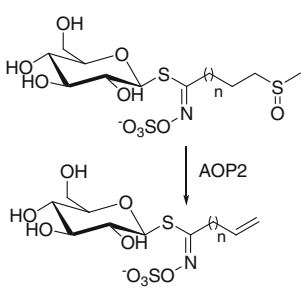

Fig. 2 Biosynthesis of the alkenyl glucosinolates from the methylthioalkyl precursor. AOP2: 2-oxoglutarate dependent dioxygenase

Methods and Materials

Plant Material and Growth Conditions Seeds of the *Arabidopsis thaliana* (L.). Heynh. ecotypes Col-5 and Ru-0 were obtained from the Nottingham Arabidopsis Stock Centre (NASC). Seeds were sown on wet soil (Levington F2 compost:vermiculite; 4:1) and cold treated for 2 d at 4°C to get homogenous germination. Seedlings were pricked out 2 wk after cold treatment and transferred to individual 40×40×50 mm plastic plant cells. Plants were grown under short day conditions in a controlled environment chamber (12 h light: 12 h dark regime, 100–150 µmol $m^{-2}s^{-1}$ during light period; 22°C during light and 20°C during dark).

Cloning of an Ortholog of the Arabidopsis thaliana 2-oxoglutarate Dependent Dioxygenase 2 (AtAOP2) from Brassica nigra An ortholog of the *A. thaliana* gene coding for the 2-oxoglutarate dependent dioxygenase 2 (*AtAOP2; At4g03060*) was cloned from *B. nigra* (L.) Koch genomic DNA by PCR using *Pwo* DNA polymerase (Roche Applied Science) according to the supplier's instructions. We named this ortholog *BniGSL-ALK*.

The oligonucleotide primers (MWG Biotech, Ebersberg, Germany) used for amplification of *BniGSL-ALK* were designed on published sequences from *Brassica oleracea*: the genomic DNA sequence *BoGSL-ALK* (AY044425; Li and Quiros, 2003) and the corresponding region of clone B21H13 (AC122543). The sequence of the forward primer was 5'-*atcc***catg**ggtgcagacacttctcaacttc-3' (in bold: start codon; underlined: *Nco*I site; in italics: additional triplet of an *Eco*RV restriction site) and that of the reverse primer was 5'-gcgcacgtg**tta**tgctccagagacg-3' (in bold: stop codon; underlined: *Pml*I restriction site).

For cloning purposes, the environment of the original translation initiation site, contained in the forward primer, was changed to create an *Nco*I restriction site, and an additional 5'ATC-triplet of an *Eco*RV restriction site also was included. A *Pml*I restriction site was included in the reverse primer. The PCR amplified product was cloned into *Eco*RV- restricted pBluescript SK+and partially sequenced.

Ectopic Expression of BniGSL-ALK in Arabidopsis thaliana An *Nco*I/*Pml*I-restricted fragment containing *BniGSL-ALK* was excised from the pBluescript construct, inserted into the binary vector pCAMBIA3301, where it is under the

control of a CaMV35S promoter, and the integration sites of the insert were verified by sequencing. The *BniGSL-ALK* expression construct was transferred into *Agrobacterium tumefaciens* (strain GV3101) by electroporation (Sambrook et al., 1989). Transformation of *A. thaliana* with *A. tumefaciens* was performed according to the "floral dip method" (Clough and Bent, 1998). As the *bar* gene in the *BniGSL-ALK* expression construct confers phosphinothricin (Basta) resistance to transformed plants, seeds were sowed on soil wetted with a Basta solution and watered with this Basta solution every second day. Plantlets resisting this treatment were transferred to individual pots, watered subsequently without selection agent, and the presence of the transgene was verified by PCR analysis. For this purpose, DNA was extracted from leaves as described by Edwards et al. (1991).

RNA Extraction and Northern Blot Analysis Total RNA was extracted from leaves of 5 wk-old *A. thaliana* plants as described by Logemann et al. (1987). Ten µg of total RNA was fractionated on denaturing 1.5% formaldehyde agarose gels (Sambrook et al., 1989), and equal RNA loading was determined by ethidium bromide staining. The transfer of RNA to Hybond-N nylon membrane (GE Healthcare, Little Chalfont, UK) was done by capillary blotting (Sambrook et al., 1989). A 0.5 kb gel purified (QiaexII Kit, Qiagen, Crawley, UK) fragment generated by PCR amplification on the cloned *BniGSL-ALK* was used as probe. The labeling of the probe was performed with ^{32}P-dCTP (MP Biomedicals, UK) using the DecaLabel DNA Labeling Kit as indicated by the supplier (Fermentas, St. Leon-Rot, Germany). Hybridization was performed in Church buffer at 65ºC overnight (approximately 16 h), and washes were carried out once at 65ºC in 1xSSC, 0.1% SDS for 20 min, and once at 65ºC in 0.1xSSC, 0.1% SDS for 20 min. The Blot was exposed for a day to a BioMAX MS film (Kodak, Hemel Hempstead, UK).

Extraction of Glucosinolates Fully expanded leaves from 5 wk-old *A. thaliana* plants were collected and freeze dried. In the case of the analyzed transgenic line Col-5 (+*BniGSL-ALK*)-4, homozygous plants of the T3 generation were used. Leaf material was ground to a fine powder with a pestle and mortar, and 20 mg were used for the extraction of glucosinolates. The remainder of the extraction process was carried out as previously described (Heaney and Fenwick, 1993).

Analysis of Glucosinolates by HPLC Samples were analysed by high performance liquid chromatography (HPLC) on an Agilent 1200 series instrument equipped with a Phenomenex Luna 3 micron C18(2) (150×2 mm) column. Freeze dried plant tissue was extracted with boiling 80% methanol for 5 min, and the process repeated. At this stage, either 2-propenylglucosinolate or benzylglucosinolate was added as a standard. Combined supernatants were concentrated to dryness with nitrogen gas, and the residue was reconstituted in water (1 ml). A barium/lead acetate (Rossiter et al., 1990) solution (0.1 ml) was added to each sample and allowed to precipitate. After centrifugation, the extract was applied to a DEAE-A25 sephadex column and treated with desulfatase (Rossiter et al., 1990). Desulfoglucosinolates were separated by using a water-acetonitrile gradient (solvent A water, solvent B acetonitrile; 0 – 15 min 25 % B; 15–17 min 70 % B) at a flow rate of 0.2 ml min^{-1} and monitored at 229 nm. Retention times of known standards were used to identify desulfoglucosinolates, and sample peaks were confirmed by LC-MS. For mass spectrometry, an Applied Biosystems QTrap interfaced with APCI source was used. The source temp was set to 475°C, and the MS was run in the Enhanced Mass Spectrum mode scanning in the range 70–500 amu.

Extraction of Glucosinolate Hydrolysis Products Leaves of *A. thaliana* plants (100–200 mg of fresh weight) were crushed and incubated for 10 min at room temperature. The homogenate was extracted with dichloromethane (4 ml), dried with anhydrous $MgSO_4$, centrifuged, and the organic phase concentrated to approximately 200 µl under a flow of nitrogen.

Analysis of Glucosinolate Hydrolysis Profile by GC-MS The dichloromethane extracted glucosinolate hydrolysis products were analyzed by Gas Chromatography-Mass Spectrometry (GC-MS) on a Hewlett-Packard 6890 gas chromatograph linked to a 5973 mass selective detector. Injections were made onto an HP-5MS 5% Phenylmethylsiloxane (30 m×0.25 mm × 0.25 µm) column in the pulsed split (20:1) mode using the following temperature program: inlet temp 225°C; initial temperature 40°C, 5 min; 5°C min^{-1} until 180°C; 10°C min^{-1} until 280°C; hold for 10 min. All compounds were identified by using standards and by their mass fragmentation patterns (Spencer and Daxenbichler, 1980).

Insect Cultures The crucifer specialist aphid *Brevicoryne brassicae* (L.) was maintained at 18°C, with a 16/8 h L/D photoperiod. Aphids were cultured on individual 4 wk-old *Brassica nigra* plants, each plant being enclosed within a perforated bread bag. Aphids were transferred to fresh plants every 1–2 wk.

The aphid parasitoid *Diaeretiella rapae* (McIntosh) (obtained from Rothamsted Research, Harpenden, UK) was maintained at 23°C (16 h light) and 18°C (8 h dark). Standardized cohorts of parasitoids were produced by allowing mated 2–3 d-old adult insects to parasitize mixed

age *B. brassicae* in a Petri dish for approximately 2 h. Parasitized aphids then were transferred to a fresh *B. nigra* plant (unless otherwise stated) on which they continued to feed. Aphid mummies were removed from these plants approximately 8 d later so that on emergence parasitoids were not provided with cues that might influence behavioral responses. Adult male and female parasitoids were kept together, and mating was assumed. Adult parasitoids were provided with a dilute honey solution, and females were used in the bioassays approximately 72 h after emergence.

Aphid Mean Relative Growth Rate Bioassays Young (<24 h-old) *B. brassicae* nymphs were collected from *B. nigra* plants. Each nymph was weighed (MX5, Mettler-Toledo, Greifensee, Switzerland) and transferred individually to a 5 wk-old *A. thaliana* plant. Each plant then was covered with a perforated bread bag and maintained for 5 d at 18°C with a 16/8 h L/D photoperiod. Each aphid then was reweighed and returned to the same plant. The mean relative growth rates (MRGR) were calculated using the following equation:

$$MRGR = (\ln(W_1) - \ln(W_0))/d$$

where W_1=end weight (mg), W_0=start weight (mg) and d= development time (days) (Castle and Berger, 1993).

Comparisons of MRGR values of *B. brassicae* reared either on *A. thaliana* ecotype Col-5 or the Col-5 transgenic line expressing a functional 2-oxoglutarate dependent dioxygenase (*BniGSL-ALK*) were made. Statistical analysis of the MRGR values was completed using unpaired *t*-tests (Genstat 6th Edition).

Olfactometry A Y-tube olfactometer, of the design previously described by Du et al. (1996) was used to record behavioral responses of female *D. rapae* to *A. thaliana* plants infested with *B. brassicae*. A glass Y-tube olfactometer was used, which had 12 mm internal diameter, 100 mm stem and 100 mm arms at 60° angle. Air was pumped through Teflon tubing by a Dymax30 pump (Charles Austen Pumps Ltd., Byfleet, Surrey, UK) through an activated charcoal filter before being regulated by a flowmeter to 800 ml/min. The airflow then was split by a brass T-junction (Swagelok, OH, USA), each flow of 400 ml/min then passing into an airtight glass chamber (T. Westlake — Artistic & Scientific Glassblower, Kidlington, Oxfordshire, UK) into which the volatile source was placed. From the two glass chambers, air flowed through additional Teflon tubing into the arms of the olfactometer via modified glass quick fit sockets. A white cardboard screen was placed around the olfactometer, in order to exclude any visual cues, and lighting was provided by a fluorescent strip held 300 mm above and 100 mm in front of the branches of the olfactometer. A single female *D. rapae* was introduced into the stem of the olfactometer and then given 5 min to make a choice. During this period, if the parasitoid failed to move more than 50 mm up the stem of the olfactometer, it was excluded from the experiment. Parasitoids were recorded as having selected an odor if the insect moved more than 50 mm up one of the arms and remained beyond this point for more than 30 sec. Insects that moved more than 50 mm up the stem but did not select an arm of the olfactometer were recorded as not having selected an odor. After each individual was tested, the position of the odor sources was swapped in order to account for any directional bias by the parasitoids. These criteria are similar to those previously described (Girling et al., 2006; Blande et al., 2007). Glassware was washed with acetone and distilled water and then baked overnight at 200°C.

In the following two experiments, two 5 wk-old (3 wk after pricking out) *A. thaliana* plants were presented as odor sources. Responses of naïve *D. rapae* females to *A. thaliana* ecotypes Ru-0 and Col-5 and the transgenic line Col-5 (+*BniGSL-ALK*)-4 were recorded. In both experiments, responses of naïve female parasitoids were recorded to a *B. brassicae* infested plant and an uninfested plant of the same ecotype/transgenic line. In each experiment, responses were recorded from two ecotypes/transgenic lines in this way. A final comparison was completed by taking the aphid infested plant of each ecotype/transgenic line and presenting these opposite each other. In an initial experiment, naïve *D. rapae* were reared on *B. brassicae*, which in turn were reared on *B. nigra*. *B. brassicae* used to infest Ru-0 or Col-5 plants in this experiment were previously reared on the corresponding ecotype. In a second experiment, naïve *D. rapae* were reared on *B. brassicae*, which in turn were reared on Col-5. *B. brassicae* used to infest Col-5 or transgenic plants in this experiment were previously reared on the corresponding ecotype or transgenic line. For each comparison, plants were replaced after every 10 or 15 replicates. Each plant was either left uninfested or infested with approximately 100 *B. brassicae* (mixed age) for approximately 72 h before completing the bioassay. Naïve female parasitoids, produced as previously described, were used in bioassays.

Chi-square values were used for statistical analysis of numbers of parasitoids responding to each odor source.

Air Entrainments For air entrainments of *B. brassicae* infested *A. thaliana* plants, plants were grown as described above. However, 2 wk after being sown, seedlings were pricked out into the center of 60 mm diam pots. A plastic sheath (5 mm diam) then was carefully placed around each seedling. Seedlings were allowed to continue to grow under the same conditions for a further 3 wk. Approximately 100

mixed age *B. brassicae*, previously reared on the corresponding *A. thaliana* ecotype or transgenic line, were transferred onto a test plant. Three days later, a glass vessel (60 mm diam) was placed around the plant. The vessel was in two parts and was held together with clips, clamping around the plastic sheath that protected the hypocotyl of the plant. Charcoal filtered air was pumped into the vessel at 300 ml min^{-1} through polytetrafluoroethylene (PTFE) tubing (1.6 mm inner diam). Air was drawn out of the vessel at 200 ml min^{-1} through a separate outlet, thereby creating a positive pressure within the vessel and preventing atmospheric air from entering. Air entrainments were completed within a growth chamber set to 12 h light, 150 µmol $m^{-2}s^{-1}$, 65% relative humidity, and constant 20°C. Volatiles were trapped onto Tenax TA (50 mg, mesh 60–80, Supelco, Bellefonte, PA, USA) held in injector liners by plugs of silanized glass wool. Before use, liners were first washed with 2 ml of redistilled diethyl ether before being thermally desorbed at 200ºC under a flow of helium. Tenax TA filled liners were fitted to both the inlet (providing an extra layer of filtration of air entering the vessel) and outlet of each glass vessel. Volatiles were trapped onto the Tenax TA for a period of 4 h. The liners were then thermally desorbed by using an Optic 2 programmable injector (Anatune, Cambridge, UK) connected to a Hewlett Packard 6890 Series gas chromatograph fitted with a Hewlett Packard 5973 mass selective detector (GC-MS). Injector conditions were equilibrated for 30 sec and then ramped from 50 to 200ºC at 16°C s^{-1}. An HP-5MS column (30 m× 0.25 mm × 0.25 µm) was used. The carrier gas was helium (constant flow 30 cm s^{-1}). Initial oven temperature was 50°C held for three min, then ramped to 200ºC at 10ºC min^{-1} and held for a further 2 min.

A comparison of volatile chemicals emitted by the *A. thaliana* ecotype Col-5, the Col-5 (+*BniGSL-ALK*)-4 transgenic line, and the ecotype Ru-0 when infested with approximately 100 mixed age *B. brassicae* (previously reared on the corresponding ecotype or transgenic line) or left uninfested was completed.

Results

Altering the Glucosinolate Profile of the Arabidopsis thaliana Accession Col-5 by Expressing the Dioxygenase BniGSL-ALK A homolog from *Brassica oleracea*, called *BoGSL-ALK*, also has been cloned and characterized previously (Li and Quiros, 2003). We cloned a *Brassica nigra* gene that encodes a putative polypeptide that shows over 90% and about 60% sequence similarity to BoGSL-ALK and AtAOP2, respectively (data not shown). By analogy to *BoGSL-ALK*, we called this gene *BniGSL-ALK*. We expressed it under the control of a CaMV35S promoter in the *A. thaliana* ecotype Col-5, where the predominant glucosinolate in rosette leaves is 4-methylsulfinylbutylglucosinolate (Table 1). As expected, the glucosinolate content of rosette leaves of the transgenic plants expressing *BniGSL-ALK* [called hereafter Col-5 (+*BniGSL-ALK*)] differed qualitatively from the glucosinolate content of the wild-type Col-5 plants. A positive correlation between the transgene expression level and the degree of change of the glucosinolate profile (data not shown) was observed in all characterized independent primary transformants. The glucosinolate profile of rosette leaves of the T3 progeny of the high transgene expression line Col-5 (+*BniGSL-ALK*)-4 is shown in Table 1. It lacked the short-chain methylsulfinylalkylglucosinolates characteristic of the wild-type Col-5 completely, and contained primarily 3-

Table 1 The concentrations of glucosinolates in rosette leaves of five week old Col-5 and Col-5 (+ *BniGSL-ALK*)-4 plants. It was not possible to measure 6-methylsulfinylhexyl-glucosinolate* in the transgenic plant as it co-runs with 3-butenyl glucosinolate. Values are reported as the mean±SE (n=3). 2-Hydroxybut-3-enylglucosinolate is the sum of the *R* and *S* forms

Total	17.83	28.01

butenylglucosinolate and 2-hydroxybut-3-enylglucosinolate and to a lesser extent 2-propenylglucosinolate. Transgenic plants maintained at least wild-type levels of the longer chain methylsulfinylalkylglucosinolates (Table 1). Of the two indolylglucosinolates detected in rosette leaves of both the wild-type Col-5 and the transgenic line, only the levels of indol-3-ylmethylglucosinolate were significantly higher in the latter (Table 1) by a factor of 1.6. Aliphatic glucosinolate and total glucosinolate content in rosette leaves were also higher in the transgenic line compared with wild-type Col-5 (Table 1).

As Col-5 does not possess a functional epithiospecifier protein (ESP) (Lambrix et al., 2001; de Torres Zabala et al., 2005) both the wild-type and the Col-5 (+*BniGSL-ALK*) transgenic lines produce isothiocyanates upon hydrolysis of rosette leaves. Consequently, the hydrolysis profile of the transgenic line Col-5 (+*BniGSL-ALK*)-4 gave the expected 2-propenylisothiocyanate, 3-butenylisothiocyanate, and 5-vinyloxazolidine-2-thione that correspond to the modified glucosinolate profile. The hydrolysis profiles of both wild-type Col-5 and of the transgenic line Col-5 (+*BniGSL-ALK)*)-4 are shown in Fig. 3A and 3B.

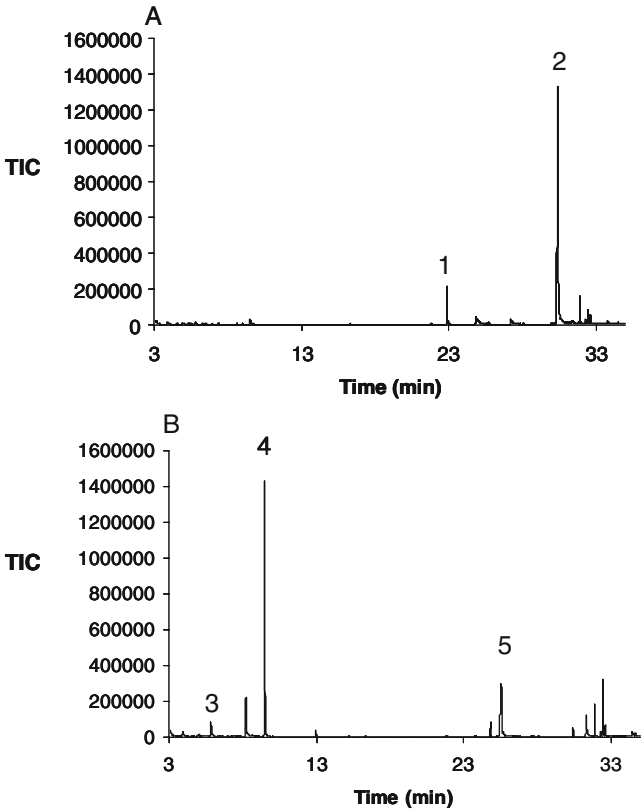

Fig. 3 Glucosinolate hydrolysis products from rosette leaves (5 wk-old) of; **a** wild-type Col-5, peak 1=methylthiobutylisothiocyanate, 2=4-methylsulfinylbutylisothiocyanate **b** transgenic line Col-5 (+*BniGSL-ALK*)-4, peak 3=2-propenylisothiothiocyanate, peak 4=3-butenylisothiocyanate, peak 5=5-vinyloxazolidine-2-thione, analysed by GC-MS. TIC=total ion current

Aphid Mean Relative Growth Rate Bioassays The mean relative growth rate (MRGR) of *B. brassicae* (Fig. 4) was significantly lower when feeding on Col-5 plants transformed with a gene encoding a functional 2-oxoglutarate dependent dioxygenase (*BniGSL-ALK*), compared with wild-type Col-5 plants (t=2.44, P=0.025). This difference corresponds to an increased weight gain of approximately 0.03 mg for aphids feeding on wild-type Col-5 plants compared to aphids feeding on the transgenic Col-5 (+*BniGSL-ALK*)-4 plants during the five-day period of this experiment. It was subsequently recorded that aphids took approximately 0.5 days longer to complete development when feeding on transgenic Col-5 (+*BniGSL-ALK*)-4 plants compared to Col-5 wild-type plants.

Air Entrainments Col-5 plants infested with *B. brassicae* produced no detectable quantities of glucosinolate-derived volatile chemicals (data not shown). However, from air entrainments of plants of the transgenic line Col-5 (+*BniGSL-ALK*)-4 infested with *B. brassicae*, relatively large amounts of 3-butenylisothiocyanate were identified (Fig. 5A, chromatogram a) with a trace of 2-propenylisothiocyanate. In the uninfested line, only a trace amount of 3-butenylisothiocyanate was detected (Fig. 5A, chromatogram b). The *Arabidopsis* ecotype Ru-0 infested with *B. brassicae* produced 2-propenylisothiocyanate (Fig. 5B, chromatogram c), while the uninfested plant produced no detectable isothiocyanate (Fig. 5B, chromatogram d).

Olfactometry Two experiments were carried out to evaluate the response of the parasitoid *D. rapae* towards *B. brassicae* infested and uninfested plants with different

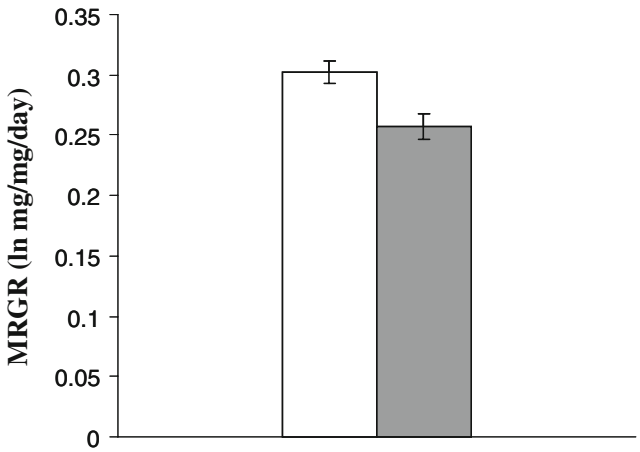

Fig. 4 Mean relative growth rate (MRGR) of individual *Brevicoryne brassicae* confined to single *Arabidopsis thaliana* Col-5 or Col-5 (+*BniGSL-ALK*)-4 plants (Mean±SE, n=15). White bars=Col-5; Grey bars = Col-5 (+*BniGSL-ALK*)-4

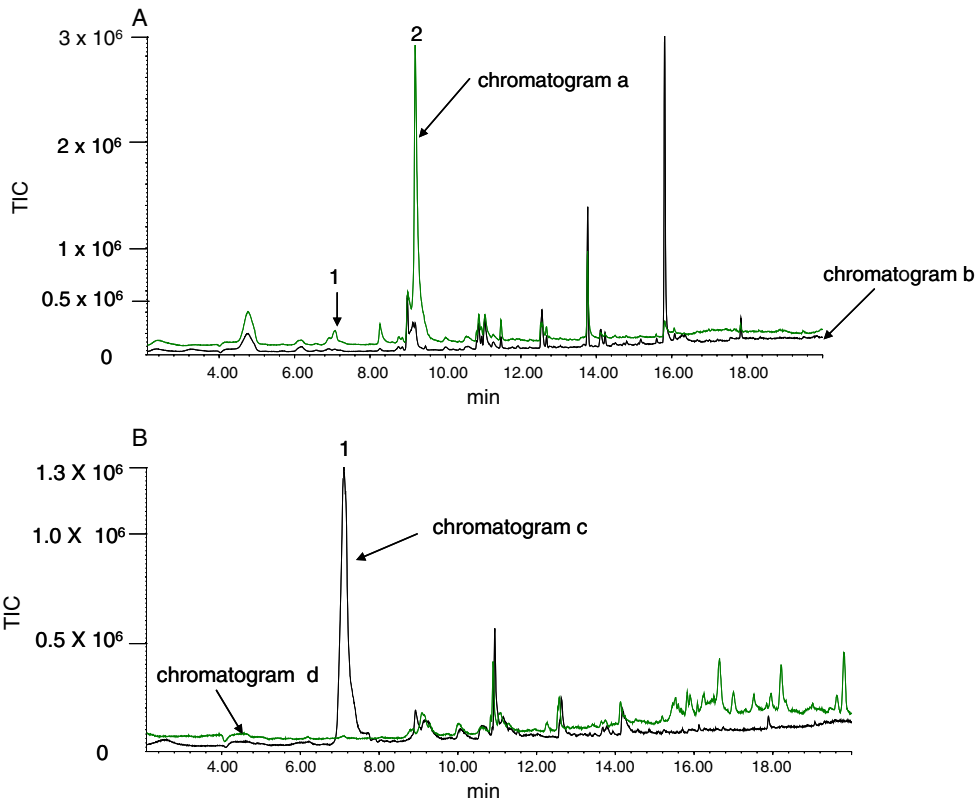

Fig. 5 Air entrainments of (A) transgenic Col-5 (+*BniGSL-ALK*)-4 plants infested with *Brevicoryne brassicae* (trace a) and uninfested (trace b); (B) ecotype Ru-0 infested with *B. brassicae* (trace c) and uninfested (trace d). Plants (5 week old) were exposed to 100 aphids and volatiles were collected 72 h post infestation. Glucosinolate hydrolysis products were analysed by GC-MS. Peak 1=2-propenylisothiothiocyanate, peak 2=3-butenylisothiocyanate. TIC=total ion current

glucosinolate profiles. Results from these experiments indicate that naïve female parasitoids discriminate between aphid infested and uninfested Ru-0 or the transgenic Col-5 (+*BniGSL-ALK*)-4 plants, with *D. rapae* females showing a preference for aphid infested plants. By contrast, *D. rapae* females did not discriminate between aphid infested and uninfested Col-5 plants (Figs. 6A and 6B). When both a *B. brassicae* infested Ru-0 and Col-5 plant were presented as an odor source, parasitoids were again able to discriminate between the odor sources (Fig. 6A). However, naïve *D. rapae* females did not discriminate between aphid infested Col-5 and Col-5 (+*BniGSL-ALK*)-4 plants (Fig. 6B).

Discussion

In order to examine the effect of differing glucosinolate profiles and/or glucosinolate hydrolysis profiles on the crucifer specialist, *B. brassicae*, and its natural enemy, the parasitoid, *D. rapae*, we created transgenic *A. thaliana* lines that overexpress a gene from *B. nigra* encoding a dioxygenase. *B. nigra* accumulates 2-propenylglucosinolate (Cole, 1976) indicating the presence of a functional *AtAOP2* ortholog whose expression in the *A. thaliana* Col-5 background would be expected to result in a glucosinolate profile predominantly composed of 3-butenylglucosinolate. The glucosinolate profile of rosette leaves of transgenic plants that express *BniGSL-ALK,* the *AtAOP2* ortholog we cloned from *B. nigra,* differed from that of the wild-type Col-5 plants and contained the alkenylglucosinolates 3-butenylglucosinolate, 2-hydroxybut-3-enylglucosinolate, and 2-propenylglucosinolate (Table 1). This shows that the *BniGSL-ALK* gene we cloned and transformed into the plant is functional and responsible for converting 4-methylsulfinylbutylglucosinolate and 3-methylsulfinylpropylglucosinolate into the respective alkenylglucosinolates. The transgenic Col-5 (+*BniGSL-ALK*) plants maintain concentrations of the longer chain methylsulfinylalkylglucosinolates (Table 1) suggesting that BniGSL-ALK is unable to catalyze the conversion of these glucosinolates.

The glucosinolate profile changes that we observed in the transgenic Col-5 (+*BniGSL-ALK*)-4 line are in accordance with an earlier report where the authors transformed the Columbia ecotype with *BoGSL-ALK*, a *Brassica oleracea* ortholog of *AtAOP2*, and observed the appearance of the same glucosinolates as we described above (Li and Quiros, 2003). The appearance of 2-hydroxybut-3-enyl glucosinolate in Col-5 (+*BniGSL-ALK*)-4 plants is probably not due to the enzymatic activity of the introduced dioxygenase but to that of another, recently identified dioxygenase (Hansen et al., 2008). The absence of 2-hydroxybut-3-enylglucosinolate in the wild-type Col-5 is

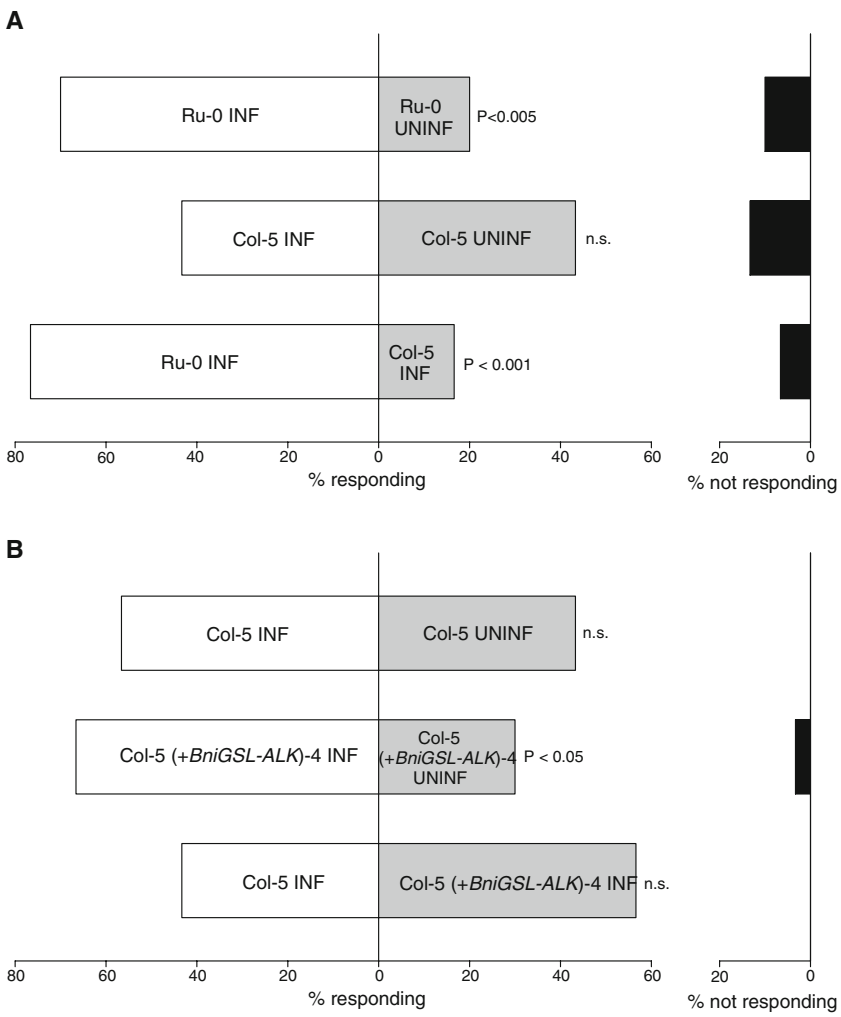

Fig. 6 (A) Responses of naïve *Diaeretiella rapae* females in a Y-tube olfactometer to Ru-0 or Col-5 plants either infested with *Brevicoryne brassicae* or uninfested using *D. rapae* reared on *B. nigra* (n=30); (B) Responses of naïve *Diaeretiella rapae* females in a Y-tube olfactometer to Col-5 or the transgenic line Col-5 (+*BniGSL-ALK*)-4 either infested with *B. brassicae* or uninfested using *D. rapae* reared on Col-5 (n=30); INF=infested, UNINF=uninfested, Col-5 (+*BniGSL-ALK*)=transgenic line expressing *BniGSL-ALK*

due to the absence of substrate (i.e., 3-butenylglucosinolate) as a consequence of the lack of a functional *AtAOP2*.

The fact that indol-3-ylmethylglucosinolate levels were slightly higher in the rosette leaves of the Col-5 (+*BniGSL-ALK*)-4 plants than in the wild-type Col-5 was unexpected. *AtAOP2* is involved in the side chain modifications of aliphatic glucosinolates, and no role in indolylglucosinolate biosynthesis has been reported (Kliebenstein et al., 2001b). Our results are, however, in accordance with a recent report describing a higher total amount of foliar indolylglucosinolate in *A. thaliana* lines that express *BoGSL-ALK* (Wentzell et al., 2007). In addition, we measured a higher total amount of glucosinolates in rosette leaves of the transgenic plants, which was largely due to an increase in aliphatic glucosinolates. In a survey of glucosinolate contents in 39 *A. thaliana* ecotypes, the *GS-AOP* locus (or closely linked loci) was revealed to control 61% of the variation in leaf aliphatic glucosinolates, and ecotypes with *GS-AOP*^{null} presented four times lower aliphatic glucosinolate concentrations than ecotypes with *GS-ALK* (Kliebenstein et al., 2001a). Wentzell et al. (2007) describe a doubling of total foliar aliphatic glucosinolate content in *A. thaliana* lines that express *BoGSL-ALK*. Expressing the *B. nigra* ortholog *BniGSL-ALK* in Col-5 seems to have a similar effect, although the increase in total foliar glucosinolate levels in our transgenic plants was less pronounced than in the above-mentioned study.

The crucifer specialist *B. brassicae* has developed a defense mechanism that allows it to sequester plant-derived glucosinolates (Francis et al., 2001; Kazana et al., 2007), but shows a reduced MRGR when fed on the transgenic Col-5 (+*BniGSL-ALK*)-4 plants compared to the wild-type Col-5. This could be a direct effect of the *BniGSL-ALK* expression, and can be explained by one or a combination of the glucosinolate related changes i.e., change in profile from methylsulfinylalkylglucosinolates to alkenylglucosinolates, increased amounts of indol-3-ylmethylglucosinolate, or increase in the total content of glucosinolates. Previous work with an *A. thaliana* mutant (*atr1D*) that overproduces indolylglucosinolates (Kim et al., 2008) has shown that

these plants are toxic to *Myzus persicae*. However, the increase in indolylglucosinolates in our transgenic plants was small in comparison to that of the *atr1D* mutant. The subsequent changes in hydrolysis products (i.e., production of alkenylisothiocyanates instead of methylsulfinylalkylisothiocyanates, increased amount of hydrolysis products released) could also contribute, although the impact of glucosinolate hydrolysis products produced during attack on these aphids is not clear (Barth and Jander, 2006). However, of significance is the presence of 5-vinyloxazolidine-2-thione in the hydrolysis profile. It is possible that this degradation product has an adverse effect on aphid performance, and this requires further investigation. In addition, plant-aphid interactions are not static, and several, although sometimes conflicting, studies have shown that aphid attacks affect gene expression and glucosinolate levels (Mewis et al., 2005, 2006; de Vos et al., 2007; Kusnierczyk et al., 2007), and such results may contribute to what we observed.

Air entrainment results presented here suggest that the higher volatility of 2-propenylisothiocyanate and 3-butenylisothiocyanate compared with that of 4-methylsulfinylbutylisothiocyanate may be an important determining factor in olfactometry results with naïve *D. rapae* females. Ecotype Ru-0 produced 2-propenylisothiocyanate when infested with *B. brassicae*, but this compound was not detected from uninfested plants. Similarly, the transgenic line Col-5 (+*BniGSL-ALK*)-4 produced 3-butenylisothiocyanate when infested with aphids, while only trace amounts of this compound were detected from uninfested plants. In both cases, naïve *D. rapae* females were able to discriminate between *B. brassicae* infested and uninfested plants. By contrast, for ecotype Col-5 no detectable quantities of glucosinolate-derived volatile chemicals were detected in air entrainments, and naïve female parasitoids were unable to discriminate between aphid infested and uninfested plants. Similarly, it was found (Girling et al., 2006) that naïve *D. rapae* females were unable to discriminate between a Col-*gl* plant infested with *M. persicae* and an uninfested plant. However, parasitoids were able to discriminate between these two odor sources if they were first provided with oviposition experience; thereby suggesting that the volatile profiles of aphid infested and uninfested plants did in fact differ.

By exploiting the wild-type Col-5 and the transgenic line Col-5 (+*BniGSL-ALK*)-4, we were able to record behavioral responses of *D. rapae* females to near isogenic *A. thaliana* plants with contrasting glucosinolate hydrolysis profiles. Interestingly, although more parasitoids responded to aphid infested Col-5 (+*BniGSL-ALK*)-4 plants when presented as odor sources against aphid infested Col-5 plants, the difference was not significant. This suggests that although naïve *D. rapae* females did not discriminate between aphid infested and uninfested Col-5 plants, the odor from the wild-type plant was either weakly attractive or in some way disrupted the behavioral response of the parasitoids to the transgenic plants. By contrast, naïve *D. rapae* females did discriminate between *B. brassicae* infested Ru-0 plants and similarly infested Col-5 plants. This result provides evidence of discrimination between *B. brassicae* infested *A. thaliana* ecotypes by naïve *D. rapae* females, and may also reflect the importance of glucosinolate cues accumulated as the parasitoid emerges from the aphid mummy (Blande et al., 2004). This is because parasitoids responding to Ru-0 plants were reared on *B. brassicae* infested *B. nigra* plants, which like Ru-0 accumulate 2-propenylglucosinolate as the main secondary metabolite. However, although reared on *B. brassicae* infested Col-5 plants, which accumulate 4-methylsulfinylbutylglucosinolate as opposed to the alkenylglucosinolates produced by the transgenic plants, naïve *D. rapae* responded to transgenic but not wild-type plants.

Results presented here indicate that transforming Col-5 plants with *BniGSL-ALK* may increase indirect defense against *B. brassicae* by increasing apparency to its natural enemy, *D. rapae*. Coupled with the reduced MRGRs of *B. brassicae* when feeding on transgenic plants compared with wild-type plants this would suggest that the transformation enhanced both direct and indirect defense against this specialist insect herbivore. This and other work manipulating glucosinolate and hydrolysis profiles by transgenic approaches will lead to a better understanding of the role of secondary metabolites in plant-insect interactions.

also play a role in regulating plant diversity (Chou 1999), establishment of invasive species (Bousquet-Mélou et al. 2005), and the dynamics in arid environments (Karageorgou et al. 2002).

In the Northern Mediterranean basin, *Pinus halepensis* Miller (Pinaceae, Pinales) is a pioneer and expansionist species that colonizes abandoned agricultural lands characterized by high biodiversity (Roche and Tatoni 1995). Owing to its richness of secondary metabolites (Macchioni et al. 2003), *P. halepensis* may play an important role in plant succession through several processes. For example, secondary compounds (terpenoids and/or phenolic compounds) can affect root symbionts and site quality, by interfering with decomposition, mineralization, and humification (Kainulainen and Holopainen 2002). They can also be involved with interspecific competition phenomena through allelopathic interactions (Rice 1984). Indeed, *P. halepensis* may inhibit seedling establishment of various species in pine stands, suggesting the allelopathic nature of litter, leaf leatchates, and/or root exudates (Fernandez et al. 2006, 2008; Navarro-Cano et al. 2009). Other conifers such as *Pinus sylvestris* L. (Bulut and Demir 2007), *P. densiflora* (Sieb. et Zucc.) (Kato-Noguchi et al. 2009), *Picea abies* (L.) Karst. (Pellissier 1994), or *Picea mariana* (Mill.) (Mallik and Newton 1988) also have allelopathic potential.

Allelopathic potential may be modified by several factors such as the age of the donor plant (Inderjit and Asakawa 2001). Therefore, to understand the role of *P. halepensis* in secondary succession, it is essential to evaluate whether allelochemicals vary in diversity, amount, or function in different plant organs (needles vs. roots), and at different successional stages. For this reason, we analyzed the composition of secondary metabolites in aqueous extracts of roots and needles of *P. halepensis* by searching for polar (fatty acids and phenolic compounds) and less polar compounds (terpenoids) known to be allelopathic (Rice 1984), and we determine whether the chemical diversity of aqueous extracts depends on changes in the age of *P. halepensis* stands.

Methods and Materials

Samples Sites In order to evaluate the variability and allelopathic potential of *P. halepensis* in relation to different stages of secondary succession, three age classes of *P. halepensis* were chosen: (i) Young *P. halepensis* (<15-years-old) called successional stage "Y"—that included meadows colonized by dispersed individuals; (ii) Medium-aged *P. halepensis* (±30-years-old) called successional stage "M"—monospecific or recently closed forest stands, without understory; and (iii) Old *P. halepensis* (>60-years-old) and called successional stage "O"—mature forest with well-developed understory.

Three replicates were collected from each successional stage. Sites were selected along the Southern hillside of the Luberon Mountains in the Natural Regional Park (South of France), on the basis of similar global index (climatic and topoedaphic conditions), by using a model developed by CEMAGREF (Ripert and Vennetier 2002). All sites featured deep agricultural soils (>1 m) of Rendoll in "Soil Taxonomy" (Soil Survey Staff 1999) with no slope and high fertility for *P. halepensis*.

Plant Material Collection and Aqueous Leachates Preparation Needles and roots were collected from five individuals at each site. Needles were harvested from the entire tree crown, and roots were sampled in close proximity to the pines (diam <1.5 m). Just after harvest, needle and root extracts were soaked in water (50 g fw of tissue in 250 ml of distilled water). Extracts were done at room temperature (18°–20°C) and kept in darkness for 24 h. Needle extracts simulated leaf leaching, while root extracts simulated root exudates.

Bioassays. The phytotoxicity of aqueous extracts was tested in previous studies with *Lactuca sativa* seeds, *Linum strictum* (allelopathy, Fernandez et al. 2006), and *Pinus halepensis* (autotoxicity, Fernandez et al. 2008). In these studies, phytotoxicity was analyzed in terms of germination rate and seedling growth (roots and hypocotyles) (Fernandez et al. 2006, 2008), but also in terms of sapling growth (Monnier et al. 2008).

Chemical Analyses

Instrumentation GC-MS analyses were performed on a Hewlett-Packard 6890 GC coupled with an HP5973N Mass Selective Detector. The GC was equipped with an HP-5MS capillary column (30 m×0.25 mm× 0.25 µm—J&W Scientific). Samples were injected with an ALS 7673 Automatic Injector in splitless mode (2 µl for 1 min) for polar compounds (phenolics and fatty acids), and in pulsed splitless mode (5 µl at 25 psi for 1 min) for less polar compounds (terpenoids). Purge flow was set to 50 ml/min after 1 min, except for qualitative studies of polar compounds, for which 30 ml/min were used. Helium (99.995%) was used as carrier gas. A constant flow of 1 ml/min was maintained throughout the runs. Three different oven temperatures were used for qualitative and quantitative studies of polar compounds, and one for less polar compounds. The first program began at 70°C, ramped to 270°C at 5°C/min, and remained at this temperature for 10 min. The second program began at 50°C, increased to 220°C at 5°C/min, and remained at this temperature for 6 min. The third program began at 50°C, increased to 160°C at 2°C/min, and remained at this temperature for 5 min. The

injector temperature (250°C) and MSD transfer line heater (280°C) were the same for all injections. The mass spectrometer parameters for EI mode were: ion source, 230°C; MS quadrupole, 150°C; electron energy, 70 eV; Electron Multiplier Energy 1100–1300 V. Data were acquired in scan mode from 40 to 500 amu for qualitative analyses and quantitative analyses of less polar compounds, and in SIM mode for quantitative analyses of polar compounds.

Chemicals HPLC grade methylene chloride, ethyl acetate, cyclohexane, and acetonitrile were obtained from SDS (Peypin, France). HPLC grade water was used for extractions and a Milli Q system was used for analytical procedures. N, O−bis(trimethylsilyl)trifluoroacetamide (BSTFA) containing 1% trimethylchlorosilane (TMCS) was used as the derivatizing reagent for qualitative studies with polar compounds. Methylation reagent (methyle iodure, 99.5% purity), internal standard (3-chloroanisole, >97% purity or undecane, 99% purity), HPLC grade methanol, phenolics, fatty acids, phase transfer catalysts (tetrahexylammonium bromure—THAB, > 99% purity), and tri-n-butylmethylphosphonium polymer bound (1.4 mmol Cl^-/g resin—TBMP) were used for quantitative analyses. Analytical grade sodium chloride and potassium dihydrogenophosphate were provided by Prolabo (VWR, France).

Qualitative Analyses

Polar Compounds Qualitative studies of *P. halepensis* fatty (di)acids and phenolics of root and needle extracts were carried out with three randomly-sampled extracts (10%) mixed for each analysis.

The mixed solution was extracted×3 with ethyl acetate (25 ml). The resulting three fractions were pooled, concentrated to dryness, and suspended in methylene chloride (1 ml). The procedure was repeated twice, and the combined solutions were evaporated to dryness by using a stream of helium to remove residual water.

Acetonitrile (200 µl) and BSTFA+1%TMCS (200 µl) were added to the residue. The resulting solution was incubated for 1 h at 70°C, cooled, filtered, and analyzed by GC-MS to produce the trimethylsilyl derivatives.

Less Polar Compounds Aqueous extracts (10 ml of a 10% solution of each extract) were mixed with cyclohexane (1 ml) containing undecane (2 mg/ml) for 1 h. After phase separation, the organic layers were injected onto the GC-MS.

Compound identification was done by comparison of MS spectra to those of reference standards. Database searches in the HP mass spectral libraries were conducted for unidentified components. Retention indexes of compounds were determined relative to Wisconsin Diesel Range Hydrocarbons injection (Interchim, Montlucon, France) and confirmed by comparison with those expected in literature (Adams 1989).

Quantitative Analyses

Polar Compounds Quantitative analyses were performed on needle and root extracts of young, medium, and old pines using a method adapted from Fiamegos et al. (2004). An extraction-derivatization technique was used for phenolics via Phase Transfer Catalysis (PTC). The methylation and extraction methodology was improved to fit phenolics and fatty acids and diacids. The method was tested for a small number of compounds (2 or 3) from each chemical family: fatty acids (palmitic and stearic acids), fatty diacids (succinic and azelaic acids), simple phenols (catechol and pyrogallol), acetophenones (acetovanillone and acetosyringone), phenolic acids (4-hydroxybenzoic, protocatechuic, and gallic acid), and cinnamic acids (*p*-coumaric, caffeic, and sinapic acids). These compounds were selected based on their occurrence in *P. halepensis* (qualitative analysis) or ability to be methylated under these conditions. The quantified derivatives may include several allelochemicals because of the methylation process.

Stock solutions (1 mg/ml) of each compound were prepared by dissolving pure standards (25 mg) in deionized water (25 ml). Methanol/water (1:1 *v*/*v*) was used for less soluble compounds. THAB in dichloromethane (0.1 M; 217.3 mg in 5 ml) and the internal standard were dissolved in dichloromethane.

The procedure was carried out in 35 ml-Pyrex® tubes equipped with PTFE screw caps. Each individual extract (10 ml) was added with stirring to the following solution: KH_2PO_4 buffer (500 µl of a 1 M solution; pH 8.0), TBMP (50 mg), THAB in dichloromethane (100 µl of a 0.1 M solution), internal standard in dichloromethane (50 µl of a 100 µg/ml solution), dichloromethane (850 µl), and methyle iodure (100 µl). Tubes were sealed and heated (80°C) for 1 h to allow methylation. The solutions were cooled, saturated with NaCl, and vigorously shaken. After separation, the organic layer was removed, filtered through a filter syringe (0.45 µm), and analyzed by GC-MS.

The same procedure was used to methylate standards for calibration curves (constructed by taking the ratio of external variable standard to internal constant standard).

Less Polar Compounds An identical procedure was used for less polar compounds. Quantitation was relative to undecane.

Table 1 Mean concentration (± standard deviation) of compounds in root and needle extracts of *Pinus halepensis* (ng/ml)

Statistical Analyses Variation in chemical composition by organ type and successional stage was analyzed by using a Canonical Analysis of Principal coordinates (CAP). This is a useful analysis of multivariate data by reference to prior hypotheses [here: no effect of pine compartment or age of pine (successional stage) on chemical composition (Anderson and Willis 2003)]. CAP was the most powerful test for compositional differences among assemblages. As factors appeared to be significant from CAP, they were analyzed by using a Principal Component Analysis (PCA). XL stat® (ver. 4.01) was used for this analysis. Finally, differences in the concentration of each compound by age and pine compartment were tested with the *Kruskall-Wallis test* followed by *post hoc NSK test.* Statgraphics® (version 2.1) was used for these statistical analyses. The chemodiversity index of each tree was calculated according to Iason et al., (2005): $D_{chem} = -\sum [c \log(c)]$ where c is the proportional concentration of each chemical compound.

Results

Chemical Composition Aqueous extracts from needles and roots from the different stands of *P. halepensis* showed a complex mixture of at least 59 identified compounds belonging to different functional phytochemical groups (Knudsen and Gershenzon 2006). Nine monoterpenes, 20 oxygenated monoterpenes, 3 sesquiterpenes, 6 oxygenated sesquiterpenes, 4 fatty acids, 10 phenolic compounds, and 7 others (Table 1) were found in mixtures and consisted predominantly of phenolics (50%), fatty acids (44%), monoterpenoids (5%), and sesquiterpenoids (1%).

Effect of Organ and Successional Stage on Leachates We observed a significant effect of organ type (Canonical Analysis of Principal coordinates, F=20.90; P<0.001) and successional stage (CAP, F=2.87, P<0.001) on chemical composition of leachates.

Figure 1 represents a two-dimensional mapping of the Principal Component Analysis. Axis 1 represents 25.7% of the information, and is characterized on the positive side by two oxygenated sesquiterpenes (α-eudesmol, α-cadinol) and α-terpineol (an oxygenated monoterpene). The negative side shows the concentration of total fatty acids, succinic acid, myrtenol (an oxygenated monoterpene), and a monoterpene derivative (bornyl or isobornyl acetate). Axis 2 represents 15.28% of the information, and is characterized on the positive side by oxygenated and non-oxygenated monoterpenes (e.g., *trans*-pinocarveol, ß-myrcene) and a phenolic compound (4-hydroxybenzoic acid). The hierarchical ascending classification distinguishes two main groups according to organ type. The 1st group is situated on the positive side of Axis 1 and includes all needles analyzed. Needles then were characterized by two oxygenated sesquiterpenes and three oxygenated monoterpenes (α-eudesmol, α-cadinol, and α-terpineol). The second group is located on the negative side of the Axis 1 and includes all the roots analyzed. Roots then were characterized by high concentrations of total fatty acids and other compounds (see above) such as succinic acid.

The "needles group" can be subdivided into 2 sub-groups: young needles (with some young roots) occurring on the positive side of Axis 2 had the highest monoterpene concentrations, while the older needles were located on the negative side of Axis 2.

The Chemodiversity Index (D_{chem}; Iason et al. 2005) was calculated with pooled data from all functional groups and shows that needles have a higher chemical diversity than young and medium-aged pine roots and, to a lesser extent old roots (Fig. 2). When the index is calculated for functional groups, needles have a higher diversity index for total sesquiterpenes (D_{chem} mean of 2.38 for needles and 1.19 for roots), while roots have a higher diversity index for monoterpenes (D_{chem} mean of 3.20 for roots and 2.40 for needles; Tukey tests and one-way Anova, P<0.05). For phenolics and fatty acids, young needles have the highest diversity (D_{chem}=2.38).

Discussion

Numerous compounds were observed in aqueous extracts of *Pinus halepensis*. Monoterpenoids (e.g., α-pinene; sabinene; β-pinene; β-myrcene; α-terpinene; *p*-cymene; γ-terpinene, fenchol, camphor, α-terpineol) and sesquiterpenoids (e.g., β-caryophyllene; α-muurolene; guaiol; α-eudesmol) were found in needles, litter, and needle emissions (Ormeño et al. 2007), as well as in *Pinus halepensis* essential oil (Macchioni et al. 2003). Moreover, the diversity index for monoterpenes in *Pinus halepensis* needles is high (1.7 to 3.1) compared to *Pinus ponderosa* or *Pinus sylvestris* needles (0.9 to 1.5 and 0.8 to 1.7, respectivly) (Iason et al. 2005; Thoss and Byers 2006). Several of these simple phenolics found in *P. halepensis* have been found previously (e.g., gallic acid, 4-hydroxybenzoic acid, vanillic acid, syringic acid, and *p*-coumaric acid) (Robles et al. 2003), as well as in other *Pinus* species (Alonso et al. 2002; Cannac et al. 2007). Fatty acids were recently found in the needles and litter of several conifers (Song and Cui 2003).

The influence of organ and successional stage on the chemical composition of leachates confirms the difference between root and needle leachates—an observation that

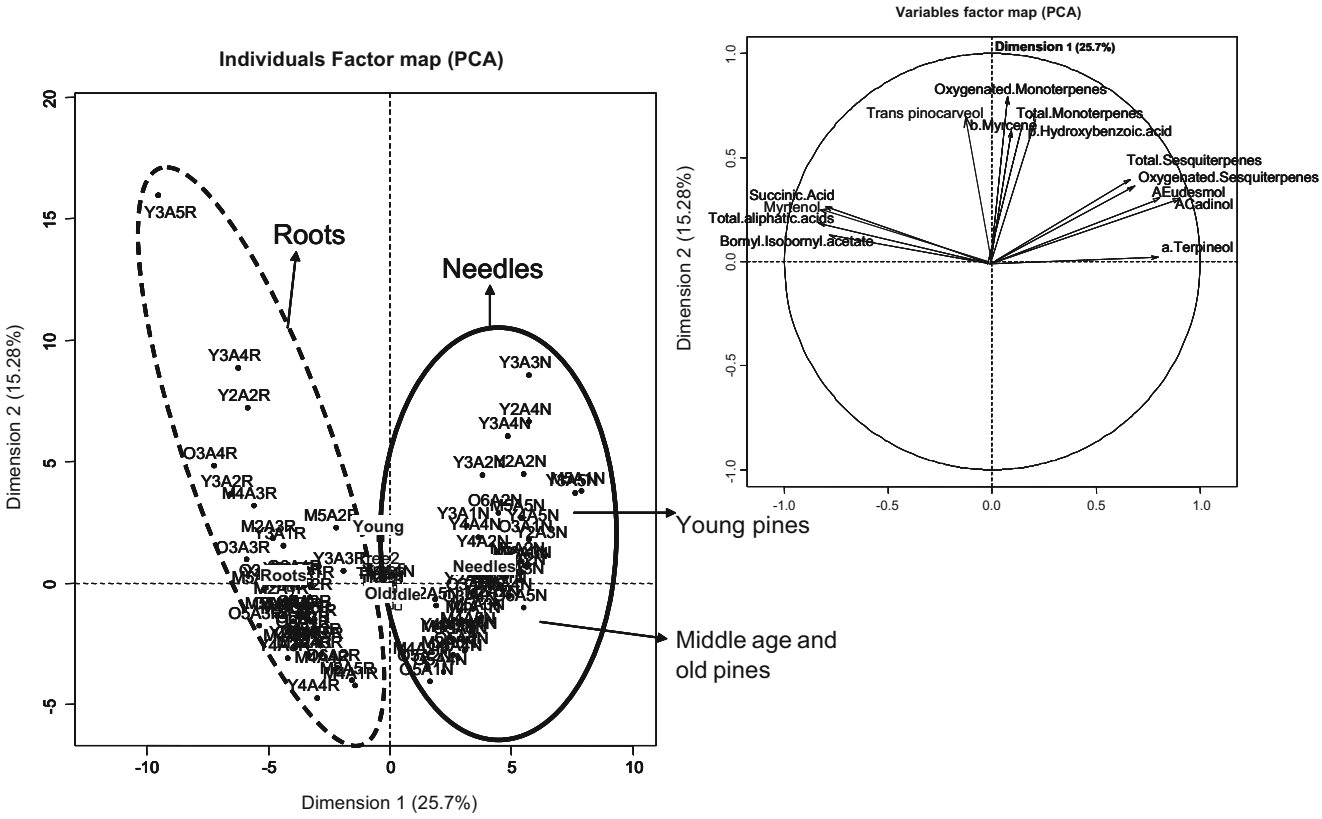

Fig. 1 Two-dimensional mapping of the Principal Component Analysis performed for chemical compounds from different age and organs of *Pinus halepensis* (Y: young <15 years; M: middle age±30 years; and O: old >60 years) and organ (last letter N: needles; R: roots)

parallels the work of Macchioni et al. (2003) with the essential oil of different *Pinus* organs. In general, the concentrations of allelochemicals in conifers decline with age (Liu and An 2003) as does composition and relative amounts of constituents (Julkunen-Tiitto et al. 1996). The chemical variability of *P. halepensis* organs and stage suggest that different organs (i.e., needles or roots) release different chemicals into the environment at different stages and times. Needles show greater variation with the age of the stand. Two sub-groups were identified that had differences between the dominant phytochemical groups in young vs. older pines stands. The highest monoterpene concentration occurred in younger pines needles (Fig. 1) and may be responsible for inhibiting seed germination (Vokou et al.

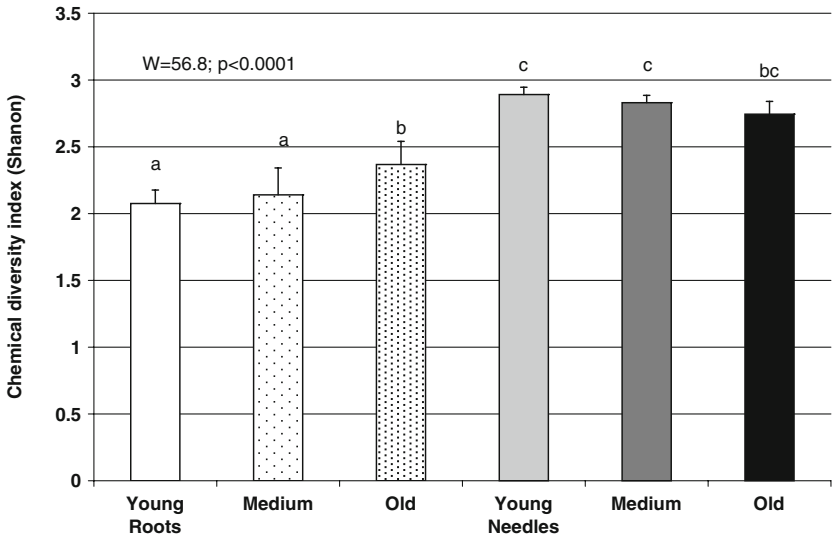

Fig. 2 Chemical diversity of *Pinus halepensis* leachates from different organs and age of calculated according to Iason et al., (2005) (Mean ± SD)

2003) and facilitating the establishment of young pine stands (Fernandez et al. 2006).

The capability of *P. halepensis* to synthesize a rich phenolic mixture during early stages of colonization may confer a competitive advantage in the competition among plants or pathogens. Moreover, the high diversity of compounds in older roots is not surprising given the abundance of competing microbes, insects, and roots of other plants in the same environment. Root monoterpene diversity also may impact tritrophic interactions in soil as these compounds are implicated in indirect defense mechanisms against root feeders. Several studies have now demonstrated that roots can recruit herbivore enemies by releasing chemical cues into soil (Hiltpold and Turlings 2008).

As mentioned previously, secondary metabolites may function in the defense of one plant against another via allelopathic processes. *P. halepensis* leachates, whether from needles or roots, are allelopathic toward some, but not all, plants. Biosensor plants—i.e., *Avena sativa, Lactuca sativa,* and *Lemna minor* (Nektarios et al. 2005)—are inhibited by *P. halepensis* leachates. The leachates also negatively affect wild plants, including: *Festuca arundinacea*, *Cynodon dactylon*, *Linum strictum*, and *Pinus halepensis* (Nektarios et al. 2005; Fernandez et al. 2006, 2008). These findings suggest that the release rate and level of allelochemicals are important factors in the environments in which they occur. Castaldi et al. (2009) showed that *Arbutus unedo* leaves and root extracts were detectable in soil extracts. Similarly, *P. halepensis* extracts may contain a chemical composition similar to those released in nature. Pine needles seem to have higher allelopathic activity in fresh tissue, moderate activity in senescing tissue, and low activity in decaying pine needles (Nektarios et al. 2005). In addition, *P. halepensis* needle litter also negatively affects herbaceous plants (Nektarios et al. 2005), but has no effect on other species—e.g., *Quercus ilex* (Broncano et al. 1998) or *Pistacia lentiscus* (Maestre et al. 2004).

Secondary coumpouds are recalcitrant to decomposition (Vitousek and Reiners 1991). As this constitutes one significant way for allelochemicals to enter the environment (Rice 1984), they can directly influence microbial activity (White 1994), and soil productivity (Bloom and Mallik 2004). *P. halepensis* forests are prone to accumulate relatively thick needle layers below their canopy (Garciaple et al. 1995) and would seem to have the potential to influence biotic interactions in litter (Inderjit and Nilsen 2003) and plant dynamics through allelopathic interactions and mechanical effects on seedling recruitment (Fernandez et al. 2008; Navarro-Cano et al. 2009).

Our previous data showed that young needles and old roots were responsible for most of the allelopathic and autotoxic interactions (Fernandez et al. 2006, 2008; Table 2). The present investigation gives more detail on the principal compounds in both young needles and old roots known to be allelopathic—i.e., sinapic and caffeic acids (phenolic acids) (Table 1) even if both are in low concentrations in *P. halepensis* leachates compared to other compounds (Table 1). Mixtures of phenolic acids and other organic compounds can cause inhibitory effects even though the concentration of individual compounds are well below inhibitory levels (Blum 1996). Caffeic acid (CA) had higher concentrations in both young needles and old roots.

Table 2 Sensitivity of several target species to the highest dose of *Pinus halepensis* extracts from roots and needles and stand age (Y: young < 15 years old, M: medium aged, O: old aged, >60 years old, S: senescent, D: decaying)

This acid is ubiquitous in plants. As with most cinnamic acids, caffeic acid is implicated in many biological interactions (Batish et al. 2008) including allelopathy (Rice 1984) and microbial interactions (Harrison et al. 2007). This compound induces stress in plants, alters physiological and resulting biochemical reactions, and detrimentally impacts plant growth. It is a potent root growth inhibitor (Gallet 1994; Barkosky et al. 2000), and disrupts plant-water relationships and photosynthesis (Barkosky et al. 2000). This phenolic acid changes protease, peroxidase, and polyphenol oxidase activities in root development (Batish et al. 2008) and either interfers with absorption of potassium and phosphorus (Glass 1974), or depolarizes cell membranes in roots (Glass and Dunlop 1974). Caffeic acid has many biological activities and may play a key role in giving *P. halepensis* a competitive advantage over other plants.

Acknowledgments This study was funded by the CNRS within the framework of the Zone Atelier "Arrière-pays Méditerranéen". We are grateful to the Luberon Natural Regional Park. The authors are indebted to many private owners who granted permission for work in their forest. We also thank, Prof David Mouillot (University of Montpellier II) for his help in statistical analysis and Stephanie Jim from University of California, Berkeley for proofreading the English.

exists about toxic effects (Lamuela-Raventos et al. 2005). In general, the dietary intake of flavonoids traditionally has been regarded as beneficial due to their antioxidant properties; however, supporting data predominantly has come from *in vitro* studies that applied unrealistic high concentrations. Recently, the view has changed, and flavonoids now are less assumed to act as direct antioxidants but rather as inhibitors of pro-oxidant enzymes, such as NADPH oxidases and lipoxygenases, or as chelators of transition metals that mask pro-oxidant actions of reactive nitrogen (NOS) and oxygen species (ROS) (Schewe et al. 2008).

In sharp contrast to the above, (–)-catechin, one of the four isomers of the catechin epimers with *o*-hydroxyl groups on ring B, has been implicated as a chemical weapon of spotted knapweed, *Centaurea maculosa* Lam., which is now classified as a subspecies of *C. stoebe* L., *C. stoebe* ssp. *micranthos* (Gugler) Hayek (Ochsmann 2002). This knapweed species is regarded as an invasive plant in western United States (Callaway et al. 1999; Weir et al. 2003). *Centaurea stoebe* is well known in Europe, as it is one of the more wide-spread knapweed species and is especially common in abandoned dry grasslands (Dostalek and Frantik 2008). Studies that were carried out by Bais and colleagues (Bais et al. 2003; Weir et al. 2003) claimed to provide evidence that (–)-catechin has phytotoxic properties strong enough to support potential contributions of this compound to the invasive success of *C. stoebe* in the western United States. Based on this and similar studies that involved other invasive knapweed species, the novel weapons hypothesis was developed. It states that metabolites of introduced plant species may confer competitive advantages against non-adapted native species (Callaway and Ridenour 2004). The debate concerning the efficacy and ecological relevance of the epimeric mixture of (±)-catechin that is exuded by the roots of *C. stoebe* is ongoing. Besides growth inhibitory effects against some plant species at high concentrations, (±)-catechin also may act as a growth regulator and inducer of systemic resistance at lower concentrations (Weir et al. 2003; Prithiviraj et al. 2007).

We know that diverse abiotic and biotic stresses disturb the redox equilibrium in cells of affected organisms; the thus generated ROS may trigger signal cascades that activate various genes involved in specific response reactions (Wojtaszek 1997; Foyer and Noctor 2005; Gechev et al. 2006; Noctor et al. 2007; Miller et al. 2008). However, if the cell fails to control the levels of ROS, oxidative damage of DNA is inevitable (Halliwell 2006). Iron homeostasis also is vital for the cell. This transition metal is an essential nutrient of plants, yet it often limits growth and, conversely, over-accumulation leads to oxidative stress (Walker and Connolly 2008). In cells, iron is bound to proteins, ferritins, and usually is set free by reductive processes (Laulhere and Briat 1993). Reduced iron can react with H_2O_2 to form hydroxyl radicals ($^{\bullet}OH$), which have enormous potential to damage various organic molecules (Halliwell 2006).

Bais et al. (2003) explored the pro-oxidative effects of (–)-catechin by applying solutions that contained 100 μg ml^{-1} to root tips of *Centaurea stoebe* and *C. maculosa*, the first a known producer of (±)-catechin, and to *Arabidopsis thaliana*, the widely-used model plant in molecular plant physiology. Only the root tips of *C. stoebe* did not show any visible symptoms of induced cell death when ROS production was monitored by imaging generation of dichlorofluorescein (DCF) in the (–)-catechin-treated root tips. Similarly, by using another fluorescent probe, indo-1, the authors showed that levels of Ca^{2+} ions increased in root tips of all tested plants except *C. maculosa* after treatment with a solution of (–)-catechin (100 μg ml^{-1}). Based on this evidence, they proposed that (–)-catechin acts a chemical weapon that contributes to the invasive success of *C. stoebe*. Initially, this study was praised as a fundamental contribution to the respectability of allelopathy (Fitter 2003). Later, however, concerns that the concentrations required for these effects were unrealistic in soil by several orders of magnitude were voiced (Blair et al. 2005, 2006). These concerns recently led to a rejection of the hypothesis that (±)-catechin acts as phytotoxin in allelopathic interactions of *C. stoebe* on the basis of experimental evidence: (1) the concentration of (±)-catechin in soil is too low; (2) (±)-catechin is unstable at pH values above 5, as found in the majority of soils; (3) (±)-catechin is decomposed by extracellular enzymes; and (4) (±)-catechin is only weakly phytotoxic but a strong antioxidant (Blair et al. 2009; Duke et al. 2009a,b). In a series of studies, the originators of the novel weapons hypothesis, concomitantly claimed further support for (±)-catechin as a phytotoxic allelochemical by showing results from experiments that indicated higher susceptibility to (±)-catechin to species in the invaded than in the native range, conditional, however, on the soil type (Inderjit et al. 2008; He et al. 2009; Thorpe et al. 2009).

In this controversy, one further problematic issue has been neglected. Caution needs to be considered when using dichlorofluorescein to detect ROS formation in tissues. The dichlorofluorescein assay is subject to a serious artifact in that it produces what it is purported to measure, i.e., ROS (Bonini et al. 2006). In the cell that possess peroxidase activity, the probe-derived radical may be oxidized, thereby producing further ROS regardless of the initial oxidant (Rota et al. 1999; Bonini et al. 2006). Consequently, the toxic properties of (−)-catechin may have been overestimated by the method applied by Bais et al. (2003). Antioxidative properties of (−)-catechin may contribute to the fact that the producing root tips of *C. stoebe* yield

negative results for ROS production in imaging of DCF-infiltrated tissue. The redox chemistry of (±)-catechin is complex: it has *o*-hydroxyl groups on its ring B, which may either scavenge ROS or chelate free iron ions. Recently, we have shown that pro-oxidative effects of the naphthoquinone juglone, a well-known phytotoxic compound alleged to be the allelopathic agent of the walnut tree (Jose 2002), are strongly enhanced if free iron is chelated directly by juglone (Chobot and Hadacek 2009). In this study, we applied variants of the deoxyribose degradation assay (Halliwell et al. 1987) to explore the redox chemistry of juglone in the presence of free and chelated iron ions [chelating agent ethylenediaminetetraacetic acid (EDTA)] as well as at low and high levels of ROS caused by low and sub-lethal dosages of MeOH.

By assuming that (±)-catechin interacts with ROS, we designed variants of seedling growth assays that resemble different stress levels. This can be achieved simply by adding the organic solvent MeOH (Chobot and Hadacek 2009). MeOH is oxidized to formaldehyde and formate, and during these reactions, ROS are formed (Dobrzynska et al. 1999). Moreover, in attempts to create more complex stress scenarios, all assays were performed simultaneously both in complete dark and in a light/dark regime. If (±)-catechin interacts with signal cascades in the cell, we predicted that similar effects should be visible in a plant as well as in a brine shrimp mortality assay. In a previous study, we demonstrated that nonlinear effects (hormesis) of juglone on seedling growth were due to its excellent capabilities as a redox cycler (Chobot and Hadacek 2009). To explore whether (±)-catechin possesses properties similar to juglone, we decided to contrast the electrochemical potentials of both compounds. This can be measured by cyclic voltammetry, at pH levels characteristic for the cytoplasm and the vacuole, 7.4 and 3.6, respectively. Cyclic voltammetry is one of the less expensive electrochemical methods that are available to study redox chemistry in combination with chemical assays (Firuzi et al. 2005; Chobot et al. 2008).

(±)-Catechin has been shown to be unstable in soils at pH values higher than 5 (Duke et al. 2009a). The pH-dependent instability, oxidation of (±)-catechin (Guyot et al. 1995), may contribute to the variable recovery rates from soils that have been reported in the literature (Blair et al. 2005, 2006; Inderjit et al. 2008; Duke et al. 2009a). To obtain information about (±)-catechin stability in our assay system and in the cell, we used HPLC analysis after 24, 96, and 240 h at pH 3.6 and 7.4, the vacuole and cytoplasm pH, respectively. The deoxyribose degradation assays were performed at pH 7.4.

This combination of analytical, chemical, and biological assays aimed to provide insight into possible mode of actions of (±)-catechin in biotic interactions, not only to contribute to the debate about its acting as a chemical weapon for the invasive *C. stoebe* but also to understand the potential benefits of (±)-catechin accumulation in plant tissues and root exudation.

Materials and Methods

Chemicals Most chemicals were obtained from Sigma Aldrich (St. Louis, MO, USA) unless otherwise stated; water had Milli-Q quality.

Seedling Growth Assays Seeds of black mustard (*Brassica nigra* L.) were obtained from Flora Geissler GmbH (Fisibach, Switzerland) and of white mustard (*Sinapis alba* L.) from B and T World Seeds (Paguignan, France). Solvents were analytical grade. Vapor sterilization of seeds was performed by using commercially available bleach and concentrated HCl (Clerkx et al. 2004). Various variants of the assay were performed; one on agar medium, the other on filter paper. The assays were performed in Petri dishes (9 cm diam, Greiner Bio-One, Kremsmünster, Austria). The agar medium consisted of solidified Murashige and Skoog (MS) basal medium (Murashige and Skoog 1962); (±)-catechin monohydrate (Sigma Aldrich) was dissolved in 2 ml MeOH, and was added to the agar solution after autoclaving. An identical amount of MeOH also was added to the control plates. The surface sterilized seeds (7–9) were transferred to the agar medium with a sterile forceps and actively pressed into the medium to assure maximum contact with the seed surface. Preliminary experiments indicated that effects of the test compounds caused more pronounced effects if this procedure was applied. Filter paper disks (Schleicher and Schuell 520 B 1/2, 60 mm diam) were moistened with 1 ml of a 10%-methanolic aqueous solution containing the test compound in a two-fold serial dilution from 6 to 200 µg ml^{-1}. This measure was taken to prevent crystallization of (±)-catechin (Perry et al. 2005b). The moistened filter papers were placed in 9 cm-Petri dishes. Surface-sterilized seeds (7–9) were transferred to the filter paper with sterilized forceps. Petri dishes were kept sealed for 48 h; then, the sealing tape was removed and MeOH was allowed to evaporate. Water was added to replenish the liquid and to keep the filter paper moistened.

For each concentration, four replicate Petri dishes were prepared. Two were incubated at 25±2°C with a 12 h photoperiod in a temperate greenhouse; the other two were kept completely in dark in the same location. Scoring was performed after 5 days. For practical reasons, of each tested concentration five representative seedlings were chosen for measurement of shoot and root development. The seedlings were photographed with an Olympus

D500 digital camera equipped with a macro lens with 10x magnification. Image analysis was carried out for shoots and roots separately by using Image J 1.36b (Wayne Rasband, NIH, USA, http://rsb.info.nih.gov/ij/). The mean of the pixel counts of the control seedlings was determined as 100% for the quantitative assay (Roberts and Boyce 1972).

Brine Shrimp Assay For each experiment, 0.5 g cysts of *Artemia salina* L., obtained from NovoTemia (JBL GmbH & Co. KG Neuhofen, Germany), were hatched in 25 ml saline aqueous solution (g per 100 ml: 2.3 NaCl, 0.4 Na_2SO_4, 0.07 KCl; pH 8.0±0.2, adjusted with HCl and/or NaOH). For hatching, illumination was performed with a 60 W lamp from a distance of 40 cm for 1 h. The hatched larvae (nauplii) were transferred to an incubator (±25.0°C). One hundred µl of the stock solution (300 µg ml^{-1}) were serially diluted in 96-well microplates, and 50 µl of suspension of 24-h old larvae (6–30 larvae) were added. After 24 h, the wells were scored visually for dead animals (larvae without any movement for at least 10 s) by using an Olympus BHZ 2 stereomicroscope (magnification 8–70 x). Fifty µl of 0.1 M HCl were used to kill all animals. In a second scoring survey, all animals were counted for each well to calculate the number of surviving nauplii for each concentration tested, as required for a quantal biological assay (Roberts and Boyce 1972). $MnCl_2$ served as a positive control. The negative control was the saline solution without test compound. One set of experiments was performed with addition of 5 % MeOH to the stock saline solution of the tested compound; for dilution, only saline solution was used.

Deoxyribose Degradation Assays (H_2O_2/Fe^{3+}/Ascorbic acid) Procedures followed those described earlier for the deoxyribose assay (Halliwell et al. 1987; Aruoma 1994). Here, the ability of the test compound to interact with the reduction of iron (III) by ascorbic acid and the subsequently formed hydroxyl radicals is explored (for a description see Chobot and Hadacek 2009). Briefly, (±)-Catechin monohydrate was dissolved in an aqueous KH_2PO_4/KOH buffer solution (50 mM, pH 7.4); to 125 µl of this solution, 25 µl of a 10.4 mM 2-deoxy-D-ribose solution in the same buffer system and 50 µl of an solution of Fe^{3+} (50 µM) were added. Further, 25 µl 10.0 mM aqueous solution of H_2O_2 and finally 25 µl of 1.0 mM ascorbic acid in buffer were added to start the Fenton reaction. Malonlyldialdehyde (MDA) was determined photometrically at 532 nm after reaction with thiobarbituric acid and subsequent extraction of the red pigment with 1-butanol. The blank contained the full reaction mixture without 2-deoxy-D-ribose. Assays were performed in triplicate.

Deoxyribose Degradation Assays (H_2O_2/Fe^{3+}) This modification was carried out without the addition of ascorbic acid, which was replaced by the same volume of buffer. This variant allows assessing whether the tested compound can reduce iron (III) to iron (II). Scoring was performed after 1 h. The negative control was the H_2O_2/Fe^{3+}/ascorbic acid system mixture that lacked the test compound. The blank contained the full reaction mixture without 2-deoxy-D-ribose.

Deoxyribose Degradation Assays (Fe^{3+}/Ascorbic acid) H_2O_2 was replaced by the same volume of water. Deoxyribose degradation depended strongly on the diffusion of air oxygen into the liquid. This variant allows assessment of the interactions of the tested compound with the H_2O_2 that is formed by reduction of molecular oxygen present in the solution. Consequently, scoring was performed only after 16 h. The blank contained the full reaction mixture without deoxyribose. The negative control was the H_2O_2/Fe^{3+}/ascorbic acid system mixture lacking the test compound.

Deoxyribose Degradation Assays (Fe^{3+}) This modification of the deoxyribose assay was carried out without the addition of H_2O_2 and ascorbic acid, which were replaced by the same volumes of buffer or water. This allows assessment of the reducing capacity of the tested compound of molecular oxygen to H_2O_2 as well as that of iron (III) to iron (II). Scoring was performed after 16 h (diffusion of air oxygen).

Blanks were performed to assess possible reactions between thiobarbituric acid and the tested compound. The values were used to correct the readings obtained in the various modifications of the assay. The blank contained the full reaction mixture without deoxyribose. The negative control was the H_2O_2/Fe^{3+}/ascorbic acid system mixture lacking the test compound (100% MDA).

To the reaction mixture of the deoxyribose degradation assay, 50 µl of Fe^{3+} solution (50 µM) were added. In one series, those 50 µl contained 52 µM EDTA dissolved in buffer, which was premixed with the aqueous $FeCl_3$ solution (1:1 v/v). In the other series, the EDTA solution was replaced by the same volume of the buffer. In the first series, EDTA chelated the iron ions, preventing them from being chelated by the test compound; in the second series, the iron ions were chelated by the test compound.

Cyclic Voltammetry Voltammetric curves were recorded at ambient temperature in a three-electrode µAutolab PGSTAT type III system (EcoChemie Inc., The Netherlands). The working electrode was a glassy carbon electrode (3 mm diam), Ag/AgCl (saturated KCl) was used as a reference electrode, and platinum wire as a counter electrode. The

glassy carbon electrode was cleaned with MeOH and water, and polished before every measurement. The effective scan rate of the CV was 50 mV s^{-1}. The scan potential was from −250 to +1200 mV for (±)-catechin at pH 3.6 and 7.4, for juglone from −400 to +1200 mV at pH 7.4 and from −400 to +1350 mV at pH 3.6. Both substances were dissolved in degassed water. The concentration was 1 mM. The solution for analyses was prepared by mixing 1 ml of the water solution with 9 ml of the degassed buffer. We used phosphate buffer pH 7.4 or acetate buffer pH 3.6. The ionic strength of the buffers was 0.22 M. The ionic strength of the acetate buffer was adjusted by K_2SO_4. The electrolytes were degassed by argon for 10 min, and measurements were carried out under argon atmosphere. Juglone was obtained from Fluka (Buchs, Switzerland).

HPLC Analysis (±)-Catechin monohydrate (Sigma Aldrich, St. Louis, MO, USA) was dissolved in an aqueous KH_2PO_4/K_2HPO_4 buffer solution (0.1 M, pH 7.4) and CH_3COONa/CH_3COOH (0.1 M, pH 3.6) to give a 1 mM solution of (±)-catechin. The HPLC System was a Dionex Summit equipped with a photodiode array detector (PDA) and a Famos autosampler. The column was a Phenomenex Synergi Max C12, 150×2 mm, 5 µm particle size. The column oven was adjusted to 40°C, and the flow rate was 0.2 ml min^{-1}. Solvent A was water : MeOH : *o*-phosphoric

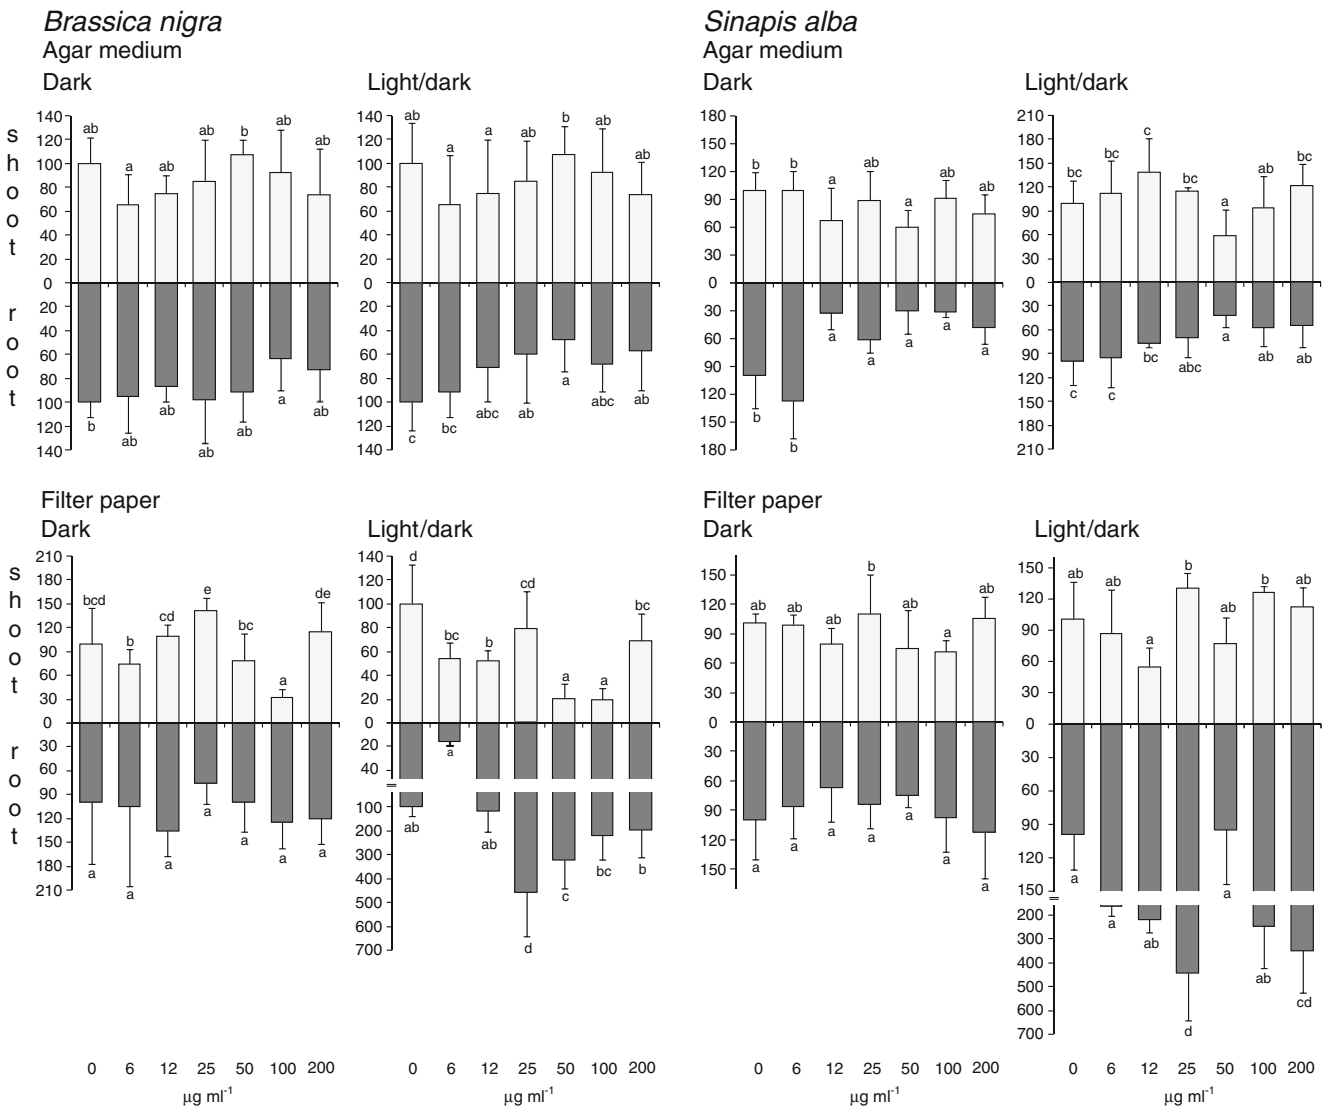

Fig. 1 Effects of (±)-catechin on postgerminative shoot and root growth of *Brassica nigra* and *Sinapis alba* tested on MS agar medium (0.2% MeOH, v/v)) and filter paper (10% MeOH, v/v) after 5 days in temperate greenhouse at 25±2°C in complete dark or a 12 h photoperiod. Growth is expressed as mean of the control treatment; *bars*, means; *error bars*, standard deviation; *N*=5; letters indicate different levels of significance (95% probability, Duncan's multiple range test); 6 (19.48), 12 (38.96), 25 (81.16), 50 (162.33), 100 (324.67), 200 (649.3) µg ml^{-1} (µM)

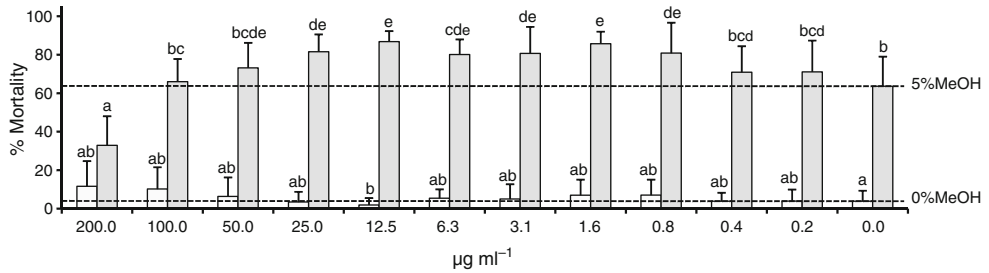

Fig. 2 Effects of (±)-catechin on mortality of 24 h-old nauplii of brine shrimp (*Artemia salina*) in saline aqueous solution after 24 h; one variant with addition of MeOH, the other with 5% (v/v); mortality rate is expressed as percentage of dead larvae; *bars*, means; *error bars*, standard deviation; $N=8$; letters indicate different levels of significance (95% probability, Duncan's multiple range test)); 6 (19.48), 12 (38.96), 25 (81.16), 50 (162.33), 100 (324.67), 200 (649.3) µg ml^{-1} (µM)

acid (9 : 1 : 0.5, v/v/v), solvent B was pure MeOH. The gradient started with 100% of A for 2 min and then linearly changed to 100% of B within 98 min. The final concentration was held further for 10 min. Five µL of (±)-catechin solutions were injected. UV spectra were recorded from 590 to 220 nm. The experiment was repeated twice. One series only, however, is shown.

Statistics Statgraphics Plus 5.0 (Statistical Graphics Corp., Rockville, MD, USA) was used to perform analyses of variance (ANOVA) with Duncan's multiple range tests at a confidence level of 95%.

Results

Seedling Growth Figure 1 summarizes the results that were obtained when (±)-catechin was applied in concentrations from 6 to 200 µg ml^{-1} agar medium or filter paper treated with aqueous solution. In both setups, crystallization of (±)-catechin affected the testing of higher concentrations, 100 and 200 µg ml^{-1}, respectively. The two assay designs, as well as the different light regimes, specifically affected the growth of the seedlings of both brassicaeous species. Both mustards were affected similarly by specific conditions, but showed variable susceptibility. The effect that a specific concentration caused on the development of the seedlings ranged from retardation (inhibition) to induction of growth. This depended on the specific assay setup, light regime, or organ (root or shoot). The most notable inhibition was visible in white mustard seedlings, which were grown on agar medium in the dark, starting from 12 µg ml^{-1}. The presence of light slightly attenuated this effect. The black mustard seedlings were less affected. In the filter paper assay, in contrast, the presence of light caused a strong stimulation of root growth in both black mustard and white mustard, but only in the light/dark regime. In many instances, the effects were non-linear, i.e. the highest concentration applied did not cause the strongest effect that was observed within the range of tested concentrations.

Brine Shrimp Assay When 5% MeOH was added to the culture medium, the mortality of the brine shrimp nauplii increased (Fig. 2). In the absence of MeOH, only one concentration (12.5 µg ml^{-1}) significantly decreased mortality rate; however, the difference of means was negligible (4 to 2%). In contrast, when 5 % MeOH was added, the highest concentration tested (200 µg ml^{-1}) attenuated mortality by half (64 to 33%).

Deoxyribose Degradation Assays The results obtained in the variants of the deoxyribose degradation assay are illustrated in Fig. 3. (±)-Catechin was tested in concentrations from 2–500 µM. In the classical setup with H_2O_2 and ascorbic acid (Fig. 3a), (±)-catechin decreased the formation of MDA in a dose-dependent fashion. The effect was more pronounced, when Fe^{3+} was chelated by (±)-catechin (Fig. 3a) than by EDTA (Fig. 3b). This was evident in the difference of the means, as well as in the first concentration that differed significantly from the control. When ascorbic acid was left out, the levels of MDA decreased dramatically (Figs. 3c and d). Although some of the concentrations tested significantly differed from the control, the effects of increasing concentrations of (±)-catechin were negligible compared to the variant when ascorbic acid was present. These rather weak effects did not allow a differentiation of whether Fe^{3+} was chelated by (±)-catechin (Fig. 3c) or EDTA (Fig. 3d).

The additional variants of the assay were scored only after 16 h. Due to absence of H_2O_2 in the reaction mixtures, the observation of effects depended on the diffusion of oxygen from the air into the liquid. The presence of ascorbic acid accelerated the decomposition of deoxyribose into MDA. Again, (±)-catechin attenuated the decomposition process; if Fe^{3+} was chelated directly by (±)-catechin (Fig. 3e), the effect was more pronounced

◀**Fig. 3** Degradation of 2-D-Deoxyribose quantified by formation of malonlyldialdehyde (MDA) by hydroxyl radicals generated in the Fenton reaction; in the variants (**a**)–(**d**) H_2O_2 and scoring was performed after 1 h; in variants (**e**)–(**h**) no H_2O_2 was added and formation of ROS depended on diffusion of air oxygen into the liquid of the reaction mixture, thus scoring was performed after 16 h; 100 % MDA represents the mean formation of MDA by the standard variant with addition of ascorbic acid, H_2O_2, and $FeCl_3$; *bars*, means; *error bars*, standard deviation; N=3; letters indicate different levels of significance (95% probability, Duncan's multiple range test); 2 (0.58), 4 (1.16), 8 (2.32), 15 (4.35), 30 (8.70), 60 (17.40), 125 (36.25), 250 (72.50), 500 (145) µM (µg ml^{-1}) (±)-catechin

than if Fe^{3+} was chelated by EDTA (Fig. 3f). If ascorbic acid was absent, the levels of MDA generally decreased; in fact, they were the lowest of all variants (Figs. 3g and h). In contrast to the variants where H_2O_2 was present (Fig. 3c and d), in this variant chelation of Fe^{3+} by EDTA (Fig. 3h) caused a significant pro-oxidative effect at the higher concentrations tested. Conversely, when Fe^{3+} was chelated by (±)-catechin, none of the tested (±)-catechin concentrations significantly differed from the control (Fig. 3g).

Cyclic Voltammetry The voltammogram of juglone (Fig. 4) shows one prominent reduction peak (reduction of quinone) and two prominent oxidation peaks (back oxidation of ring B and irreversible oxidation of ring A). The unusual high potential of the oxidation of the hydroxyl group located on ring A is caused by the strong electronegative effect of the adjacent carbonyl function on ring B, which affects the density of the electrons on ring A. The irreversibility of the oxidation of the hydroxyl group on ring A is probably caused by undetectable follow-up reactions of the semiquinone. A comparison of the voltammograms measured at pH 7.4 (cytoplasm) and 3.6 (vacuole) showed that the peak maxima shift to more positive potentials (for B from −0.18 to 0.02 V, for A from 1.01 to 1.21 V, for B' from −0.22 to 0.03 V). At lower pH, the irreversibility of the oxidation of ring A is maintained.

The cyclic voltammogram of (±)-catechin (Fig. 4) is similar to juglone. It shows a quasi-reversible oxidation of the catechol part of the molecule (ring B) and oxidation of resorcinol part of the molecule (ring A). The latter oxidation is not reversible, probably due to follow-up reactions. Similar to juglone, a comparison of the voltammograms measured at pH 7.4 (cytoplasm) and 3.6 (vacuole) showed that the peak maxima shift to more positive potentials (for B from 0.24 to 0.48 V, for A from 0.65 to 0.84 V, for B' from 0.12 to 0.28 V, respectively).

Stability of (±)-Catechin in Aqueous Solutions at Variable pH Figure 5 illustrates the obtained results. At pH 3.6, (±)-catechin remained stable in solution even after 240 h (Fig. 5a). Peak #3 is an impurity or decomposition product that was already present in the commercial sample. At pH 7.4, the first decomposition products (e.g., #1, #4, and #7) were visible. The solution started to have a yellowish hue. After 96 h, several decomposition products were detectable. The color of the solution was now yellow (Fig. 3c). The last analysis, after 240 h, indicated that some decomposition peaks had undergone further reactions because their height decreased (e.g., #1 and #7). A comparative analysis of the UV spectra of the decomposition products revealed that peaks eluting later than 30 min were characterized by UV spectra with broad absorbance maxima above 300 nm (#5–#7) in contrast to those eluting earlier (Fig. 5b).

Discussion

Juglone is a well known for its phytotoxic activity (Szabo 1999; Reigosa and Pazos-Malvido 2007), and is a candidate compound for the allelopathy of the walnut tree (Jose 2002). It offers itself, thus, as positive control for the evaluation of phytotoxic effects of (±)-catechin. (±)-Catechin, however, inhibited seedling growth less efficiently by several orders of magnitude; in all variants of the seedling growth assay, juglone totally inhibited growth at concentrations of 50 and 100 µg ml^{-1}, 0.3, and 0.6 mM, respectively (Chobot and Hadacek 2009). Significant differences to this control growth were observed starting from 6 µg ml^{-1}, 0.04 mM, depending on the setup of the assay. Although (±)-catechin managed to affect the growth at similar low concentrations (6 µg ml^{-1}=0.02 mM), in some variants, it never succeeded in inhibiting seedling growth totally. Juglone is known for its pronounced phytotoxic activities at comparatively low concentrations; it even has been

suggested as a reference for an allelopathy index (Szabo 1999). (±)-Catechin has been shown to cause variable effects on different plant species (Weir et al. 2003; Perry et al. 2005a). In this study, we specifically explored the extent of stress level variation on seedlings. In a previous study with juglone (Chobot and Hadacek 2009), we suggested that milieu-dependent radical scavenging reactions of juglone correlate with the stress-attenuating hormetic effects of juglone under higher stress levels (when levels of free radicals are also high). In this regard, (±)-catechin was an even better candidate for exploration in similar assays because its lower phytotoxicity facilitated monitoring the effect across a wider range of sub-lethal concentrations. However, before the discussion of the effects observed in the biological assays may be extended to ecological implications, the effects of (±)-catechin in the deoxyribose degradation assay merits explanation.

The deoxyribose degradation assay was developed to detect hydroxyl radicals, which are formed in the Fenton reaction (1) (Halliwell et al. 1987; Aruoma 1994).

$$H_2O_2 + Fe^{2+} \longrightarrow {}^{\bullet}OH + Fe^{3+} + OH^- \quad (1)$$

In this assay, ascorbic acid, which always is added as the last of all reagents, reduces iron (III) to iron (II) and starts the Fenton reaction. In case of flavonoids, chelation of iron has been implicated in contributing to the antioxidant activity (Cheng et al. 2003). By adding EDTA to the iron solution, the deoxyribose assay offers the possibility of studying the effect of the test compound when iron is either chelated by itself or by EDTA (Aruoma 1994). The iron chelated by EDTA still participates in the Fenton reaction (compare controls in Fig. 3a and b); for detailed reactions see Chobot and Hadacek (2009). Thus, depending on the setup of the assay, iron gets chelated either by (±)-catechin or EDTA (2).

(2)

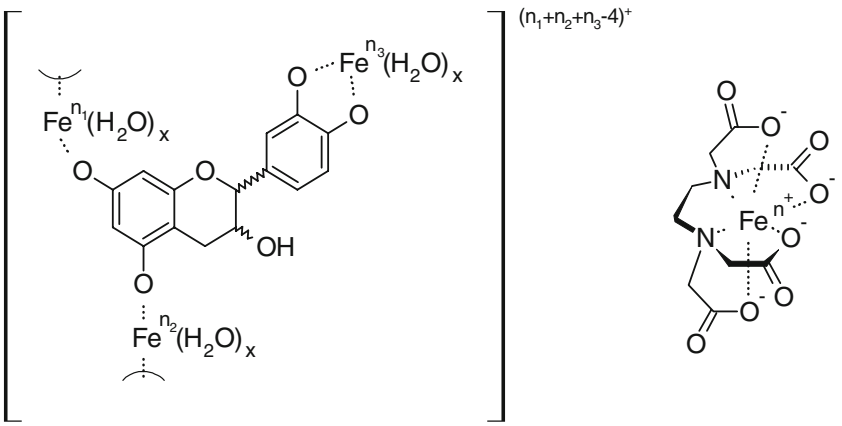

Figure 3a shows the classical variant of the deoxyribose degradation assay. The addition of ascorbic acid creates certain levels of hydroxyl radicals that trigger the formation of MDA. The mean of the control for the classical variant represents 100 % on the y axes of all bar graphs shown in Fig. 3. At lower concentrations (2–8 µM), (±)-catechin chelates the iron ions present in the reaction mixture (2). However, the functionality of the iron is not affected, as the levels of MDA remain unchanged. If iron is chelated by EDTA (Fig. 3b), the levels of MDA also remain unchanged. Ascorbic acid reduces iron (III) to iron (II). With increasing concentrations of (±)-catechin, it starts to react with H_2O_2. The illustrated reactions comprise only a portion of those that are possible. The decreasing levels of MDA in Fig. 3a and b may be explained by the fact that increasing amounts of (±)-catechin reduce H_2O_2 to water by transfer of two electrons (3). Of all ingredients in the reaction mixture, ascorbic acid has the greatest affinity for reducing iron; (±)-catechin does not compare. This is shown by the variants of the deoxyribose degradation assay illustrated in Fig. 3c and d. In this setup, no ascorbic acid was added.

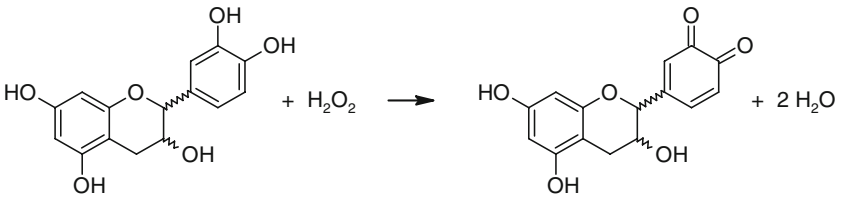
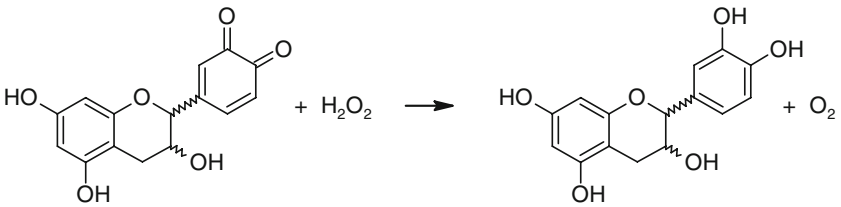
Increasing levels of (±)-catechin did not reduce iron (III), neither if it was chelated by (±)-catechin nor by EDTA. This explains the more or less constants levels of MDA when concentrations of (±)-catechin increased.



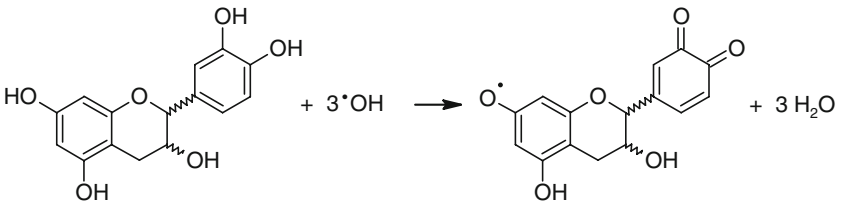
(3)

When (±)-catechin reduces H_2O_2 to water, (±)-catechin gets oxidized to a quinone. This quinone also may react with H_2O_2 and oxidize it to molecular oxygen. During this reaction the quinone is reduced back to (±)-catechin (4).

(4)



Besides the previously illustrated reactions (3, 4), (±)-catechin also may reduce hydroxyl radicals produced by the Fenton reaction to water (5). Such reactions also might provide the precursors for polymerization into proanthocyanidins and condensed tannins (Dixon et al. 2005).

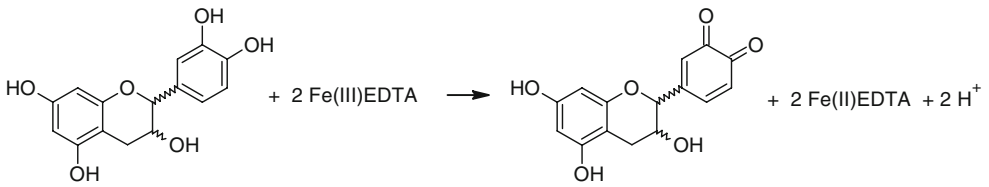


(5)

Slight differences existed between the setup with and without EDTA, which will be explained below.

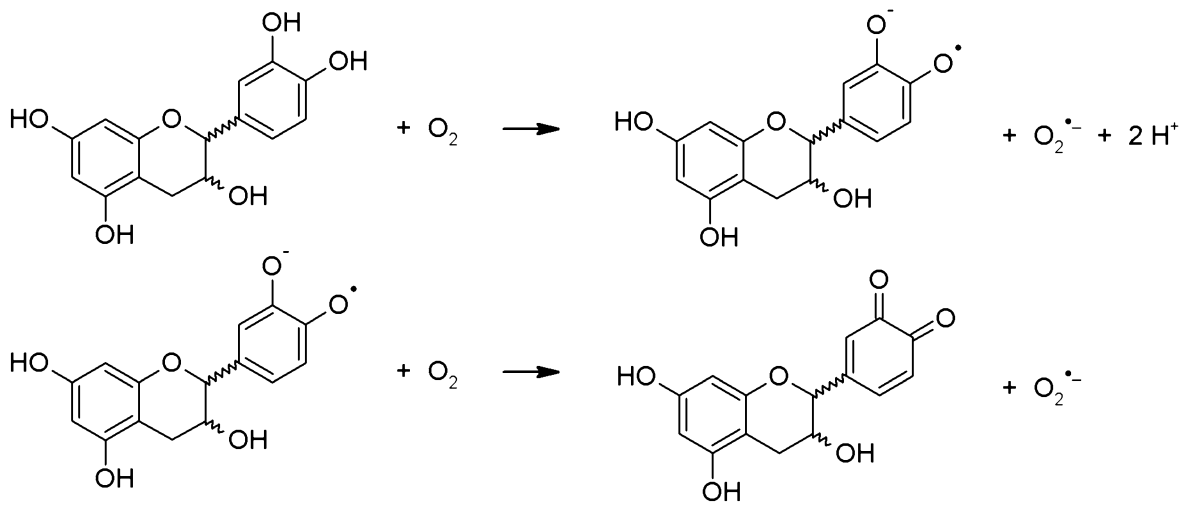
The levels of MDA in Fig. 3a–d were scored after 1 h. In a second series of variants of the deoxyribose degradation assay, no H_2O_2 was added to the reaction mixture. Hydroxyl radical formation depended of the oxidation of diffused oxygen from the air (for detailed reactions see Chobot and Hadacek 2009). Figure 3e and f illustrate that after 16 h, levels of MDA that compare or even exceed that of the standard setup with H_2O_2 could be found in the solution. Similarly, increasing concentrations of (±)-catechin decreased the levels of MDA. Again, the decrease

of MDA was more pronounced in the variant without the addition of the EDTA than in the variant with the addition. The variants of the deoxyribose degradation assay (shown in Fig. 3g and h) revealed that iron chelated by EDTA may be reduced by (±)-catechin (6). Compared to ascorbic acid, this reaction is characterized by a much slower kinetic because the effect only became visible after 16 h.



(6)

Simultaneously, (±)-catechin also may reduce molecular oxygen to superoxide anion radical (7), which can be reduced by iron(II) to H_2O_2 (8).



(7)

(8)

H_2O_2 may then further react with iron(II), which becomes increasingly available as rising amounts of (±)-catechin replenish the reduced iron(II) pool. The above outlined reactions represent possible reaction sequences involved in the pro-oxidative effect visible in Fig. 3h. However, if the iron was chelated by (±)-catechin, no reduction of iron in its complex with (±)-catechin occurred. This indicates that the reduction of the iron chelated by (±)-catechin is not allowed thermodynamically in contrast to the EDTA–iron complex. Consequently, the slightly higher levels of MDA in Fig. 3f compared to Fig. 3e may be explained by underlying pro-oxidative effects. In the variants where scoring was performed after 1 h (Fig. 3a vs. Fig. 3b), a similar phenomenon is visible. However, no pro-oxidative effect is visible in Fig. 3d, the variant where ascorbic acid was not added. Although the obtained results allow no unambiguous designation of a specific reaction causing this effect, it is evident that the iron(III) in the iron–EDTA complex is more reactive than in the iron–(±)-catechin complex. This supports the conclusion that chelation of iron adds to the antioxidative effects of (±)-catechin, just as it has been postulated for other flavonoids (Yoshino and Murakami 1998; Mira et al. 2002) and (±)-catechin in dimethyl sulphoxide solution (Bodini et al. 2001).

What implications do these insights have for the interpretation of biological assays of (±)-catechin? In the

seedling development assays we carried out, we observed many non-linear effects, especially in the filter paper assay where seedlings were subjected to high MeOH concentrations in the initial phase. We varied the photoperiod and concentration of the organic solvent MeOH (low in agar medium and high on filter paper) in the test solution of (±)-catechin. Non-linear effects, i.e., non-dosage-dependent stimulation or inhibition of seedling growth, were visible. Such effects also were observed by Weir et al. (2003) and Prithiviraj et al. (2007) who studied the effect of (–)-catechin on a wide range of co-occurring species. The latter authors also attributed this to hormesis, the phenomenon whereby the compound stimulates at low concentrations and inhibits in higher concentrations; it is described by the classical statement of the famous physician Philippus Theophrastus Aureolus Bombastus von Hohenheim, better known as Paracelsus, who lived at the end of the middle ages: "All things are poison and nothing is without poison, only the dose permits something not to be poisonous" [Paracelsus (1538) Third Defensio]. Hormesis is a phenomenon that has long been known but usually has been ignored due to the fact that nobody knew how to explain it (Stebbing 1982). In a recent study, we suggested that milieu-dependent anti- and pro-oxidative activity of juglone may account for hormetic effects caused by this compound under high stress levels (Chobot and Hadacek 2009).

In the present study, we obtained results for (±)-catechin that showed considerable variation depending of the setup of the assay. Identical concentration levels either caused inhibition (agar medium assay) or stimulation of growth (filter paper assay), see light/dark regime in Fig. 1. The stimulation at higher concentrations was visible both in black and white mustard. Thus, our results strongly support a view that was previously voiced by Weir et al. (2003); these authors suggested that (±)-catechin may be a growth regulator. Plants that are exposed to sub-lethal levels of abiotic stress conditions—as in our assay and those carried out in other labs—may exhibit a broad range of morphogenic responses. Those include inhibition of cell elongation, localized stimulation of cell division, and alterations in the cell differentiation status, the stress-induced morphogenic response (SIMR). The similarity in the responses to distinct stresses is postulated as being orchestrated by increased ROS production and altered phytohormone transport (Potters et al. 2007, 2009). The results obtained from our assays resemble such stress-induced morphogenic responses. The idiosyncratic variation of the effects observed at identical concentrations could have been caused by a combination of stress factors that resulted in different levels of morphogenic responses. In contrast to clinical studies, ecological studies are usually less standardized and, as a consequence, lower inter-laboratory comparability exists. In our assays, exact reproducibility of assay conditions—which are nearly impossible to achieve—were replaced by utilizing a low and high level stress scenario to characterize the stress-induced morphogenic response (SIMR) of our test organisms.

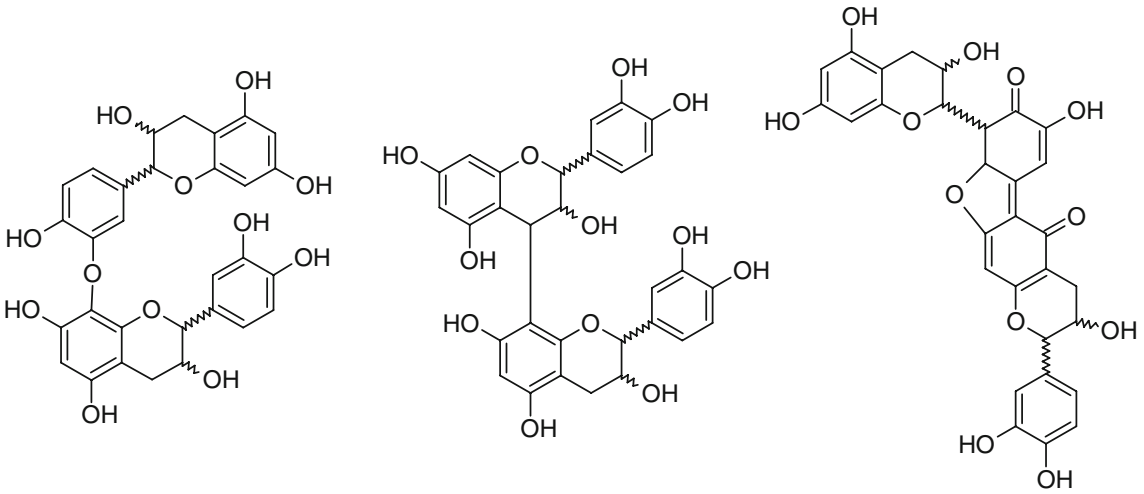
Artemia salina, the brine shrimps, is a crustacean. It susceptibility to (±)-catechin and juglone provides information about potential ecotoxicological effects of these compounds (Nunes et al. 2006). The brine shrimp assay also provides information about intracellular generation of ROS (Matthews 1995; Chobot et al. 2006). The antioxidative effects of (±)-catechin visible in the chemical assays are reflected in the lower mortality rates observed at 5% MeOH concentrations in the saline aqueous solution where concentrations of (±)-catechin increased. Conversely, no change in mortality rates occurred when no MeOH was added to the saline solution. Within the range of tested concentrations, (±)-catechin did not trigger the formation of notable amounts of ROS, as is the case for juglone (IC_{50}= 0.27 mM) (Matthews 1995).

The results from the chemical and biological assays discussed thus far point more to an antioxidative role, (as pointed out by Duke et al. 2009a,b), than to pro-oxidative activity of (±)-catechin (as suggested by Bais et al. 2003). Antioxidative effects were more pronounced when the tested organisms were subjected to higher levels of stress; (±)-catechin reduced these high levels of ROS by scavenging them. Conversely, (±)-catechin may generate ROS, but compared to juglone, which we tested in a similar variant of the deoxyribose assay (Chobot and Hadacek 2009), the pro-oxidative effect is weak. Still, it may account for some of the inhibitory effects of (±)-catechin visible in the seedling growth assays.

Juglone is well known as an efficient redox cycler (Petrova et al. 1990; Bertin et al. 2003). In a recent study, we demonstrated that juglone may either scavenge or generate ROS depending on the milieu (Chobot and Hadacek 2009). The results obtained in our electrochemical experiments provide some evidence that suggest classifying (±)-catechin also as a redox cycler. The cyclic voltammograms of juglone and (±)-catechin show similarities. Both compounds displayed several oxidation peaks, one of which was reversible and accompanied by a corresponding reduction peak, as expected for a redox cycler. At pH 7.4, the peaks showed lower electrode potentials compared to pH 3.6 (Petrova et al. 1990; Martinez et al. 2005). This suggests that compounds such as juglone and (±)-catechin may have evolved to be most reactive in the milieu of the cytoplasm rather than the milieu of the vacuole. Juglone was characterized by reversible peaks at lower redox potentials than (±)-catechin. Juglone, which is a quinone, first gets reduced to trihydroxynaphthalene (Chobot and Hadacek 2009); this compound then is easily oxidized back into the quinone. (±)-Catechin is oxidized first to the

quinone, which then gets reduced to the phenol. In summary, these reactions require lower electrochemical potentials for juglone than for (±)-catechin. In the case of flavonoids, lower electrochemical potentials have been correlated with increased antioxidative properties (Kilmartin and Hsu 2003; Han et al. 2009). Consequently, the results obtained from the electrochemical studies suggest classifying (±)-catechin as a redox cycler, although not so efficient a one as juglone.

In the assessment of potential effects in biotic interactions, (±)-catechin stability is a crucial issue. This flavan-3-ol is a precursor of condensed tannins, which are widespread within plants, and arise from radical polymerization of the semiquinones of (±)-catechin (Dixon et al. 2005). The initial pH in our buffer solutions was 7.4, as in the cytoplasm. HPLC analyses of a 1 mM buffer solution showed that (±)-catechin is decomposed at pH 7.4 but not at pH 3.6. This suggests that (±)-catechin is reactive in the cytoplasm but not in the vacuole. Uptake in roots is evident; brown discoloration occurs when roots are treated with aqueous (±)-catechin solutions (Duke et al. 2009a; unpublished results). HPLC analyses demonstrate that decomposition of (±)-catechin begins already in the aqueous solution. In the rhizosphere, the speed of these reactions may be increased by extracellular enzymes (Duke et al. 2009b). No phenolic acids were detected as were in studies that focus on the decomposition of (±)-catechin in soils (Tharayil et al. 2008). Such phenolic acids, however, may be products of reactions affected by the presence of soil microbes (Pillai and Swarup 2002). The UV-spectra of the peaks of the decomposition products detectable in the HPLC analysis indicate various dimers of (±)-catechin that are formed by radical polymerization of semiquinones (Guyot et al. 1996b) (9).



(9)

The last structure illustrated in this series (9) contains more conjugated double bonds than the other two dimers of (±)-catechin, six vs. three. This chemical characteristic is responsible for the UV spectra that shows absorbance maxima above 300 nm (#5–#7 in Fig. 5b). The HPLC analyses also indicate that only after24 h does (±)-catechin start to decompose. This suggests that our chemical assays were unaffected by the instability of (±)-catechin, but not our biological assays. It is quite possible that such decomposition products could affect the growth of seedlings as well. For instance, decomposition products of (±)-catechin inhibit β-glucosidase activity (Guyot et al. 1996a) and might inhibit other enzymes as well. The tanning effect is well known.

The results from our experiments provide little support for (±)-catechin as a chemical weapon. Rather, they support the recent criticism of this potential function (Blair et al. 2009; Duke et al. 2009a,b): (1) the deoxyribose degradation assay indicated only weak pro-oxidative activity that does not compare favorably to pro-oxidative activities of renowned phytotoxic compounds such as juglone, and suggests that the ROS generating effect of (±)-catechin as shown by imaging of dichlorofluorescein might have been overestimated due to artifact formation; (2) the inhibition of seedling growth reveals more hormesis-like effects, especially under increased stress; (3) the previous hormesis-like effect may be facilitated by the pronounced antioxidative effects of (±)-catechin (Duke et al. 2009a); (4) the

antioxidative properties of (±)-catechin that are evident in the brine shrimp assay and the lack of increased mortality rates also suggest low ecotoxicological potential; and (5) (±)-catechin is stable only at very low pH levels. Consequently, the necessity of proving phytotoxicity in the field, an ultimate proof for allelopathy (Romeo 2000), remains still to be demonstrated for (±)-catechin. The many studies that claim allelopathic activity for (±)-catechin in the field do not provide convincing evidence that it is actually involved in this effect. The observed effects potentially could be caused by different soil chemistry in native and invasive soils that affects the availability of nutrients. Recent cross-continental studies (e.g., Inderjit et al. 2008; He et al. 2009; Thorpe et al. 2009) do not provide any attention to soil chemical characteristics, nor even to pH.

The wide occurrence of (±)-catechin in plants, however, suggests that it might confer benefits, either when accumulated or exuded by roots. Within tissues this benefit might be contributing to stress tolerance as many other phenolic compounds do (Close and McArthur 2002; Grace 2005; Hatier and Gould 2008). In the rhizosphere, (±)-catechin might protect the root tip as follows: Decomposition of soil organic matter (SOM), a process that occurs in soils containing plant litter, especially cellulose, involves transition metal-dependent generation of hydroxyl radicals by the Fenton reaction (Goodell et al. 1997, 2006; Baldrian and Valaskova 2008;). First, exuded (±)-catechin likely chelates iron in a fashion such that its participation in the Fenton reaction is energetically unlikely, and, second, it may scavenge free radicals potentially harmful to the root tips.

ERRATUM

Pretreatment of Clover Seeds with Nod Factors Improves Growth and Nodulation of *Trifolium pratense*

Dominika Maj · Jerzy Wielbo · Monika Marek-Kozaczuk · Stefan Martyniuk · Anna Skorupska

Published online: 30 July 2009

Erratum to: J Chem Ecol (2009) 35:479–487
DOI 10.1007/s10886-009-9620-x

The original article unfortunately contained a mistake. The authors regret overlooking and failing to cite a key laboratory study entitled "Nod-factor-treated *Medicago truncatula* roots and seeds show an increased number of nodules when inoculated with a limiting population of *Sinorhizobium meliloti*" by Macchiavelli, R. and Brelles-Mariño, G. (2004) J. Exp. Botany, 55: 2635–40. That paper, a pioneering contribution, showed that not only roots, but also seeds are able to perceive Nod Factors, as evidenced by higher number of nodules in the plant.

The online version of the original article can be found at http://dx.doi.org/10.1007/s10886-009-9620-x.

de-novo only after herbivore-damage (Paré and Tumlinson 1999). Among the HIPV, some compounds are emitted immediately upon herbivore damage, while the synthesis of others is truly induced, and it takes a certain time after initial infestation before they are emitted (Turlings et al. 1998). Several genes involved in the biosynthesis of HIPV now have been identified, and this opens the possibility to apply molecular tools to study their role both as attractants for natural enemies and as signaling compounds within and between plant species (Baldwin et al. 2001; Kappers et al. 2005; Paschold et al. 2006; Schnee et al. 2006; Ton et al. 2007; Frost et al. 2008).

Maize has been a model plant since the beginning of the studies on these chemically-mediated tritrophic interactions (e.g., Turlings et al. 1990), and the volatile blends emitted from the aboveground shoot, as well as from the belowground roots, are well characterized (Degen et al. 2004; Köllner et al. 2004; Rasmann and Turlings 2008). Despite detailed knowledge on the chemical composition and the relevance of the entire blend as a host location cue to a range of parasitoid species (Tamò et al. 2006), we still lack an understanding of the relative importance of individual compounds or group of compound to specific parasitoids. Specifically, the importance of minor compounds that are emitted in quantities below the threshold level or compounds which cannot easily be detected by common analytical methods is unknown.

In this study, we used a combination of different fractionation methods (filtering tubes, preparative GC and different solvents) and olfactometer bioassays in order to study the attractiveness of different fractions of a blend of HIPV emitted by maize seedlings infested by *Spodoptera littoralis* (Lepidoptera: Noctuidae) to females of the parasitoid *Cotesia marginiventris* (Hymenoptera: Braconidae). *Cotesia marginiventris* is an important larval parasitoid of *Spodoptera* spp. larvae, which are major pest insects that cause substantial economic damage to maize throughout the Americas. The attraction of *C. marginiventris* females to *Spodoptera*-induced maize volatiles has been investigated in a series of previous studies, which showed clearly that this wasp strongly prefers volatiles emitted by caterpillar-infested maize seedlings over non-infested healthy seedlings (Turlings et al. 1991a, b; 2004). Recent studies, however, indicate that not all compounds emitted by infested seedlings are attractive, and some might even be repellent or mask attractiveness (D'Alessandro and Turlings 2005; D'Alessandro et al. 2006). This was evident from a series of experiments in which we tested attraction of *C. marginiventris* females to volatiles emitted by *Spodoptera*-infested maize seedlings after passing the volatile blend through a selection of adsorbent-containing filter tubes (D'Alessandro and Turlings 2005). Surprisingly, the volatile blend that broke through a filter filled with silica had lost all attractiveness to naïve females, although it still contained at least 70% of the volatiles of the original blend. By contrast, the volatile compounds that were adsorbed by the filter (silica extract) and subsequently extracted with a solvent and applied to filter paper were extremely attractive to *C. marginiventris* females.

Hence, the objective of the current study was to confirm and examine the high attractiveness of the volatiles in the silica extract, as a first step towards characterizing and identifying key volatile compounds or combinations of compounds that are used as foraging cues by *C. marginiventris*. Modifying the release of such key compounds in maize seedlings or applying synthetic versions of these compounds in a maize field could be part of a sustainable and environmentally sound strategy to control *Spodpotera* larvae feeding on maize.

Methods and Materials

Insects and Plants

The caterpillar *Spodoptera littoralis* (Boisduval) (Lepidoptera: Noctuidae) and the solitary endoparasitoid, *Cotesia marginiventris* (Cresson) (Hymenoptera: Braconidae) were reared as previously described (Turlings et al. 2004). Adult parasitoids were kept in plastic cages in incubators (25±1°C, 16:8 h L/D) and transferred to the laboratory 30 min before the bioassays. Two-4-d-old naive females were used in the bioassays. Plants (*Zea mays*, var. Delprim) were grown in plastic pots (10 cm high, 4 cm diam) with commercial potting soil (Ricoter Aussaaterde, Aarberg, Switzerland) in a climate chamber (25± 2°C, 60% r.h., 16:8 h L/D, and 50,000 lm/m2). Plants used for the volatile collection were 10-12-d-old and had 3 fully developed leaves. The evening before the volatile collection they were infested with 20 s instar *S. littoralis*, which were released in the whorl of the youngest leaf. After infestation, plants were kept under laboratory conditions (25±2°C, 40± 10% r.h., 16:8 h L/D, and 8000 lm/m2), and volatiles were collected on the following day, between 10 A.M. and 4 P.M.

Volatile Collection

Volatiles were collected by passing the herbivore induced volatile blend over a filter tube filled with 25 mg silica (63–200 mesh, 60 Å, Brunschwig, Basel, Switzerland) for 2.5 h and by adsorbing the breakthrough volatiles on a filter tube that contained 25 mg of the highly adsorbent SuperQ (25 mg, 80–100 mesh, Alltech Associates, Inc., Deerfield, IL, USA). Silica is a rather weak adsorbent and used mainly to adsorb polar compounds. Many volatiles break through the silica filters and can be recollected on SuperQ, which is a strong adsorbent and

commonly used to collect a broad range of different volatile compounds (D'Alessandro and Turlings 2005). Volatiles retained by the silica filters were desorbed with 300 µl dichloromethane (Suprasolve, GC-grade, Merck, Darmstadt, Germany) (silica extract). The volatiles adsorbed on the SuperQ filters were extracted with 150 µl dichloromethane (breakthrough). Further details on the volatile collection and volatile filtration are described by D'Alessandro and Turlings (2005). Several samples were pooled in order to obtain a standardized stock solution for each treatment (silica extract and breakthrough), which was stored at −80°C in small vials (Supelco, Amber Vial, 7 ml with solid cap w/PTFE Liner), and used throughout the experiments for all fractionation steps and bioassays.

Fractionation and Analyses of Volatile Blends

The silica extract was separated into several fractions by preparative gas-chromatography (preparative GC). For this purpose, a Hewlett Packard HP 6890 GC with an automated column injection system (HP G1513 A) was either equipped with a non-polar (HP-1 MS, 30 m, 0.25 mm ID, 0.25 µm film thickness; Alltech Associates, Inc, USA) or a polar column (HP-Innowax, 30 m, 0.25 mm ID, 0.25 µm film thickness; Alltech Associates, Inc, USA). Helium at constant pressure (non-polar column: 19.39 psi; polar column: 45.14 psi) was used as carrier gas, and 5 µl of the silica extract were injected in the "on column mode". After injection, the non-polar column temperature was maintained at 40°C for 3.5 min and then increased to 100°C at 8°C/min and subsequently to 200°C at 5°C/min followed by a post-run of 5 min at 250°C. The polar column was also maintained at 40°C for 3.5 min but then increased to 250°C at 8°C/min followed by a post-run of 5 min at 250°C. Fractions were recollected at specific retention times as indicated in Fig. 3 on Pasteur pipettes that contained 20 mg of SuperQ. The precise retention time for each fraction was calculated by installing the outlet of the GC column to a flame ionization detector (FID) prior to the fractionation steps verified by re-analyzing an aliquot of the recollected volatiles by GC-FID. For each fraction, a separate recollection pipette was attached at the outlet of the GC column and cooled to 4°C with ice in order to recollect all volatiles after GC-separation. Ten aliquots of 5 µl silica extract were recollected on one pipette in order to obtain sufficient material for one bioassay. All volatiles were desorbed from the SuperQ filters with 200 µl dichloromethane and applied to filter paper disks for the bioassay as described below. The recollection efficiency of the preparative GC procedure was calculated by injecting a mixture of synthetic volatile compounds with known concentration and was ≥80% except for (*Z*)-3-hexenal that was recollected with approximately 66% efficiency (data not shown).

To separate non-polar from polar compounds in the silica extract we first desorbed the volatiles collected on the silica filters with 300 µl methanol (Suprasolve, GC-grade, Merck, Darmstadt, Germany). The silica extract in methanol similarly was attractive to the wasps just as the silica extract obtained with dichloromethane (data not shown), and it contained the same major compounds as found in the dichloromethane (Fig. 5). Subsequently, 1 ml of hexane was added to 1 ml of the silica extract in methanol, thoroughly shaken, and placed in the −80°C freezer in order to separate the non-polar hexane phase from the polar methanol phase. Each phase was transferred to a separate vial by a 1 ml GC-syringe and stored in the freezer until used for the bioassays as described below.

To identify the volatile compounds, at least one 2-µl aliquot of the silica extract and the breakthrough extract were injected in a gas chromatograph (Agilent 6890 Series GC system G1530 A) coupled to a mass spectrometer that operated in the electron impact mode (Agilent 5973 Network Mass Selective Detector; transfer line 230°C, source 230°C, ionization potential 70 eV, scan range 33–280 amu) in the pulsed splitless mode onto either the non-polar or the polar column with helium at constant flow (0.9 ml/min) as carrier gas. Oven temperature and ramp were similar to that described above for the preparative GC analyses. The identities of volatiles were confirmed by comparing their mass spectra with those of the NIST 02 library

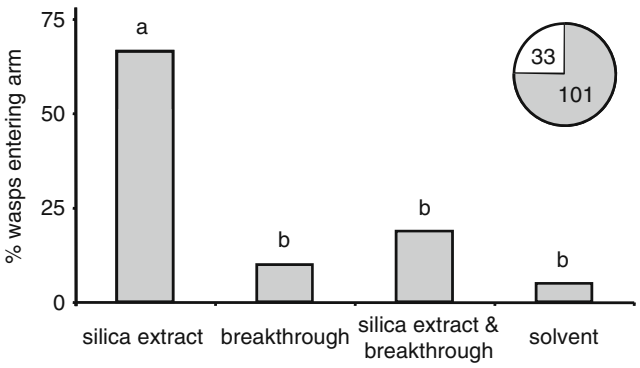

Fig. 1 Olfactometer responses of *Cotesia marginiventris* to different volatile extracts of a blend with volatile compounds emitted by *Spodoptera*-infested maize seedlings. Chemical composition of the extracts are given in Fig. 2. The pie-charts indicate the number of wasps that entered an olfactometer arm (*grey*) and the number of wasps that did not make any choice and remained in the center of the olfactometer (*white*). Different letters above the bars indicate significant differences among the various extracts (GLM: $P<0.05$)

and by comparing the retention times with those of previous analyses (D'Alessandro and Turlings 2005).

Olfactometer Bioassays

All extracts and fractions were tested for attractiveness to parasitoids in a four-arm olfactometer as described by D'Alessandro and Turlings (2005). Cleaned and humidified air entered the odor source vessels at 1.2 l/min (adjusted by a manifold with four flowmeters; Analytical Research System, Gainesville, FL, USA) via Teflon tubing and carried the volatiles through to the olfactometer compartment. Half of the air (0.6 l/min/olfactometer arm) was pulled out via a volatile collection trap that was attached to the system above the odor source vessels. An aliquot of 100 µl of each extract or 50 µl of the fractions obtained by preparative GC was placed on a filter paper (1/2 disk, 55 mm diam, Schleicher & Schuell GmbH, Dassel, Germany) that was inserted in the glass tube connecting the odor source vessels to the olfactometer arms. After letting the solvent evaporate for 2 h, wasps were released in groups of 6 into the central part of the olfactometer. Wasps that had entered an arm of the olfactometer after 30 min were counted and removed. Wasps that did not enter an arm after this time were removed from the central part of the olfactometer and considered as "no choice". Bioassays were replicated at 4 to 8 d, and for each replicate a total of four groups of 6 wasps were tested as described before

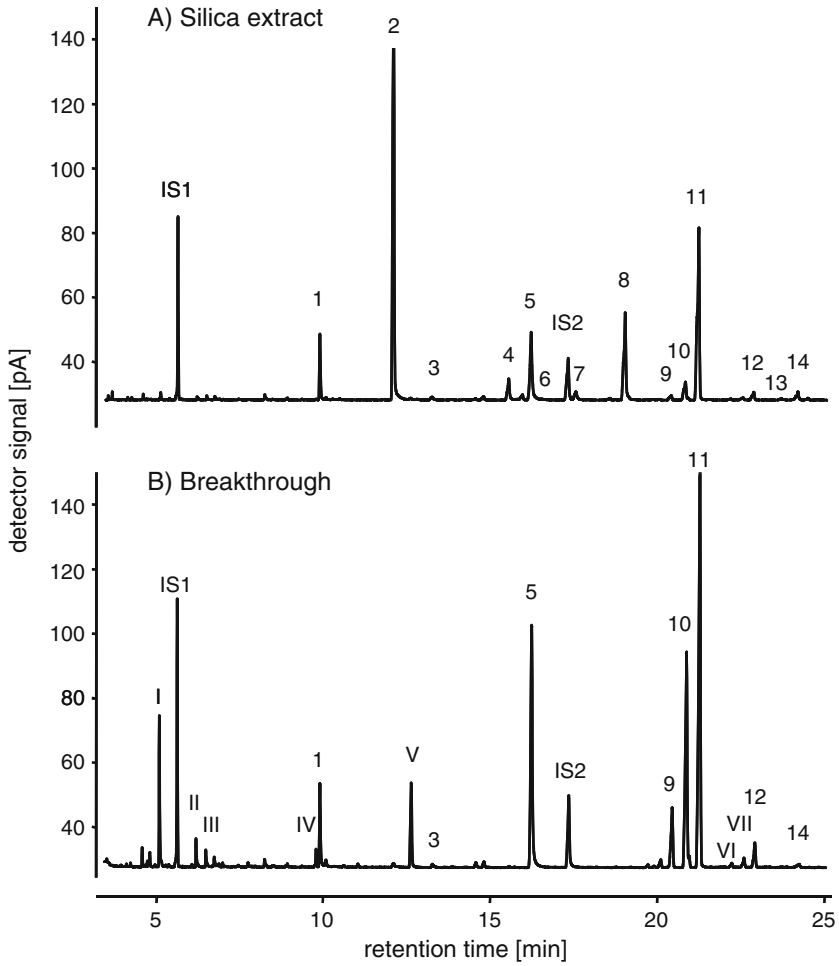

Fig. 2 GC-FID chromatograms of different extracts of a blend with volatile compounds emitted *Spodoptera*-infested maize seedlings that were obtained by passing the entire blend over a silica containing filter tube. Silica extract = volatiles retained in the silica filter. Breakthrough = volatiles that broke through the filter. The entire blend of *Spodptera*-infested maize seedlings contains the combination of both chromatograms. The compounds are: 1 = (*Z*)-3-hexenyl acetate, 2 = linalool, 3 = benzyl acetate, 4 = phenethyl acetate, 5 = indole, 6 = unknown compound, 7 = methyl anthranilate, 8 = geranyl acetate, 9 = (*E*)-β-caryophyllene, 10 = (*E*)-α-bergamotene, 11 = (*E*)-β-farnesene, 12 = β-sesquiphellandrene, 13 = (*E*)-nerolidol, 14 = (3*E*,7*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT), I = (*Z*)-3-hexenal, II = (*E*)-2-hexenal , III = (*Z*)-3-hexen-1-ol, IV = β-myrcene, V = (3*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), VI = unknown sesquiterpene, VII = unknown sesquiterpene. Some compounds are not appearing well as a peak on this scaling, but their location is still indicated with a number. Compounds were identified by GC-MS analyses as indicated in Methods and Materials

(Turlings et al. 2004). All bioassays were carried out between 10 A.M. and 4 P.M.

Statistical Analyses

The functional relationship between parasitoids' behavioral responses and the different volatile extracts and fractions offered in the four-arm olfactometer was examined with a generalized linear model as described earlier by D'Alessandro and Turlings (2005). The model was fitted by maximum quasi-likelihood estimation in the software package R (R: A language and Environment for Statistical Computing, Version 1.9.1, Vienna, Austria, 2006, ISBN 3-900051-07-0, http://www.R-project.org), and its adequacy was assessed through likelihood ratio statistics and examination of residuals. Due to possible differences in the evaporation rate of individual compounds from filter papers, we included the time effect as an explanatory variable in the statistics. However, in none of the experiments was a time effect found, so only statistical values of the treatment effects (volatile extract or fraction) are indicated in the results.

Results

Fractionation over Selective Filter Tubes

In a first four-arm olfactometer experiment, we compared the attraction of females of the parasitoid *C. marginiventris* to the volatile compounds emitted by *Spodoptera*-infested maize seedlings that were trapped on a silica containing filter tube (silica extract) to the ones that broke through the filter (breakthrough), as well as to a reconstitution of the whole volatile blend (silica extract and breakthrough)

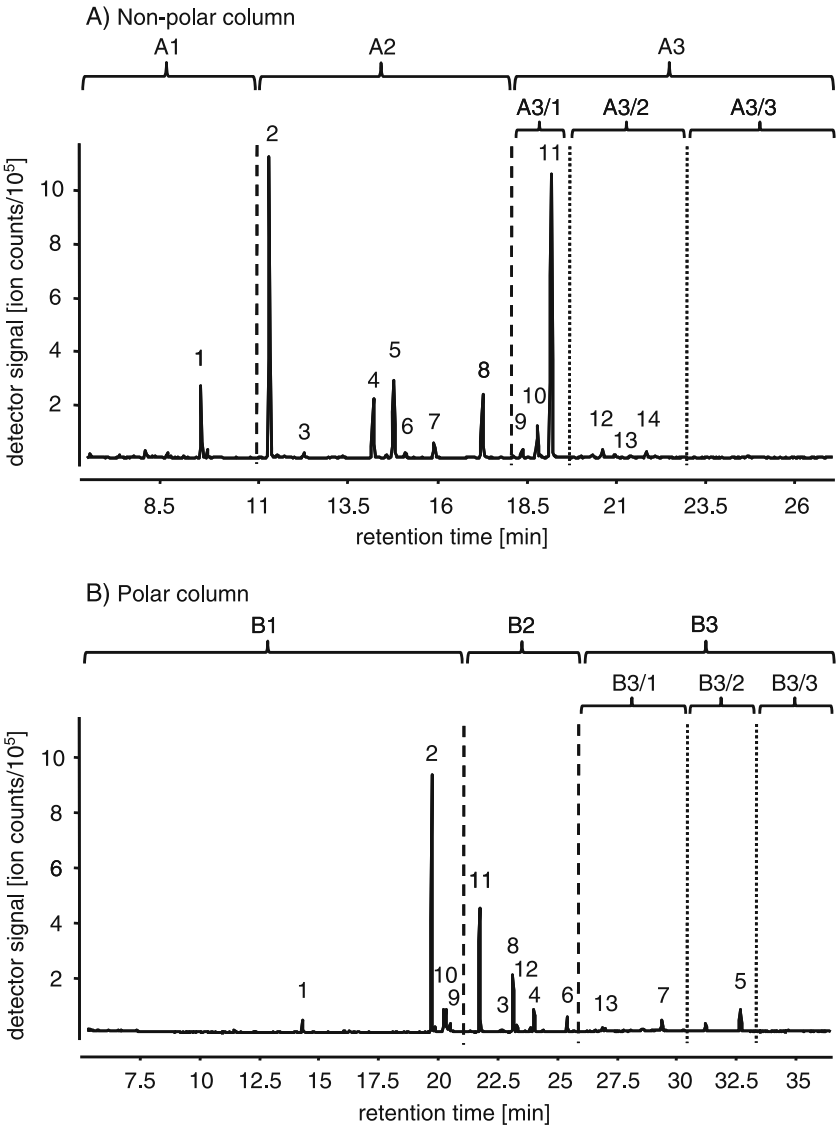

Fig. 3 GC-MS chromatograms of the highly attractive silica extract in dichloromethane indicating different fractions that were isolated by preparative GC on two different columns. The identity of the compounds is given in Fig. 2

and to the solvent only. There was a significant difference in the attractiveness of these various odor sources (GLM: $F_{3,92} = 14.19$, $P<0.001$) (Fig. 1). As in the previous study (D'Alessandro and Turlings 2005), naïve *C. marginiventris* females were extremely attracted to the silica extract, but not to the volatile blend that broke through the filter (Figs. 1 and 2). Interestingly, the silica extract was also more than 3 times as attractive as the reconstitution of the whole blend. The precise composition of each volatile extract is shown in Fig. 2. The amounts of the individual compounds found in the different extracts were not quantified in this study, but the chromatographic analyses of the extracts indicated that they were similar to the previous study (D'Alessandro and Turlings 2005).

Fractionation by Preparative GC

In order to determine the most attractive compounds in the attractive silica extract, the extract was further fractionated into three volatile extracts by preparative gas chromatography (preparative GC) on a non-polar GC-column (HP-1 MS) (Fig. 3A: A1, A2, A3) and tested for attraction in the olfactometer. Significantly more wasps entered the arm with fraction A3 than with fractions A1 and A2, but the latter were still more attractive than solvent only (Fig. 4A; GLM: $F_{3,124} = 14.19$, $P<0.001$). Subsequently, the most attractive fraction of the silica extract was again fractionated into three extracts (Fig. 3A: A3/1, A3/2, A3/3) and tested for attraction. Fraction A3/2 was not attractive, while fractions A3/1 and A3/3 were similarly attractive to the wasps (Fig. 4A; GLM: $F_{3,116} = 4.07$, $P<0.01$).

A second fractionation of the silica extract was carried out on a polar column (HP-Innowax) (Fig. 3B). The most attractive fraction resulting from a first fractionation step was fraction B3, but all fractions with HIPV were significantly more attractive than solvent only (Fig. 4B; GLM: $F_{3,124} = 7.73$, $P<0.001$). Further fractionation of the most attractive fraction B3 resulted in two fraction, B3/1 and B3/2, that were more attractive than solvent only (Fig. 4B; GLM: $F_{3,60} = 14.60$, $P<0.001$).

Fractionation with Different Solvents

In a subsequent experiment, we separated less polar from more polar compounds by the use of different solvents. Volatiles adsorbed on the silica filter were first desorbed with methanol. This methanol extract was similarly as attractive as the dichloromethane extract used in the previous experiments (data not shown), and both of these extracts contained the same major HIPV (Figs. 2 and 5). By adding a similar amount of hexane to the silica extract in methanol, we obtained a hexane phase that contained non-polar compounds and a methanol phase with polar compounds (Fig. 5). In olfactometer bioassays, we found that

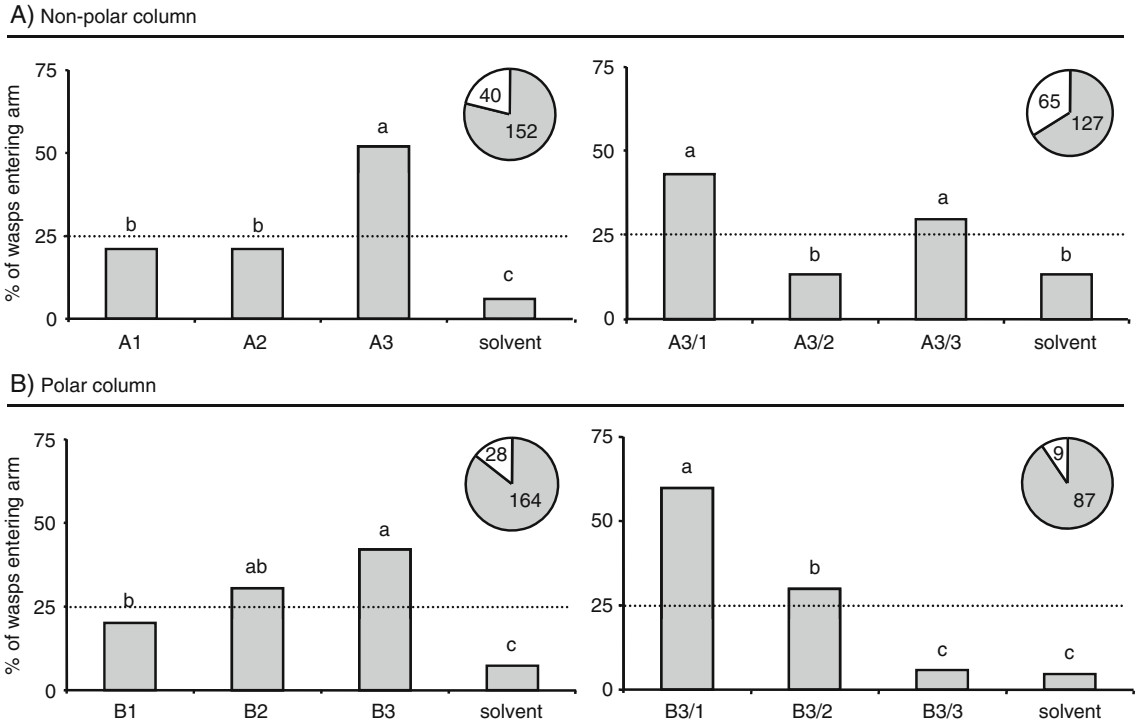

Fig. 4 Olfactometer responses of *Cotesia marginiventris* to different fractions of the silica extract that were isolated by preparative GC as indicated in Fig. 3. Explanations to the pie-charts and to the statistics are given in Fig. 1

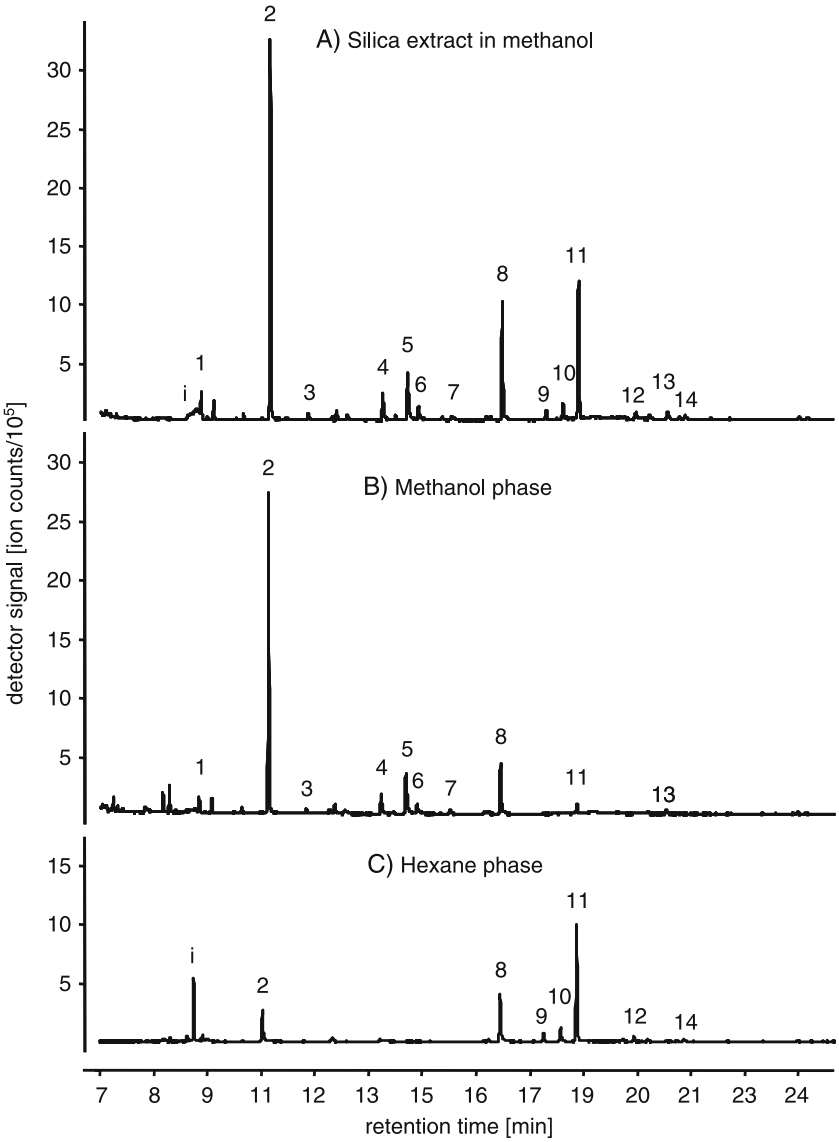

Fig. 5 GC-MS chromatograms of the highly attractive silica extract in methanol and different fractions that were isolated by using solvents with different polarities. The identity of the compounds is given in Fig. 2

the polar methanol phase was significantly more attractive than the less polar hexane phase, but the latter was more attractive than the solvents only (Fig. 6A, GLM: $F_{3,92}$ = 65.60, P<0.001). Comparing the methanol phase to the whole silica extract in methanol showed that the latter was significantly more attractive than the extract without the less polar compounds, indicating that some attractive compounds are soluble in hexane and were either missing or strongly reduced in the methanol phase (Fig. 6B, GLM: $F_{1,46}$ = 6.68, P<0.05).

Discussion

In this study, we used a combination of fractionation methods and olfactometer bioassays to characterize the most attractive compounds of the volatile blend emitted by *Spodoptera*-infested maize seedlings that are used by the solitary endoparasitoid *C. marginiventris* as host-location cue. Similarly, as in a previous study (D'Alessandro and Turlings 2005), the extract that was obtained by passing the entire HIPV-blend over a silica filter tube and contained rather polar compounds and was highly attractive to naive *C. marginiventris* females, whereas the breakthrough extract was not attractive at all to this wasp even though it also contained most measurable HIPV (Figs. 1 and 2). Further separation of less polar from more polar compounds in the silica extract proved that the wasp preferred polar over non-polar compounds (Figs. 5 and 6). However, the detectable polar compounds that were present in the attractive silica extract but not in the non-attractive breakthrough extract (compounds 2, 4, 6, 7, 8, and 13) could not explain the high attractiveness of the silica extract. First, a combination of synthetic versions of

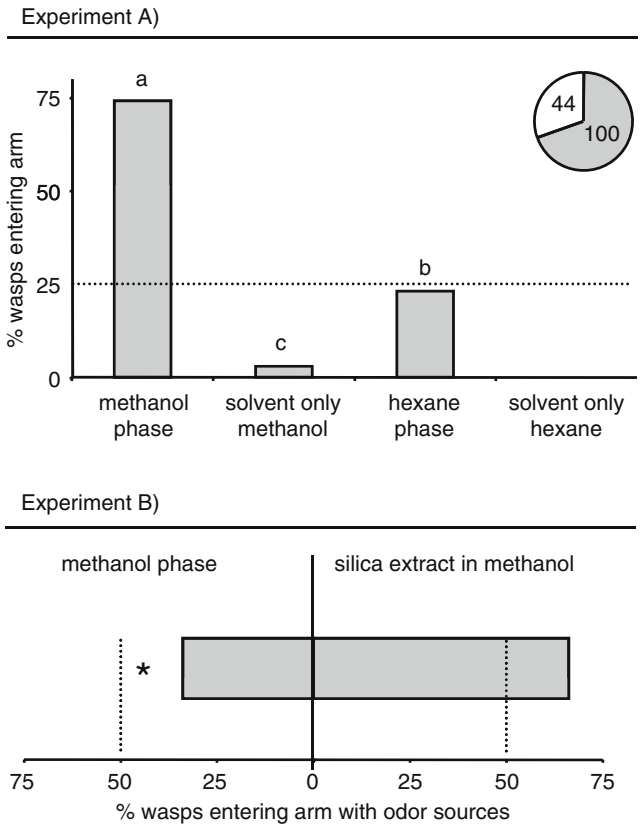

Fig. 6 Olfactometer responses of *Cotesia marginiventris* to different volatile fractions that were isolated by using solvents with different polarities as indicated in Fig. 5. A) Comparison of the polar and the non-polar fraction as well as the solvents as control. Explanations to the pie-charts and to the statistics are given in Fig. 1. B) Comparison of the polar fraction to the entire silica extract in methanol

compounds 2, 4, 7, 8, and 13 was not attractive to the wasps (data not shown). Second, further fractionation of the silica extract by preparative GC did not result in a clear allocation of these compounds to attractive and non-attractive fractions. For instance, although compound 13 was present in the most attractive fraction in some bioassays (fractions A3, B3, and in B3/1), in others it was present in the least attractive fraction (fraction A3/2) (Figs. 3 and 4). Similarly, compound 7 was present in the highly attractive fraction (B3/1), but fraction A2 was significantly less attractive than fraction A3 although it also contained this compound as well as most of other compounds that were present in the highly attractive silica extract. Finally, the unknown compound 6 was present in fractions with medium attractiveness. Overall, our experiments suggest that the compounds detected in the chemical analyses, are not likely to be the most attractive ones, nor the only ones that are needed by *C. marginiventris* as host location cues.

Another interesting observation was that the silica extract, which contained only a fraction of the whole blend, was by far more attractive than the entire blend of herbivore-induced maize volatiles (Figs. 1 and 2). This suggests that certain compounds within a blend of HIPV have either repellent effects on the attraction of *C. marginiventris* or are masking the attractiveness of other attractive compounds. Similar findings have been found in earlier studies and with other insect species. For instance, naïve females of the parasitoid *Microplites rufiventris* clearly preferred volatile blends that did not contain indole, a major HIPV of maize, over blends that contained indole at normal concentration, and this difference was due to a masking effect of the volatile compound indole itself (D'Alessandro et al. 2006). Another common plant compound that recently has been claimed to interfere with the attraction of certain parasitic wasps is isoprene (Loivamaki et al. 2008). By contrast, other studies have shown synergistic effects of certain volatile compounds. For instance, neither nonanal nor geranylacetone alone was attractive to the parasitoid females of *Apanteles carpatus*, a parsitoid of the cloth moth *Tineae pennionella*, but a one-to-one blend of both compounds was as attractive as an extract of all volatile compounds from moth-infested beaver pelt (Takács et al. 1997). Similarly, the egg parasitoid *Chrysonotomyia ruforum* of the herbivorous sawfly *Diprion pini* did not respond to the sesquiterpene (*E*)-β-farnesene, an oviposition-induced pine twig volatile, if offered to the females as an individual compound at different doses (Mumm and Hilker 2005). However, the parasitoid was significantly attracted to this compound when tested together with the odor of pine twigs without eggs. These studies illustrate, that optimal attraction requires the presence of a specific combination of compounds. Unfortunately, so far no general pattern could have been recognized that would help to determine which compounds reduce or enhance the attractiveness of odor sources to a foraging insect (reviewed by Schröder and Hilker 2008).

One reason for the lack of a clear understanding of synergistic and antagonistic effects of individual compounds within complex blends might be the fact that insects respond to volatile compounds in a dose-dependent manner (De Boer and Dicke 2004; Ngumbi et al. 2005; Yan and Wang 2006). Such effects also have been reported in earlier studies with the parasitoid *C. marginiventris* (Fritzsche Hoballah et al. 2002; Turlings et al. 2004). The surprising finding in this study was the strong attraction of *C. marginiventris* to some fractions that contained volatile compounds in extremely low quantities (e.g., A3/3). In fact, the concentrations of these compounds were below the detection limit of the GC analyses, i.e., in the pico-gram range or lower, which has made it impossible to identify the compounds thus far. Previous electrophysiological analyses with *C. marginiventris* showed that some HIPV elicited strong electroantennographic responses in the antennae of the insects at concentrations

below the detection level of the GC analyses (Gouinguené et al. 2005). These observations strongly suggest that minor, yet unknown compounds, play a crucial role in the attraction of *C. marginiventris* to *Spodoptera*-induced maize volatiles. In fact, the olfactory sensitivity of insects is astonishing. For instance, by using the moth *Spodoptera littoralis,* it was nicely demonstrated that around five molecules of the sex pheromone and around ten molecules of a specific plant odor hitting the antenna during one second were sufficient to trigger a heartbeat frequency change (Angioy et al. 2003). It is likely that compounds emitted in such low quantities are likely to escape chemical analysis.

Another complicating factor in identifying minor compounds that are highly attractive to parasitoids is the specific chemical structure of some volatiles. The chemical diversity of volatiles compounds emitted by plants is enormous, ranging from alkanes, alkenes, alcohols, ketones, aldehydes, ethers, and esters to carboxylic acids and others (Niinemets et al. 2004). It is likely that a single volatile sampling and analyses method cannot provide the entire picture of the qualitative and quantitative composition of an herbivore-induced volatile blend. In this study, it is possible that key compounds did not chromatograph well and either did not elute or were eluted throughout the analyses by "bleeding" off the column. This latter possibility could also explain the attractiveness of multiple fractions that might all have contained elusive compound(s). Thus, alternative approaches to conventional volatile collection methods and GC analysis are needed to unravel the identity of highly attractive minor compounds and for a better understanding of the attractiveness HIPV-blends in general. Recent studies that have applied novel methods, such as PTR-MS, have revealed the presence of methanol in the volatile blend of a number of herbivore-infested plants, a compound, that has not been detected with conventional trapping and GC analysis methodologies (Penuelas et al. 2005; von Dahl et al. 2006). Other promising approaches might benefit from novel statistical tools (van Dam and Poppy 2008; Pareja et al. 2009) or also might consider that some plant volatiles are suppressed rather than induced upon insect infestation (Gaquerel et al. 2009). In conclusion, when new methods are used to analyze HIPV blends in a more comprehensive manner, the eventual identification of key attractants or repellents for parasitoids and predators may provide potential to improve biological control of insect pests. The transformation of maize plants with a gene responsible for the biosynthesis of a (*E*)-ß-caryophyllene, a key volatile attractant for entomopathogenic nematodes of the Western corn rootworm, is a recent example of how the HIPV-blend can be modified to successfully control this ferocious root pest of maize plants (Degenhardt et al. 2009).

Acknowledgements We thank the members of the Laboratory of Fundamental and Applied Research in Chemical Ecology (FARCE) at the University of Neuchâtel for continuous support and stimulating discussions on behavioral and chemical aspects. We are grateful to Yves Borcard and students of the University of Neuchâtel for parasitoid rearing and Syngenta (Stein, Switzerland) for the weekly shipments of *S. littoralis* eggs. Statistical advice was provided by Ingrid Ricard and Anthony Davison (EPF Lausanne, Switzerland). This project was possible due to the Research Fellow Partnership Program of the North-South Centre at the ETH-Zurich (RFPP-fellowship) and funded by the Swiss Agency for Development and Cooperation (SDC).

et al. 2005). In contrast, HIPVs are emitted as a delayed response to herbivore feeding damage. HIPVs in cotton (*Gossypium hirsutum* L) and other plants include *cis*-3-hexenyl acetate, *cis*-3-hexenyl butyrate, indole, and various terpenoids such as (*E,E*)-α-farnesene, (*E*)-β-farnesene, (*E*)-β-ocimene, and linalool (Dicke 1994; Loughrin et al. 1994; McCall et al. 1994; Cortesero et al. 1997).

Although, the emission of volatiles is assumed to represent a generalized response to herbivore damage, the blends of volatile compounds released from herbivore damaged plants differ qualitatively and quantitatively depending on the plant species and variety (Dicke et al. 1990; Loughrin et al. 1994; Hoballah et al. 2002), the herbivore species (De Moraes et al. 1998; Loughrin et al. 1994; McCall et al. 1994), and the stage of the herbivore (Takabayashi et al. 1991; Du et al. 1996). For instance, corn (*Zea mays* L.) plants infested by beet armyworm *Spodoptera exigua* (Hübner) caterpillars emit linalool, (3*E*)-4,8-dimethyl-1,3,7-nonatriene, (*trans*)-α-bergamotene, and (*E*)-β-farnesene as major compounds, all of which have not been detected in the headspace of soybean (*Glycine max* L.) plants infested by the same species (Turlings et al. 1993). In cotton, feeding by corn earworm *Helicoverpa zea* (Boddie) or *S. exigua* caterpillars induces the production of distinctive volatile blends that are qualitatively and quantitatively different (Loughrin et al. 1994; McCall et al. 1994). McCall et al. (1994) reported that cotton plants damaged by *H. zea* emit several compounds including (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene, (3*E*)-4,8-dimethyl-1,3,7-nonatriene, (*Z*)-3-hexenyl butyrate, (*E*)-2-hexenyl butyrate, (*Z*)-3-hexenyl-2-methylbutyrate, (*E*)-2-hexenyl-2-methylbutyrate, and indole. Loughrin et al. (1994) conducted a similar study with cotton plants damaged by *S. exigua* and reported several compounds including some of the above, and many which were not reported by McCall et al. (1994) such as (*Z*)-jasmone, (*E*)-β-farnesene, and (*E,E*)-α-farnesene. Such differences in the composition of volatiles induced by different herbivores may convey herbivore-specific information to parasitoids, and thus shape their foraging strategies (Dicke and Sabelis 1988; Turlings et al. 1990, 1995; McCall et al. 1993). In particular, the volatile blend signature produced by plants in response to different herbivores may be used by specialist parasitoids as signals for host specificity (Du et al. 1996; De Moraes et al. 1998). For instance, the specialist parasitoid *Cardiochiles nigriceps* Viereck can exploit differences in volatile blends produced by cotton or corn plants in response to different herbivores, thus distinguishing infestation by its host *H. virescens* from that of the closely related *H. zea* (De Moraes et al. 1998).

The question of whether specialist and generalist parasitoids show differential responses to different suites of host-related volatiles has been a major focus of evolutionary ecology in recent years (Vet et al. 1993; Geervliet et al. 1996; Bernays 2001; Chen and Fadamiro 2007; Stilmant et al. 2008). It has been predicted that specialist parasitoids that utilize fewer numbers of hosts are likely to possess a more highly sensitive (high olfactory sensitivity to host-related chemical cues) and narrowly-tuned (selective) host detection olfactory system than generalist parasitoids (Vet and Dicke 1992; Cortesero et al. 1997; Smid et al. 2002; Chen and Fadamiro 2007). However, few studies have compared olfactory response and sensitivity to host-related volatiles in specialist and generalist parasitoids, and they have produced contrasting results (Elzen et al. 1987; Vet et al. 1993; Geervliet et al. 1996; Chen and Fadamiro 2007). On the one hand, some studies have reported relatively greater response for specialists compared to generalists (Elzen et al. 1987; Vet et al. 1993). Additionally, Geervliet et al. (1996) recorded no differences in behavioral responses of the specialist, *Cotesia rubecula* Marshall and the generalist, *Cotesia marginiventris* (Cresson) to host-related volatiles, and both species were unable to distinguish between plant volatiles induced by their hosts vs. those induced by non-host species. Similarly, Smid et al. (2002) reported no differences in the receptive range of the specialist, *C. rubecula* and the generalist, *Cotesia glomerata* L. to a wide range of host-related odor compounds. Such discrepancies suggest that diverse species of specialist and generalist parasitoids may respond differently to different types of host-related volatiles. Furthermore, even within a broad category of specialist or generalist parasitoids, differences may exist among species based on the degree of specialization (De Moraes et al. 1998; Tamo et al. 2006).

In this study, we tested the above prediction by using a tritrophic model system consisting of cotton (plant), *H. zea* and *S. exigua* (herbivores), and two parasitoids (Hymenoptera: Braconidae) with different degrees of host specificity, *Microplitis croceipes* (Cresson) and *C. marginiventris*. *Microplitis croceipes* is a relatively specialist parasitoid specific to the caterpillars of *H. zea* and *H. virescens*, while *C. marginiventris* is a generalist parasitoid of caterpillars of a wide range of lepidopteran species, including *S. exigua*, *H. zea*, *H. virescens* (Jalali et al. 1987; Turlings et al. 1990; Lewis et al. 1991; Röse et al. 1998). Both parasitoids were selected as experimental models for this comparative study because they have served as models in previous studies of parasitoid olfaction, and because several aspects of their responses to host-related volatiles have been characterized (e.g., Dmoch et al. 1985; Li et al. 1992; Cortesero et al. 1997; Röse et al. 1998; Park et al. 2002; Gouinguené et al. 2005). We used the coupled gas chromatography electroantennogram detection (GC-EAD) technique to test for similarities and differences in antennal responses of both parasitoid species to headspace volatiles of cotton plants infested with *H. virescens* (a host species for both parasitoids) vs. *S. exigua* (a host species for *C. marginiventris*

but not for *M. croceipes*). Based on the results of a recent study in which we recorded differences in the electroantennogram (EAG) responses of both parasitoids to various synthetic host-related volatile compounds (Chen and Fadamiro 2007), we hypothesized that *M. croceipes* would show relatively greater GC-EAD responses than *C. marginiventris* (generalist) to the HIPV components of cotton headspaces, whereas the GLV components, which are emitted passively by plants and as a generalized response to herbivore damage, would elicit relatively greater GC-EAD activity in the generalist.

Methods and Materials

Plants

Cotton (*G. hirsutum*, var. max 9) plants were grown in individual pots (9 cm high, 11 cm diam) in a greenhouse (Auburn University Plant Science Greenhouse Facility) at 25°C±10, 15:9 h (L/D) photoperiod and 50±10% relative humidity. Seeds were planted in a top soil/vermiculate/peat moss mixture. Plants used for headspace volatile collections were 4–6 wk-old.

Caterpillars (Parasitoid Hosts)

Two lepidopteran species, *H. virescens* and *S. exigua* were used as parasitoid hosts. Both species are distributed throughout the United States and are important pests of agricultural crops including corn, and cotton. Eggs purchased from Benzon Research (Carlisle, PA, USA) were used to start laboratory colonies. Caterpillars of both species were reared on a laboratory-prepared pinto bean diet (Shorey and Hale 1965) at 25±1°C, 75±5% relative humidity and 14:10-h (L/D) photoperiod.

Parasitoids

The parent cultures of *M. croceipes* and *C. marginiventris* were provided by the USDA-ARS, Insect Biology and Population Management Research Laboratory (Tifton, Georgia) and the University of Georgia, Tifton campus (contact: John Ruberson), respectively. *Microplitis croceipes* was reared on caterpillars of *H. virescens*, its preferred host (Stadelbacher et al. 1984; King et al. 1985), whereas *C. marginiventris* was reared on caterpillars of its main host *S. exigua* (Jalali et al. 1987). The rearing procedures were similar to those of Lewis and Burton (1970), and the rearing conditions were the same as described above for the caterpillar hosts. For each species, newly emerged adults were collected prior to mating, sexed, and placed in groups of 2 individuals of opposite sex (mated individuals) in a 6-cm diam plastic Petri dish supplied with water and sugar sources. Water was provided by filling a 0.5 ml microcentrifuge tube with distilled water and threading a cotton string through a hole in the cap of the tube. About 4–6 drops (2 µl per drop) of 10% sugar solution were smeared on the inside of the Petri dish cover with a cotton-tipped applicator. Female parasitoids (aged 3–5 d-old) of both species were used.

Collection and GC Analysis of Headspace Volatiles

The methodology and protocols used for volatile collection were similar to those reported by Gouinguené et al. (2005), but with some modifications. Headspace volatiles were collected both from caterpillar damaged and undamaged cotton plants. To induce the production of HIPVs from plants, 30 second instars of *H. virescens* or *S. exigua* were allowed to feed on a potted cotton plant for 12 h prior to volatile collection. The pot with the potting soil was wrapped with aluminum foil to minimize evaporation of water and volatiles. The plant (with the feeding caterpillars) was then placed in a volatile collection chamber (Analytical Research Systems, Inc., Gainesville, FL, USA) consisting of a 5 l glass jar. A purified (activated charcoal) air stream of 500 ml/min was passed through the jar at room temperature for 24 h. The results of a pilot test that compared headspace volatile collection for 24 h vs. 12 h showed no noticeable differences in the number or relative proportion of the peaks, however the 24 h duration was selected because it produced consistent profiles in which all key peaks were detected in relatively higher amounts. Headspace volatiles were trapped with a trap containing 50 mg of Super-Q (Alltech Associates, Deerfield, IL, USA) and eluted with 200 µl of methylene chloride. The resulting extracts (200 µl) were stored in a freezer (at −20°C) until use. Another container with potting soil without plant was used to check for miscellaneous impurities and background noise. The collection system was checked and controlled for breakthrough of the trap during sampling. One µl of each headspace volatile extract was injected into a Shimadzu GC-17A equipped with a flame ionization detector (FID). The dimension of capillary column used was as follows: Rtx-1MS, 0.25 mm I.D., 0.25 µm film thickness (Restek, Bellefonte, PA, USA). Helium was used as carrier gas at a flow rate of 1 ml/min. The GC oven was programmed as follows: inject at 40°C, hold at 40°C for 2 min, and then increase by 5°C/min to 200°C for a total of 40 min. The temperature of both injector and detector was set at 200°C.

GC-EAD Recordings

The extracts were subjected to coupled gas chromatography-electroantennogram detection (GC-EAD) analyses with

females of both parasitoids to detect biologically active peaks (components). GC-EAD analyses were conducted with samples of headspace volatiles from cotton plants infested with *H. virescens* or *S. exigua* caterpillars and detected with antennae of *M. croceipes* or *C. marginiventris* females (total of 4 combinations or treatments). The GC-EAD techniques used were similar to those described by Smid et al. (2002). Briefly, the system was based on the above Shimadzu GC-17A equipped with a FID and coupled to an EAG detector. The dimension of the GC capillary column was the same as described above. The column effluent was mixed with 30 ml/min make-up helium and split at a ratio of 1:2 (v/v), with one part going to the FID and the other through a heated (220°C) transfer line (Syntech®, Hilversum, the Netherlands) into a charcoal filtered, humidified airstream (1000 ml/min) directed at the antenna preparation (EAG detector). The GC oven was programmed as above. The antenna preparation and EAG techniques were the same as previously described (Chen and Fadamiro 2007). Glass capillaries (1.1 mm I.D.) filled with Ringer solution were used as electrodes. Parasitoids were first anaesthetized by chilling, and the head was isolated. The reference electrode was connected to the neck of the isolated head, while the recording electrode was connected to the antennal tip (with the last segment of antenna cut off). Chlorinated silver-silver chloride junctions were used to maintain electrical contact between the electrodes and input of a 1× preamplifier (Syntech®). The analog signal was detected through a probe (INR-II, Syntech®), captured and processed with a data acquisition controller (IDAC-4, Syntech®), and later analyzed with software (GcEad 32, Syntech®) on a personal computer. A 3-µl aliquot of each sample was injected for a GC-EAD run. Five successful GC-EAD recordings were obtained for each treatment. GC-EAD traces were overlaid on the computer monitor and inspected for significant and consistent qualitative and quantitative differences among treatments.

GC-MS Analyses

The GC-EAD active peaks in each treatment were identified by gas chromatography-mass spectrometry (GC-MS) using an Agilent 7890A GC coupled to a 5975C Mass Selective Detector, with an HP-5 ms capillary column (30 m×0.25 mm I.D., 0.25 µm film thickness). One µl of each headspace extract was injected into the GC in splitless mode and under the GC conditions described above for GC-EAD. The chromatographic profiles were similar to those obtained from GC-EAD recordings, thus making it possible to match the peaks. Mass spectra were obtained by using electron impact (EI, 70 eV). Identification of EAD-active peaks was done by using NIST 98 library (National Institute of Standards and Technology, Gaithersburg, Maryland) and by comparing with published GC profiles of cotton head space volatiles (Thompson et al. 1971; Loughrin et al. 1994; McCall et al. 1994). The structures of the identified compounds were confirmed by using commercially available synthetic standards with purity >97% (as indicated on the labels) obtained from Sigma® Chemical Co. (St. Louis, MO, USA). Significant differences in the amounts of each volatile component emitted by *H. virescens* damaged vs. *S. exigua* damaged cotton plants were established by using the Student's *t*-test ($P<0.05$, JMP® 7.0.1, SAS Institute 2007).

GC-EAD Analyses with Synthetic Blend

In order to confirm the observed differences in the GC-EAD responses of both parasitoids to the headspace extracts, a synthetic blend that mimicked the headspace of caterpillar-infested cotton plants was prepared. This blend was formulated to mimic closely the active components of the headspace of cotton plants infested with *H. virescens*, although the same compounds were detected also in the headspace of cotton plants infested with *S. exigua.* It consisted of 13 synthetic volatile compounds that were identified as key biologically active components in the headspace volatiles of cotton plants infested with *H. virescens*, and blended at an approximate ratio in which they were detected in the headspace. The compounds were purchased from the above source with purity >97% and included *cis*-3-hexenal, *trans*-2-hexenal, *cis*-3-hexen-1-ol, *cis*-3-hexenyl acetate, *trans* -2-hexenyl acetate, linalool, *cis*-3-hexenyl butyrate, *trans*-2-hexenyl butyrate, indole, *cis*-jasmone, α-farnesene, α-humulene, and *trans*-nerolidol, blended in the ratio of 4.8, 7.8, 1.9, 19.8, 12.2, 2.2, 13.3, 11.1, 7.2, 0.4, 4.6, 4.3, and 10.2, respectively. Each compound was diluted in hexane and blended at the above ratio to obtain a 100 µg/µl solution. A 3-µl aliquot of the blend (100 µg/µl) was injected for a GC-EAD run. Five successful GC-EAD recordings were obtained for each parasitoid species as described above.

Quantification of GC-EAD Responses

GC-EAD responses of both parasitoids to different volatile components were quantified by using a measurement marker tool available with the GC-EAD software (GcEad 32). This tool enabled the quantification of EAD peaks in microvolts (µV). Significant differences in GC-EAD responses of both parasitoid wasps to each volatile component were then established by using the Student's *t*-test ($P<0.05$: JMP® 7.0.1, SAS Institute 2007).

Results

GC and GC-MS Analysis of Headspace Volatiles

The GC profiles of the extracts of headspace volatiles from cotton plants infested with *H. virescens* or *S. exigua* vs. uninfested (undamaged) plants are shown in Fig. 1. A total of 30 peaks (volatile components) were detected in the headspace of plants infested with *H. virescens* or *S. exigua* (Fig.1a, b). Identical compounds were detected in both extracts, meaning that no qualitative differences were recorded. However, noticeable *quantitative* differences were recorded. In particular, 18 peaks were significantly elevated in the headspace of plants infested with *H. virescens* compared to those infested with *S. exigua* (Table 1). These elevated peaks, as identified by GC-MS, included *cis*-3-hexenal, *cis*-3-hexen-1-ol, α-pinene, β-myrcene, *cis*-3-hexenyl butyrate, *cis*-3-hexenyl-2-methyl butyrate, *cis*-jasmone, α-farnesene, *trans*-nerolidol, and several other HIPV components. No peaks were elevated obviously in the headspace of plants infested with *S. exigua*, relative to those infested with *H. virescens*. Most of the above peaks were not detected or were detected in insignificant amounts in the headspace of undamaged plants (Fig. 1c). Only five peaks (components) were slightly detectable in undamaged plants and were identified by GC-MS as α-pinene, *trans*-2-hexenyl butyrate, linalool, *n*-decanal, and caryophyllene. However, all five components were detected in much greater amounts in the headspace of caterpillar-infested plants.

GC-EAD Responses

Similarities were recorded in the GC-EAD responses of *M. croceipes* and *C. marginiventris* females to volatiles from cotton infested with the two caterpillar species. Sixteen components of the headspace of caterpillar-infested plants elicited consistent GC-EAD responses in both parasitoid species (Figs. 2 and 3). As identified by GC-MS, these volatiles included several GLVs (*cis*-3-hexenal, *trans*-2-hexenal, *cis*-3-hexen-1-ol, and *trans*-2-hexen-1-ol) and HIPVs [(*E*)-4,8-dimethyl-1,3,7-nonatriene, *cis*-3-hexenyl butyrate, *trans*-2-hexenyl butyrate, *n*-decanal, *cis*-3-hexenyl-2-methyl butyrate, *trans*-2-hexenyl-2-methyl butyrate, indole, isobutyl tiglate, (*E*)-2-hexenyl tiglate, *cis*-jasmone, caryophyllene, α-*trans* bergamotene, α-farnesene, α-humulene, β-farnesene, β-hemachalene, and *trans*-nerolidol]. More importantly, key differences were recorded in

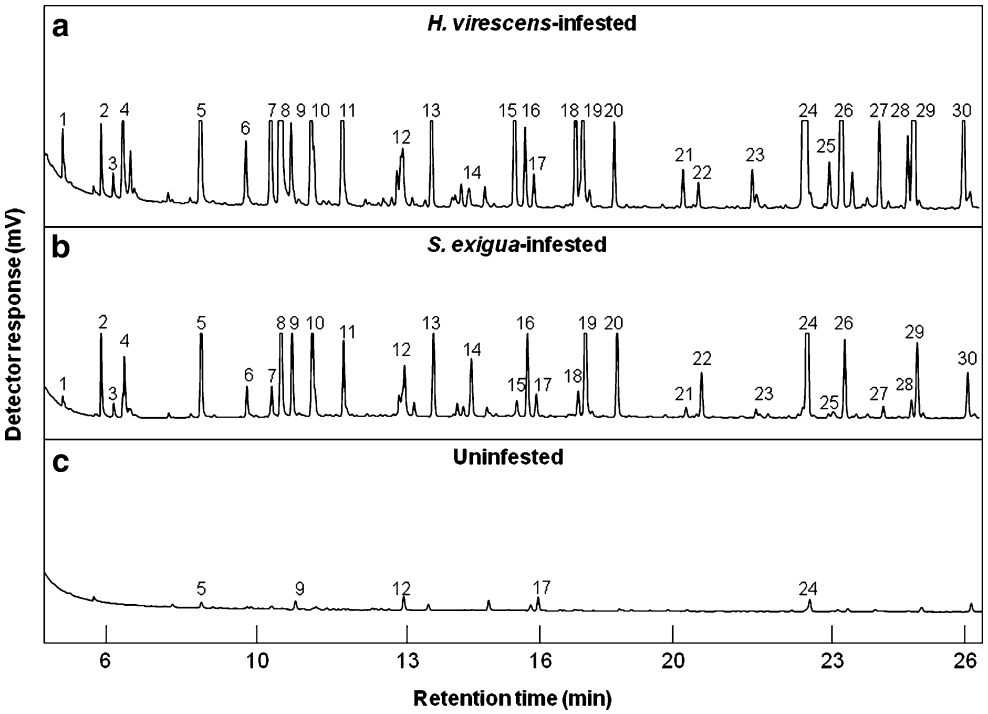

Fig. 1 Chromatographic profiles of headspace volatiles collected from cotton plants infested with *Heliothis virescens* (**a**) or *Spodoptera exigua* (**b**) caterpillars, vs. undamaged control plants (**c**). Identified compounds: (1) *cis*-3-hexenal; (2) *trans*-2-hexenal; (3) *cis*-3-hexen-1-ol; (4) *trans*-2-hexen-1-ol; (5) α-pinene; (6) β-pinene; (7) myrcene; (8) *cis*-3-hexenyl acetate; (9) *trans*-2-hexenyl acetate; (10) limonene; (11) β-ocimene; (12) linalool; (13) unknown; (14) (*E*)-4,8-dimethyl-1,3,7-nonatriene; (15) *cis*-3-hexenyl butyrate; (16) *trans*-2-hexenyl butyrate ; (17) *n*-decanal; (18) *cis*-3-hexenyl-2-methyl butyrate; (19) *trans*-2-hexenyl-2-methyl butyrate; (20) indole; (21) isobutyl tiglate; (22) (*E*)-2-hexenyl tiglate; (23) *cis*-jasmone; (24) caryophyllene; (25) α-*trans* bergamotene; (26) α-farnesene; (27) α-humulene; (28) β-farnesene; (29) β-hemachalene; (30) *trans*-nerolidol

Means across the same row for the same headspace extract followed by different letters are significantly different ($P<0.05$, *t*-test).

the response patterns of both parasitoids to the different components of the headspace extracts. Quantitatively, *C. marginiventris* (generalist) showed significantly greater GC-EAD responses to the GLV (e.g., *cis*-3-hexenal, *trans*-2-hexenal and *cis*-3-hexen-1-ol) components of the two extracts, compared to *M. croceipes* (specialist) (Table 2, Figs. 2, 3). In contrast, several HIPV components of both extracts (e.g., *cis*-3-hexenyl acetate, linalool, *cis*-3-hexenyl butyrate and *trans*-2-hexenyl butyrate) elicited significantly greater responses in *M. croceipes*, compared to *C. marginiventris*. In addition, α-humulene also elicited greater response in *M. croceipes* than in *C. marginiventris*, but this was significant only for *H. virescens*-infested headspace extract. *Microplitis croceipes* showed relatively greater GC-EAD responses than *C. marginiventris* to indole and *cis*-jasmone, but these differences were significant only for *S. exigua*-infested extract. Note that responses of *C. marginiventris* to some of the HIPV components were very low and barely detectable (Figs. 2, 3). In general, the GC-EAD responses of both parasitoid species to the synthetic blend mimicked their responses to the headspace volatiles of caterpillar-infested plants (Table 2, Fig. 4). A confirmatory test in which the synthetic blend was tested at a reduced amount (i.e., 1 µl of a 0.1 µg/µl solution of the blend was injected for a GC-EAD run) produced results similar to those shown in Fig. 4, suggesting that the amounts tested in the

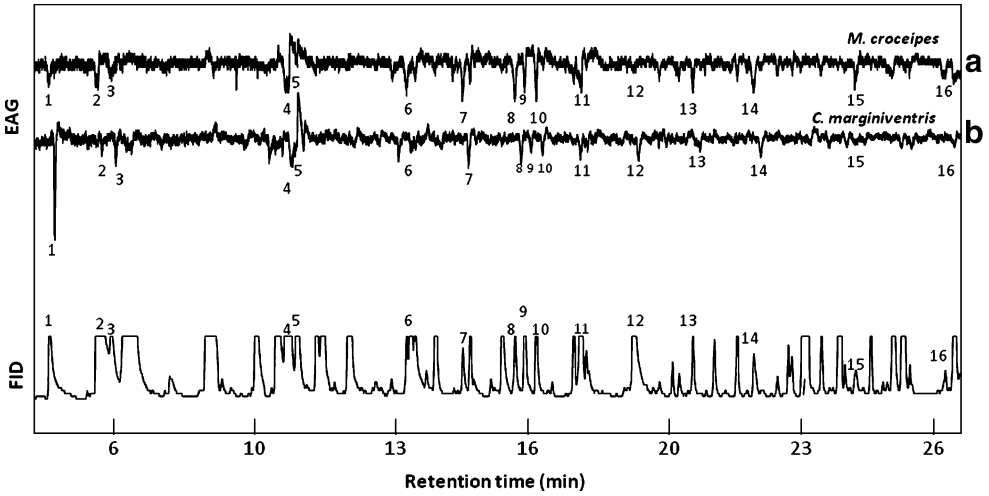

Fig. 2 GC-EAD responses of *Microplitis croceipes* (**a**) and *Cotesia marginiventris* (**b**) to headspace volatiles from *Heliothis virescens* damaged cotton plants. GC-EAD active compounds: (1) *cis*-3-hexenal; (2) *trans*-2-hexenal; (3) *cis*-3-hexen-1-ol; (4) *cis*-3-hexenyl acetate; (5) *trans* -2-hexenyl acetate; (6) linalool; (7) (*E*)-4,8-dimethyl-1,3,7-nonatriene; (8) unknown; (9) *cis*-3-hexenyl butyrate; (10) *trans*-2-hexenyl butyrate ; (11) *trans*-2-hexenyl-2-methyl butyrate; (12) indole; (13) *cis*-jasmone; (14) α-farnesene; (15) α-humulene; (16) *trans*-nerolidol. Note that responses of *C. marginiventris* to some of the HIPV components were almost too low to be detectable in this and the next two figures. GC-EAD responses of both species to the various compounds are quantified in Table 2

initial experiment with the synthetic blend were neither too high nor physiologically irrelevant.

Discussion

The results show that *M. croceipes* and *C. marginiventris* females were capable of responding antennally to many but not all of the caterpillar-induced cotton volatiles, with both parasitoid species showing differential electrophysiological responses to the different blend components. Compared to undamaged plants, cotton plants emitted detectable amounts of a wide range of volatiles, specifically 30 compounds, in response to damage by *H. virescens* or *S. exigua*. In general, our results are in agreement with those previously reported by other authors on the induction of cotton volatiles (Loughrin et al. 1994; McCall et al. 1994), but with some important differences. Loughrin et al. (1994) and McCall et al. (1994) reported 23 and 22 compounds, respectively, from the headspace of caterpillar-infested cotton plants, most of

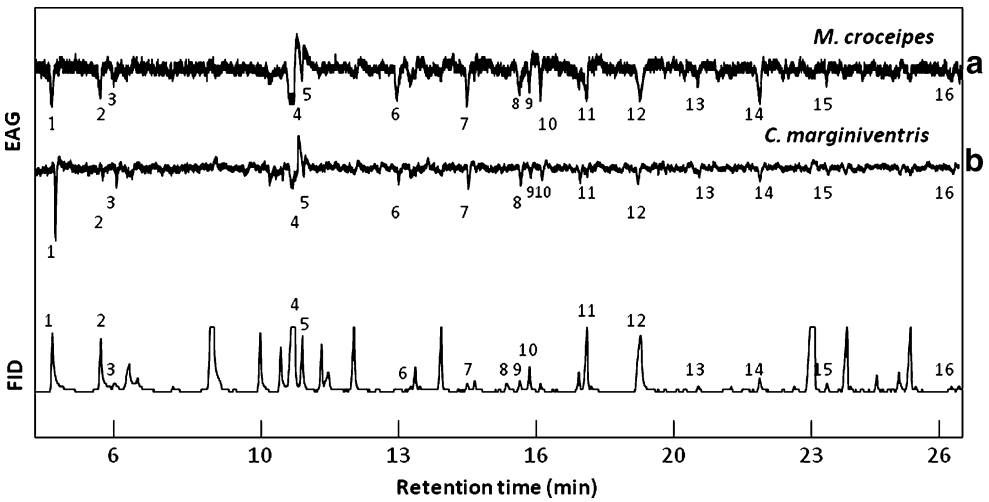

Fig. 3 GC-EAD responses of *Microplitis croceipes* (**a**) and *Cotesia marginiventris* (**b**) to headspace volatiles from *Spodoptera exigua* damaged cotton plants. which were identified also in our study. These compounds included GLVs such as *cis*-3-hexenal, *trans*-2-hexenal, and *cis*-3-hexen-1-ol, and HIPVs such as *cis*-3-hexenyl acetate, linalool, (*E,E*)-4,8-dimethyl-1,3,7-nonatriene, *cis*-3-hexenyl butyrate, *trans*-2-hexenyl butyrate, *trans*-2-hexenyl-2-methyl butyrate, indole, *cis*-jasmone, (*E,E*)-α-farnesene, α-humulene, and *trans*-nerolidol. However, we detected additional volatile compounds that were not reported by Loughrin et al. (1994) and McCall et al. (1994), including *n*-decanal, (*E*)-2-hexenyl tiglate, and β-hemachelene. The differences

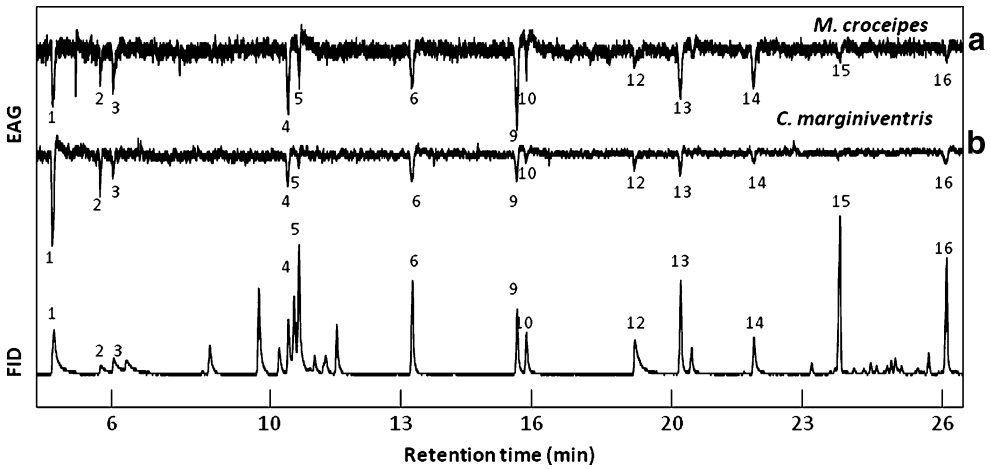

Fig. 4 GC-EAD responses of *Microplitis croceipes* (**a**) and *Cotesia marginiventris* (**b**) to a synthetic blend mimicking the headspace volatiles of caterpillar-infested cotton plants. The blend consisted of 13 compounds (listed below) identified as key biologically active components in the headspace volatiles of cotton plants infested with *Heliothis virescens*, and blended at an approximate ratio in which they were detected in the headspace. Synthetic compounds: (1) *cis*-3-hexenal; (2) *trans*-2-hexenal; (3) *cis*-3-hexen-1-ol; (4) *cis*-3-hexenyl acetate; (5) *trans* -2-hexenyl acetate; (6) linalool; (9) *cis*-3-hexenyl butyrate; (10) *trans*-2-hexenyl butyrate; (12) indole; (13) *cis*-jasmone; (14) α-farnesene; (15) α-humulene; (16) *trans*-nerolidol. GC-EAD responses of both species to the various compounds are quantified in Table 2

may be due to several factors, including differences in headspace volatile collection methodology, sensitivity of the analytical system, and cotton cultivar. For instance, we collected cotton volatiles continuously for 24 h beginning 12 h after plants were infested with caterpillars. Loughrin et al. (1994) collected volatiles for 3-h durations in each trap continuously for 60 h, beginning 1 h after plants were infested with caterpillars, while McCall et al. (1994) collected volatiles continuously for 2 h beginning 16–19 h after caterpillar feeding began. Furthermore, differences in the species/strains and stages of caterpillars tested may be important. Loughrin et al. (1994) used *S. exigua* caterpillars, while *H. zea* caterpillars were used by McCall et al. (1994). In the present study, we tested *H. virescens* and *S. exigua* caterpillars.

We recorded major differences in the amounts of volatiles induced by *H. virescens* vs. *S. exigua*. Of the total 30 components identified, 18 were detected in significantly higher amounts in the headspace of *H. virescens* damaged plants, compared to *S. exigua* damaged plants. These results suggest that the essential difference between the volatile blends induced by both caterpillar species is *quantitative*, rather than *qualitative*. Similar differences in the headspace volatile composition of plants infested by different herbivore species have been reported in cotton (McCall et al. 1994; Loughrin et al. 1994; De Moraes et al. 1998), corn (De Moraes et al. 1998; Turlings et al. 1998), cabbage (Agelopoulos and Keller 1994; Geervliet et al. 1997), and tobacco (De Moraes et al. 1998). It has been proposed that herbivore-specific volatile blends that differ significantly and consistently may provide reliable, information-rich signals to foraging parasitoids (De Moraes et al. 1998). Thus, the change in proportions or ratios of volatile compounds in the headspace of *H. virescens* damaged cotton plants, compared to *S. exigua* damaged plants may convey herbivore-specific information to specialist parasitoids, such as *M. croceipes*. On the other hand, generalist parasitoids, such as *C. marginiventris*, which have a wide host range, may not necessarily use herbivore-specific signals for host location. It is important to note that the use of plant volatiles by both parasitoids to locate host-infested plants may suggest that both are generalists in terms of host habitat location.

Only 16 of the 30 volatiles consistently elicited GC-EAD responses in *M. croceipes* and *C. marginiventris*, suggesting that not all components are perceived by both parasitoids, a finding in concert with those previously reported for some other parasitoid wasps (Li et al. 1992; Park et al. 2001; Smid et al. 2002; Gouinguené et al. 2005). The reason why parasitoids do not perceive all components of the headspace volatile of caterpillar-damaged plants is an interesting evolutionary question that deserves to be addressed. It is note worthy that most of the 16 GC-EAD active volatile compounds were among those elevated in *H. virescens* damaged plants. Our results showed no obvious *qualitative* differences in the range of compounds detected by either parasitoid species.

This is the first comparative study of GC-EAD responses of both parasitoid species to herbivore-induced cotton volatiles. In one of the few similar studies on other tritrophic systems, Smid et al. (2002) reported no differences in the GC-EAD responses of the specialist parasitoid, *C. rubecula* and the generalist, *C. glomerulata* to a wide range of volatiles from Brussels sprouts damaged by two species of *Pieris* caterpillars. In contrast, Gouinguené et al. (2005) reported some key differences in the GC-EAD responses of three parasitoid wasps to maize volatiles damaged by *Spodoptera littoralis* Boisduval caterpillars. Relatively more compounds elicited GC-EAD responses in the generalists, *C. marginiventris* and *Campoletis sonorensis* (Cameron), compared to *Microplitis rufiventris* Kok., which is found more often on *S. littoralis* (Gouinguené et al. 2005).

The major difference recorded in our study was in the intensity of GC-EAD response of both parasitoids to several compounds. We utilized a measurement tool in the GC-EAD software to quantify and then establish significant differences in GC-EAD responses of the two parasitoid species to the various volatile components. The generalist, *C. marginiventris* showed significantly greater GC-EAD responses than the specialist, *M. croceipes* to most GLV components, whereas several HIPV components elicited comparatively greater responses in *M. croceipes*. Similar differences in the intensity of response of parasitoids to host-related compounds also were reported by Gouinguené et al. (2005). The authors reported that the generalist parasitoids, *C. marginiventris* and *C. sonorensis*, showed a greater sensitivity to cotton GLVs *cis*-3-hexanal, *trans*-2-hexenal, and *cis*-3-hexen-1-ol) than the more restricted *M. rufiventris*. Our results in which females of the generalist *C. marginiventris* showed comparatively greater GC-EAD responses to GLVs (*cis*-3-hexenal, *trans*-2-hexenal, and *cis*-3-hexen-1-ol), which are continuously present in the plant and released in freshly damaged plants, support our hypothesis, and they are somewhat in agreement with previous electrophysiological (Gouinguené et al. 2005; Chen and Fadamiro 2007) and behavioral studies (Cortesero et al. 1997; Hoballah et al. 2002; D'Alessandro and Turlings 2005; Hoballah and Turlings 2005). Similar to our results, Gouinguené et al. (2005) also reported that *C. marginiventris* showed little or no antennal response to several HIPVs including β-myrcene, β-caryophyllene, bergamotene, and β-farnesene. In contrast, the specialist *M. croceipes* showed greater GC-EAD responses to the HIPVs, which are more specifically linked to its host. These findings were verified by the results of the GC-EAD tests with the synthetic blend, which also showed the same differences in the intensity of response of both parasitoids.

In general, *M. croceipes* showed slightly greater GC-EAD responses to headspace volatiles collected from cotton damaged by its host species (*H. virescens*) than to headspace volatiles collected from cotton that was damaged by the non-host species (*S. exigua*). Our GC data showed that the essential difference between the volatile blends induced by *H. virescens* vs. *S. exigua* is in the amounts and consequently the ratios of the same compounds. De Moraes et al. (1998) also reported that the main difference in the volatile blends of plants damaged by *H. virescens* vs. *H. zea* was in the ratios of identical compounds. Those authors further reported that the specialist parasitoid *C. nigriceps* could distinguish behaviorally plants damaged by its host, *H. virescens* from those damaged by *H. zea* (a non-host species), possibly by exploring the differences in the ratios of identical compounds in the volatile blends. Thus, the differences recorded in our study in the ratios of the same compounds in the blends induced by the two caterpillar species may be exploited by *M. croceipes* to differentiate plants damaged by its host from non-host species. This proposition is supported by our GC-EAD results which showed greater response of *M. croceipes* to volatiles from *H. virescens* damaged plants, compared to *S. exigua* damaged ones. The need to discriminate hosts from related non-hosts based on subtle differences in the ratios of identical compounds in blends is without doubt a challenging task for specialist parasitoids, such as *M. croceipes*. Thus, it is likely that other unknown minor compounds as well as host-specific volatiles also may play a role in differentiation of host vs. non-host by *M. croceipes*.

In contrast, no obvious differences were observed in the response of *C. marginiventris* to volatile blends induced by either caterpillar species. Our data for *C. marginiventris* are in agreement with the report by Geervliet et al. (1996) that a related generalist species, *C. glomerata* was unable to distinguish between plant volatiles induced by its hosts vs. plant volatiles induced by non-host species. However, *C. glomerata* was able to discriminate between plant volatiles induced by its hosts vs. volatiles induced by non-host species after learning (Geervliet et al. 1998). This suggests that associative learning may improve the overall ability of *C. marginiventris* to respond to the HIPV components of the volatile blends, as has been reported for some other generalist parasitoids (Turlings et al. 1989, 1993; Vet and Groenewold 1990; Vet 1999; Steidle and van Loon 2003; Tamo et al. 2006). Indeed, there is evidence that associative learning may improve response of *C. marginiventris* to induced volatiles (D'Alessandro and Turlings 2005). Furthermore, the results of an ongoing study in our laboratory suggest that associative learning may enhance the behavioral response of *C. marginiventris* to host-related volatiles (unpublished data).

The recorded differences in the antennal sensitivity of *M. croceipes* and *C. marginiventris* to host-related volatiles may be related to differences in the abundance and distribution of olfactory sensilla on the antennae of both parasitoid species. Sensilla placodea has been identified as the main olfactory sensilla responsive to host-related volatiles in *M. croceipes* (Ochieng et al. 2000) and *Cotesia* spp. (Bleeker et al. 2004). A comparative study of antennal morphology of the closely related *C. rubecula* and *C. glomerata* revealed significant differences in the density and distribution of this sensilla type (Bleeker et al. 2004). In an ongoing comparative study of antennal sensilla of *M. croceipes* and *C. marginiventris* in our laboratory, we recorded relatively greater numbers of olfactory sensilla placodea on *M. croceipes* than on *C. marginiventris* antennae (unpublished data). This difference in the density of olfactory sensilla may explain the differences in GC-EAD responses of both parasitoids recorded in this study.

In summary, the results may provide insight into how specialist parasitoids can distinguish between plants damaged by their hosts vs. plants damaged by closely related non-hosts, even though the different hosts may induce the emission of *qualitatively* similar volatile blends. The data suggest that differences between similar blends in the *ratios* of identical volatile compounds may contribute to host specificity in specialist parasitoids, such as *M. croceipes*. Additionally, unknown minor compounds as well as host-specific volatiles also may play a role in differentiation of different host-plant complexes. Further discrimination may be mediated at short range by host contact kairomones (which are typically of relatively lower volatility), such as host feces (Loke and Ashley 1984; Dmoch et al. 1985; Afsheen et al. 2008) and caterpillar chemical footprints on infested plants (Rostas and Wölfling 2009). Future behavioral studies are necessary to confirm whether or not the ability of *M. croceipes* to distinguish between plants damaged by its host and non-host caterpillars (Rosé et al. 1997), is in fact mediated by the subtle quantitative differences in volatile blends recorded in this study. If confirmed, the neurophysiological mechanisms that mediate this fine scale ability for odor discrimination will be addressed in the future by using single sensillum and neuroanatomical techniques.

Here, we addressed induced indirect plant defense at different levels of biological integration. An example of an induced indirect defense mechanism is the production of volatiles by plants in response to herbivory. These volatiles are used by parasitoids or predators to locate their herbivorous victims. Herbivore-induced plant volatiles (HIPVs) mainly comprise green leaf volatiles (GLVs), terpenoids, and phenolics (Dudareva et al. 2006). The composition of induced volatile blends can vary qualitatively or quantitatively (Dicke and Hilker 2003). With this variation, the plant can provide the natural enemies of herbivores with detectable and reliable information (Vet and Dicke 1992; Dicke 1999). The induced volatile production is orchestrated by at least three main signal-transduction pathways: the jasmonic acid (JA), salicylic acid (SA), and ethylene (ET) pathways (Dicke and Van Poecke 2002; Kessler and Baldwin 2002). These pathways can be differentially induced by different herbivore species (Heidel and Baldwin 2004; Schmidt et al. 2005; De Vos et al. 2005), leading to the emission of an herbivore-specific volatile blend (Vet and Dicke 1992; Ozawa et al. 2000; Walling 2000; Leitner et al. 2005).

Jasmonic acid (JA) is a member of a family of compounds collectively known as jasmonates or oxylipins, produced by the jasmonate pathway (Fig. 1). Leaf-feeding insects, such as the larvae of herbivorous Lepidoptera, especially induce the jasmonate pathway (Kessler and Baldwin 2002; De Vos et al. 2005). The production of jasmonates from linolenic acid (18:3) and linoleic acid (18:2) is initiated in the plastid and completed in the peroxisome and cytosol (Schaller et al. 2005). Lipases that release linolenic acid from membrane lipids, mainly originating from damaged cell walls, are thought to play an important role in regulating the response to herbivore-derived cues (Farmer and Ryan 1992; Schaller et al. 2005). Linolenic acid and linoleic acid subsequently are converted by lipoxygenase (LOX) (Bell et al. 1995), allene-oxide synthase (AOS) (Laudert and Weiler 1998), and allene-oxide cyclase (AOC) (Ziegler et al. 1997) into 12-oxophyto-dienoic acid (OPDA). A parallel cascade converts hexadecatrienoic acid (16:3) to dinor-oxophytodienoic acid (dnOPDA) (Weber et al. 1997). After the activity of 12-oxophytodienoic acid reductase (OPR) (Stintzi and Browse 2000) and three ß-oxidation steps, the oxylipins OPDA and dnOPDA are metabolized to form JA (Schaller et al. 2005). Another branch, starting at 9- or 13-hydroperoxide formed by the lipoxygenase, leads to the production of GLVs through the action of hydroperoxide lyase (HPL) (Bate et al. 1998).

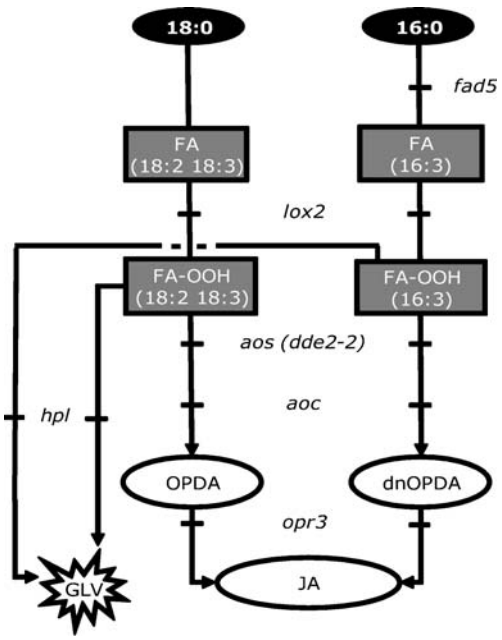

Fig. 1 Biosynthetic route of jasmonates in infested *Arabidopsis thaliana* leaves. *FA* Fatty Acid; 16:0 = hexadecanoic acid; 16:3=7Z, 10Z,13Z-hexadecatrienoic acid; 18:0 = octadecanoic acid; 18:2= 9Z,12Z-octadecadienoic acid (linoleic acid); 18:3=9Z,12Z,15Z-octadecatrienoic acid (linolenic acid); *dn-OPDA* dinor-oxo-phytodienoic acid; *OPDA* oxo-phytodienoic acid; *JA* jasmonic acid; *GLVs* green leaf volatiles. The HPL pathway also utilizes 9− and 13− hydroxides from hexadecanoic, linoleic and linolenic acid. Mutations affecting the biosynthesis are indicated in *italics*

Thus, herbivory results in a change in the oxylipin signature in a plant (Vollenweider et al. 2000). However, it remains to be unraveled what the relative contribution of the different oxylipins is in the induction of indirect defense in terms of HIPV emission and the attraction of natural enemies of herbivores. Evidence for the involvement of jasmonates in herbivore-induced responses does not stem only from the induction of JA and its intermediates upon herbivory. Exogenous application of jasmonates mimics the effects of herbivory. For example, exogenous application of methyl jasmonate (MeJA) and caterpillar-feeding induce in Arabidopsis similar, but not identical, transcriptional responses (Reymond et al. 2004). De Vos et al. (2005) demonstrated that there is roughly a 50% overlap in gene induction in Arabidopsis after MeJA treatment and herbivory by caterpillars or thrips. Besides MeJA, other jasmonates also trigger transcriptional changes. Interestingly, exogenous treatment with OPDA, JA, or MeJA results in overlapping but not identical gene-expression profiles in Arabidopsis (Taki et al. 2005).

Second, jasmonates also influence the emission of volatiles by plants. The production of volatiles by JA-treated plants is quantitatively and qualitatively similar compared to induction by herbivory in Lima bean (Dicke et al. 1999; Ozawa et al. 2000). Application of OPDA has effects on secondary metabolite production similar to applying MeJA, in cell cultures of several plant species (Gundlach and Zenk 1998). However, exogenously applied OPDA but not JA induces diterpenoids in Lima bean plants (Koch et al. 1999).

A third line of evidence for the involvement of jasmonates in herbivore-induced responses comes from mutant analyses. For example, Arabidopsis *opr3* and *aos* mutants show different gene-expression profiles in response to JA, MeJA, OPDA, and mechanical damage compared to wild-type plants, thus indicating distinct signaling roles for dnOPDA, OPDA and JA (Stintzi et al. 2001; Taki et al. 2005). Indeed, *opr3* mutants that lack JA still show oxylipin-dependent resistance to pathogens and herbivores, implying a role for jasmonates other than JA in plant defense (Stintzi et al. 2001).

Mutations in the oxylipin pathway also affect indirect defense. In *Nicotiana attenuata* for example, AOS-silenced plants (as-*aos*), display a reduced JA accumulation and terpenoid emission, and antisense-*hpl* mutants release fewer GLVs (Halitschke et al. 2004). Similarly, two antisense-*hpl*-mutants show an altered production of GLVs in Arabidopsis (Shiojiri et al. 2006a). These oxylipin-mediated effects on volatile emissions are accompanied by effects on interactions of plants with natural enemies of herbivores (Shiojiri et al. 2006b; Halitschke et al. 2008).

Thus, several lines of evidence demonstrate the involvement of jasmonic acid in herbivore-induced responses, including indirect defense, yet also suggest roles for other intermediates of the jasmonate pathway such as dnOPDA or OPDA. As predators and parasitoids are able to discriminate JA-induced from herbivore-induced volatiles (Dicke et al. 1999; Gols et al. 1999; Van Poecke and Dicke 2002), other signals besides JA are likely required for the induction of indirect defenses. Mutant plants altered in signaling pathways with a changed volatile emission represent some of the most powerful tools of testing the mechanisms that underlie HIPV production. The investigation of the effects of altered HIPV production in behavioral assays then is a valuable key to unravel the ecological relevance of these signaling pathways. Here, we followed a molecular ecological approach to study the involvement of several intermediates from the jasmonate pathway in the induction of plant volatiles by leaf-feeding herbivores. We used *Arabidopsis thaliana* to dissect the jasmonate pathway and analyze the effects on indirect defense after attack by leaf-feeding herbivores. In particular, we were interested in the contribution of the two sub-pathways that originate from galactolipids (16:0) or phospholipids (18:0) (Schaller et al. 2005), with special interest in dnOPDA, OPDA, and JA. For this, we selected mutants with altered production levels of dnOPDA, OPDA, and JA (Weber et al. 1997; Stintzi and Browse 2000; Stintzi et al. 2001; Von Malek et al. 2002). For caterpillar-infested mutants and their corresponding wild-type plants, the levels of dnOPDA, OPDA, and JA were quantified. Subsequently, HIPVs were collected, and volatile blend composition was quantitatively analyzed. Finally, we quantified caterpillar-feeding rate and conducted behavioral bioassays with parasitoid wasps to determine the effects of the observed differences in oxylipin profiles and HIPV blend composition after caterpillar-feeding on species interactions.

Methods and Materials

Plants and Insect Material Arabidopsis seeds (*A. thaliana*; genotypes Columbia (Col-0), Wassilewskija (WS), *fad5*, *opr3*, and *dde2-2*) were germinated on an autoclaved mixture of commercially available potting soil and 33% sand, and cultivated in a growth chamber at 21±2°C, 50 to 60% relative humidity (RH), and L8:D16h photoperiod with 80 to 110 μmol m^{-2} sec^{-1} PPF. The selected mutant *fad5* has a Col-0 background, and is incapable of biosynthesizing 7Z,10Z,13Z-hexadecatrienoic acid (16:3) (Weber et al. 1997); the mutant *dde2-2* also has a Col-0 background and is defective in allene oxide-synthase (AOS) (Von Malek et al. 2002). The mutant *opr3* has a WS background and lacks the most relevant isozyme of 12-oxo-phytodienoate reductase (OPR) (Schaller et al. 2000; Stintzi and Browse 2000; Stintzi et al. 2001). Two-wk-old seedlings were transferred to plastic cups (5 cm diam) filled with the earlier described soil mixture. Plants were watered twice a week. When plants were full-grown, vegetative plants, i.e., 6–8 wk after sowing, they were used for experiments.

Herbivore-induced defense responses were initiated by caterpillars from *Pieris rapae*, the small cabbage white. *Pieris rapae* was reared on Brussels sprouts plants (*Brassica oleracea* var. *gemmifera*, cv Cyrus) in a climatized room (L16:D8h; 20±2°C and 70% RH).

The parasitoid wasp *Diadegma semiclausum* was reared on *Plutella xylostella* caterpillars feeding on Brussels sprouts in a climatized room (L16:D8h; 20±2°C and 70% RH). Emerging wasp species were provided ad libitum with water and honey for 2–5 d until experiments were conducted, and are referred to as 'naïve' wasps, as they had received no exposure to plant material, nor an oviposition experience.

Plant Treatments Defense responses were induced by herbivore feeding, or by spraying the plant with JA. Plants were infested by equally distributing 20 first-instar *P. rapae* larvae over the fully expanded leaves. Herbivore feeding was mimicked by spraying JA. Four plants were sprayed with 5 ml of 1.0 mM (±)–JA (Sigma-Aldrich) aqueous solution. JA treatment was performed outside the climate room, for ca 15 min, under comparable climatic conditions. After treatment, plants were placed back into the climate room. In all experiments, plants were treated 24 h before the experiments and kept in a climate room (21±2°C, 50–60% RH; L8:D16h photoperiod and 80 to 110 μmol m^{-2} sec^{-1} PPFD).

Quantitative Analysis of Jasmonate Family Members The abundance of dnOPDA, OPDA, and JA, was determined for each of the used Arabidopsis genotypes. After 24 h, *P. rapae* larvae were removed. All rosette leaves from infested or uninfested control plants were harvested, immediately weighed, and frozen in liquid nitrogen for storage. Extraction of the oxylipins was performed according to the protocol described by Weber et al. (1997). For quantifying the derivatized oxylipins, a gas chromatograph (Hewlett–Packard 5890) equipped with a 30 m×0.25 mm HP-MS column (Hewlett–Packard) coupled to a mass-spectrometer (model 5972, Hewlett–Packard) was used. Helium was used as carrier gas with a flow of 1 ml min^{-1}. The column temperature at the moment of injection was 100°C. The temperature gradient was 100°C to 160°C at 20°C min^{-1}, 160°C to 238°C at 3°C min^{-1}, and 238°C to 300°C at 30°C min^{-1}. Quantification was done by measuring selective ions *m/z*=224 for methyl jasmonate, *m/z*=278 for methyl dnOPDA, *m/z*=238 for methyl OPDA, *m/z*=226 for methyl dihydrojasmonate (Internal Standard used for methyl JA), and *m/z*=240 for methyl tetrahydro-OPDA (Internal Standard used for methyl dnOPDA and methyl OPDA). Internal standards, methyl dihydrojasmonate and methyl tetrahydro-OPDA, were synthesized according to the protocol described by Weber et al. (1997).

Amounts of dnOPDA, OPDA, and JA were calculated per gram fresh weight. In cases where the oxylipin quantity was below the detection level for a certain sample, a value of 0.01 was assigned to these samples. Values were log10 transformed. The following fixed effects-model was used for each oxylipin to screen for differentiation per genotype: $\log 10(O_{ij}) \sim G_i + T_j + G : T_{ij} + \varepsilon_{ij}$, where O = oxylipin quantity per gram fresh weight; G = genotype; T = treatment; ε = residual; i=1,…,4; and j=1,2. Subsequently, per oxylipin two-tailed *t*-tests among Genotype:Treatment combinations were performed to obtain *P* values. For the 2004 data, the *t*-tests were followed by a Benjamini and Hochberg false discovery rate (BH-FDR) multiple comparison correction, to obtain the *q* values (Benjamini and Hochberg 1995). All linear models were performed in the R environment (R Development Core Team 2008) with R packages for linear mixed-effects models.

Headspace Collection and Volatile Analysis Dynamic headspace sampling was done for sets of 4 plants in a climate room (20±2°C, 70% RH; L8:D16h photoperiod and 90 to 110 µmol m^{-2} sec^{-1} PPFD). Twenty-four h before trapping, the pots were removed, soil with the roots were carefully wrapped in aluminum foil, and the 4 plants were placed together in 2.5-liter glass jar. Plants either were left uninfested or were infested with 20 first-instar (L1) *P. rapae* per plant. Just before trapping, jars were closed with a Viton-lined inert glass lid having an inlet and outlet. Air was sucked out with a vacuum pump at 100 ml min^{-1} with the incoming air purified through a steel cartridge filled with 200 mg Tenax-TA (20/35-mesh, Grace-Alltech, Deerfield, MI, USA). A same kind of cartridge was used to trap emitted plant volatiles at the outlet. After 3.5 h of trapping at continuous light, fresh weights of the 4 plants were measured. Headspace collections of uninfested and infested plants, for all the genotypes, were carried out in parallel on one experimental day.

Headspace samples were analyzed with a Thermo TraceGC Ultra™ (Thermo Fisher Scientific, Waltham, MA, USA) connected to a Thermo TraceDSQ quadrupole mass spectrometer (Thermo Fisher Scientific, Waltham, MA, USA). Before desorption of the volatiles, the cartridges were dry-purged with helium at 30 ml min^{-1} for 20 min at ambient temperature to remove moisture. Samples were desorbed from the cartridges by using a thermal desorption system at 250°C for 3 min (Model Ultra Markes Llantrisant, UK) with a helium flow at 30 ml min^{-1}. Analytes were focused at 0°C on an electronically-cooled sorbent trap filled with Tenax and Carbograph (Unity™, Markes International LTD, Llantrisant, UK). Volatiles were transferred without split to the analytical column (Rtx 5MS, 30 m×0.25 mm i.d., 1.0 µm film thickness, Restek, Bellefonte, PA, USA) by ballistic heating of the cold trap to 300°C. The GC was held at an initial temperature of 40°C for 3.5 min followed by a linear thermal gradient of 10°C min^{-1} to 280°C and held for 2.5 min with a column flow of 1 ml min^{-1}. The column effluent was ionized by electron impact ionization at 70 eV. Mass spectra were acquired by scanning from 45 to 400 m/z with a scan rate of 3 scans sec^{-1}.

Compounds were identified by using the deconvolution software (AMDIS version 2.64, NIST, USA) in combination with NIST 98 and Wiley 7th edition spectral libraries and by comparing their retention indices with those from literature (Adams 1995). Characteristic quantifier ions were selected for each compound of interest. Metalign software (PRI-Rikilt, Wageningen, The Netherlands) was used to align chromatograms of all samples and integrate peak areas for the signals of the quantifier ions. Peak areas were converted to peak area per gram fresh weight of leaf material.

Areas of quantifier ions per gram fresh weight were log10 transformed, and for each HIPV compound the following mixed model was used to screen for HIPV compound differentiation per genotype: $\log 10(V_{ijk}) \sim G_i + T_j + G : T_{ij} + R_k + \varepsilon_{ijk}$, where V = area of quantifier ions per gram fresh weight; G = genotype; T = treatment; R = replicate; ε = residual; i=1,…,5; j=1,2; and k=1, …,5. Both G and T were used as fixed effects and R as a random effect. Subsequently, two-tailed *t*-tests followed by a Benjamini and Hochberg false discovery rate (BH-FDR) multiple comparison correction were conducted per compound for the genotypes (Benjamini and Hochberg 1995).

Similarities among plant genotypes based on volatile profiles were analyzed by using LEGG, a nonlinear dimensionality reduction method based on uncentered Pearson correlations among volatile profiles, which are used to generate 3-dimensional networks, for details see Van Poecke et al. (2007).

Behavioral Assays The effects of HIPV alterations as a result of mutations in the jasmonate pathway on behavioral responses were tested for the parasitoid species *Diadegma semiclausum*. Behavioral assays were carried out in a closed Y-tube olfactometer system as described in detail by Takabayashi and Dicke (1992). To investigate the behavioral responses of 3 to 7-d-old mated *D. semiclausum* females, a modified Y-tube olfactometer was used (Bukovinszky et al. 2005). In short, filtered air was led through activated charcoal and split into two air streams (4 l min^{-1}) that were led through 5-liter glass vessels containing the odor sources that consisted of 4 plants each. Plants were infested with 20 L1 *P. rapae* or sprayed with 1.0 mM JA solution 24 h before starting the bioassay. Plants were kept overnight in a climate room (21±2°C and 50 to 60% RH, L8:D16h photoperiod and 80 to 110 µmol m^{-2} sec^{-1} PPF). The olfactometer was illuminated with 4 high-frequency fluorescent tubes (Philips 840, 36 W) from above at an intensity of 60±5 µmol photons m^{-2} sec^{-1}. All experiments were conducted in a climatized room (20±2°C).

Individual wasps were transferred into the Y-tube olfactometer, and their behavior was observed and scored as described in detail by Bukovinszky et al. (2005). Odor sources were interchanged to compensate for any unforeseen asymmetry in the set-up after every 5 wasps tested. Choices between odor sources were statistically analyzed by using a chi-square test, with the null-hypothesis that no preference existed.

The total area of consumed leaf-tissue was analyzed for the plants used in the bioassay. Therefore, after an experiment, all individual leaves of each rosette were taped on paper and scanned with a Hewlett–Packard scan jet 3570c. For quantification of the consumed leaf area, analysis was performed with KS400 version 3.0 software service pack 9 (Carl Zeiss Vision, Oberkochen, Germany). The consumed leaf area per genotype was statistically compared by using ANOVA (SPSS 15.0, Chicago, IL, USA).

Results

Quantitative Analysis of Jasmonate Family Members We quantified the levels of dnOPDA, OPDA, and JA in leaf-tissue from the mutants *dde2-2*, *opr3*, and *fad5*, after 24 h of herbivory by *Pieris rapae*, and from uninfested plants (Fig. 2, Supplementary Table 1). As the *dde2-2* and *fad5* mutants have a Col-0 background, while the *opr3* mutant has a WS background, both wild-type accessions were included as well.

Analyses of Col-0 were performed both in 2004 and 2005. Even though plants were grown in a controlled environment, the levels of oxylipins varied between the years (Fig. 2). Therefore, the 2004 dataset was analyzed separately from the 2005 dataset. Constitutive levels of OPDA and JA are

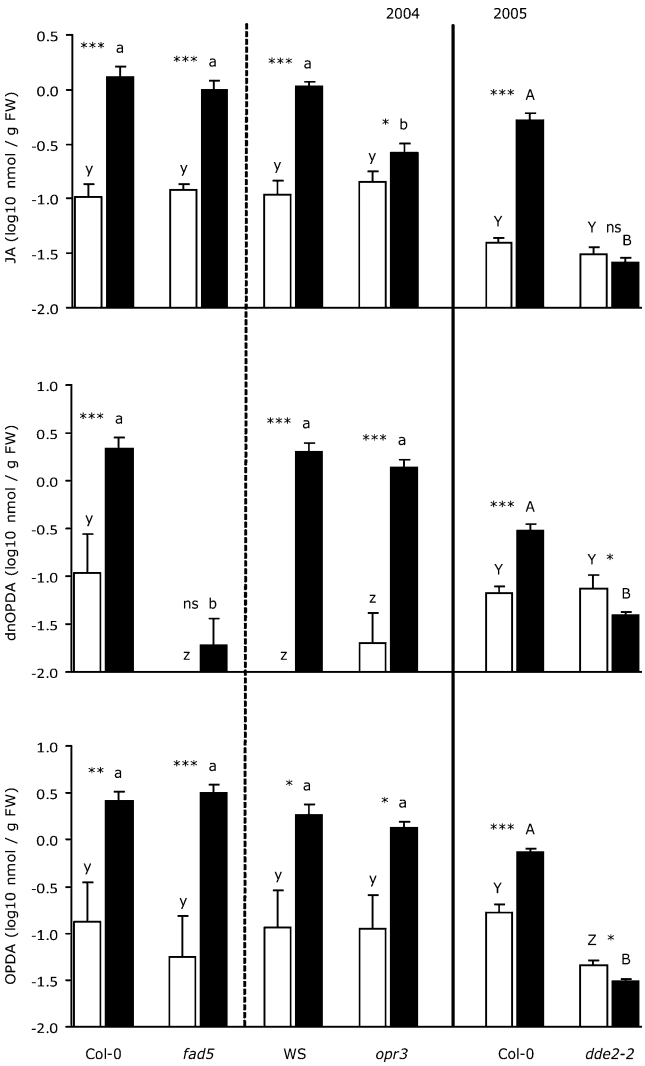

Fig. 2 Oxylipin amounts in *Arabidopsis thaliana* after 24 h of *Pieris rapae* feeding. Extracted oxylipin concentration for *P. rapae*-infested (*black bar*) or uninfested (*white bar*) leaves. Mean oxylipin values + SE are shown (N=4, see also Supplementary Table 1). *Dashed line* separates wild-type accession backgrounds for 2004. *Asterisks* indicate significant differences between infested and uninfested plants within a genotype (*P<0.05; **P<0.01; ***P<0.001; *ns* not significantly different). Bars for infested leaves marked with the same letter are not significantly different (data from years 2004 and 2005 were analyzed independently, for the 2004 data we used *lower case letters* and for data from 2005 *capitals*) (2004: q value >0.05; 2005: P value >0.05). dnOPDA amounts in undamaged *fad5* and WS plants were below detection limit

similar in both wild-type accessions, whereas constitutive dnOPDA levels are lower in WS compared to Col-0 (Fig. 2). Herbivory by *P. rapae* induced all three oxylipins to similar levels in Col-0 and WS plants (Fig. 2).

Mutations in oxylipin biosynthetic genes clearly affected the oxylipin signatures. In *dde2-2* plants, induction of dnOPDA, OPDA, or JA by herbivory was completely abolished. In fact, a decrease in dnOPDA and OPDA levels was observed in *dde2-2* plants in response to herbivory. Moreover, constitutive OPDA levels were lower in the *dde2-2* mutant.

A mutation in *FAD5* resulted in constitutively lower dnOPDA levels that could not be induced by herbivory. However, this mutation did not affect either constitutive or herbivore-induced levels of OPDA or JA.

A mutation in *OPR3* hampered the induction of JA after herbivory: herbivory resulted in significantly lower JA levels compared to the WS wild-type. Constitutive levels of all three oxylipins were unaffected by *OPR3* mutation.

In short, the oxylipin mutations have the expected effects on oxylipin production: the *fad5* mutant only affects dnOPDA levels, *opr3* only affects JA levels, and *dde2-2* affects the levels of dnOPDA, OPDA, and JA. Thus, these three mutants allow us to dissect the roles of dnOPDA, OPDA, and JA levels in indirect defense.

Volatile Analysis To assess the effects of altered oxylipin signatures on HIPVs, we measured the volatile emissions in uninfested and *P. rapae*-infested Col-0, WS, *dde2-2, fad5*, and *opr3* plants (Supplementary Table 2). Compounds for which an influence on discriminative behavior by carnivorous arthropods was known were selected and presented in Fig. 3 (De Boer et al. 2004; Dicke et al. 1990b; Shimoda et al. 2005). HIPV production in wild-type Col-0 and WS showed both similarities and differences. For example, *P. rapae* feeding induced the emission of methyl salicylate (MeSA), the sesquiterpene (*E,E*)-α-farnesene, and the homoterpene (*E,E*) 4,8,12-trimethyltrideca-1,3,7,11-tetraene (TMTT) to similar levels in both accessions. However, Col-0, but not WS, showed the induction of the monoterpene linalool, whereas WS, but not Col-0, showed induction of the GLVs (*Z*)-3-hexenal and (*Z*)-3-hexen-1-ol acetate, and of the monoterpenes β-myrcene and both stereoisomers of β-ocimene.

A mutation in *FAD5* did not result in an altered HIPV emission for the analyzed compounds, thus indicating that dnOPDA does not play a role in HIPV induction. In contrast, a mutation in *DDE2-2* abolished the induction of all analyzed HIPVs, except for 1-nonanol. A mutation in *OPR3* blocked induction of all analyzed HIPVs, except for the GLVs.

To compare total volatile blends instead of single compounds among accessions, the variation in volatile profiles among genotypes was explored further by using the algorithm locally linear embedding graph generator (LEGG). LEGG analysis resulted in a 2D network of genotypes, generated by using a non-linear dimensionality

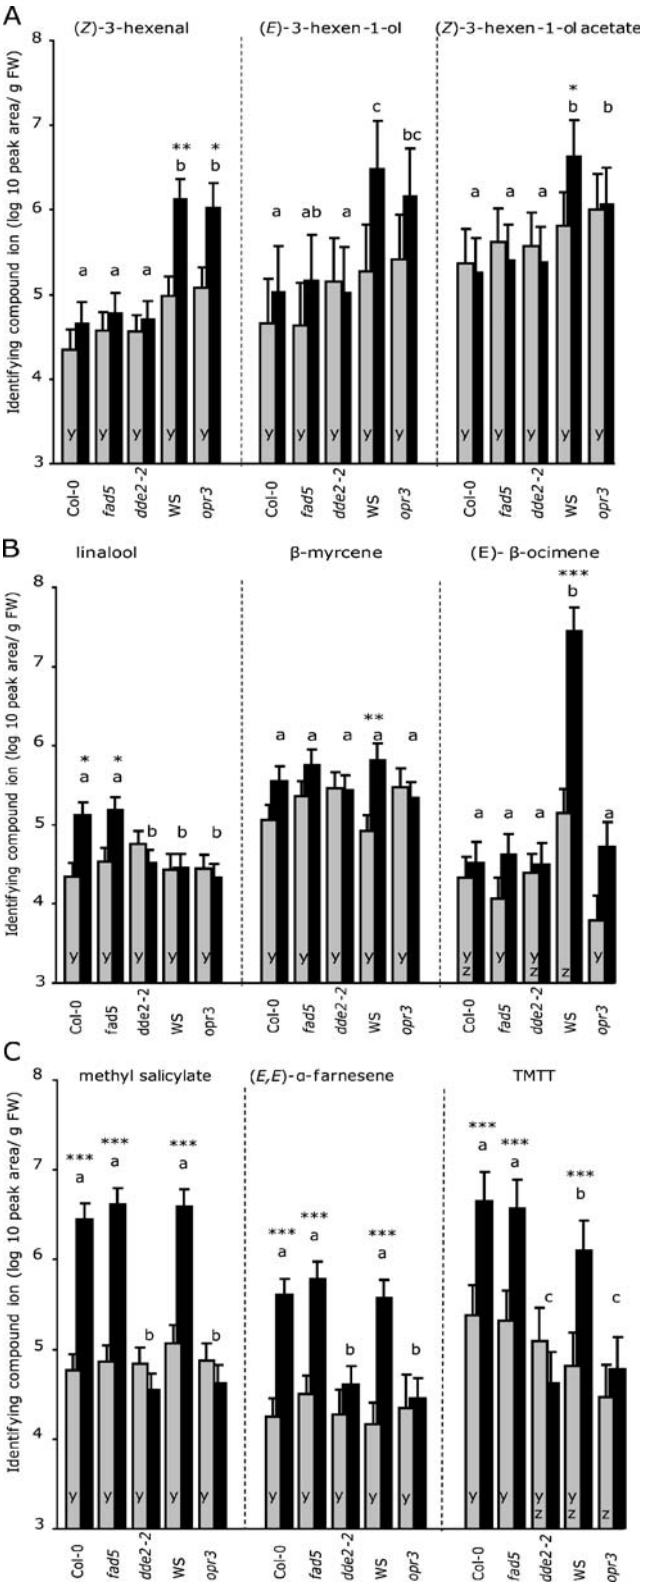

Fig. 3 Characteristic *Arabidopsis thaliana* HIPV-compounds per genotype treatment. **a**: GLVs; **b**: monoterpenes **c**: methyl salicylate (MeSA), (*E,E*)-α-farnesene, and (*E,E*) 4,8,12-trimethyltrideca-1,3,7,11-tetraene (TMTT). Given is the mean + SE for compound-representative ions (N=4–5 replicates per treatment, see also Supplementary Table 2). *Asterisks* indicate significant differences between uninfested (*grey bars*) and *Pieris rapae*-infested (*black bars*) leaves within a genotype (*P< 0.05; **P<0.01; ***P<0.001). Bars that are marked with the same letter are not significantly different, (y–z = uninfested plants, a–c = infested plants), q value >0.05. *Dashed lines* divide separately analyzed compounds

reduction method (Fig. 4) (for LEGG details see Van Poecke et al. (2007) and the legend of Fig. 4). This demonstrated a strong relationship between volatile profiles emitted by uninfested plants of the various genotypes plus caterpillar-infested plants of the *dde2-2* and *opr3* mutants. In contrast, HIPVs from caterpillar-infested Col-0, *fad5*, and WS showed a much weaker correlation with the volatile blend from uninfested genotypes. LEGG analysis also showed that the HIPVs from Col-0 and WS show similarities.

Thus, headspace analysis for the mutants *fad5*, *dde2-2*, *opr3*, and their respective wild-types pointed out that only hampered JA levels (i.e., the common denominator in *dde2-2* and *opr3* plants) resulted in an altered production of HIPVs.

Behavioral Assays To investigate whether the changes in HIPV profiles due to the mutations in the jasmonate pathway affect indirect defense, we investigated the behavioral responses of a parasitoid wasp species towards HIPVs originating from *dde2-2*, *opr3, fad5*, and their wild-types in a Y-tube olfactometer (Fig. 5). *Diadegma semiclausum* females preferred volatiles of infested plants over uninfested plants for all mutants or wild-types (P<0.001). However, HIPVs from caterpillar-infested wild-type plants were significantly more attractive than HIPVs from caterpillar-infested mutants *dde2-2* or *opr3* (for both mutants P<0.05). The wasps did not discriminate between volatiles of herbivore-infested *fad5* plants and infested wild-type plants.

A possible explanation for the observed differences in HIPV emission and parasitoid attraction among mutants and wild-type plants is that the mutation altered the feeding behavior of the herbivore. A reduced attraction to infested mutant plants might have resulted from a reduced feeding rate on the mutant plants. However, this is not supported by our data on feeding rates: the amount of leaf area consumed did not differ when the caterpillars were feeding on plants of *opr3*, *fad5*, or their wild-types WS and Col-0 (308±21.6, 285±15.8, 284±18.1, 295±17.7 mean mm^2 ± SE / plant, respectively; P>0.05). Moreover, the caterpillars even consumed more leaf material of *dde2-2* plants compared to wild-type Col-0 (211±12.4 and 169±10.8 mean mm^2 ± SE / plant,

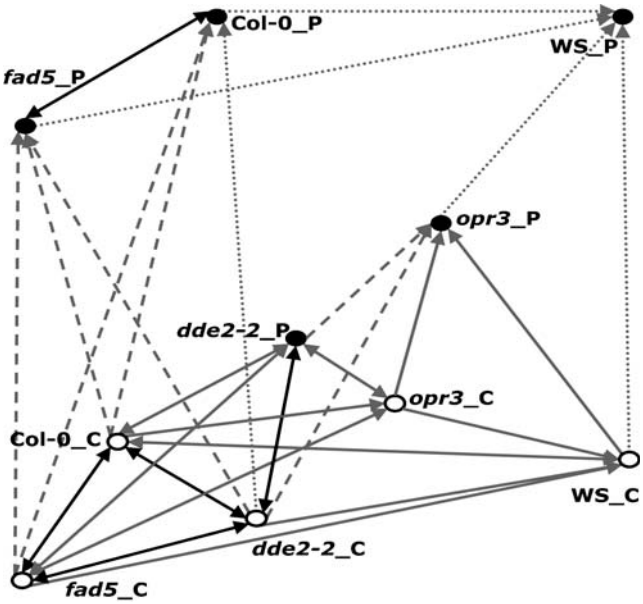

Fig. 4 Visualization of the relationships among HIPV blends of different *Arabidopsis thaliana* genotype-treatment combinations. To assess the similarities among volatile blends from different genotype-treatment combinations, LEGG analysis was applied to the volatile blends of the *Pieris rapae*-infested (_P ; black nodes) and uninfested (_C; white nodes) plants of different genotypes. Similarities were calculated as uncentered Pearson correlation coefficients, based on the quantitative information on 22 volatile compounds for each genotype treatment combination (1-pentanol; (*E*)-2-penten-1-ol; hexanal; (*Z*)-3-hexenal; (*E*)-3-hexen-1-ol; 1-hexanol; heptanal; α-pinene; 1-octen-3-ol; 6-methyl-5-hepten-2-one; β-myrcene; (*Z*)-3-hexen-1-ol acetate; (*Z*)-β-ocimene; (*E*)-β-ocimene; (*E*)-2-nonen-1-ol; linalool; (*E*)-4,8-dimethyl-1,3,7-nonatriene; 1-nonanol; methyl salicylate; undecanal; (*E,E*)-α-farnesene; (*E,E*) 4,8,12-trimethyl-1,3,7,11-tridecatetraene). The similarities were visualized using non-linear dimensionality reduction. Similarities among the profiles that were determined by LEGG are depicted as directed links. Similarities can be compared based on the presence, absence or strength of the directed links. The strength of the similarities is indicated by shading and line-type. Arrow lengths do not illustrate strength of connections. Thus, *solid black arrows* connect blends from genotype-treatment combinations that are highly similar (0.984<r^2<0.990). This similarity decreases from *solid grey arrows* (0.974<r^2<0.984); *dashed grey arrows* (0.964<r^2<0.974); to *dotted grey arrows* (0.951<r^2<0.964). Blends from genotype-treatment combinations that are not connected are relatively dissimilar. A genotype-treatment combination at the base of an arrow represents a near neighbor of the genotype-treatment combination directed at. Arrows that point both ways represent genotypes-treatment combinations that are both near neighbors of each other. For example, the volatile blend from *P. rapae*-infested *dde2-2* mutants is highly similar to the blend from uninfested *dde2-2* and other uninfested genotypes (nearest neighbours both ways, with relatively strong connections), whereas the blend of *P. rapae* infested Col-0 is quite dissimilar from uninfested Col-0 (uninfested Col-0 is a nearest neighbour of infested Col-0, but not the other way around, and the connection is relatively weak). In short, LEGG provides a relatively easy visual interpretation of similarities among volatile blends based on all 22 components

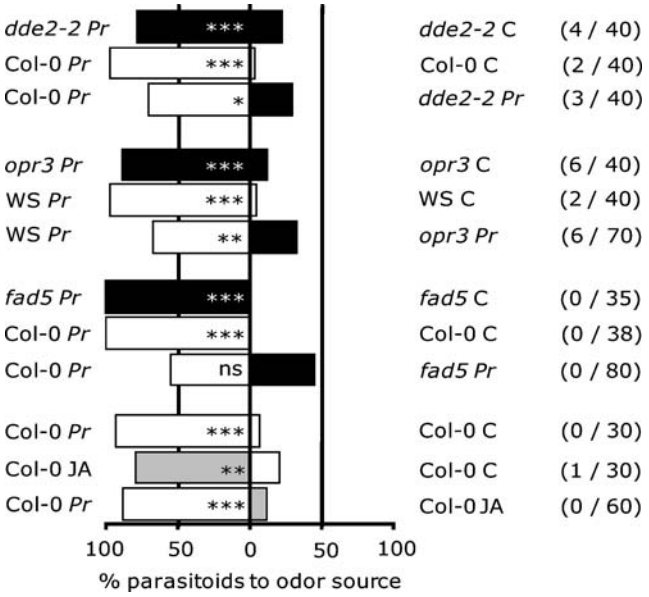

Fig. 5 Preference of naïve *Diadegma semiclausum* females to volatiles of differently treated *Arabidopsis thaliana*, as assessed in the Y-tube olfactometer. Plants were infested with *Pieris rapae* (*Pr*) or treated with JA 24 h before (JA) or were left untreated (C). *Data* represent total number of parasitoids that chose for any of the two odor sources as determined in 3–4 replicate experiments, each on a different day with new odor sources. Asterisks indicate a significant difference within a choice test: **P*<0.05; ***P*<0.01; ****P*<0.001; *ns* not significantly different (χ^2-*test*). The number of wasps that did not make a choice and the total number of tested parasitoids is given in *parenthesis*

respectively; $P<0.05$). Thus, the mutations do not result in reduced feeding and, thus, altered caterpillar-feeding rates cannot explain the observed changes in headspace composition or parasitoid attraction.

We verified the importance of JA signaling in indirect defense by assessing the attractiveness of volatiles induced in the plants by the application of 1 mM JA. Exogenous JA treatment of Col-0 plants made them more attractive than non-treated Col-0 control plants (Fig. 5, $P<0.01$). However, when these JA-sprayed plants were tested against *P. rapae*-induced Col-0, the wasps preferred the latter ($P<0.001$).

Discussion

The jasmonate pathway plays a pivotal role in the induced plant defense response against many arthropod herbivores, including indirect defense responses. However, the role of the different (intermediate) products of this pathway in these defense responses is unclear. Even though it was shown recently that JA needs to be conjugated to an amino acid for functionality, and that OPDA does not serve as a substrate for the conjugating enzyme, there are several reports that indicate a distinct role of OPDA in direct and indirect defenses, possibly through its electrophile properties (Ribot et al. 2008). Therefore, we set out to unravel the involvement of the jasmonate pathway products dnOPDA, OPDA, and JA in caterpillar-induced indirect defense by using a molecular ecological approach. We selected *Arabidopsis thaliana* mutants, *fad5*, *opr3*, and *dde2-2*, for which we quantified oxylipin levels, HIPV emission, and ultimately assessed parasitoid attractiveness towards HIPVs.

Based on previous work, summarized in Fig. 1, we expected the *fad5* mutant to show reduced levels of 16:3 derived compounds; the *dde2-2* mutant to show reduced levels of both 16:3 and 18:3 derived compounds; and *opr3* mutants to show reduced levels of JA. Our data confirmed these expectations: after herbivory *fad5* showed no induction of dnOPDA, *opr3* was hampered in the induction of JA, and *dde2-2* showed no induction of dnOPDA, OPDA, and JA (Fig. 2). Additionally, these data also demonstrated that 1) the 16:3 pathway does not contribute to constitutive or herbivory-induced levels of JA, and 2) that herbivory-induced levels of dnOPDA and OPDA do not depend on JA accumulation through a feedback loop.

Mutation of the *FAD5* gene did not result in an altered emission of HIPVs, showing that dnOPDA does not play a role in HIPV-mediated indirect defense. On the other hand, mutations in *DDE2-2* or *OPR3* did show clear effects on HIPV production, resulting in reduced induction of many volatiles, especially the terpenoids, thus indicating roles of OPDA and/or JA in HIPV-indirect defense. As *dde2-2* (which lacks both OPDA and JA) or *opr3* (which lacks only JA) show very similar HIPV production, we conclude that JA, and not OPDA, is the most important oxylipin in HIPV production. A minor role for OPDA cannot be excluded, as *opr3* plants, showing moderate JA induction, still showed induction of a few volatile compounds, such as GLVs, while *dde2-2* plants, lacking OPDA and JA induction, did not. However, it is likely that this difference between *opr3* and *dde2-2* is caused by differences in the genetic background: none of the three genotypes with a Col-0 background (Col-0, *fad5*, and *dde2-2*) showed induction of GLVs, whereas WS did. The lower GLV-levels produced by Col-0, *fad5*, and *dde2-2* plants are most likely caused by a dysfunctional HPL1 enzyme in the Col-0 background (Duan et al. 2005). In any case, the role of OPDA or earlier intermediates is minor, as LEGG analyses show that the composition of the overall volatile blend of *opr3* and *dde2-2* plants is similar (Fig. 4). Moreover, the blends of infested *dde2-2* and *opr3* plants were similar to the blends of uninfested controls, while they were different from the blends of infested wild-type plants (Fig. 4).

Parasitoid behavioral assays reflected the results obtained by headspace analyses: mutation of *FAD5* did not affect parasitoid behavior, whereas infested plants of both *opr3* and *dde2-2* showed reduced parasitoid attraction

compared to wild-type plants (Fig. 5). Some compounds were still induced in the mutants *dde2-2* and *opr3*: 1-nonanol and (*Z*)-3-hexenal, respectively (Supplementary Table 2, Fig. 3). These compounds might explain the attractiveness of infested mutants *dde2-2* and *opr3* over uninfested controls. These results indicate that other signals besides JA or its intermediates are involved in HIPV production. This is illustrated also by the observation that JA-treated Col-0 plants were less attractive to the wasps than caterpillar-infested Col-0 (Fig. 5; see also Van Poecke and Dicke (2002)). Similar results also have been obtained for other plant-herbivore-carnivore systems (Bruinsma et al. 2009; Dicke et al. 1999).

The combination of biochemical and behavioral analyses of Arabidopsis wild-type and mutant plants not only gives insight into which plant hormones influence indirect defense, but also through which volatile compounds these hormones exert their effects. Inhibition of JA production influenced mono-, sesqui-, and homoterpene volatile emissions as well as the emission of the shikimate pathway-derived methyl salicylate (MeSA). Even though exogenous JA is known to induce GLV production in Arabidopsis (Van Poecke 2002), we did not find any effect of the lack of JA on *P. rapae*-induced GLV emissions in Arabidopsis.

The importance of monoterpenes in plant-insect interactions is well studied (Dicke et al. 1990a; Rose et al. 1998; Shimoda et al. 2005; Mumm et al. 2008; Opitz et al. 2008). Even though Col-0 and WS differed in the identity of monoterpenes induced by *P. rapae* feeding, with Col-0 showing mainly induction of linalool and WS showing mainly induction of (*Z*)- and (*E*)-β-ocimene, lack of JA had a similar inhibitory effect on monoterpene induction in both accessions. Lack of JA also affected emission rates of the sesquiterpene (*E,E*)-α-farnesene and the diterpene-derivative (*E,E*) 4,8,12-trimethyltrideca-1,3,7,11-tetraene (TMTT), demonstrating that JA influences not only the plastid-localized mono- and diterpene production, but also the sesquiterpene production located in the cytosol. Both (*E,E*)-α-farnesene and TMTT are known to influence plant-insect interactions (Van Poecke 2002; De Boer et al. 2004; Ibrahim et al. 2005).

Besides terpenoids, the induction of MeSA also was impaired in JA-lacking mutants. This indicates that hampering the JA pathway consequently impedes some step in the biosynthesis of MeSA. Previous studies using Arabidopsis demonstrated that blocking the SA pathway affects the emission of both MeSA and TMTT and results in decreased parasitoid attraction (Van Poecke and Dicke 2002; Van Poecke 2002). Thus, both JA and SA are required for herbivore-induced emissions of MeSA and TMTT. Such synergism also has been recorded for spider-mite induced volatile emissions of tomato plants (Ament et al. 2004).

In summary, the present study has shown the value of using a molecular ecological approach for elucidating the relative importance of jasmonic acid and its intermediates in indirect defense. By dissecting the jasmonate pathway through the use of selected mutants, we have gained a better understanding of the ecological role of oxylipins in HIPV-mediated indirect plant defense. Even though the importance of the octadecanoid pathway in indirect defense had been demonstrated previously (Thaler et al. 2002; Halitschke et al. 2004; Kessler et al. 2004; Shiojiri et al. 2006a, b), the relative contribution of the different oxylipin compounds to indirect defense had remained unclear. Here, we demonstrated that in Arabidopsis the 16:0 branch of the oxylipin pathway does not play a role in HIPV-mediated indirect defense. Moreover, we demonstrated that from the 18:0 pathway, jasmonic acid is the main actor in HIPV-mediated indirect defense, with limited or no contribution from pathway intermediates such as OPDA. The data strengthen the value of using a molecular ecological approach in advancing our understanding of multi-trophic plant-insect interactions.

Acknowledgements The authors thank Leo Koopman, Frans van Aggelen, and André Gidding for culturing the insects, Ted farmer for training RMPvP to execute oxylipin signature analysis, Philippe Reymond for providing us with Arabidopsis seeds of mutants *fad5* and *opr3*, Beat Keller for supplying us with seeds of Arabidopsis mutant *dde2-2*, Roland Mumm for critically reading an earlier version of the manuscript, Iris Kappers for help with volatile analysis, and Roland Mumm and Iris Kappers for fruitful discussion, Harro Bouwmeester for providing facilities at Plant Research International, and the Netherlands Organization for Scientific Research (NWO/ALW) for a VICI grant (865.03.002; T.A.L.S. and M.D.).

given host plant move within the plant to find adequate sources of food (Johnson and Zalucki 2005). They sometimes need to abandon their host and select another plant, for example when the plant resource is exhausted (Johnson and Zalucki 2005), when the competition from other herbivores becomes too strong (Pats and Ekbom 1992), when the plants' defense affects their health (Kester et al. 2002), following infection by a disease (Evans and Allaway 1983), or because of predation pressure (Bernays 1997). When they leave the host plant, their most relevant choice is to find a similar host to which they have adapted (Jermy et al. 1967; de Boer 2004), sparing the need to readjust their metabolism to a new food source. Actually, habituation to a host plant involves a number of changes, that include physiological adaptations, for example of taste perception (del Campo et al. 2001; Renwick 2001) as well as learning (Saxena and Schoonhoven 1978; Carlsson et al. 1999).

From an evolutionary point of view, it would make sense that larvae would express innate preferences for stimuli from suitable host plants and innate avoidance of stimuli from non-host plants. This holds true at least partly for contact chemoreception where taste neurons are tuned either to phagostimulant molecules or to potentially noxious compounds that are deterrent (Chapman 2003). Olfaction represents a different challenge, because plant odors are complex and variable, composed of ubiquitous chemicals such as green odors (Visser 1986), which makes any recognition task less easy. Larvae are equipped with olfactory sensilla located on their antennae and on the maxillary palps, representing approximately 78 neurons (Dethier and Schoonhoven 1969) that project into the antennal lobe (Kent and Hildebrand 1987; Itagaki and Hildebrand 1990). Electrophysiological studies confirm that some of these neurons detect plant odors, on the antenna (Dethier and Schoonhoven 1969; Dethier 1980) and on the maxillary palps (Roessingh et al. 2007). Despite this limited sensory equipment, neonate larvae of several Lepidoptera species are able to orient towards odors released from their host plants and to express specific choices (Huang and Mack 2002; Singh and Mullick 2002; Castrejon et al. 2006), presumably by recognizing patterns of combined odors and contact chemicals (Dethier 1976).

In this work, we used neonate larvae of the European corn borer (ECB), *Ostrinia nubilalis* Hübner (Lepidoptera: Crambinae) and tested their innate preferences towards odors released from a host and a non-host plant, respectively maize and spinach. ECB is considered a highly polyphagous species that has been reported on over 200 plant species (Hodgson 1928; Jackson et al. 2005 and references therein). Most adult females lay their eggs on maize (Bethenod et al. 2005; Bengtsson et al. 2006). They prefer maize over hop (*Humulus lupulus* L.), which is considered the ancestral host in Europe (Pelozuelo et al. 2004; Malausa et al. 2008). Recent molecular data suggest the species is composed of sympatric strains that exploit different host plants. In France, two strains coexist: a maize strain, which damages maize crops (used in this study) and a second strain, which oviposits and develops preferentially on hop and mugwort (*Artemisia vulgaris* L.) (Bethenod et al. 2005; Malausa et al. 2005; Leniaud et al. 2006).

Even if ECB larvae are polyphagous, they probably avoid feeding on a number of non-host plants that emit repellent or deterrent chemicals. One of the plants that ECB larvae and adults seem to avoid is spinach (*Spinacea oleraceae* L.). Spinach produces phytoecdysteroids (PEs) that act as a constitutive defense (Schmelz et al. 2000) and increases their synthesis and transport in response to damage from herbivores (Schmelz et al. 1998, 1999; Soriano et al. 2004). In the laboratory, ECB larvae avoid feeding on spinach, especially on younger leaves (F. Marion-Poll, unpubl. observations), which happen to have the richest content in PEs (Schmelz et al. 1999). ECB larvae also avoid feeding on a diet containing PEs such as 20-hydroxyecdysone (20E), which they detect with contact chemoreceptor neurons located in several of their taste sensilla (Marion-Poll and Descoins 2002). Deterrent cells with a similar sensitivity profile also are present in tarsal sensilla of the adults, and females avoid laying eggs when PEs are present at the surface of maize (Calas et al. 2007). PEs are generally toxic to insects because they interfere with ecdysone signaling (Dinan 2001). Although ECB larvae can detoxify PEs by producing fatty acyl ester conjugates (Rharrabe et al. 2007), we observed that larvae avoid feeding on a diet that contains PEs. Since ECB larvae and adults avoid PEs, we wondered if ECB larvae would be deterred by odorants emitted by spinach.

In this study, we monitored the orientation behavior of neonate ECB larvae stimulated with volatiles from maize or from spinach by using a locomotion compensator. Considering previous data, we expected larvae to orient towards maize odors and possibly walk away from spinach odors. Odors were sampled by head space entrainment with humidified air forced through a plastic bag that enclosed the leaves of a plant. The stimulus concentration was adjusted by changing the amount of air flowing through the bag. We also delivered odors at different pulsing regimes because the temporal structure of the odor plume has been shown to be of special importance to the orientation of adult moths towards pheromone or plant volatiles (Cardé and Willis 2008). Odor pulsing also has been recently reported to influence orientation of larvae of the Colorado potato beetle towards host-plant odors (Hammock et al. 2007). Our results demonstrate that ECB larvae showed a slight positive anemotaxis or did not orient to odorless humidified air stream, whatever the pulsing conditions. Conversely, they oriented spontaneously to odors emitted

by maize and spinach. At a stimulus stream of 40 ml/min, ECB larvae avoided spinach odors at odor pulses of 2 sec or lower pulse regimes. However, ECB larvae were attracted or repelled by maize odors depending on the stimulus stream dilutions (20, 40, or 60 ml/min) and their temporal pattern. Intermittent odor stimuli were found to elicit upwind orientation towards maize odor, while continuous or slow-pulsing stimuli induced a reversal of the orientation that is maintained over gaps of odorant stimuli of up to 10 sec.

Methods and Materials

Plant Culture 'Centena' maize were grown in individual pots in a greenhouse at 22±2°C during daytime and 18±2°C overnight, with a 16 L:8D photoperiod. Spinach 'Géant d'hiver' potted plants were grown in a climatic chamber at around 15±2°C day and night. Maize plants were watered four times weekly, and fertilized with Peters® General Purpose Fertilizer (J. R. Peters Inc., Allentown, PA, USA) at 100 ppm in aqueous solution twice each week as part of the regular watering schedule. Maize was used when it had developed 7 leaves (about 80 cm high). Spinach was used when it had grown 17 leaves (about 12 cm high). These experiments were performed in 2005 and 2006.

Insects ECB pupae were sent from INRA (Le Magneraud, France), where a culture is maintained on an artificial diet. Emerging adults were maintained in a cage at 25±0.5°C and 70–80% R.H. and fed sugar water *ad libitum*. Eggs were collected from a wetted filter paper placed on the top of the cage. Individual egg clusters were stored in glass vials (12 mm ID; 7.5 mm-long). Each vial was sealed with a cotton plug that was lightly wetted daily with distilled water to prevent desiccation. Upon hatching, larvae were starved 6–12 h prior to the experiments. Pilot observations indicated that this starving phase was necessary to obtain reproducible results.

Locomotion Compensator Experiments were performed with a locomotion compensator, TrackSphere LC-100 (Syntech, Hilversum, NL). This device is composed of a white sphere (100 mm diam) coupled to two step-motors driven by a controller (Van Tilborg et al. 2003). A video-camera inserted in the light path of a stereomicroscope monitored the position of the insect and the controller drove the step-motors so that the image of the insect remained in the center of the visual field. The position changes (dx_i, dy_i) of the insect were collected at a rate of 10 Hz, and the insect track was calculated and displayed on a PC screen under the control of the tracking software TrackSphere™ v 3.1 (Syntech, Hilversum, NL).

Stimulus Delivery A constant stream of humidified and charcoal-filtered air at 80 ml/min was supplied through an aluminum tube (1.6 cm ID, 27 cm-long; outlet: 3 cm from the top of the sphere) directed horizontally towards the top of the sphere. The airflow was controlled with a programmable controller (CS-55, Syntech, DE). An adjustable fraction of the airstream could be diverted either to a Nalophane® bag that enclosed a plant (stimulus), or to an empty tube (blank) by using a three-way electronic valve. The outflow of each of these streams was re-injected into the mainstream within the aluminum tube in order to maintain a constant flow. For maize, the stimulus stream was set at 20, 40, and 60 ml/min; for spinach, we used 40 ml/min. The stimulus was delivered continuously, or regularly pulsed at 1, 2, 5, 6, 9, or 10 sec half-periods (1 sec pulse = 1 sec odor ON followed by 1 sec odor OFF) over the duration of the experiment.

Experiment Prior to each recording session, each insect was allowed to walk freely on the top of the sphere for 1 min. In order to limit visual cues, the sphere was surrounded by a circle of white paper (30 cm diam, 30 cm high), and the experimental room was illuminated by red light. Each recording session lasted 5 min. We monitored 30 larvae for each stimulus condition and 10 larvae for the blank controls. Each larva was used only once. We used one plant per stimulus condition and airflow frequency i.e., 21 maize plants (3 airflow conditions×7 stimulus conditions) and 7 spinach plants.

Data Measured and Statistical Analyses The raw data (dx_i, dy_i, i=1 to 3000) were first converted into rectangular coordinates ($x_i = \sum_{j=0}^{i} dx_j$ and $y_i = \sum_{j=0}^{i} dy_j$) and averaged down to 1 Hz (X_j and Y_j, j=1 to 300) for further analyses.

Each point of the track at time j was characterized by a displacement vector for 1 sec with the rectangular and polar coordinates (X_j, Y_j) and (L_j, θ_j), respectively. L_j is the distance (in mm) walked during 1 sec, and was computed by $L_j = \sqrt{DX_j^2 + DY_j^2}$. θ_j represents the angle formed by the trajectory vs. the origin, and was defined by $\sin \theta_j = DX_i / L_j$ and $\cos \theta_j = DX_j / L_j$ where $DX_j = X_j - X_{j-1}$ and $DY_i = Y_i - Y_{i-1}$. Walking speed (WS_i, in mm/sec) provided directly L_j. For each track, these values were averaged, and we computed two derived parameters: the "upward length" (UL; in mm) and the straightness (rectilinear index: RI). UL is the summed projection of the displacements made by the insect on the axis parallel to the airflow $UL = \sum_{j=1}^{300} DY_j$. Positive and negative values of UL indicate a track oriented either towards or away from the stimulus. Straightness is computed as $RI = L_{300} / TL$, and varies between 0 (sinuous path) and 1

(straight line). It is the ratio between the length of the track vector (from the origin to the final point of the track, L_{300}) and the length of track: TL, computed as the sum of the length or the elementary displacement vectors $TL = \sum_{j=1}^{300} L_j$.

For each experimental condition (stimulus intensity and frequency), we tested whether the mean angles were distributed uniformly around 360° by Rayleigh *Z* tests. When the uniform distribution was rejected, attraction (angle of mean vector=0°) or avoidance (angle of mean vector = 180°) were tested by using *U* tests as described by Batschelet Batschelet (1981). Calculations and statistical tests were made by using Oriana (Kovach Computing Services, UK).

In addition to the analysis of the angular orientation, we performed an ANOVA by using a GLM procedure followed by multiple mean comparisons with Minitab 12.2 (Minitab Inc., State College, PA, USA). We separately studied walking speed, upward length (UL), and straightness (RI) in order to examine whether the presence of a plant odor and the way it was delivered modified the walking response of the neonate caterpillar. We used a 3-way ANOVA with partial interactions between factors to evaluate the effects of stimulus flow (20, 40, and 60 ml/min), pulse regime (1, 2, 5, 6, 9, and 10 sec pulse, and continuous) and stimulus quality (blank air, maize, or spinach). We could not test the interaction between stimulus quality and stimulus intensity, since we used only one dilution for spinach (40 ml/min). To comply with ANOVA requirements (homoscedasticity for response variables and normal distribution of the residuals), the straightness (RI) was analyzed after an Arcsine(square root) transformation. Although UL values did not follow a Gaussian distribution, the major effects pointed to by the ANOVA are reliable because the method is particularly robust to such divergence in well replicated assays, and clear trends pointed by very high *F* values. Means per experimental groups were compared using the multiple comparison Tukey test at 5% wherever useful (Minitab 12.2). Conclusions drawn from this global analysis were supported fully by non parametrical Kruskal-Wallis tests performed to evaluate the effect of a given factor on UL on appropriate subsets of values, and additional ANOVAs performed on complementary subsets of data with only blank and maize evaluated for all the combinations of stimulation ratio x pulse regime, and with only medium stimulus flow (40 ml / min) with all stimuli: blank, maize, and spinach evaluated over the whole range of pulse regime.

Results

ECB larvae walked continuously and vigorously on the top of the sphere, as soon as they were placed on it. We observed only a few occasional stops during which they lifted their heads up and waved them, as if they were sampling the environment. Under a range of air flow and pulse regimes, the tracks were oriented clearly towards maize odors (Fig. 1a) and directed away from spinach odor (Fig. 1b) while they circled in the presence of simply humid air (Fig. 1c). In order to analyze the tracks, we first examined the mean vector length and angle of the tracks (Table 1). Under this analysis, these two parameters were not found to be significant when larvae were subjected to humidified air (except for pulsing regimes 1 sec and 2 sec at 40 ml/min), when subjected to maize odors delivered at a low airflow (20 ml/min) under several stimulus regimes (1 sec to 6 sec) and at 1 sec stimulus regime for maize at 40 ml/min and spinach at 40 ml/min. The vector length and angle was significant to highly significant with all other stimulus conditions.

We focused our analysis on three variables: walking speed, straightness, and upward length (Fig. 2). We first examined the speed of the larvae under the different stimulus conditions (Fig. 2a and Table 2). The average walking speed across all experimental conditions was 0.67 cm/s (N=1,050). Almost all larvae walked continuously during the experimental session. Speed was highly (P<0.001) affected by all three controlled factors (pulse regime, stimulus flow, and plant odor). This was tested by an ANOVA (Table 2). The average speed observed in the presence of spinach (0.61±0.01 cm/s, N=210; mean±s.e.m.) was significantly lower than with maize (0.70±0.01 cm/s, N=630; P<0.05). Speed in blank (0.65±0.01 cm/s, N=210) was intermediate. The pulse regime strongly (P<0.001) interacted with odor and with the stimulus flow (Table 2).

We then analyzed the straightness (RI) of the tracks (Fig. 2b and Table 2). RI was affected the same way and at the same degree (P<0.001) as speed by the three stimulation parameters. Odors increased the straightness of the paths as compared to the blank ($F_{2.812}$=715). The value of RI under blank air (RI=0.24±0.01, N=210) was significantly lower (about a third) than in the presence of maize (RI=0.75±0.01, N=630) or spinach (RI=0.74±0.01, N=210). Straightness decreased with pulse regime ($F_{6.812}$=6.95) and was affected by the stimulus flow ($F_{2.812}$=56.5). We further tested interactions between these factors. The pulse regime strongly interacted with odor ($F_{12.812}$=7.93) and with the stimulus flow ($F_{12.1049}$=10.1). With maize, the straightness was noticeably lower at 20 ml/min (RI=0.66±0.02, N=210) than at 40 ml/min (RI=0.78±0.01, N=210) or 60 ml/min (RI=0.82±0.01, N=210).

Upward length (UL) was by far the variable that was most influenced by pulse regime and the odor (P<0.001), either directly or in interaction with another parameter of stimulation (Fig. 2c and Table 2.) In turn, a weak direct effect of stimulus flow (P=0.047) was observed. UL was

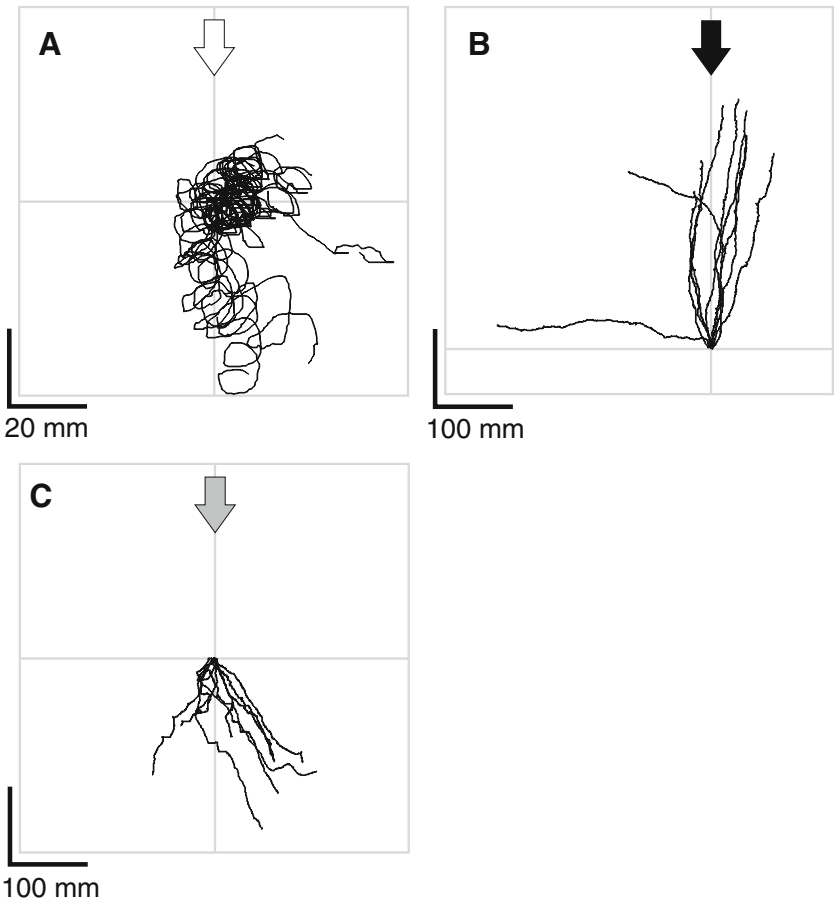

Fig. 1 Representative tracks of neonate ECB larvae walking during 5 min in the presence of different odors on the locomotion compensator. A 80 ml/min stream of air was directed to the top of the sphere (*arrow* on the *top* of each graph) and pulsed at different rates (here: 5 sec stimulus ON followed by 5 sec OFF) and mixed with different ratios of a stimulus flow (here: 40 ml/min) vs. pure air. Each graph displays 10 tracks obtained from 10 different larvae. **a** Odors collected from maize (7 leaves, 80 cm high) enclosed in a nalophane bag. *Horizontal* and *vertical bars* = 100 mm. **b** Odors collected from spinach (17 leaves, 12 cm high). *Horizontal* and *vertical bars* = 100 mm. **c** Humidified air. *Horizontal* and *vertical bars* = 20 mm

dramatically modified by the odor ($F_{2.812}$=134). It was low when no odors were delivered whatever the stimulus flow and pulse regime (UL=6.8±2.5 cm, N=210). This changed in the presence of plant odors. With spinach odor, caterpillars significantly moved downwind (UL=−93± 5 cm, N=210, P<0.05). With maize odors, the average: 14.3±5.6 cm (all stimulus flows and pulse regime N=630) was similar to the odorless situation. However, this value averages contrasting situations, depending on the odor intensity and the pulsing rate. ECB caterpillars moved opposite to the stimulus when maize odor was delivered continuously (UL=−178±10 cm at 60 ml/min; UL=−122± 14 cm at 20 ml/min). Long pulses (9 and 10 sec) also were repellent, except at 20 ml/min where pulsing with 10 sec stimuli sufficed to restore an attraction (UL=120±10). The direction of the tracks clearly depended on stimulus flow and pulse regime.

Discussion

ECB neonate larvae orient towards or away from maize odors depending on the air flow and on the pulsing rate. They orient away from spinach odors at the air flow of 40 ml/min irrespective of the stimulus structure above 1 sec pulses. In the absence of plant odors, ECB larvae tend to walk in a circle and do not express any anemotactism. However, they are able to use the wind direction, when they have experienced odors, to maintain their direction during time intervals of up to 10 sec. Since the larvae tested here were never exposed to a plant since hatching, these experiments reflect their innate orientation strategies in response to plant odors. Spinach odors were repellent within the air streams tested, suggesting that they contain compounds that contribute to plant defense, in addition to the production of phytoecdysteroids. Maize odors exerted either an attraction or repellency depending on the stimulus conditions, e.g., air stream and pulse regime.

These results confirm and extend previous studies on the orientation of neonate larvae that express a range of locomotory and orientation responses towards host plant odors (Harris et al. 1999; Müller and Hilker 2000; Singh and Mullick 2002; Castrejon et al. 2006) or towards plants damaged by conspecifics (Singh and Mullick 2002; Carroll et al. 2008). However, nearly all of these studies used different olfactometers ranging from simple olfactory tubes to “artificial plants”. Such diversity makes difficult any comparison between insect species. The great advantage of

[a] Pulse regime: 1, 2, 5, 6, 9, 10 sec. (1 sec = 1 sec odor ON followed by 1 sec odor OFF); cont. = continuous stimulation.

Average orientation is given by the mean vector of the tracks, defined by its length R and the angle to the wind direction. R varies between 0 and 1 and its variance equals 1-R: the straighter and the most similar the directions of the tracks the closer R to 1. Bolds values indicate that random orientation can be rejected with $P<0.001$, or $P<0.01$ (**) or $P<0.05$ (*)

[b] Bold R indicate that the directions of the elementary vectors of the tracks are significantly distributed around the value of the angle of the mean vector (Rayleigh tests).

[c] Bold values (mean±s.e.m.) indicate that the angle of the mean vector does not differ from 0° (+), upwind walk, or 180° (−), downwind walk (V tests).

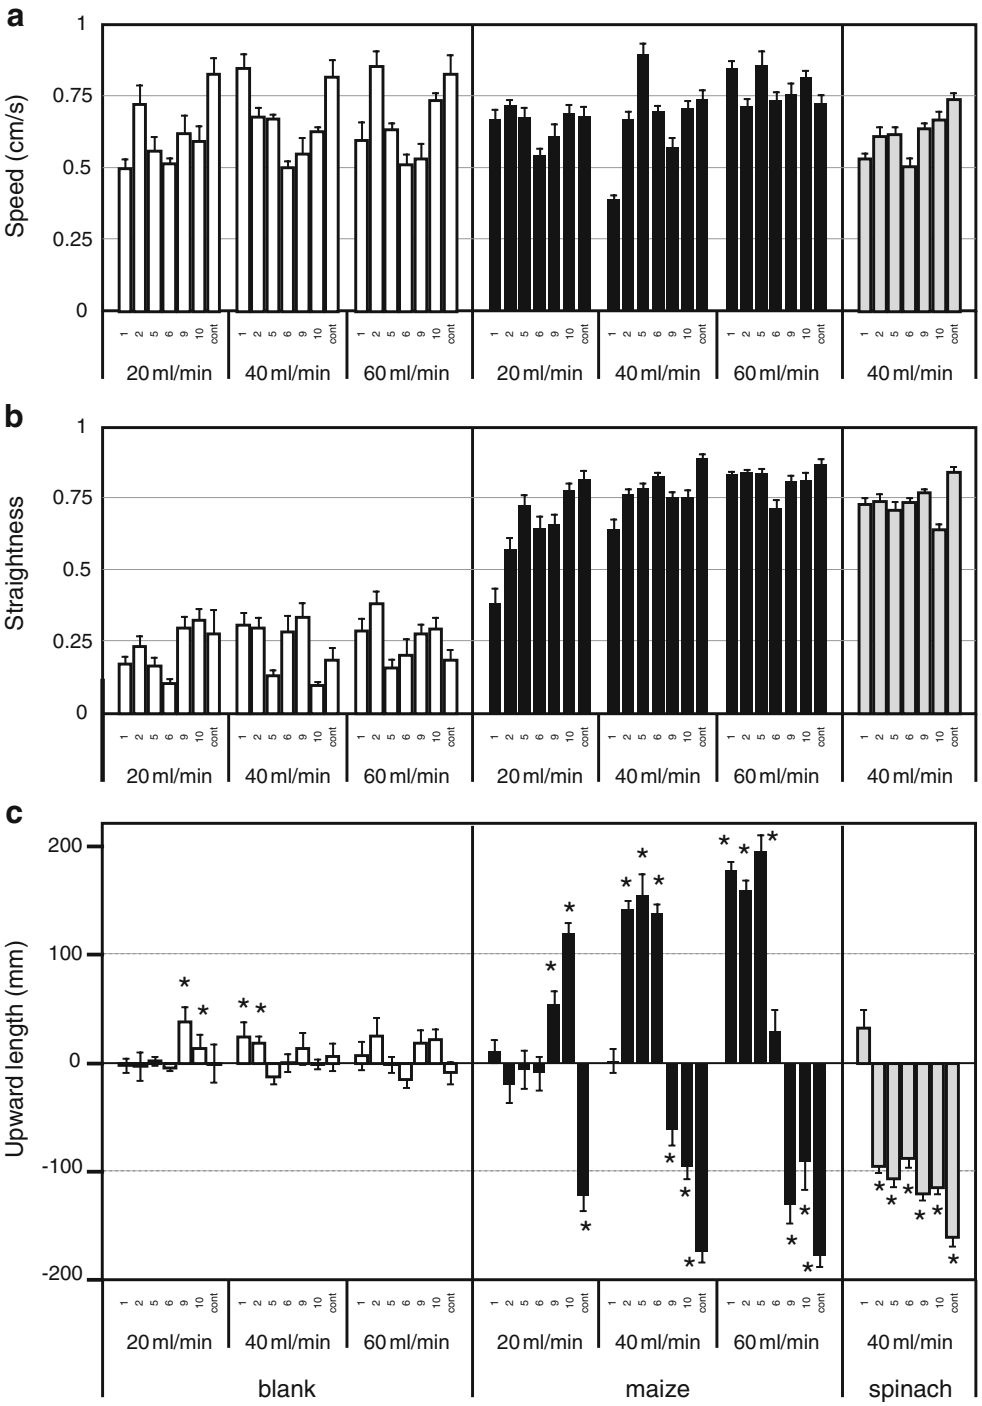

Fig. 2 Histogram of the parameters (mean ± s.e.m.) measured from tracks recorded with different odors and stimulus regimes. Three odor conditions were tested: humidified air (*white bars*; N=10 larvae per stimulus condition), maize (*black bars*) and spinach (*grey bars*) volatiles (N=30 larvae per stimulus condition). These odors were delivered at different airflows (20, 40, 60 ml/min) and under different pulse regimes (1, 2, 5, 6, 9, 10 sec pulses and continuous odor). See text for the significance of the parameters displayed. **a** Speed (cm/s). **b** Straigthness. **c** Upward length (mm): * indicate when the mean vector was significantly oriented up- or downwind

a locomotion compensator over other approaches is that it allows exploring odorant-mediated anemotaxis in an open field without influence from other stimuli (surface structure, gravity, limits of the arena, etc) and allows recording trajectories and decomposing them easily into different components.

ECB neonate larvae express a robust walking behavior on a locomotion compensator. Even in the absence of any stimulus, they move continuously, provided they are hungry. Once ECB larvae experienced an odor and chose an orientation, they usually kept walking in the same direction even when the odor was removed from the airflow for several seconds (up to 10 sec). This strategy seems adapted to cope with erratic messages provided by odor plumes in a turbulent environment. Actually, adult insects generally orient better in the presence of intermittent stimuli than within a continuous odor plume when they are flying (Baker et al. 1985; Cardé and Willis 2008). For walking

Table 2 Effect of stimulation conditions on the displacement of ECB larvae: excerpt of the ANOVA tables showing F values for the sources of variation evaluated

Source of variation (df)	Pulse regime (PR) (6,812)	Stimulus flow (SR) (2,812)	Odor (2,812)	PR x SR (12,812)	PR x odor (12,812)
Walking speed	14.2	29.6	9.34	5.88	6.70
Straightness (RI)	6.95	56.5	715	10.1	7.93
Upward length (UL)	31.6	3.07 *	134	46.1	33.4

All factors and binary interactions significantly contributed to the displacement variables ($P<0.001$ for F values) with the exception of the stimulus flow whose contribution to Upward length was much weaker (* $P=0.047$).

insects, intermitted stimuli improve orientation in carrion beetles (Böhm 1995) and Colorado potato beetle larvae (Hammock et al. 2007) but have no effect in others, such as haematophagous bugs that orient towards pulsed CO_2 (Barrozo and Lazzari 2006) or possibly *Lobesia botrana* larvae, which stop and search for odor cues upon cessation of the stimulus (Becher and Guerin 2009).

While flying insects may need to adopt an active searching strategy to cope with the erratic nature of odorant stimuli in the open air, larvae that are already on their host plants or on their food (Gerber and Stocker 2007) remain confined to the boundary layer of their plant, and may not need to care about the temporal structure of the stimulus. Actually, ECB larvae do not seem to improve their orientation with pulsed stimuli as compared to Colorado potato beetle larvae, which better orient towards intermittent stimuli (1:1 sec pulses) than to a continuous odor (Hammock et al. 2007). Our observations merely show that they are capable of taking into account discrete odor stimuli over a large range of pulsing rates and of modulating their search strategy accordingly. The most striking feature of these observations is that once larvae have been stimulated by a pulse of odor, they lock to the direction chosen even when the stimulus is interrupted by 10 sec. Further studies are needed to elucidate how long this memory is maintained, and if neonate larvae are able to display casting as observed in adults (Cardé and Willis 2008).

The reversal of orientation of ECB larvae stimulated with maize odors at different pulse regimes was unexpected, and it is not clear why it happened. Short odor pulses of 1 sec up to 6 sec induced an attraction when odors were delivered at 40 and 60 ml/min. Odor pulses of 9 sec or longer were repellent. At the lowest stimulus flow (20 ml/min), there was no significant orientation towards short odor pulses, while 9 and 10 sec pulses induced a clear attraction, and continuous stimulation was repellent. One could argue that this effect is due to differences among plants (because single plants were used for each pulse regime in our experimental protocol). This hypothesis can be ruled out because we would then expect a random effect of the pulse regime, while we observed sequential increases or decreases in upward length according to the pulse regime.

Several hypotheses could account for the effect of the pulsing regime on the attractivity or repellency of maize odors. First, the odor mixture might change in intensity and in quality with the stimulus regime. In our experimental setup, the air was pushed through the bag containing the plant on demand. Longer stimulus pulses might exhaust the bag's content and induce the release of different quantities of odorants than when discrete amounts of air are sampled with short stimulus pulses. These odorants can be either repellent or less attractive to ECB larvae, depending on their concentration in the air stream. For example, in *Drosophila* (and other insects), odorants are attractive or repellent depending on the concentration (Acebes and Ferrus 2001; Devaud 2003), and this effect is linked both to the nature of the odor and to the number of glomeruli activated during the response (Semmelhack and Wang 2009). Second, olfactory receptors of ECB larvae may adapt to some odorants when delivered continuously, as in *Drosophila* larvae (Cobb and Domain 2000), but not when these odors are pulsed. This issue could be resolved by detailed electrophysiological studies. Third, larvae could integrate the temporal structure of the odorant stimulation in their search strategy. If the larvae are not on a plant, odors are likely to be intermittent; or the opposite, if larvae are on a plant, odors are likely to be continuous and concentrated. However, one would expect such odors to induce an arrestment and a local search, rather than a reversal of the direction of orientation. Further studies are needed to clarify these hypotheses, for example, by re-designing the odor delivery system (using a continuous flow over the plant), by sampling and analyzing odors released in different pulsing conditions, by correlating more precisely the timing of the odor stimulation with the behavior of the larvae (as in Hammock et al. 2007), or by

using synthetic stimuli allowing a better control over the concentrations released.

In this work, we tested the hypothesis that ECB larvae would walk away from spinach, which is unsuitable as a host plant. Spinach odors were repellent over the whole range of pulsing rates used in this experiment except with 1 sec pulses that elicited no orientation. This is reminiscent of 1 sec maize odor pulses delivered at 20 and 40 ml/min that elicited no orientation, possibly because of a low odor concentration. It remains to be tested whether spinach odors delivered at a different concentration are still repellent or if they could become stimulatory. From a neurobiological point of view, some odors induce either attraction or avoidance depending on the concentration, while others induce aversive reactions (Kreher et al. 2008; Semmelhack and Wang 2009). Our present data cannot resolve the issue, which should be approached by testing different odors dilutions of spinach, using the same approach as with maize.

That spinach odor might be repellent to ECB larvae is particularly interesting. From previous work, we know that spinach contains phytoecdysteroids, primarily 20-hydroxyecdysone (Schmelz et al. 1998). Phytoecdysteroids are composed of a sterol ring with a lateral chain and are non-volatile molecules found in plants and other organisms (Lafont 1997). Most of them are agonists or antagonists of insect molting hormones, thus making them good candidates as natural pesticides (Marion-Poll et al. 2005). Our observations suggest that ECB larvae detect specific volatiles emitted by spinach, which are either directly linked to the metabolism of this family of molecules or produced in addition to them, or which correspond to a combination of green volatiles emitted at different flows than maize.

Finally, one wonders how spinach odors or maize odors would affect the orientation behavior of larvae when they are emitted within an odorant background. Earlier experiments on *Leptinotarsa decemlineata* using a locomotion compensator, showed that potato odors could be either masked by the odorant background (Thiery and Visser 1986) or mislead by the odor of a non-host plant (Thiery and Visser 1987). This could be of importance in assessing the impact of mixed cropping not only on female oviposition but also on larval dispersal within fields.

either parent); an additive pattern, whereby hybrid traits are intermediate between the two parental types; or no difference between hybrids and parental taxa (Fritz et al. 1999). None of these responses dominates in studies published to date. In 127 studies of susceptibility of plant species and their hybrids to attack by herbivorous insects, hybrid susceptibility appears the most common pattern (39%), and hybrid resistance appears to be reasonably rare (10%), while 22% of studies identified an additive pattern, and almost one-third (29%) found no differences between parents and hybrids (Fritz et al. 1999; Dungey and Potts 2003; Hallgren et al. 2003; O'Reilly-Wapstra et al. 2005). An additive pattern has been found in interactions between eucalypt hybrids and mammalian herbivores (Scott et al. 2002).

Development of interspecific eucalypt hybrids for forest plantations is a silvicultural strategy adopted in many eucalypt-growing regions worldwide to maximize tree performance by combining the desirable traits of different species (de Assis 2000). Eucalypts are known to form hybrids readily with related species (Griffin et al. 1988). Traits for improvement through hybridization include growth rate, coppicing and propagation ability, pulp yield, wood density, and resistance to frost, drought, salinity (Dale and Dieters 2007), and pests and diseases (Potts and Dungey 2004). The eucalypts are a diverse group of trees and shrubs (> 800 species), generally considered to belong to the genera *Eucalyptus* (Brooker 2000), *Angophora,* and *Corymbia* (Ladiges and Udovicic 2000; Ochieng et al. 2007a, b) in the family Myrtaceae. One prominent characteristic of the group is the high essential oil content of the leaves, and the oils vary substantially among taxa (Bignell et al. 1998; Dunlop et al. 1999; Asante et al. 2001; Keszei et al. 2008), thus affecting feeding preferences of insect herbivores (Edwards et al. 1993; Steinbauer et al. 2004). An understanding of how characters important to plant herbivores (e.g., secondary chemicals and physical leaf characteristics) vary between species and their hybrids enables an understanding of the mechanisms of host choice by insect herbivores (Hallgren et al. 2003).

We examined variations in foliar chemical composition, leaf physical characteristics, and feeding by herbivorous beetles with three taxa: two allopatric species (*Corymbia citriodora variegata* (CCV) and *C. torelliana* (CT)) and their hybrid (CT × CCV). All are important in subtropical hardwood plantation forestry where the hybrids have significant advantages in growth, and tolerance to disease, insects, and frost, and also have been successfully vegetatively propagated (Lee 2007; Lee et al. in press). This tolerance to insects is, however, anecdotal, and needs quantification. The model pest species chosen to examine patterns of herbivory was *Paropsis atomaria* Olivier (Coleoptera: Chrysomelidae: Paropsina), a major pest of the commercially valuable CCV (Carnegie et al. 2008). *Paropsis atomaria* is an ideal model for this study, as adults and larvae feed on the same foliage, and thus allow a test of linkages between oviposition preference and larval performance. In addition, the test taxa represented a known host (CCV), a novel host (CT), and their F1 hybrid (CT × CCV).

Methods and Materials

Study System

Corymbia citriodora subsp. *variegata* (CCV) belongs to the Section Politaria, and recent studies have shown that it is genetically indistinguishable from *C. citriodora* subsp. *citriodora* and *C. henryi* (Ochieng et al. 2008; Shepherd et al. 2008), although the taxa are chemically distinct (Asante et al. 2001). It has a sympatric distribution with *P. atomaria*, although it was recorded only recently as a host (Nahrung 2006). *Corymbia torelliana* (CT) occurs naturally in about a 350×80 km zone in northern Queensland (Boland et al. 1992), a vicinity to which *P. atomaria* has recently expanded its range (Nahrung 2006). *Corymbia torelliana* (CT) is not a host for *P. atomaria*, although around 20 other eucalypt species are (CAB International 2005). An artificial hybrid between CT and CCV has been prepared for commercial purposes, and is planted widely throughout the insect's range (Lee 2007). All lifestages (except pupae) of *P. atomaria* occur on the host plant, with oviposition by females determining subsequent larval feeding habitat, and the long-lived adults and all four larval instars feeding on new growth, removing apical leaves. This results in a characteristic broom-topped appearance to trees (Carne 1966).

Foliage Collection

Seed was collected from one open-pollinated tree of each pure taxon (i.e., CT and CCV), thus ensuring that all samples had the same mother (were at least half-sibs). Hybrid (CT × CCV), seed was collected from one CT mother artificially pollinated from a single CCV father (i.e., full sibs). Neither of the hybrid parents were the same trees (families) as the pure taxon, so as to ensure a more representative sampling rather than looking only at intra-familial responses. Plants were sown from seed in potting mix comprising 50% pine bark fines, 25% peat (Aussie Peat) composted, and 25% perlite to which Osmocote® and Ag lime were added each at 4 kg/m^3, and gypsum, Micromax (fertilizer) and Hydroflow (wetting agent) were added each at 1 kg/m^3. Seedlings were raised in the glasshouse for the first 6 wk under mist, and then put under shadecloth for 2 wk before being put out into full

sun. Plants were repotted later into 130 mm diam pots and housed in a glasshouse (24°C, ambient light) for several months prior to use in experiments.

Foliage used in all experiments (physical analysis, chemical analysis, and feeding trials) was sourced from about 20 individual plants of each taxon. Only the first two—four fully expanded apical leaves were used for all trials to standardize the age of foliage during testing.

Foliar Analyses—Physical Analysis

Moisture content and specific leaf weight (SLW) (used as an indicator of leaf toughness—see Steinbauer 2001) were determined by measuring the fresh weight (FW) of leaves (to nearest 0.001 g), drying them in paper envelopes at ambient temperature for 3 wk, and re-weighing them (DW). Leaf area (mm^2) was estimated by using Compu Eye Leaf and Symptom Area software (Bakr 2005). Moisture content was calculated as (FW - DW)/FW, while SLW was determined as DW/area.

Foliar glabrousness was determined as the mean number of leaf trichomes in the field of view of a dissecting microscope (×40). The thickness (width) of the leaf lamina was measured under a dissecting microscope (×40) by cutting 4 small strips (~5 mm wide) and averaging the measurements per leaf (N=12). Data were analyzed using StatView (V 5.0.1). One-way *ANOVA* was used to analyze moisture content (following arcsine-square root transformation), SLW, and lamina thickness, with *Fishers LSD* test used for *post-hoc* comparisons. *Kruskall Wallis* test was used for leaf glabrousness, as data were not normally distributed. Twelve replicates of each foliage type were conducted for each parameter.

Foliar Analyses—Chemical Analysis

Replicate samples (N=5) of foliage (2.07±0.019 g FW) from 5 randomly chosen plants of each taxon were collected, and cut into squares (≤ 1 cm^2), and extracted with hexane (Sigma-Aldrich ≥ 99%) (≈ 15 ml) for 50 min, stirring for 1 min, three times within this period. The extract was filtered through filter paper (Whatman) and stored in the freezer (−20°C) until analysis (Jones et al. 2002; Rapley et al. 2004c).

Samples (1 µl) were analyzed with a gas chromatograph (GC) (Agilent 6890 Series) coupled to a mass spectrometer (MS) (Agilent 5975) and fitted with a silica capillary column (Agilent, model HP5-MS, 30 m×250 µm ID × 0.25 µm film thickness). Data were acquired under the following GC conditions—inlet temperature: 250°C, carrier gas: helium at 51 $cm.s^{-1}$, split ratio 13:1, transfer-line temperature: 280°C, initial temperature: 40°C, initial time: 2 min, rate: 10°$C.min^{-1}$, final temperature: 260°C, final time: 6 min. The MS was held at 280°C in the ion source with a scan rate of 4.45 $scans.s^{-1}$.

Peaks that were present in blank hexane (control) samples were discarded from analysis in test samples. Tentative identities were assigned to peaks with respect to a Kovats Retention Index analysis and the National Institute of Standards and Technology (NIST) mass spectral library. Mass spectra of peaks from different samples with the same retention time were compared to ensure that the compounds were indeed the same.

The presence of peaks in the chromatograms, and their relative areas were analyzed by nonparametric methods (*Bray-Curtis* cluster analysis and multidimensional scaling (*MDS*) ordination) (Clarke 1993) to ascertain whether any differences could be detected among the samples. The use of relative percentage area for the peaks removes the need for standardizing concentrations from samples where slightly different total mass of components has been extracted from leaf material. Instead, it is the relative amount of each component that is compared, thus ensuring that comparisons can be made among samples of unknown total concentrations.. Each point in the *MDS* plot represents an individual plant, and points that are close together (clumped) correspond to individuals with similar peak composition (presence and abundance). Since they represent relative differences among samples, the axes of an *MDS* plot are dimensionless. *MDS* has been used successfully in previous studies to analyze chromatographic data (e.g., Hayes et al. 2006).

To determine whether clusters of individual plants relating to the taxa investigated were significantly different from each other, we used an analysis of similarity (*ANOSIM*). The *ANOSIM* tests are a range of Mantel-type permutations of randomization procedures, which make no distributional assumptions. These tests depend only upon rank similarities, and thus are appropriate for this type of data. We used a similarity percentages (*SIMPER*) analysis to determine which peaks were the most important in contributing to any differences between groups, and to assess similarity between individuals within each group. The software used for the multivariate analysis was Primer 5 for Windows (V 5.2.9, Clarke and Gorley 2001).

Herbivory Trials—Field Assessment

Two field sites in Queensland (Site I S 26.595° E 151.915°; Site II S 26.101° E 151.623°) containing CT, CCV and CT × CCV were monitored for the incidence (proportion of trees with damage) of characteristic damage caused by *Paropsis atomaria*. Both plantations were established in March 2004 so were the same age at time of sampling (January 2008). Site I comprised a single tree plot design with each family/seedlot represented by one randomly

allocated individual in each of twenty blocks of 100 trees each. One half (i.e., 10 blocks) of the entire site was sampled. Site II comprised 20 lines of 10 trees each. Each plant type was represented by at least 4 such line-plots, each representing a different family/seedlot except CCV which was represented by only one line-plot. Larvae, beetles, and egg batches were present at both sites when censuses were conducted. Each tree was scored for its suitability as a host for *P. atomaria* by recording the presence or absence of *P. atomaria* lifestages. χ^2-pairwise comparisons were made for each site to compare the beetle incidence on each taxon.

Herbivory Trials—Laboratory Bioassays

The same plants used in the chemical and physical foliar attribute studies were used to provide foliage for laboratory bioassays with *P. atomaria*.

Herbivory Trials—Larval (No-Choice) Trials

Field-collected egg batches were held in a controlled-temperature cabinet at 25°C, 16L:8D photoperiod. Unfed (except on egg chorion) neonate larvae were transferred with a soft paintbrush, with larvae from different egg batches divided among treatments to control for possible maternal effects. Eight larvae were placed directly onto test foliage for each replicate (N=11 per taxon). The experiment was conducted in a controlled temperature cabinet at 16°C, 16L:8D. The group size was selected as that above which mortality was constant (Duffy et al. 2008), while 16°C represented the temperature at which mortality was lowest (Nahrung et al. 2008) in previous laboratory studies. A piece of moist filter paper was provided to slow desiccation of treatment foliage. Mortality was recorded, old foliage and filter paper were removed, and fresh filter paper and foliage were added every 3–4 days. Care was taken to ensure that larvae were provided an excess of foliage, such that they never consumed all foliage present. When larvae reached the fourth instar, the replicate was transferred to a larger plastic cage (160×110×35 mm), and upon pre-pupation (dorso-ventral flattening and cessation of feeding) individuals were transferred to separate, numbered, sterilized-soil-filled cells of a plastic modular tray (cell dimensions 20×20 mm). When pupae formed, they were weighed (to nearest 0.001 g) on an electronic balance, and returned to their cell until adult emergence. On emergence, sex was determined under a dissecting microscope (×40), using tarsal differences of the foreleg as the discriminating factor (Baly 1862).

Overall larval mortality, development time and pupal weight were used to assess larval performance on the different foliage types. One-way *ANOVA* was used to compare foliage type among these performance parameters, with proportion data arcsine-square root transformed prior to analysis, and *Fisher's LSD* test used to *post-hoc* test. A *Kaplan-Meier* survival curve (Kaplan and Meier 1958) was plotted for each foliage type, and non-parametric pairwise comparisons were made (P<0.05) to compare larval survival rate on different taxa.

Herbivory Trials—Adult Feeding (Choice) Trials

Field collected beetles were housed in gauze cages and provided with fresh *Eucalyptus cloeziana* foliage prior to use. Twenty-four hours before the start of the trial, beetles were removed from foliage, their sex determined as above, and deprived of foliage until the trial began. For each replicate, one male-female beetle pair was placed into a plastic arena (160×110×70 mm). An apical branch comprising the first 2–4 fully expanded leaves of each foliage type was inserted through holes in the base of the cage into water below. Visually-estimated equivalent biomass was provided of each type in each replicate; twelve replicates were run simultaneously under ambient laboratory conditions. The experiment ran for 3 d, after which adults were removed and the remaining area of each leaf was estimated by placing it under a clear plastic sheet of grid-squares (3×3 mm) and counting the number of squares (to nearest 0.25 of a square) of foliage. The amount of foliage eaten was determined by multiplying the number of grid-squares by 9 mm^2. One-way *ANOVA* was used to detect differences between treatments, and a *Fisher's LSD* test was used to identify where those differences lay. Data for all herbivory trials were analyzed with StatView (V 5.0.1).

Results

Foliar Analyses

Moisture content was the only parameter measured not to differ significantly among different taxa (Table 1). *C. ciriodora* subsp. *variegata* (CCV) had the highest specific leaf weight and lamina thickness, and no leaf hairs (Table 1). In almost all cases, results for the hybrid either lay between that of each parent, or was not different from CT.

The compounds identified in extracts were primarily mono- and sesquiterpenes, as well as some waxes and long-chain hydrocarbons that could not be identified unambiguously. The percentage of individuals in each taxon group from which the component was identified is shown (Appendix 1). Chromatograms produced from hexane extracts of leaves of the three taxa were distinctly different from each other. The composition of components was consistent between replicates / individuals, however, the relative amounts varied among

Table 1 Moisture content, SLW, lamina thickness and glabrousness of *Corymbia citriodora* subsp. *variegata* (CCV), *Corymbia torelliana* (CT) and their hybrid (CT × CCV). The final row shows analysis results, and different letters within columns designate significant differences between taxa

Taxon	Moisture content (%)	Specific Leaf Weight (mg/mm^2)	Lamina thickness (μm)	Leaf surface glabrousness (# trichomes)
CCV	77.2±1.6	0.098±0.007 a	126.2±5.4a	0a
CT × CCV	74.0±1.9	0.052±0.006 b	102.4±4.3b	87.3±25.3b
CT	80.0±0.8	0.054±0.007 b	88.7±3.9c	106.9±23.6b
ANOVA/Kruskall-Wallis results	$F_{2,30}$ = 2.3 P=0.12	$F_{2,30}$ = 13.9 P<0.001	$F_{2,33}$ = 17.4 P<0.001	H_2 = 23.79 P=0.03

taxa. The CT samples were highest for the late-eluting components, the CCV samples highest for the early-eluting components, and the CT × CCV samples either intermediate between the two parental species or showing an additive response (Fig. 1).

In addition to visual chromatographic differences, the samples were statistically distinguishable, and pairwise comparisons demonstrated that all taxa differed from each other (*ANOSIM*: *Global* R=0.814, P=0.001; CCV, CT: R=0.964, P=0.008; CCV, CT × CCV: R=0.834, P=0.008; CT, CT × CCV: R=1, P=0.008). The *MDS* output (Fig. 2), provides a visual representation of the data described by the *ANOSIM*. Each point on the figure represents an individual extract. Points that are close together are more similar, and those farther away are more different.

The *SIMPER* analysis is a measure of the similarities of samples within a defined grouping (in this case taxa studied). All groups have high levels of similarity, but the CCV samples are the most dispersed (Fig. 2).

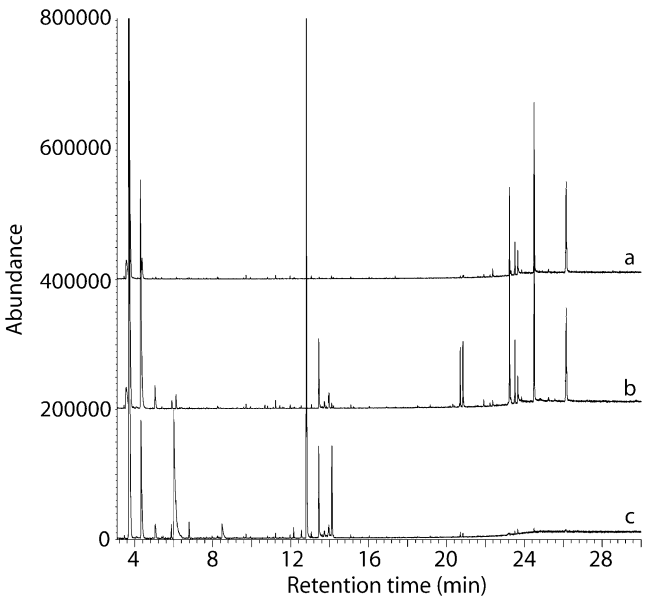

Fig. 1 Chromatograms produced by hexane extracts of *Corymbia* leaves. A typical extract from *Corymbia torelliana* (CT) is shown on top (**a**), a typical extract from *Corymbia citriodora* subsp. *variegata* (CCV) is shown on the bottom (**c**), and a typical extract from the hybrid (CT × CCV) is shown in the center (**b**)

The mean percentage area (± s.e.) under the peak for the most important peaks used to distinguish between the taxa are listed (Appendix 2). These peaks account for over 50% of the total dissimilarity between the groups. The peaks are listed in the table in order of increasing dissimilarity between the groups, i.e., the first peak contributes most to the overall dissimilarity. Retention time is as given in Appendix 1.

Herbivory Trials

The proportion of trees associated with *P. atomaria* did not differ between sites (χ^2 = 3.04, P=0.08) so data from the two sites were combined for subsequent taxa-level analysis. Three-quarters (153/204) of CCV trees were damaged by *P. atomaria*, while less than 30% (67/232) of CT trees exhibited damage symptoms. Sixty-five percent (202/313) of hybrid CT × CCV trees were associated with *P. atomaria.* Again, the hybrid was intermediate between the parental taxa. Pairwise comparisons (Bonferroni-adjusted, P=0.02) demonstrated that each taxon differed significantly from the others (CCV, CT χ^2 = 92.4, P<0.001; CCV, CT × CCV χ^2=6.3, P=0.01; CT, CT × CCV χ^2 = 67.8, P<0.001).

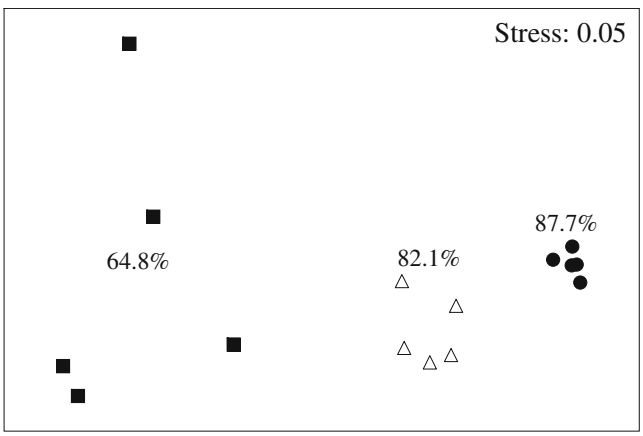

Fig. 2 Two-dimensional MDS ordination of the 15 *Corymbia* extracts including SIMPER measures of average similarity. The plot is based on fourth-root transformed abundances and a Bray-Curtis similarity matrix. Extracts from each taxon cluster separately. Symbols: *Corymbia citriodora* subsp. *variegata*-CCV (■), *Corymbia torelliana*-CT (●), their hybrid-CT × CCV(△)

Table 2 Mean ± s.e. mortality, development time and pupal weights of *Paropsis atomaria* larvae reared on *Corymbia* taxa. Different letters within columns designate significant differences between taxa

Taxon	Larval mortality (%)	Development time (days)	Pupal weight (g)	
			male	female
CCV	84.1±6.8 a	42.6±1.0	0.12±0.01 a	0.18±0.01 a
CT × CCV	54.5±8.3 b	42.6±0.9	0.10±0.01 b	0.14±0.01 b
CT	51.1±6.4 b	40.9±0.5	0.12±0.01 a	0.17±0.01 a

Overall larval mortality (proportion dying before pupation) was highest on CCV (Table 2) (*ANOVA*: $F_{2,30}$ = 8.5, P=0.001), although mortality *rate* differed significantly only between the two parent taxa (Fig. 3) (test statistic = 5.1, P=0.02). Larval development time did not differ according to rearing host (*ANOVA*: $F_{2,21}$ = 1.5, P=0.25), but pupal weight differed depending on sex (males were smaller than females) and natal host taxon (*ANOVA*: sex: $F_{1,36}$ = 70.0, P<0.001; taxa: $F_{2,36}$ = 9.2, P=0.0006, sex*taxa: $F_{2,36}$ = 2.2, P=0.13; Table 2), with hybrids resulting in significantly smaller adults than parent taxa for both sexes.

Feeding occurred on CCV in all replicates, whereas only 40% of replicates of CT and CT × CCV sustained adult feeding damage. The amount (mm^2) of foliage eaten differed among taxa (*ANOVA*: $F_{2,27}$ = 17.12, P<0.001), with CCV the most-preferred host (Fig. 4).

Discussion

Although there is some variability in the response, the hybrid exhibited traits intermediate to the parent species for several of the foliar characteristics investigated, and the feeding preference of *P. atomaria* followed a similar trend in both the laboratory and field (Table 3). The known host, CCV, recorded the highest field incidence of *P. atomaria*, and laboratory trials supported this pattern, with CCV the most-preferred taxon in adult feeding trials. Almost one-fifth of the foliar chemical components identified were detected only in CCV, and it may be one (or many) of these compounds that are involved in host location and selection for this species. The one with the greatest concentration was elemol, a sesquiterpenoid that has been reported previously as a dominant component of CCV leaf chemistry (Asante et al. 2001). Similarly, limonene was present in CCV and the hybrid, but was not detectable in CT. Limonene is a well known attractant for a range of insects, especially beetles (Chenier and Philogene 1989; Miller 2007). The monoterpene α-pinene is a common component of eucalypt leaf chemistry (Asante et al. 2001; Bignell et al. 1998), that varies among the taxa in this study, with high levels in both the host plant and the hybrid, and low levels in CT. α-Pinene is a known kairomone for Colorado potato beetle (*Leptinotarsa decemlineata,* Coleoptera: Chrysomelidae), and attracts the beetle (Panasiuk 1984). The high levels of both limonene and α-pinene in the host taxon and hybrid, and its lack of detectibility in extracts of the non-host plant, may explain some of the variation in behavior observed in our study.

Only two compounds were detectable in the non-host parent (CT) alone, and it is possible that these are repellent to *P. atomaria*. Ohmart (1991) speculated that adult paropsine beetles were repelled or unattracted to the volatile

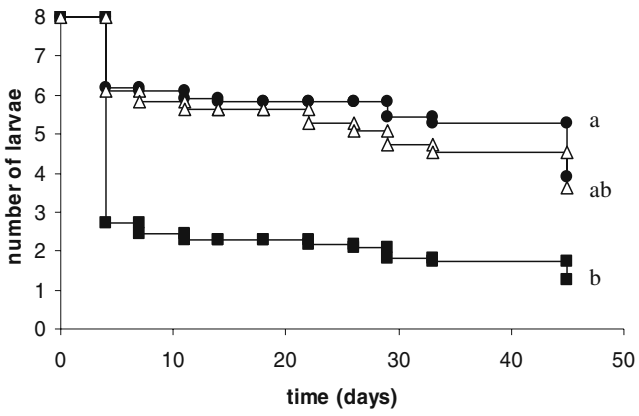

Fig. 3 Kaplan-Meier survival curve illustrating the mortality rate of *Paropsis atomaria* larvae reared on *Corymbia citriodora* subsp *variegata*-CCV (■), *Corymbia torelliana*-CT (●) or their hybrid-CT × CCV (Δ)

compounds produced by juvenile foliage of shining gum, since larvae develop just as well on this foliage type as on adult foliage on which adults feed and oviposit. There often is not a tight linkage between paropsine oviposition preference and larval performance (Carne 1966; de Little and Madden 1975; Baker et al. 2002; Nahrung and Allen 2003), and since larval habitat is determined principally by the placement of eggs by females, oviposition preference is probably a more pertinent indicator of the plant attributes used for host selection.

Assuming that *P. atomaria* adult feeding preference reflects oviposition preference, larvae would rarely encounter CT under field conditions. Larval development time was unaffected by rearing host in these trials, but subsequent pupal mass was significantly lower on the hybrid. Increased pupal weight confers increased adult fecundity in *P. atomaria* (Carne 1966), suggesting a reduction in herbivore fitness arising from larvae developing on the hybrid. This result cannot be attributed to foliar physical characteristics, since the hybrid displayed intermediate or CT-equivalent traits, but there were five chemical components detected only in CT × CCV foliage, including 1,8-cineole, α-cubebene, and β-patchoulene, which may have contributed physiologically to lower pupal weight. 1,8-Cineole and α-cubebene were detected in very low amounts in CCV foliage (Asante et al. 2001), and were probably present in trace amounts in parental foliage here, representing an additive (*sensu* Fritz et al. 1999) effect in the hybrid.

Overall larval mortality was highest on *P. atomaria*'s sympatric host, CCV, and we attribute this to the high SLW and lamina thickness in this species: leaf toughness impedes feeding establishment of neonate paropsine larvae (Ohmart et al. 1987; Larsson and Ohmart 1988; Nahrung et al. 2001); yet, unexpectedly, larvae were able to feed on the densely hairy CT foliage. Leaf trichomes are a deterrent to herbivory in many plant species (Kitamura et al. 2007; Bjorkman et al. 2008). *Paropsis atomaria* larval growth rate also appears unaffected by tannins and other phenolic compounds in host foliage (Fox and Macauley 1977): larvae absorb terpenoids and probably have a metabolic detoxification process for dealing with them (e.g., 86% of ingested 1,8-cineole was absorbed or converted to other compounds) (Ohmart and Larsson 1989).

Although hybrid susceptibility to herbivores is predicted in eucalypts (Dungey and Potts 2003; Potts and Dungey 2004), the hybrid taxon displayed intermediate susceptibility (field incidence) to *P. atomaria* in our study, as it did with respect to possum damage (Scott et al. 2002). Nevertheless, our results suggest a possible chemical basis for host selection behavior and that selection for potential resistance may be possible for this species (see also Henery et al. 2008). Differential resistance to a number of significant insect pests, including eucalypt weevil (Dungey and Potts 2003), sawflies (Jordan et al. 2002), leaf beetles (Raymond 1995; Rapley et al. 2004a), and autumn gum moth (Jones et al. 2002; Rapley et al. 2004b) has been found in other eucalypts.

Although we have detected useful chemical characteristics to distinguish among the taxa in this study, whether any of these are relevant to the host finding/acceptance behavior of *P. atomaria* is unclear. The next step is an examination of electroantennagraphic (EAG) responses of the beetle to the plant extracts, as a method of determining the cues used by beetles. Understanding the preferences of this insect pest will assist in the choice of parental taxa and hybrids used for forestry, as these hardwoods become an ever more important component of the industry.

Acknowledgments We thank Dr Simon Lawson (QPIF DEEDI) for field assistance and comments on the manuscript, Dr Chris Moore (QPIF DEEDI) for preliminary analyses of foliage and helpful discussions, Drs Martin Steinbauer (La Trobe University, Melbourne) and Manon Griffiths (QPIF DEEDI) for ms comments; Dr David Lee (QPIF DEEDI) for access to field trials. This work was funded with a grant from the Queensland Department of Tourism, Regional Development and Industry, Forestry Plantations Queensland, Forest Enterprises Australia Ltd. and Integrated Tree Cropping Ltd.

To date, management of *L. botrana* in vineyards is based mainly on insecticidal control of preimaginal stages during the second generation of the year (Ioriatti et al. 2009), even though preventive strategies, such as pheromone mating disruption, are increasingly and effectively used in Area Wide Projects (Ioriatti et al. 2008). In addition to pheromones, substantial research has been directed at finding efficient attractants for grapevine moth females because such attractants could improve the timing of management decisions. Fermented fruit juices currently are considered useful for monitoring numbers of both sexes of *L. botrana*, but their use is time-consuming because the captured insects must be handled, sorted, and identified (Thiéry et al. 2006).

L. botrana females also were attracted to essential oil of rosemary (*Rosmarinus officinalis* L.) in Greece (Katerinopoulos et al. 2005), and to tansy flowers (*Tanacetum vulgare* L.) in a Slovakian vineyard (Gabel 1992); the steam-distillate extract from tansy flowers and a synthetic blend based on that extract consistently attracted females in field cages (Gabel et al. 1992).

Susceptibility to oviposition by *L. botrana* females, as well as larval fitness, differs among varieties of *Vitis vinifera* L. (Fermaud 1998; Snjezana 2004; Moreau et al. 2006; Sharon et al. 2009). Finding a good site for oviposition is a challenging task for female grapevine moths, and their decision has a critical consequence for the life history of the offspring. For this reason, *L. botrana* females probably rely not on a single cue but rather on a combination of visual, mechanical, and chemical properties of the host plant. The contribution of olfactory cues in determining the host plant search image is not well understood (Städler 2002), and it is still unknown whether secondary metabolites emitted by grape bunches carry specific information about their suitability as oviposition substrates and food sources for the offspring. According to recent reports, *L. botrana* females use contact cues to evaluate the suitability of substrates for oviposition (Maher et al. 2006); moreover, they are attracted from long distances to odors either released from grape clusters (Tasin et al. 2005, 2006a, 2006b, 2007; Masante-Roca et al. 2007) or grape leaves and flower buds (Masante-Roca et al. 2007).

Our hypothesis is that mated grapevine moth females, after finding and selecting the host plant, also use olfaction at a closer range as a first step in the complex chain of behavioral responses to cues for discriminating suitable oviposition sites. Preliminary laboratory bioassays have shown that odor emitted from grape bunches of different varieties is able to drive the oviposition at a short range of both *L. botrana* females (Tasin et al. 2008, 2009) and the related species *Eupoecilia ambiguella* (Hübner) (Anfora et al. 2008). To verify this hypothesis, we studied how *L. botrana* oviposition was affected by the emission of grape clusters of the varieties Trebbiano and Sangiovese. These varieties, which are commonly grown in Italy and especially in the Tuscany region, were selected because they differ in susceptibility to *L. botrana* infestation under natural conditions. Mainly during the second *L. botrana* flight of the year, Sangiovese was shown to be much more susceptible than Trebbiano (Bagnoli 1990). Hence, a further aim was to establish whether olfaction plays a role in such a varietal different susceptibility.

To date, most behavioral studies on grapevine moth females have been carried out in the laboratory with fresh and synthetic material. No data are available on the attractiveness of synthetic host plant volatiles to females under field conditions, where the odor competes strongly with the canopy background (Cha et al. 2008b).

In the current study, a lure blended with the six major electrophysiologically active volatile compounds released by either Sangiovese or Trebbiano was first tested in the laboratory for its attractiveness to *L. botrana* females and its effect on oviposition. Then, traps baited with this mimic were used in a field cage placed in a vineyard, and the effect on female behavior was evaluated in terms of trap captures and oviposition preference.

Methods and Materials

Insects Moths were selected from a colony of *L. botrana* reared on an artificial diet at the IASMA-FEM Research Centre. During experiments, wild larvae were periodically collected from Tuscan vineyards and added to the colony to reduce inbreeding. Insects were reared under a 18:6 h L:D photoperiod and at 22°C. Oviposition assays and trapping tests were done with 48 to 96-h-old mated females, individually placed overnight in a little cylindrical cage (3 cm ID×5 cm) to ascertain the beginning of oviposition.

Plant Material and Collection of Volatiles Grape clusters of *V. vinifera* Sangiovese and Trebbiano varieties were collected from an experimental vineyard at Pisa University (Colignola, Italy, 43° 44′ N, 2° 0′ O) from May to September 2006. Grapevines were sprayed with fungicides to control powdery and downy mildew. No insecticides were used during the trial. The grape clusters were collected at five different phenological stages (stage 17, fully developed inflorescences; stage 23, full flowering; stage 33, beginning of berry touch; stage 35, beginning of ripening; and stage 38, berries ripe for harvest) (Eichhorn and Lorenz 1977). Per each extraction, 25 inflorescences were collected from different plants for stages 17 and 23 (total ca. 150 g), and 3 grape clusters were collected for stages 33 (total ca. 600 g), 35, and 38 (1,000 g, respectively). The cut stem of each inflorescence or grape cluster was sealed with liquid paraffin, and the material was stored in a portable refrigerator at 4°C

for transfer to the nearby laboratory. There, inflorescences or grape clusters were placed immediately in a 25×38 cm polyacetate bag (Toppits, Melitta, Sweden) for collection of volatiles (Faccoli et al. 2008). Air from the headspace of each bag was drawn at 150 ml/min through a sorbent cartridge (75 mg Super Q; Sigma-Aldrich, Milan, Italy) connected to a vacuum pump. Charcoal-filtered air was pulled back simultaneously into the bag by the same pump to maintain a constant pressure. Volatiles were collected for 6 h. Volatiles were eluted from the sorbent cartridge by solvent desorption at room temperature using 500 µl of hexane (>99% purity, Sigma-Aldrich). Five to six collections from different groups of inflorescences or grape clusters were done for each variety in each phenological stage. Some of the extracts were prepared for chemical quantification, and 0.5 µg of heptyl acetate (purity≥99%) were added as an internal standard (Bengtsson et al. 2001). Collections were reduced to 50 µl by using a slow stream of nitrogen, and were stored in 2-ml vials at −18°C until use.

For stage 33, volatiles of the two varieties were also collected directly in the field using intact grape clusters attached to the plants. This was done to determine whether there were qualitative and/or quantitative differences in volatiles collected in the laboratory vs. the field.

Chemicals Limonene, (±)-linalool, (*E*)-caryophyllene, and methyl salicylate were purchased from Sigma-Aldrich and (*E,E*)-α-farnesene from Firmenich (Geneva, Switzerland). 4,8-Dimethyl-1,(*E*)-3,7-nonatriene [(*E*)-DMNT] was synthesized by Ingve Stenstrøm (Aas, Norway).

Chemical and Electrophysiological Analyses Chemical and electrophysiological analyses were performed using methods described by Anfora et al. (2005) and Faccoli et al. (2008). Collections of plant volatiles and blends of synthetic compounds were analyzed by a Hewlett Packard (Palo Alto, CA, USA) 5890 gas chromatograph with a flame ionization detector and an Innowax column (30 m×0.2 mm × 0.32 µm) programmed from 60°C (3 min hold) at 8°C/min to 220°C (10 min) coupled to a Syntech electroantennodetector (Hilversum, The Netherlands) (GC-EAD). The antennae were cut from the moth head and suspended between two glass electrodes filled with Kaissling solution (Kaissling 1987). The mounted antennae were placed into the air stream that carried the volatiles compounds eluting from the GC column. Each sample was analyzed three times.

Volatiles collected in headspace entrapments were identified by a Perkin-Elmer AutoSystem XL Gas Chromatograph (60 m×0.32×0.5 µm DB-Wax fused silica column, J&W Scientific Inc., Folsom, CA, USA; for temperature program, see GC program above) equipped with a mass spectrometer (Perkin-Elmer TurbomassGold) with an ionization potential of 70 eV. Helium at 1.2 ml/min was used as carrier gas (GC-MS). Splitless injection (2 µl) was used. The injector was programmed at 250°C, and the transfer line was set at 220°C. Identity of GC-EAD active compounds was verified by injections with synthetic standards. The mean antennal responses were calculated by means of further GC-EAD analysis, injecting blended synthetic compounds at the constant amount of 10 ng of each one.

Laboratory Oviposition Bioassay The oviposition preference of *L. botrana* females for volatiles emitted by grape clusters of Sangiovese vs. Trebbiano was assessed with a dual-choice oviposition assay (Anfora et al. 2008; Tasin et al. 2009). Oviposition assays were conducted in ventilated cylindrical cages (25 cm ID×45 cm; metallic net, 2-mm mesh). Each cage contained two plastic and transparent conical glasses (bottom 61 mm, top 88 mm, height 130 mm), which were located 7 cm below the cage top and 10 cm from the cage sides (the glasses were separated by 25 cm). Each glass had 30 holes (1.5±0.2 mm ID) to allow volatiles to escape; one glass contained one grape cluster of Sangiovese and the other contained one cluster of Trebbiano; in both cases, the clusters were at phenological stage 33 (beginning of berry touch). At dusk, one mated female was released into the center of each cage. After 72 h at 25°C and 16:8 h L:D photoperiod, the moth was removed, and the eggs laid on glasses were counted and expressed either as the percentage of the total number of eggs laid on each glass or as the number of eggs laid per female in each cage. In this assay, the female moth's choice of oviposition site was based exclusively on visual and olfactory cues and not on contact chemoreception. This assay was replicated 18 times.

The dual-choice oviposition assay also was conducted with the synthetic lure (see Results). The synthetic lure was loaded in red rubber septa (Wheaton, 20 mm straight plug stopper, Millville, NJ, USA) at 15, 150, or 1,500 µg per septum. Septa were placed in a hood for 2 h to permit solvent evaporation (Heath et al. 1986), and subsequently were inserted into the conical glasses. One glass in the cage contained a septum with lure and the other contained a septum initially treated with solvent without lure. Oviposition was quantified as described previously, and the experiment was repeated 15 to 21 times.

To detect the possibility of a positional bias in the dual-choice oviposition assay, a preliminary experiment was performed. Oviposition was quantified after moths were released into cages that contained two empty glasses; the glasses were located on opposite sides (designated East and West) of the cage. This experiment was repeated 19 times.

Field-cage Experiment A release-capture experiment in a field cage was conducted in June and July 2008 in a thin-

meshed net tunnel (length 30 m, width 4 m, median height 2.5 m, 2-mm mesh) that covered two grapevine rows (guyot training system) of a Chardonnay vineyard at the IASMA-FEM Research Centre (San Michele all'Adige, Italy, 46° 12′ N, 11° 8′ E). The Chardonnay vineyard was chosen with the aim of avoiding a full overlapping between the volatiles from Trebbiano and Sangiovese and the background odor. The canopy height was 2.5 m, with 0.8 m between vines and 3 m between rows. A piece of mesh was used to divide the tunnel into two 15-m-long cages. All grape clusters within the cages were removed to reduce competition with natural odors. In each cage, three replicates of three differently baited traps (nine traps total per cage) were installed 1 m above the ground along the two rows: four traps were in one row and five were in the other row, with 3 m separating traps in the same row. In preliminary field trials, different trap models were evaluated for their suitability to catch females (data not shown). The traps employed consisted of square sticky base (30×30 cm) with a clear plastic cylindrical screw-top jar (8 cm ID× 11 cm height) in the middle. Thirty holes (1.5±0.2 mm ID) in the side wall of each jar allowed volatiles to escape. The screw top of each jar was fixed to the sticky base. The jar was unscrewed from its top to introduce the bait.

Three baits or treatments were compared: grape mimic, a cut grape bunch (phenological stage 33, Chardonnay from the same rows used in the experiment), and a blank. For the grape mimic, the solution (15 mg diluted in an equal volume of light mineral oil, Sigma-Aldrich) was impregnated in a rubber septum (Wheaton, 20 mm straight plug stopper). This formulation was chosen, as from the one set up in the laboratory bioassay, on the basis of preliminary tests with the aim of providing an adequate emission in field conditions and to prevent earlier evaporation of volatiles. Mated females (N=140) were released every 2nd week between the rows of each cage, for a total of three releases per cage. The releases alternated between cages so that only one cage received females in any week. At each release, the position of the traps was randomized and the grape mimic baits were replaced. The cut grape bunches were replaced every day. The number of females captured on the sticky base of the traps was determined daily for the 1st week after release, and the number of captures over the 7-day period was considered. Four weeks after the first release in each cage, *L. botrana* larvae were counted on grapevine shoots and leaves within 50 cm of each trap. Counting lasted 5 min/replicate, and presence of larvae developing in shoots and leaves was ascertained.

Statistical Analyses The software used for the statistical analyses was KyPlot 5.0 (Kyenslab Inc., Tokyo, Japan). The *Wilcoxon test* for paired samples was used to determine significant differences in the numbers of eggs laid between the two glasses in the dual-choice laboratory bioassay. Nonparametric *one-way ANOVA* (*Kruskal-Wallis test*) followed by the *Bonferroni-Dunn post-hoc multiple comparison test* was used to assess differences either in the number of eggs laid per female for the laboratory assays or in the attractiveness of the baits for the field-cage experiment. Parametric *one-way ANOVA* followed by the *Tukey post-hoc multiple comparison test* was used to assess the effect of baits on the level of pest infestation; homogeneity of variance had been determined previously with *Levene's test*.

Results

Chemical and Electrophysiological Analyses Antennae of grapevine moth mated females responded to 20 compounds from headspace collections of the two grape varieties (Table 1). The two odor profiles perceived by mated females had a high degree of similarity. Fifteen GC-EAD-active volatiles were released by both varieties; pentadecane, nonanal, decanal, and (*Z,E*)-(α)-farnesene were detected only from Sangiovese, while germacrene-(*D*) was detected only from Trebbiano.

For both varieties, several terpenes, released in all phenological stages and frequently in large amounts, elicited the highest antennal responses. The most abundant terpenes were (*E*)-DMNT at stage 17 and limonene from stage 33 to stage 38. (*E*)-DMNT, limonene, (*E,E*)-α-farnesene, (±)-linalool, (*E*)-caryophyllene, and methyl salicylate always were collected during the three grape phenological stages when *L. botrana* oviposition occurs in nature (stages 17, 33, and 35). The average amounts of emission of these terpenes are shown in Table 1. Synthetic (*E*)-DMNT elicited the strongest antennal responses in *L. botrana* mated females.

For stage 33, field-collected and laboratory-collected volatiles did not differ significantly qualitatively or quantitatively (data not shown). The chemical and electrophysiological data were used to formulate the synthetic lure.

Formulation of Synthetic Lure Since in the oviposition bioassay the volatiles emitted by the grape clusters of Trebbiano and Sangiovese did not cause a different attractiveness for *L. botrana* gravid females (see following section), a synthetic lure that approximated the emission of both varieties was prepared. The lure contained limonene, (*E*)-DMNT, (±)-linalool, (*E*)-caryophyllene, (*E,E*)-α-farnesene, and methyl salicylate. Such compounds were GC-EAD active, and always were collected from both varieties during the phenological stages 17, 33, and 35, corresponding to the three *L. botrana* flights of the year. The relative proportions of these volatiles change during the season according to the

Table 1 Relative quantities of volatile compounds, antennally active in GC-EAD experiments on *Lobesia botrana* females, collected in the headspace of bagged grapevine clusters belonging to varieties Trebbiano (T) and Sangiovese (S) at five phenological stages[a], and antennal responses to synthetic compounds[b]

[a] Quantities are relative to the most abundant compound (set at a value of 100) in each phenological stage

[b] Mean ± SD antennal responses (mV) using 10 ng of standard compounds (N=3)

[c] *Vitis vinifera* phenological stages according to Eichhorn and Lorenz (1977): 17 (fully developed inflorescences), 23 (full flowering), 33 (beginning of berry touch), 35 (beginning of ripening), and 38 (berries ripe for harvest)

[d] The average amount of the most abundant compound collected from 100 g of grape clusters in each phenological stage were: Trebbiano) 376.5± 167.4 ng/h of (*E*)-DMNT (fully developed inflorescences); 9,866.8±2,987.2 ng/h of (*E,E*)-(α)-farnesene (full flowering); 556±234 ng/h of limonene (beginning of berry touch); 80.2±19.9 ng/h of limonene (beginning of ripening); and 110.6±38.0 ng/h of limonene (berries ripe for harvest); Sangiovese) 89.6±56.8 ng/h of (*E*)-DMNT (fully developed inflorescences); 5,481.1±1,089.6 ng/h of (*E,E*)-(α)-farnesene (full flowering); 569.7±312.5 ng/h of limonene (beginning of berry touch); 54.6±27.1 ng/h of limonene (beginning of ripening); and 124.6±43.1 ng/h of limonene (berries ripe for harvest)

phenological stage of the grape. Because stage 33 corresponds to the second flight of *L. botrana*, and because the bunches at this phenological stage were used for the oviposition bioassay, the lure was formulated based on the proportions released from grapes at stage 33. Grape volatiles of stage 33 were found in the following ratios: 10:0.6:0.4:0.5:0.9:0.6 [limonene:(*E*)-DMNT:(±)-linalool:(*E*)-caryophyllene:(*E,E*)-α-farnesene:methyl salicylate] from Trebbiano and 10:1:0.4:1.5:0.4:0.3 from Sangiovese (Table 1). Because the components and their ratios were similar for the two varieties at stage 33, the synthetic lure was mixed with the six components in the approximate and simplified proportion

10:1:1:1:1:1 [limonene:(*E*)-DMNT:(±)-linalool:(*E*)-caryophyllene:(*E,E*)-α-farnesene:methyl salicylate]. Thereby, the aim was to mimic both varieties by using a lure easy to prepare. For laboratory and field bioassays, an hexane solution was prepared at the concentration of 100 μg/μl for limonene and 10 μg/μl for the other compounds, and it was used as a mother solution.

Laboratory Oviposition Bioassay In the dual-choice bioassay, oviposition (number of eggs laid per glass) was similar (T=60.0; N=18; P=0.44) for glasses containing cut grape clusters of Sangiovese and Trebbiano (Fig. 1). The effect of synthetic lure (grape mimic) on oviposition depended on lure concentration (Fig. 1). Grape mimic at 150 μg/septum induced oviposition (T=54.0; N=21; P<0.05); grape mimic at 1,500 μg/septum repelled oviposition (T=13.0; N=15; P<0.05); and grape mimic at 15 μg/septum did not affect oviposition (T=66.5; N=16; P=0.94). No bias related to the position of the glasses in the cage was detected (T=83.5; N=19; P=0.93). *L. botrana* females laid significantly more eggs (T=39.9; N=89; P<0.001) in the cages where either the grape bunches were present or the synthetic lure at the dosage of 150 μg/septum (Fig. 1).

Field-cage Experiment The recapture rate in the field-cage experiment was approximately 10% (83 individuals caught vs. 840 released). Traps baited with grape mimic caught significantly more mated *L. botrana* females than traps baited with one grape cluster or unbaited traps, and traps baited with grape clusters captured more females than unbaited traps (KW=7.2; df=2; P<0.05) (Table 2).

The numbers of grapevine moth larvae on shoots and leaves near the traps differed significantly with bait (F=59.0; df=15; P<0.001). The level of infestation was significantly higher near traps baited with synthetic lure than near unbaited traps or traps baited with grape clusters (Table 2).

Discussion

Two main goals motivated our research on olfactory communication between plant and moth: to understand the role of olfactory cues in the selection of oviposition sites by *L. botrana*, and to develop a synthetic lure based on host-plant volatiles for monitoring female flight activity in the field. Our first hypothesis was that olfactory cues could affect greatly the selection of oviposition sites among different host-plant genotypes. This was not confirmed by our results. The two varieties chosen for their different susceptibility to *L. botrana* did not show significant differences in odor profiles (volatiles released), and the volatiles from these two varieties elicited similar antennal responses. Moreover, the two odor profiles did not differ in their ability to attract ovipositing females in the dual-choice bioassay.

L. botrana is a generalist herbivore with a long list of potential host plants (Bovey 1966). Schoonhoven et al. (1998) argued that host-plant recognition for polyphagous insects should result largely from the lack of repellents rather than from the presence of specific attractants. On the

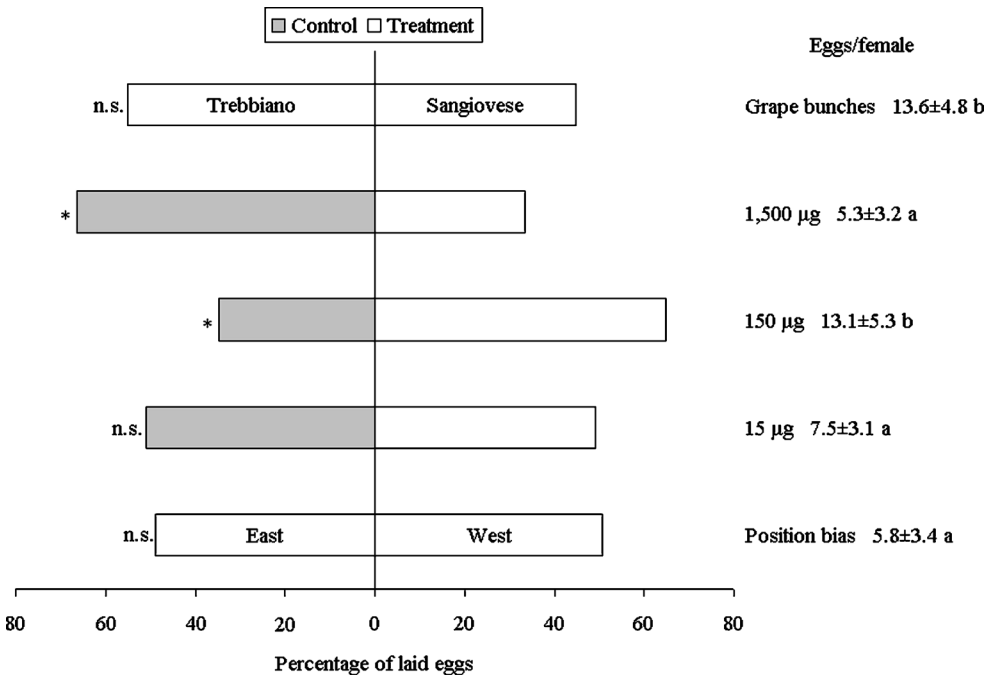

Fig. 1 Oviposition preference of gravid female *Lobesia botrana* toward Trebbiano and Sangiovese grape bunches at phenological stage 33 and a blend mimicking their released volatiles. The grape mimic was formulated to contain 15, 150, and 1,500 μg of compounds. *Asterisk* indicates significant deviation from equal preference in each experiment (P<0.05, n.s. = non significant, *Wilcoxon test* for paired samples). The mean number of eggs laid per female in each experiment is indicated in the *right* column. Values within the column followed by different letters are significantly different (P<0.001, *Kruskal-Wallis test* followed by *Bonferroni-Dunn post-hoc multiple comparison test*)

Table 2 Number of *Lobesia botrana* females captured in horizontal traps and number of *L. botrana* larvae dwelling inside grapevine leaves near the traps (within 50 cm) in the field-cage experiment[a]

	Number of females captured in traps[b]	Number of larvae near traps[c]
Grape mimic	6.3±2.6 c	9.8±0.8 c
Grape bunch	4.5±2.1 b	4.7±1.4 b
Blank	2.8±1.0 a	2.5±1.4 a

other hand, the absolute and relative amounts of ubiquitous plant volatiles have been suggested as the critical factors that mediate the species specificity of host-plant profiles (Visser 1986; Bruce et al. 2005) and, as a consequence, the differential attractiveness of varieties of a given species to certain herbivores. In our case, the ratio of the active volatiles, such as the most abundant limonene, was similar in both varieties at phenological stage 33 and thus cannot explain differences in their susceptibility to grapevine moth. The lower susceptibility expressed under natural conditions by Trebbiano vs. Sangiovese might be due to factors such as the asynchrony between susceptible phenological stage and moth flight (Bagnoli 1990), the ecological setting of the varieties, and the influence of other sensory cues (Maher et al. 2006; Moreau et al. 2006; Pavan et al. 2009). The characterization of the different sensory cues released by grapevine genotypes that differ in tolerance to grapevine moth could allow the development of innovative methods for manipulating *L. botrana* behavior.

Our synthetic lure mimic of both Trebbiano and Sangiovese attracted *L. botrana* egg-laying females either in the laboratory bioassay or in the field-cage experiment. From a comparison of the headspace collections from Chardonnay grape variety (Tasin et al. 2005) and of the blend attractants from Casana in a wind tunnel bioassay (Tasin et al. 2006b, 2007) with the set up from Trebbiano and Sangiovese, strong differences were shown in the active compounds and their ratio. In particular, we found in the collected volatiles a higher amount of limonene, which never was included in previous blends attractive to *L. botrana*. This confirms the remarkable differences that are commonly observed between cultivars and the plasticity of the moth in host recognition. It is noteworthy that, in the absence of grape bunches in the field cages, *L. botrana* females deposited their eggs on grapevine shoots and leaves, and that the larvae seemed capable of developing inside such organs. This is in agreement with the reported attractiveness of various grapevine plant parts to *L. botrana* in wind tunnel experiments (Tasin et al. 2005; Masante-Roca et al. 2007). Furthermore, Cha et al. (2008a) demonstrated that grape shoot tips and mature leaves were more attractive than unripe and ripe berries or flowers to females of *Paralobesia viteana* Clemens. Based on their analysis of the shoots of *Vitis riparia* Michx, the same authors formulated a synthetic blend that, when used as bait in traps, caught females of *P. viteana* in a vineyard (Cha et al. 2008b).

Besides attractiveness, plant volatiles are able to enhance oviposition of *L. botrana*, as in codling moth (Witzgall et al. 2005). In the oviposition bioassay, gravid females laid significantly more eggs in the presence of the odor either from the grape bunches or from the synthetic lure at the attractive dosage. Moreover, the large number of *L. botrana* larvae detected near traps baited with synthetic lure in the field bioassay corroborates our hypothesis that *L. botrana* uses olfaction to select oviposition sites, as well as the volatiles from grape bunches that likely stimulate its egg-laying behavior.

Based on our results, we conclude that *L. botrana* uses a subset of common volatiles emitted by grape clusters both to find hosts and to select oviposition sites. In this way, the behavior of *L. botrana* is similar to that of other tortricids (Wearing and Hutchings 1973; Suckling et al. 1996; Grant et al. 2007). On the other hand, the plasticity in the responses of *L. botrana* to ubiquitous plant compounds at different ratios can also explain the keeping of several plant species and grape varieties as hosts that provide different fitness (Thiéry and Moreau 2005; Tasin et al. 2007).

The lesser attractiveness of cut Chardonnay grape cluster bait vs. synthetic grape mimic bait could be due to strong competition with the natural odor in the Chardonnay vineyard, despite the removal of grape clusters on the plants within the cages. However, because the attractiveness of the grape mimic recorded in the field cage was quite

weak, we assume that its attractiveness also can be affected by the vineyard background odor. In a given environment, each plant is capable of synthesizing ten to hundreds of primary and secondary metabolites, with diverse biological properties and functions that can create complex backgrounds able to disrupt insects from selecting acceptable host plants or synthetic blends (Knudsen et al. 2008). Consequently, an artificial lure for capturing females must be able to compete with background odors. Furthermore, the approximate ratio of compounds in the blend, based on our specific extraction conditions, along with the release rates of dispensers, are both likely to be considerably discrepant from natural emissions of grapes and affect negatively the attractiveness of the lure (Heath et al. 1986; Tasin et al. 2005; Cha et al. 2008b), as the results of the oviposition bioassay suggest. In fact, the interference of the grape mimic with the *L. botrana* egg-laying behavior was dose-dependent, either attracting oviposition or inducing an antioviposition activity at a higher dose. Hence, future studies have to include the optimization of the blend rate in the field.

We agree with Bernays and Chapman (1994) that the role of odors in host location is a stronger selective force for specialists than for generalists. Nevertheless, results of our experiments provide new evidence that plant volatiles play a relevant role in all three-linked events of the host plant selection process: host finding, landing on the proper plant organ, and egg laying stimulation. Such a situation might drive the species toward a long-term specialization in host recognition.

Acknowledgements We are grateful to Prof. Ingve Stenstrøm, Agricultural University of Norway, Department of Chemistry and Biotechnology (Aas, Norway) for the synthesis of (*E*)-DMNT. We thank Elisabetta Leonardelli, Elena Pozzolini, and Anna Eriksson for technical assistance. We thank the anonymous reviewers for helpful comments. This study was funded by the Government of Autonomous Province of Trento (HOST and INTERPLAY Research Projects) and by the Italian Ministry of University and Research (PRIN 2006).

1978; Hiwot 2000). Fermentation products, e.g., residue (dregs) from tella, an Ethiopian beer-like beverage, are highly attractive to the beetles (Ministry of Agriculture and Ethiopian Agricultural Research Organization 1999). Tella is a spontaneously fermented beer (no yeast is added) that is brewed using water, flour of sorghum or other cereals, malt of barley or wheat, with crushed leaves of shiny-leaf buckthorn, *Rhamnus prinoides* Eschsch. (Rhamnaceae), instead of hops. *Pachnoda interrupta* adults also feed on the herbaceous weed abutilon, *Abutilon figarianum*, and food crops such as pearl millet, *Pennisetum glaucum* and sorghum, *Sorghum bicolor* (Schmutterer 1969; Grunshaw 1992; Jago 1995; Sastawa and Lale 2000). During the early 1990s, the sorghum chafer emerged as a key pest on sorghum in Ethiopia (Hiwot 2000). Mean percent loss of sorghum yield due to *P. interrupta* infestation can be as high as 70% (Yitbarek and Hiwot 2000). Efficient control methods for this pest insect are lacking, but trapping by using fruit (mainly *Musa* spp.) as bait shows promise for decreasing the pest population (Ministry of Agriculture and Ethiopian Agricultural Research Organization 1999). The efficiency of trapping could be improved by using better traps and synthetic, standardized attractants (Wolde-Hawariat et al. 2007). Previous field experiments indicate that compounds commonly found in the odor profile of flowers and fruits have potential as attractants for *P. interrupta*, with high levels of attraction especially to methyl salicylate and eugenol (Wolde-Hawariat et al. 2007). Single compounds are efficient lures for many scarab species that feed on fruits and flowers (Donaldson et al. 1990), and studies have shown a high degree of overlap between active compounds identified from different food sources (Stensmyr et al. 2001). Continued efforts in field testing of novel synthetic attractants for the Japanese beetle, *Popillia japonica*, have led to the development of lures far outperforming initial versions (Potter and Held 2002).

In search of attractants for pest insects, various approaches have been employed. Trial-and-error field screening of compounds has led to the identification of powerful attractants, e.g., for *P. japonica* (Potter and Held 2002). A commonly employed method in search of field attractants is gas chromatography with electroantennographic detection (GC-EAD; Arn et al. 1975), which allows the identification of antennally active compounds in the volatile blends emitted by hosts. GC-EAD has led to the identification of several powerful kairomonal field attractants (see e.g., Linn et al. 2005). Few studies, however, have employed single sensillum recordings (SSR) to identify behaviorally active compounds (Stensmyr et al. 2001; Larsson et al. 2002, 2003; Ulland et al. 2008), even though SSR may be a highly sensitive tool in detecting physiologically active components in the volatile profiles of host plants (Wibe 2004), including compounds that do not elicit detectable GC-EAD responses (Blight et al. 1995; Wu et al. 1995; Barata et al. 2002). SSR usually has been employed as a means of describing and understanding the sense of olfaction, specifically the olfactory receptor populations of antennae and palps (see e.g., Larsson et al. 2001; Mustaparta 2002).

We employed GC-EAD on volatile collections from sorghum and abutilon to identify compounds responsible for attraction of *P. interrupta* to these plants in the field. We also screened olfactory receptor neurons (ORNs) on the sorghum chafer antenna with potential kairomones using SSR. The behavioral activity of several compounds active in GC-EAD and SSR was tested in field trials, in search of potent attractants. Such attractants could be used in future control efforts, either in mass trapping or in monitoring, or as part of integrated pest management.

Methods and Materials

Insects for Electrophysiological Experiments Male and female sorghum chafers were collected at Rasa (09°55′N, 40°05′E), located 255 km northeast of Addis Ababa, Ethiopia. Adult beetles were sexed based on the presence of a ventral, abdominal groove in males (Rigout 1989), and kept separately. After transport to Alnarp, Sweden, adults were kept in clear plastic boxes (30×12×22 cm, Cofa Plastics AB, Stockholm, Sweden) with a 1:1:1 mixture of planting soil (Yrkesplantjord, Weibull Trädgård AB, Hammenhög, Sweden), peat (Växa trädgårdstorv, Econova Garden AB, Åse, Sweden) and composted cow dung (Simontorps Bas, Weibull Trädgård AB). Boxes were kept at 25°C, 70% relative humidity, and a L16:D8 h cycle. The beetles were fed with apples and bananas *ad libitum*.

Headspace Plant Volatile Collection Volatiles were collected from the developmental stage of the plant most attractive to the beetles, during the time of day when the beetles feed intensively, i.e., 10 am to 4 pm. For abutilon, the top 20 cm of a single abutilon plant, including flowers, seed pods, and leaves, was enclosed for each collection. For sorghum, volatiles were collected from a single panicle at the soft dough stage (milky stage). Polyacetate bags (35×43 cm; Toppits Scandinavia AB, Sweden) sealed with steel wire around the stem of the plant were used for aerations. An activated charcoal filter was placed next to the stem to filter incoming air. Volatiles were collected on glass tube columns (3.5 mm i.d.× 50 mm) packed with 25 mg SuperQ®, mesh 80/100 (Alltech, Deerfield, IL, USA) with glass wool and Teflon stoppers at both ends (Birgersson and Bergström, 1989). The filter was placed in the polyacetate bag and connected by PVC tubing to a small battery operated pump (PAS-500 Personal Air Sampler, Supelco, Bellefonte, PA, USA). The flow of the pump was 200 ml/min, and collections were made in the field

for 2 h. Immediately after collection, the columns were rinsed with 200 µl of redistilled hexane into 1.1 ml tapered glass vials (1.1 STVG, Chromacol Ltd., Welwyn Garden City, UK). Vials with extracts were kept in an icebox for transportation to the laboratory, and thereafter kept at —18°C until analysis.

Gas Chromatograph-Coupled Electroantennographic Detection (GC-EAD) The response of *P. interrupta* antennae to volatiles was studied by GC-EAD using an Agilent Technologies gas chromatograph (GC), model 6890, equipped with a fused silica capillary column (30 m×0.2 mm) coated with Innowax (0.25 µm film thickness) (Agilent Technologies Inc., Santa Clara, CA, USA). For each run, 2 µl of sample were injected in splitless mode. Hydrogen was used as mobile phase at a linear velocity of 45 cm/sec. The oven temperature was programmed from 40°C (5 min hold) to 230°C at 5°C/min. Compounds eluting from the column were split 1:1 in a four-way splitter, with nitrogen as make up gas (20 ml/min), and delivered to the FID and to the antenna. Compounds were carried to the antenna through a glass tube by a charcoal-filtered and humidified air stream at 0.5 m/sec. Antennae were mounted according to Leal et al. (1992) and Wolde-Hawariat et al. (2007). The antenna was excised with fine forceps and placed in an antennal holder (Hillbur 2001; JoAC, Lund, Sweden), and the signal was amplified (JoAC) and analyzed with GC-EAD software (Syntech, Hilversum, The Netherlands). EAD responses to FID peaks were defined as repeatable deflections of the baseline. Each extract was tested on five different antennae per sex, for a total of ten antennae per extract.

Chemical Identification Samples of plant volatile collections were analyzed by combined gas chromatography and mass spectrometry (GC-MS) Hewlett Packard 6890 GC and 5973 MS (Agilent Technologies Inc.). Extracts were injected with an HP 7683 auto injector in splitless mode. The GC was fitted with the same column under the same conditions as for GC-EAD, but usinig helium (35 cm/sec) as carrier. Peaks were matched between GC-EAD and GC-MS by retention index. Identifications of compounds were confirmed by comparison of mass spectra in the NIST 1998 and Wiley 1998 commercial mass spectral databases, and with those of authentic GC standards, except for methyl anthranilate, which was not available at the time when GC-MS analysis was done.

Synthetic Compounds Synthetic standards for all experiments were purchased from Sigma-Aldrich (for purity and CAS number, see Table 1). A total of 82 compounds were used in single sensillum recordings (Table 1). The compounds include volatiles commonly found in flowers (Knudsen et al. 2006), volatiles from tropical fruit (Macku and Jennings 1987; Ibáñes et al. 1998; Boudhrioua et al. 2003; Carasek and Pawliszyn 2006; Clara et al. 2007; Pandit et al. 2009), and volatiles related to microbial degradation and fermentation (Chatonnet et al. 1992; Fischer et al. 2000; Xiao and Ping 2007). Approximately half of the compounds used previously have been found to elicit behavioral or electrophysiological activity in the sorghum chafer or related scarab beetles (Stensmyr et al. 2001; Larsson et al. 2003; Wolde-Hawariat et al. 2007).

Single Sensillum Recordings (SSR) Single synthetic compounds were diluted to 1 µg/µl in acetone or hexane, depending on polarity (Table 1). Highly volatile compounds were diluted to 1 µg/µl in paraffin oil. Blends of 2–10 compounds, with each component at the same concentration as in the single compound dilutions, were also prepared for screening purposes (see below; Table 1). Stimuli were prepared by applying 10 µl of 1 µg/µl solution to a 1.5× 1 cm piece of Whatman filter paper (No. 3, Whatman, Maidstone, United Kingdom) that was placed in a disposable Pasteur pipette (150 mm soda lime glass, VWR International, Stockholm, Sweden). For compounds diluted in hexane or acetone, solvent was allowed to evaporate before stimuli were used in experiments. After evaporation of solvent, 1 ml pipette tips were put on the wide end of the Pasteur pipettes, to reduce any further evaporation of the test compound(s). Between trials, stimulus pipettes were kept at —18°C, to avoid evaporation. For comparison, stimulus pipettes containing only solvent as well as empty pipettes were prepared. To ensure that stimulus pipettes were not exhausted, new ones were prepared once per week (after having been used a maximum of ten times), except for screening pipettes, where new ones were prepared each day.

Insects were restrained with Parafilm (PM-992, Pecheney plastic packaging, Menasha, WI, USA) and fixed on microscope slides (ca. 76×26 mm, Menzel-Gläser, Braunschweig, Germany) using dental wax (Surgident periphery wax, Heraeus Kulzer GmbH, Hanau, Germany), with the lamellae held open on a wax surface using 2-3 mm long pieces of thin tungsten wire. A silver grounding electrode was inserted into the abdomen. Sensilla were contacted with a tungsten electrode (diam 0.12 mm, Harvard Apparatus Ltd, Edenbridge, United Kingdom) electrolytically sharpened in a saturated KNO_2 solution (Hubel 1957), using a DC-3K Rechts PM-10 piezo micromanipulator (Märzhäuser Wetzler GmbH, Wetzler, Germany). The signal from the ORNs was registered and amplified 10 times with a probe (INR-02, Syntech), amplified 200 times with a Syntech UN-06 AC/DC amplifier, and transferred to a computer through an IDAC-4-USB (Syntech), where it was visualized and analyzed with the software Autospike v. 2.2 (Syntech).

A constant flow of 0.5 m/sec of charcoal-filtered and humidified air was delivered through a glass tube with its outlet approximately 15 mm from the antenna. Stimuli were presented to the insect by inserting the stimulus pipette

%, minimum purity in percent

through a hole in the glass tube, and blowing an air puff of 2.5 ml during 0.5 sec through the pipette into the air stream, using a stimulus controller (Syntech SFC-1/b). Control stimuli were delivered first, followed by screening stimuli containing multiple compounds (screening blends listed in Table 1). For all screening stimuli that elicited a positive response of approximately≥40 Hz, the pipettes loaded with all compounds in the blend(s) were brought from the

freezer and tested individually after thawing at room temperature for 5 min.

The net response to a stimulus was obtained by counting action potentials (spikes) during 0.5 sec starting from the time after the stimulation period at which the earliest response for the neuron was found, and deducting the number of action potentials during 0.5 sec immediately prior to the response. Each neuron was also subjected to blank stimuli (i.e., only solvent), and the net response to the blank was deducted from the response to the test compounds. The resulting value was doubled to obtain a value corresponding to spikes/sec (Hz). The time between the start of the stimulation period and the onset of a response, i.e., increased number of action potentials, sometimes varied between different recording sessions, due to slight variations in the air flow. For each neuron, counting of action potentials was started from the time at which the earliest response in that neuron occurred.

Field Experiments Related to GC-EAD Field experiments with the sorghum and abutilon compounds were carried out at Rasa, Ethiopia (see above). A complete randomized block design with $N = 10$ was used. The distance between traps was 10 m, and blocks were separated by at least 50 m. Dispensers were placed in cardboard holders (78×37 mm, Silvandersson AB, Knäred, Sweden) fitted into a slot in the vanes of Japanese beetle traps (Trécé, Palo Alto, CA, USA), which were suspended approximately 3 m above ground from wooden poles. The traps were emptied daily, and lures were replaced in the morning before the onset of activity for adult *P. interrupta*. Unbaited traps were used as a negative control.

Experiments were performed during two periods: July 11–16 and October 7–13, 2006. The latter tests were done during the cropping season, when the sorghum had seeds in the milky stage. The July experiments were carried out in a grazing area characterized by scattered *Acacia* trees. In October, traps were placed along the borders of five sorghum fields located approximately 500 m from the July test sites. Compounds were applied to dental cotton rolls (No. 3, Q-dent, Germany). The individual sorghum compounds, (*Z*)-3-hexen-1-ol, tridecane, 1-octen-3-ol, and 1-octanol, were applied at a dose of 100 mg each. In addition to the sorghum compounds, eugenol and methyl salicylate also were tested. Two of the sorghum-related blends were tested both in July and in October: a blend of the four sorghum compounds with the same total dose (100 mg) as for the individual compounds and in a ratio mimicking what was found in the sorghum headspace, i.e., 10 mg (*Z*)-3-hexen-1-ol+30 mg tridecane +30 mg 1-octen-3-ol+30 mg 1-octanol, and the same sorghum blend with the addition of 30 mg methyl salicylate. In addition to these, three more blends were tested in October: the sorghum blend with the addition of 30 mg eugenol, the sorghum blend with the addition of 30 mg eugenol and 30 mg methyl salicylate, and a blend of 50 mg eugenol and 50 mg methyl salicylate.

The individual abutilon compounds were also tested at a dose of 100 mg: (*Z*)-3-hexen-1-ol (the same traps as in the sorghum experiment), tetradecane, methyl anthranilate, and methyl salicylate. Methyl anthranilate was tested only individually in October. An abutilon blend at a total dose of 100 mg and with ratios mimicking the headspace collections was also tested as follows: 20 mg (*Z*)-3-hexen-1-ol+20 mg tetradecane+5 mg methyl anthranilate + 55 mg methyl salicylate. In addition, a blend without methyl salicylate was tested. Furthermore, in October, a blend consisting of the abutilon blend with the addition of 30 mg eugenol was added to the experiment.

Field Experiments Related to SSR The materials and methods used in SSR-related field experiments were the same as those used for field experiments related to GC-EAD, except $N = 5$ and treatments were moved one step within blocks each day to minimize any impact of possible position effects. Some previously untested compounds also were applied to new dispenser types (see below).

Six novel compounds selected by SSR were tested on 4–9 July 2008 on unused farmland with sparse vegetation near the village of Embuay Bad in Ethiopia (09°48′N, 40°00′E), 1206 m above sea level, 265 km northeast of Addis Ababa, Ethiopia. Five of the novel compounds tested (anethole, benzaldehyde, racemic 2,3-butanediol, isoamyl alcohol, and methyl octanoate) were selected on the basis that they elicited strong SSR response in separate ORN classes that did not respond to compounds previously tested in the field. For comparison, we also included eugenol and methyl salicylate. Methyl benzoate was tested for reasons different from the other compounds—it was included since it activated the same ORN type as methyl salicylate, which previously had been shown to be highly attractive. Olfactory receptor neurons responding to eugenol did not respond to other compounds included in the screening process. Practical limitations forced us to forego testing of some compounds as it was not possible to acquire necessary quantities in suitable purity, and other compounds were not included since they are more commonly associated with foliage than fruit or flowers.

A dose of 100 mg of pure compound (for purity and CAS number, see Table 1) was loaded onto a dispenser that was matched to the volatility (as indicated by boiling point) of the compound. This rough estimation was used to obtain comparable evaporation rates. Cotton rolls (no. 2 dental cotton roll, Demedis GmbH, Langen, Germany) were used as dispensers for anethole, eugenol, methyl benzoate, methyl octanoate, and methyl salicylate. For dispensing benzaldehyde and 2,3-butanediol, cotton rolls were pushed into 4 ml

vials (45×14.7 mm, clear, Skandinaviska GeneTec AB, Västra Frölunda, Sweden) until the cotton was level with the rim of the opening of the vial. Compound was applied to the cotton roll after it had been placed in the vial. For isoamyl alcohol, a dispenser was made where a cotton roll was put inside a vial closed with a cap (black, closed top, 13 mm, Skandinaviska GeneTec AB). A hole of approximately 2 mm diam was made in the cap. The cotton roll was placed so that it was in direct contact with the cap when the cap was screwed tight to the vial. The chemical was not applied to the cotton roll directly beneath the hole in the cap, but instead towards the edge of the vial, before screwing on the cap.

Statistical Analysis For field experiments, data for total catch of *P. interrupta* (cumulative over the field testing period) per trap was square root-transformed ($\sqrt{(\times+1)}$). Data was analyzed with a *General Linear Model* (*GLM*), with treatment (type of lure) as a fixed effect, and block as a random effect (Minitab 14 for Windows). Significant *GLM*s were followed by *Tukey's b post hoc* test. The significance level used in all tests was $\alpha=0.05$. Trap catch data is presented in graphs as untransformed means with error bars denoting standard error of the mean.

RESULTS

GC-EAD Analyses and Identification of Host Plant Volatiles Several compounds in both the abutilon (Fig. 1a) and the sorghum (Fig. 1b) headspace collections elicited consistent responses in *P. interrupta* antennae. The EAD-active compounds collected from abutilon headspace extracts were identified as (*Z*)-3-hexen-1-ol, tetradecane, methyl salicylate, and methyl anthranilate (Fig. 1a), and in sorghum as tridecane, (*Z*)-3-hexen-1-ol, 1-octen-3-ol, and 1-octanol (Fig. 1b). Similar antennal responses were recorded from antennae of females (not shown). In abutilon headspace extracts, methyl salicylate was a major constituent, making up approximately 14.4% of the extract. In sorghum extract, however, it was present at low concentrations, and did not elicit any antennal responses. Despite a low concentration of methyl anthranilate in the abutilon extract, this compound elicited a strong antennal response.

Field Experiments Related to GC-EAD During July and October, there were no significant differences in trap catches between the sorghum blend, which caught an average of 12 beetles per trap over the experimental period in July and 11 beetles in October (blend 8, Fig. 2), and the individual sorghum compounds. In July, traps baited with methyl salicylate caught significantly more beetles (21 beetles/trap) than traps baited with tridecane or (*Z*)-3-hexen-1-ol. Eugenol baited traps caught significantly more beetles (40 beetles/trap) than all other treatments, except the sorghum blend with the addition of methyl salicylate (40 beetles/trap, blend 9, Fig. 2a). In October, the sorghum blend with eugenol (82 beetles/trap, blend 10) and the sorghum blend with eugenol and methyl salicylate (70 beetles/trap) attracted by far the highest numbers of beetles, followed by the sorghum

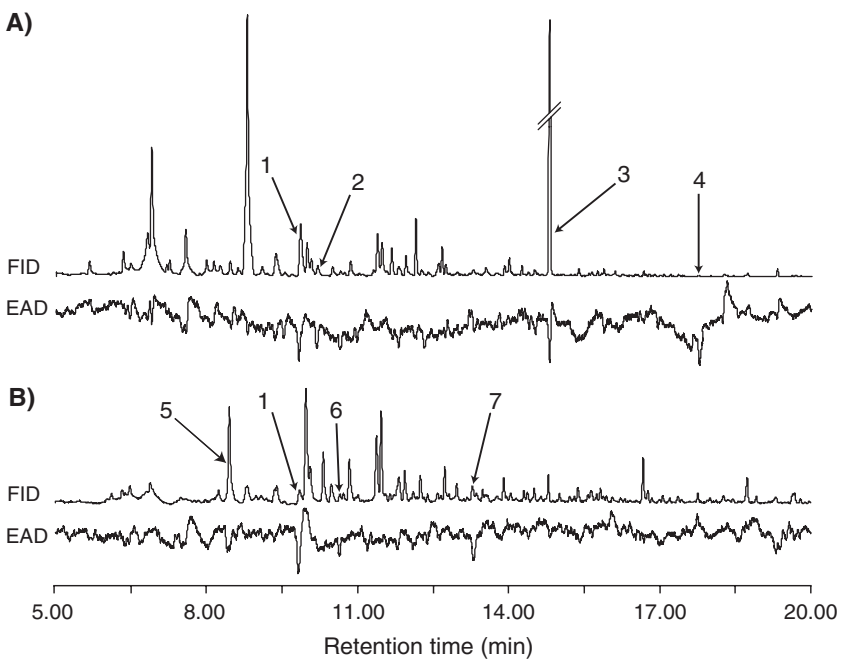

Fig. 1 Simultaneous response of flame ionization detector (FID) and male *Pachnoda interrupta* antennae (EAD) to volatile compounds collected from **a** abutilon and **b** sorghum. The upper traces in each figure represent the signal from the FID and the lower traces represent the signal from the EAD. The compounds collected from abutilon headspace extracts were identified as (*Z*)-3-hexen-1-ol (1), tetradecane (2), methyl salicylate (3), and methyl anthranilate (4), and in sorghum tridecane (5), (*Z*)-3-hexen-1-ol (1), 1-octen-3-ol (6), and 1-octanol (7)

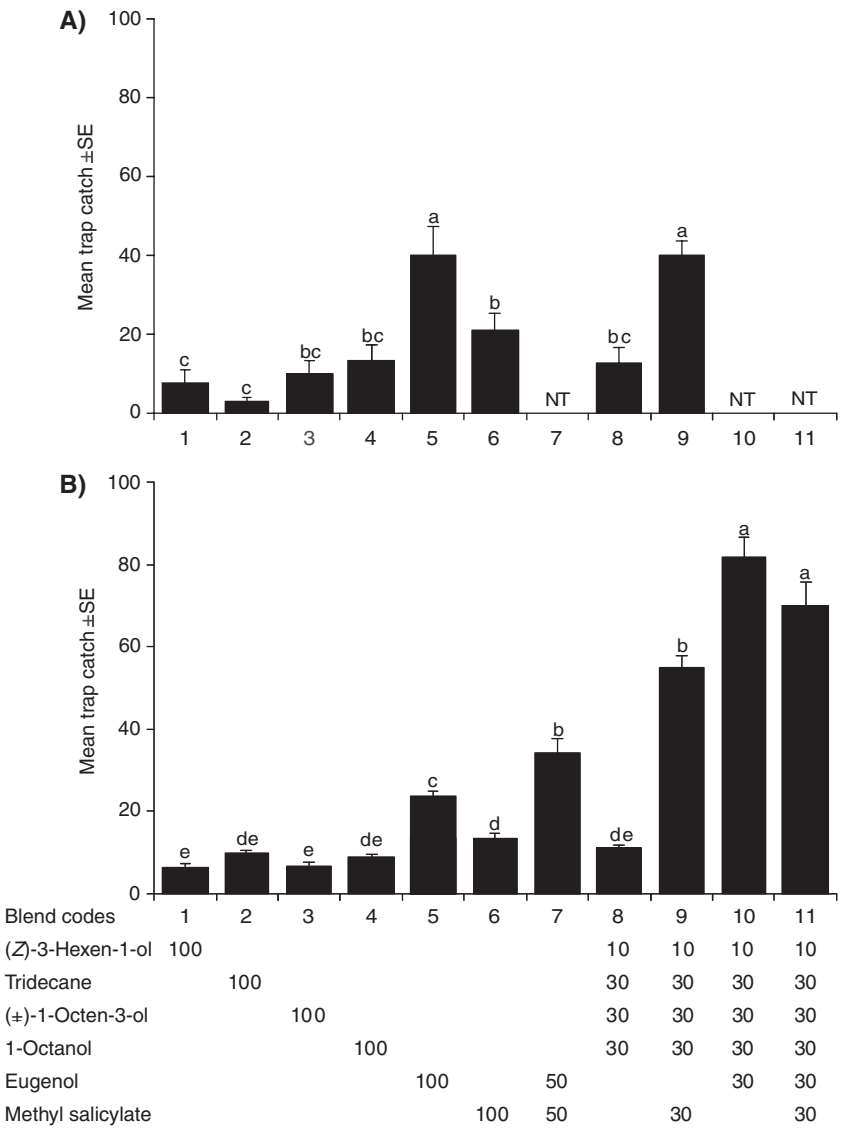

Fig. 2 Number of *Pachnoda interrupta* captured in traps baited with synthetic sorghum compounds in **a** July, 2006 and **b** October, 2006. Unbaited traps caught no insects and were not included in the comparison. *GLM*: July, (N= 10, F=78.1, df=7, 63, P<0.001); October, (N= 10, F=114.1, df=10, 90, P<0.001). Error bars show the standard error of the mean. Subgroups denoted by different letters are significantly different at α=0.05 (N= 10, *Tukey's b*). NT indicates that the treatment was not tested

blend with methyl salicylate, the two-component eugenol-methyl salicylate blend, and eugenol alone. In both July and October, the four-component abutilon blend caught significantly more beetles (22 beetles/trap in July and 17 in October, blend 7, Fig. 3) than traps baited with the single compounds (*Z*)-3-hexen-1-ol and tetradecane. While there were no significant differences in trap catches between traps baited with the abutilon blend and the blend without methyl salicylate (15 beetles/trap) in July, the complete blend caught more beetles in October. In both seasons, there were no significant differences in trap catch between the abutilon blend and methyl salicylate presented as a single compound or eugenol as a single compound. When methyl anthranilate was added as a single compound in October, it was as attractive as the abutilon blend and eugenol and methyl salicylate (20 beetles/trap, Fig. 3b). The other treatment that was added, the four-component abutilon blend combined with eugenol, was equally attractive (42 beetles/trap, blend code 9, Fig. 3b) as the binary mixture of methyl salicylate and eugenol (37 beetles/trap), and more attractive than any other treatment. During both seasons, all treatments caught significantly more beetles than the unbaited control traps. Male and female beetles followed the same pattern of attraction, with no clear differences between the sexes in which baits were most attractive (data not shown).

Single Sensillum Recordings The antennal morphology of *P. interrupta* is similar to that of the closely related scarab *P. marginata*, as described by Stensmyr et al. (2001). *P. interrupta* has a typical scarab antenna, where sensilla are present on the inner surfaces of the three lamellae at the tip of the antenna. Most sensilla are of the placodea morphological type, with a small minority of smooth peg and coeloconic sensilla. Our SSR recordings

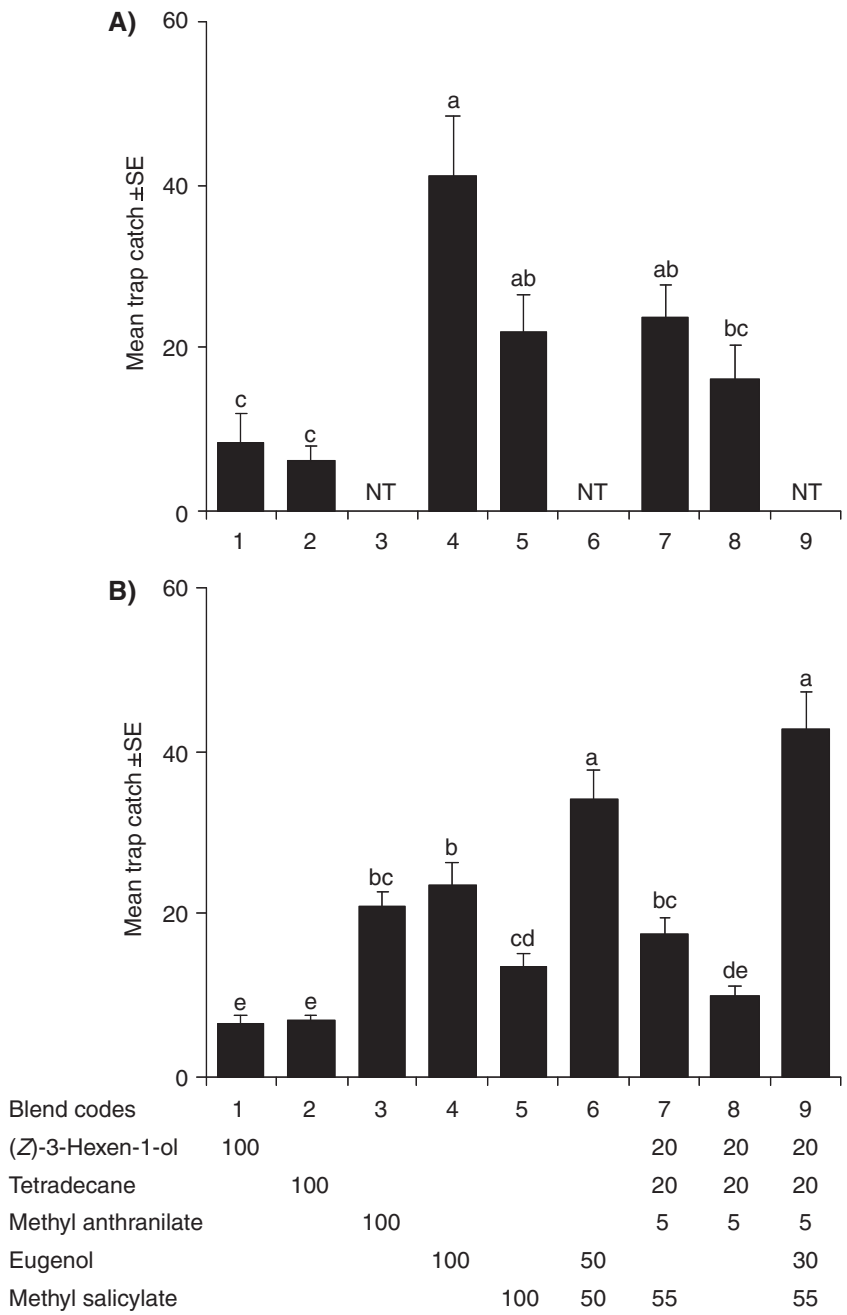

Fig. 3 Number of *Pachnoda interrupta* captured in traps baited with synthetic abutilon compounds in **a** July, 2006 and **b** October, 2006. Unbaited traps caught no insects and were not included in the comparison. *GLM*: July 2006, (N= 10, F=12.7, df=5, 45, P<0.001); October 2006, (N= 10, F=42.1, df=8, 72, P<0.001). Error bars show the standard error of the mean. Subgroups denoted by different letters are significantly different at α=0.05 (N= 10, *Tukey's b*). NT indicates that the treatment was not tested

stem from sensilla placodea, as we only managed to get intermittent contacts with ORNs of the other morphological types.

Contacted sensilla typically contained two ORNs, which in most cases could be separated by differences in spike amplitude (Fig. 4). In sensilla containing two neurons, both neurons sometimes fired simultaneously, resulting in double spikes with amplitudes greater than that of either neuron by itself. When subjected to synthetic stimuli, ORNs usually responded strongly with a train of action potentials (spikes) to a few compounds. Recordings were obtained from a total of 156 sensilla in males and females. Data for the sexes were pooled, as no types of ORNs were numerous enough for a meaningful comparison between the sexes. Out of the 156 sensilla, 50 sensilla contained no ORNs responding to the stimulus spectrum tested. ORN response to stimulation with control stimuli (blank) normally was below 10 Hz (data not shown), but 3 ORNs gave a blank response of 50 Hz or above and were excluded from analysis, since we deemed that there was a risk that the cells had either been injured and were not responding properly, or that some contamination had been present in the odor stimulation system. We also excluded 8 ORNs for which no compound elicited a net response of

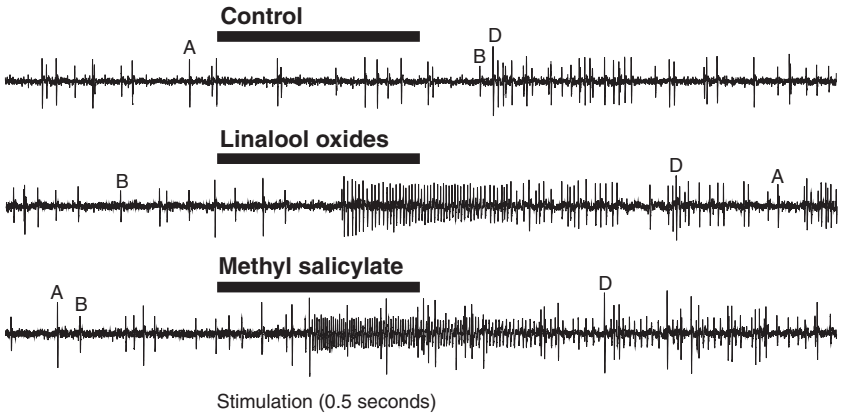

Fig. 4 The two ORNs present in this sensillum are distinguished by the amplitudes of their action potentials. The ORN responding to linalool oxide (denoted "A") has a higher amplitude than the ORN responding to methyl salicylate (B). There are also double spikes, where both neurons fire simultaneously (D), that have a greater amplitude than either neuron by itself

40 Hz or above, as these weak responses were unlikely to indicate key stimuli suited for evaluation in field trials. The remaining 97 neurons responded with a net response of 40 Hz or above to at least one stimulus. Of the 82 test compounds, 57 elicited spike responses over 80 Hz at least once (Table 1). Not all responses could be assigned to a specific class, but 94 responding ORNs could be grouped tentatively into 26 classes (Table 2). In most cases, ORNs responded to a single compound or a group of functionally or structurally similar compounds with one eliciting a stronger response than the rest. For some neurons, several compounds elicited strong responses, with no clear ranking between the 2–3 best compounds. A few ORNs had wide response spectra, with 5–10 compounds eliciting strong responses. For ORN classes, the average response to ligands is shown down to 40 Hz (Table 2).

Several of the ORN classes responded to stimulation with compounds that commonly occur in the volatile profiles of fruit and flowers (Table 2). There also were classes that responded to stimulation with compounds associated with foliage, i.e., green leaf volatiles (GLVs). No ORN response was found to ethanol, acetone, acetic acid, or propionic acid, and there was only one response to ethyl acetate. However, ORNs responded to isovaleric acid, acetoin, racemic 2,3-butanediol, 4-ethylphenol, and 4-methylphenol.

Field Experiments Related to SSR Traps baited with racemic 2,3-butanediol caught significantly more beetles over the experimental period than traps baited with other compounds (an average of 205 beetles/trap, Fig. 5; $F=80.56$, $P<0.001$), catching three times more beetles than the second best bait, eugenol (which caught 69 beetles/trap), and six times more than the third best, methyl salicylate (36 beetles/trap). Apart from 2,3-butanediol, traps baited with previously untested compounds did not catch significantly more *P. interrupta* than the unbaited control traps. Males and females follow the same pattern of attraction; there were no clear differences between the sexes for which baits were most attractive (data not shown).

Discussion

Some insect species require specific blends of several compounds to be attracted to their host (Bruce et al., 2005), e.g., the apple maggot fly, *Rhagoletis pomonella* (Linn et al., 2005), the grapevine moth, *Lobesia botrana* (Tasin et al. 2006, 2007), and the fruit fly, *Drosophila melanogaster* (Zhu et al. 2003; Ruebenbauer et al. 2008). However, for many fruit and flower visiting scarabs, individual compounds constitute efficient attractants (Donaldson et al. 1990). Relying on key compounds rather than specific blends could be an efficient general host detection strategy for a polyphagous herbivore such as *P. interrupta*. Such a strategy could be enhanced by the presence of reliable signals from plants that attract animals for pollination or fruit (seed) dispersal. Our results from field experiments with blends that mimic the hosts abutilon and sorghum indicated that *P. interrupta* is attracted to a few key components in the volatile profiles of these plants, rather than ratio-specific blends (Fig. 2 and 3), and thus we focused our search for attractants on single compounds. As we also noted that the most attractive compounds were associated with fruits and flowers (e.g., eugenol and methyl salicylate), rather than foliage [e.g., (*Z*)-3-hexen-1-ol], we primarily tested floral- and fruit-related kairomones in the single sensillum screening. Among the kairomones selected for screening, many have been found in several hosts of *P. interrupta*, e.g., banana (Macku and Jennings 1987; Ibáñes et al. 1998; Boudhrioua et al. 2003) guava (Carasek and Pawliszyn 2006), mango (Clara et al. 2007; Pandit et al. 2009), and various flowers (Knudsen et al., 2006). We also included fermentation volatiles (Chatonnet et al. 1992; Fischer et al. 2000; Xiao and Ping 2007), since the sorghum

Table 2 Olfactory receptor neuron classes in the sorghum chafer, *Pachnoda interrupta*

(*Z*)-3-Hexenyl acetate [42]	

Average net response in Hz to key ligands shown in [brackets]; for n=1, net response shown (all responses above 40 Hz are included)
ORNs grouped according to stimuli that excite their strongest responses
"n" indicates number of ORNs that belong in each class

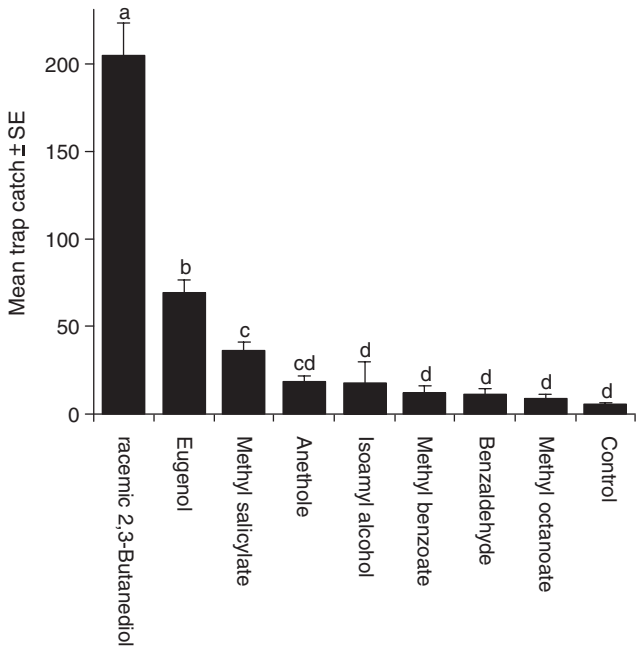

Fig. 5 Average trap catch of *Pachnoda interrupta* in July 2008. The type of bait had a significant effect on catch (*GLM*, $N=10$, $F=80.56$, $df=8, 72$, $P<0.001$). Error bars show the standard error of the mean. Subgroups denoted by different letters are significantly different at $\alpha=0.05$ ($N=10$, *Tukey's b*)

chafer has been reported to be attracted to residue from the fermentation of tella beer. The use of single sensillum recordings (SSR) for screening of potential kairomones enabled us to select compounds for field testing that activate separate olfactory receptor neuron (ORN) classes. Regardless of how information from the olfactory system is interpreted at higher levels of the nervous system, the activation of additional components of the ORN array should increase the likelihood of releasing a behavior, compared to redundant activation of the same ORN classes with several different compounds. Behavioral redundancy between compounds that activate the same ORN class has been observed in the bark beetle *Ips typographus*, where compounds detected by the same ORN do not cause any synergistic repellent effects when combined in field trapping experiments (Andersson et al. 2009). Broad response spectra for ORNs could be an efficient solution for detecting several compounds that relay essentially the same information (Baker et al. 1998; Cossé et al. 1998; Wojtasek et al. 1998; Larsson et al. 2002).

The best field attractants in our study (Fig. 2, 3 and 5) and in a previous study (Wolde-Hawariat et al. 2007) were all detected by single ORN classes — no response to these ligands were found in other ORN classes (Table 2). Thus, activation of a single ORN class seems to be sufficient for the release of attraction behavior. Results from *I. typographus* also indicate that several compounds may cause sufficient activation of a single ORN class to release behavior (Andersson et al. 2009). Methyl benzoate thus was included in the field experiment as it was a secondary ligand of methyl salicylate ORNs (Table 2). Methyl salicylate was highly attractive to *P. interrupta* in the field (Wolde-Hawariat et al. 2007), and to *P. marginata* in a two-choice bioassay (Larsson et al. 2003), even though it was detected by one of the least commonly found ORNs in *P. marginata* (Stensmyr et al. 2001). Methyl salicylate is the primary odorant for a particular ORN in the moth *Mamestra brassicae*, and as in *P. interrupta*, this neuron also has a weaker secondary response to methyl benzoate (Ulland et al. 2008). In *M. brassicae*, egg-laying was inhibited by the presence of methyl salicylate on dispensers near the host plant (cabbage) while methyl benzoate was not tested (ibid.). In our field experiments, catches of *P. interrupta* in traps baited with methyl benzoate were not significantly higher than that of control traps (Fig. 5). Testing of other compounds that elicit secondary responses in ORN classes that respond to attractive compounds could shed light on their role in insect behavior. Despite the fact that *P. interrupta* is attracted strongly to fermentation products such as tella beer residue (Ministry of Agriculture and Ethiopian Agricultural Research Organization 1999), ORNs that respond to primary fermentation products such as ethanol, acetic acid, propionic acid, or acetone, appear to be absent or rare on the *P. interrupta* antenna. Some of these compounds are attractive to other insects that feed on fermenting substrates (e.g., fruit), such as *D. melanogaster*, which are attracted to acetic acid, acetone, and ethanol in lab trapping bioassays (Zhu et al. 2003; Ruebenbauer et al. 2008). We did, however, find ORNs in *P. interrupta* that responded to other substances related to fermentation and microbial degradation, such as racemic 2,3-butanediol, acetoin, 4-ethylphenol, 4-methylphenol, and ethyl acetate (one neuron). The ORN class in *P. interrupta* responding to 2,3-butanediol also responded to acetoin. In the closely related *P. marginata*, acetoin was significantly more attractive than a blank control in a two-choice bioassay, while racemic 2,3-butanediol was not (Larsson et al. 2003). This is interesting as both ligands are detected by the same ORN, and none of the other ORN classes found in the study respond to either compound (Stensmyr et al. 2001). Acetoin and 2,3-butanediol are active in other beetle species as well, where certain isomers or mixtures of isomers are often needed to elicit activity. Meso-2,3-butanediol, (2*R*,3*R*)-2,3-butanediol, and (*R*)-acetoin are emitted by female *Rhizotrogus majalis* and detected only by male antennae in EAD (Nojima et al. 2003). Male *Scapanes australis* emit acetoin, 2-butanol, and 2,3-butanediol, with the first two being necessary and sufficient to attract both sexes in field trapping experiments (Rochat et al. 2002). (*R*)-acetoin has been identified as a female-emitted sex pheromone in the summer chafer, *Amphimallon solstitiale* (Tolasch et al. 2003). In the palm

weevil, *Rhynchophorus palmarum*, acetoin is a synergist to male-emitted volatile aggregation pheromones. The addition of either acetoin or plant matter is necessary to elicit high levels of attraction; the pheromone alone does not suffice (Said et al. 2005).

In the SSR screening, we found ORNs that responded to five of the seven compounds identified as active by GC-EAD (methyl anthranilate, methyl salicylate, (*Z*)-3-hexen-1-ol, 1-octanol, and 1-octen-3-ol), but we did not find any responses to tetradecane or tridecane (Table 1, 2). It is possible that tetradecane and tridecane are detected by one or several rare ORN types, or by ORNs present in smooth peg sensilla or sensilla coeloconica, to which we had only intermittent contacts. Discrepancies between electroantennographic and single sensillum methods have been observed in previous studies (Blight et al. 1995; Barata et al. 2002; Wibe 2004). Wibe (2004) compared GC-EAD and GC-SSR as tools for identification of active compounds for the pine weevil, *Hylobius abietis*, in aerations of sawdust from Norway spruce (*Picea abies*), and found that GC-SSR led to the identification of a higher number of active compounds than GC-EAD.

Apart from racemic 2,3-butanediol, the most attractive compounds in the field were eugenol, methyl anthranilate, and methyl salicylate (Fig. 2, 3, and 5). These compounds are common floral volatiles (Knudsen et al. 2006), with eugenol and methyl salicylate often found in aerations of *Acacia* spp. flowers (Lamarque et al. 1998). Methyl salicylate also is found in leaf odors (Buttery et al. 1982; Loughrin et al. 1997; Shulaev et al. 1997), and is a common defensive compound in higher plants in response to herbivory (Kessler and Baldwin 2001). In field experiments, volatiles emitted from surrounding vegetation thus may include some of the compounds tested, or similar compounds, which could affect the results of field experiments. In the sites used, there is seasonal variation in vegetation and phenology. A salient example is sorghum, which has flowers and seeds in stages attractive to the beetles in October, but not in July. This also coincides with life cycle changes in the beetles, which may affect trap catch. Sorghum chafers mate and feed in July, while in October, the newly emerged adults feed only before going into aestivation until July the following year. Experiments evaluating the effects of these factors were outside the scope of our study.

By using SSR to target a large fraction of the peripheral olfactory system, we identified racemic 2,3-butanediol as an efficient field attractant, without needing to test all of the 57 compounds in our screening that elicited response (Table 1, 2). This compound could be useful in future control or monitoring, especially since it is highly attractive to both male and female *P. interrupta*. Future field experiments should clarify which isomers of 2,3-butanediol (or mixtures thereof) are responsible for attraction. Field tests also should include other fruit- or flower-related compounds that activate so far untested ORN classes, as well as further compounds related to microbial degradation or fermentation, and blends of the best attractants. *P. interrupta* may serve as a useful model for future research on host searching in polyphagous fruit- and flower-feeding insects.

Acknowledgments We thank the National Herbarium of Addis Ababa University (Science Faculty) for the identification of *A. figarianum*. We acknowledge the Plant Protection and Regulatory Department of Ministry of Agriculture and Rural Development of Ethiopia for providing traps for experiments. This work was financed mainly by a grant from the Swedish International Development Agency (Sida/SAREC), for which the authors are grateful. In addition, Swedish support was supplied by the IC-E^3 Linnaeus program. The authors are also grateful for the complimentary financial support provided by the Ethiopian Institute of Agricultural Research, especially the secretariat for the Agricultural Research Fund.

Canopy gap dynamics have been studied intensively in the cool temperate forests of Japan where *Fagus crenata* is the main climax species (Nakashizuka 1984; Yamamoto 2000). The mortality rate of current-year *F. crenata* seedlings is high because of the occurrence of damping-off at several weeks after germination. Further, the mortality rate is lower for seedlings growing in the gaps than those growing under shaded conditions (Hashizume and Yamamoto 1975; Maeda 1988; Nakashizuka 1988; Sahashi et al. 1994, 1995; Abe et al. 2005). However, the factors that affect resistance to fungal invasion are unclear.

Generally, tree seedlings resist fungal invasion by forming a specific tissue (Tippett and Hill 1984; Eyles et al. 2003; Agrios 2005; Laflamme et al. 2006) and by producing antifungal substances (Bonello and Pearce 1993; Ingham 1973; Siegrist et al. 1994; Agrios 2005; Treutter 2006). Therefore, differences in the resistance of seedlings grown under different light conditions to fungal invasion should be considered by comparing the histological structure (periderm formation) and chemical content (concentration of phenolic compounds) of the seedlings. Increase in the concentration of phenolics has been reported in seedlings grown in gaps or under increased light intensity (Entry et al. 1991; Nichols-Orians 1991). From a phytopathological viewpoint, the confirmation of whether such differences in defense mechanisms are attributable to light conditions in the field is essential for a better understanding of gap dynamics.

In order to determine the resistance factors that affect mortality due to damping-off in current-year *F. crenata* seedlings, we identified the causative fungal species, and we compared the tissue structure of the periderm in the seedling hypocotyls and the change in the total phenol concentrations between current-year seedlings grown under two different light conditions in a natural beech forest in northern Japan.

Methods and Materials

Study Site The field study was conducted in a secondary forest of *F. crenata* (39°59' N, 140°54' E) in Appi, Iwate Prefecture in northern Honshu, Japan. The canopy height in the forest was 25 m. An experimental plot was established along 75 m of the forest road (4 m width, no pavement, and rare traffic) and 25 m into the closed stand. An area less than 5 m from the forest road was designated as the forest-edge plot, and an area more than 10 m wide was designated as the closed-stand plot. The forest-edge plot was established under canopy facing north, and had leaf litter of *F. crenata* that was not extremely dry. The relative illuminations in the closed-stand and forest-edge plots were evaluated by using a light meter, model LI-250 (Li-COR Inc., Lincoln, NE, USA), and they were 2.6% (SE, ±0.22) and 35.5% (SE, ±3.03), respectively.

Seedling Observation, Fungal Isolation, and Inoculation From the forest-edge and the closed-stand plots, 100 and 101 current-year seedlings, respectively, were randomly selected. These seedlings were observed from May 28, 2004 (soon after germination) to September 28, 2004 (just before leaf coloring in autumn) to detect the occurrence of damping-off and to determine the factors related to seedling death. Dead seedlings were collected when their leaves wilted.

Fungus Isolation from Dead Seedlings Seedlings that had died because of damping-off were collected, and the lower parts of their hypocotyls were sterilized in 70% ethanol solution and 1% sodium hypochlorite solution for 1 min each, rinsed twice with sterile distilled water, transferred onto 1% malt-extract agar (MEA), and incubated at 20°C in darkness. Two wk after incubation, the fungi that emerged from the tissues were isolated and maintained on MEA plates. The fungal species to which the isolates belonged were identified on the basis of the morphological characteristics of the cells in the culture medium and on the hypocotyls, as observed under a light microscope.

Inoculation of Isolated Fungi into Seedling Hypocotyls Four fungi, which were isolated at high frequencies from the dead seedlings, were grown on 1% MEA for 3 wk and used for an inoculation test. Seeds of *F. crenata* collected from Appi in October 2005 were peeled, and the cotyledons with the seed coat were sterilized with 1% sodium hypochlorite solution for 1 min. These were then potted in enameled iron dishes (33 cm×38 cm; depth, 5 cm) containing Kanuma pumice (4 cm), which had been autoclaved at 121°C for 30 min. The potted seeds were incubated at 4°C in darkness for 1 mo, according to a previously described method of germination (Katsuta et al. 1998). After germination, these dishes were transferred to a growth chamber (NK system, LP-1.5PH; Nihonika Co., Osaka, Japan), and the seedlings were grown at 15°C under a cycle of 15 hr fluorescent light (3.0 μmol cm^{-2} s^{-1}) and 9 hr darkness for 1 mo until the cotyledons had fully expanded and the first pair of true leaves had developed. Subsequently, several mycelial disks (5 mm diam) taken from the colonies of the four fungal species and non-mycelial 1% MEA disks were inoculated onto a wound sliced into the hypocotyls. We used 19–23 seedlings in each treatment. The development of disease symptoms and the number of dead seedlings were periodically recorded over 20 d.

Inoculation of Pathogenic Fungi under Two Different Illumination Conditions Two pathogenic fungi were used for another inoculation test that was performed under two

different illumination conditions. Seeds were potted in the same dishes as described above and incubated at 4°C in darkness for 1 mo. After incubation, the seedlings were grown in the same growth chamber under either high illumination (36.1 μmol cm^{-2} s^{-1}) or low illumination (2.9 μmol cm^{-2} s^{-1}), achieved by using a shading net, at 15°C under a cycle of 15 hr fluorescent light and 9 hr darkness for 1 mo until the cotyledons were fully expanded and the first pair of true leaves developed. Two pathogenic fungi were inoculated into a wound sliced into the hypocotyls of these seedlings by using the same method as that used in the previous inoculation test. The test seedlings were observed for 2 wk and were categorized as healthy, partially diseased, or wilted.

Tissue Structure of Hypocotyls For histological analysis, 3 healthy seedlings were collected randomly from both the forest-edge and the closed-stand plots on June 1, June 15, July 6, and September 10. The lower parts of the hypocotyls were cut and fixed in 5% glutaraldehyde in 0.1% sodium phosphate buffer, pH 7.2, and stored at 4°C. The parts were rinsed thrice in the phosphate buffer and post-fixed overnight at 4°C in 2% osmium tetroxide prepared in the same buffer. Samples were then rinsed thrice with the buffer, dehydrated in an ethanol series, and embedded in Poly/Bed 812 (Polyscience Inc., Warrington, PA, USA). Thin cross-sections (2 μm) were cut with glass knives on an MT2-B ultramicrotome (Sorvall Instruments; DuPont Co., Wilmington, DE, USA) and gently heat-fixed to glass microscope slides. The sections were stained with 0.1% toluidine blue O for 10 min, destained with distilled water, air dried, mounted in Eukitt mounting reagent (O. Kindler, Breisgau, Germany) beneath a cover slip, and observed under an Optiphoto light microscope (Nikon Co., Tokyo, Japan). In addition, to localize the phenolics in the tissue, an HM440E sliding microtome (Microm, Walldorf, Germany) was used to cut 30 μm-thick cross-sections of fixed hypocotyls of seedlings collected from the forest-edge and closed-stand plots on June 1, June 15, and July 6. The cross-sections were stained with 2% (w/v) $FeSO_4$ solution for about 1 hr to stain polyphenolic compounds with Fe (II) ions (Suzuki et al. 2003). The sections were mounted in the staining solution beneath a cover slip and observed under an Optiphoto light microscope.

Analysis of Total Phenolics Healthy seedlings were collected randomly from the forest-edge and closed-stand plots just after germination on May 28, June 15, July 6, and September 10 in 2004. From the collected seedlings, hypocotyls were taken, and their FWs were measured. Two hypocotyls from 2 seedlings were cut into less than 1-mm pieces with scissors, and the phenolics were extracted in 5 ml methanol in the dark over night at room temperature. The methanol extracts were filtered, adjusted to 5 ml, and stored at −20°C. Total phenolics were analyzed according to the Folin-Ciocalteau method (Waterman and Mole 1994). The methanol extracts (100 or 200 μl) were added to distilled water (900 or 800 μl, respectively). A phenol reagent (500 μl) (Wako, Osaka, Japan) was added to the samples, and samples were mixed by vortex. Na_2CO_3 solution (20% v/v, 2.5 ml) was added continuously and mixed, and distilled water (1 ml) was added to the sample. After 20 min, absorbance of the reactants was recorded at 700 nm (by using an ultraviolet-visible spectrophotometer, V-530; JASCO Co., Tokyo, Japan). A standard curve was prepared as follows: gallic acid (Wako, Osaka, Japan) (0.05, 0.1, 0.2, and 0.4 μg μl^{-1} of methanol) was subjected to the treatment described above for the methanol extracts, and each sample was analyzed thrice; the results were averaged. The amount of total phenolics in the hypocotyls was calculated by using the standard curve. Two seedlings were used for each analysis, and the results of five replicates were averaged. The concentrations of total phenolics were expressed as mg gallic acid equivalents g^{-1} FW (±SE).

Antifungal Activity Tests Seedling hypocotyls were randomly collected from the forest-edge (FW 67.9 g, equivalent to 487 seedlings) and closed-stand (FW 81.2 g, equivalent to 657 seedlings) plots on June 25. They were cut into pieces with scissors into fragments less than 5 mm long and then extracted in methanol (1 l) for 2 d in the dark at room temperature. The methanol extract was evaporated at 35–40°C, and the concentrated sample (approximately 100 ml) was extracted thrice with ethyl acetate (100 ml). The ethyl acetate phase (300 ml) was rinsed twice with saturated NaCl solution (150 ml) and dried overnight with Na_2SO_4. It was then evaporated and used for the antifungal activity test as follows. The ethyl acetate phase, equivalent to FW 5, 10, or 20 mg, was evaporated and dissolved in 50% methanol (5 μl). Samples were added to the wells (10 mm diam) of a microplate (Asahi Techno Glass, Tokyo, Japan) and mixed with the spore solution (2.5×10^3 spores in 500 μl) of a pathogenic fungus. As a control, 50% methanol (5 μl) was used instead of the sample. The plate was incubated in the dark at 20°C for about 48 hr. Twenty-five spores were selected randomly from each well, and the percentage of germinated spores was calculated. Each sample was tested thrice, and the percentage of germinated spores was averaged.

Statistical Analysis The Ekuseru-Toukei 2008 (Social Survey Research Information Co., Ltd.) software package was used for statistical analysis. The difference in survival rate between forest-edge and closed-stand plots was evaluated by Logrank test in survival analysis. Differences in the

amount of total phenolics between the hypocotyls of the seedlings from the forest-edge plot and those of the seedlings from the closed-stand plot were evaluated by Student's *t-test* for each sampling date. The square root of each percentage of spore germination in the antifungal activity test was converted to its arc sine (Sokal and Rohlf 1995), and the differences between the control and the different concentrations of the ethyl acetate phases of the hypocotyls of the seedlings from the forest-edge and closed-stand plots were evaluated by two-way ANOVA and were followed by Tukey's test. Differences were considered significant at $P<0.05$.

Results and Discussion

Seedling Survival and Mortality in the Field Between June and September, seedling death was observed mainly in late June and July after true leaves had expanded fully in both the forest-edge and closed-stand plots. On September 28, the mortality of seedlings was 7% and 50% in the forest-edge and closed-stand plots, respectively (Fig. 1), and was significantly different between the two plots ($\chi^2=42.57$, $df=1$, $P<0.01$, logrank test in survival analysis). All seedlings had died due to damping-off, as indicated by their discolored hypocotyls and wilted leaves; no seedling had been damaged by rodents.

From June to July, the true leaves of most seedlings were damaged by insect herbivory. This damage was classified as severe (complete loss of true leaves and stem above the cotyledons) or slight (partial loss of true leaves). The percentage of severely damaged, slightly damaged, and undamaged seedlings was 18.0, 48.0, and 34.0, respectively, in the forest-edge plot and 2.0, 70.3, and 27.7, respectively, in the closed-stand plot. Damping-off occurred only from the severely damaged seedlings in the forest-edge plot, however, it occurred in every insect-damage category in the closed-stand plot. A part of the severely damaged seedlings survived and produced new shoots from the base of the cotyledons in the forest-edge plot.

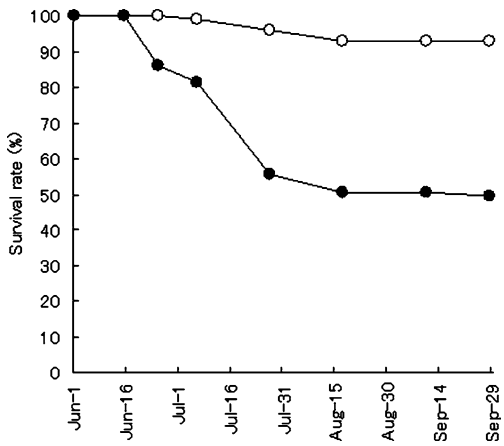

Fig. 1 Survival rates (%) of current-year seedlings grown under two different light conditions in a natural *Fagus crenata* forest. The relative light intensities were 35.5% in forest-edge plot (*open circle*) and 2.6% in closed-stand plot (*closed circle*). *N* seedlings=100 in forest-edge plots and *N*=101 in closed-stand plots

Fungi Isolated from Diseased Seedlings and Inoculation Tests From the lower part of the hypocotyls of the dead seedlings collected from both sites, four major fungi, *Colletotrichum dematium*, *Cylindrocarpon* sp., *Phomopsis* sp., and *Discosia* sp. were isolated (Table 1) throughout the experimental period.

Inoculation Test The results of the inoculation test showed that *C. dematium* and *Cylindrocarpon* sp. induced necrosis in the hypocotyls that resulted in the wilting of the seedlings (Table 2). No disease symptoms were observed in the seedlings inoculated with *Phomopsis* sp. or *Discosia* sp. The results of the inoculation test performed under two different illumination conditions showed that *C. dematium* and *Cylindrocarpon* sp. induced necrosis in the hypocotyls and caused seedling death under low light intensity, but did not induce disease symptoms under high light intensity (Fig. 2).

Periderm Formation Anatomical studies of the lower part of the hypocotyls of the healthy seedlings from each plot revealed histological differences in the epidermal and cortical tissue (Fig. 3). On June 1, live epidermal and cortical tissue was found in the seedlings from both plots (Fig. 3a, e). On June 15, dead epidermal tissue surrounded live cortical tissue in the seedlings from both plots, but the layer of dead epidermal tissue was denser in the seedlings from the forest-edge plot than in those from the closed-stand plot (Fig. 3b, f). On July 6, periderm formation was observed in the seedlings from the forest-edge plot but not in those from the closed-stand plot (Fig. 3c, g). On September 10, periderm formation also was observed in the surviving seedlings from the closed-stand plot, but the periderm was thinner in these seedlings than in those from the forest-edge plot (Fig. 3d, h).

Distribution of Phenolic Compounds Light micrographs of sections of the seedlings from the forest-edge plot immersed in Fe (II) solution showed that epidermal cells were stained black to dark brown on June 1 (Fig. 4a). Positively stained cells were observed in the outer part of the layer of dead epidermal tissue and cortical tissue on June 15 (Fig. 4b) and in the periderm on July 6 (Fig. 4c). The Fe (II)-stained cells were almost always localized with the cells containing black substances in resin-embedded sec-

Table 1 Isolation rate of fungi from hypocotyls of the dead current-year *Fagus crenata* seedlings exhibiting damping-off in two different light conditions, the forest-edge and the closed-stand plots in a natural beech forest

Plot	Isolated fungi	25-Jun	6-Jul	27-Jul	17-Aug	28-Sept
Forest-edge	No. of seedlings	0	9	5	5	0
	Colletotrichum dematium	-	44.4	20.0	0.0	-
	Cylindrocarpon sp.	-	55.6	40.0	20.0	-
	Phomopsis sp.	-	44.4	40.0	80.0	-
	Discosia sp.	-	44.4	80.0	20.0	-
	Other fungi	-	22.2	40.0	100.0	-
Closed-stand	No. of seedlings	7	16	11	3	2
	Colletotrichum dematium	71.4	87.5	54.5	66.7	100.0
	Cylindrocarpon sp.	85.7	62.5	36.4	66.7	100.0
	Phomopsis sp.	0.0	25.0	81.8	33.3	0.0
	Discosia sp.	28.6	18.8	18.2	33.3	0.0
	Other fungi	0.0	6.3	18.2	0.0	0.0

Isolation rate (%) of each fungus was emergence rate from dead seedlings in each sampling date

tions (Fig. 3, 4). The sections of the seedlings from the closed-stand were stained similarly to those from the forest-edge, however, the Fe (II)-stained cells were rare in June 15 and July 6, when the black substance also were rare (Fig 3f, g).

Concentration of Total Phenolics in the Hypocotyls The concentration of total phenolics in the hypocotyls from the forest-edge plot increased after May 28 (Fig. 5), and that in hypocotyls from the closed-stand plot increased slightly after June 15 (Fig. 5). The concentrations in the hypocotyls from the forest-edge plot on June 15 ($P<0.001$), July 6 ($P<0.001$), and September 10 ($P<0.01$) were significantly higher (2.1, 2.2, and 3.7 times, respectively) than the corresponding concentrations in the hypocotyls from the closed-stand plot (Fig. 5).

Antifungal Activity Compared with the control, the ethyl acetate phases of the hypocotyls from the forest-edge plot, equivalent to FW 5, 10, and 20 mg significantly inhibited spore germination of *C. dematium* ($P<0.01$ in each treatment) (Fig. 6). Spore germination also was significantly inhibited by the ethyl acetate phases of the hypocotyls from the closed-stand plot, equivalent to FW 10 and 20 mg ($P<0.01$ in each treatment) (Fig. 6). The inhibitory activity on the spore germination of the hypocotyl extracts from the forest-edge plot was significantly higher than that of the extracts from the closed-stand plot ($F=5.932$, $df=1$, $P<0.05$, Fig. 6). The values of the spore germination were different among the concentration of the ethyl acetate phases ($F=34.46$, $df=3$, $P<0.01$).

In natural *F. crenata* forests in Japan, damping-off in current-year seedlings has been reported to be caused by *C. dematium* (Sahashi et al. 1995). *Cylindrocarpon* sp. also has been isolated from current-year *F. crenata* seedlings that exhibit damping-off (Kobayashi et al. 1984), but its pathogenicity has not been confirmed. We isolated *C. dematium* and *Cylindrocarpon* sp. from diseased hypocotyls of current-year *F. crenata* seedlings that had died of damping-off in both the forest-edge and closed-stand plots (Table 1). We inoculated the four fungal species isolated in this study into the hypocotyls and found that *C. dematium* and *Cylindrocarpon sp.* induced hypocotyls necrosis and damping-off in the current-year seedlings (Table 2). This proved that *C. dematium* and *Cylindrocarpon* sp. are pathogenic to current-year *F. crenata* seedlings, and that damping-off can occur in both the forest-edge and closed-stand plots. The results of another inoculation test con-

Table 2 The percentages of each disease symptom observed on hypocotyls of current-year seedlings under an inoculation test with four fungi isolated from dead *Fagus crenata* seedlings exhibiting damping-off

Inoculated fungi	No. of seedlings	No symptom	Partial necrosis on hypocotyls	Wilted
Colletotrichum dematium	20	70.0	15.0[a]	15.0[a]
Cylindrocarpon sp.	19	31.6	63.2[a]	5.3[a]
Phomopsis sp.	23	100.0	0.0	0.0

ducted under two different illumination conditions showed that both fungi induced damping-off under low light intensity but not under high intensity (Fig. 2).

Field observations showed that the survival rate of *F. crenata* seedlings was substantially higher in the forest-edge plot than in the closed-stand plot (Fig. 1). Previous field studies also have shown that *F. crenata* seedlings survive better under high illumination, which is observed mainly in gaps, and that under low light conditions, the incidence of damping-off is high (Nakashizuka 1988; Sahashi et al. 1994). Therefore, light deficiency may result in high mortality due to damping-off. We also found from the inoculation test that damping-off occurred under low but not under high light intensity (Fig. 2), thus suggesting that impaired carbon allocation due to low illumination decreases the resistance of hypocotyls to fungal invasion. Therefore, survival of seedlings that grow under the forest-edge may be attributable, at least in part, to an increase in the resistance to damping-off with increased illumination.

In the forest-edge plot, mortality due to damping-off occurred only in the severely damaged seedlings that had been induced by insect herbivory. This suggests that severe leaf loss that impairs carbon allocation decreases the resistance of the seedling hypocotyls to fungal invasion. The survival of a part of the severely damaged seedlings from the forest-edge plot might be attributable to the maintenance of photosynthesis in the cotyledons. However, few insect-damaged seedlings were included in this study, and the relationship between the severity of insect herbivory and seedling mortality needs to be studied by using a greater number of seedlings.

The periderm contributes to the prevention of pathogen invasion in woody plants (Tippett and Hill 1984; Ichihara et al. 2000; Eyles et al. 2003; Agrios 2005; Laflamme et al. 2006). On July 6, we observed that periderm formation in hypocotyls was much more apparent in healthy seedlings

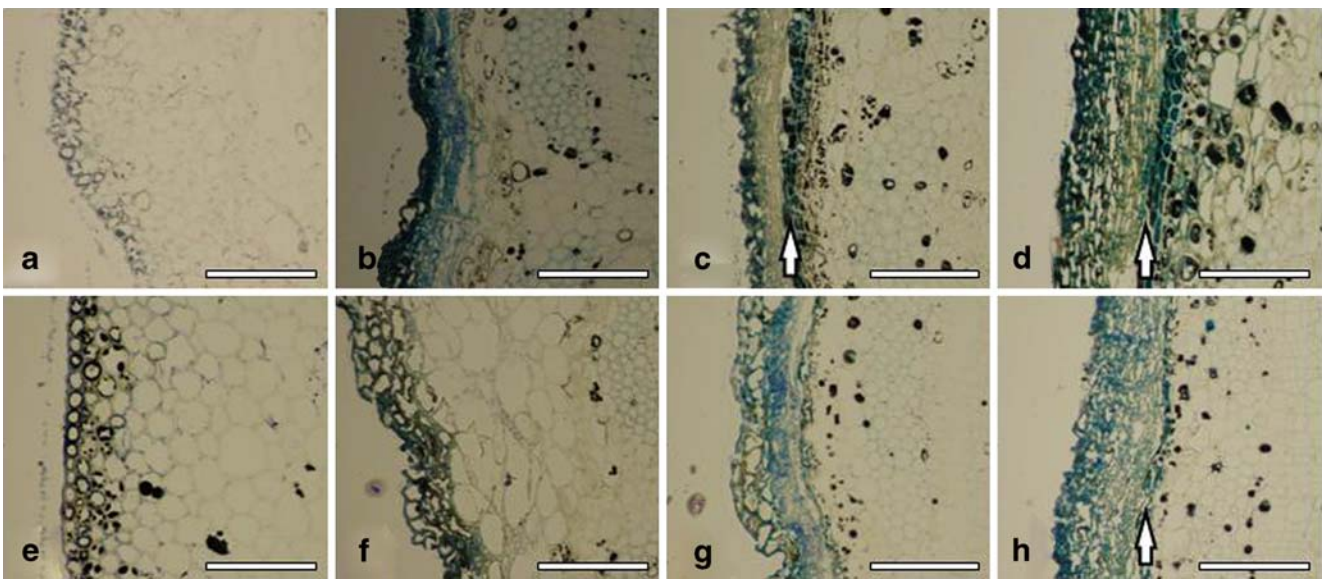

Fig. 3 Microphotographs showing cross sections of hypocotyls of current-year *Fagus crenata* seedlings collected from a natural beech forest. **a-d**: seedlings were collected from the forest-edge plot; **e-h**: seedlings were collected from the closed-stand plot. from the forest-edge plot than in those from the closed-stand plot (Fig. 3). The periderm may have prevented fungal invasion of the seedlings from the forest-edge plot, which could account for the difference in the mortality between the two plots. Additionally, the layer of dead epidermal tissue, which formed before periderm formation, may also have contributed to the prevention of fungal invasion, because this layer was denser in the seedlings from the forest-edge plot than in those from the closed-stand plot. Periderm degradation and poor development of the dead epidermal tissue layer under low light intensity is likely caused by a decrease in the allocation of photosynthates to hypocotyls because photosynthesis would be decreased in the seedlings from the closed-stand plot. However, the relationship between the allocation of photosynthates and periderm formation in hypocotyls must be studied in more detail.

In general, plants resist fungal invasion by producing phenolic compounds with antifungal activity (Grayer and Harborne 1994; Agrios 2005). Phenolics are involved in the resistance against pathogens in plant seedlings (Bonello and Pearce 1993; Siegrist et al. 1994) and in germinating seeds (Ceballos et al. 1998). The ethyl acetate phase of the methanol extract of seedling hypocotyls from both plots showed antifungal activity, and this activity was higher in the seedlings from the forest-edge plot (Fig. 6). Furthermore, the total phenol concentration on July 6, when damping-off occurred, was higher in the seedlings from the forest-edge plot than in those from the closed-stand plot (Fig. 5). Thus, seedlings in the forest-edge plot may

Data and error bars indicate means and standard errrors (N=5). Hypocotyls were collected immediately after germination on May 28

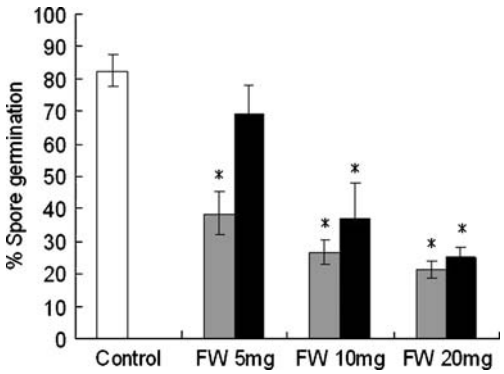

Fig. 6 Antifungal activity of the ethyl acetate phase of the methanol extracts of hypocotyls of seedlings collected from the forest-edge and closed-stand plots in a natural beech forest. The germination of *Colletotrichum dematium* spores with or without the ethyl acetate phases of hypocotyls of the seedlings from the forest-edge and closed-stand plots were observed. The bars and error bars indicate the means of the germination rate and standard errors (N=3). Extracts of seedlings collected from the forest-edge and the closed-stand seedlings are represented with grey and black bars, respectively. Values marked with * are statistically different from the control (Tukey test; P<0.01)

survive by preventing pathogen invasion via phenol production. Additionally, because phenolics were distributed in the outermost parts of the living tissue and in the outer part of the dead epidermal tissue layer, these compounds can effectively impede fungi at invasion. Previous studies have shown that high light intensity results in an increase in the concentration of defense substances, such as total phenolic compounds and tannins (Entry et al. 1991; Nichols-Orians 1991).

We concluded that the difference in the mortality due to damping-off between conditions of high and low light intensity is influenced by both histological and chemical defense mechanisms. The degree of photosynthesis and allocation of photosynthates to hypocotyls could affect the effectiveness of the defense mechanisms against fungal invasion. Increased illumination associated with gap dynamics decreases the incidence of damping-off, which promotes seedling regeneration (Augspurger 1984; Sahashi et al. 1994; Jarosz and Davelos 1995; Hood et al. 2004).

Our results indicate that seedlings growing at improved light conditions associated with gap dynamics show increased resistance against fungal disease. Our study indicates that not only *C. dematium* but also *Cylindrocarpon* sp. are pathogenic and can cause damping-off in current-year *F. crenata* seedlings. Resistance against these fungi could be attributed to changes in production of phenolics and in tissue structure. These changes may be important to promote seedling regeneration. Moreover, because light conditions vary across forest floors, the relationship between light conditions to which each seedling is exposed and the mortality or resistance of the seedling should be studied in association with the resistant factors. This relationship is important for future research in order to understand one of the environmental threshold levels that determine survival of individual seedlings. In addition to light conditions, future studies need to address how other factors such as temperature, humidity, light quality, and host genetic variation affect disease resistance of seedlings. Moreover, the antifungal substances associated with this chemical defense in hypocotyls of *F. crenata* seedlings must be identified.

The frequent occurrence of PAs in honey (RIVM 2007; Kempf et al. 2008), pollen, and pollen loads of bees (Boppré et al. 2005, 2008) shows that bees are confronted with PAs during natural foraging conditions. Honey foraged from PA-containing plants may contain up to 3.9 µg PAs per gram of honey (Deinzer et al. 1977; Betteridge et al. 2005).

It seems likely that the nectar of PA-plants contains PAs as well, but there is no direct confirmation. On the other hand, there are data on PAs in pollen. These suggest that pollen of PA-plants as well as pollen loads of foraging bees contain high PA concentrations. Up to 14 mg/g for *Echium vulgare* and 0.8 mg/g for *Senecio jacobaea* have been reported (Boppré et al. 2005, 2008). Since floral nectar always is contaminated with plant pollen (which may contain high amounts of PAs) it is difficult to determine the original nectar PA load.

Apart from the ongoing discussion on the ecological role of toxic nectar in plant-pollinator relationships (reviewed by Adler 2000; Raguso 2008), there are numerous examples where plant alkaloids have been shown to be constituents of floral nectars (Baker 1977; Detzel and Wink 1993; Adler 2000; Nicolson and Thornburg 2007). Thus far, deterrence and mortality effects of monocrotaline on butterfly species have been investigated (Masters 1991; Landolt and Lenczewski 1993), but only the effects of a few PAs have been tested against honey bees (Detzel and Wink 1993; Tan et al. 2007). While some work on pollinator toxicity has been performed in the course of pesticide approval, there is only limited information on the mode of action for toxins from natural sources like nectar and pollen. The results of a recent pollen analysis of contaminated honeys (Kempf et al. 2008) indicate strongly that some PA-plants, like *Echium vulgare* are attractive bee plants. To date, there is only one report on the effect of PAs on the fitness and behavior of honey bees: Detzel and Wink (1993) have reported a LD_{50} of 0.1% for the PA heliotrine under no-choice conditions.

The focus of this study was to investigate the effect of PAs in the bee diet on the behavior and health of bees. We were interested particularly to learn how bees handle and metabolize these hazardous plant constituents in order to escape their toxicity.

Since honey bees are social insects that live in colonies of up to 80,000 individuals, we chose laboratory experiments with small caged bee groups. These tests were designed in accordance to the OECD guidelines for the testing of chemicals (OECD 1998: Honeybees, Acute Toxicity Test).

Since only 1,2-unsaturated tertiary PAs but not their *N*-oxides are converted into toxic intermediates through bioactivation by cytochrome P450 enzymes, 1,2-unsaturated tertiary PAs are regarded as pro-toxic, while the respective PA-N-oxides (PA-Noxs) are non-toxic *per se*. However, the *N*-oxides are reduced easily to the pro-toxic free bases in the presence of weak reducing agents. Generally, this happens in the intestines of any herbivore that feeds on a PA-plant. This is why PA-containing plants are essentially toxic although they often store PAs exclusively as *N*-oxides in their tissues (Hartmann and Witte 1995) (Fig. 1).

1,2-Unsaturated PA toxification by hepatic cytochrome-P450 enzymes is well-studied in vertebrates, and acute, chronic, and genotoxic effects are documented (Culvenor et al. 1976; Mattocks 1986; Stegelmeier et al. 1999; Fu et al. 2004). The bioactivation is initiated by hydroxylation of the necine base followed by a spontaneous dehydratization to form pyrrolic ester structures that readily react with cellular nucleophiles (Fu et al. 2004). The structural prerequisite here is the concurrent presence of the 1,2-double bond and an allylic ester functionality. Similar mechanisms can be assumed for mutagenic and toxic effects observed in insects (Frei et al. 1992; Narberhaus et al. 2005; Hartmann and Ober 2008).

Hence, the tests should shed light on the question whether there are different impacts on bees for tertiary PAs and PA-Noxs, respectively. These studies were complemented by feeding monocrotaline and 1,2-dihydro-monocrotaline. These two compounds are structurally closely related, but the latter does not bear the generally required cytotoxic feature of the 1,2-double bond. By studying these compounds, it should be possible to link an observed mortality directly to the toxic principle of the 1,2-double bond.

We also tested known steps of PA metabolism in insects to see whether bees have evolved mechanisms to cope with

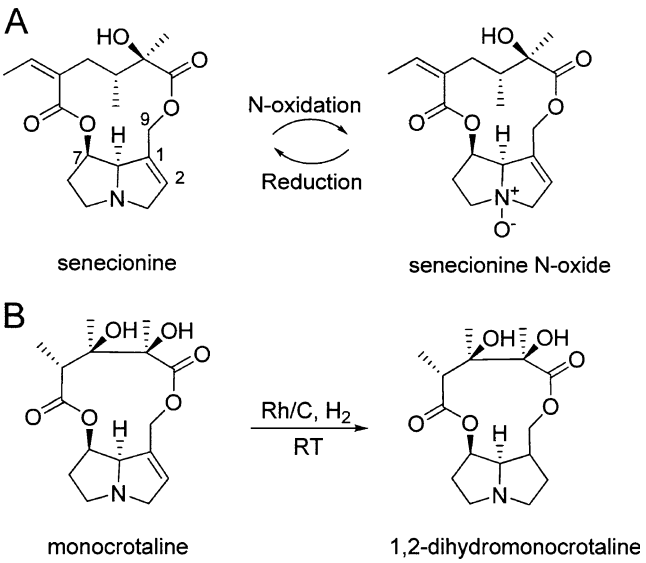

Fig. 1 Examples of pyrrolizidine alkaloid (PA) structures and reactions

natural occurring PAs. In these studies, we intended to monitor elevated excretion of ingested PAs, detoxification of ingested tertiary PAs via *N*-oxidation, and toxification via reduction of 1,2-unsaturated PA-Noxs into 1,2-unsaturated tertiary PAs.

Finally, we addressed the question to what extent trophallaxis is influenced by PA-food uptake. Inside bee colonies, a pronounced horizontal nectar transfer from bee to bee can be observed. Furthermore, foraging bees that return to the hive with poor-quality food experience difficulties in finding unloader bees that are in charge of unloading and storing the nectar in the hive. This in turn results in lower recruiting success from dance attendees to head for this poor food source. Overall, high PA content (in our sense i.e., poor quality) could trigger a lower PA intake into the hive if there were deterrence effects because of high PA concentrations.

Methods and Material

Plant Material Plants of *Senecio vernalis* were obtained in spring 2007 from a wild population in the vicinity of Braunschweig. The inflorescences were collected, lyophilized, powdered, and stored dry in the dark at room temperature until alkaloid extraction.

Bees Summer bees (*Apis mellifera*) collected from a honeycomb from the edge of the colony were used for the feeding experiments. Immediately after the tests, bees where anaesthetized by gaseous CO_2, stored at −18°C, and lyophilized just before analysis.

Preparation of the PA-mix Lyophilized plant material (*Senecio vernalis*, flowering specimens) was extracted according to Hartmann and Toppel (1987). The purified mixture of total plant PAs was analyzed by GC-FID/NPD and GC-MS. It contained senecionine (81%), seneciphylline (15%), integerrimine (1.5%), retrorsine (0.9%), and senecivernine (0.4%). No other components were detected by this method. This purified mixture of tertiary PA is referred to as "PA-mix".

Chemical N-oxidation of Tertiary Alkaloids The *N*-oxidation of the PA-mix from *S. vernalis* (see above) was performed as reported by Cymerman Craig and Purushothaman (1970). All alkaloids of the PA-mix were converted chemically to the corresponding PA-Nox (Fig. 1, *A*) with essentially the same quantitative composition as the "PA-mix". This mixture is referred to as "PA-Nox-mix".

Preparation of 1,2-Dihydromonocrotaline Monocrotaline (99.0%) was obtained from Fluka (Steinheim, Germany). Hydrogenation of the 1,2-double bond was performed as recently described by Marín-Loaiza et al. (2008). Further purification was achieved by column chromatography on silica gel 60 (mesh 230–400) using the solvent system CH_2Cl_2/MeOH/NH_4OH_{conc} (83:15:2/ v:v:v). The purity of the collected fractions was checked by capillary GC and GC-MS analysis. Fractions that contained only 1,2-dihydromonocrotaline were combined. Reaction products of several reactions were combined yielding about 100 mg (average yield per reaction: 40%). Purity and identity were confirmed by GC-MS.

Feeding Experiments Feeding experiments were conducted in the summer seasons 2007 and 2008 with two different bee colonies. Because of the relative early onset of fall conditions in summer 2007, it was not possible to finish all tests in time. To assure as much as possible the highest possible degree of reproducibility in the data set, we here refer to results obtained in 2008. Where possible, we complemented and confirmed the results with data from 2007. The experiments were conducted with minor modifications to the recommended OECD Guidelines for the testing of chemicals (1998). The OECD guidelines recommend one test series with 3 cages that contain ten bees for each concentration (30 bees per data point). In order to generate a more solid dataset, we conducted 3 independent test series for each compound and each concentration (equals 90 individual bees per data point). The particular test compounds (PA-mix, PA-Nox-mix, monocrotaline, and 1,2-dihydromonocrotaline) were dissolved in a 50% (*w*/*w*) sucrose solution at concentrations of 0.02, 0.2, and 2.0% (*w*/*w*). In the 2007 experiments, in addition to these concentrations, a PA level of 0.002% was tested, but omitted for subsequent experiments because it did not display any effects.

In a preliminary experiment, PA-containing diets were offered to bees, and their effects on the feeding behavior and mortality were studied. The PA diets consisted of a purified mixture of 1,2-unsaturated PA isolated from a natural source (*Senecio vernalis*). Two diets were offered: A mixture of the tertiary PAs (free bases) and a mixture of the respective *N*-oxides (Nox). A 0.2% PA content is what one can expect for flower heads of PA-plants. Furthermore, the highest reported value for the PA content in pollen is 1.4% (Boppré et al. 2005). For floral nectar, unfortunately, no data are available. The tested concentrations ranged from 0.02 to 2%, and covered the maximum PA level that an individual honey bee might encounter in nature.

The second test series (monocrotaline/1,2-dihydromonocrotaline) was conducted to examine two questions: (1) Are observed effects of the PA-mixes really caused by the PAs and not by contaminations that possibly were not removed completely during PA-mix purification? (2) Since

the 1,2-double bond is a prerequisite for PA toxicity, what is the effect of the structurally related 1,2-saturated derivative? Monocrotaline was chosen because it is readily available and 1,2-dihydromonocrotaline because it can be obtained with high purity through chemical synthesis. Monocrotaline and 1,2-dihydromonocrotaline were not used to test for differences between 11- and 12-membered PA ring systems.

All solutions were offered to starved bees for 2 h. Starvation status was checked approximately 2 h after the bees were separated from the colony by dissecting 10 randomly picked bees and checking the content of the honey stomach. If all honey stomachs were confirmed empty, the tests were started. After 2 h, the food was changed to a pure 50% sucrose solution *ad libitum* for an additional 46 h. The amount of the consumed PA solution was determined as the loss of weight of the feeding dish after the first 2 h feeding period. Together with each PA test series, two control groups were conducted. One control group (required for the OECD protocol) obtained pure sucrose solution during the first 2 h, while the second did not get any food during the first 2 h. Since all bees were already starving before the tests started, this adds additional stress (starvation) that might also cause mortality. A high mortality in the first 2 h, however, would be reflected in lower food consumption, which then would be misinterpreted as deterrence. The additional control was introduced to recognize deterrence and to distinguish whether mortality in the PA feeding test is a consequence of additional starvation stress induced by strong deterrence or the result of the PA content of the diet. All cages were kept in an incubator at 25±2°C, in darkness, and at a relative humidity of 50–70%. Dead bees of each cage were collected, and the numbers of dead bees were counted after 2, 4, 6, 24, 30, and 48 h. The dead individuals of each time point were stored separately, so subsequent chemical analyses could be done in consideration of the time of death.

Alkaloid Extraction from Bees Lyophilized bees were ground with stainless steel balls (1 to 4 mm diam) in a paint shaker (Merris Minimax MK4, Glattbrugg, Switzerland) in two cycles of 90 s each. Extraction of the bees was conducted according to Hartmann and Toppel (1987). Briefly, homogenates were extracted twice with 500 µL 1 M HCl and left to stand for 10 min. Subsequently, extracts were centrifuged (10 min at 13,000 rpm) and subjected to one of the following work-up methods:

Method A: This was used for monocrotaline and 1,2-dihydromonocrotaline feeding solutions and the horizontal transfer experiment. The extract was made basic with NH_4OH (25%) and applied to an Extrelut® NT20 column (Merck, Darmstadt, Germany) (1.4 ml/g Extrelut®). The PAs were eluted with CH_2Cl_2 (6 ml/ g Extrelut®). The organic solvent was evaporated, and the residue was dissolved in 50 µl MeOH. The amount of monocrotaline, 1,2-dihydromonocrotaline or tertiary PA-mix per bee was quantified by using heliotrine as an external standard (concentration 1 mg/ml).

Method B: This was used for analysis of extracts that contained exclusively PA-mix. Immediately after grinding of the bees, 50 µl of a monocrotaline solution (1 mg/ml in MeOH) were added as internal standard. Monocrotaline was used instead of heliotrine for quantification, because of chromtographically insufficient peak separation for peaks of interest. The procedure was subsequently processed as described for method A.

Method C: This was used for the determination of tertiary PAs and PA-Noxs. To evaluate the ratio of tertiary PAs vs. PA-Noxs, essentially method B was applied, but the supernatant obtained after centrifugation was divided into halves. One half was treated as described in method B to account for the amount of tertiary PAs. To the second half, an excess of Zn dust was added to reduce the PA-Noxs into the corresponding tertiary PAs (see also Fig. 1, *A*). After stirring at room temperature for 3 h, the solution was made basic, and the extraction was finished as described in method A. The result accounted for the sum of tertiary PAs and PA-Noxs (total PAs). The content of PA-Noxs was calculated by subtraction of total PAs by tertiary PAs.

The total PA uptake was calculated on the basis of food consumption during the 2 h feeding period, and correlated to the recovered PA amount.

Analytical Procedures GC-FID/NPD analysis: An Agilent 6890N Network GC System (Agilent Technologies, Wilmington, DE, USA) was equipped with a ZB-1 capillary column (30 m×0.32 mm×0.25 µm f_{th}, Phenomenex, Aschaffenburg, Germany). Conditions: injector 250°C; temperature program 100°C (3 min)–6°C min–310°C (3 min); split ratio 1:10; injection volume 1 µl; carrier gas He (1.2 ml/min). The eluting compounds were detected simultaneously by using a fused-silica Y-splitter and an FID and an NPD detector.

GC-MS analysis: An Agilent 6890N Network GC System was coupled with an Agilent mass spectrometer 5975B inert EI/CI MSD. For GC separation, a DB-1 fused-

silica column (30 m×0.32 mm×0.25 µm f_{th}, J&W Scientific, Waldbronn, Germany) was used. Conditions were the same as above.

The quantitative analysis of the PAs was performed by capillary GC-FID, the identification of the individual PA structure was confirmed by GC-MS in comparison to spectra and retention indices (RIs) recorded from authentic reference compounds (Witte et al. 1993). The retention index (RI) was calculated by a set of hydrocarbons (even numbered from C10 to C28) by linear interpolation.

Horizontal PA Transfer (Trophallaxis) The experiment of bee-to-bee transfer of PAs was performed in the summer season 2007. Recent studies have shown that PAs frequently are found in retail honey and in pollen loads collected by bees (RIVM 2007; Boppré et al. 2008; Kempf et al. 2008). We wanted to test whether the uptake of PA-food influences the exchange of PA-contaminated food among bees. These experiments were planned as a simulation of the natural occurring plant-to-bee and bee-to-bee transfer, and the final PA-deposition in the honey comb.

Two cages with 10 bees each were supplied with a diet containing 0.2% or 2% PA-mix in 50% sucrose solution for 1 h. After 1 h the PA diet was removed and an additional ten bees were released into the cages. These bees were marked with yellow color spots and had no food access beforehand. After 1 h of contact (without any food supply) the experiment was stopped, and the two groups (marked/not marked) were analyzed separately for PAs. The experiment was repeated three times. PA extraction and PA content was determined as described above. All bees of the experiment were analyzed per group (N=10 individuals per group) and thus the values represent the mean PA content per group.

Statistical Methods Means of food consumptions and mortalities in the feeding experiments with PA-mix, PA-Nox-mix (Fig. 2), monocrotaline, 1,2-dihydromonocrotaline (Fig. 4), and the total tertiary PA amounts in the different bee-groups of the feeding experiment with 2%-PA-mix (Fig. 5) were tested for significant differences by One-way ANOVA followed by a Student-Newman-Keuls test for all pairwise comparisons. These tests were performed by using SigmaStat® 3.1 (Systat Software GmbH, Erkrath, Germany).

Results

PA-mix and PA-Nox-mix Feeding Experiments The feeding of the PA-Nox-mix showed a significantly lower food consumption at the highest concentration tested (2% PA content, Fig. 2), indicating substantial deterrent effects. Concerning mortality, only the 2% PA-mix (containing 1,2-unsaturated tertiary PA) showed a marked increase (Fig. 2), while the PA-Nox-mix did not cause any mortality.

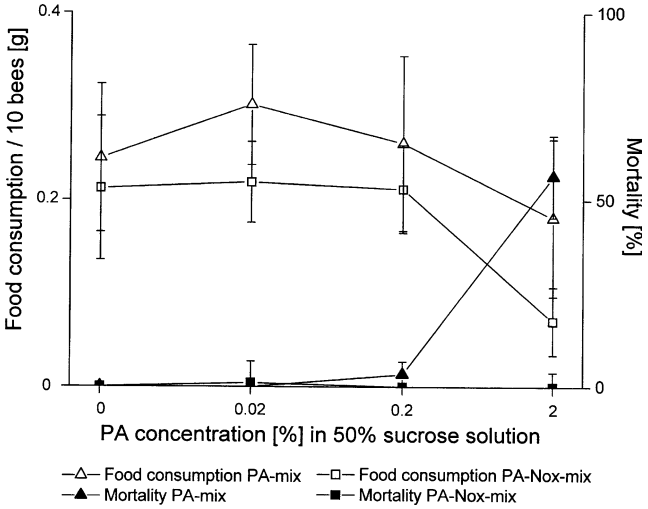

Fig. 2 Comparison of food consumption and mortality (means ± SD) in experiments (N=9) with tertiary PA-mix and PA-Nox-mix. The food consumption of 2% PA-Nox-mix was significantly different (P<0.01) to all other concentrations. The same applies for the mortality observed for 2% tertiary PA-mix (significant difference (P<0.01) to all other concentrations)

In parallel to the regular control groups (0% PA) that had access to sucrose solution throughout the test (48 h), a second control group was established. The time-depending mortality of the starving control group was compared to the 2% PA-mix group and the 0% PA control group (Fig. 3). Figure 3 shows that there can be a high mortality of up to 45% caused obviously by starvation within the first 2 h. But as soon as the remaining individuals had access to regular food (after 2 h), they recovered immediately, and fatal casualties were no longer observed. On the other hand, the increase of mortality caused by the 2% PA-mix clearly showed a different time course. Up to 6 h the mortality rate increased slowly then escalated and kept on ascending and reached mortality rates up to 70% after 48 h (Fig. 3). As expected, the 0% PA control group showed almost no mortality. All individual test series exhibited the same tendencies.

Because stress related mortality induced by starvation could be excluded, the observed mortality rate in PA feeding experiments must be linked directly to PA toxicity and not to PA deterrence and rejection of PA food.

Monocrotaline and 1,2-Dihydromonocrotaline Feeding Experiments To expand the results for the PA-mix experiments, a second test series was conducted. Instead of the PA-mix, pure monocrotaline and its 1,2-dihydro derivative (Fig. 1, *B*) were applied. The feeding protocol was exactly

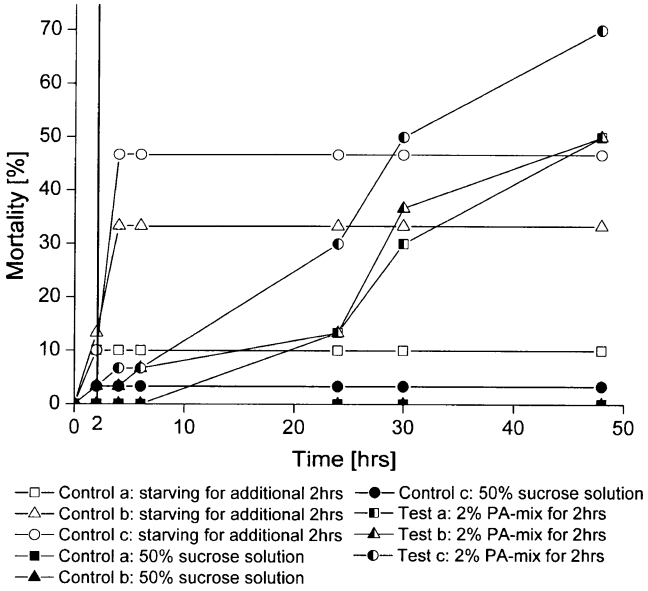

Fig. 3 Comparison of bee mortality in experiments with 2% PA-mix diet (offered for 2 h) (half filled symbols) and the control experiment starvation for 2 h (empty symbols) respective 0% PA diet (*filled symbols*). The curves a to c represent three individual test series (N=10). The time point of food replacement into 50% sucrose solution *ad libitum* is marked (2 h)

the same as that used for the PA-mix experiments. No significant deterrence was observed for these compounds (Fig. 4). Monocrotaline caused mortality effects at concentrations of 2%. The curve progression of monocrotaline resembled the result obtained for the PA-mix. On the other hand, increasing concentrations of 1,2-dihydromonocrotaline did not cause a marked increase in mortality (Fig. 4). The analysis of the control groups showed the same pattern

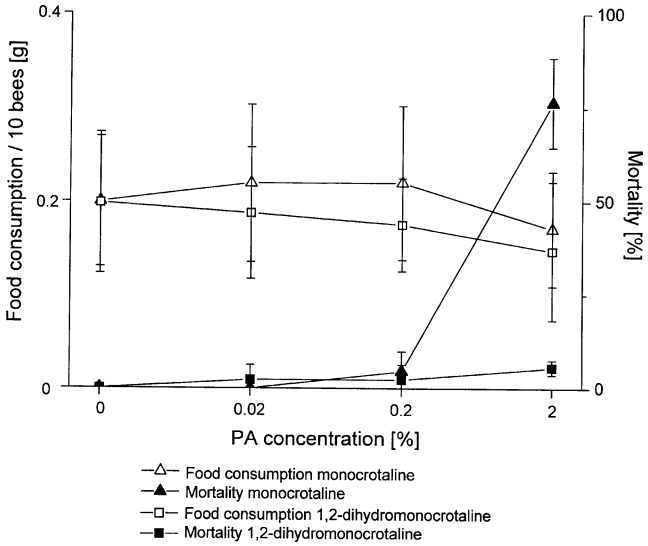

Fig. 4 Comparison of food consumption and mortality (means ± SD) in experiments (N=9) with monocrotaline and 1,2-dihydromonocrotaline. The mortality of 2% monocrotaline was significantly different (P<0.01) from all other concentrations

as obtained for the PA-mix (Fig. 3). The mortality profile for these tested compounds established that the 1,2-double bond of the PA nucleus is an essential feature of PA toxicity in honey bees.

Chemical Analysis of PA-Treated Bees Qualitative and quantitative PA analysis was conducted for distinct groups of bees. The observed effects of the PA feeding should be correlated to the total PA content (PA and PA-Nox) found in individuals of different experiments. The bees of the respective group were picked randomly and analyzed individually. We distinguished early deceased (2 to 30 h), late deceased (>30 h), and surviving bees. The results are summarized in Fig. 5. Bees of the first group showed on average 175 µg PA/bee. The second group exhibited an average PA content of 250 µg/bee. The surviving individuals (48 h) had the lowest PA load (in average 50 µg PA/bee). Because of the selected experimental conditions (sucrose feeding, darkness, humidity, and temperature) bees did not defecate during the assays (48 h). Thus, the PA levels of bees after the treatments were not altered by excretion but only by metabolism.

The comparison of the PA-profile of the PA-mix offered with the diet and the profile of PAs found in bees after 48 h (deceased and surviving bees) demonstrated no significant alteration (Fig. 6). This suggests no discrimination in the uptake of individual PAs from the mixture, and identical metabolic stability of the compounds stored in the bees' bodies. To check for an overall recovery of administered PAs, all bees of one cage were analyzed quantitatively. About 61% of the consumed PAs could be extracted and analyzed by GC-FID/NPD and GC-MS methods. For a single bee, analyzed 46 h after feeding on the PA diet, a maximal load of 200 µg was calculated (Fig. 5, *C*). Considering the average body weight of 100 mg, this amount of 0.2% PAs testifies to a relatively high tolerance towards PAs under these conditions. However, there is an enormous variation of almost one order of magnitude between the PA loads of the individual bees within one experimental set (Fig. 5, *B*).

Conversion of PA-Noxs to Tertiary PAs In most PA-containing plants, bees are facing the non-toxic PA-Noxs, which are the dominating plant constituents. As already mentioned, these *N*-oxides are easily reduced in the intestines of herbivores, yielding the pro-toxic tertiary PAs. Obviously, bees were not harmed by PA-Nox feeding (see Fig. 2). Hence, we wanted to check whether bees have developed mechanisms to maintain the PAs in the non-toxic *N*-oxide state. Individual bees of a group that had access to a PA-Nox-mix (2%) for 2 h and subsequently 46 h of regular food were analyzed for co-occurrence of both PA-forms (Method C). The result indicated that some reduction

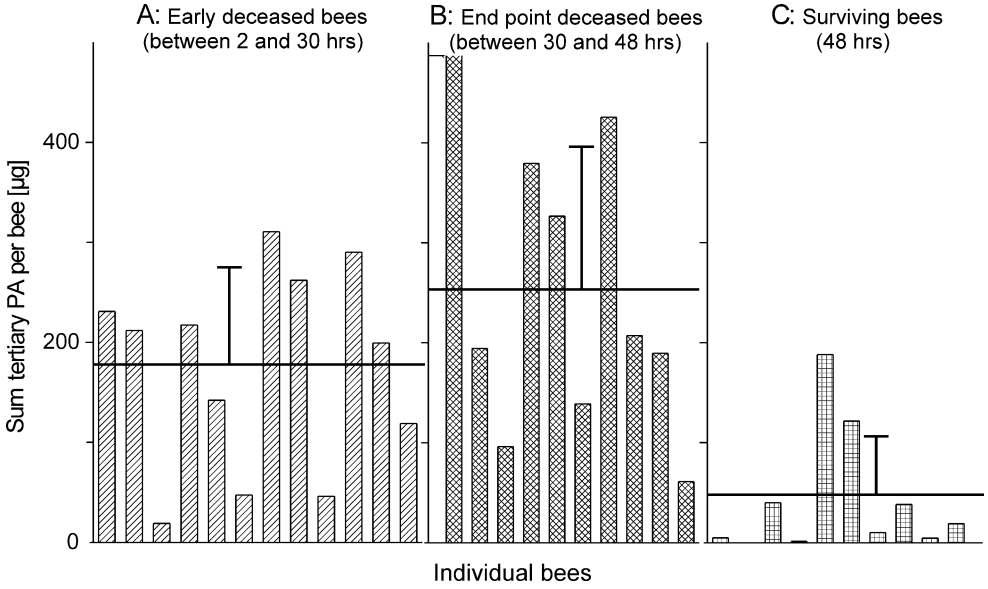

Fig. 5 Amount of pyrrolizidine alkaloid (PA) per individual bee (means ± SD) after feeding of 2% PA-mix divided into different groups: Early deceased bees (between 2 and 30 h) (*A*); end point deceased bees (between 30 and 48 h) (*B*); surviving bees (48 h) (*C*). Total tertiary PA amounts in bees of group *C* were significantly different ($P<0.05$) from total tertiary PA amounts found in group *A* and *B*

occurs. An average of 69% of the administered PA-Noxs was converted into tertiary PAs (Fig. 7). Thus bees have no specific mechanism to maintain the N-oxides in the harmless form. The maximum level of tertiary PAs did not exceed 50 µg/bee (Fig. 7, bee #8). The overall amount of PAs seems rather low, but this is most likely caused by the strong deterrence effect of the PA-Nox-mix (see Fig. 2).

Conversion of Tertiary PAs into PA-Noxs As mentioned above, some specialized insects are able to convert potentially hazardous tertiary PAs into PA-Noxs for "safe" storage or fast excretion. We analyzed bees that had access to the tertiary PA-mix (2%) for 2 h and subsequently 46 h of regular food for the occurrence of possible PA-Nox by using Method C. In all analyzed bees, no such conversion was detectable.

Horizontal Bee-to-bee PA Transfer The bees without direct PA contact showed approximately 4% (2% PA diet) and 15% (0.2% PA diet) of the PA load that was found in bees that had direct PA contact. Thus, at least under laboratory conditions, we demonstrated that horizontal transfer (trophallaxis) of PA contaminated food is possible. In addition, if the content of the honey stomach contained high PA concentrations, the observed exchange to other bees was reduced.

Discussion

Recent studies have documented PA contamination of honey, and have raised concerns of potential health risks

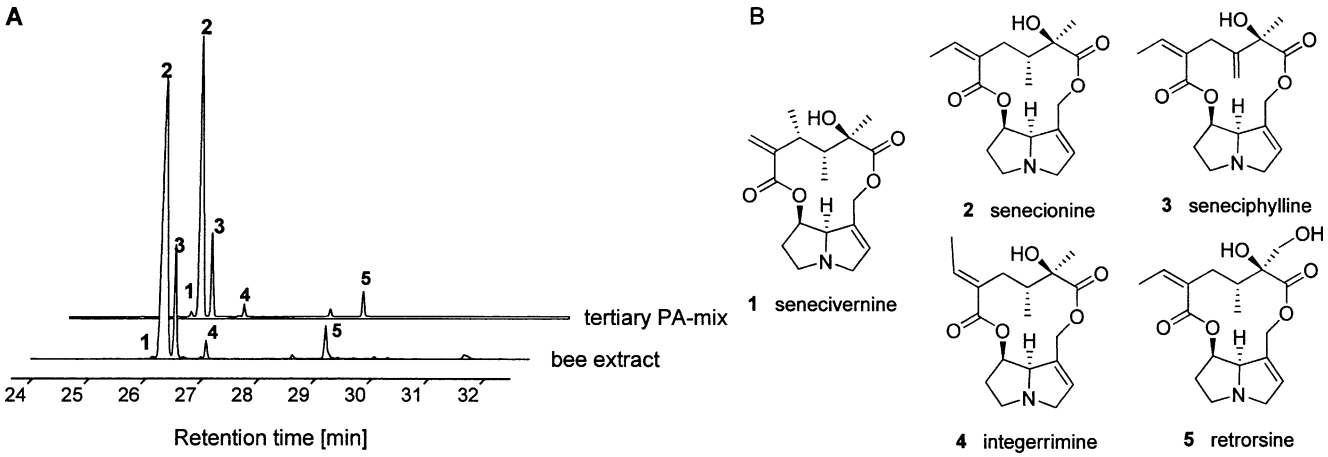

Fig. 6 Comparison of GC-NPD chromatograms (*A*) of the components (*B*) of the PA-mix (*A*, upper chromatogram) and a PA profile found in bees after feeding 2% PA-mix diet and 48 h test duration (*A*, lower chromatogram)

for consumers (Edgar et al. 2002; Kempf et al. 2008). The food supply of honey bees depends to a great extent on the acquisition of nectar and pollen from flowers. It is still an open question whether floral nectar of PA-plants naturally contains PAs, since PA contamination found in honey also could be caused by pollen. Any honey that was found to contain PAs was also found to be contaminated with pollen of PA-plants (Kempf et al. 2008). The genuine occurrence of PAs in floral nectars has been suggested frequently but never proved unequivocally (Detzel and Wink 1993; Gaffal and Gammal 2003; Singaravelan et al. 2005; Gegear et al. 2007). It seems that the alkaloid content of nectar generally is lower than in pollen (Detzel and Wink 1993). Since up to 3% of flowering plants contain PAs (Culvenor 1980), there is a high probability that honey bees are exposed to these potentially toxic compounds. So far, no data have been available to explain how bees accomplish this challenge.

Toxicity and Deterrence The first approach was to expose bees to a naturally occurring PA mixture. The PA-mix obtained from *S. vernalis* contained PAs of the senecionine-type, representing one of the most prominent and toxic classes of macrocyclic PAs (Hartmann and Witte 1995; Fu et al. 2004). The results of the feeding experiments with the 2% PA-mix showed high mortalities compared to the PA-free control. Monocrotaline showed a similar toxicity profile (increased mortality at >30 h).

Thus far, only the influence of heliotrine, a representative of PA monoesters of the lycopsamine type, has been tested on honey bees, and a LD_{50} of 0.1% was determined (Detzel and Wink 1993). Since the test conditions were quite different (this study: 2 h PA feeding pulse; Detzel and Wink: continuous feeding of a PA diet for 48 h), it seems understandable why we did not observe such high mortality rates in our experiments at PA concentrations of 0.2%. In fact, both experiments demonstrated that adult worker bees could safely handle quite high PA amounts in their diets. During the feeding period of 48 h, the bees did not defecate, and thus were unable to reduce the ingested PA load by excretion.

The observed PA concentrations among one distinct group of bees varied by almost one order of magnitude (Fig. 5, *B*) and demonstrated impressively the dimension of biological variation even under idealized laboratory conditions and among closely related individuals.

Strikingly, in the feeding experiment with the 2% PA diet, the average PA load of the surviving bees was markedly lower (50 µg/bee) as compared to the two groups of deceased bees (175 and 250 µg/bee, respectively; Fig. 5). The real PA load might be even higher, since our quantification measure only covered soluble and extractable PAs but not PAs bound to cellular structures or polar degradation or detoxification products. As a consequence, the results of the 2%-test might be interpreted as "the dose makes the poison", and bees that only cautiously sipped the highly contaminated diet were able to survive. Since we did not observe any noticeable effects in repellency or mortality for the experiment with the 0.2% PA diet, it seems that bees can deal safely with PA concentrations found in their environment. A similar result was found for the alkaloids nicotine/anabasine and caffeine, which did not deter bees when administered in natural concentrations. Nicotine and caffeine were even found to stimulate feeding (Singaravelan et al. 2005).

The design of the experiments allowed us to distinguish between mortalities caused by potential stress through starvation, possibly caused by deterrent effects of the food (Fig. 3), and mortality caused by the ingestion of pro-toxic tertiary 1,2- unsaturated PA (Figs. 2 and 4). The results indicate that the toxicity observed at high concentrations (2% PA diet) of the tertiary PA-mix or monocrotaline must be caused by the ingested PAs. PA-Noxs as well as tertiary PAs that lack the 1,2-double bond (i.e., 1,2-dihydromonocrotaline) were non-toxic. We, therefore, suggest that the toxic effects observed with 1,2-unsaturated tertiary PAs are caused by cytochrome P450-mediated bioactivation (see Introduction). The PA-Nox-mix showed a significant deterrence effect at a concentration of 2%. As mentioned, most potential nectar plants of bees (species of the Asteraceae and Boraginaceae) contain PAs mainly as *N*-oxides (Hartmann and Witte 1995; Boppré et al. 2005, 2008). The repellent effect may represent an essential adaptation of bees to recognize plant PAs and consequently to provoke individuals to prevent the ingestion of hazardous amounts.

Metabolism The conversion of PA-Noxs to tertiary PAs is usually regarded as an unspecific reduction (see Introduction).

Therefore, we analyzed how bees metabolize PA-Noxs. In all instances, the PA-Noxs were at least partially converted to the corresponding tertiary PAs in the intestines. The extent of conversion varied strongly, but the overall dose of toxic tertiary PAs never exceeded 50 μg tertiary PA/bee (Fig. 7). This was in accordance with the average content observed for the surviving bees in the feeding experiment with 2% PA diet (Fig. 5, *C*).

We also examined the ability of bees to convert pro-toxic tertiary PAs into non-toxic PA-Noxs. This reaction is a well-known detoxification mechanism that has been demonstrated for several specialized insects that sequester PAs from their food plants and utilize them for their own benefit (Hartmann and Ober 2008). We never detected any significant *N*-oxidation of tertiary PAs in bees (data not shown). Thus, detoxification of PAs by *N*-oxidation can be excluded as a mechanism of detoxification in bees. This is corroborated by the fatalities observed with bees at high 1,2-unsaturated tertiary PA concentrations (Figs. 2 and 4).

Trophallaxis Experiment Our experiments of the horizontal PA transfer among bees revealed that bees that ingested high amounts of PAs (feeding on 2% PA diet) donated only 4% of their load to other bees, while bees that ingested lower amounts of PAs (0.2% PA diet) transmitted more than 15%. Obviously, the receiving bees are able to recognize a possibly hazardous load brought in by the foraging workers. Speaking for the colony, this deterrent effect would be beneficial, since foraging bees with high PA loads are less likely to be unloaded in the hive and, therefore, are less likely to recruit new workers for their potentially dangerous nectar source (Gould and Gould 1995; Seeley 1995). Possibly, the same sensory system that elicits feeding deterrence in the field is also involved in the control of trophallaxis.

In summary, our results suggest that adult worker bees are not deterred by PA concentrations that reflect natural conditions. Beyond that, bees apparently tolerate natural PA contamination of their food without adverse effects. Important questions and consequences arise, however, when we consider the observed PA tolerance of individuals in respect to PA transmission by trophallaxis within the bee community. If bees do not discriminate PA-containing food *per se*, PAs would be a natural component of honey and could only be avoided by limiting the access of bees to PA-plants. Are bees able to protect their offspring from contact with PAs? The well-documented mutagenic effects of PAs would be even more harmful during early developmental stages of the larvae. Are there any chronic effects of low PA concentrations on the fitness of the colony? Further studies are in progress to address these questions. We expect that the answers will provide useful information as to what extent bees are adapted to handle naturally occurring toxins such as PAs and thus prevent detrimental effects on their colonies. Perhaps this will improve our understanding of the phenomenon of unexplained mortality of bees, sometimes observed by beekeepers.

have shown that extracts of *L. bostrychophila* affect the settling behavior of conspecifics, with the deterrent effect depending on the concentration of the extract and the polarity of compounds in the extract (Green 2005). Recent work also has indicated that extracts of fungal colonies can affect the substrate chosen by *L. bostrychophila* (Green 2008), although the compounds responsible for this effect were not analyzed. So, *L. bostrychophila* can respond to chemicals in their environment. Before looking in more detail at the behavioral effect of compounds in their habitat, it is necessary to have a clearer idea of the role played by compounds produced by *L. bostrychophila*. Howard and Lord (2003) have identified several different fatty acids—ranging from C_{16} to C_{20}—and some fatty acid amides in extracts of the cuticle of *L. bostrychophila*, and they suggested that cuticular compounds could have a role in maintaining populations of *L. bostrychophila*. Although the behavioral effects were not investigated, they did find that cuticular compounds, in particular a fatty acid amide, stearamide, could inhibit the adhesion of certain fungal conidia to the cuticle (Lord and Howard 2004).

Fatty acids have been reported widely as components that are easily extracted from either the cuticle of insects (Jarrold et al. 2007; Gołębiowski et al. 2007, 2008a, b) or from the whole insect (Buckner and Hagen 2003; Reinhard et al. 2003). Fatty acid methyl esters are much less widely reported from insects (Moshitzky et al. 2003; Herman et al. 2005), especially since derivatization of the fatty acids (to more volatile methyl esters) prior to GC-MS does not allow the two different compounds to be distinguished. Fatty acids commonly encountered in insects, foods, or substrates can affect behavior of insects, attenuating the feeding-stimulant effect of sugars for *Diabrotica virgifera virgifera* (Bernklau and Bjostad 2008) and decreasing the re-mating behavior of female *Bombus terrestris* (Baer et al. 2000).

The aim of this study was to build on the work of Green (2005) and relate the behavioral effect of insect extracts (repellence) to the compounds extracted from *L. bostrychophila*. The most repellent extract of *L. bostrychophila* was fractionated, based upon the solubility of compounds in methanol and water, re-tested (to identify the most repellent fraction), and analyzed by GC-MS to see if some of the main compounds, particularly fatty acid amides, fatty acids, and fatty acid methyl esters, could be detected in the un-derivatized extracts, and whether these chemicals could help to explain the effects of the extracts. Thin layer chromatography was used to check for the presence of other lipids in fractions and extracts. Aside from providing more information on the chemical ecology of *L. bostrychophila*, there is the possibility that compounds identified in repellent extracts could be used to protect vulnerable areas from *L. bostrychophila*.

Methods and Materials

Insects The culture of *L. bostrychophila* was kept in a growth chamber (Vindon Scientific, UK) (76% RH, 28±2°C) on a 1: 1: 1: 1 mixture, by mass, of wheatgerm (Community Foods, UK); dried skimmed milk powder ("Marvel", Premier International Foods, UK), active yeast ("Quick Yeast"; Doves Farm, UK), and organic flour (Shipton Mill, UK). Insects were collected from the main culture by placing filter paper (5 cm diam) onto the surface of the diet media and allowing insects to crawl onto the paper. Insects were decanted into a 2 l ceramic dish and chilled for 10 min (5±2°C) before they were sieved (250 μm mesh) to retain adults and late stage nymphs. Insects were frozen (−18°C) and weighed (2.52 g).

Preparation of Insect-Extracts Four different extracts were tested for their effects on the settling behavior of *L. bostrychophila*. Sequential extracts of whole freshly collected insects were prepared in hexane (hexane) and aqueous 80% methanol (80%MeOH). The 80%MeOH extract was then sub-divided into two fractions based upon the compounds in the dried extract that would dissolve in either methanol (MFr) or water (WFr). First, sequential extracts of fresh sieved insects were prepared in 50 ml aliquots of hexane (10 min) and 80% methanol (24 h) (as described in Green 2005) with 12 h between extractions to allow evaporation of hexane. Each extract was filtered through an IST Isolute ® SPE frit (20 μm pore size), evaporated under a stream of nitrogen, and the amounts extracted into hexane (7.2 mg) and 80%MeOH (212 mg) were calculated. The 80%MeOH extract was divided into two fractions as follows. Methanol was added to 100 mg of dried extract, which was then agitated to dissolve as much material as possible. The sample was left to settle, and the supernatant was removed (MFr1), taken to dryness, and weighed (83 mg). The remaining solid was dried under a stream of nitrogen and weighed (WFr1, 17 mg). The remainder of the dried 80%MeOH extract (112 mg) was dissolved in 80% methanol to 10,000 ppm, 1,000 ppm, 100 ppm, and 10 ppm for bioassay. After bioassay and GC-MS analysis of this first sample a further 11 samples of booklice (2±0.7 g) were collected periodically over 1 month and extracted sequentially in hexane (mean extract weight=3.4±1.24 mg) and 80%MeOH (mean extract weight=311±101 mg). There was insufficient material in the individual hexane extracts for bioassay and for GC-MS analyses, so the hexane extracts for samples one to 12 were combined (44.5 mg). The proportions of the 12 samples extracted into hexane and 80%MeOH were 0.2±0.04% and 16±1%, respectively. Each of the 11 additional 80%MeOH extracts was fractionated, as described above, to yield methanol fractions (MFr2 to MFr12) and water fractions (WFr2 to WFr12). Sequential

extracts of the foods used to rear *L. bostrychophila* in culture—wheatgerm, dried skimmed milk powder, active yeast, and organic flour—were prepared in the same way to produce hexane and 80%MeOH extracts and then MFr and WFr.

GC-MS Analysis The hexane extracts and the methanol fractions of both insects and diet components were analyzed by GC-MS at 5,000 ppm. A Perkin-Elmer AutoSystem XL GC coupled to a Perkin-Elmer TurboMass MS (quadrupole) was used for analyses of samples. A 30 m×0.25 mm i.d.× 0.25 μm DB-5MS column (J. & W. Scientific, USA) was used with an oven program of 40–300°C at 3°C/min then 300°C for 4 min. The carrier gas was helium at a flow rate of 1 ml/min, and 1 μl injections (split 1:10) at 220°C were made by an autosampler. These injections equated to the extract from either 61 insects, for the combined hexane extract, or 0.9±0.07 insects for the MFr samples (N=12). Detection was by MS, fitted with an EI source operated at 70 eV with a source temperature of 180°C, and mass spectra were recorded in the range m/z 38–600 with 0.5 s scan time and 0.2 s inter-scan delay. The software was Turbomass, version 5.4.0. Peaks were integrated and peak-areas calculated for all detected compounds in each extract. Compounds contributing >2% of the total detected peak areas in this sample were putatively identified by comparison with published spectra in the NIST-database (Ausloos et al. 1992). Retention indices were calculated against an *n*-alkane series (C_{16} to C_{44}; Supelco, USA) so that the carbon chain length could be estimated for unknown compounds. The EI-spectra of compounds in the hexane extract and methanol fractions closely matched those of hexadecanoic acid, methyl ester (methyl palmitate; 16:0); (*Z*)-9-hexadecenoic acid (palmiteoleic acid; 16:1); *n*-hexadecanoic acid (palmitic acid; 16:0); (*Z*,*Z*)-9,12-octadecadienoic acid, methyl ester (methyl lineolate; 18:2); (*Z*)-9-octadecenoic acid, methyl ester (methyl oleate; 18:1); (*Z*)-9-octadecenoic acid (oleic acid; 18:1); (*Z*,*Z*)-9,12-octadecadienoic acid (linoleic acid; 18:2); and octadecanoic acid (stearic acid; 18:0). These eight compounds, together with octadecanoic acid, methyl ester (methyl stearate; 18:0) were purchased from Sigma-Aldrich, UK, dissolved to 10 mM in chloroform, and analyzed under the GC-MS conditions described above. Stearamide (octadecanamide) (Acros Organics) was analyzed as a standard to observe if it was present in the extracts.

Thin Layer Chromatography Methanol fractions (10 mg ml^{-1}) and the single hexane extract (1 mg ml^{-1}) were prepared. Marker compounds, dissolved in 2 ml aliquots of solvent, were either a mix of fatty acids (2 mg, 2.3 mg, 7 mg, and 3.2 mg, respectively, of C_{16}, $C_{16:1}$, C_{18}, and $C_{18:1}$ in chloroform); $C_{18:1}$ (2 mg in chloroform) or cholesterol (4.5 mg in acetone) (Sigma-Aldrich, UK). Aliquots (30 μl) were applied to an aluminum-backed analytical TLC-plate (20×20 cm, Kieselgel 60, Merck, Darmstadt, Germany) that had been activated by heating at 100°C for 1 h. The TLC plate was developed according to the method of Kupke and Zeugner (1978). First, the plate was run twice in chloroform (65); methanol (30); water (5), until the solvent front had risen 4 cm from the bottom of the plate (2.5 cm from the origin). The plate was dried, pre-saturated in solvent vapor and then developed in hexane (80); diethyl-ether (20); acetic acid (1.5) until the solvent front had migrated to 9.3 cm. For visualization, the plate was sprayed with 5% sulfuric acid in ethanol and charred at 200°C (Buckner and Hagen 2003). The Rf values for each spot were calculated. All extracts and samples were taken to dryness after use, and 5 ml of hexane were added before the vials were flushed with nitrogen to exclude air. Samples were then stored at −18°C.

Effects of Extracts, and Fractions Thereof, on the Settling Behavior of L. bostrychophila Several different experiments were conducted to observe the effects of extracts and compounds on the distribution-behavior of *L. bostrychophila*. The procedure was the same in each case. For the first set of experiments, using an 80%MeOH extract of whole *L. bostrychophila*, pairs of glass-fiber discs (Whatman GF/A grade, 2.1 cm diam) were laid onto a tray covered in aluminum foil, and aliquots (100 μl) of an 80%MeOH extract of booklice (10,000 ppm) were applied to one of the discs (treated), with 100 μl of 80%MeOH applied to the other (solvent blank). This was repeated for 1,000 ppm, 100 ppm, and 10 ppm concentrations. For the controls, solvent was applied to both discs, and for the purposes of comparison one was randomly assigned as treated and one as blank. Given that the weight of an individual insect—collected as described above—is 45±1.4 μg (Green 2005), it was possible to estimate the numbers of insects represented by 100 μl aliquots of the different concentrations of this 80% MeOH extract with ±3.1% margin of error. Once dry, each pair of discs was fixed 1.5 cm apart at the center of individual 9 cm Petri-dishes with solvent-free glue (Pritt Stick, Henkel Consumer Adhesives, UK), thus ensuring that insects could not get underneath the discs during the experiment. Dishes were made escape-proof with a 0.5 cm band of Fluon ® around the inside-rim. The Petri-dishes were equilibrated, at 28±1°C and 76±1.5% RH, in a growth chamber (Binder KBWF 240). Bioassays were conducted as described in Green (2008), except that saturated salt (NaCl) solution and plastic bags were not required to maintain humidity. The position of insects was recorded, after 12 h, by photographing the dishes with a digital camera (Sony® Cybershot™). Insects upon either of the two discs were designated as having selected, while insects remaining in the

dish had not selected. All dishes were placed in a freezer (−18°C) for 2 h, and the insects in each dish were counted: from this, the number of insects that were not on either disc (non-selecting) could be calculated. The MFr1 and WFr1 samples—approximated to their concentration in the 80% MeOH extract, 8,000 ppm and 2,000 ppm, respectively—also were presented to groups of *L. bostrychophila* separately and in combination to establish a link between the compounds detected in the GC-MS-analysis and behavior. A summary of the choices presented to groups of *L. bostrychophila* in the first set of experiments is shown in Table 1. The 11 additional 80%MeOH extracts were dried, re-dissolved in methanol, and the supernatant was tested at 8,000 ppm (MFr2 to MFr12).

Effects of Fatty Acids and Fatty Acid Methyl Esters on the Settling Behavior of L. bostrychophila The eight compounds identified in the extracts by GC-MS, plus methyl stearate, were dissolved in chloroform and 100 µl aliquots of 10 mM, 1 mM, 0.1 mM, 0.01 mM, and 0.001 mM were presented to groups of *L. bostrychophila* on glass fiber discs in treated vs. solvent-blank bioassays, using the method described above.

Statistical Analysis The *Kruskal-Wallis test* (SPSS, v.16.0.0) was used to compare the percentage of insects selecting among groups presented with different choices. *The Mann-Whitney U test* (SPSS, v.16.0.0) was used to compare the percentage of insects selecting between the control group and each experimental group. The percentage of selecting insects was sub-divided into those on the blank disc and those on the treated disc, and the proportions of insects selecting each disc—within each experiment—were compared with the *Wilcoxon signed ranks test*. All tests were two-tailed. All bioassay and chemical data are presented ± the standard error of the mean (SE), where appropriate.

Results

GC-MS Analysis Methyl palmitate, palmiteoleic acid, palmitic acid, methyl lineolate, methyl oleate, lineoleic acid, oleic acid, and stearic acid could be identified in most of the 12 methanol fractions (Fig. 1). The exception was sample MFr2, where the methyl esters of palmitic, linoleic, and oleic acids were not detected. Stearamide was not detected in any of the samples. The molar concentration of identified compounds ranged from 0.02±0.004 (methyl palmitate) to 1.2±0.11 mM (linoleic acid), equating to a mass of 7±0.45 ng and 260±32.4 ng per insect, respectively (Table 2). Fatty acids and fatty acid methyl esters made up approximately 30% and 95±2.4% (N=12) of the detected peaks in the hexane extract and methanol fractions, respectively. Furthermore, the proportion of the samples that were fatty acids and fatty acid methyl esters was lower in the hexane samples (3.36%) than in the methanol fractions (11.2±1.20%; N=12). All eight compounds were present in the combined hexane extract (Fig. 1c), but they were less concentrated and less material was extracted per insect when compared with the methanol fractions (Table 2). The NIST database gave equivocal results for the structures of the remaining compounds in the hexane extract, although a comparison of the retention times of compounds in the hexane extract with a standard alkane mixture indicated that the compounds eluting after 70 min were between 27 and 31 carbons in length (Table 3). Palmitic acid (0.33 µM), linoleic acid (1.7 µM), and oleic acid (0.44 µM) were detected in the 5,000 ppm hexane extract of wholewheat organic flour.

Table 1 Choices presented to *Liposcelis bostrychophila* in the first set of bioassays

Groups of insects were presented with 80% methanol extracts (80%MeOH) water fractions of the 80%MeOH extract (WFr1) and methanol fractions of the 80%MeOH extract (MFr1) at the concentrations indicated. Ten replicates of each treatment; 20 replicates of the control (solvent blank vs. solvent blank)

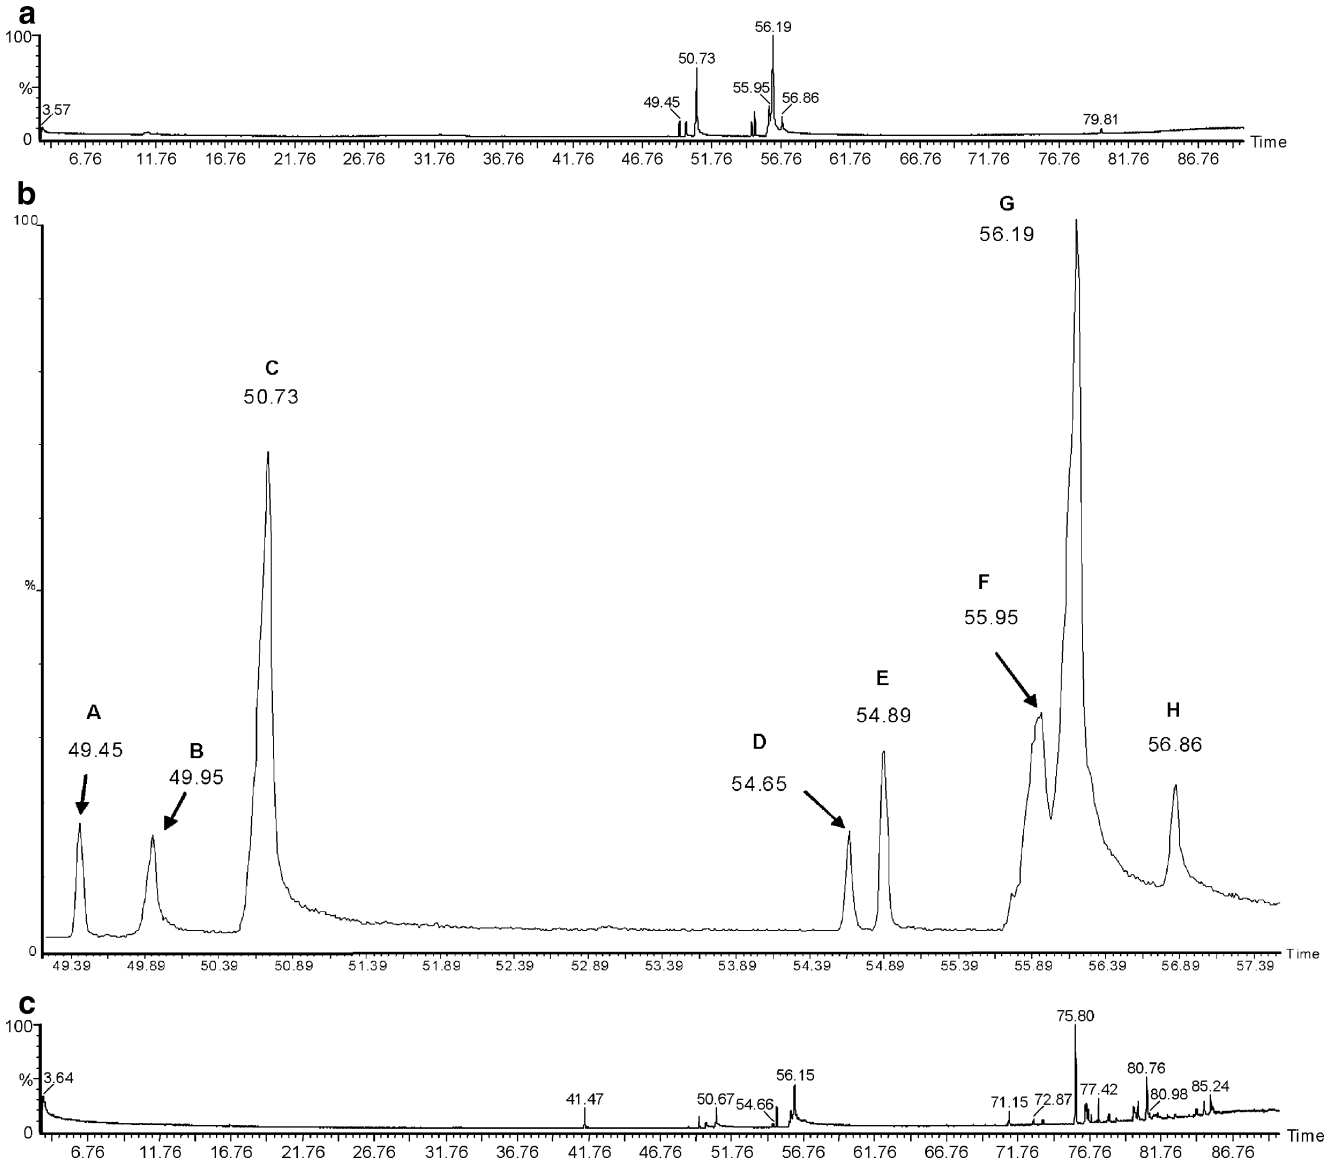

Fig. 1 GC chromatogram of a typical methanol fraction (MFr4) prepared from an 80% methanol extract of whole *Liposcelis Bostrychophila* (**a**); an expanded view of the region where the fatty acids and fatty acid methyl esters elute (**b**) and a GC-chromatogram from a hexane extract of whole *L. bostrychophila* (**c**) (**b**). *A* = methyl palmitate; *B* = palmiteoleic acid; *C* = palmitic acid; *D* = methyl lineolate; *E* = methyl oleate; *F* = linoleic acid; *G* = oleic acid and *H* = stearic acid

These molarities were equivalent to 0.68, 0.69, and 0.21% of their concentration in the 5,000 ppm hexane extracts of *L. bostrychophila*. Similarly, the hexane and methanol fraction of dried active yeast contained palmitic acid (0.33 μM): 0.11% and 0.68%, respectively, of the concentration in the 5,000 ppm insect samples. Fatty acids or their methyl esters were not detected in the hexane extract or methanol fraction of skimmed milk powder or wheatgerm.

Thin Layer Chromatography The methanol fractions and hexane extract contained fatty acids (Rf=0.48) and cholesterol (Rf=0.37). By comparing the relative positions of the marker-compounds with those in the fractions and extract and by reference to published data (Kupke and Zeugner 1978) it was possible to tentatively identify triacylglycerols in the MFr samples (Rf=0.80) and four putative phospholipids (Rf=0.08, 0.13, 0.18, and 0.26). Triacylglycerols and phospholipids were not detected in the hexane extract, although cholesterol esters (Rf=0.97) and two unknown compounds (Rf=0.99 and 0.62) were visible.

Effects of Extracts, and Fractions Thereof, on the Settling Behavior of L. bostrychophila Each 100 μl aliquot of the 80%MeOH extract (10,000 ppm) was equivalent to a density of 77 insects per cm^2 or 267 insects per disc, with the numbers decreasing proportionately with the concentration

Table 2 Compounds detected by GC-MS in either a hexane extract or in methanol fractions of *Liposcelis bostrychophila*

Compound	Hexane extract at 10,000ppm[a]			Methanol fractions at 8,000ppm[a]		
	Molarity, mM	Mass of compound, per insect, ng	Proportion of hexane extract, %	Molarity, mM (SE)	Mass of compound, per insect, ng (SE)	Proportions of methanol fractions, % (SE)
Methyl palmitate	0.01	0.002	0.02	0.02 (0.004)	2.7 (0.45)	0.06 (0.013)
Palmiteoleic acid	0.17	0.035	0.43	0.38 (0.06)	68.7 (11.84)	1.20 (0.184)
Palmitic acid	0.98	0.02	0.25	0.50 (0.06)	95.4 (15.6)	1.61 (0.203)

			Total=3.36			Total=11.16 (1.202) [b]

[a] 5,000 ppm samples were analyzed by GC-MS, so the molar concentration of each compound has been scaled-up by a factor of 2 and 1.6 for the hexane extract and methanol fractions, respectively. The mass of compound per insect and proportions are independent of the extract concentration. The mean molarity; mass of compound per insect, and the proportions of fatty acids (FA) or fatty acid methyl esters (FAME) in the methanol fractions were calculated from 12 samples, except for methyl palmitate, methyl lineolate and methyl oleate (N=11)

[b] The methanol-soluble FA and FAME are 8.9±0.96% of the 80%MeOH extract (10,000 ppm), by mass

of extract. The effect of the insect extracts on settling behavior of *L. bostrychophila* depended on the choices presented. An 80%MeOH extract of whole insects (10,000 ppm) deterred settling if it was paired with a blank (untreated) disc (*Mann-Whitney U* test, $P<0.01$; Fig. 2). There was a point between 10,000 ppm and 1,000 ppm when this deterrent effect was lost (Fig. 2). The results were different when both discs were impregnated with extract. Groups of *L. bostrychophila* distributed equally between two discs that both had 10,000 ppm 80%MeOH extract applied (*Wilcoxon matched pairs test*, $P>0.05$; Fig. 2). Once there was an order of magnitude difference between the extracts applied to each disc (i.e., 10,000 ppm vs. 1000 or 10,000 ppm vs. 100) more of the insects settled on the disc to which the lower concentration was applied (*Wilcoxon signed ranks test*, $P<0.05$; Fig. 2), although the insects did not select between 10,000 ppm and 10 ppm (*Wilcoxon signed ranks test*, $P>0.05$). The choices presented also affected the overall level of selection, i.e., the proportions of insects selecting either disc, remaining constant with two treated discs. In contrast, when there was a choice between an untreated disc and treated disc, overall selection declined as the concentration of extract on the treated disc increased (*Mann-Whitney U test*, $P<0.01$; Fig. 3).

A 10,000 ppm hexane extract (equivalent to 3,530 insects per cm^2 or 12,230 per disc) deterred settling (*Wilcoxon signed ranks test*, $P<0.05$; Fig. 4) but less than a methanol fraction (MFr1) (*Mann-Whitney U test*, $P<0.01$; Fig. 4). Overall selection was not different between the hexane extract and MFr1 sample (*Mann-Whitney U test*, $P>0.05$). For comparative purposes, to reflect the levels of hexane- and 80% methanol-soluble compounds extracted from the insects, an 82-fold dilution of the hexane extract (120 ppm) was tested and found to affect neither the level of selection (*Mann-Whitney U test*, $p>0.05$) nor the choice of disc (*Wilcoxon signed ranks test*, $P>0.05$) (data not shown). The MFr1 (8,000 ppm) and WFr1 (2,000 ppm) samples deterred settling of *L. bostrychophila* (*Wilcoxon signed ranks test*, $P<0.05$; Fig. 4). The WFr1 sample was less deterrent than the MFr1 (*Mann-Whitney U test*, $P<0.05$; Fig. 4), which was confirmed when both MFr1 and WFr1 samples were presented to insects in the same dish (*Wilcoxon signed rank*, $P<0.01$; Fig. 4). There was variability in the proportions of insects selecting either disc among the MFr2 to MFr12 samples (8,000 ppm) (*Kruskal Wallis test*, 11 df, $P<0.01$), but the overall levels of selection for each sample were not different from a control

[a] *KI* Kovats index. KI's were calculated by comparing the retention times of a standard alkane series with those of compounds in the hexane extract

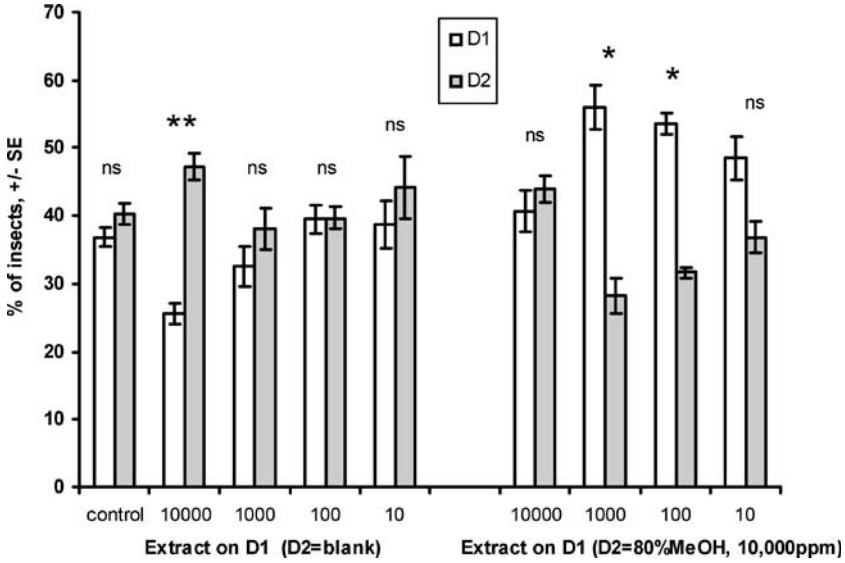

Fig. 2 Proportions of insects (%±se) selecting each disc when *Liposcelis Bostrychophila* were given a choice between either a treated disc (impregnated with different concentrations of an 80%MeOH extract) and blank disc or two treated discs that both had an 80%MeOH extract applied. The concentration of the 80%MeOH extracts of *L. bostrychophila* applied to D1 are in ppm. A comparison was made between the proportion of insects selecting each disc with the *Wilcoxon matched pairs test*, $^{**}P<0.01$; $^{*}P<0.05$ and *ns* = no significant difference. Each *bar* is the mean of ten replicates, except the control group ($N=20$)

group (*Mann-Whitney U test*, $P>0.05$). Each methanol fraction, including MFr2—in which methyl palmitate, methyl lineolate, and methyl oleate were not detected—deterred settling of *L. bostrychophila* in relation to a blank disc (*Wilcoxon signed rank test*, $P<0.01$) (data not shown). The level of deterrence was similar among the samples even though the number of insects represented by the methanol fractions varied between 112 and 188 (±3.1%) per disc.

Effects of Fatty Acids and Fatty Acid Methyl Esters on the Settling Behavior of L. bostrychophila Seven of the nine compounds tested repelled insects at 10 mM (*Wilcoxon signed ranks test*, $P<0.001$; Table 4), and repellence was associated with overall selection that was either increased (methyl palmitate, palmitic acid, methyl lineolate, and oleic acid) (*Mann-Whitney U test*, $P<0.001$ to <0.05; Table 5) or not different from the control (palmiteoleic acid, methyl oleate and lineoleic acid) (*Mann-Whitney U test*, $P>0.05$; Table 5). So, fatty acids and fatty acid methyl esters can affect the settling behavior of *L. bostrychophila*. The effect of each compound at concentrations <10 mM was different. The repellent effect was lost at 1 mM for all except methyl palmitate (*Wilcoxon signed ranks test*, $P<0.05$; Table 4), and the proportions of selecting insects either remained similar or increased. With the exception of linoleic acid, the fatty acids and fatty acids methyl esters were at concentrations below 1 mM in the repellent methanol fractions (Table 2). Methyl stearate—not detected in the extracts of booklice—was the only compound to deter settling of insects below 1 mM (*Wilcoxon Signed ranks test*, $P>0.05$; Table 4), although 0.1 mM palmiteoleic acid attracted *L. bostrychophila* (*Wilcoxon Signed ranks test*, $P<0.05$) and resulted in increased overall selection (*Mann-Whitney U test*, $P<0.05$; Table 5). Methyl lineolate and methyl oleate were the two other compounds that affected settling behavior of *L. bostrychophila*, with reduced overall selection when these two compounds were each presented at 0.01 mM (*Mann-Whitney U test*, $P<0.05$; Table 5).

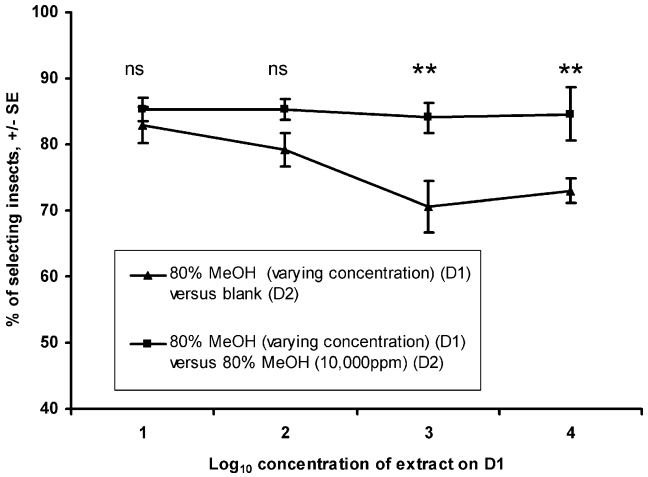

Fig. 3 Proportions of insects (%±se) selecting either disc when *Liposcelis Bostrychophila* were given a choice between either a treated and blank disc or two treated disc. 80% MeOH=80% methanol extract of *L. bostrychophila*, prepared after extraction with hexane. D1 and D2 are disc 1 and disc 2, respectively. Selection was compared between the proportions selecting using the *Mann Whitney U-test* $^{**}P<0.01$ and *ns* = no significant difference. Each point is the mean of ten replicates

Discussion

Extracts of *L. bostrychophila* deter settling of conspecifics, with the magnitude of the effect dependent on both the concentration of the extract and the solvents used to extract the material. Extracts of insects are known to affect the behavior of the same species, with the mixture of

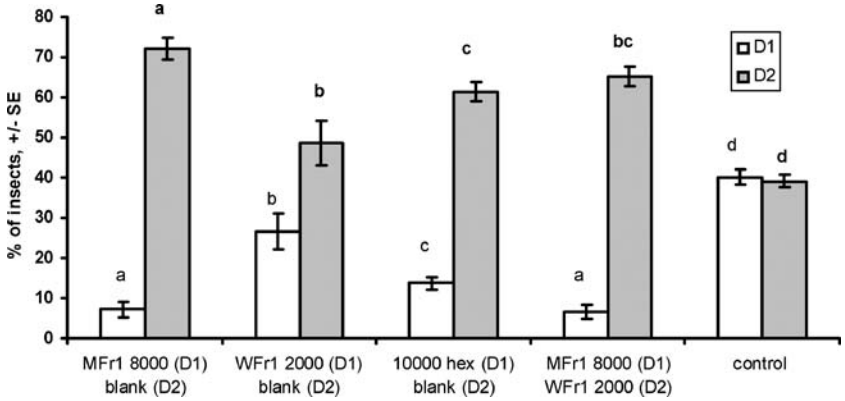

Fig. 4 Proportions of insects (%±se) selecting each disc when *Liposcelis Bostrychophila* were given a choice between either a treated disc (impregnated with MFr, WFr or a hexane extract) and blank disc or two treated discs to which either MFr or WFr had been applied. MFr1 8000 = methanol soluble fraction of an 80%MeOH extract at 8,000 ppm; WFr1 2000 = water-soluble fraction of an 80% MeOH extract at 2,000 ppm and 10,000 hex=10,000 ppm hexane extract. There was a difference among the proportions of insects selecting disc 1 (D1) and among those selecting disc 2 (D2) (*Kruskal-Wallis test*, $P<0.05$). Different *letters* indicate significant differences between the proportion of insects selecting disc 1 (letters in *normal text*) and disc 2 (letters in *bold*) (*Mann Whitney U-test*; $P<0.05$). The proportions of insects selecting either disc 1 or disc 2 within a treatment were different for all groups ($P<0.05$) except for the control (*Wilcoxon signed ranks test*). $N=10$ for all groups except the control ($N=20$)

compounds being particularly important in social insects for nest-mate recognition (Lucas et al. 2005) even though individual compounds in the extracts can act either as attractants or deterrents (Reinhard et al. 2003). *Liposcelis bostrychophila* is not a social insect but can occur in large groups that persist as long as resources (i.e., food and space) and a suitable microclimate permit. This persistence of groups may be modulated by physical and chemical

***P<0.001; **P<0.01; *P<0.05

interactions among individuals. Chemicals from large groups of individuals might build up to repellent levels, causing dispersal. The settling behavior of *L. bostrychophila* appears to be governed by a balance between the repellence exerted by high concentrations of extract (i.e., large numbers of insects) and the proximity of an area with either fewer or no insects. This suggests that the choices could exert a push-pull effect (Miller and Cowles 1990; Cook et al. 2007). The fact that *L. bostrychophila* did not differentiate between two repellent extracts until there was at least an order of magnitude difference between the concentrations of extract on each disc provides additional support for this hypothesis. When there was a choice between two repellent extracts (i.e., 80%MeOH, 10,000 ppm), effectively two extracts with a push-effect, overall selection was not affected when compared with a control group. It is possible that the regulation of settling behavior by short-range chemical cues can be disrupted by the build-up of volatiles emitted from concentrated extracts, as suggested by Green (2008). The effect of volatile compounds on the behavior of *L. bostrychophila* requires clarification by further study.

Hexane extracted less material from samples of *L. bostrychophila* than 80%MeOH, so although the hexane extract repelled settling of *L. bostrychophila* at 10,000 ppm it represented considerably more insects per disc than either the 80%MeOH extract or the 8,000 ppm methanol fractions. Insect extracts usually are prepared in apolar solvents, such as hexane (Kaib et al. 2002; Roux et al. 2006; Scott et al. 2008) or chloroform (Nelson and Charlet 2003), and as a result, hydrocarbons (straight chain saturated/unsaturated and methyl branched) predominate in the extracts (Howard and Blomquist 2005; Juárez and Fernandez 2007). Similarly, as yet unidentified long chain (>C_{27}) hydrocarbons were the main compounds detected in the hexane extract of *L. bostrychophila*.

Within the deterrent methanol fractions, saturated, mono-enoic, and dienoic fatty acids and fatty acid methyl esters with between 16 and 18 carbons were found to dominate the compounds detected by GC-MS. Although fatty acids and fatty acid methyl esters were present in the hexane extract, they were at a much lower concentration. Palmitic, oleic, and linoleic acids are widely thought to be the major fatty acids present in insects (Stanley-Samuelson et al. 1988), and while it is less usual to find these compounds with fewer than 16 carbons atoms or more than 18, there are exceptions (Thiéry et al. 1995; Jarrold et al. 2007; Gołębiowski et al. 2008a). Fatty acids were extracted from wholewheat flour and yeast, and were detected in the hexane extract (palmitic, linoleic, and oleic acids) or the methanol fraction (palmitic acid). These three fatty acids could have been extracted from the undigested diet within booklice or from particles of diet sticking to the surface of individuals, although they have been identified previously in hexane extracts of the cuticle of booklice (Howard and Lord 2003). Other fatty acids and fatty acid methyl esters present in the extracts of whole booklice are either not extracted from the diet-components by hexane and 80% methanol, or are products of the metabolism of *L. bostrychophila*. It is not uncommon for there to be qualitative differences in the profiles of fatty acids between insects and their diet (Bashan et al. 2002; Chamberlain and Black 2005; Cakmak et al. 2007).

At the highest concentration tested (10 mM), the methyl-esters of palmitic- and stearic acids were repellent, as were all the other unsaturated fatty acids and their derivatives, whereas

the saturated fatty acids (palmitic and stearic) did not affect repellence or overall selection. Similarly, unsaturated fatty acids have been found repellent to ants (Howard et al. 1982; Dani et al. 1996), to boll weevils (Bird et al. 1987), and to deter the oviposition of mosquitoes (Hwang et al. 1984), while saturated fatty acids did not have any effect. Fatty acid methyl esters affect sexual signaling of *Tegenaria atrica* (Araneae) (Prouvost et al. 1999) and have a role in signaling in honey bee colonies (Trouiller et al. 1992). Other species of insect can be attracted or repelled by fatty acid methyl esters that are not necessarily of insect-origin (Singh et al. 1985; Bird et al. 1987; Henderson et al. 1991). The absence of fatty acid methyl esters from one of the methanol-soluble fractions did not reduce the repellence of the extract, indicating that these compounds are not essential for repellence, although the individual compounds repelled *L. bostrychophila* at 10 mM.

At 10 mM, the compounds were between 8- (linoleic acid) and 600-fold (methyl palmitate) more concentrated than found in the repellent methanol fractions. Most of the fatty acids and fatty acid amides did not affect the settling of *L. bostrychophila* at concentrations approaching those found in the insect extracts: strongly suggesting that a combination of compounds is likely to be responsible for the effects of extracts. Interaction among a mixture of linoleic, stearic, and oleic acids is a factor in host-recognition by larvae of *Diabrotica virgifera*, with a combination of these compounds as attractive as a crude fraction of maize seedlings (Hibbard et al. 1994). Fatty acids also can affect ovipositing insects by either stimulating or inhibiting egg-laying (Horikoshi et al. 1997; Parr et al. 1998; Li and Ishikawa 2006). Mixtures of fatty acids derived from eggs of *Cydia pomonella* (Thiéry et al. 1995) and *Lobesia botrana* (Gabel and Thiéry 1996) inhibit further egg-laying on a substrate. Behavioral effects are not exclusive to mixtures of fatty acids, as individual compounds, for example octanoic (caprylic) acid, determine orientation to—and oviposition on—host plants (Legal et al. 1999). The oviposition behavior of *L. bostrychophila* was not investigated, but it follows that if an organism is deterred from an area—whether there is any additive deterrence to oviposition or not—the number of eggs laid will be reduced.

For the purposes of protecting a vulnerable area and minimizing re-infestation, an ideal compound would be one that is highly repellent, causing maximal overall selection in the local area with most—or ideally all—insects choosing the untreated disc. All compounds at 10 mM, except palmitic and stearic acids, would fit into this category. As a treatment to include in a trap, it would be desirable to have increased overall selection with few or no insects on the blank disc. Palmiteoleic acid (0.1 mM) is the most significant compound with this effect, although methyl oleate (0.1 mM) is marginally attractive to *L. bostrychophila*. The use of these compounds as attractants or deterrents would require care to avoid contamination of the area to be protected, especially since monitoring and trapping would be carried out adjacent to foodstuffs or precious museum collections.

The extracts and compounds tested above were derived from *L. bostrychophila*, but there are chemicals in the habitat of booklice that are not of insect origin, especially those compounds that emanate from the stored products that are infested. Fungal hyphae produce palmitic, stearic, oleic, and linoleic acids, and the concentration of these compounds varies both over time and between species (Stahl and Klug 1996). *Liposcelis bostrychophila* respond to differences in fungal chemistry, selecting between extracts of different species (Green 2008), and it could be that the fatty acid composition of these extracts is responsible for this effect. The balance of repellent and attractant fatty acids in fungi might affect which species is selected as food by *L. bostrychophila*, as has been suggested for some species of mycophagous collembola (Nilsson and Bengtsson 2004). Therefore, extracts and fatty acids either repel *L. bostrychophila* as a result of the density of insects that they represent, or the insects move away because the insects do not recognize the mixture of compounds on the discs as a suitable food.

In summary, the results of this study could have a practical application, but they help also to explain more of the chemical ecology of *L. bostrychophila*, building on previous work (Howard and Lord 2003; Lord and Howard 2004; Green and Turner 2005; Green 2005, 2008). Compounds that were not detected by GC-MS constituted between 89 (methanol fractions) and 97% (hexane extract) of the samples. By using thin layer chromatography, it was possible to identify some of these unknown compounds, such as cholesterol, and to tentatively identify phospholipids and triacylglycerols, which are likely to have been extracted from inside the insect. It is not yet known how the different fatty acids and fatty acid methyl esters interact either with each other or with other compounds extracted from the insect. Further work will investigate the effect of combinations of fatty acids and fatty acid methyl esters on settling behavior of booklice; will seek to identify other compounds in the insect extracts; and will look for compounds left behind as *L. bostrychophila* move around their habitat to see whether these could have a function in governing settling and dispersal of populations.

Acknowledgements Dr's. M.-J. Howes and G. Kite are thanked for their advice and technical assistance with the mass spectrometer. I am grateful to Mr. Dudley Farman for running GC-MS analyses of some samples at NRI (University of Greenwich). Dr. P. Stevenson and Professor M. Simmonds are thanked for their comments on a previous version of this manuscript. Anonymous reviewers are thanked for their very helpful suggestions, which significantly improved the manuscript.

Holst, 1942) as an important natural mechanism of disease resistance in honeybee colonies. One of the most important aspects of hygienic behavior is that individual bees must detect and respond to appropriate stimuli from the diseased larvae early in the progression of the infection, before the pathogen becomes infectious. In this way, the quick and efficient detection and removal of diseased larvae by many bees prevents disease transmission throughout the colony.

Specifically, in this study, we investigated the hygienic response of honeybees to the fungal pathogen, *Ascosphaera apis*, which causes chalkbrood disease in larvae (Gilliam et al., 1983). Chalkbrood infection begins in the gut of a larva and grows slowly outward until it penetrates the cuticle. This typically occurs after a fifth instar has been capped, but before pupation begins. At this point, rapid growth and sporulation of the fungus occurs (Gilliam and Vandenberg, 1997). When adult bees remove infected larvae after the fungus has penetrated the cuticle, spores are ingested by adult bees and fed back to healthy larvae in the bee food. The healthy larvae ingest the spores, and the infection is perpetuated. Therefore, for hygienic behavior to be effective against chalkbrood, adult bees must remove the infected larva before the fungus has penetrated the cuticle.

Previous studies have suggested that the detection and subsequent removal of diseased larvae are guided by olfactory stimuli (Masterman et al., 2000, 2001; Gramacho and Spivak, 2003; Spivak et al., 2003). Differences in the degree of hygienic behavior at the colony level result from the relative speed and efficiency with which individual bees perform the behavior (Arathi et al., 2000, 2007; Arathi and Spivak, 2001). A response threshold model was postulated to describe the differences in colony-level expression of the behavior (Arathi and Spivak, 2001). In the laboratory, electrophysiological and behavioral conditioning of the proboscis-extension response (PER) were used to demonstrate that individual bees, from colonies selectively bred for hygienic behavior (see Methods), can detect larvae infected with chalkbrood, and discriminate between diseased and healthy brood at lower stimulus levels, compared to non-hygienic bees (Masterman et al., 2001; Spivak et al., 2003; for review, Fahrbach and Mesce, 2005). These studies, however, did not identify the specific volatile chemicals that bees use to detect diseased larvae, and did not test whether the application of such volatiles to healthy larvae could elicit an appropriate behavioral response in the field or not. In the present study we tested two hypotheses: 1) that hygienic behavior of honey bees can be elicited in field colonies by experimental application of appropriate olfactory stimuli; and 2) that hygienic behavior is based on a threshold response, in which colonies containing bees with the highest olfactory sensitivity to diseased brood initiate the hygienic response more quickly compared to colonies containing bees with a lower olfactory sensitivity.

Methods

Breeding The breeding program for colonies that display hygienic behavior began in 1993 at the University of Minnesota. Rapid-hygienic and slow-hygienic lines of bees (*sensu* Wilson-Rich et al., 2009) were selected from colonies derived from the Italian subspecies *Apis mellifera ligustica*. Colonies were selected initially based on their abilities to survive winter in Minnesota, to increase the population rapidly in spring, to produce large amounts of honey, and to be gentle (not sting) during normal management. If the colonies displayed the above set of traits, they were tested for hygienic behavior using a freeze-killed brood assay (Spivak and Reuter, 1998), which is an indirect measure of a colony's hygienic behavior. The removal of freeze-killed brood is correlated with the removal rates of diseased brood; colonies that uncap and remove >95% of freeze-killed pupae within 24 h will tend to remove diseased brood rapidly. Colonies that exhibited the most rapid removal rates were chosen to raise queens for the next generation. Daughter queens then were instrumentally inseminated with semen from drones of other rapid-hygienic colonies. The criterion for choosing rapid-hygienic colonies for breeding is an arbitrary cutoff established at 95% removal of freeze-killed brood within 24 h. Freeze-killed brood tests of many colonies yield a continuum of values, with colonies that remove a higher proportion of freeze-killed brood having higher degrees of hygienic behavior.

Volatile Collection Volatiles were collected from bees for two reasons. The first was to identify the changes between healthy and diseased brood. Three types of larvae were used: a) healthy fifth instars, b) fifth instars in the early stage of chalkbrood infection, and c) larvae fully overcome with fungal mycelia (mummies). Early stage chalkbrood-infected larvae were identified under a dissecting scope by a subtle discoloration of the larval cuticle, with no evidence of visible sporulation. Each type of larva was removed from the comb with sterile forceps and placed in quick-fit glass aeration chambers (46-cm-long × 19-cm-wide, RodaViss chambers, ARS, Gainesville, FL, USA). The disease was confirmed by fungal growth through the larva after the volatile collections were completed. Collections were determined to be from healthy larvae if no larvae showed clinical symptoms of disease at the conclusion of the volatile collection period. Each collection consisted of: a) 25 healthy fifth instars, b) 25 early-stage infection larvae, or c) 75 mummies. The second reason for collecting volatiles was for use in the gas chromatography-electroantennogram (GC-EAD) experiment. For this, volatiles were collected from a large quantity of healthy larvae or from diseased larvae placed in a larger aeration chamber (80-cm-long × 40-cm-wide, RodaViss chambers, ARS, Gainesville, FL, USA).

For each experiment, the volatile collection apparatus was constructed as follows: charcoal-filtered and humidified air at 0.5 Lmin^{-1} was passed over the larvae and then through pre-conditioned Super-Q adsorbent (30 mg, Grace, *nee* Alltech, Deerfield, IL, USA) traps for 24 h at room temperature. Each trap was eluted with 150 μl methylene chloride forced through the absorbent with filtered nitrogen gas. Elutions were stored at -70°C until used.

Chemical Analysis To identify the disease-related volatiles, chromatograms from the healthy, early-stage infected and fully diseased brood were compared. For the purposes of identification, 174 ng of butyl butyrate, as an internal standard, were added to 40 μl of extract, with 1μl samples of extract analyzed by gas chromatography-mass spectrometry (GC-MS) on an HP-6890 (Agilent Inc., Palo Alto, CA, USA) gas chromatograph linked to an HP 5973 mass spectrometer in the electron impact mode (70 eV, Agilent, Palo Alto). An HP-1 column (30 mm × 0.25 mm ID × 0.25 μm, J & W Scientific, Folsom, CA, USA), with helium as carrier gas, was used for the analyses; injection was splitless. The oven temperature was held at 50ºC for 5 min, then increased at 5ºC min^{-1} to 110°C, then 25°C min^{-1} to 230°C and held at this temperature for 10 min. Volatile compounds were confirmed by comparison of their chromatographic retention times and mass spectra with commercially available standards analyzed on the same instrument.

To isolate compounds perceived by bees, GC-EAD was used for the diseased-brood samples, the healthy larvae samples, and the standards. Aliquots (4 μl) of extracts were analyzed with an Agilent 6890 N gas chromatograph equipped with a TR-Wax column (30 m × 0.32 mm ID × 0.25 μm; Thermo Electron Corp, Belefonte PA, USA). This column permitted better separation of the compounds of interest than the HP1 column. Injection was splitless with helium as carrier gas. The oven temperature was held at 50°C for 5 min, then increased by 5°C min^{-1} to 110°C, then by 25°C min^{-1} to 200°C, and held at this temperature for 5 min. The effluent was split (SGE splitter, SGE Incorp., Austin, TX, USA) to allow simultaneous recording of the flame ionization detector (FID) and the EAD responses. Nitrogen was used as a make-up gas for the FID and as an auxiliary make-up gas (~15 mL min^{-1}) to carry the effluent to the EAD. GC-EAD Pro (Syntech, Hilversum, Netherlands) was used for simultaneous recording of the FID and EAD signals.

EAD recordings were obtained from excised antennae of bees that were 15–20 days old, as this is the age of bee that performs hygienic behavior (Arathi et al., 2000). In 2007, bees of known age were obtained by placing frames with brood ready to emerge in a cage in an incubator for 24 h. Emerged bees were marked with enamel paint on the thorax and returned to the source colonies for collection 15–20 days later. Three source colonies used for the GC-EAD tests were from the University of Minnesota breeding program and were deemed greater than 95% hygienic based on freeze-killed brood tests. The antennae were held between stainless steel electrodes (Syntech), and connections to the electrodes were made with conductivity gel (Spectra Gel® 360, Parker Laboratories, Fairfield, NJ, USA). A humidified air stream, containing the GC effluent, was delivered at 20 ml min^{-1} through a 44-cm glass tube to the antenna.

Field Bioassay I. Topical Applications The topical application assay tested the hypothesis that hygienic behavior of honey bees can be elicited in field colonies by experimental application of appropriate olfactory stimuli to healthy larvae. The assays were conducted in August 2007. Twelve colonies were chosen for the bioassay based on the freeze-kill removal method (one of the source colonies for the GC-EAD analyses also was used in this assay). A comb containing larvae was removed from each of the twelve colonies, and the position of 25 fifth instars on the comb was marked on a transparency overlaying the comb. A Picospritzer II (General Valve Corporation) was used to dispense 0.5 μl of each treatment onto healthy larvae. Five treatments were applied to separate groups of 25 healthy larvae: benzyl alcohol (Sigma-Aldrich, St Louis, MO, USA), 2-phenylethanol (Fluka, Steinheim, Germany), phenethyl acetate (Sigma-Aldrich, St. Louis, MO, USA), deionized water, and a mixture of equal parts benzyl alcohol, 2-phenylethanol, and phenethyl acetate. The compounds were drawn up by capillary action into a 5 μl capillary tube, and a 3 msec pulse of air at 80 psi was used to puff the compound onto a given larva. Neighboring larvae were not treated. The comb then was returned to the colony from which it was taken. At 4 h and 24 h, the transparency was replaced on the frame, and the number of larvae that the adult bees had removed was recorded.

Field Bioassay II. Paraffin Larval Dummies The assay utilizing paraffin larval dummies tested the hypothesis that hygienic behavior is based on a threshold response in which bees with the highest olfactory sensitivity to diseased brood initiate the hygienic response more quickly compared to bees with a lower olfactory sensitivity. Paraffin larval dummies were made by melting paraffin wax at 60–65°C with a 10^{-2} dilution of methyl linolenate (Acros Organics, NJ, USA). Methyl linolenate is one of several compounds present in brood pheromone of fifth instar larvae. When this compound is added to a paraffin wax dummy and placed in a larval cell, adult bees cap the cell containing the dummy (Le Conte et al., 1990). The addition of chalkbrood volatile compounds to wax dummies that contain brood pheromone

should result in a decrease in capping of these dummies, if adult bees detect and respond to the disease-related compounds. Bees are unable physically to remove paraffin dummies from the cell at nest temperatures (32–34°C), because the paraffin is soft and sticky. Therefore, in this assay, when brood pheromone was added to the paraffin dummy, and bees placed a wax capping over the dummy, it was an indication that the adult bees accepted the 5th instar as normal. When both brood pheromone and disease volatile(s) were added to the paraffin, and the bees did not cap the dummies with wax, it was assumed that bees detected the disease volatiles and exhibited hygienic behavior.

The response threshold model was tested by measuring the differential abilities of adult bees to detect chalkbrood compounds at differing concentrations. Using the mixture of wax and methyl linolenate, a total of eight treatments was formulated: phenethyl acetate at 10^{-2} (v/v) and 10^{-9}, 2-phenylethanol at 10^{-2} and 10^{-9}, benzyl alcohol at 10^{-2} and 10^{-9}, and a mixture of the previous three compounds at 10^{-2} and 10^{-9}. The concentrations were chosen based on differences in the frequency of capping observed in the preliminary development of this assay. Additional treatments consisted of methyl linolenate (in wax) alone and of paraffin wax without the addition of methyl linolenate or disease-associated compounds. The liquid wax containing each treatment was poured into plastic drinking straws (0.5 cm diam) and allowed to cool and harden. The straw then was cut away from the wax, and the wax was cut into 25 mm sections to create larval dummies.

The assays were conducted in August 2008. Six colonies that displayed varying degrees of hygienic behavior, ranging from 39% to 99%, as determined through freeze-killed brood assays (see Fig. 3), were chosen for this bioassay. A comb containing fifth instars was removed from the colony. Combs with fifth instars were chosen so that the larval dummies would be in context with actual fifth instars that were about to be capped with wax by adult bees. Twenty larval dummies of each treatment were placed into empty cells, and their location was marked on a transparency. No more than two treatments were tested on a single comb at a time. The combs were then returned to the colony and the number of dummies the bees capped with wax was recorded after 24 h.

Statistical Analysis Binomial regressions were performed to compare the proportion of healthy topically treated larvae removed or paraffin dummies left uncapped in response to each treatment, with the degree of hygienic behavior of the colony as a covariate. The delta method was used to calculate the student's t value for contrasts between treatments with differences declared at $\alpha=0.05$. Analyses were done with *Arc* (Cook and Weisberg, 1999).

Results

Chemical Analysis Mass chromatograms of volatiles collected from healthy fifth instars and larvae in early stages of chalkbrood infection are shown in Figure 1. Three peaks associated with diseased brood were non-detectable in collections from the healthy brood; these peaks appeared in the early stage diseased larvae and increased in quantity in those fully diseased. GC-MS analyses identified these compounds as phenethyl acetate, 2-phenylethanol, and benzyl alcohol. GC-EAD analyses of the volatiles of larvae in the early stages of chalkbrood infection showed that bee antennae responded consistently to these compounds (Fig. 2).

Field Bioassay I. Topical applications Colonies with higher degrees of hygienic behavior removed more treated larvae at 4 h ($t=4.844$, $df=54$, $P<0.001$) and at 24 h ($t=8.917$, $df=54$; $P<0.001$) compared to colonies that displayed slower hygienic behavior. There were no significant differences in the slopes of the regression lines among treatments; all colonies responded similarly to all treatments 4 h and 24 h after treatment (interaction between treatment and hygienic behavior for all; $P>0.05$).

At 4 h, most larvae treated with 2-phenylethanol, benzyl alcohol, the mixture, and water were not removed. However, more larvae treated with phenethyl acetate were removed compared to all other treatments: 2-phenylethanol ($t=4.485$, df=54, $P<0.001$), benzyl alcohol ($t=4.483$, df=54, $P<0.001$), the mixture ($t=6.181$, df=54, $P<0.001$), and water ($t=3.557$, df=54, $P<0.001$). Phenethyl acetate removal rates ranged from 0 to 84%.

At 24 h, there were significant differences in removal among all treatments (Table 1 and Fig. 3). Larvae treated with phenethyl acetate were removed in greatest numbers followed by larvae treated with the mixture, 2-phenylethanol, benzyl alcohol, and water (Fig. 3).

Field Bioassay II. Paraffin Larval Dummies None of the colonies capped paraffin dummies that lacked brood pheromone. The addition of the brood pheromone component, methyl linolenate, to the dummies resulted in a significant increase in capping. Capping of brood pheromone dummies ranged from 70% to 95%.

As predicted, when dummies were treated with both brood pheromone and one or a mixture of the disease volatiles, the bees in all colonies capped significantly fewer dummies treated with higher concentrations (10^{-2}) of the diseased larval compounds, as compared to dummies treated with lower concentrations (10^{-9}). This was true for all compounds: phenethyl acetate ($t=4.437$, $df=9$, $P<0.001$), 2-phenylethanol ($t=9.778$, $df=9$, $P<0.001$), benzyl alcohol ($t=7.388$, $df=9$, $P<0.001$), and the mixture

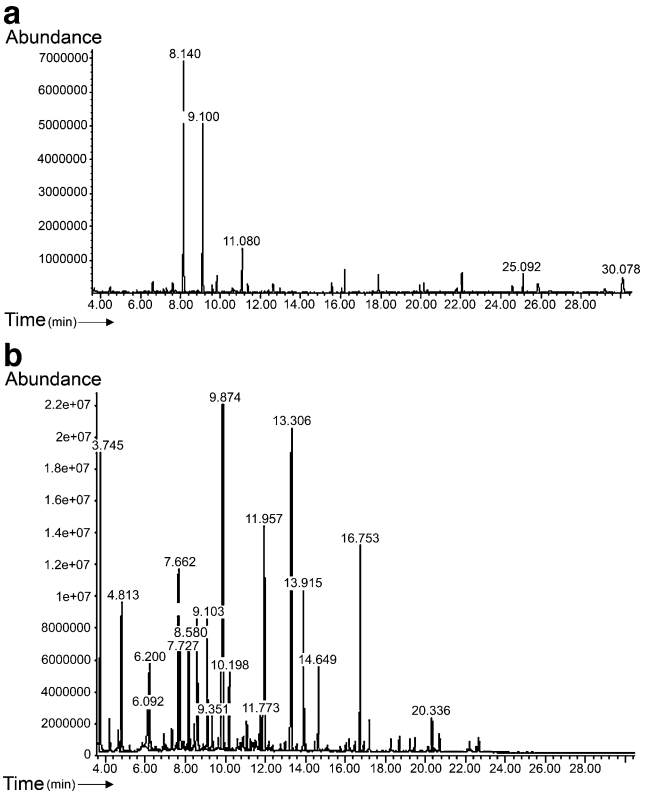

Fig. 1 Representative total ion mass chromatograms of volatile chemicals released by a) healthy 5th instar honeybee larvae and b) 5th instar larvae in early stages of chalkbrood infection. Retention time (min) of compounds of note: 8.14- butyl butyrate (IS), 8.58- benzyl alcohol, 9.1- (*E*)-β-ocimene, 9.874- 2-phenylethanol, 11.957- phenethyl acetate

(t=3.138, df=9, P=0.001) (Fig. 4). Colonies with higher degrees of hygienic behavior capped significantly fewer larval dummies (P<0.001). There were no significant differences in the slopes of the regression lines among treatments in the paraffin experiment, and the interaction between treatment and hygienic behavior, for all treatments, was not significant (P>0.05).

At the higher concentration (10^{-2}), there was no significant difference among the number of dummies capped for the treatments phenethyl acetate, the mixture, and paraffin alone. Dummies treated with phenethyl acetate, the mixture, and paraffin were capped significantly less than those treated with 2-phenylethanol and benzyl alcohol. All dummies treated with compounds at the 10^{-2} concentration were capped significantly less than those treated with the brood pheromone component alone, methyl linolenate (Table 2).

At the lower concentration (10^{-9}), dummies treated with phenethyl acetate and the mixture were capped significantly less frequently than dummies treated with methyl linolenate, 2-phenylethanol or benzyl alcohol. There was no difference in the numbers of dummies capped between the treatments methyl linolenate alone and 2-phenylethanol, methyl linolenate alone and benzyl alcohol, and between 2-phenylethanol and benzyl alcohol. There was no significant difference in the removal of dummies treated with phenethyl acetate or with the mixture (Table 3).

Discussion

This is the first identification of volatile compounds associated with diseased honeybee larvae that elicit hygienic behavior in adult honeybees. Three volatile compounds collected from larvae infected with the fungal pathogen, *Ascosphaera apis*, were not detected in healthy brood, and elicited electroantennogram responses from adult honeybees. Our bioassays showed that of the three compounds, phenethyl acetate elicited the greatest hygienic responses from bees in field colonies.

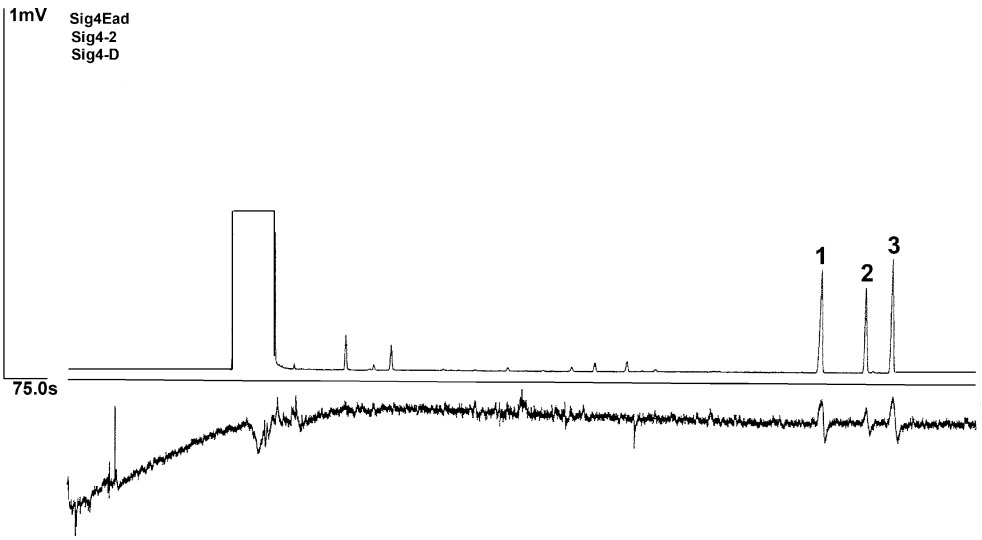

Fig. 2 Representative coupled gas chromatographic-electroantennographic detection (GC-EAD; flame ionization detection response shown on top; EAD response shown on bottom) traces of compounds collected from early stage chalkbrood-infected larvae, using antennae of 15–20 day-old honeybees. Numbered peaks correspond to compounds that elicited consistent EAD responses: 1) phenethyl acetate, 2) 2-phenylethanol, and 3) benzyl alcohol

Table 1 Student's *t* and *p* values of delta contrasts between odorant treatments for proportion of topically treated larvae removed by adult bees at 24 hours. Larvae were treated with 0.05 µl of an individual chemical or a mixture of the three chemicals

$\alpha = 0.05$, $df = 54$.

Colony-level behavioral responses to parasites and pathogens are an integral part of social immunity, but reports of social animals detecting and responding to diseased conspecifics are not common. Such behavioral responses generally involve avoidance or engagement (e.g., grooming or removal) of conspecifics that are infected, which likely involves the detection of disease-related chemical stimuli. For example, gregarious Caribbean spiny lobsters *Panulirus argus*, which occupy communal dens, exhibit avoidance behavior of lobsters infected with a lethal virus, even during early periods when the lobsters are not yet infectious (Behringer et al., 2006). Leaf cutting ants, *Acromyrmex echinatior,* use self- and allo-grooming behaviors in defense of the fungal disease *Metarhizium anisophae* (Hughes et al., 2002). Ants detect oleic and linoleic acids, emitted from dead adult conspecifics in their nests, and exhibit necrophoric or undertaking behavior, which favor colony health by reducing contact with potential pathogens (Wilson et al 1958; Akino and Yamaoka, 1996; Howard and Tschinkel, 1976). Honeybees also display necrophoric behavior, although the chemical cues have not been identified (Visscher, 1983). Our study demonstrated that disease-related odorants are important because the early detection and efficient removal of the source of the pathogen reduce disease transmission among individuals within the nest.

Our field bioassays confirmed two hypotheses, previously tested only in laboratory assays (Masterman et al., 2001; Spivak et al., 2003): 1) hygienic behavior of honey bees is elicited by olfactory stimuli; and 2) the expression of hygienic behavior depends on the olfactory response threshold of individual bees within the colony. Colonies that contain a majority of bees with high olfactory sensitivity respond quickly to low concentration stimuli associated with diseased brood, while colonies of bees with lower sensitivity take longer to respond, allowing transmission of spores and expression of clinical symptoms.

The compounds that elicited consistent GC-EAD responses, phenethyl acetate, 2-phenylethanol, and benzyl alcohol, were present both in larvae in the early stages of infection and in mummies, but were absent from healthy larvae. At this time, it is unclear whether the chemicals are produced by the larvae (pheromonal) or by the fungus (kairomonal). Laboratory inoculation with chalkbrood of potato dextrose agar, pollen and homogenized and sterilized brood failed to produce emissions of these volatiles, suggesting that the compounds are produced only in the presence of live brood (Baldwyn Torto, USDA, unpublished data).

When 0.5 µl of synthetic disease-associated volatile chemicals were applied topically to healthy larvae, adult bees responded to the olfactory stimulus and removed healthy larvae as though they were diseased. The degree of hygienic behavior, as indicated by the amount of freeze-killed brood removed within 24 h, was affected by the colony level response. The more hygienic a colony, the more likely the removal of larvae treated topically with disease-associated compounds. Bees removed up to 100% of healthy larvae treated with phenethyl acetate within 24 h, which is roughly the same time it takes bees from a rapid-hygienic colony to remove freeze-killed brood. We have not determined the odor of freeze-killed brood for comparison.

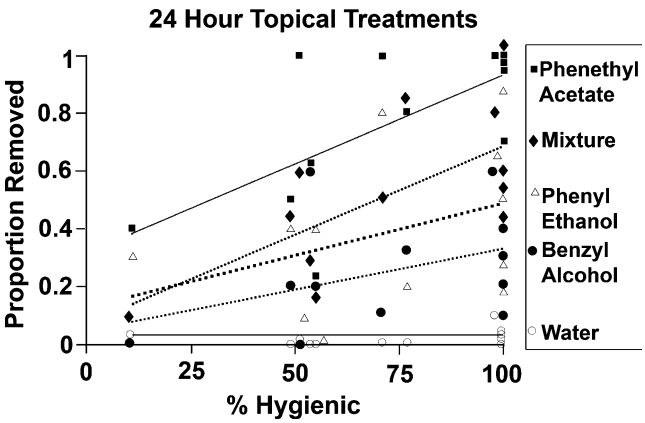

Fig. 3 Regression lines comparing the proportion of healthy larvae removed by adult bees, for each treatment at 24 h (y-axis), to the degree of hygienic behavior [based on the percent of dead brood removed in the freeze-killed brood assay (x-axis)]. Each point corresponds to the results from one of the twelve colonies treated. Treatments applied topically to larvae included de-ionized water (N=10 larvae per colony), phenethyl acetate, 2-phenylethanol, benzyl alcohol, or a mixture of the three chemicals (N=25 larvae per colony for each chemical treatment). Regression lines correspond to the compound listed to the right of each line. Significantly different proportions of larvae were removed for each treatment (Table 1; Student's *t,* a= *0.05, df= 54; P*<0.002)

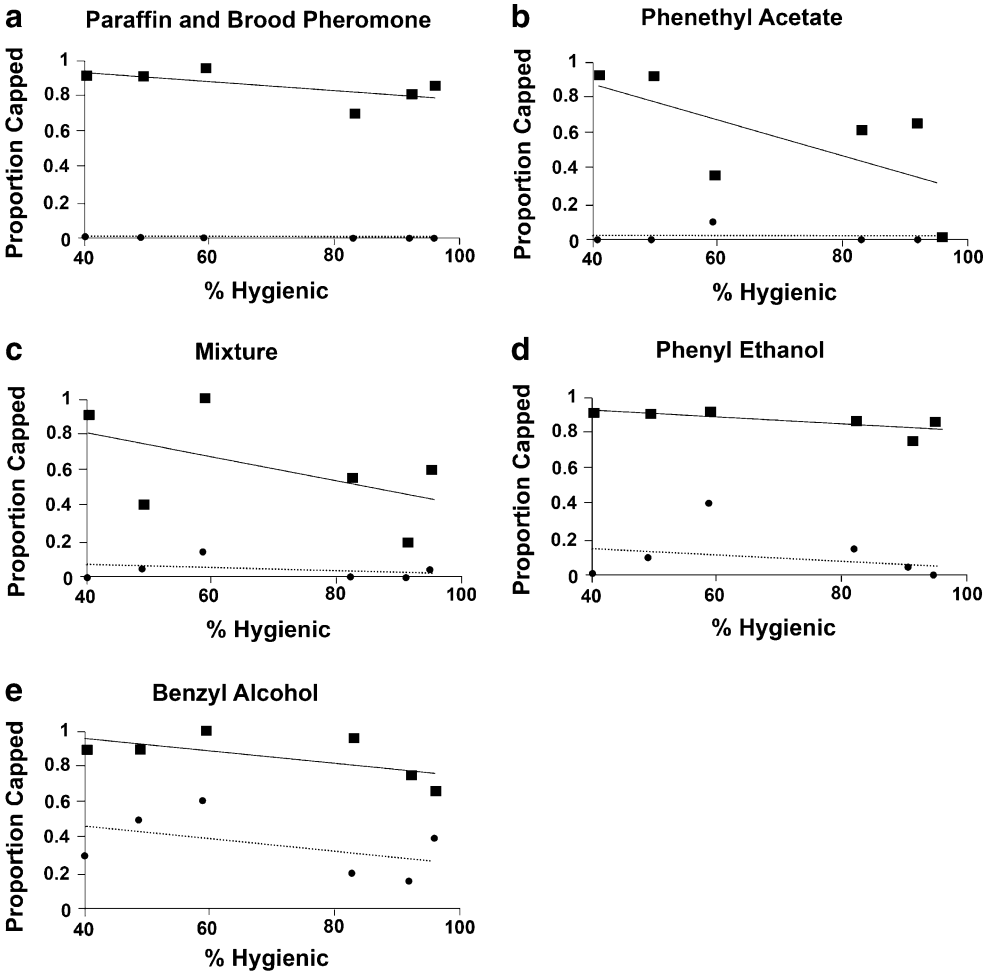

Fig. 4 Regression lines comparing the proportion of paraffin larval dummies capped with wax by adult bees to the degree of hygienic behavior (based on the percent of dead brood removed in the freeze-killed brood assay). Bees are unable to remove paraffin dummies, thus a lower proportion of capping was an indication of rejection of the cell's contents by adult bees; i.e., hygienic behavior. A) Rejection of dummies treated with brood pheromone (squares, top line) and paraffin dummies (circle, bottom line). B – E) Rejection of dummies treated with each compound or a mixture of the compounds, at high concentrations (10^{-2}; circles, bottom lines) and low concentrations (10^{-9}; squares, top lines). Each point corresponds to the results from one of the six colonies treated. Treatments (20 per treatment per colony): paraffin wax only, paraffin wax plus brood pheromone (methyl linolenate), paraffin wax plus brood pheromone plus one of phenethyl acetate, 2- phenylethanol, benzyl alcohol, or a mixture of the three

Bees are very sensitive to abnormal stimuli from larvae. For example, when larvae are touched with a paintbrush, larvae are removed within 5 h (Free and Winder, 1983). Our original intent was to test the response-threshold hypothesis by diluting disease-related compounds in a solvent. However, we observed that application of hexane or pentane alone induced very rapid removal, within 4 h, indicating that solvents elicited an unnatural and abnormally fast removal response. Although bees did not remove larvae treated with water (control in one assay), water was not a suitable solvent for phenethyl acetate, 2-phenylethanol, or benzyl alcohol. Thus we used an indirect bioassay to test

Table 2 Student's *t* and *p* values of delta contrasts between various treatments of paraffin larval dummies capped with wax by adult bees at 24 hours. Paraffin dummies were treated with one component of brood pheromone (methyl linolenate) alone at a 10^{-2} concentration (v/v), or brood pheromone (10^{-2}) plus one additional chemical or a mixture of three chemicals at a 10^{-2} concentration (v/v)

the response-threshold hypothesis by combining brood pheromone and disease volatiles at two different concentrations in paraffin larval dummies. When one component of brood pheromone, methyl linolenate, was added to a paraffin dummy placed within a cell, bees capped that dummy with wax as though it were a 5th instar ready to pupate. However, when both brood pheromone and disease-related volatile(s) were added to the paraffin, bees from rapid-hygienic colonies did not cap the dummies with wax; apparently they detected the disease-associated volatiles over the brood pheromone and behaved accordingly. We observed that bees with less olfactory sensitivity (slow-hygienic colonies) were not able to detect the disease-associated volatiles over the brood pheromone, and initiated the capping of the dummy. We determined that there was a significant correlation between the level of hygienic behavior, as indicated by the freeze-killed brood assay and the lack of capping of the treated paraffin dummies. Thus, the lack of capping in this assay was an indirect, but sensitive, measure of the level of hygienic behavior of the tested colonies.

We expected that a mixture of phenethyl acetate, 2-phenylethanol, and benzyl alcohol would elicit an increased response from honeybees over any of the compounds tested singly. However, our two bioassays showed no difference between responses to the mixture and that of phenethyl acetate alone, suggesting a lack of mixture-specific synergistic effects. It should be noted that only one ratio of components was tested in our bioassays; it is possible that a different ratio may give enhanced stimulation.

The results of this study have a practical application for beekeepers and important implications for the health of honey bees. It is critical that the beekeeping industry reduce its reliance on chemical treatments for diseases and parasitic mites due to the risk of contaminating hive products with residue, and the development of resistance to the treatments by the pathogens and parasites (Milani, 1999; Wallner, 1999). The most sustainable solution is to breed bees selectively for resistance to diseases and mites. To date, hygienic behavior is one of the few resistance mechanisms that has a simple field assay that beekeepers can employ. Colonies that rapidly remove freeze-killed brood tend to be behaviorally resistant to two brood pathogens, chalkbrood, *A. apis*, and American foulbrood, *Paenibacullus larvae* (Spivak and Reuter, 2001a). Colonies that rapidly remove freeze-killed brood also tend to detect and remove pupae infested with the parasitic mite, *Varroa destructor* (Spivak, 1996). However, the correspondence between the removal of freeze-killed brood and removal of diseased or parasitized brood is not perfect. For example, when 18 rapid-hygienic colonies, as determined by the freeze-killed brood assay, were challenged with American foulbrood pathogen, two colonies developed persistent clinical symptoms of the disease (Spivak and Reuter, 2001a). Also, colonies selected for hygienic behavior still require treatments to control *V. destructor*, as the bees are unable to detect and remove sufficient infested pupae during high mite infestations (Spivak and Reuter, 2001b; Ibrahim et al, 2007). While hygienic behavior is a generalized response to the presence of diseased, parasitized, and abnormal pupae, it is necessary to have a more specific assay to breed colonies selectively for resistance to a particular pathogen or parasite. The experiments performed here could be modified to focus on the specific stimuli that elicit detection and removal of larvae infected with the American foulbrood pathogen and pupae infested with *V. destructor*, thus furthering efforts to breed bees for resistance to these economically important problems.

2003; Billen 2006). The insect body is covered by a cuticle that is made up of layers, the outermost layer (epicuticle) is composed of a mixture of lipids synthesized by oenocytes (Lockey 1988). These lipids regulate permeability and prevent desiccation (Ayasse et al. 2001; Ayasse 2006). However, there is evidence that the epicuticlar lipids of Hymenoptera also act as pheromones and/or as caste/sex recognition cues (Singer 1998; Ayasse et al. 2001; Ayasse 2006). Bioassays have demonstrated that cuticular hydrocarbons of some species act as sex pheromones and that the cuticular hydrocarbons of some parasitic insects are similar to those of their respective host species (Singer 1998). As an example, cuticular waxes of drones, food storers, foragers, and queen attenders of *Apis mellifera* are used to discriminate intraspecific roles inside the colony (Fröhlich et al. 2001). In contrast, behavioral and chemical assays that involve males and females of the solitary bee *Amegilla dawsoni* suggest that cuticular hydrocarbons are important in sexual communication (Simmons et al. 2003). Cuticular hydrocarbons also are a clue to understanding one of the most spectacular biological phenomena: orchid pollination through sexual mimicry (or pseudocopulation) (Ayasse 2006). Sexual mimicry was detected in the Neotropical orchids *Trigonidium obtusum* and *Mormolyca ringens*, which are pollinated by *Plebeia droryana* males and *Nannotrigona testaceicornis* stingless bees, respectively (Singer 2002; Singer et al. 2004).

The Dufour gland is important in bees. It is located at the base of the sting apparatus, ventrally to the poison gland, and opens into the dorsal vaginal wall (Roubik 1989; Cruz-López et al. 2001; Abdalla et al. 2004). It normally is present in some females of Apoidea, but is absent or vestigial in workers of *Melipona* species (Patricio et al. 2003). The Dufour glands secrete a variety of compounds (macrolactones, hydrocarbons, triglycerides, and terpenoids), and each species has a particular chemical composition (Abdalla et al. 2004). In *Nannotrigona testaceicornis* workers, the major substance is geranylgeranyl acetate (Cruz-López et al. 2001); the same compound is detected in labial secretions of *Bombus* males and used as a territorial pheromone (Kullenberg et al. 1970). In *Melipona bicolor* virgin queens, the Dufour gland contains predominantly hydrocarbons, while in *Melipona bicolor* physogastric queens, isobutyrate and acetate esters are the main components. Compositional differences in the Dufour gland of queens may indicate the queen's fecundity condition, while the oxygenated compounds in secretions of physogastric queens may increase their attractiveness to males (Abdalla et al. 2004).

Communication between bees also can be achieved through cephalic volatile compounds. Many species of stingless bees and honeybees produce cephalic substances that serve as alarm or sexual pheromones, and odor trail markers (Luby et al. 1973; Hefetz et al. 1979; Bian et al. 1984; Engels et al. 1987, 1997; Roubik et al. 1987; Francke et al. 2000; Cruz-López et al. 2005). *Trigona, Oxytrigona, Scaptotrigona, Cephalotrigona, Lestrimelitta*, and *Nannotrigona* deposit cephalic substances on vegetation as a trail marker (Roubik 1989). Analyses of *Frieseomelitta varia* and *F. silvestrii* volatiles in cephalic secretions reveal the presence of volatile oxygenated compounds (Cruz-López et al. 2002). Cephalic secretions from newly emerged, nurse, and forager workers, virgin and physogastric queens, and males of *Melipona bicolor* are caste-sex specific. They consist of hydrocarbons, alcohols, esters, and acids. These secretions differentiate the tasks performed by workers and the physiological reproductive condition of queens (Gracioli-Vitti et al. 2004).

Both species studied in our present work, *Nannotrigona testaceicornis* and *Plebeia droryana*, belong to the Trigonini group. *P. droryana* is one species in a large group of small stingless bees, the *Plebeia* group, and is considered "basic" since it does not have many derived characters. Members of the *Plebeia* group are found in the New World, as well as in Australia, Asia, and Africa (Moure 1961; Michener 2000). The chemical features of caste-sex recognition in *N. testaceicornis* and *P. droryana* (Meliponinae) are limited, and studies of interspecific and intraspecific communication are necessary to understand the intricate behaviors.

Methods and Materials

Biological Material All stingless bees were collected at the "Aretuzina" farm in São Simão, SP, Brazil. Foraging workers from three different *N. testaceicornis* colonies and one colony of *P. droryana* (N=8 of each species) were collected while flying away from their colonies. Males of *P. droryana* (N=8) were collected while attempting copulation with *Trigonidium obtusum* flowers (Orchidaceae) (Singer 2002). Males of *N. testaceicornis* (N=8) were collected while attempting copulation with *Mormolyca ringens* flowers (Orchidaceae) (Singer et al. 2004).

Chemicals *n*-Alkane standards (C_{10}–C_{37}) were obtained from petroleum (100 ml), by silica gel (Acros Organics, USA, 0.035–0.070 mm, 60 A) column chromatography using bidistilled hexane as solvent. The distilled and bidistilled solvents—ethyl acetate (99.5%) and hexane (98.5%) both from Synth, Brazil—and diethyl ether (99%); Nuclear, Brazil) were obtained according to the method described by Perrin et al. (1980). Iodine (Rothyl, USA, 99%), dimethyl disulfide (Aldrich, Germany, 99%), anhydrous magnesium sulphate (Nuclear, Brazil, 99%), anhydrous sodium thiosulphate (Merck, Brazil, 99%),

chloroform-D (Cambridge Isotope Laboratories, USA, 99.8%), farnesol—mixture of isomers (Aldrich, USA, 95%), farnesyl acetate—mixture of isomers (Aldrich, USA, 95%), (*S*)-(+)-2-heptanol (Aldrich, USA, 99%), (*S*)-(+)-2-nonanol (Aldrich, USA, 97%), (±)-2-heptanol (SAFC, USA, 97%), (±)-2-nonanol (Aldrich, USA, 99%), and (±)-2-undecanol (Fluka, France, 98%) were used as provided. Synthetic standards of lauryl acetate, octadecyl acetate, tetradecyl dodecanoate, and hexadecyl hexadecanoate—all 99% purity—were prepared in our laboratory using usual procedures (Larock 1989). The spectroscopic properties of these synthetic standards were compared with data in the literature (Bertsch et al. 2004).

Cuticular Wax Extracts Foraging workers (*N*=8) and males (*N*=8) of *N. testaceicornis* and *P. droryana* were freeze killed (−18°C) and dipped into bidistilled hexane (2 ml, for 5 min). The solvent was evaporated under a flow of nitrogen. Extracts were dissolved in hexane (1 mg/ml) and analyzed by gas chromatography-mass spectrometry (GC-MS) by injecting 1 µl of each extract (Table 1).

Abdomen and Cephalic Extracts After washing with bidistilled hexane (2 ml), bee abdomens and heads of foraging workers and males of *N. testaceicornis* and *P. droryana* were separated and macerated with bidistilled ethyl acetate (2 ml). Extracts were filtered, evaporated with nitrogen, dissolved in ethyl acetate (1 mg/ml), and analyzed by GC-MS (1 µl of each extract) (Table 1).

GC-MS Analyses were carried out with an HP 6890/5973 system equipped with an HP5 fused silica capillary column (30 m×0.25 mm×0.25 µm). Helium was used as carrier gas, at a flow rate of 1 ml/min in splitless mode. Spectra were taken at 70 eV, and the scanning speed was 2.89 scans/s from *m/z* 40 to 550. The interface temperature was maintained at 280°C, and the injector temperature was 250°C. The temperature program used to analyze wax samples went from 50°C–290°C at 12°C/min with a final hold time of 20 min. Derivatized samples used a temperature program from 50°C–290°C at 12°C/min with a final hold time of 50 min.

Chiral GC-FID Analyses GC-FID analyses were conducted with an Agilent Technologies 6850 chromatograph equipped with a chiral capillary column (Chrompack CP-Chirasil-Dex CB; 25 m×0.25 mm×0.25 µm). The carrier gas was highly purified hydrogen with a flow rate of 0.8 ml/min. Injector and detector temperatures were 180°C and 220°C, respectively. (*S*)-(+)-2-Nonanol and (±)-2-nonanol were dissolved in bidistilled ethyl acetate (100 µg/ml) and injected in split mode (1/50); the oven temperature was programmed from 50°C to 100°C at 0.4°C/min. The same procedure was used to analyze a 2:1 mixture of (±)-2-nonanol (100 µg/ml) and (*S*)-2-nonanol (50 µg/ml). Abdominal and cephalic extracts of *P. droryana* males were dissolved in 20 µl of bidistilled ethyl acetate. A 4:1 mixture composed of male *P. droryana* extracts and (±)-2-nonanol (25 µg/ml) were co-injected in splitless mode. The temperature program increased from 50°C–100°C at 0.4°C/min, then from 100°C–180°C at 30°C/min), and then held at 180°C for 20 min.

Retention Indexes Identification of the extract components were made based on comparison of their retention indices (Van den Dool and Kratz 1963), as well as by computer matching of the mass spectra obtained with those in the Wiley 275 mass spectral library of the GC/MS data system and other published mass spectra (Adams 2001; Table 1). Retention indexes for the *n*-alkane standards (C_{10}–C_{37}) were taken as whole numbers from 1000 to 3700. The (*Z*) and (*E*)-alkenes were identified by their Equivalent Chain Length (ECL = RI/100) values compared with the literature (Ashes et al. 1980; Howard and Baker 2003).

DMDS/I_2 Derivatizations The samples with alkenes were dissolved in bidistilled hexane (2 ml) and treated with dimethyl disulfide (DMDS; 200 µl) and iodine solution (100 µl of 32 mg of I_2 in 2 ml of distilled diethyl ether). Reaction mixtures were stirred overnight at 50°C with magnetic stirring. Reaction mixtures were quenched with aqueous sodium thiosulfate solution (2 ml of 1 g $Na_2S_2O_3$ in 10 ml of distilled water). The organic phase was extracted, dried over anhydrous MgSO4, and evaporated to dryness with a nitrogen stream (Buser et al. 1983; Vincenti et al. 1987). The derivativitized samples were dissolved in bidistilled hexane (50 µl), and 1 µl of each sample was analyzed by GC-MS.

NMR Analyses ^{1}H-NMR spectra were recorded with Varian INOVA 500 (499.88 MHz) spectrometer equipped with a 5 mm probe. $CDCl_3$ was used as the solvent. ^{13}C- NMR analyses were recorded with a Varian INOVA 500 (125.69 MHz) spectrometer equipped with a nanoprobe of 50 µl. $CDCl_3$ (77.0 ppm) was used as internal standard. Methyl, methylene, methane, and carbon nonbonded to hydrogen were discriminated using DEPT-135° and DEPT-90° spectra (distortionless enhancement by polarization transfer).

Field Tests The responses of *P. droryana* and *N. testaceicornis* to the synthetic secondary alcohols [(*S*)-(+)-2-heptanol, (*S*)-(+)-2-nonanol, a 1:1 mixture of (*S*)-(+)-2-heptanol and (*S*)-(+)-2-nonanol, (±)-2-heptanol, (±)-2-nonanol, and (±)-2-undecanol] were evaluated in December 2008 and again in January 2009. Compounds were tested in an open

Table 1 GC-MS analyses of *Nannotrigona testaceicornis* and *Plebeia droryana* extracts

field close to several *Meliponini* nests at the University of São Paulo, Ribeirão Preto-SP, Brazil. Strips of filter paper containing approximately 2 μl (1.65 mg) of each (*S*)-2-alkanol were deposited 1.5 m from a shelf containing colonies of *P. droryana*, *N. testaceicornis*, *S.* aff. *depilis*, *F. varia*, *F. silvestrii, Tetragonisca angustula* and *Friesella schrottkyi*. The experiment was repeated on three different shelves containing the same species. Strips were monitored for 10 min to test the ability of alkanols to elicit behavioral responses. At the end of the observing period, the specimens around the paper trips were collected, counted and identified.

Results

Extracts of Cuticular Waxes N. testaceicornis male cuticular waxes (eight specimens=0.800 mg) were found to be composed of *n*-alkanes (16.58%; *n*-C23, *n*-C25, *n*-C27, and *n*-C29), *n*-alkenes (53.39%; *n*-(*Z*)-9-C27, *n*-(*Z*)-9-C29, and *n*-(*Z*)-9-C31), an *n*-alkadiene (4.18%; *n*-9,21-C31), an aromatic alkane (5.18%; 2-phenyl-tridecane), and terpenes (11.0%; α-copaene, *Ar*-curcumene, α-murolene, δ-cadinene, 1-*cis*-calamenene, cadalene, and squalene) (Table 1). *N. testaceicornis* worker cuticular waxes (eight specimens) =0.568 mg) were composed of *n*-alkanes (22.69%; *n*-C15, *n*-C21, *n*-C23, *n*-C25, *n*-C27, and *n*-C29), *n*-alkenes (50.37%; *n*-(*Z*)-9-C25, *n*-(*Z*)-9-C27, *n*-(*Z*)-9-C28, *n*-(*Z*)-9-C29, and *n*-(*Z*)-9-C31), an *n*-alkadiene (2.62%; *n*-9, 21-C31), and terpenes (10.13%; α-copaene, *Ar*-curcumene, α-murolene, δ-cadinene, 1-*cis*-calamenene, α-calacorene, cadalene, and squalene).

P. droryana male cuticular waxes (eight specimens= 0.904 mg) consisted of *n*-alkanes (19.61%; *n*-C25, *n*-C27, *n*-C29, and *n*-C31), *n*-alkenes (72.83%; *n*-(*Z*)-9-C25 to *n*-(*Z*)-9-C29, *n*-(*Z*)-9-C31, and *n*-9-C33), and terpenes (0.37%; δ-cadinene) (Table 1). *P. droryana* foraging worker waxes (eight specimens=0.800 mg) contained *n*-alkanes (16.81%; *n*-C25, *n*-C27, and *n*-C29), *n*-alkenes (69.62%; *n*-(*Z*)-9-C25 to *n*-(*Z*)-9-C29, *n*-(*Z*)-9-C31, and *n*-9-C33), terpenes (3.88%; α-copaene, *Ar*-curcumene, δ-cadinene, 1-*cis*-calamenene, geranyl linalool, and squalene), and a terpenic ester (2.30%, nerolidol acetate).

Abdomen Extracts N. testaceicornis male abdomens (eight specimens=0.400 mg) were composed of *n*-alkanes (6.07%; *n*-C25 and *n*-C27), *n*-alkenes (63.88%; *n*-(*Z*)-9-C27, *n*-(*Z*)-9-C29, and *n*-(*Z*)-9-C31), an *n*-alkadiene (7.08%; *n*-9,21-C31), terpenes (11.60%, α-copaene, *Ar*-curcumene, δ-cadinene, 1-*cis*-calamenene, and squalene), and a steroid (3.04%; stigmast-5-en-3β-ol) (Table 1). The abdomens of *N. testaceicornis* foraging workers (eight specimens=0.464 mg) contained *n*-alkanes (0.52%; *n*-C25 and *n*-C27), *n*-alkenes (3.58%; *n*-(*Z*)-9-C27, *n*-(*Z*)-9-C28, *n*-(*Z*)-9-C29, and *n*-(*Z*)-9-C31), an *n*-alkadiene (0.33%; *n*-9,21-C31), a branched alkatetraene (0.37%; 7,11,15-trimethyl-3-methylene-1,6,10,14-hexadecatetraene), terpenic esters (84.35%; farnesyl acetate and geranyl-geranyl acetate), a long chain ester (0.04%, lauryl acetate), and a steroid (0.27%; stigmast-5-en-3β-ol).

The structure of geranylgeranyl acetate (**1**) was determined by GC-MS and ^{1}H- and ^{13}C-NMR using the crude abdominal secretion extracts of *N. testaceicornis* workers. EIMS (70 eV)–*m/z* (%): 332 (M^{+}, 0.1), 272 (4.0), 257 (4.0), 243 (1.0), 229 (4.0), 217 (1.0), 203 (7.0), 189 (8.0), 175 (4.0), 161 (15.0), 147 (14.0), 133 (19.0), 119 (26.0), 107 (37.0), 93 (56.0), 81 (52.0), 69 (100), 55 (15), 41 (44). ^{1}H NMR (499.88 MHz, $CDCl_3$): δ 1.57–1.70 ppm (4 *s*, 15 H), 1.98 (*m*, 6H), 2.04 (*s*, 3H, CH_3COO), 2.05 (*m*, 6H), 4.60 (*d*, 2H, *J*=6.5 Hz), 5.10 (*m*, 3H), 5.30 (*t*, 1H, *J*=6.5 Hz). ^{13}C NMR (DEPT 135° and 90°, 125.69 MHz, $CDCl_3$): δ 16.00 ppm (CH_3), 16.10 (CH_3), 16.50 (CH_3), 17.70 (CH_3), 21.10 (CH_3), 25.71 (CH_3), 26.22 (CH_2), 26.64 (CH_2), 26.77 (CH_2), 39.55 (CH_2), 39.69 (CH_2), 39.74 (CH_2), 61.42 (CH_2), 118.24 (CH), 123.61 (CH), 124.19 (CH), 124.40 (CH), 135.00 (C), 135.51 (2C), 144.50 (C), 172.50 (C = O).

Abdomens from male *P. droryana* (eight specimens= 0.704 mg) were composed of *n*-alkanes (3.51%; *n*-C25, *n*-C27, *n*-C29, and *n*-C31), *n*-alkenes (23.56%; *n*-(*Z*)-9-C25, *n*-(*Z*)-9-C29, *n*-(*Z*)-9-C31, and *n*-9-C33), a terpene (0.17%; squalene), an alcohol (0.08%; (*S*)-2-nonanol), an aldehyde (0.15%; nonanal), acids (8.81%; *n*-C12, *n*-C14, *n*-C16, *n*-C18, and mixtures of C18:2 and C18:3 fatty acids), and steroids (10.59%; ergostadien-3β-ol, ergost-5-en-3β-ol, stigmast-5-en-3β-ol, and stigmastadien-3β-ol) (Table 1). *P. droryana* foraging worker abdomens (eight specimens= 0.400 mg) contained *n*-alkanes (0.63%; *n*-C25 and *n*-C27), *n*-alkenes (4.94%; *n*-(*Z*)-9-C25, *n*-(*Z*)-9-C27, *n*-(*Z*)-9-C29, *n*-(*Z*)-9-C31, and *n*-9-C33), terpenes (36.42%; mainly terpenic alcohols: (*E*,*E*)-farnesol, (*E*,*Z*)-farnesol, and geranyl linalool), an ester (0.27%; tetradecyl dodecanoate), aldehydes (50.25%; *n*-C14 and *n*-C16), acids (0.25%; *n*-C14 and *n*-C16), and steroids (2.32%; ergostadien-3β-ol, ergost-5-en-3β-ol, stigmast-5-en-3β-ol, and stigmastadien-3β-ol).

Cephalic Extracts of N. testaceicornis males (eight specimens=0.400 mg) were composed of *n*-alkanes (4.88%; *n*-C23, *n*-C25, and *n*-C27), *n*-alkenes (55.48%; *n*-(*Z*)-9-C27, *n*-(*Z*)-9-C29, and *n*-(*Z*)-9-C31), an *n*-alkadiene (6.17%; *n*-9,21-C31), esters (14.07%; mainly constituted of hexadecyl hexadecenoate and hexadecyl octadecenoate), a spiroacetal (0.58%; (*E,E)*-2,8-dimethyl-1,7-dioxaspiro[5.5] undecane) (Kitching et al. 1989; Booth et al. 2006), and steroids (10.92%; ergost-5-en-3β-ol and stigmast-5-en-3β-

ol) (Table 1). *N. testaceicornis* foraging worker cephalic extracts (eight specimens=0.232 mg) were composed of *n*-alkanes (6.86%; *n*-C15, *n*-C23, *n*-C25, *n*-C27, and *n*-C29), *n*-alkenes (38.04%; *n*-9-C15, *n*-9-C23, *n*-(*Z*)-9-C25, *n*-(*Z*)-9-C27, *n*-(*Z*)-9-C28, *n*-(*Z*)-9-C29, and *n*-(*Z*)-9-C31), an *n*-alkadiene (4.36%; *n*-9,21-C31), a branched alkatetraene (0.68%, 7,11,15-trimethyl-3-methylene-hexadecatetraene), a terpene (0.26%; α-copaene), esters (23.37%; hexadecyl hexadecenoate, hexadecyl hexadecanoate, hexadecenyl octadecenoate, and hexadecyl octadecenoate), an aldehyde (0.71%; nonanal), a spiroacetal (2.36%; (*E,E*)-2,8-dimethyl-1,7-dioxaspiro[5.5]undecane) (Booth et al. 2006; Kitching et al. 1989), and steroids (7.33%; ergost-5-en-3β-ol and stigmast-5-en-3β-ol).

P. droryana male cephalic extracts (eight specimens=0.600 mg) contained *n*-alkanes (4.86%; *n*-C25, *n*-C27, and *n*-C29), *n*-alkenes (55.96%; *n*-(*Z*)-9-C25, *n*-(*Z*)-9-C27, *n*-(*Z*)-9-C29, *n*-(*Z*)-9-C31, and *n*-9-C33), acids (1.17%; *n*-C14 and *n*-C16), an ester (0.66%, octadecyl acetate), an alcohol (0.40%, (*S*)-2-nonanol), and steroids (21.90%; ergostadien-3β-ol, ergost-5-en-3β-ol, stigmast-5-en-3β-ol, and stigmastadien-3β-ol) (Table 1). *P. droryana* foraging worker cephalic extracts (eight specimens=0.200 mg) were composed of *n*-alkanes (8.47%; *n*-C25, *n*-C27, and *n*-C29), *n*-alkenes (78.27%; *n*-(*Z*)-9-C25, *n*-(*Z*)-9-C29, *n*-(*Z*)-9-C31, and *n*-9-C33), terpenes (1.16%; α-copaene, *Ar*-curcumene, δ-cadinene, and 1-*cis*-calamenene), and steroids (6.87%; ergostadien-3β-ol, ergost-5-en-3β-ol, stigmast-5-en-3β-ol, and stigmastadien-3β-ol).

DMDS/I_2 Derivatization of Extracts The DMDS derivatized *n*-alkenes present in waxes, cephalic, and abdomen extracts of males and workers of *P. droryana* and *N. testaceicornis* were analyzed by GC-MS. Mass spectra of the DMDS derivatized *n*-alkenes displayed fragment *m/z* 173 (94%, $[CH_3(CH_2)_7CH = SCH_3]^+$), indicating the double bond position at C-9, and base peaks (100%) at *m/z*: 243 $[CH_3(CH_2)_{12}CH = SCH_3]^{+\cdot}$ (*n*-C23); 271 $[CH_3(CH_2)_{14}CH = SCH_3]^{+\cdot}$ (*n*-C25); 285 $[CH_3(CH_2)_{15}CH = SCH_3]^{+\cdot}$ (*n*-C26); 299 $[CH_3(CH_2)_{16}CH = SCH_3]^{+\cdot}$ (*n*-C27); 313 $[CH_3(CH_2)_{17}CH = SCH_3]^{+\cdot}$ (*n*-C28); 327 $[CH_3(CH_2)_{18}CH = SCH_3]^{+\cdot}$ (*n*-C29); 355 $[CH_3(CH_2)_{20}CH = SCH_3]^{+\cdot}$ (*n*-C31); and 383 $[CH_3(CH_2)_{22}CH = SCH_3]^{+\cdot}$ (*n*-C33). The DMDS derivative of *n*-hentriacontadiene had two sets of fragments at *m/z* 173/353 $[CH_3(CH_2)_7CH = SCH_3]^{+\cdot}/[CH_3(CH_2)_8CH{=}CH(CH_2)_{10}CH = SCH_3]^{+\cdot}$ and *m/z* 187/339 $[CH_3(CH_2)_8CH = SCH_3]^{+\cdot}/ [CH_3(CH_2)_7CH = CH(CH_2)_{10}CH = SCH_3]^{+\cdot}$, indicating the presence of double bonds at C-9 and C-21.

Field Test Workers from three of seven stingless bee species, i.e., *P. droryana* (*N*=4), *N. testaceicornis* (*N*=2), and *Frieseomelitta silvestrii* (*N*=6), were attracted to paper strips containing the test compounds. The stingless bees flew around the strips of paper containing (*S*)-(+)-2-heptanol and the mixture of (*S*)-(+)-2-heptanol/(*S*)-(+)-2-nonanol (1:1). They did not fly around the paper containing the racemic mixture of 2-heptanol, 2-nonanol, and 2-undecanol, and rarely landed on these strips—if so, only for very short periods. Aggressiveness was not observed. Males were present in the nests and flying outside, but were not attracted.

Discussion

Nest construction and colony organization were performed by queens and workers upon detection of chemical signals. Stingless bee males have restricted tasks. Two to 3 week-old males stay inside the colony helping with building activities, trophallaxis, nectar dehydration, incubation, and nest defense. As adults, they leave the colony, but temporarily congregate nearby waiting for a queen to fly out from the nest (Roubik 1989; Velthuis et al. 2005). Male communication signals have not been investigated thoroughly, but this topic merits investigation.

The overall chemical composition of both cuticular waxes and cephalic extracts from *N. testaceicornis* males and workers are similar. However, minor compounds distinguish one sex from the other—e.g., phenyl tridecane is only present in male cuticular waxes (Table 1). Nonanal, pentacane, pentadecene, 9-tricosene, and 7,11,15-trimethyl-3-methylene-1,6,10,14-hexadecatetraene are present in the cephalic secretion of *N. testaceicornis* workers, distinguishing them from males that do not contain these constituents (Table 1).

Interspecies chemical comparisons revealed that the predominant constituents in *N. testaceicornis* cuticular waxes were heptacosane, (*Z*)-9-nonacosene, and 9,21-hentriacontadiene. In *P. doryana*, the predominant hydrocarbons were *n*-pentacosane and (*Z*)-9-heptacosene. These compounds help to differentiate chemically between these stingless bee species (Table 1). Insect cuticular hydrocarbons are important surface pheromones in inter- and intraspecific communications, mainly in nestmate recognition (Singer 1998; Abdalla et al. 2003). Thus, our results are consistent with the use of hydrocarbons in recognition systems.

Cuticular waxes of *P. droryana* workers and males were similar, but the cuticular waxes of workers had more terpenes and nerolidyl acetate than males (Table 1). Cuticular waxes from workers and males are similar in *P. droryana* and *N. testaceicornis*. This also was observed in workers and males of *Melipona scutellaris* (Kerr et al.

2004). Therefore, it seems to be common in stingless bees, where cuticular hydrocarbons of males and workers of the same species have similar chemical compositions.

The cuticular components of social insects are both individually produced (mainly by glands) or acquired from environmental sources (food, nest material, and other sources) (Moritz and Heisler 1992; Downs and Ratnieks 1999). Therefore, they generally are used as cues for nestmate recognition, and each colony has its own chemical template (Nunes et al. 2008). This explains why workers and males have many cuticular chemical similarities.

Abdomen extracts of *N. testaceicornis* workers consist of terpenyl acetates (approx. 84%), with geranylgeranyl acetate as the main constituent, while males secret linear *n*-alkanes, *n*-(*Z*)-9-alkenes, *n*-9,21-hentriacontadiene, and some sesquiterpenes (Table 1). Geranylgeranyl acetate was detected previously in extracts of the abdominal Dufour glands from *N. testaceicornis* workers (Cruz-López et al. 2001). This diterpene ester is absent in male extracts; the main chemical difference between *N. testaceicornis* abdomen extracts of males and workers. Abdomenal extracts of *P. droryana* males and workers were distinct. Large quantities of long chain aldehydes (tetradecanal and hexadecanal) and terpenic alcohols [(*E*,*E*)-farnesol, (*E*,*Z*)-farnesol, and geranyl linalool] were present in abdomen extracts of workers, while the major constituents in male abdomen extracts were (*Z*)-9-heptacosene and fatty acids (linoleic and linolenic acids, present in about 40% of the abdomen extracts) (Table 1). Therefore, workers and males of *P. droryana* and *N. testaceicornis* could be distinguished easily by the chemical composition of their abdomen extracts (Table 1).

The chemical differences between abdominal extracts of *N. testaceicornis* and *P. droryana* workers and males are remarkable as both have distinct constituents. *N. testaceicornis* has geranylgeranyl acetate and (*Z*)-9-nonacosene, respectively. Workers and males of *P. droryana* have tetradecanal and unsaturated fatty acids (linoleic and linolenic acids), respectively (Table 1). Abdominal extracts not only distinguish one species from the other, but also the sexes. The Dufour gland is not present in males, and is probably responsible for the striking chemical differences in abdomenal extracts (Abdalla et al. 2004). The Dufour gland also is absent in workers of *Trigona*, *Oxytrigona*, *Cephalotrigona*, *Scaptotrigona*, *Partamona*, and *Lestrimelitta* (Lello 1976; Patricio et al. 2003). However, all species of the *Plebeia* group, including *P. droryana*, have Dufour glands (queens and workers). *N. Testaceicornis* is distantly related to the *Plebeia* group, and Dufour glands are present in queens and workers. Dissection of the abdomens of *N. testaceicornis* and *Plebeia* sp. workers (later identified as *Plebeia droryana*) revealed a large sac at the end of the abdominal tip with a duct opening into the vagina (Patricio 1995; Cruz-López et al. 2001). The Dufour gland in *N. testaceicornis* is lined with a single layer of Type I secretory cells (Noirot and Quennedey 1974) with a peculiar cranelate epicuticle and vesicular smooth endoplasmic reticulum, as shown by transmission electron microscopy images (Patricio 1995). Preliminary studies of Dufour gland secretions from *Plebeia* sp. revealed tridecane, pentadecane, hexadecane, farnesol, and geranyl geraniol; however, not all constituents have been identified (Patricio 1995).

Both species also can be differentiated by cephalic extracts. *N. testaceicornis* male and worker extracts are characterized by 9,21-hentriacontadiene and long chain esters (hexadecyl hexadecenoate and hexadecyl octadecenoate), which are absent in *P. droryana* (Table 1). The short-chain esters in *N. testaceicornis* and *P. droryana* cephalic extracts of foraging workers also were detected in eleven Brazilian stingless bee species (Francke et al. 2000). However, most long chain esters (tetradecyl dodecanoate,

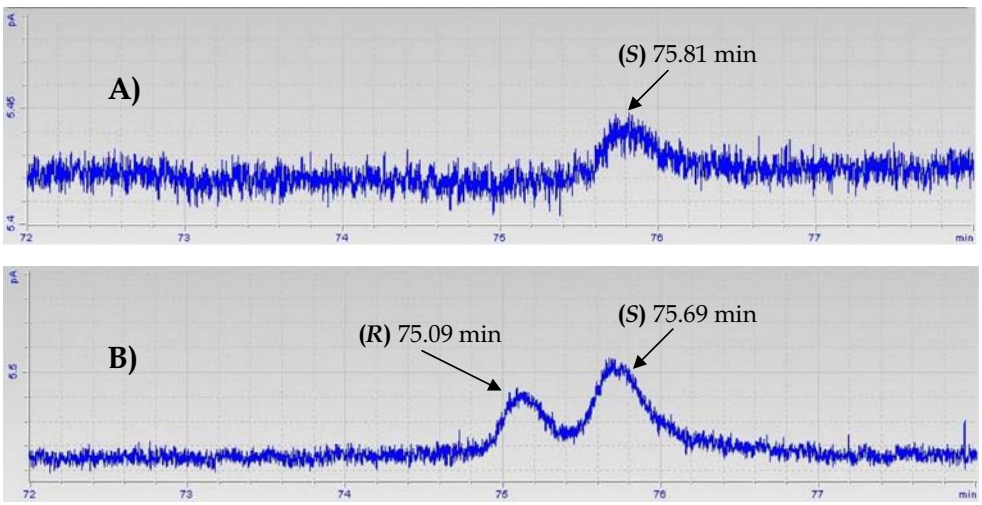

Fig. 1 Absolute configuration of natural 2-nonanol from cephalic extracts of *Plebeia droryana* males determined by GC-FID with chiral column (Chrompack CP-Chirasil-Dex CB; 25 m×0.25 mm×0.25 μm; 50°C to 100°C at 0.4°C/min). A) natural 2-nonanol from cephalic extracts of the *P. droryana* males; and B) 4:1 mixture of cephalic extracts of *P. droryana* males and synthetic (±)-2-nonanol

hexadecyl hexadecenoate, hexadecyl hexadecanoate, hexadecenyl octadecenoate, and hexadecyl octadecenoate) had not previously been detected in stingless bees (Table 1). These long chain esters can play specific roles in the chemical communication of stingless bees. This is similar to hexyl decanoate, the trail pheromone of *Trigona recursa* foraging workers (Jarau et al. 2006).

n-Alkanes and *n*-alkenes were more abundant in cephalic extracts of *P. droryana* workers, while steroids were more abundant in male cephalic extracts, thus differentiating the cephalic extracts of these two sexes. A spiroacetal, (*E,E*)-2,8-dimethyl-1,7-dioxaspiro[5.5]undecane (Kitching et al. 1989; Booth et al. 2006), was found in male and worker cephalic extracts of *N. testaceicornis*. Other spiroacetals are known as alarm pheromones in rove beetles, fruit flies, and wasps (Fletcher and Kitching 1995; Zhang et al. 1999; Bruschini et al. 2006, 2008).

(*S*)-2-Nonanol is a component in the cephalic extracts of *P. droryana* males. Its absolute configuration was determined by chiral-gas chromatography (Fig. 1) using (±)-2-nonanol and (*S*)-2-nonanol to optimize the chromatographic conditions and confirm the (*S*) absolute configuration of the compound—a novel result. Curiously, the 2-alkanols were not detected in cephalic and abdominal extracts of *P. droryana* and *N. testaceicornis* workers. Thus, these are chemical signals used by males and/or queens and detected by workers. 2-Alkanols have also been detected in cephalic extracts of the workers from several stingless bee species (*Trigona hyalinata, T. spinipes, T. hypogea, T. truculenta, Tetragona clavipes, Frieseomelitta trichocerata, F. xanthopleura, F. silvestrii languida, Tetragonisca angustula, Geotrigona mombuca*, and *Lestrimelitt*a *limao*). This suggests that they might act as alarm pheromones (Luby et al. 1973; Johnson et al. 1985; Francke et al. 2000). However, in our experiments, only workers of *P. droryana*, *N. testaceicornis*, and *Friesiomelitta silvestrii* were attracted to (*S*)-(+)-2-heptanol and to the mixture of (*S*)-(+)-2-heptanol/(*S*)-(+)-2-nonanol (1:1), while a racemic mixture of secondary alcohols [(±)-2-heptanol, (±)-2-nonanol, and (±)-2-undecanol] was not attractive. Males did not respond to these alcohols. The selective attraction exerted by the chiral 2-alkanols suggests that the (*S*)-2-alkanols convey a specific signal between the sexes. Worker bees behaved as if they were searching for something while flying around the pieces of paper, but were not aggressive. This observation suggests that these are not alarm or recruting pheromones, but rather a chemical signal detected by workers. However, we did not detect this component in *Plebeia droriana* worker extracts only in male cephalic and abdomenal extracts, indicating that the worker bees detect, but do not emit, this chemical signal. Thus, the differentiation of the chemistry of workers and males of these two bee species was important to detect signals produced by one and both sexes.

The large differences in worker and male head and abdominal and extracts for both species were assigned to the presence of specific glands with different compositions according to sex, caste, or age (Cruz-Landim and Mota 1993; Gracioli-Vitti et al. 2004). The chemical signals from the head and abdomen may play important functions in the colonial context as caste and sex recognition.

In summary, we have shown for the first time the *N. testaceicornis* and *P. droryana* interspecific chemical differences and the chemical constituents that differentiate males from workers that might be useful in future behavioral studies of stingless bees'.

Acknowledgments We thank FAPESP (Fundação de Amparo a Pesquisa do Estado de São Paulo) for scholarships that made the present contribution possible (Adriana Pianaro, Proc. n°. 03/09358-3; Cristiano Menezes, Proc. n° 07/50218-1) and the Chemistry Institute of UNICAMP for support. We also acknowledge Paulo Nogueira-Neto for providing the stingless bees species and Carol H. Collins (IQ/UNICAMP) for critically revising the manuscript.

germination and growth of wheat (*Triticum aestivum*) and *Phalaris minor* in laboratory bioassays. The essential oils of *L. stoechas* and *L. angustifolia* also have been determined to have phytotoxic effects on the seedling growth of *A. retroflexus* and *Portulaca oleracea* that infest tomato (*Lycopersicon esculentum*) and cotton (*Gossypium* spp.) crops (Argyropoulos et al. 2008). In addition, volatile compounds from *L. angustifolia* have a negative effect on the germination of common cocklebur (*Xanthium strumarium* L.), sterile wild oat (*Avena sterilis* L), and short spiked canarygrass (*Phalaris brachystachys* L.) (Uremis et al. 2009).

There are several reports on the chemical constituents of extracts and essential oils from various *Lavandula* spp. Chemical classes represented in the species include phenolics (Areias et al. 2000) and terpenes (Salido et al. 2004; Aburjai et al. 2005). Tiliacos et al. (2008) determined that a substantial component of *Lavandula intermedia* is made up of two compounds, coumarin and herniarin (7-methoxycoumarin). Angioni et al. (2006) determined via gas chromatography and mass spectrometry (GC/MS) that the main component of essential oils from *L. stoechas* is fenchone, a monoterpene that accounts for 52.6% of the leaf/stem and 66.2% in flowers. Another terpene, camphor, accounted for 13.1% and 27.1%, respectively.

It is not known, however, which compounds are involved in the phytotoxicity of *Lavandula* extracts. In addition, no published papers were found on the effect of *Lavandula* spp. on germination and seedling growth of ARG, other than our initial screening work presented in Haig et al. (2005). The current study aimed to determine the broader potential of the compounds found in lavender extracts in order to find new potential natural herbicides. Several lavender species and their individual plant parts were tested to determine the extract of highest potency. This extract was subjected to bioassay guided fractionation, and its chemical constituents analyzed to determine novel herbicide chemistries.

Methods and Materials

Aqueous Extract Preparation Several species of lavender (*Lavandula allardii*, *L. stoechas*, *L. x intermedia*, *L. dentata, L. angustifolia, L. x heterophylla*, and *L. viridis*) were collected near Charles Sturt University, Wagga Wagga, NSW and dried for 72 h at 40°C. Samples were divided into stem and leaf tissues and flower sub-samples prior to drying. Dehydrated plants and individual parts were milled into a fine powder through a 1 mm sieve. Ten grams of lavender powder were added to 100 ml of sterile, deionized water and placed in a dark incubator at 20°C for 3 d. Extracts were swirled gently by hand for 30 sec each day. The resulting extract was filtered through 4 layers of muslin cloth, vacuum-filtered through Whatman #1 filter paper, and sterilized via a 0.25 μm filter. This extract was considered to be the full strength extract (100%). Additional concentrations used in these experiments were obtained via serial dilution of the full strength extract.

Bioassays of Plant Extracts Commercial herbicide-susceptible *L. rigidum* (HS-ARG) seeds were sterilized for 2 min with 2.5% NaClO, rinsed thoroughly with distilled water, and placed in a 25°C incubator (12 h light/12 h dark) for 2 d. Fifteen pre-germinated ARG seeds were sown in petri plates lined with Whatman #1 filter paper that contained 4 ml of plant extract or distilled water in the case of the control. Seven extract concentrations were used: 0.1, 1, 5, 10, 25, 50, and 100% and a water control. After 3 d of incubation, seedling root and shoot lengths were measured. Three replications were arranged using a randomized complete block design. An identical experiment also was conducted using samples of ARG with known resistances to several modes of action that involve acetyl CoA carboxylase (ACCase) inhibitor resistance, ACCase inhibitors plus glyphosate resistance (HR-ARG), ACCase inhibitory plus acetolactate synthase (ALS) inhibitor herbicide resistances, and triazine resistance.

To determine whether lavender phytotoxicity was species specific, the most phytotoxic extract, *L. x intermedia* cv. Grosso, also was tested against canola (*Brassica napus* L.), wheat (*Triticum aestivum* L.), and subterranean clover (*Trifolium subterraneum* L.). Screening was similar to that described previously, with one exception. Wheat and subterranean clover were surface sterilized for 15 min prior to pre-germination rather than the 2 min for ARG and canola.

Stability of Extract Three 400 ml aliquots of 100% *L. x intermedia* cv. Grosso were stored in 500 ml glass Schott bottles under the following conditions: 4°C in the dark, 25°C in continuous light, and 25°C dark for a total of 256 days. To monitor phytotoxicity and determine the occurrence of basic chemical transformations within the 256 day period, pH and electrical conductivity were recorded on day 2, 4, 8, 16, 32, 64, 128, and 256 with a TPS digital pH meter and an Activon Pocket Conductivity Meter. On each sampling day, the original extract (100%) was serially diluted to concentrations of 50, 25, 10, 5, 1, 0.1, and 0% (control). The bioassay procedure was identical to that described above.

Solvent Extraction A large volume of *L. x. intermedia* cv. Grosso was prepared for fractionation and chemical

analysis by adding 175 g of dried powder to 1,750 ml of sterile, distilled water in a 2 L Schott bottle. The mixture was stored in the dark for 72 h at 20°C prior to filtering through 4 layers of muslin cloth, followed by vacuum filtering through one layer of 90 mm Advantec # 2 filter paper to remove fine particles. A 0.25 µm filter was used to sterilize the solution. The resulting 1,200 ml was sequentially partitioned with five solvents of increasing polarity: hexane, diethyl ether, dichloromethane, ethyl acetate, and *n*-butanol. Four aliquots of 300 ml of solvent were washed through the aqueous layer to exhaustively remove compounds of like polarity. The five solvent fractions were dried by the addition of anhydrous Na_2SO_4, and rotary evaporated to dryness at 40°C.

Chemoassay of Solvent Fractions Phytotoxicity bioassays were undertaken for each of the five solvent fractions, in addition to the aqueous residues, before and after solvent extraction using the bioassay procedure described. Concentrations of 20, 200, and 1,000 ppm were prepared by dissolving the dried solvent fraction in methanol. Four ml of each concentration were added to a 9 cm glass petri-plate that contained Advantec #2 filter paper. For the control, methanol only was added to the control dish and allowed to evaporate. After the methanol had completely evaporated from every plate, 4 ml of sterile, deionized water were added to each dish. A randomized complete block design was employed, with 3 replications, using 15 pre-germinated ARG seedlings per plate. Root and shoot growth were measured after incubation for 72 h in the dark at 25°C.

Column Liquid Chromatography (LC) Fractionation The most phytotoxic solvent fraction (hexane) underwent more focused phytotoxicity-guided isolation by using traditional column liquid chromatography (LC) to target the most herbicidal compounds, hence making the identification task that used spectroscopy more practical. The LC column was 200×37 mm i.d. and contained a packing of 200–400 mesh silica gel with a flow rate of 50 ml/8 min. Hexane fraction evaporate (0.37 g) was added to the top of the column for gradient elution. By using gradient elution, the polarity of the liquid mobile phase was altered gradually from non-polar (hexane) to increasingly more polar (methanol) (Table 1). Overall, 38×50 ml sub-fractions were collected from the initial hexane fraction. Vials containing enough mass for bioassays were made up in methanol to concentrations of 20, 200, and 1,000 ppm.

GC/MS Conditions A Varian 3400 CX gas chromatograph (GC) was coupled with a Varian Saturn 2000 ion trap mass spectrometer (MS). The GC was fitted with a DB-5 (30 m× 0.32 mm i.d.×1 µm) fused silica capillary column (J&W Scientific). The programmed column temperature was set at 40°C and held for 1 min, then increased to 70°C at 10°C/min for 3 min, increased to 125°C at 5°C/min for 11 min, then increased to 240°C at 10°C/min for 11.5 min, held at 240°C for 10 min, increased to 290°C at 50°C/min for 1 min, held at that temperature for 5 min. Ultra-pure helium was used as carrier gas (linear velocity of 34 cm/s). One µL sample splitless injections were undertaken at the injection temperature of 280°C. The Varian Saturn 2000 MS detector employed the electron ionization mode. The MS was programmed to scan a mass range of 50 to 650 m/z every 0.700 sec with a solvent delay time of 4.5 min. Data were analyzed by using the Varian (Walnut Creek, CA, USA) Saturn Chromatography Work Station software (Version 1.3), and tentative identification of chemicals in the solvent fractions were made from the NIST 2005 mass spectral library database. Pure reference standards were injected to confirm identification of specific chemicals having a high fit of above 900 (out of a possible 1,000) in the NIST database. A high match with the reference standard mass spectrum and an identical retention time indicates the presence of these chemicals.

Table 1 Mobile phase gradient elution for LC

Vial #	Gradient
1–10	100% hexane
11–14	1% ethyl acetate in hexane
15–18	3% ethyl acetate in hexane
19–22	5% ethyl acetate in hexane
23–26	10% ethyl acetate in hexane
27–30	20% ethyl acetate in hexane
31–32	50% ethyl acetate in hexane
33–34	100% ethyl acetate
35–36	100% methanol
37–38	100% methanol

Infrared Analysis To confirm MS identification of phytotoxic compounds, IR spectral fingerprinting was undertaken. The Pye-Unicam SP3-100 Infrared Spectrometer had a 0.1 mm path length, and the scan was done from the 4,000 to 700 cm^{-1} range. Less than 0.2 g of sample were dissolved in analytical grade chloroform.

Chemoassay of Coumarin and its Structural Derivatives Coumarin was compared against 18 of its structural derivatives across the concentration range: 1, 5, 10, 25, 50, and 100 ppm. Pure reference standards of 18 coumarin structural derivatives were purchased from Sigma-Aldrich, Australia and dissolved in AR methanol to obtain concentrations of 1, 5, 10, 25, 50, and 100 ppm by using serial dilution. Four ml of each coumarin-derivative concentration were added to glass petri-dishes, lined with Advantec #2

filter paper. After the methanol had evaporated, 4 ml of sterile, deionized water were added to each dish. The remainder of the bioassay was conducted as described above.

Soil Trials In order to minimize probable volatilization of constituents before effects on soil or plant, incubator conditions were lowered to 15°C, with 12 h L: 12 h D.

Lavender Extract To assess the effect of *L. x intermedia* cv. Grosso extracts in soil where myriad microbial interactions and soil processes are occurring in contrast to agar based bioassays, bioassays were conducted in plastic 4 cm diam, 10 cm long cylindrical vials (50% soil:50% peat moss). Ten pre-germinated ARG seeds were sown evenly in the vials, which had been pre-moistened with 10 ml tap water and covered with 0.2 cm soil. Nine days after sowing, ARG seedlings were sprayed with 3.5 ml of either control, 10, 25, 50, or 100% extract with a hand-held aspirator. Every 3 d over 3 wk, 3.5 ml of water were added to each vial to prevent wilting. Total germination counts were tabulated and above-ground ARG seedlings were harvested prior to drying for 72 h in a 70°C plant dehydrator. Dry weights were measured for statistical analyses. Three replicates were arranged in a complete randomized block design.

Coumarin Coumarin concentrations used were 0, 125, 250, 500, and 1,000 ppm. Each concentration, including the control, contained a 5% methanol −95% deionized water ratio. Methanol initially was used to dissolve semi-water soluble coumarin before water was added. The 5% MeOH −95% DI water mixtures were sprayed onto the soil as described for the lavender extract pot trial. All concentrations were done in triplicate, in a randomized complete block design.

Statistics The majority of the ARG root and shoot length data from bioassays and chemoassays was analyzed via ANOVA using Genstat® v.11. Data presented in Fig. 1, root and shoot measurements, were converted to % of control values prior to analysis to facilitate a common starting point for the different species for ease of comparison. Least significant differences (LSD) at $P=0.05$ for all data were calculated to enable comparisons. For the pot trial experiments, dry weights also were subjected to analysis of variance.

Results

Bioassays Since root growth appeared to be a more sensitive parameter than shoot growth, only root growth data are presented. Not all lavender species had the same phytotoxic potential. Overall, *L. x intermedia* cv. Grosso was the most phytotoxic species ($LSD_{species}=1.8$, $P<0.001$). Table 2 demonstrates that the stem and leaf extract of *L. x intermedia* cv. Grosso was the most phytotoxic against ARG seedlings ($LSD_{species*extract}=2.6$, $P<0.01$). This extract inhibited ARG root growth by >94% compared with the control. All extracts of all species except for *L. stoechas* and *L. viridis* inhibited ARG root growth by >70%. As the stem and leaf extract of *L. x intermedia* cv. Grosso was the most phytotoxic, the remainder of the research was conducted with this extract.

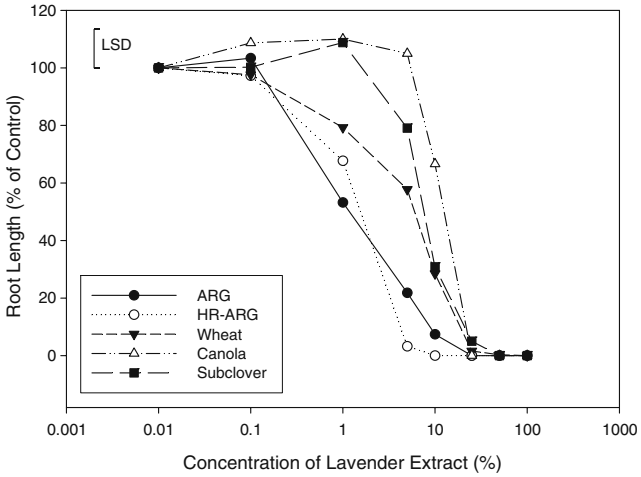

Fig. 1 Effect of *Lavandula x intermedia* cv. Grosso on root growth of several plant species ($LSD_{interactions}=13.4$, $P<0.001$)

When this extract was tested on additional plant species, it was phytotoxic to multiple species (Fig. 1). All resistance samples were equally susceptible, and only results for the ACCase plus glyphosate resistant sample (HR-ARG) are included. Overall, lavender was increasingly phytotoxic towards test species as follows: canola < subterranean clover < wheat < HS-ARG = HR-ARG. There were differences in root growth between each level ($LSD_{species}=4.5$, $P<0.001$). Root growth of HS-ARG, was not significantly different from HR-ARG, however, overall they were most inhibited by *L. x intermedia* cv. Grosso extract. At concentrations of 25% extract and above, there were no significant differences in root growth among species. Maximum differences in suppression of root growth were seen at 5 and 10% extract concentrations ($LSD_{spp\ x\ conc}=13.4$, $P<0.001$). There were no significant differences among species at concentrations less than 1%.

Stability of Extracts Figure 2 shows the effect of the 1% cv. Grosso extract on ARG root growth over time. Although there was a significant change in phytotoxicity over time under different storage regimes ($LSD_{interactions}=7.3$, $P<$

Table 2 Effect of 10% extracts from different *Lavandula* species on annual ryegrass root growth

Lavandula species	ARG root length (mm)[a]	
	Stem & leaf extract	Flower extract
L. x intermedia cv. Grosso	3.1	9.3
L. x heterophylla	5.8	13.9
L. angustifolia cv. Edgerton Blue	7.7	15.3
L. x allardii cv. Mitchum	8.6	16.1
L. dentata cv. Candicans	13.4	19.0
L. viridis	39.1	40.3
L. stoechas cv. Fairy wings	49.8	52.8

LSD $_{spp * extract}$=2.6, P<0.01

[a] distilled water control mean=58.9 mm

0.001), by day 128, all three extracts had similar phytotoxicities, regardless of storage conditions. All extracts reduced ARG root growth by 40%. In no treatment was the phytotoxicity lost between day 2 and day 256. While phytotoxicities of both the 25°C light and 4°C dark treatments did not change significantly, the 25°C dark treatment increased significantly when comparing day 2 and day 256. Average root length in this treatment decreased from 41 to 26 mm.

The pH of the 100% extracts stored under different conditions varied from 5.0 to 6.0 over 256 days, while the electrical conductivity (EC) of the 100% extracts ranged from 5.3–6.3 dS/m. The observed effect on root growth is more likely due to presence of extract rather than pH or EC effects, as the latter two are well within reported limits suitable for plant growth.

Chemoassay of Solvent Fractions There were differences in the phytotoxicity of the solvent fractions (LSD=2.7, P< 0.001). From least to most toxic, the extracts ranked as follows, with phytotoxicity increasing significantly between each extract: remaining extract, dichloromethane, ethyl acetate, *n*-butanol, diethyl ether, and hexane. The effect of concentration also was significant (LSD=1.9, P<0.001). Figure 3 shows the response curve for each fraction (LSD $_{interactions}$=5.3, P<0.001). The hexane fraction inhibited ARG root growth by 61% at 20 ppm, whereas the diethyl ether extract inhibited it by 16% at 20 ppm and ~99% at 200 ppm. The ethyl acetate and *n*-butanol extracts inhibited ARG root growth by <10%, while the dichloromethane extract actually stimulated ARG growth at this concentration (20 ppm).

Chromatography When the hexane fraction was further fractionated, most of the eluent mass was found in sub-fractions 33 and 34. A green crystalline solid was observed in sub-fraction 33, while there was a white crystalline solid in sub-fraction 34. Comparisons with pure reference standards and near-infra red analysis confirmed that sub-fraction 33 consisted entirely of coumarin while sub-fraction 34 consisted entirely of 7-methoxycoumarin. The dose response curves are plotted on Fig. 3. Sub-fraction #33 inhibited root growth by 89% at 20 ppm, whereas sub-fraction #34 was much weaker, with only 25% inhibition at

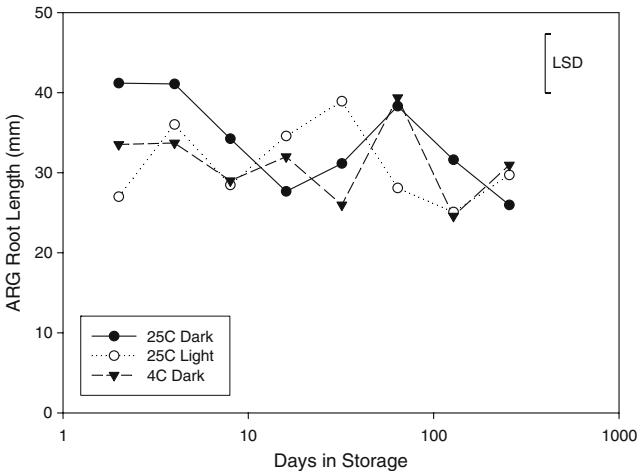

Fig. 2 Changes in phytotoxicity of *Lavandula x intermedia* cv. Grosso extract (1%) under different storage regimes (LSD $_{interactions}$=7.3, P<0.001)

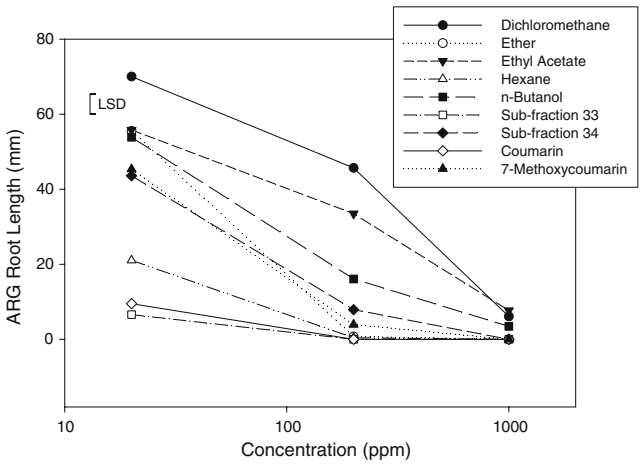

Fig. 3 Inhibition of annual ryegrass (ARG) root growth due to different solvent fractions and sub-fractions (LSD $_{interactions}$=5.3, P<0.001)

this concentration. A coumarin concentration as low as 20 ppm inhibited ARG root length by 84%.

Chemoassay of Coumarin and Structural Derivatives Dose-response data of the 18 pure reference samples tested are shown in Table 3. Coumarin demonstrated superior phytotoxic potential against ARG root growth ($LSD_{interactions}$= 3.6, $P<0.001$) although 7-hydroxycoumarin had a similar dose-response curve, providing 100% root inhibition at 100 ppm. Only 17 chemicals inhibited ARG root growth by >70% at the highest concentration used in this experiment, 100 ppm. Four chemicals inhibited ARG root growth by <20%.

Soil Trial Figure 4 shows the effect of *L. x intermedia* cv. Grosso extract on ARG shoot weight when sprayed post-emergence. All concentrations reduced ARG shoot weight compared with the distilled water control (LSD=0.45, $P<$ 0.001). Concentrations above 10% reduced ARG shoot weight by more than 50%. The 100% extract reduced shoot weight by almost 90%.

The coumarin dose-response curve in soil is shown in Fig. 5. All concentrations of coumarin reduced ARG shoot weight compared with the control (LSD=0.40, $P<0.001$). Concentrations of 250 ppm and above inhibited ARG shoot weight by <50%. A concentration of 1,000 ppm reduced ARG shoot weight by almost 80%.

Discussion

In this study, multiple *Lavandula* species were tested for phytotoxic effects on ARG growth in an attempt to discover potential natural herbicide leads. *Lavandula stoechas* was the least phytotoxic species, inhibiting ARG root growth by <20%. The stem and leaf extract of *L. x intermedia* cv. Grosso, inhibited ARG growth by 94%. This high phytotoxicity was observed for multiple species. When extracts were tested for stability, there was no loss of phytotoxicity over a 256 day period. This is an important consideration for potential future users who generally would keep herbicides between cropping seasons prior to application.

Although the plant extract itself had been known to have potential as a herbicidal treatment, one aim of this research was to isolate specific phytotoxic compounds. Coumarin was the main constituent of the most herbicidal sub-fraction of the highly toxic hexane fraction, and was active at low concentrations. Coumarin is a well known phytotoxin that has been tested in laboratory studies for its effect on germination and growth of wild oats (*Avena fatua*) (Goodwin and Taves 1950), timothy grass (*Phleum pratense*) (Avers and Goodwin 1956), beggar's ticks (*Bidens pilosa*) (Pergo et al. 2008), barnyard grass (*Echinochloa crus-galli*) (Chon and Kim 2004), alfalfa (*Medicago sativa*), velvetleaf (*Abutilon theophrasti*), and Italian ryegrass (*Lolium multiflorum)*

Table 3 Effect of coumarin structural derivatives on annual ryegrass (ARG) root growth

Chemical	ARG Root Length (mm)[a]					
	1ppm	5ppm	10ppm	25ppm	50ppm	100ppm

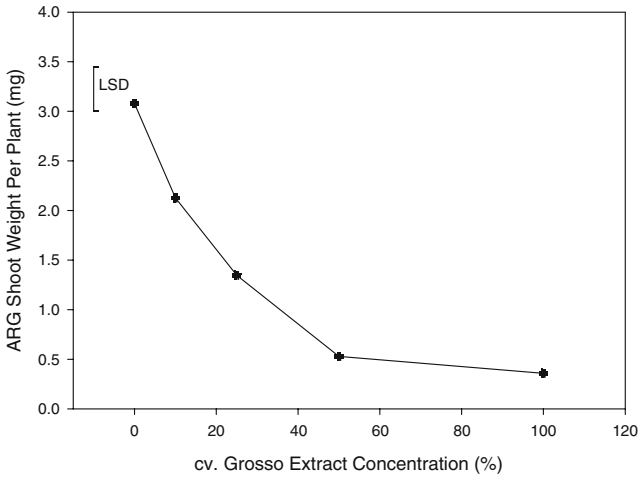

Fig. 4 Effect of *Lavandula x intermedia* cv. Grosso extract on annual ryegrass (ARG) when applied to soil post-emergence (LSD=0.45, $P<0.001$)

(Dornbos and Spencer 1990). Although coumarin has been tested on *L. multiflorum*, there are no literature reports of herbicidal properties against ARG, the most important weed in southern Australian winter wheat crops.

Due to coumarin's demonstrated potency against ARG, 18 structural analogues of coumarin were investigated to determine whether any variants of the coumarin lead structure, that consists of a unique coumarin heterocyclic ring system, enhanced ARG inhibition compared with coumarin itself. Coumarin remained the most biologically active compound tested. Low coumarin concentration of 20 ppm reduced ARG root growth by 84%.

The finding that coumarin was active on ARG with resistances to a range of herbicide modes of action suggests that its mode of action was different from herbicides to which resistance has occurred. Such a chemical option is desirable since evolution of herbicide resistance in ARG has threatened the viability of some existing options (Broster and Pratley 2006).

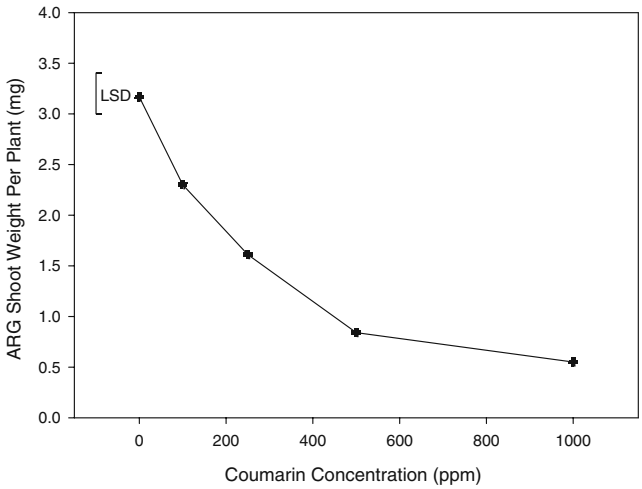

Fig. 5 Effect of coumarin on annual ryegrass (ARG) when applied to soil post-emergence (LSD=0.40, $P<0.001$)

Although lavender extract and pure coumarin bioassays both revealed promising herbicidal activities in the laboratory, the real test for potential herbicides is their effectiveness in the field where myriad soil characteristics and microbial interactions come into play. Dias et al. (1995) determined that aqueous extracts of *L. stoechas* inhibited germination of *Phalaris minor*, a weed of wheat crops, in laboratory bioassays. However, when Dias et al. (2004) conducted a soil pot trial with this extract, it was unsuccessful as a pre-emergence treatment. The authors suggested that factors such as light, microbial interactions, and metabolism were responsible for the loss in bioactivity in soil. Considering that many of the compounds previously identified in the literature are volatiles, it is likely that many extract components volatilize and are not available to exert an effect, whereas in petri plates, the volatiles are somewhat contained for a greater length of time and thus elicit an effect.

In this study, the lesser effect of extract in soil than that in the petri plate bioassay was expected due to myriad soil influences. However, both the lavender extract and coumarin had significant inhibitory effects on the growth of ARG in soil trials at all concentrations tested. The dose response curves (Figs. 4 and 5) are similar for both spray applications. This is not surprising as the most phytotoxic lavender fraction contained coumarin as the main active constituent.

Other natural herbicides have been found in plants. Leptospermone is a naturally occurring triketone with herbicidal properties in the Australian native, *Callistemon citrinus* (Cornes 2005). This compound was modified by Syngenta to make a potent synthetic derivative, mesotrione, which is almost 100 times more potent than the initial lead chemical (Cornes 2005). This herbicide (Callisto®) has been developed to control broadleaf weeds in (*Zea mays*) crops and is being used successfully as a pre-emergence and post-emergence herbicide (Cornes 2005). Thus, this approach offers promise in the search for alternative control options for weeds that are developing resistance to existing commercial herbicides, and could play a role in integrated weed management regimes.

Acknowledgements Sincere thanks go to Dr. Nigel Urwin for supplying the plant material and to David Waters, Shane Hildebrand and the late Kim Ashton who assisted with plant collection and processing. The authors also thank the Australian Research Council (ARC) for financial support.

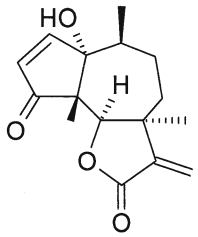
Table 1 Chemical properties of parthenin

formula	$C_{15}H_{18}O_4$
molecular weight	262.12 g/mol
chemical class	sesquiterpene lactone, pseudoguaianolide
nomenclature	1,6β-dihydroxy-4-oxo-10αH-ambrosa-2,11(13)-dien-12-oic acid-γ-lactone



has been identified as the most abundant inhibitor in an Indian population of *P. hysterophorus* (Kanchan and Jayachandra 1980), and its phytotoxicity has been verified on a variety of plant species (Datta and Saxena 2001; Belz et al. 2007). Although parthenin has been found in virtually all *P. hysterophorus* plant parts, it occurs most abundantly in trichomes on the surfaces of the leaves (Rodriguez et al. 1975; Reinhardt et al. 2004). By investigating the dynamics of parthenin accumulation in leaves of *P. hysterophorus*, Reinhardt et al. (2006) showed that the parthenin content of leaves increased with plant age, reaching a peak at the beginning of flowering. Accumulation of high levels of parthenin in or on leaves right until the end of the plant's life cycle suggested that a parthenin-mediated allelopathic potential in *P. hysterophorus* mainly relies on leaching of the compound from leaf residues, thus inhibiting or impeding the recruitment of other species, rather than leaching from leaf surfaces of actively growing plants. Simulating the natural release of inhibitors from decomposing leaf residues by aqueous extraction confirmed this assumption, as leaching of parthenin from leaf material high in parthenin was sufficient to account for up to 100% of the observed extract toxicity (Belz et al. 2007). Thus, if the success of *P. hysterophorus* in invading and establishing new territories actually involves residue allelopathy, parthenin should account for a major part.

Although the natural release of parthenin from leaf trash by way of leaching is not well characterized, the amount of parthenin that leaf material of a single senescent *P. hysterophorus* plant can introduce into the environment has been estimated at approximately 270 mg (Reinhardt et al. 2006). Thus, large quantities of parthenin could enter the soil through decomposing plant material, and estimated concentrations according to plant leaf contents ascribe an allelopathic potential in laboratory bioassays (Belz et al. 2007). However, knowledge of the amount of toxin released to the environment is merely a first step in proving a hypothesis of allelopathy (Fuerst and Putnam 1983). Once an allelochemical enters the soil environment, a number of interacting processes may take place, some of which may transform or degrade the compound and, thus, alter its activity. These processes are influenced by the nature of the compound, organisms present, soil properties, and other environmental factors (Cheng 1992). Therefore, proving a hypothesis of allelopathy must go beyond the production of phytotoxic concentrations by ensuring that the compound accumulates or persists long enough at levels sufficient to affect the development of other plants (Radosevich and Holt 1984). Although it is well-known that the behavior of allelochemicals in soils is a major determining factor for allelopathy, studies that investigate the accumulation of parthenin as well as its fate and persistence in soils are absent. The fact that soils previously infested with *P. hysterophorus* showed a plant growth inhibiting activity (Kohli and Batish 1994), suggests a possibility for direct effects of allelochemicals or their metabolites and/or the accumulation of phytotoxic levels over time. The prospect that parthenin is the major allelochemical responsible for this soil activity still necessitates understanding its soil behavior.

Therefore, the aim of this study was to investigate whether or not parthenin is sufficiently persistent, phytotoxic, and bioavailable in soils to cause an allelopathic effect that could contribute to the invasiveness of *P. hysterophorus*. We investigated these aspects by using soil samples from naturally invaded sites within the KNP, South Africa, that show long lasting *P. hysterophorus* infestation, as well as soil samples from adjacent, uninfested sites. Furthermore, we used commercially available soil samples employed, among other things, for degradation studies with pesticides. The role of various abiotic and biotic factors in the degradation of the compound was investigated, and phytotoxic levels required to directly affect the growth of target plants in a soil environment were quantified. The accumulation and bioavailability of parthenin in soil over time was further studied. This allows for a better understanding of the importance of parthenin as an allelochemical and ultimately for assessing the importance of allelopathy in the invasiveness of *P. hysterophorus*.

Methods and Materials

Origin of Parthenin Parthenin was extracted from *P. hysterophorus* plants (seeds collected at Skukuza in the KNP, South Africa) that were germinated under greenhouse conditions (15/9 h L:D, 22/18°C, 300/0 μE/m^{2}s) in a one-to-one mixture (*v*/*v*) of quartz sand and garden soil (Humusoil, Floragard, Germany) at the University of Hohenheim, Germany. Parthenin was isolated from organic extracts (*tert*-butyl methyl ether) of the leaf surface and fractionated by preparative high performance liquid chromatography (HPLC; Varian model chromatograph) with UV detection (Varian UV-VIS detector model 345) as described by Belz et al. (2007). Purity of isolates was quantified by HPLC-DAD (photodiode array detection) at ≥95%.

Origin of Soils Top soil samples (0–20 cm) were collected from various sites and included an organic soil (compost soil; CS), three 'standard soils' with certain characteristics provided by LUFA Speyer (Landwirtschaftliche Untersuchungs- und Forschungsanstalt Speyer, Germany), and four soil batches from the KNP, South Africa (Table 2). Samples were sieved at 2.0 mm and either used field-fresh (CS) or after storage at room temperature at 20% water-holding capacity (WHC). All stored soil samples were preincubated for 2 wk under test conditions (40% WHC, 20±2°C, darkness) prior to the start

of the experiment. The physico-chemical properties of the soils as given in Table 2 were determined by the soil laboratory LUFA Speyer.

Soil Persistence Studies—General Protocol An equivalent of 50 g of dry soil was added to glass jars (290 ml Sturzglas with glass lids, Weck, Germany) and adjusted to 40% WHC with demineralized water. Parthenin dissolved in a one-to-one mixture of acetone and demineralized water (*v*/*v*) was added to each soil sample to obtain a parthenin concentration of 10 µg/g dry soil (10 µl acetone/g dry soil). This concentration seemed relevant to mirror a natural situation of invasion based on the calculated potential parthenin levels in top soil (≤2 cm) at a plant density of 1–4 plants/m^2 [9.6–43.0 µg/g dry soil; after Van der Laan (2006)] and the parthenin levels found by us in naturally infested soil samples (0.1–6.4 µg/g dry soil). After addition of parthenin, soil samples were stirred thoroughly with a spatula to ensure an even distribution. Loose-fitting glass lids that allowed air circulation were placed on each jar, and jars were kept at 20± 2°C and darkness in growth chambers. Demineralized water was replenished every 3–4 d to maintain samples at 40% WHC by differential weighing. Initial sampling was done immediately after application and after 1 h to determine recovery rates, and thereafter another 14 times at intervals adapted to record degradation under the various specific experimental modifications. One jar was sampled at each time and stored at −20ºC until analyzed. In order to determine the influence of abiotic and biotic factors, the general protocol was modified as follows.

Influence of Abiotic Factors The dependence on soil type was studied with three standard soils (2.1, 3A, and 5M; Table 2). Concentration dependence was evaluated with six initial parthenin concentrations ranging from 8 to 820 µg/g dry soil. The influence of soil moisture was assessed at 20, 40, and 80% WHC, and the influence of ambient temperature was studied at 20, 25, and 30°C.

Influence of Biotic Factors The significance of microorganisms was investigated through the sterilization and preconditioning of soils. Sterilization of CS soil was done by autoclaving for 60 min at 120°C (1× sterilized) and repeated after 2 wk of incubation under test conditions (2× sterilized). Sterile, demineralized water was used to adjust and replenish soil moisture, and all preparation steps as well as replenishment of water were done under sterile conditions. Incubation of soil samples during the test was, however, non-sterile. An artificial preconditioning treatment of CS soil was done under test conditions with parthenin at four different concentrations ranging from 0 to 1,000 µg/g dry soil. The time intervals for preconditioning were adapted to allow for a degradation of parthenin lower than the limit of detection (2 wk at 10 µg/g, 3 wk at 100 µg/g, and 5 wk at 1,000 µg/g). The hypothesis of a natural preconditioning for parthenin degradation in *P. hysterophorus* infested soils was investigated by using soil samples collected from naturally infested sites and adjacent, uninfested sites in KNP, South Africa (Skukuza, Crocodile Bridge).

Chemical Analysis Parthenin was analyzed by organic solvent extraction of soil samples. At first, demineralized water was added to obtain a final volume of 15 ml/50 g dry soil. No water was added to soil samples adjusted to 80% WHC. Subsequently, 85 ml of a one-to-one mixture of acetone and *tert*-butyl methyl ether (*v*/*v*) were given to each soil sample followed by 30 min shaking extraction on a mechanical shaker at 200 motions/min (KS501digital, Fa. IKA Labortechnik). A 30 min sedimentation period followed. The supernatant was filtered through approximately 40 g of a one-to-one (*v*/*v*) mixture of Na_2SO_4 and quartz (cryst., 0.6–1.2 mm, Fa. Roth). An aliquot of 40 ml was concentrated in a rotary vacuum evaporator at 40°C followed by vacuum centrifugation at 40ºC (RVC 2–25, Fa. Christ, with cooling trap) until a volume of 600 µl was obtained. After the addition of 400 µl acetonitrile (ACN), samples were centrifuged (20 min, 14,000 rpm), and transferred to HPLC vials. HPLC analysis was done on a Waters model chromatograph with DAD detection (photodiode array detector, Waters 991). A Synergi polar C-18 reversed phase column [250 mm by 4.6 mm (4 µm), Phenomenex, Germany] was used, and eluted with a gradient of 15% ACN and 85% Na_2HPO_4-buffer (1 mM, pH 2.4, 10% ACN) for 0–5 min (0.65 ml/min flow rate), 56% ACN and 44% Na_2HPO_4-buffer for 5–19 min (0.75 ml/min flow rate), 100% ACN for 19–27 min (0.75 ml/min flow rate), then reequilibrated to starting conditions. Injection volume was 50 µl.

Parthenin was identified and quantified at 220 nm by using external calibration curves. The retention time was 17.3±0.2 min. Instrumental limits of quantification were determined at 220 nm according to Frehse and Thier (1991) at a fortification range of 0.25–10 µg/ml based on standard solutions of parthenin. The limit of quantification was 2.18 µg/ml or 0.11 µg/g soil based on a 50 g dry soil sample. Recovery rates for the analytical procedure were 99.3±5.4% at a fortification level of 10 µg parthenin/g dry soil on average for all experimental soils.

Soil Phytotoxicity Studies Phytotoxicity of parthenin in different soils was studied in a germination assay conducted in glass petri dishes (4.5 cm diam.) with *Lactuca sativa* L. var. *capitata* cv. Maikönig as test species. The fast growing, evenly germinating receiver *L. sativa* was preferred as it was shown to be as comparable in sensitivity to parthenin

as to some indigenous species (Belz et al. 2007). The quantity of soil per petri dish was calculated to give 120% WHC with the applied 2 ml of test solution per dish (4.0 g dry soil/petri dish for SA1, 4.5 g for SA2, 4.6 g for SA3, and 3.4 g for SA4). The aqueous test solution contained parthenin in nine different concentrations to give 0–1.6 mg/g dry soil and 1% acetone as solvent (5 µl/g dry soil). Controls received water and acetone only. For each treatment, 15 seeds were placed on the soil surface, and petri dishes were sealed with parafilm. Each treatment was replicated three times, and petri dishes were positioned in a randomized design in a growth chamber (12/12 h, 24/18°C, 50/0 µE/m^{2}s). After 7 d, total seedling length was measured (≥1 mm), and concentration-response curves were calculated using Equation 1.

Soil Phytotoxicity over Time The biological activity of parthenin in CS soil over time was studied at an initial concentration of 700 µg/g dry soil. Nineteen soil samples were treated with parthenin and incubated following the above described general protocol for soil persistence. Treated soil samples were harvested continuously over a period of 3 wk (one jar at a time) and stored at −20ºC until used. Two untreated soil samples (controls) were incubated in the same way and harvested at the beginning and the end of the incubation period. After thawing, soil samples were kept under a hood for 2 h and stirred every 15 min in order to evaporate acetone residues. Subsequently, each soil sample was readjusted to 40% WHC and split. One part (25 g) was chemically processed for quantification of parthenin, and the remaining part was used for bioassays.

To bioassay the remaining toxicity of parthenin in the harvested soil samples, 3.5 g of soil (40% WHC) were weighed per petri dish in triplicate for each harvest time, and demineralized water was added to give 120% WHC (1.3 ml/petri dish). After the addition of 15 seeds/petri dish, dishes were sealed with parafilm and incubated as described above. Total seedling length was measured after 7 d (≥1 mm), and responses over time were modeled by using Equation 1.

Soil Accumulation Studies The possibility of an *accumulation* of parthenin in soil over time due to a periodic exposure was evaluated by a single, double, and triple application of 400 µg/g dry soil at a time interval of 38 d each. The experimental procedure followed the above described general protocol for soil persistence studies with CS soil.

Data Analysis Mathematical modeling of concentration-response curves in phytotoxicity studies as well as degradation curves of parthenin in soil was done by nonlinear regression analysis using the logistic Equation of Streibig (1988) (Equation 1).

$$y = c + \frac{d - c}{1 + e^{b*LN(x/\alpha)}} \quad (1)$$

- y expected response in bioassay or soil toxin concentration
- x toxin concentration in bioassay or incubation time in soil
- d expected response of untreated controls in bioassay or soil toxin concentration at time $x = 0$
- c expected response at indefinitely large concentrations in bioassay or soil toxin concentration at $x \rightarrow \infty$
- b rate of change around α
- α EC_{50} (effective concentration giving 50% response in bioassay) or DT_{50} (time where 50% of the applied toxin concentration disappeared)

In case of hormetic responses in bioassay, modeling used the extended logistic regression model of Cedergreen et al. (2005), whereas the rate of increase in responses at subinhibitory concentrations (a) was fixed to −0.5 according to the smallest residual sum of squares. Significance of hormesis was assessed by the 95% confidence interval for the estimate of the theoretical upper bound of the hormetic effect f and was given for $f>0$. Characteristic features of the hormetic response were derived by estimation from fitted curves. The kinetics of parthenin degradation in soil as modeled according to Equation 1 was compared further to a commonly used first-order kinetics model [$y=d$*exp(-kx) with k as the proportionality coefficient (Aldworth and Jackson 2008; Etzerodt et al. 2008)] in order to find the most appropriate model describing the degradation. All modeling was done with SPSS®, and the quality of curve fitting was assessed by F test for lack-of-fit based on an analysis of variance (P=0.05) or by graphical assessment of the distribution of data around regression lines. Comparison of curves was done by horizontal assessment (F test, P=0.05).

Once the concentration-response curves were fitted, the estimated DT_{50} (time where 50% of the applied toxin concentration disappeared) and b values (rate of degration) were used in a subsequent correlation analysis to quantify the significance of covariance with soil characteristics and experimental conditions. Quantification was done by the *Pearson* correlation coefficient r_P in case of a linear relation and the *Spearman* coefficient r_S in case of a nonlinear relation.

Results

The disappearance of parthenin from soil was characterized by a variable lag-phase period that ranged from a few hours after application up to several days, depending on experimental

conditions (Figs. 2, 4, 7). Comparison of HPLC-DAD chromatograms of treated soil after different incubation periods showed several unidentified metabolites, indicating that parthenin disappearance involves degradation of the compound (Fig. 1). Evaluation of the most appropriate model to describe the degradation showed that the first-order kinetic model failed to properly fit the data more frequently than the logistic model. In addition, the logistic model showed, on average of the various experimental conditions, smaller residual sum of squares, and was thus considered more adequate to describe parthenin degradation kinetics.

Degradation in Different Soils The DT_{50} values of parthenin differed significantly depending on the soil type used, while b values as a measure for the rate of degradation around DT_{50} did not (average b=1.99±0.17; mean ± standard error). Thus, degradation curves were merely shifted along the time axis (Fig. 2a). Parthenin disappeared most rapidly in the standard soil 3A with a DT_{50} of 43.1±5.3 h and, thus, significantly faster than in standard soils 5M and 2.1. Parthenin disappeared most slowly in standard soil 2.1 with a DT_{50} of 88.9±6.8 h, which was, however, not significantly different from standard soil 5M (DT_{50} 65.6±6.3 h).

Influence of Initial Substrate Concentration The initial soil parthenin concentration significantly influenced the rate of degradation (b), and the DT_{50} in CS soil, but curves did not significantly differ at 8 and 17 µg/g dry soil, 44 and 93 µg/g, or 425 and 820 µg/g (Fig. 2b). A significant positive correlation between initial parthenin concentration and b values of the curves as well as DT_{50} values also was observed (Fig. 3a). At the lowest concentration, the degradation of parthenin started after 9 h (DT_{10}=8.9±1.3 h), and 90% disappeared during the first nine days (DT_{90}=210.4±23.0 h). Increasing the initial parthenin concentration delayed the onset of degradation and led to a

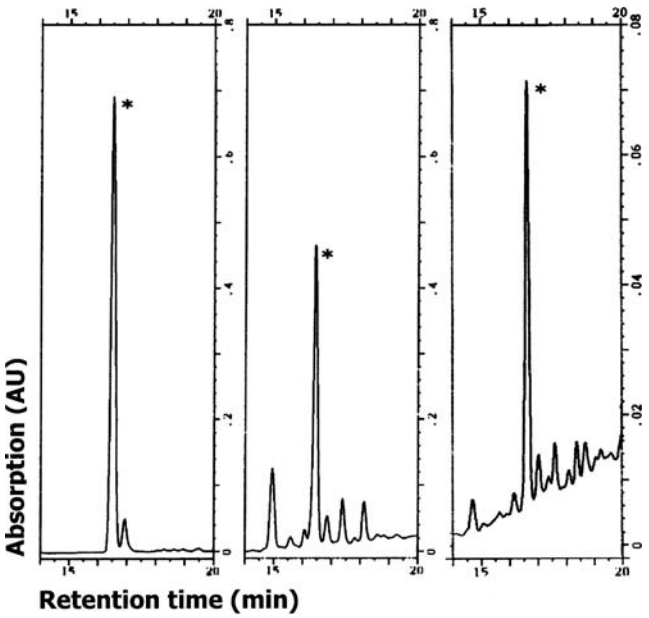

Fig. 1 HPLC-DAD chromatograms (220 nm) of compost soil samples incubated with parthenin at 1,000 µg/g dry soil for 1 h (*left*) or 16 d (*middle*) and of a natural infested soil sample (SA4; *right*); *= parthenin

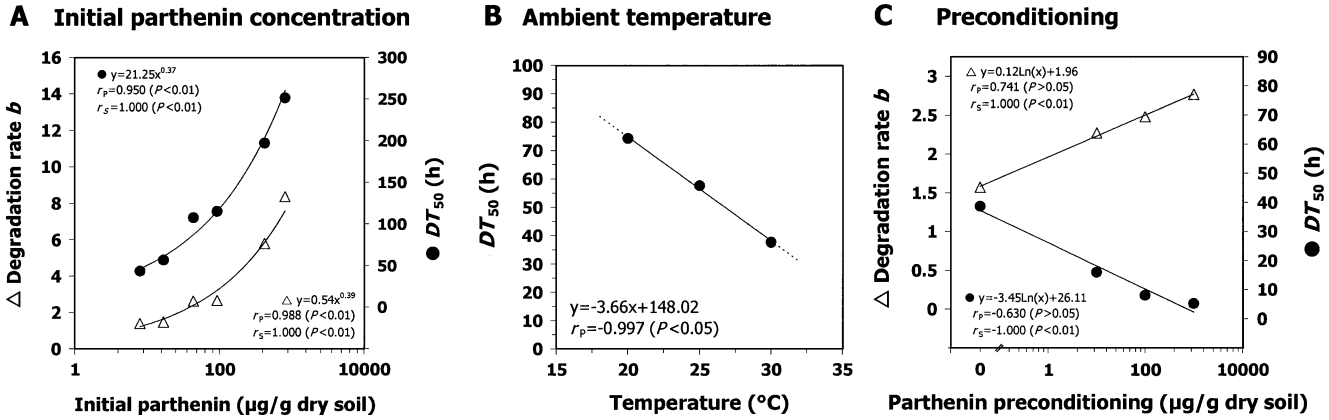

Fig. 3 Correlation of DT_{50}-values of parthenin or degradation rates *b* with initial substrate concentration (**a**), ambient temperature (**b**), and preconditioning (**c**); DT_{50} disappearance time 50%; *b* rate of change around DT_{50}; r_P *Pearson* correlation coefficient; r_S *Spearman* correlation coefficient; *P* probability level; degradation in compost soil CS at 10 µg/g soil (except **a**), 40% *WHC* water holding capacity, 20°C (except **b**), and darkness

prolonged lag-phase of about eight days at 820 µg/g (DT_{10}=193.1±9.1 h), which is nearly 22-fold later than at 8 µg/g. However, due to an increase in degradation rates with increasing concentration, 90% of the highest concentration disappeared during 14 days after application (DT_{90}=326.6±11.8 h), which is only less than 2-fold slower than at 8 µg/g. This showed that the degradation of parthenin is concentration-dependent and characterized by an expansion of the initial lag-phase with increasing concentration followed by an accelerated rate of degradation.

Influence of Soil Moisture Soil water content only significantly influenced the degradation of parthenin under dry conditions, with curves not differing at 40 and 80% WHC (DT_{50}=48.7±0.2 h at 40%; 53.9±0.2 h at 80%) (Fig. 2c). Degradation at 20% WHC was on average almost 2-fold slower than at the higher water contents, whereas the degradation rate was not significantly different at any soil moisture content (average b=2.05±0.12). As a consequence, DT_{50}-values did not correlate with soil moisture content (r_P=−0.689; P=0.516).

Influence of Ambient Temperature The incubation temperature had a significant influence on the disappearance of parthenin in the CS soil, whereas *b* values of the degradation curves did not (average b=1.80±0.11). Thus, degradation curves again were merely shifted along the time axis. The DT_{50} of parthenin was highest at 20°C (76.4±4.3 h) and decreased significantly by 1.3-fold at 25°C and 2.2-fold at 30°C. The observed negative correlation between incubation temperature and DT_{50}-values was significant at P=0.05 (r_P=−0.997) (Fig. 3b).

Influence of Soil Sterilization Sterilization of the CS soil prior to application of parthenin significantly delayed the onset of degradation and increased the DT_{50} of parthenin despite accelerating the rate of degradation. Compared to unsterilized soil (DT_{50}=69.6±5.4 h), sterilization led to a 5-fold slower degradation for the single sterilization treatment and a 9-fold slower degradation for the double treatment (Fig. 4a). The degradation curves of both sterilized soils showed on average 2-fold higher rates of degradation (*b*) as the unsterilized soil (b=1.41±0.15). Soil sterilization, therefore, enhanced the soil persistence of parthenin considerably.

Influence of Soil Preconditioning A subsequent degradation of 10 µg/g dry soil after preconditioning of CS soil with three different concentrations of parthenin showed a pronounced preconditioning effect (Fig. 4b). Parthenin degraded the slowest in the absence of a preconditioning (DT_{50}=38.7±2.0 h), more than 2-fold faster at a preconditioning of 10 µg/g, more than 4-fold faster at 100 µg/g, and more than 7-fold faster at 1,000 µg/g. Accordingly, there was a negative correlation between DT_{50}-values and preconditioning concentration (Fig. 3c). A preconditioning with parthenin steepened the degradation curve, although differences in *b*-values were not significant. Nonetheless, the observed nonlinear correlation between degradation rates (*b*) and preconditioning concentration was significant (Fig. 3c). Due to the steepening of the curves, 90% of the applied parthenin at 1,000 µg/g disappeared within 9.1 h after the onset of degradation (DT_{10}=2.3±0.3 h), while it took 147.2 h in the absence of a preconditioning after a lag-phase of 9.6 h. This showed that parthenin can disappear more rapidly from preconditioned soils.

Influence of P. hysterophorus Infestation Considering the observed preconditioning effect under laboratory conditions, soils infested with *P. hysterophorus* should be preconditioned

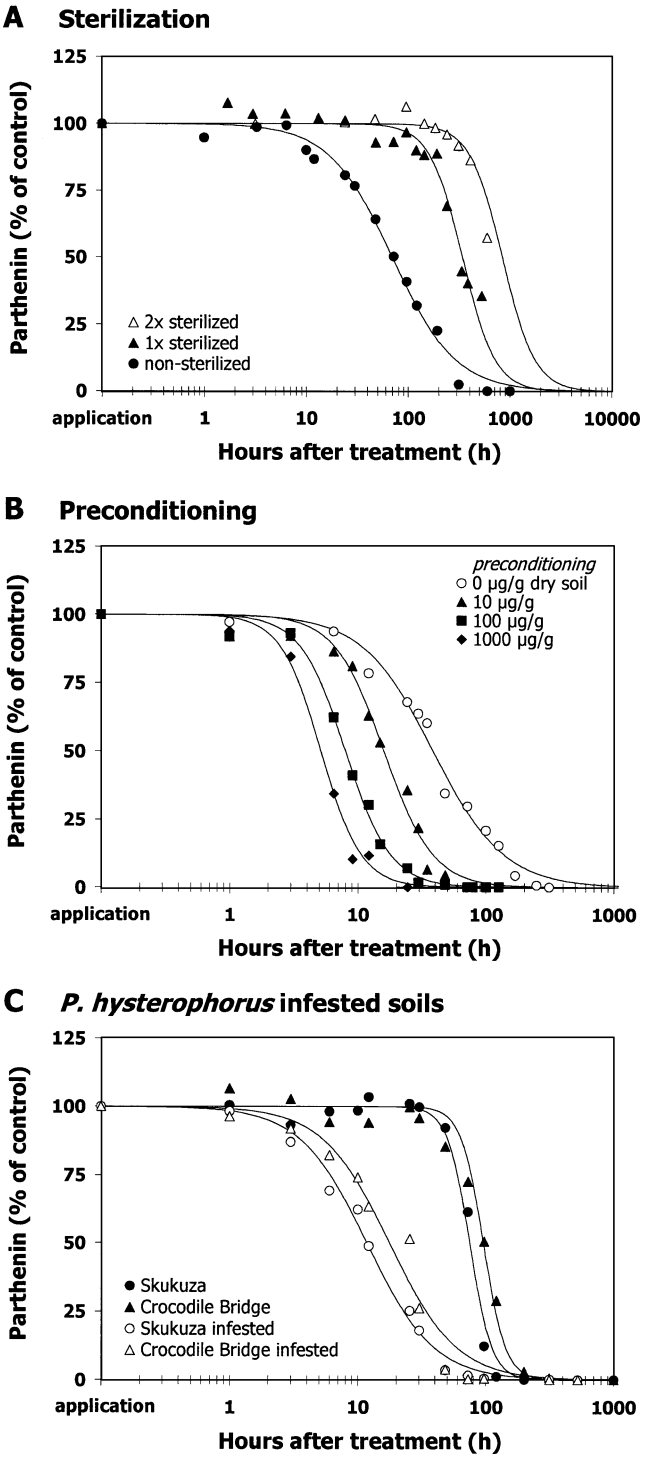

Fig. 4 Degradation of parthenin in soil as related to preceding sterilization (**a**; R^2=0.96), soil preconditioning with different parthenin concentrations (**b**; R^2=0.99), and natural infestation with *Parthenium hysterophorus* of two South African soils (location Skukuza and Crocodile Bridge) (**c**; R^2=0.97); degradation in compost soil (except **c**) at 10 µg/g soil, 40% *WHC* water holding capacity, 20°C, and darkness

for parthenin degradation if parthenin is actually released from plant material. Investigation of the degradation of parthenin in two naturally infested soils (SA1 and SA4) in comparison with adjacent, uninfested soils (SA2 and SA3) showed that degradation curves of both infested and uninfested soils did not significantly differ. However, parthenin, based on DT_{50}-values, was degraded 6-fold faster in the infested soil samples SA1 and SA4 (average DT_{50}= 14.4±1.1 h) (Fig. 4c). The degradation curves of the infested soils were further characterized by 3-fold lower rates of degradation (average b=1.66±0.15). Prior to the start of the experiment, chemical analysis of soil samples showed traces of parthenin in the infested soils (0.77±0.09 µg/g dry soil on average; Fig. 1), while no parthenin was detectable in the uninfested soils. After two weeks of preincubation under test conditions, no parthenin, however, was detectable in the infested soils either.

Correlation of Soil Characteristics with Degradation Investigation of the relationship between soil characteristics (Table 2) and DT_{50} values of the eight different soils showed a highly significant negative correlation for potential cation exchange capacity (CEC_{pot}; r_P=−1.000, P<0.001) and the clay content of the soils (r_P=−0.998, P=0.007) (Fig. 5). Correlations between DT_{50} values and the remaining soil characteristics as given in Table 2 were not significant (P> 0.05). This indicated that parthenin degradation is favored in clayey soils with high CEC_{pot}.

Soil Phytotoxicity Studies The phytotoxicity of parthenin in a soil substrate was studied by using the South African soil samples from *P. hysterophorus* infested (SA1 and SA4) and uninfested sites (SA2 and SA3). The bioassay showed that parthenin was more phytotoxic in the uninfested soils. However, the concentration-response curves of both infested and uninfested soils did not significantly differ (Fig. 6a). The uninfested soils showed on average a 4-fold higher parthenin phytotoxicity (EC_{50}=153.7±11.1 µg/g dry soil) than the infested soils (629.9±34.7 µg/g), and concentration-response curves were significantly shallower (average $b_{uninf.}$=1.57± 0.13, $b_{inf.}$=2.51±0.29). Accordingly, at the EC_{10} response level, 7-fold higher amounts of parthenin were needed in the infested soils (average EC_{10}=37.8±6.0 µg/g).

Soil Phytotoxicity over Time The question of whether parthenin remains bioavailable in a soil environment was investigated by monitoring the decline of the phytotoxic effect at 700 µg/g in CS soil. This concentration level nearly caused a 50% inhibition of plant growth in CS soil in a preliminary bioassay. The chemical analysis of parthenin degradation revealed an onset at 10.4±0.6 days (DT_{10}), a DT_{50} of 12.7±0.3 days, and 90% disappeared within 15.6± 0.9 days. Bioassay results showed that the observed initial

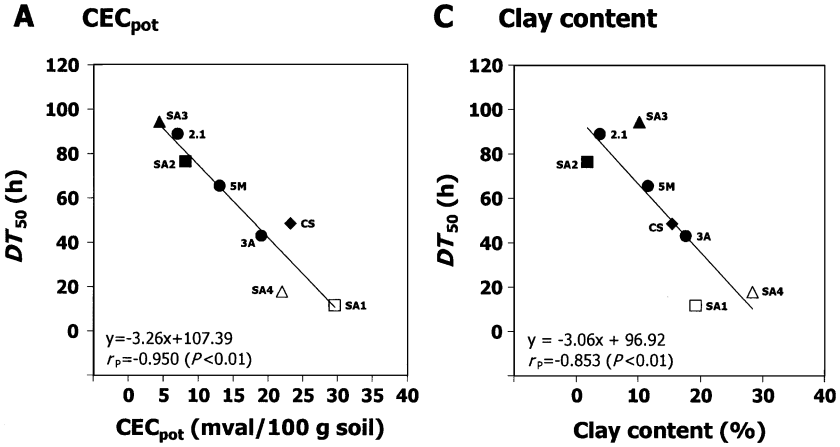

Fig. 5 Correlation of DT_{50}-values of parthenin with soil characteristics (see Table 2 for soil labeling); DT_{50} disappearance time 50%; CEC_{pot} potential cation exchange capacity; r_P *Pearson* correlation coefficient; *P* probability level; degradation at 10 µg/g soil, 40% *WHC* water holding capacity, 20°C, and darkness

inhibition by parthenin (46% of control) persisted for about 1.1 days (90% response level) before it declined. Stimulatory effects appeared from about 4.1 days (1% response level) after the start of the experiment. The stimulatory effect proved significant and reached a maximum of 191% of control at 10.5 days after application. As the chemical analysis estimated the onset of degradation at 10.4 days after application, the observed earlier decline in phytotoxicity and the induction of hormetic effects could not be caused by degradation of the active compound (Fig. 6b).

Soil Accumulation Studies The periodic application of parthenin at 400 µg/g again showed a pronounced and significant preconditioning effect along with a significant change in degradation rates at the second and third application (b_1=14.89±1.81; average $b_{2/3.}$=2.61±0.15) (Fig. 7). Parthenin was degraded with a DT_{50} of 210.5± 1.7 h for the first application, degraded more than 6-fold faster for the second application, and more than 13-fold at the third application. For the last application, the degradation started as early as 6.1 h after application (DT_{10}), and 90% had disappeared within 37.6 h. There was no indication for an accumulation of parthenin to biologically active levels in the CS soil, as the lower limits (C) of the three degradation curves did not significantly differ. Thus, at each application, parthenin was degraded to concentrations below the detection limit (<0.07 µg/g dry soil).

Discussion

After phytotoxins have been released into soils, the expression of their phytotoxicity can be significantly modified by physical, chemical, and biological soil properties. Testing the hypothesis of a compound's involvement in allelopathic interactions, therefore, requires an examination of its fate and persistence in soil, and soil concentrations

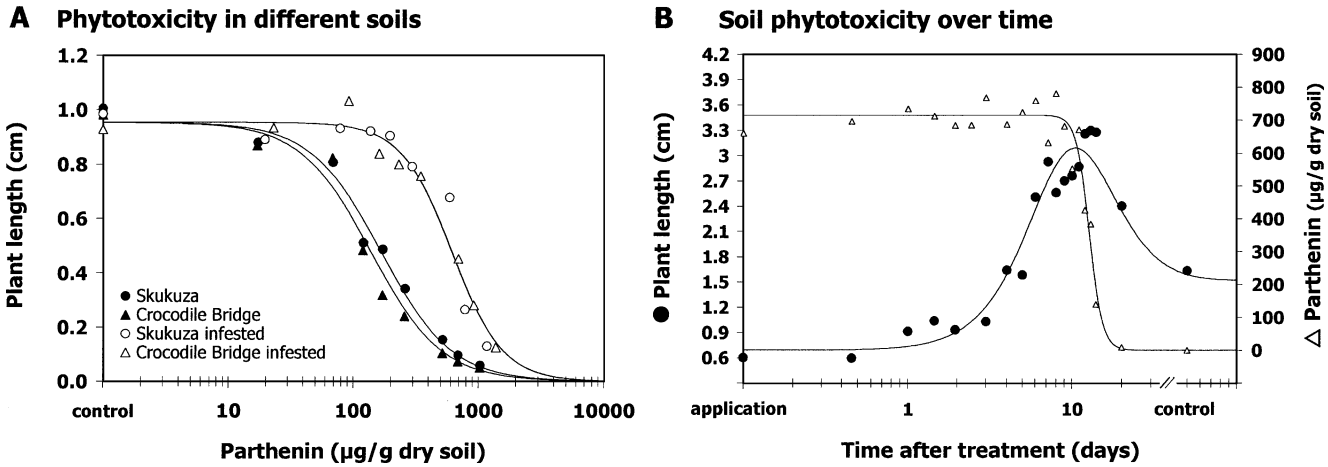

Fig. 6 Phytotoxicity of parthenin in soil as measured by total plant length (root + shoot) of *Lactuca sativa* as related to initial substrate concentration and soil type (**a**; R^2=0.88) or incubation period of 700 µg/g dry soil of parthenin in compost soil CS (**b**; $R^2_{bioassay}$=0.72; $R^2_{degradation}$=0.94); bioassay at 120% *WHC* water holding capacity, 24/18°C and 50 µE/m^{2}s for 12/12 h (**a**, **b**); degradation at 40% WHC, 20°C, and darkness (**b**)

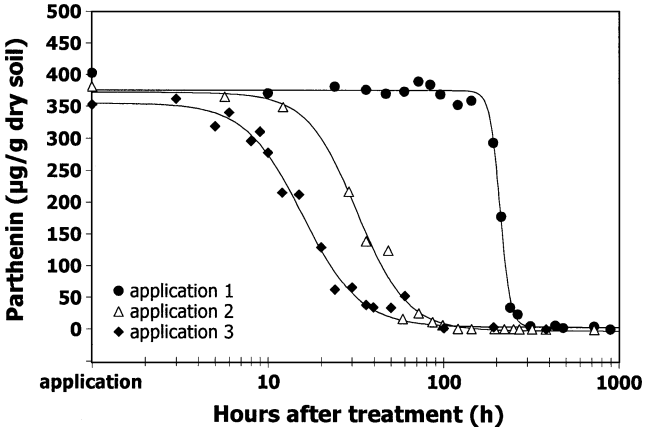

Fig. 7 Degradation of parthenin in compost soil CS after recurrent application of 400 µg/g soil at a time interval of 38 days each (20°C; darkness; 40% *WHC* water holding capacity); R^2=0.99

must be proven to adversely affect the receiving plant. Despite a promising allelopathic potential in the lab, short half-lives and very low field levels of major phytotoxins often deny an involvement in allelopathic interference and let other mechanisms of interference come to the fore. A recent example for this is the strong evidence refuting (–)-catechin involvement in the invasiveness of *Centaurea stoebe* L. (Duke et al. 2009a, b), despite previous reports (Bais et al. 2003; Inderjit et al. 2006; Perry et al. 2007). The investigation of the persistence of parthenin in soil revealed that parthenin also is quickly degraded with a mean DT_{50} of 59 h in six uninfested soils under standard experimental conditions. Abiotic and biotic variables proved to significantly impact parthenin degradation. Notably, preconditioning could reduce the observed standard DT_{50} value to nearly 5 h. Therefore, parthenin is considered to have rather low persistence in soil.

Regarding the inherent physico-chemical characteristics of soils, parthenin turned out to be degraded faster in clayey soils with high CEC_{pot}. The importance of soil characteristics in degradation of allelochemicals is well known (Dalton et al. 1989; Kobayashi et al. 2004), and selected soil characteristics also have been shown to be correlated closely to mineralization, degradation, and/or sorption/desorption of certain commercial pesticides (Sparling et al. 1998; Olvera-Velona et al. 2008). In the case of parthenin, CEC_{pot} proved to be indicative of the capacity of soils to degrade parthenin. The primary factors that determine CEC_{pot} are the amount and type of clay and soil organic matter content (Scheffer and Schachtschabel 2002). In this study, a significant correlation between DT_{50} of parthenin and clay content of soils, but not C_{org} was observed. Calvet et al. (1980), however, pointed out that the correlation between the degradation of non-ionic herbicides and soil organic matter is not always very good across the range of 0 to 4% organic matter. This range includes all but one of the soils tested in this study, so the soils used might have contained too little C_{org} for a significant correlation. As parthenin proved more stable in certain soil types, it might be expected that *P. hysterophorus* could especially invade these soil types if parthenin-mediated allelopathy were operative. Such evidence, however, does not exist under natural conditions, as *P. hysterophorus* preferably colonizes clay loam to clay soils, and is especially capable of out-competing other plant species on heavy cracking clays (Parthenium Weed Management 2004). Thus, *P. hysterophorus* seems to preferably and most efficiently colonize soils that have a higher capacity to degrade parthenin.

The influence of initial substrate concentration supports the graphically derived assumption that parthenin degradation is not true first-order kinetics as DT_{50}-values did change with concentration. The same has been observed previously for other allelochemicals (Borek et al. 1995; Etzerodt et al. 2008), and is suggested to apply for most current-generation agrochemicals (Aldworth and Jackson 2008). Degradation of higher initial parthenin concentrations proved to be characterized by a broad lag-phase preceding the onset of degradation. This may indicate a possible involvement of microorganisms, as high concentrations may cause paralysis or toxicity to soil microorganisms and, thus, result in a delayed onset of degradation due to required adaptation and acclimation (Bending and Rodriguez-Cruz 2007; Etzerodt et al. 2008). Despite the observed prolonged lag phase, higher concentrations completely disappeared just less than 2-fold more slowly than lower concentrations. Parthenin-mediated plant interactions may thus be rather short-lived even if high amounts of parthenin are released.

Manipulation of soil moisture showed no significant influence between 40 and 80% WHC. However, the degradation of parthenin was delayed significantly at 20% WHC, which may be a further indication for the involvement of microorganisms, as their activity significantly decreases under dry conditions (Schricker 1996). The optimum soil moisture content for microorganism activity ranges between 40 to 70% WHC (Schricker 1996; Terytze et al. 2000), which would explain the observed lack of correlation between the tested soil moisture levels and DT_{50} values of parthenin.

Ambient temperature was significantly correlated with parthenin disappearance in terms of a faster degradation with increasing incubation temperature. A fast, temperature-sensitive disappearance of parthenin can, therefore, be expected to occur in the tropic and subtropic environments under which *P. hysterophorus* flourishes, albeit with seasonal fluctuation. As most microorganisms are mesophilic and promoted by increasing temperatures within a certain

temperature range (Scheffer and Schachtschabel 2002), the observed temperature dependence may further support the assumption of a microbial involvement.

Additional evidence for a microbial degradation could be obtained by a significantly declined degradation in sterilized soils and an enhanced degradation at repeated applications. This is consistent with findings of a microbial transformation of parthenin (Bhutani and Thakur 1991; Abdel Halim et al. 2007), and it points to the possibility of enriching soils with microorganisms that are capable of degrading parthenin, a phenomenon that is well known from several commercial herbicides (Walker et al. 1993; Pussemier et al. 1997). Hence, it was no surprise that soil samples previously infested with *P. hysterophorus* showed on average a 6-fold higher capacity to degrade parthenin than adjacent, uninfested soils. This along with the quantifiable presence of parthenin in both infested soil samples showed that parthenin must have actually been released by *P. hysterophorus* plants or plant residues under field conditions and degraded in the soil beneath the sampled stands. Therefore, the observed low persistence of parthenin in these soils might have resulted from a natural preconditioning for parthenin degradation. On the other hand, DT_{50} values of the infested and adjacent soil samples both followed the observed correlation to CEC_{pot} and clay content. This raises the question of which aspect is more decisive for parthenin degradation: a preconditioning effect or physico-chemical soil factors? Degradation studies with pesticides have shown that for naturally faster degrading soils, an enhancement of biodegradation by repeated applications is small or negligible (Bischoff et al. 2005). However, our results showed that degradation curves in soils that differed in physico-chemical soil factors were merely shifted along the time axis, while degradation rates b also changed in the case of preconditioning or repeated application, and *P. hysterophorus* infestation. Hence, physico-chemical factors alone do not explain observed degradation kinetics of infested soils. Rather, the fate of parthenin in soil is most likely governed by physico-chemical processes combined with microbial activity, whereas the importance of the particular process may fluctuate depending on the situation.

Apart from this, it is difficult to find adequate soils for use as 'control soils'. This study used soil samples from adjacent, uninfested sites as control, which is a common practice in allelopathy research (Weidenhamer et al. 1989; Kohli and Batish 1994). Analysis showed, however, that the current 'control soils' differed markedly in soil characteristics. Additionally, allelopathic plant infestation may further cause changes in soil characteristics (Kohli and Batish 1994; Inderjit 1998), and thus it is obvious that the role of infestation is difficult to prove with such differing soils. The isolation of microorganisms capable of degrading parthenin and the possibility of enrichment by parthenin may shed light on this. A knowledge of the spectrum of microorganisms that degrade parthenin may further help to explain the fact that we found indications for a biodegradation in South African and German soils that could be expected to differ in their spectrum of microorganisms.

As our results indicated the formation of several, unidentified metabolites, we considered the possibility that parthenin could be degraded to a more toxic compound. Concentration-response curves for the inhibition of *L. sativa* by parthenin in soil revealed a higher phytotoxicity in uninfested soil samples that showed a higher persistence of parthenin. Thus, the phytotoxicity of parthenin is impaired if degraded faster, i.e., in soils with high CEC_{pot}/clay content and/or preconditioned for parthenin degradation. A possible explanation for this is that parthenin is transformed to metabolites of lower or no phytotoxicity. A parthenin-mediated allelopathic effect might, therefore, be based on parthenin as the primary allelochemical and require high soil levels or a periodic exposure to compensate for rapid degradation. Evidence for such high soil levels were not found in the current study. In five soil samples taken at three different times (August 2005, November 2006, October 2007) at two sites in the KNP with high *P. hysterophorus* infestations, we measured parthenin levels between 0.1 and 6.4 µg/g dry soil, even though one sampling event was in early August, a time when most *P. hysterophorus* leaf residues are expected on the soil surface (Weeds of National Significance 2003). These soil concentrations are 6–2628 times lower than the currently observed EC_{10} values in bioassays, the virtual 'no observable effect levels'. Thus, quantified levels for the KNP soils are too low to deduce a significant impact on neighboring plants.

In addition, a comparison of the phytotoxic effect in soil over time with the respective degradation curve showed that the onset of degradation lags behind the loss in phytotoxicity. A plausible explanation for this is that parthenin does not remain fully bioavailable in the soil. The high recovery rates during the lag-phase showed, however, that inactivation obviously does not provide protection from the applied acetone/TBME extraction. Hence, the estimated soil concentration should represent both the biologically available and unavailable fraction of parthenin. The exposure of recipient plants to parthenin in the infested KNP soils is, thus, even lower than currently determined. A lowering of the bioavailability further induced growth stimulatory effects. Hormetic effects at low concentrations are well known for parthenin from pure compound studies (Belz et al. 2007; Belz 2008) and plausibly such effects would also appear if parthenin concentrations in soil were lowered by inactivation. Hence, the phytotoxicity of parthenin in soils is impaired by a time-dependent decline in bioavailability and the induction of hormesis. A comparison of the concentration-response

values obtained with a single parthenin application with concentrations that occur under natural field conditions, however, is not straightforward, as such a comparison does not account for temporal allelochemical dynamics (Inderjit et al. 2006; Perry et al. 2007). As our samplings consistently detected low levels of parthenin, this issue may be relevant here, and future studies that account for a periodic exposure of recipient plants are required.

Finally, we wanted to determine whether or not parthenin accumulates in soils over time to levels sufficient to affect the development of other plants. Other compounds such as juglone or phenolic acids can accumulate in soil through a mechanism of reversible sorption (Cecchi et al. 2004; von Kiparski et al. 2007). The triple application of parthenin at 400 µg/g soil, however, provided no indication that parthenin accumulates in soils.

In summary, although previous studies assigned parthenin a role in the invasion success of *P. hysterophorus*, this study revealed several aspects that hamper the extent to which parthenin is involved in allelopathy of *P. hysterophorus*. Parthenin was rather quickly degraded without any evident accumulation to toxic levels over time. Schmidt (1988) and Schmidt and Ley (1999) claimed that a rapid bioinactivation of suspected allelochemicals in natural soils makes it unlikely that these compounds are important mediators of plant–plant interactions under natural conditions. Furthermore, inactivation and degradation of parthenin can lead to hormetic growth stimulation. A soil-based allelopathic activity mediated by parthenin may, thus, be rather short-lived and/or hormetic without significant residual activity. The chemical control of another plant will require the release of high amounts of parthenin. High or biologically active soil concentrations of parthenin were not demonstrated in our analysis of infested soil samples. Finally, *P. hysterophorus* seems to be particularly invasive and capable of outcompeting other plant species under soil and environmental conditions that favor the degradation of parthenin. Based on this, we conclude that the present state of research provides insufficient evidence to support the hypothesis that parthenin contributes to the invasiveness of *P. hysterophorus*.

On the other hand, given that parthenin-containing leaf leachates of *P. hysterophorus* stimulate plant chlorophyll content (Kumari and Kohli 1987), one can speculate that self-stimulatory allelopathy rather than inhibitory allelopathic interactions may contribute to the capacity of *P. hysterophorus* to form dense pure stands. Self-stimulating effects are presumed to be important for the dominance of a species in a natural habitat (Schlee 1992) and may, thus, be a key process involved in altering the balance among species. Furthermore, a periodic parthenin input from both live plants and decaying plant residues into soil and/or the contribution of other allelochemical(s), could still conceivably produce an allelopathic effect. Bioassay-guided isolation identified parthenin as the leading putative allelochemical of *P. hysterophorus*, but additionally several phenolic acids and other plant constituents as minor inhibitors (Kanchan and Jayachandra 1980). Allelopathy of *P. hysterophorus* could possibly involve a complex mixture of compounds that act additively or synergistically. Tharayil et al. (2008) recently showed that phenolic acids significantly extended the persistence and bioavailability of companion compounds in allelochemical mixtures. Companion compounds could inhibit microbial growth and diminish populations able to degrade parthenin. Thus, an allelopathic hypothesis cannot be conclusively rejected. That said, the weed is extremely effective at invading disturbed areas with poor groundcover (e.g., overgrazed pastures, wastelands) or bare sites with exposed soil (e.g., roadsides, stockyards, watering points) (Weeds of National Significance 2003; Parthenium Weed Management 2004) and does not usually establish in or displace undisturbed vegetation. The latter would be expected if allelopathy is operative in plant succession (Rice 1977). Any *P. hysterophorus* potential allelopathic effects may, therefore, be of secondary importance in consideration of the plant's other highly competitive features such as a large and persistent seedbank, a fast germination rate, a short life cycle, a high fecundity, multiple generations per year, a biennial capacity, and an efficient use of resources.

Acknowledgements We acknowledge Christine Metzger and Jochen Schöne for technical assistance, the Kruger National Park and Llewellyn C. Foxcroft for soil samples, and the financial support by the National Research Foundation, South Africa. We are also grateful to Frank E. Dayan and three unknown reviewers for commenting on an earlier version of the manuscript.

lipid layer, cuticular hydrocarbons (CHCs) are universally present (Lockey 1988) and are particularly numerous in social insects, especially the ants, which makes CHC profile analysis problematic (Martin and Drijfhout 2009b). Ants often are referred to as chemical factories since they are known to posses over 50 distinct exocrine glands (Billen 2004), the majority of which are active in pheromone production (Billen and Morgan 1998). The availability of gas chromatography (GC) with flame ionization detection in the late 1950s, and more recently GC-mass spectrometry (GC-MS), has made CHC studies accessible to biologists. In insects, studies on non-hydrocarbon signals, such as recognition proteins that are the focus of much vertebrate research (Hurst et al. 2001), remain an important but peripheral field (Dapporto et al. 2008; Turillazzi et al. 2007). In ants, the focus on CHCs is well founded, as the nest-mate discrimination systems in several ant species are known to be based on hydrocarbons (Bonavita-Cougourdan et al. 1987; Yamaoka 1990; Lahav et al. 1999; Akino et al. 2004; Martin et al. 2008a; Greene and Gordon 2007; Guerrieri et al. 2009), and these compounds are known to be perceived by ants (e.g., Ozaki et al. 2005).

The first ant CHC profile was reported in 1970 (Martin and MacConnell 1970). Since then, CHC profiles for over 80 ant species have been published, and the number continues to grow rapidly. Although there have been various reviews on the roles of semio-chemicals, including CHCs in social insects (Bradshaw and Howse 1984; Lenoir et al. 1999, 2001a, b; Howard and Blomquist 2005), none has comparatively categorized the various CHCs described across these studies. The aim of this review is to compare the various CHCs described from 1970 to 2007 across 78 ant species from five different subfamilies. We looked for patterns that may reveal some general insights into the roles of ant CHCs.

Methods and Materials

A literature search was conducted to identify published papers from 1970 through 2007 on ant species whose CHCs were analyzed in detail. These included studies on the postpharyngeal gland (PPG), an exocrine gland unique to ants that is involved in pheromone communication (Soroker et al. 1995; Oldham et al. 1999). The CHC profiles of the PPG, and the cuticle are always similar (Bagnères and Morgan 1991; Soroker et al. 1995; Akino et al. 2004). However, studies on the contents of the Dufour's gland were excluded, as these glands contain trail and alarm pheromones, as well as CHCs (Regnier and Wilson 1968; Morgan et al. 2003). The various studies used differing extraction methods; e.g., solvent extraction with hexane or pentane, solid phase microextraction (SPME), and solid sampling (Morgan 1990). The GC conditions (non-polar columns with either 100% or 95% methyl-silicon) and temperature profiles (50/70°C to 300/350°C) were similar across the majority of studies. However, there was no conformity on the level of analysis, which has improved greatly over time, or how the compounds were reported. Across the studies, only 44% reported CHCs proportions; 8% of these studies placed the CHC in arbitrary groups (e.g., >1%, >10%), while the remaining 48% of the studies simply reported compounds as present or absent. A further complication is that only about half of the studies attempted to determine positional isomers. Due to this variation in data quality, and the vast quantity of data collated, we restricted our review to the presence (indicated by 'X' in Table 1) or absence of each compound irrespective of the chain-length. The chain-length data for each CHC (not shown) was used to calculate the total number of compounds and ratio of single compounds vs. homologous series. A hierarchical cluster analysis of all CHCs (present or absent) was performed using the statistical package for social sciences (SPSS v14; Field 1970) with squared Euclidean distances with average linkage (between groups).

Results and Discussion

Across the 78 species, almost 1,000 CHCs have been described (Table 1). These are composed of 187 distinct homologous series belonging to ten distinct hydrocarbon groups (Tables 1, 2), which are all built upon the same *n*-alkane backbone with 1, 2, or 3 double bonds or the inclusion of 1, 2, 3, or 4 methyl groups. Among the 78 species, the sequence of occurrence was as follows: *n*-alkanes > monomethylalkanes > dimethylalkanes > alkenes > dienes>> trimethylalkanes>> methylalkenes > methylalkadienes > trienes > tetramethylalkanes (Table 2). As the CHC structures become more complex, fewer species produce them, e.g., 73 species produced methylalkanes, while only one produced tetramethylalkanes (Fig. 1). Furthermore, more complex CHC structures are usually produced by species that already produce the more simple structure, except in three rare cases (*Atta colombica*, *Pachycondyla apicalis*, and *Camponotus fellah*) (Table 1, Fig. 1).

n-Alkanes were found in all 78 species except in the queens of *Formica gnava* and *F. occulta* (Table 1). Odd-numbered C_{25} to C_{35} *n*-alkanes typically dominate ant CHC profiles, as is almost universally the case in insects (Lockey 1988; references cited herein). Odd-numbered *n*-alkanes also are characteristic components of epicuticular waxes produced by terrestrial higher plants (McDuffee et al. 2004). In insects, the primary function of CHCs is to act as anti-desiccation and waterproofing compounds (Edney 1977), and their abundance is correlated with varying environmental conditions (Wagner et al. 2001; Martin and

Table 2 Summary of the major classes of cuticular hydrocarbons extracted from ant (Hymenoptera: Formicidae) species

Name	Number of compounds	Number homologous series	Frequency[a]
n-Alkanes	23	1	97%
Monomethylalkanes	194	19	96%
Dimethylalkanes	602	96	84%
Trimethylalkanes	48	29	22%
Tetramethylalkanes	4	4	1%
Alkenes	47[b]	10	73%
Dienes	51[b]	16	27%
Trienes	1	1	1%
Methylalkenes	17	7	4%
Dimethylalkenes	6	4	1%
TOTALS	993	187	

[a] Percentage of 78 species possessing each CHC group

[b] Positional isomers determined in only a few cases

Drijfhout 2009a). At ambient temperatures, *n*-alkanes heavier than C_{18} are solid; however, the addition of a double bond or methyl group into the alkane reduces their melting point by up to 50°C (Gibbs and Pomonis 1995a). Furthermore, while the melting points of pure CHCs occur over a narrow temperature range, mixtures of CHCs result in melting occurring continuously over a broad temperature range (Gibbs 1995b). This may help explain why monomethylalkanes are also present in all 78 species (except *F. montana* and *Atta colombica*). Like *n*-alkanes, theses compounds occur as homologous series (Table 2) of a variety of chain-lengths, but C_{19} to C_{33} *n*-alkanes are predominant and often comprise >50% of the total peak area of the entire profile. This combination of *n*-alkanes and monomethylalkanes will result in a waterproof layer that remains flexible since, when combined, they have a solid-liquid phase transition over a wide range of ambient temperatures (Gibbs 1995b). Some of the monomethylalkanes also may be used as chemical communication signals (Nelson 1993), but their ubiquity means that they could be general indicators only. They may also be linked to dimethyl production because in the ant *F. cinerea,* which produces large quantities (>30%) of 7,15-dimethylalkane, an unusually high proportion (>20%) of 7-monomethylalkane also was produced (Martin et al. 2008c). The ubiquity of *n*-alkanes, and their flexible response to environmental factors, makes it difficult to encode stable and distinctive signals that must be a prerequisite for species and nest-mate recognition. However, alkanes might be used to convey a simple message such as whether or not an ant is a forager (Greene and Gordon 2003; Martin and Drijfhout 2009a) or whether or not a queen is mated (Hora et al. 2008).

Dimethylalkanes are by far the most numerous group of compounds, with over 600 presently described (Table 1). They are species-specific, and can even be colony-specific (Martin et al. 2008b). These compounds are usually produced at one chain-length or as a short homologous series (Table 2), and are typically present in small quantities relative to *n*-alkanes and monomethylalkanes. As dimethylalkanes represent over half of all CHCs currently described in ants, it is not surprising that several studies have suggested that dimethylalkanes play an important role in recognition (Johnson et al. 2001; Endler et al. 2004; Martin et al. 2008b; Guerrieri et al. 2009). Furthermore, there are a vast number of possible dimethyl positions that potentially exist, but have yet to be described.

Only 13 species did not produce any dimethylalkanes (Table 1). Of these, 12 species produce alkenes, although monomethylalkanes and *n*-alkanes were still produced. Double bond positions have been determined in around half of the studies showing that the odd positional isomers dominate (*Z*9, 33 spp; *Z*7, 11 spp; *Z*11, 4 spp. vs. *Z*8, 4 spp; *Z*10, 3 spp; *Z*12, 2 spp). Only *Myrmicaria eumenoides* appears to have exploited the full potential of alkenes, producing nine different positional isomers and ten different positional dienes. These may be used in nest-mate recognition because it has been shown that the ant *Formica exsecta* uses nest-specific distributions of $C_{21:1}$ to $C_{33:1}$ *Z*9-alkenes for nest-mate discrimination (Martin et al. 2008a). The true alkene diversity will be

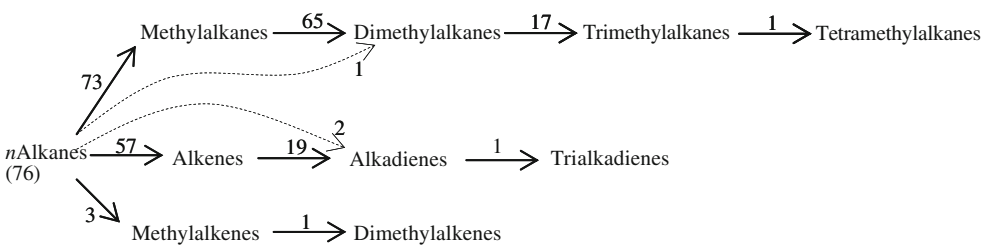

Fig. 1 Number of species (over arrows) producing cuticular hydrocarbons (CHCs) belonging to each of the ten CHS subgroups

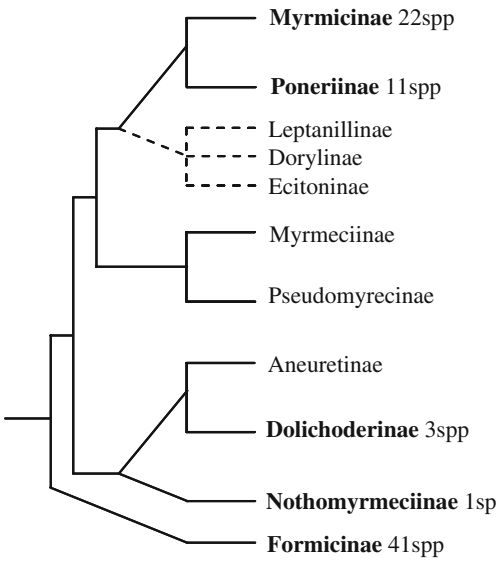

Fig. 2 Subfamily phylogeny within the Formicidae adapted from Hölldobler and Wilson (1990)

revealed only with the systematic determination of double bond positions.

Currently only three species (Table 1) produce CHCs that contain both double bonds and methyl branches (Fig. 1). Interestingly, one of these species is *Nothomyrmecia macrops,* the most primitive known ant, which produces large amounts (65%) of methylalkenes and methylalkadienes. This manifestation is biochemically complex since it requires pathways that combine both the insertion of double bonds and methyl groups. This suggests that the genetic architecture for the production of all hydrocarbons was already present in ancestral ants, and has been maintained throughout their subsequent vast radiation. This parallels the finding that the key biosynthetic gene subfamily used in pheromone production existed prior to the radiation of Lepidoptera (Liénard et al. 2008). Although few species currently appear to synthesize this type of complex CHC profiles, a recent study that used high temperature (HT) columns to analyze CHC profiles of two species of tropical ants (Menzel et al. 2008) found that *Crematogaster modiglianii* and *Camponotus rufifemur* produce 14 methylalkenes, all of which occurred at chain-lengths greater than C_{34}. In fact, in these two species, more than 96% of the total ion chromatogram (peak area) is composed of CHCs with a chain-length greater than C_{34}. Chain lengths this long can only be reliably detected by using HT columns.

In summary, the vast majority of compounds occurred at chain-lengths between C_{19} and C_{33}, with $C_{25}/C_{27}/C_{29}$

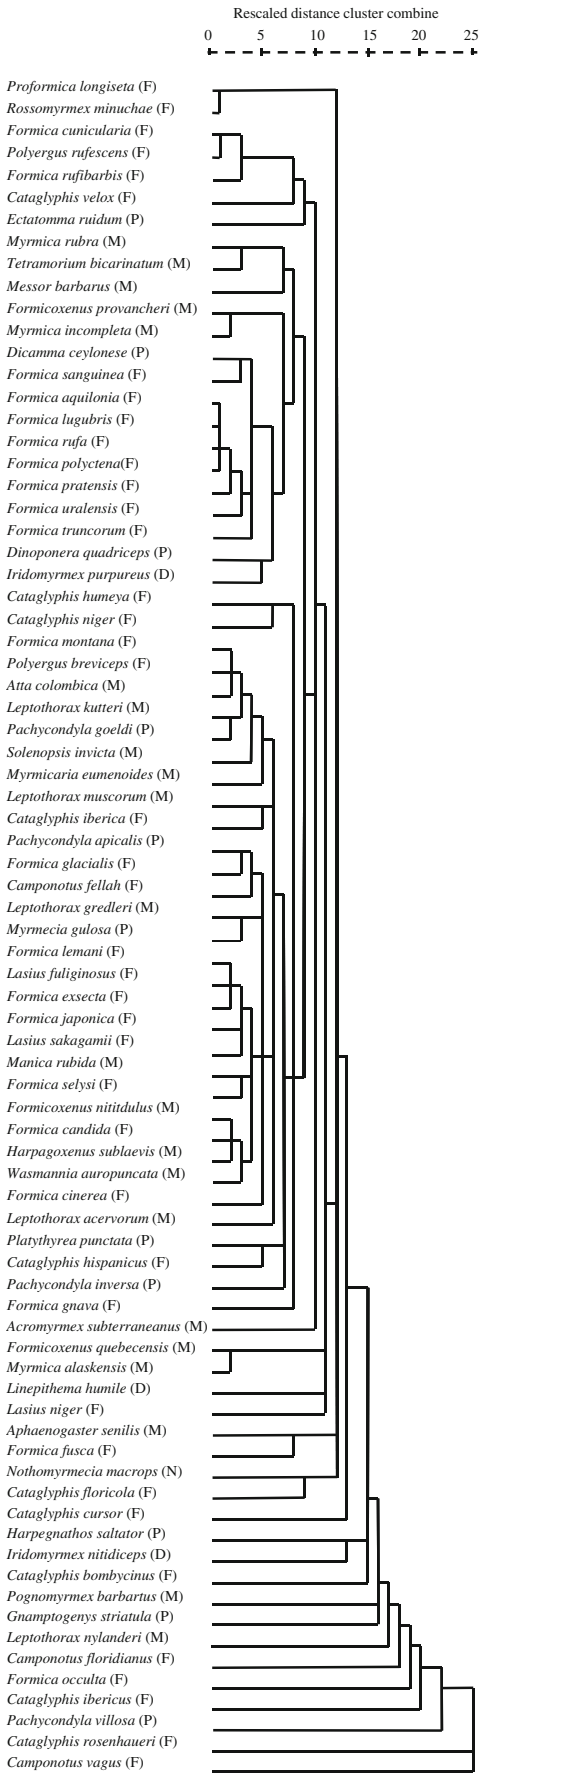

Fig. 3 Dendrogram of ant species (Hymenoptera: Formicida derived from a hierarchical cluster analysis of published cuticular hydrocarbon data. Subfamilies are Myrmicinae (M), Poneriinae (P), Dolichoderinae (D), Nothomyrmeciinae (N), and Formicinae (F)

compounds usually being the most abundant. However, this seems to be a reflection of the limitations of the GC columns used rather than a true reflection of the ants' biosynthetic capabilities. For example, *Formica tuncorum* and *F. pratensis* have been analyzed using both standard (Nielsen et al. 1999; Martin et al. 2008c) and HT columns (Akino 2006; Martin and Drijfhout 2009a). In these species, CHCs larger than C_{34} accounted for 56% (*F. tuncorum*) and 51% (*F. pratensis*) of the total ion chromatogram (peak area) of the profile. Current HT columns can reach 440°C, and can detect chain-lengths up to C_{60}. Alternatively, matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS) has been used to detect CHCs up to C_{60} in termites (Cvačka et al. 2006).

The 78 ant species included in this review were grouped into their respective five subfamilies (Fig. 2) based on the phylogeny given in Hölldobler and Wilson (1990).

The cluster tree based on all the CHCs (Fig. 3) and the phylogenetic tree (Fig. 2) showed no similarity, with species from several subfamilies producing the same CHCs (Table 1). For example, species belonging to three different subfamilies (*Dinoponera quadriceps*, *Iridomyrmex purpureus*, and several *Fromica* spp. [Fig. 2]) are clustered together (Fig. 3) because they all produced some of the same CHCs such as 11,15- and 13,17-dimethyls, several monomethyls, and *n*-alkanes (Table 1). Even very closely related species (e.g., *Formica fusca* and *Formica lemani*) can be very different chemically, with *F. fusca* workers producing dimethyls but no alkenes whereas *F. lemani* workers produce only *Z*9-alkenes and *n*-alkanes (Martin et al. 2008b). Cvačka et al. (2006) also noticed that neither GC-MS nor MALDI-MS were able to describe the phylogenetic relationships among the 12 species of diverse insect taxa studied (termites, ants, a cockroach, and a flesh fly).

The image of an ant as a chemical factory is well supported by this review, with the 78 species producing about 1,000 individual hydrocarbons. Using the basic *n*-alkane backbone, ants have exploited two major biochemical pathways, the introduction of double bonds and of methyl branches. This has allowed them to produce the rich and varied CHC profiles that we see. In the future, the use of HT columns and a systematic determination of bond and methyl group positions will add significantly to the already remarkable hydrocarbon diversity found in ants. It appears that complex CHCs were already biosynthesized by primitive ants, and this may explain why no association between CHC profiles and phylogeny was found in either this or previous studies (Morgan et al. 2003; Cvačka et al. 2006). The ubiquity of *n*-alkanes and many monomethlyalkanes means that they are unlikely to convey complex information among ants, whereas the diversity of unsaturated compounds and especially the dimethyls make them excellent discriminatory compounds. This is further supported by the finding that almost all ants so far studied produce either alkenes or dimethyls, but rarely both. Furthermore, ants control the chain lengths of these key groups of CHCs in order to encode species (Martin et al. 2009c) and nest-mate information (Martin et al. 2008a). The ability of ants to produce such a large diversity of CHCs, having a range of biophysical properties, has helped them adapt to environments that range from tropical to arctic, as well as to develop a complex chemical communication system.

When a male chrysomelid encounters a conspecific female, it first touches the female with its antennae and palpi, then mounts her, and finally mates. Both physical surface stimuli or chemical contact stimuli of the females might elicit this male mating behavior. Upon disturbance and contact, adult leaf beetles of the subfamily Chrysomelinae are known to release defensive secretions from elytral and pronotal glands (Deroe and Pasteels 1982). Defensive secretions of species of the subtribe Chrysomelina, including the genus *Phaedon,* contain isoxazolinone glycosides that act as deterrents against ants (Pasteels et al. 1982; Sugeno and Matsuda 2002). Thus, when a male encounters a conspecific adult, it may be exposed to both highly polar compounds (from defensive glands) and to non-polar CHC.

We investigated the mating behavior of the mustard leaf beetle *Phaedon cochleariae* (F.) (Chrysomelidae: Chrysomelinae) and studied the role of cuticular chemical contact stimuli for mating induction. First, we recorded parameters of mating behavior of males with living conspecific males and females; the percentage of mating attempts and duration of matings with living conspecifics were used as reference for further bioassays with crude cuticular extracts of male and female *P. cochleariae.* Active extracts were subjected to fractionation and further bioassays to characterize the compounds that elicit mating behavior. In addition, we analyzed the CHC profiles of male and female beetles by GC-MS and compared the compositions by multivariate statistics.

Methods and Materials

Beetles All *P. cochleariae* used for bioassays and chemical analyses were taken from a laboratory colony maintained in a climate chamber at 20°C, 70% relative humidity, and a 16:8 hL:D cycle. Newly emerged beetles were separated by sex; batches of 50 beetles of the same sex were kept together in plastic containers (20×20×6.5 cm; Gerda, Schwelm, Germany) containing moist paper towels and food. All life stages were reared on leaves of Chinese cabbage, *Brassica rapa* L. ssp. *pekinensis*.

Crude Dichloromethane Extracts of Beetles Prior to extraction, 21-d-old beetles were killed by freezing at −18ºC for 30 min and thawed for 15 min at room temperature. For the initial bioassays, crude extracts from males and females were prepared by extracting batches of 42 beetles of each sex for 10 min in 1 ml dichloromethane. For fractionation, another extract was prepared by extracting 250 females for 10 min in 3 ml dichloromethane. These extracts were concentrated under a gentle stream of nitrogen to dryness, dissolved in 420 µl and 2.5 ml dichloromethane, respectively [i.e., 1 beetle equivalent (BE) per 10 µl], and were stored at −18°C until used for bioassays, chemical analysis, or fractionation.

Fractionation of Extracts A dichloromethane extract prepared as described above was subjected to fractionation according to the scheme outlined in Fig. 1. After each fractionation step, the fractions were concentrated to dryness and dissolved in dichloromethane so that the concentration of each fraction always corresponded to 1 BE per 10 µl. First, the extract was fractionated by silica gel column chromatography (Pasteur pipettes filled with 600 mg silica gel 60; particle size 0.063–0.200 mm, Merck, Darmstadt, Germany). The column was pre-washed with 1 ml hexane; the samples were loaded; and compounds were eluted with 1.4 ml hexane (the CHC) and 1.4 ml methanol (defensive compounds). Both fractions were bioassayed. The methanol fraction also was used for thin layer chromatography. The hexane fraction was further fractionated by $AgNO_3$ column chromatography (Pasteur pipettes filled with 350 mg 10% $AgNO_3$ in silica gel;≥ 99%, Fluka, Buchs, Switzerland) to separate saturated hydrocarbons from olefins. The column was pre-washed with 1 ml hexane; the samples were loaded; and the

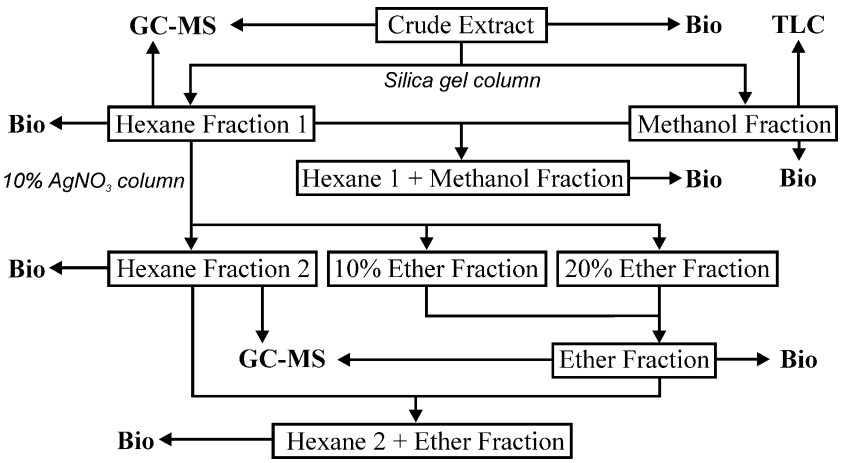

Fig. 1 Fractionation scheme for the cuticular crude dichloromethane extract of 250 female *Phaedon cochleariae*. "Bio" means that 400 µl (40 beetle equivalents=BE) of these fractions were used for (40) behavioral bioassays. GC-MS and TLC refer to extracts that where analyzed by GC-MS (2 BE) and TLC (80 BE), respectively

hydrocarbons were eluted successively with 1.4 ml each of hexane, 10% and 20% butyl methyl ether in hexane, respectively. Saturated hydrocarbons eluted in the hexane fraction and olefins in the combined ether fraction. Both fractions were tested separately and in combination in bioassays. All fractions were stored at −18°C until used in bioassays or chemical analysis.

Behavioral Bioassays All bioassays were conducted in Petri dishes (5.5×1.2 cm) lined with filter paper between 13:00 and 15:00 h CET at 22–24°C. A Petri dish was illuminated by a 60 W bulb placed 40 cm above the dish; no daylight or other light was available in the bioassay room. To guarantee sexual maturity only 21-d-old beetles were used. Test males were kept individually in Petri dishes for at least 1 d before the bioassay was begun to obviate male-male mating attempts just prior to the tests. A bioassay was initiated by placing a test male in a dish. We recorded whether a test male started a copulation attempt, and if so, how long this attempt lasted. A bioassay was terminated after 10 min, unless the test male still attempted to mate. In this case, the trial was terminated at the end of the attempt. Thus, we determined "% male response", i.e., the percentage of males exhibiting a copulation attempt, and "duration of copulation", i.e., the time a male took for copulation. For each bioassay, N=40 males were tested, and each one was offered a new mating object.

In a first step, we analyzed the mating behavior of males towards conspecific, living males and females. A single potential mate was placed in a Petri dish 10 min prior to bioassay start. In a second step, we offered a dead male or female to a test male. The potential mates were killed by freezing (1 h at −18°C), and the dead specimens were glued onto the filter paper in the middle of a Petri dish 24 h before the beginning of the trials (5Star™ glue stick; Code: 296026). This set-up excluded the possibility that behavior of the partner influences male mating behavior. In a third step, we investigated the role of chemical cues for male mate choice. Bioassays were performed with cuticular extracts and fractions that were applied to glass beads (KnorrPrandell, Lichtenfels, Germany, manufacturer information: 4×3 mm; dark green Rocailles-drop). A single glass bead was glued onto the filter paper in the center of a Petri dish and was treated with 10 µl of the extract or fraction to be tested (1 BE) 24 h before the trial started to allow evaporation of the solvent. Crude dichloromethane extracts of both sexes were tested, whereas all other fractions used for bioassays were from females only.

Chemical Analysis Chemical identification and quantification of CHC were performed on a coupled gas chromatograph-mass spectrometer system (7890A GC – 5975C MSD; Agilent, Waldbronn; Germany), equipped with a cold-injection system (CIS4, Gerstel, Mühlheim a. d. Ruhr, Germany). A 1 µl aliquot of each sample was injected at 150°C, and the CIS was immediately heated to 300°C at 12°C/s. A fused silica column (DB-5MS, 30 m×0.32 mm i.d.×0.25 µm film thickness, J & W Scientific, Folsom, CA, USA) was used for separation with a constant helium flow of 1.2 ml/min. The oven temperature program was started at 100°C and then heated to 300°C at a rate of 5°C/min (50 min). Electron impact ionization was 70 eV.

Hydrocarbons were identified by their mass spectra (Nelson and Sukkestad 1970; Nelson et al. 1972; Pomonis et al. 1980) and corroborated by their retention indices (Kováts 1965; Carlson et al. 1998). The double-bond positions of trienes were characterized by their typical mass fragments (Karunen 1974; Conner et al. 1980; Millar 2000). The double-bond positions of monoenes and dienes were determined by interpreting the mass spectra of the dimethyl disulfide (DMDS) derivatives (Francis and Veland 1981). We used the 10% ether fraction containing monoenes and the 20% ether fraction with dienes (Fig. 1) for DMDS derivatization. Methyl-branched alkenes were hydrated under a H_2 and D_2 atmosphere, respectively, by using palladium on activated charcoal as a catalyst to determine the position of the methyl group and the relative position of the methyl group to the double bound position (see electronic supplementary material; Fig. 1). Peak areas relative to total peak areas were calculated. Peaks with areas <0.1% were not included in the quantitative analyses.

For quantification of CHC, 10 µl of an *n*-eicosane solution (0.1 mg/ml in hexane) were added as an internal standard (IS) to 20 µl of each crude extract and fraction, respectively. Each of these samples contained 2 BE. For quantification of CHC and subsequent discriminant analysis, individual beetles (N=40 for each sex) were extracted for 10 min each in 125 µl dichloromethane, and 10 µl IS was added for quantification.

Thin layer chromatography (TLC) of the methanol fractions (80 BE) was conducted in order to determine whether the methanol fraction contained defensive compounds. TLC was performed by using silica gel 60 F_{254} plates (0.2 mm, 20×20 cm, Merck, Darmstadt, Germany) developed with chloroform:methanol in a ratio of 8:2 (*v*:*v*) (Sugeno and Matsuda 2002). After development, spots were recorded under UV_{254}-light and visualized with thymol-sulfuric acid (Stahl 1967).

Statistical Analysis All statistical analyses were conducted with SPSS 17 (SPSS Inc., Chicago, IL, USA) or Statistica 7.0 (StatSoft Inc., Tulsa, OK, USA). Differences in the percentage of males responding to the potential mates in each bioassay were analyzed by χ^2-tests, and differences in copulation duration were analyzed by the Kruskal-Wallis H test. Data were corrected for multiple comparisons by using the Bonferroni-Holm-correction.

A canonical discriminant analysis (DA) was performed to determine whether CHC profiles of males and females could be separated based on the relative composition of compounds. Each peak area was transformed according to the Aitchison's formula (Aitchison 1986):

$$Z_{ip} = 1\mathrm{n}\left[\frac{A_{ip}}{g(A_p)}\right],$$

where A_{ip} is the area of peak i for beetle p; $g(A_p)$ is the geometric mean of all peaks for beetle p; and Z_{ip} is the transformed area of peak i for beetle p. To apply the transformation formula to profiles that did not possess all peaks, the constant 0.01 was added to each relative peak area (Aitchison 1986; Steiger et al. 2007). Variables for the DA were selected based on U-values calculated by Mann-Whitney U test statistics (measurement for between-group differences). Low U-values indicate high inter-group variability. Two separate DAs were performed based on the 25 peaks with the lowest U-values, either selected from all hydrocarbons or from saturated hydrocarbons only (active fraction in bioassays). Wilks' λ and the percentage of individuals correctly classified by a leave-one-out cross validation were used to assess the quality of the DAs.

Results

Chemistry of Cuticular Extracts The CHC profiles of male and female *P. cochleariae* contain the same compounds; 67 peaks were detectable in both sexes (Table 1, Fig. 2). Hydrocarbons of males and females included *n*-alkanes, monomethyl alkanes, dimethyl alkanes, olefins with one, two, or three double bonds, and monomethyl branched alkenes. The chain-length of the hydrocarbons ranged from C19 to C45. The profiles of males and females were dominated by long-chained methyl-branched alkenes (42.1±7.0% and 52.0±4.6%, of total peak area in male and female CHC profiles, respectively) and 2-methylalkanes with even-chained carbon backbones (31.7±9.7% and 23.0±7.2%, respectively), whereas *n*-alkanes represented only a small amount of the total hydrocarbons (1.0±0.3% and 0.7±0.2%, respectively). The most prominent peaks were 2-MeC28, 27-MeC39-16/18-ene, 29-MeC41-18/20-ene, and 31-MeC43-20/22-ene. The mass spectra of the DMDS derivates of unbranched monoenes showed the typical fragments for double bonds at position 7 (*m/z* 145/M-145) or 9 (*m/z* 173/M-173), and those of 6,9-dienes were characterized by fragments at *m/z* 131, *m/z* 155, and *m/z* 203. Trienes showed distinct fragments at *m/z* 108, $[CH_3CH_2(CH{=}CH)_3H]^+$ and M-56, $[H(CH{=}CH)_3R]^+$, characteristic for 3,6,9-trienes (Millar 2000). Methyl-branched alkenes had varying double bond positions, and those of them with chain lengths ≥C31 had a constant spacing of 7 or 9 methylene-groups between the methyl-branching and the double bond. Counting from the ω-end of the molecules, we detected 13-MeC$_x$-21-ene and 15-MeC$_x$-23-ene (7 CH_2-groups), or 12-MeC$_x$-22-ene, 13-MeC$_x$-23-ene, 14-MeC$_x$-24-ene, and 15-MeC$_x$-25-ene (9 CH_2-groups).

Although the CHC profiles of males and females were qualitatively similar, the profiles were sex specific with respect to relative CHC quantities. Significantly different patterns of relative CHC compositions were detected both when running a DA based on 25 peaks either selected from all 67 hydrocarbons or when conducting the DA based on 25 peaks selected from saturated hydrocarbons only (marked with c and d, respectively, in Table 1). The canonical roots of both DAs clearly separated the male from female CHC pattern (Fig. 3; all hydrocarbons: Wilks' $\lambda=0.119$, $\chi^2=139.2$, $P<0.001$; saturated hydrocarbons: Wilks' $\lambda=0.135$, $\chi^2=130.4$, $P<0.001$). In the DA based on all hydrocarbons, 95.0% of the cross-validated cases were correctly classified according to their sex. In the DA based on saturated hydrocarbons, 91.3% were correctly classified by cross-validation.

The TLC analysis revealed that surface washes of *P. cochleariae* with dichloromethane not only extracted CHC but also defensive compounds. Three major spots that correspond to literature R_f-values for nitropropanoyl isoxazolinone glycosides typical for adults of the subtribe Chrysomelina (Sugeno and Matsuda 2002) were detected in the methanol fraction (*Rf* 0.27, 0.43, and 0.54, respectively).

Behavioral Bioassays The majority of the test males attempted to mate with living females (88%) and males (93%) (Fig. 4A), but they copulated significantly longer with females (Fig. 4B). Similar results were obtained in bioassays in which dead males or females were offered to test males (Fig. 4). When crude dichloromethane extracts of males or females were applied to glass beads, the percentage of males attempting to mate with the beads treated with male or female crude extract was as high as with living or dead beetles (Fig. 4A). The duration of the mating attempts with the glass beads treated with male crude extract was as long as with beads with female crude extract (Fig. 4B). Altogether, the percentage of the test males showing mating attempts did not differ among all the treatments, but there were significant differences in the duration of the copulation attempts.

The non-polar hexane fraction 1 (Fig. 2C) elicited mating in the test males, but the percentage of males attempting to mate was significantly lower than to that elicited by the crude extract. The polar methanol fraction containing the defensive compounds did not elicit any copulation responses (Fig. 5A). The male responses to the combination of hexane

[c] Peak was selected for DA based on all hydrocarbons.

[d] Peak was selected for DA based on saturated hydrocarbons.

[e] 17-MeC31-6/8-ene refers to 17-MeC31-6-ene+17-MeC31-8-ene.

[f] No reference alkanes were available for the calculation of the retention indices.

and methanol fraction did not differ significantly from those to the crude dichloromethane extract or to the hexane fraction (Fig. 5A). The duration of copulations did not differ when the glass beads were treated with dichloromethane extract, hexane fraction, or with a combination of hexane and methanol fraction. Alkanes (hexane fraction 2; Fig. 2D) elicited as much mating behavior as the total CHC fraction (hexane fraction 1; Fig. 2C), whereas alkenes (ether fraction; Fig. 2E) elicited no mating behavior at all (Fig. 5A). The percentage of males showing mating attempts towards the combination of alkane and alkene fractions was the same as to the alkanes alone (Fig. 5A), but the duration of mating attempts differed when comparing these types of potential mating objects (Fig. 5B). Test males tried to mate with beads treated with the combined alkane and alkene fractions longer than with beads treated only with the alkane fraction.

Discussion

Cuticular hydrocarbons (CHC) play an essential role in male mating behavior of the mustard leaf beetle, *P. cochleariae*. The CHC profile of this species is a complex mixture of straight-chained and methyl-branched saturated and unsaturated hydrocarbons with a wide range of carbon backbones (C19 – C45). The high percentage of 2-methyl alkanes seems to be typical for chrysomelids, representing major compounds in the CHC profiles of nearly all leaf beetle species investigated (Dubis et al. 1987; Nikolova et al. 1999; Nelson et al. 2002, 2003; Nelson and Charlet 2003; Peterson et al. 2007; Geiselhardt et al. 2009). The large quantities of methyl-branched alkenes in *P. cochleariae* is striking. This substance class has been reported from only a few insect species but across a wide taxonomic range, including Lepidoptera (Francke et al. 2000), Coleoptera (Golden et al. 1992), Diptera (Sonnet et al. 1979; Etges and Jackson 2001), and Hymenoptera (Brown et al. 1990; Menzel et al. 2008). The same methyl-branched alkenes as detected in *P. cochleariae* have been reported from the tropical ant *Camponotus rufifemur* (Menzel et al. 2008), where remarkably, this substance class comprised up to 98% of all hydrocarbons. The function of these compounds in *P. cochleariae* remains unclear since they are not involved in male mate recognition, as test males did not respond to the alkene fraction. The only single fraction that elicited male mating behavior was the saturated hydrocarbon fraction. This fraction consisted mainly of 2-methyl alkanes (60.2%), other

Designation of fractions corresponds to Fig. 1. Numbers refer to numbers in Table 1. IS=internal standard

monomethyl alkanes (20.4%), dimethyl alkanes (17.7%), and only a small proportion of *n*-alkanes (0.9%). The only chrysomelid in which the active compounds of the contact pheromone have been characterized is *G. atrocyanea* (Sugeno et al. 2006). Males of this species respond mainly to 9-MeC27, 11-MeC27, 9-MeC29, and 11-MeC29, whereas 13-MeC27, 13-MeC29, 15-MeC29, and *n*-alkanes elicit only a low activity.

The CHC profiles of *P. cochleariae* showed no sex-specificity in their qualitative composition. The qualitative CHC profiles of males and females were also similar in other leaf beetle species such as the Colorado potato beetle, *L. decemlineata* (Dubis et al. 1987; Nelson et al. 2003), the northern corn rootworms, *Diabrotica barberi* and *D. longicornis*, (Golden et al. 1992), and the blue milkweed beetle, *C. cobaltinus*, (Peterson et al. 2007). Nevertheless, the relative proportions of the compounds differed between the sexes. In *C. cobalticus*, these differences were perceived by males and used for sex recognition (Peterson et al. 2007). Male *C. cobalticus* attempted to copulate with dummies treated with cuticular extract from conspecific females but not with dummies treated with male extract. In contrast, *P. cochleariae* males did not discriminate between males and females, even though DAs of CHC profiles of males and females clearly demonstrated that theses could be separated based on CHC quantities. Dummies treated with male cuticular extract elicited as much mating response as dummies treated with female extracts. Thus, CHC in *P. cochleariae* are used as a general copulation-eliciting pheromone rather than as a sex pheromone.

Males of the two-spotted ladybird beetle, *Adalia bipunctata*, also lack the ability to discriminate between sexes by using CHC (Hemptinne et al. 1998). In this species, sex recognition is based on the behavior of the potential mates.

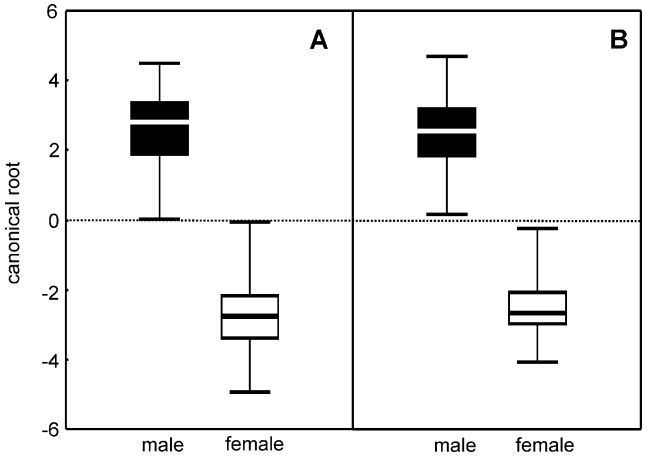

Fig. 3 Canonical roots of the discriminant analysis of cuticular hydrocarbon (CHC) profiles of *Phaedon cochleariae* males and females (40 for each sex) based on the 25 CHC with the lowest *U*-values for between-group differences in a Mann-Whitney *U* test. Peak selection was based on (**A**) all hydrocarbons or (**B**) on saturated hydrocarbons only (active fraction in bioassays). Boxes indicate 25% and 75% percentiles, bars inside boxes are medians, and whiskers indicate minima and maxima

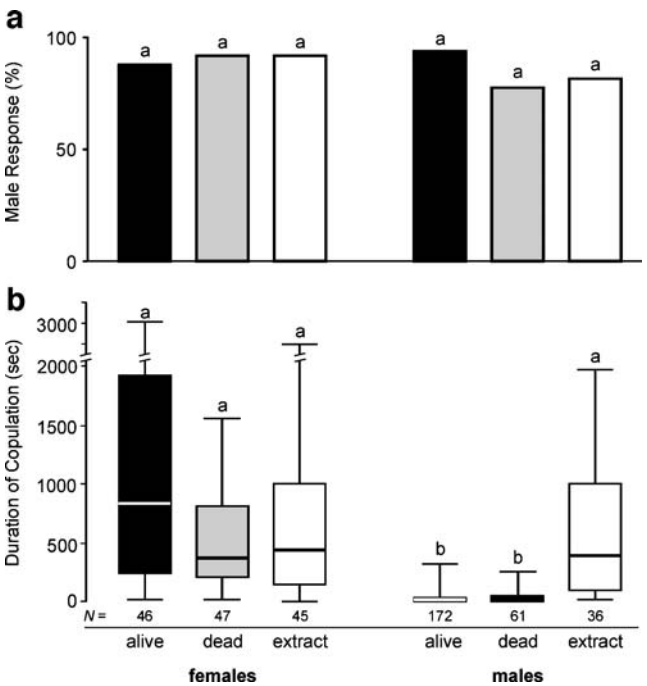

Fig. 4 *Phaedon cochleariae* male mating responses (**A**) and duration of copulation attempts (**B**) with conspecific living or dead females and males, respectively, and with glass dummies treated with cuticular crude extracts from females or males. Mating response test: N=40 (= 100%) for each trial. Boxes indicate the 25% and 75% percentiles, the bars inside the boxes are the medians, and whiskers indicate the minima and maxima. Different letters above columns and whiskers indicate significant differences evaluated by a χ^2-test (**A**) or a Kruskal-Wallis H test (**B**) (α=0.05 for both tests). All data were Bonferroni-Holm-corrected for multiple comparisons

Females encountered by a male stop moving and thus signal their readiness to mate, whereas encountered males try to run away and escape. In *P. cochleariae*, sex recognition seems to be mediated by physical contact cues rather than sex-specific behavioral cues since test males were able to discriminate between dead males and females. This discrimination ability was not detectable when considering percentage of mating attempts, but when recording copulation duration. Males copulated much longer with dead females than with dead males. Similar results were obtained with living beetles. Interestingly, the test males attempted to mate with glass dummies treated with crude extracts of males or females as long as with dead or living females. Thus, copulation duration differed when males encountered male and female bodies, but was the same when males encountered glass beads treated with male or female extracts. The short duration of copulation with males might be due to physical stimuli of male bodies that reduce the time of mating attempt. This implies that males recognize a

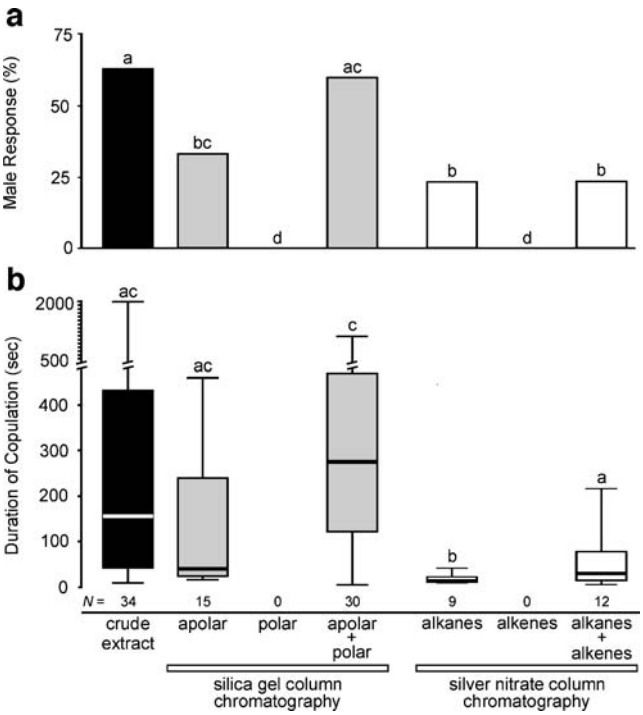

Fig. 5 *Phaedon cochleariae* male mating responses (**A**) and duration of copulation attempts (**B**) with glass dummies treated with either cuticular crude extracts of conspecifics (*black*) or fractions of this extract obtained by silica gel column chromatography [grey: hexane (*non-polar*), methanol (*polar*), and combination of both fractions (non-polar+polar)] or fractions obtained by 10% silver nitrate column chromatography [white: hexane (*alkanes*), ether (*alkenes*), and combination of both fractions (*alkanes*+ *alkenes*)]. Mating response test: N=40 (= 100%) for each treatment. Boxes indicate the 25% and 75% percentiles, the bars inside the boxes are the medians, and whiskers indicate the minima and maxima. Different letters above columns and whiskers indicate significant differences evaluated by means of χ^2-test (**A**) or Kruskal-Wallis H test (**B**) (α=0.05 for both tests). All data were Bonferroni-Holm-corrected for multiple comparisons

conspecific adult by CHC that elicit mating behavior, but discrimination between male and female adults is due to tactile cues. As this tactile sex recognition mechanism works rapidly in *P. cochleariae*, selection pressure on males to discriminate the sexes by CHC may be weak.

Although the defensive compounds released from the elytral and pronotal glands did not induce mating behavior in males when tested alone, we cannot rule out the possibility of defensive compounds functioning synergistically to the CHC in eliciting copulation behavior. Albeit not significant after the Bonferroni-correction, the combination of CHC and extract containing defensive secretion tended to elicit mating attempts more frequently than CHC alone, and males copulate longer with dummies treated with the mixture of both fractions. In the rove beetle, *Aleochara curtula*, defensive compounds act synergistically with female cuticular sex pheromones (Peschke 1983), but in this species small quantities of defensive secretion alone elicit male copulation attempts. Further studies are required to clarify the potential role of the defensive compounds in the mating behavior in *P. cochleariae*.

Acknowledgments We thank Ute Braun and Ursula Cinque, Freie Universität Berlin, for their help in growing the food plants and maintaining the beetles.

have been based on colony-specific cuticular hydrocarbons as putative recognition cues. Furthermore, Nunes et al. (2008) demonstrated differences in the chemical profiles between workers of *Frieseomelitta varia* and *Lestrimelitta limao*, which might explain the aggressive behavior observed between these species. When, however, conspecific individuals from a different colony but with similar chemical profile were introduced into a colony of *F. varia*, no aggression towards the "intruder" was observed (Nunes et al. 2008). Pianaro et al. (2007) investigated the chemical hydrocarbon profile of individuals from mixed colonies of *Melipona rufiventris* and *M. scutellaris*, and also determined the chemical composition of the colony's cerumen (i.e., beeswax mixed with plant resins). They suggested that there might be a form of "chemical competition" between the species that inhabit the same mixed colony.

Given that there are more than 400 species of stingless bees (Michener 2000), the chemical composition and role of cuticular hydrocarbons in this bee group have remained poorly investigated, especially when compared with other social insect groups. Therefore, the present study aimed to answer whether there are differences in the cuticular hydrocarbon profiles among castes, ages, and sexes of the stingless bee, *F. varia*.

Methods and Materials

Insects

The study was performed with four colonies of *F. varia*, each housed in glass-covered wooden boxes (35×24×7 cm). The colonies were kept in the laboratory and were connected to the outside through a plastic tube, which allowed free foraging of the bees.

Bees were collected individually in Eppendorf tubes (1.5 ml) and killed by freezing prior to extraction. We used 20 old workers, identified by their dark-colored scutelum, and 20 newly emerged workers, identified by their white coloration and by their activities inside the colony. In addition to the workers, 7 newly emerged males, collected inside the colony, and 8 old males, collected in a male cloud in front of a colony, as well as 6 virgin queens and 9 physogastric queens (i.e., queens with high ovarian activity) were included in the study. Old and newly emerged workers were taken from all four experimental colonies, whereas newly emerged males were collected from two different colonies. Since we captured the old males in a male cloud, their colony-origin could not be identified. The virgin queens from two different colonies were collected about 4 days after emergence. From each experimental colony, we analyzed one physogastric queen. Four physogastric queens were used for the analysis of the overall chemical composition of the cuticular hydrocarbons and 5 to identify the position of double bonds through derivatization with dimethyl-disulfide (DMDS). Due to the small sample size, however, the queens were not considered in the statistical analysis.

Hydrocarbon Extraction and Analysis

Prior to the extraction, the workers' last pair of legs was cut off to avoid contamination with resins, since old workers of *F. varia* usually carry large amounts of this material. Cuticular hydrocarbons were extracted by immersing the insects in hexane for 1 min. Samples were analyzed by gas chromatography-mass spectrometry (GC-MS), and compounds were identified through a comparison of the mass spectra from the extracts with those in the Wiley library and data of diagnostic ions present in the literature. Substances found at relative concentrations below 5% and those present in fewer than three analyzed individuals in the same experimental group were represented as traces in the table of relative concentrations (Table 1). For the quantification of the substances, we calculated the area under the respective peak in the chromatogram. Analyses were carried out by using a Shimadzu QP2010 GC-MS equipped with a DB-5MS (J&W Scientific, Folsom, CA, USA) capillary column (30 m×0.25 mm×0.25 µm). The GC injection port was set to 250°C and the transfer line to 280°C. The column temperature was held at 150°C increasing to 280°C at 3°C/min, held at 280°C for 15 min, and then raised to 300°C at 5°C/min, and then held for 15 min. Helium was used as carrier gas at 1 ml/min, and samples were injected in the splitless mode. Electron impact mass spectra were measured at 70 eV with a source temperature of 250°C. Identification of the double bond positions of alkenes and alkadienes was made through derivatization of a crude hexane extract from five physogastric queens with DMDS (Carlson et al. 1989). The extract was dried with nitrogen and re-suspended in 200 µl of magnetically stirred hexane. Subsequently, 200 µl of DMDS (Sigma-Aldrich, São Paulo, SP, Brazil) and 100 µl of iodine solution (dissolved in diethyl ether, 6% p/v) were added. The vial was then purged with nitrogen, closed, and agitated at ambient temperature for 24 h. Thereafter, the mixture was diluted in hexane and 5% sodium thiosulfate solution, thereby extracting the organic phase, which was subsequently dried with sodium sulfate and analyzed by GC-MS.

Statistical Analyses

The chemical profiles of the different groups were compared by multivariate statistical analysis. Principal component analysis (PCA) was used to define the main peaks for the comparison. Stepwise discriminant analysis was applied to contrast the individuals of different sex and

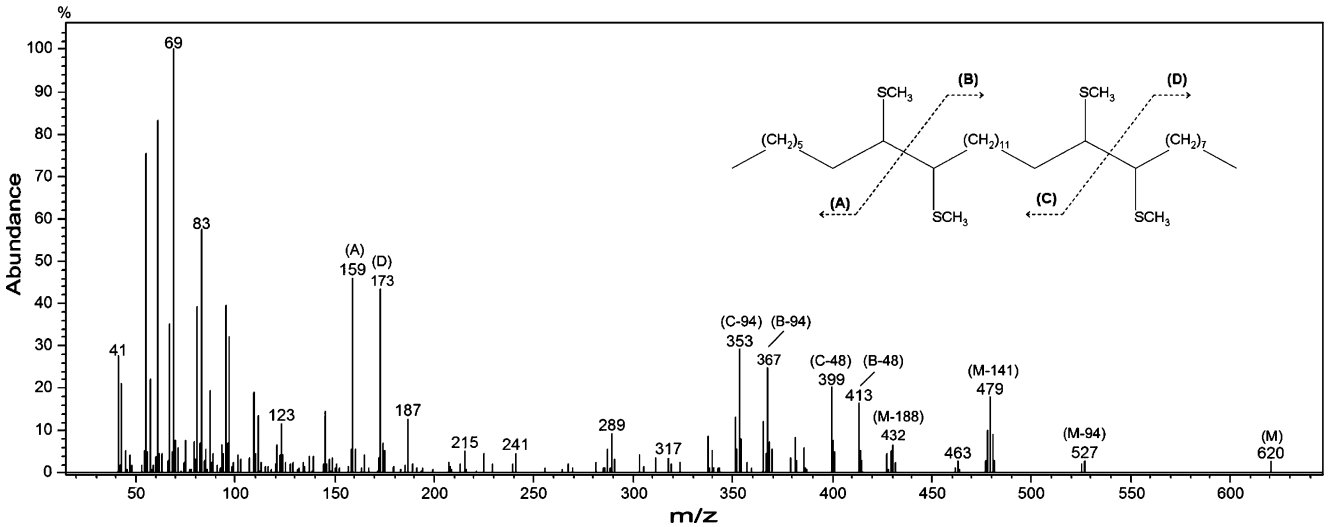

Fig. 1 Mass spectrum of DMDS derivative of 8,22–hentriacontadiene from a cuticular extract of five physogastric queens of *Frieseomelitta varia*

ages. Compounds missing in most individuals of an analyzed group as well as compounds contributing less than 5% to the first two factors, as indicated by the PCA, were excluded from the statistical analysis. The relative concentrations of the compounds used for the discriminant analysis were readjusted to 100%. To avoid errors in compositional sample data, the area under each peak was transformed according to the following formula: $Z = \ln [A_p / g (A_p)]$, where A_p is the area under the peak, $g (A_p)$ is the geometric mean for each individual compound group and Z is the transformed peak area. (Aitchison, 1986)

Results

The analysis of the chemical compounds of the cuticle of *F. varia* revealed a total of 48 substances. The majority of these compounds were hydrocarbons, although other classes of substances such as alcohols and acids were present as well. The identified hydrocarbons included saturated and unsaturated alkanes, alkenes, alkynes, and alkadienes. The compounds varied from 21 to 31 carbon atoms in chain length. The most abundant substances in all analyzed groups of these bees were alkanes (Table 1). Among these, the most abundant was heptacosane for all groups except for the physogastric queens, in which the relative proportion of pentacosane was higher (Table 1). Diagnostic ions of DMDS derivatives were used to identify the double bond positions of the alkadienes (Fig. 1, Table 2). Although different isomers co-eluted, the identifications were based on the most abundant isomer in the peak.

Young workers showed a much lower chemical diversity than old workers. In addition, we found differences in the concentration of alkanes between these two bee groups. Here, alkanes with 23 and 25 carbon atoms were present in higher relative amounts in young workers than in old workers. Furthermore, half of the branched compounds identified in old workers were not found or found only as traces in recently emerged workers.

The comparison among males of different ages demonstrated that younger individuals presented a higher diversity

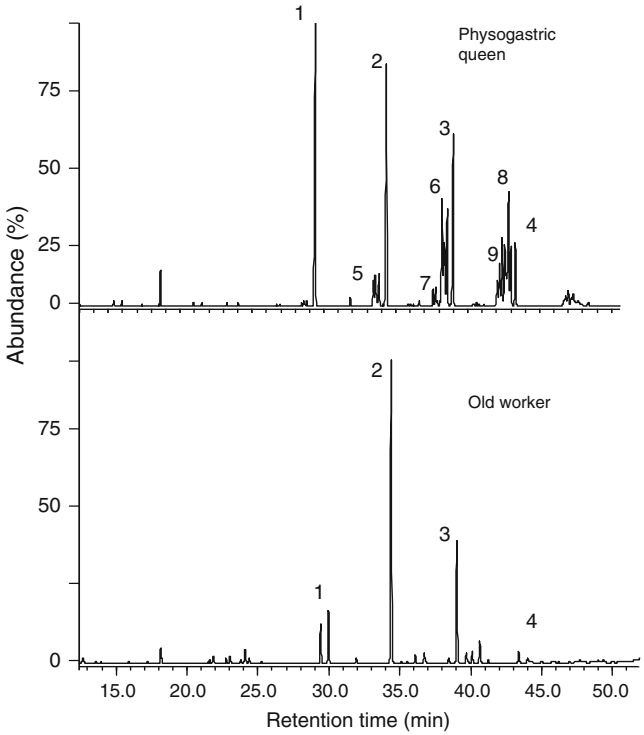

Fig. 2 Comparison between the cuticular composition of an old worker and a physogastric queen of *Frieseomelitta varia* showing differences in identified compounds between these groups. 1) C_{25}; 2) C_{27}; 3) C_{29}; 4) C_{31}; 5) *Z*-C_{27}*; 6) *Z*-C_{29}*; 7) *ZZ*-C_{29}*; 8) *Z*-C_{31}*; and 9) *ZZ*-C_{31}. (*) indicates the presence of multiple isomers

of cuticular compounds than did older individuals. As was the case with workers, young males showed higher relative amounts of tricosane and pentacosane, whereas old males showed higher relative amounts of heptacosane, nonacosane, and hentriacontane.

Comparing workers and males of the same age, we found that the cuticular extract from young workers showed a lower compound richness than that of recently emerged males. The opposite was true for the extract from old individuals, in which higher substance diversity was observed in workers. Regarding the presence or absence of specific compounds, young males show a chemical cuticular profile closer to that of old workers.

Cuticular extracts from virgin queens did not contain the major compounds identified from the other groups. In these queens, we also found higher proportions of *n*-butylpalmitate, which was either absent, or present in low concentrations, in almost all other bee groups investigated.

Physogastric queens showed a particular cuticular hydrocarbon profile. In this group, we found only traces of compounds with lower molecular weight, whereas hydrocarbons with double bonds were present in high relative amounts. Alkenes and alkadienes with 27, 29, and 31 carbon atoms occurred in much higher relative quantities in the extracts from physogastric queens than in extracts from the other analyzed groups. Alkenes and alkadienes with 31 carbon atoms were found almost exclusively in the physogastric queens. These compounds were present only as traces, if present at all, in the other groups. On the other hand, alkanes present in high relative amounts in the cuticle of the other groups (C27 and 29) were far less abundant in the physogastric queens. An examination of the chromatograms of cuticular extracts from physogastric queens shows that, as the chain length increases in carbon number, alkanes occur in lower relative amounts, whereas alkenes and alkadienes occur in higher relative amounts (Fig. 2).

Factor 1 of the principal component analysis (PCA) described 39.86% of the observed variation. Factor 1 + factor 2 described 61.30% of the total variation, whereas the sum of the first three factors described 73.10% of the observed variation. The stepwise discriminant analysis of the subset of identified compounds significantly separated the analyzed bee groups (Global model: Wilks's λ = 0.0046, $F_{15,36}$ = 14.55, P<0.001). The compounds responsible for the separation were pentacosane, hexacosane, heptacosane, 7-nonacosene, and hentriacontane. In addition, the canonical analysis demonstrated that all groups were significantly separated from each other (Fig. 3). The classification matrix indicated that a total of 81% of the individuals were allocated correctly to their predicted group; if allocation were random, the expected correct allocation would be 25%. All comparisons of treatment groups showed significant differences in the discrminant analysis (Table 3).

Discussion

The chemical analysis of the cuticular compounds of *F. varia* showed clear differences between workers and males

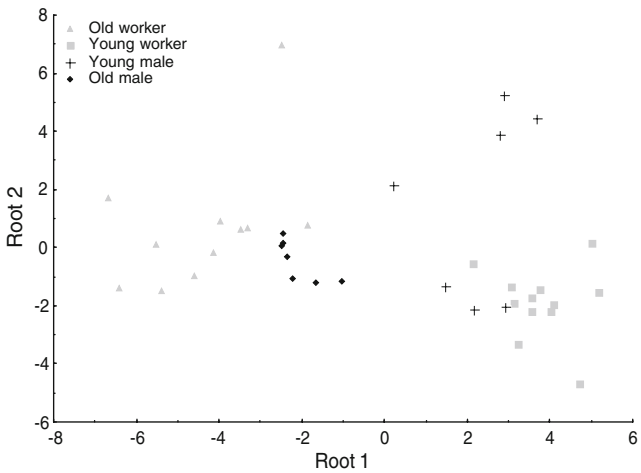

Fig. 3 Discrimination between *Frieseomelitta varia* males and workers of different ages based on cuticular hydrocarbon phenotypes

Table 3 Discriminant analysis of cuticular compounds from males and workers of *Frieseomelitta varia* of different ages

Combinations			Mahalanobis Distance	$F_{5,13}$	P
young workers	*vs*	old workers	83.36	32.45	< 0.001
young workers	*vs*	young male	33.86	13.18	< 0.001
young workers	*vs*	old male	35.62	17.60	< 0.001
old workers	*vs*	young male	78.13	23.90	< 0.001
old workers	*vs*	old male	19.84	7.28	< 0.01
young male	*vs*	old male	41.85	15.36	< 0.001

and between two age classes within these groups. For example, extracts from young individuals contained higher relative amounts of alkanes with shorter chains, such as tricosane and pentacosane, compared to older individuals, suggesting that these compounds might be a chemical cue that indicates the age of individual *F. varia* bees. Queens demonstrated a distinct chemical profile from workers and males. Yet, due to the small number of individuals analyzed, the cuticular profile of the queens could not be compared statistically to those of the workers or the males. However, our results are in accordance with many studies of cuticular compounds of social insects, which suggest that these substances could be used as chemical signals to carry information about caste, age, sex, and reproductive status of the individuals (reviewed in Howard and Blomquist 2005).

Many of the compounds identified in the cuticlular extracts of old workers of *F. varia* also have been described from other species of stingless bees (e.g., *Melipona bicolor*: Abdalla et al. 2003; *M. scutellaris* and *M. rufiventris*: Pianaro et al. 2007; *Scaptotrigona bipunctata*: Jungnickel et al. 2004; *F. varia* and *Lestrimelitta limao*: Nunes et al. 2008; *Schwarziana quadripunctata*: Nunes et al. 2009). The main compounds in these species have been demonstrated to be hydrocarbons with chain lengths varying from 19 to 33 carbon atoms, of which odd chain compounds occurred in higher relative amounts. With the exception of *M. bicolor*, cuticular extracts of these species contained high relative amounts of alkanes, mainly those with 27 and 29 carbon atoms. In *M. bicolor*, cuticular extracts from most classes of individuals contained alkenes as the major components. In accordance with our findings for *F. varia*, both quantitative and qualitative differences between gender and age have been described for *M. bicolor* (Abdalla et al. 2003). In contrast to *F. varia*, however, young workers of *M. bicolor* did not differ from virgin queens in cuticular hydrocarbon profile. For *S. quadripunctata*, Nunes et al. (2009) recently described differences among young workers, old workers, and virgin queens. However, the study did not analyze cuticular hydrocarbons from males and physogastric queens.

Since colony influence on individual odor constitution and its role in nest-mate recognition have already been described in detail elsewhere for *F. varia* (Nunes et al. 2008), in the present study we focused attention on aspects of cuticle chemical profile information not related to nest defense, and we did not consider colony as a variable in the anlaysis. The source of chemical compounds that mediate recognition behaviors, and the importance of each component in the cuticular hydrocarbon complement in this species will be addressed elsewhere.

In young workers, we found a lower diversity in the chemical composition of their cuticle than in old workers. These findings are similar to what is known from honeybees, in which both the diversity of the cuticular substances and their concentrations are lower in young than in old individuals (Breed et al. 2004). These differences between the age groups could be related to the time of exposure to potential odor sources (Breed et al. 1995, 2004; Downs and Ratnieks 1999).

Several studies on both social and solitary insects have indicated qualitative differences in the chemical composition of the cuticle, or differences in the relative concentration of the compounds, in relation to the individuals' gender. Yet, some studies found the same chemical compounds with the same relative concentrations in both sexes (Howard and Blomquist 2005). Here, we found both qualitative and quantitative differences in the chemical composition of the cuticle between males and workers. Although little is known about this subject in social insects, behavioral tests with hexane extracts or purified compounds have demonstrated that other insects such as the longhorned beetles use chemical differences on the cuticular surface for gender recognition (reviewed in Allison et al. 2004).

Recent studies with the European beewolf showed that individuals from the same family have more chemical similarities than individuals from different families (Herzner et al. 2006). The authors suggest that females can assess these chemical similarities and avoid mating with related males. A similar type of investigation with *F. varia* would provide an interesting context for the data set presented here. However, the method used to collect old males (i.e., in a male cloud) impeded us from knowing their colony origins, so we would not be able to make comparisons between the family status and the chemical composition of the males.

In *F. varia*, the cuticle of young males presented a richer chemical profile than that of old males. The observed absence of certain compounds in old males could be due to the fact that these individuals leave the hive within a few days after their emergence. Consequently, as demonstrated in honeybees, the lack of contact with colony-internal odor sources could lead to a reduced diversity in cuticular compounds (Breed et al. 1995, 2004; Downs and Ratnieks 1999).

In stingless bees, with the exception of *Melipona*, virgin queens exhibit a conspicuous behavior immediately after their emergence (Imperatriz-Fonseca and Zucchi 1995). Often, these unfertilized gynes move around rapidly inside the colony and are frequently assessed by workers. In the Meliponini, the three possible fates of virgin queens are (a) to substitute for the physogastric queen; (b) to get killed by the workers; or (c) to participate in a swarming event (Sakagami 1982). It is still unknown, how the workers identify a virgin queen immediately after her emergence. The characteristic morphology and behavior of these gynes could act as signals for their recognition by workers, and the chemical compounds associated with their cuticle could serve as an additional source of information. Thus, workers would be able to distinguish virgin queens from other individuals by either the presence or absence of certain chemical compounds, or by differences in compound concentrations. Moreover, in *F. varia*, the virgin queens might be identifiable due to the relatively high proportions of *n*-butylpalmitate present on their cuticle.

In many groups of social insects, the mechanism by which queens retain their reproductive status and recognize the status of other individuals is still unknown. Although in the honeybees, pheromones from the mandibular glands have been shown to fulfill these functions, many recent studies indicate that in other social insect species cuticular hydrocarbons are the primary cues of fertility (Monnin et al. 1998; Peeters et al. 1999; Howard and Blomquist 2005). According to Keller and Nonacs (1993), the mandibular queen pheromone in honeybees does not have the function of a control pheromone, but serves as a signal to indicate the queen's presence in the nest and to stimulate behaviors of workers that raise their fitness and, indirectly, that of the queen. Our results, based on other pheromones described, support the idea that the cuticular hydrocarbons in *F. varia* might be responsible for indicating the queen's presence in a colony. Endler et al. (2004) demonstrated that the queens of the ant *Camponotus floridanus* "mark" their eggs with cuticular hydrocarbons, and that these compounds indeed act as indicators for the queen's presence resulting in non-laying workers. The compounds identified in the cuticle of *F. varia* queens certainly do not result in worker sterility, since the workers are sterile even in the absence of the queen (Boleli et al. 1999). Yet, similar to *C. floridanus*, the queen's cuticular hydrocarbons could indicate her presence in the colony, thereby initiating all the vital worker-queen interactions such as cohort, feeding, and other behaviors related to the provisioning and oviposition process.

Acknowledgments We thank Michael Hrncir for his review of the manuscript. We also thank FAPESP for financial support provided to TMN (Proc. 05/58510-8) and RZ (04/09479-8, Programa Equipamentos Multi-usuários 2).

(e.g., *Chrysoperla*) subsist on only nectar and pollen (Brooks and Barnard 1990).

Green lacewing adults have long been known to communicate intraspecifically via substrate vibrations (e.g., Henry 1982), but only recently was it discovered that males in the genus *Chrysopa* produce aggregation pheromones from thousands of elliptically shaped glands embedded in their abdominal cuticle (Chauhan et al. 2004; Zhang et al. 2004, 2006a, b). Interestingly, female goldeneyed lacewings [Neuroptera: Chrysopidae: *Chrysopa* (= *Co.*) *oculata* Say] do not enter traps baited with pheromone (1*R*,2*S*,5*R*,8*R*-iridodial) (Chauhan et al. 2004; Zhang et al. 2004), presumably because females attract males via substrate-borne vibrations at close range (Henry 1982). However, Chauhan et al. (2007) showed that significant numbers of wild *Co. oculata* females are attracted to the vicinity of iridodial dispensers in the field, and observed that the attracted females laid eggs on soybean leaves near the dispensers. Thus, the judicious application of *Chrysopa* pheromones may provide a practical means to conserve and augment these lacewings in the field for biological control of pests.

All adult chrysopids possess paired prothoracic glands (PG) thought to produce defensive secretions (allomones) (Güsten and Dettner 1991; Szentkirályi 2001). In the course of ongoing research efforts to find aggregation pheromones for other chrysopid species, we have investigated or reinvestigated the PG secretions of ten species from five genera in the tribe Chrysopini. Blum et al. (1973) identified skatole (3-methylindole) as the compound responsible for the stench of adult goldeneyed lacewings (*Co. oculata*), with the major non-odorous (to humans) component of the secretion (93%) reportedly being 1-tridecene. The presence of skatole in PG secretions of *Chrysopa* spp. was verified by Güsten and Dettner (1991), but these authors found *(Z)*-4-tridecene in species representing five genera of Chrysopini, including six *Chrysopa* species. However, Güsten and Dettner (1991) did not include spectral data or chemical details as to how the double bond position and geometry of tridecene were determined. More recently, Zhu et al. (2000) identified *(Z)*-4-tridecene as the sole major constituent of the PG secretion in *Cl. carnea*, but they also described the secretion as "offensive-smelling", which is enigmatic since skatole was not present and tridecenes are not strong or foul smelling.

Here, we report on analyses of PG secretions for the following green lacewings from North and South America, Australia, and China: *Ceraeochrysa* (= *Ce.*) *cubana* (Hagen) (Brazil); *Chrysopa* (= *Co.*) *oculata* Say, *Co. nigricornis* Burmeister, *Co. incompleta* Banks, *Co. quadripunctata* Burmeister (USA), and *Co. septempunctata* Wesmael (China); *Chrysoperla* (= *Cl.*) *rufilabris* (Burmeister) (USA) and *Cl.* sp. (Brazil); *Plesiochrysa ramburi* (Schneider) and *Mallada* spp. (Australia).

Methods and Materials

Insects and Preparation of Extracts The sources, method of sampling the adult insects, identity, and the specialists responsible for identifying the lacewings are listed in Table 1. Identifications were aided by reference to Penny et al. (2000) and Brooks and Barnard (1990). Traps used to catch live chrysopids were modeled after a previously described trap (Aldrich et al. 1984). Iridodial lures were prepared as described before (Chauhan et al. 2007), except that octane was used as solvent instead of heptane. The plant volatile lure was prepared in an analogous manner using β-caryophyllene/ 2-phenylethanol/ methyl salicylate (1:1:1 by volume; total active ingredient=5 mg). Chemical extracts were prepared in ca. 50 µl of methylene chloride (EMD Chemicals Inc., Gibbstown, NJ, USA) by either extracting the whole thorax (earlier samples) or by excising the glands from the prothorax (later samples). The paired prothoracic glands were easily removed by fastening a lacewing, dorsal side up, under water in a dissecting dish, transversely cutting the dorsal intersegmental membrane between the prothorax and mesothorax, and making a dorso-medial incision in the prothorax exposing the bluish-colored glands in each side of the prothorax. Each gland, attached to a small piece of cuticle, was then removed with fine forceps, gently dried with tissue paper, and extracted in about 20 µl of solvent (CH_2Cl_2 or hexane) for analysis.

Chemical Standards The following commercially available standards were used: 1-tridecene, hexanoic acid, octanoic acid, skatole, 3-hexanol, 2-hexanol, tridecanol, benzaldehye, 2-phenylethanol, methyl salicylate (Aldrich Chemical Co., Milwaukee, WI, USA); nonanoic acid (Emery Industries, Cincinnati, OH, USA); nonanal, decanal, and β-caryophyllene (Bedoukian Research, Danbury, CT, USA). N-3-Methylbutylacetamide and N-3-methylbutylpropanamide were prepared by reactions of 3-methylbutylamine with acetyl and propanyl chlorides, respectively, at 0°C in the presence of triethylamine (Heath and Landolt 1988). *(Z,Z)*-4,7-Tridecadiene was synthesized starting with a −78°C suspension of hexyltriphenylphosphonium bromide (1.04 g, 2.44 mmol) in 20 ml of THF to which a 1M THF solution of lithium bis (trimethylsilyl)amide (2.3 ml, 2.3 mmol) was added. The reaction mixture was warmed to −30°C over 30 min, kept at this temperature for 1 h, and then cooled to −78°C. To this clear orange ylide solution, a 0.5 ml THF solution of *(Z)*-3-hepten-1-al [112 mg, 1 mmol; prepared by Swern oxidation (Chauhan et al. 1994) of *(Z)*-3-heptene-1-ol] was added. The reaction mixture was warmed to −30°C over 1 h, maintained at this temperature for 3 h, then quenched with 5 ml of a 25% ammonium acetate solution. The mixture was extracted with hexane (3×15 ml), and the combined extracts were washed with water (2×10 ml) and brine (10 ml), and then dried. All

Table 1 Chrysopids used for analyses of prothoracic gland secretions

Species[a]	Sex	No.	Date[b]	Location	Collection/Sampling Method

[c] 13 watt Neolite® NL-13127 (Litetronics International, Inc., Alsip, IL, USA).

volatiles were removed *in vacuo*. Preparative thin layer chromatography (SiO_2, ethyl acetate/hexane, 1:7) gave *(Z,Z)*-4,7-tridecadiene (138 mg, 76%) and *(Z,Z)*-4,7-tridecadiene (6 mg, 3%). (*Z*)-4-Undecene, (*Z*)-4-tridecene, and (*Z*)-6-tridecene were synthesized by following the Wittig reaction procedure described above for *(Z,E)*-4,7-tridecadiene. The following reactions and products were obtained: the ylide of *n*-butyltriphenyl phosphonium bromide with heptanal produced 92% 4-undecenes (*Z*:*E,* 98:2); the ylide of *n*-butyltriphenyl phosphonium bromide with nonanal yielded 98% 4-tridecenes (*Z*:*E,* 93:7); and the ylide of *n*-heptyltriphenyl phosphonium bromide with hexanal gave 94% 6-tridecenes (*Z*:*E,* 95:5).

Chemical Analyses Lacewing extracts and chemical standards were analyzed in the splitless injection mode using an HP 6890 N gas chromatograph (GC) equipped with a DB-WaxETR column (0.25 μm film thickness, 30 m×0.25 mm ID; J & W Scientific, Folsom, CA, USA), with flame ionization detection. Hydrogen was used as the carrier gas, the injector and detector temperatures were 250°C and 300°C, respectively, and the column temperature was 50°C for 2 min, rising to 240°C at 10°C min^{-1}, and held for 10 min. GC-mass spectrometry (MS) was performed with an HP 6890 GC coupled to an HP 5973 mass selective detector using a DB-WaxETR column as above (except 60-m-long), programmed at 50°C for 2 min, rising to 230°C at 15°C min^{-1}, and held for 15 min.

Alkylthiolation for determining double bond position was accomplished using dimethyldisulfide (DMDS) derivatization as described by Zhu et al. (2000). For enhanced sensitivity in analyzing the reaction products, specific ion monitoring was used based on the *m/z* 61 ion $(CH_3SCH_2)^+$, which is present at 20–50% abundance in the spectra of all DMDS adducts (Leonhardt and DeVilbiss 1985).

Phylogenetic Analysis The Willi Hennig Society edition of "Tree analysis using New Technology" (TNT) software program was used to analyze the chemical data both qualitatively and quantitatively (Goloboff et al. 2008). Settings included a driven search for 500 replicates, set to find minimum length of one time per replicate. Search parameters included sectorial search, ratchet, drift, and tree fusing.

Results and Discussion

The results of our chemical analyses of lacewing PG secretions are summarized in Table 2. Including our analyses and those of others (Güsten and Dettner 1991; Zhu et al. 2000), the PG secretions of 23 species of green lacewings have now been analyzed, representing seven genera: those genera listed in Table 2, plus *Nineta* and *Chrysopidia* spp. (Güsten and Dettner 1991). Our results strongly support the conclusions of Güsten and Dettner (1991) that *(Z)*-4-tridecene is ubiquitous in green lacewing PG secretions, and other compounds are specific to one or only some genera, or some species within the *Chrysopa* (Table 2) as this genus now stands (Brooks and Barnard 1990; Brooks 1997).

We confirmed that the compound likely responsible for the fecal odor of *Chrysopa* spp. is skatole (3-methylindole) (Blum et al. 1973; Güsten and Dettner 1991), and extended the known distribution of this foul-smelling PG compound to two additional genera of green lacewings, *Plesiochrysa* and *Ceraeochrysa*. However, earlier reports of 1-tridecene in the prothoracic gland secretions of *Chrysopa oculata* (Blum et al. 1973; Zhang et al. 2004) and *Co. nigrispinus* (Zhang et al. 2006a) are here shown to be in error. Synthetic 1-tridecene did not coelute with the tridecene found in the PG secretions of these *Chrysopa* spp., whereas synthetic *(Z)*-4-tridecene did coelute with the natural products. The mass spectrum of 1-tridecene (not shown) exhibited a molecular ion (*m/z* 182) of about 15% the intensity of the base peak, whereas in the spectrum of *(Z)*-4-tridecene the molecular ion was nearly 60%. Furthermore, alkylthiolation of the prothoracic gland secretions of *Co. oculata* and *Co. nigrispinus* produced DMDS-derivatives showing the diagnostic mass spectral fragments for 4-tridecene (Zhu et al. 2000): m/z (%) 41(37), 55(47), 61(84), 69(86), 83(25), 103(65), 173(100), 229(4), and 276(M+, 21).

Beyond the universally present *(Z)*-4-tridecene, there are considerable differences in the distribution of other compounds among species, particularly for alkenes, alkadienes, and amides (Table 2). In three of the *Chrysopa* spp. we analyzed (*Co. nigrispinus*, *Co. incompleta*, and *Co. septempunctata*) PG secretions contained a 180 molecular weight

compound, accounting for 20–30% of the excretion, which we thought to be a tridecadiene because the mass spectrum resembled that for *(Z)*-4-tridecene, but with the pattern of ions shifted two mass units lower. Indeed, the mass spectrum and retention time of the presumed lacewing tridecadiene matched the spectrum and retention time of synthetic *(Z,Z)*-4,7-tridecadiene, thus establishing the structure of the natural product. In *Plesiochrysa ramburi*, *(Z,Z)*-4,7-tridecadiene was much more abundant than *(Z)*-4-tridecene, and the eleven carbon alkene, *(Z)*-4-undecene [not 5-undecene as previously reported for *Co. nigrispinus* (Zhang et al. 2006a)], was identified as the major alkene constituent of the PG secretion based on mass spectral analysis of the DMDS derivative (Fig. 1A), and coinjection with the synthetic standard. The

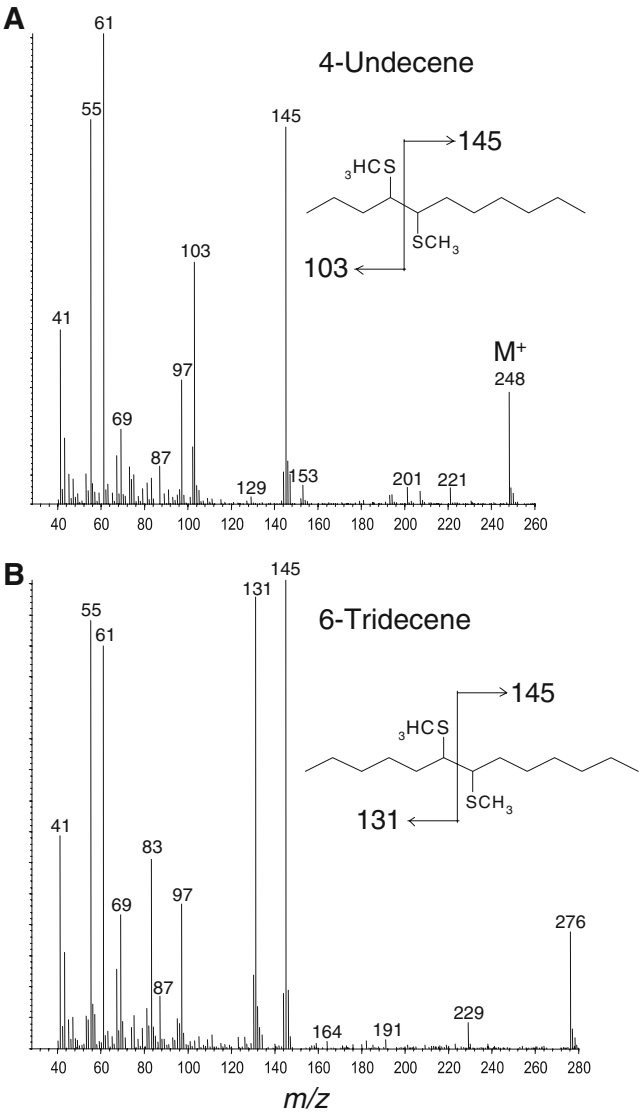

Fig. 1 Mass spectra of dimethyldisulfide derivatives of *(Z)*-4-undecene from the prothoracic gland (PG) secretion of *Plesiochrysa ramburi* (**A**), and *(Z)*-6-tridecene from the PG secretion of *Chrysopa nigricornis* (**B**)

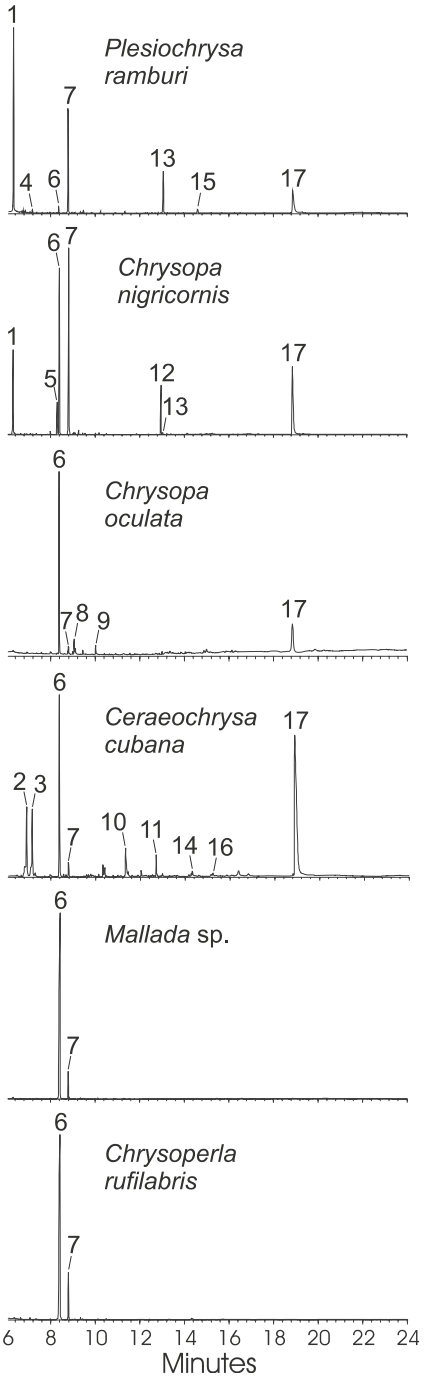

Fig. 2 Gas chromatograms of prothoracic gland extracts for representative species from the different genera and *Chrysopa* species groups analyzed [1=*(Z)*-4-undecene, 2=3-hexanol, 3=2-hexanol, 4=undecadiene, 5=*(Z)*-6-tridecene, 6=*(Z)*-4-tridecene, 7=*(Z,Z)*-4,7-tridecadiene, 8=nonanal, 9=decanal, 10=benzaldehyde, 11=hexanoic acid, 12=N-3-methybutylacetamide, 13=N-3-methylbutylpropanamide, 14=octanoic acid, 15=tridecanol, 16=nonanoic acid, and 17=skatole (3-methylindole)]

same group of *Chrysopa* spp. that express *(Z,Z)*-4,7-tridecadiene as a major PG secretion, also produced substantial quantities of N-3-methylbutylacetamide, a compound previously known as an allomone/pheromone in

cockroaches (Farine et al. 2002), yellowjacket wasps (Landolt and Heath 1987), and fruit flies (Bellas and Fletcher 1979). Curiously, the PG secretion of *P. ramburi* contained N-3-methylbutylpropanamide instead of the acetamide found in some of the *Chrysopa* species analyzed. Based on the mass spectrum of the DMDS derivative (Fig. 1B), as well as coinjection with the synthetic standard, *(Z)*-6-tridecene was also identified as a minor (*Co. nigricornis*) or trace (*Co. incompleta* and *Co. oculata*) PG component. Gas chromatograms of PG extracts for representative species from the different genera and *Chrysopa* species groups we examined are shown in Fig. 2.

Studies on pheromone biosynthesis in other insects suggest that *(Z)*-4-tridecene in lacewings may be biosynthesized from *(Z)*-9-octadecenoic (oleic) acid via successive cytosolic β-oxidation steps that remove four carbons, followed by decarboxylation (Jurenka 2004). *(Z)*-4-Undecene may be made from *(Z)*-9-hexadecenoic (palmitoleic) acid and tridecadiene most likely from *(Z,Z)*-9,12-octadecadienoic (linoleic) acid. Interestingly, *Chrysoperla carnea* is the only holometabolous insect known to synthesize linoleic acid (Cripps et al. 1986), and oleic and linoleic acids were the dominant fatty acids in abdominal extracts of *Co. oculata* in which fat body was present (JRA, unpublished data). Similarly, the biosynthesis of *(Z)*-6-tridecene may result from a single cycle of cytosolic β-oxidation of palmitoleic acid followed by decarboxylation.

The preliminary phylogenetic analysis of the semiochemical data (Table 2) resulted in an unresolved polytomy. Although the chemical signature of each of the species was distinct, the data set as a whole was more defined by autapomorphies than by synapomorphies. However, a grouping of *Chrysopa nigrispinus, Co. incompleta*, *and Co. septempunctata* was indicated based on the presence of N-3-methylbutylacetamide and the elevated expression of *(Z,Z)*-4,7-tridecadiene. Güsten and Dettner (1991) analyzed six *Chrysopa* species different from those we analyzed; all six of these *Chrysopa* were reportedly characterized by the presence of amides in their PG secretions (presumably the same acetamide we found). Thus, the *oculata-quadripunctata* grouping seems to represent a plesiomorphic clade distinct from those *Chrysopa* species that produce amides. Güsten and Dettner (1991) also noted that only *Chrysopa vididana* Schneider lacked skatole, which may be grounds to realign this species. Inclusion of other characters (e.g., morphological, molecular) in future analyses may provide further resolution.

Brooks and Barnard (1990) observed that "Chrysopidae is one of the largest and economically important families of the Neuroptera [~1200 species], [but] the classification of the family is confused." Much of the early chrysopid systematics was based on wing venation, which has been shown to be variable and unreliable (Brooks 1997). Today, quantitative computer analysis of DNA sequence data is the most powerful approach to deciphering phylogenetic relationships among insect taxa. Winterton and Freitas (2006) have applied this technique to the green lacewings, providing solid evidence that the Chrysopidae and Chrysopini are monophyletic, as well as clarifying the relationships of genera.

Apomorphic chrysopid PG semiochemicals are yet another set of quantifiable characters that may be incorporated with existing morphological, molecular, and courtship song data (Henry and Wells 2007) to further delineate relationships between green lacewings. Of course, many more species need to be analyzed chemically to lend strength to this approach. Preliminary efforts by one of us (JRA) have shown that it is feasible to obtain useful extracts of green lacewing PG secretions by briefly dipping live specimens in a minimal volume of solvent (unpublished data). At this point, the existing lacewing PG semiochemical data indicate that current *Chrysopa* spp. may be divisible based on the presence or absence of amides and skatole in their PG secretions. From a practical standpoint, the gas chromatographic "fingerprint" of chrysopid PG secretions (Fig. 2) appears to be a reliable means to help distinguish the common species of a region with the assistance of existing morphological keys (e.g., Penny et al. 2000). Certainly, one can quickly ascertain that a green lacewing that stinks is not a *Chrysoperla* species!

Acknowledgements Thanks and appreciation go to Dr. Christer Lofstedt, Section of Chemical Ecology, Lund University, Sweden, for sharing his thoughts on the biosynthesis of PG semiochemicals; to Dr. Harry Fay, Horticulture and Forestry Science, Queensland Department of Primary Industries and Fisheries, Mareeba, Australia, for coordinating the travel and research in Australia for JRA; and to Andy Carmichael, Systematic Entomology Laboratory, Beltsville, MD, for his technical support.

In the Lepidoptera, the odorant-binding proteins were classified into pheromone-binding proteins (PBPs) and general odorant binding proteins (GOBPs) based on primary sequence homology (Vogt et al. 1991). Steinbrecht (1998) proposed that OBPs function to: (1) solubilize and carry olfactory signal molecules; (2) filter signals at the periphery; (3) stimulate the olfactory system; (4) clean the peri-receptor space; and (5) deactivate odorants, but the physiological function of OBPs is still under investigation. Specific binding to pheromones has been demonstrated for the PBPs in many species (Vogt et al. 1991; Du and Prestwich 1995; Feixas et al. 1995; Maida et al. 2000), and many arguments favor the involvement of PBPs in pheromone discrimination. In contrast, the role of GOBPs is still unclear. To date, several GOBP genes have been cloned (Maíbèche-Coisné et al. 1998; Ishida et al. 2002b; Ban et al. 2003; Calvello et al. 2005). Surprisingly, binding properties of GOBP2 have been demonstrated for the major pheromonal compound in several insect species (Vogt and Riddiford 1981; Feng and Prestwich 1997).

The diamondback moth, *Plutella xylostella* (L.) (Lepidoptera: Plutellidae), is a significant pest of vegetables. Integrated pest management (IPM) strategies are being developed against this species, including olfactory-mediated behavioral manipulation. In order to exploit the molecular mechanism of the perception of volatile cues by *P. xylostella*, we investigated its repertoire of OBPs by using polymerase chain reaction (PCR) strategies and compared the GOBPs with previously reported sequences from other members of the Lepidoptera.

Methods and Materials

Insect Rearing and Collection of Tissues *Plutella xylostella* larvae were cultured indoors under a 16:8 h (L:D) light cycle at 25±1°C, 60–70% RH, and fed with Chinese cabbage, *Brassica oleracea var. capitata* L. (Brassicaceae) until pupation. Sexed pupae were kept inside glass tubes in an environmental chamber at a 16:8 h (L:D) light cycle at 25±1°C, 60–80% RH until the moths emerged. To obtain mated females, newly emerged male and female moths were paired individually in glass tubes and allowed to mate.

Antennae were collected by excising the tissue at the base from 2-d-old male and female moths and immediately transferring them to Eppendorf tubes immersed in liquid nitrogen. The same procedure was used for collecting the head (without antennae), wings, abdomen, and legs. All tissues were stored at −75°C until used experimentally.

RNA Extraction and cDNA Synthesis Total RNA was extracted from 200 antennae from sexually mature *P. xylostella* males and females by using TRIpure LS Reagent (BioTeke Corporation, Beijing, China). Single-stranded cDNA was synthesized from 1 μg of RNA with the MBI RecertAid First Strand cDNA Synthesis Kit (MBI Fermentas, Glen Burnie, MD, USA) according to the manufacturer's instructions, and single-stranded 3′RACE-ready-cDNA and 5′RACE-ready-cDNA were synthesized from 1 μg of RNA with the TaKaRa RACE cDNA Amplification Kit (TaKaRa, Dalian, China) according to the manufacturer's instructions.

Degenerate PCR for Isolation of PxylGOBP1 and PxylGOBP2 Gene Fragments The cDNAs that encode pheromone binding proteins of *P. xylostella* were amplified from antennal cDNA of males. Degenerate primers corresponding to amino acid consensus regions of several GOBP1s and GOBP2s from different species of Lepidoptera were used for PCR amplification of *P. xylostella* cDNA templates: GOBP1-forward (5′-ATGTCACGCTAGGCT TCGG-3′) and GOBP1-reverse (5′-AGGATACGCCAG CAGTGGT-3′); GOBP2-forward (5′-GAGTTCMARCACT TCTGGMG-3′) and GOBP2-reverse (5′-AAGCAV GCWGCNACYTTNAC-3′). PCR was carried out with 2 μl cDNA, 15 pmol of each primer, 10 nmol of each deoxynucleoside triphosphate (dNTP), and one unit of Taq DNA polymerase (MBI Fermentas) in the supplied buffer, giving a final concentration of 2.0 mM $MgCl_2$ in 25 μl. Cycle conditions were as follows: initial denaturation at 95°C for 3 min; 35 cycles of 94°C for 1 min, 54°C for 40 sec, and 72°C for 1 min; final extension at 72°C for 10 min. All amplification products were purified from 1.5% agarose gels using a gel extraction kit (Sunny Biotechnologies, Shanghai, China). The purified fragment was linked with pMD-18T vector (TaKaRa) and sequenced.

3′RACE-PCR 3′RACE (rapid-amplification of cDNA ends) amplifications were conducted on 2 μl of *P. xylostella* 3′ RACE-ready cDNA, with sense gene-specific primers deduced from the sequences obtained following 3′RACE outer and inner PCR amplifications of GOBP1 (GOBP1 3′ RACE outer primer: 5′-GAACATTGTCGGGAGCAGTC-3′ and GOBP1 3′RACE inner primer: 5′-GACAACACG CACAAGTTCATAC-3′); GOBP2 (GOBP2 3′RACE outer primer: 5′-CCACTGCATGAGCCGCTACTTC-3′ and GOBP2 3′RACE inner primer: 5′-AGGCTGATCCACAA CTGTGAG-3′) and with an antisense 3′RACE outer and inner primers (TaKaRa). The 50-μl amplification mix was prepared according to the TaKaRa cDNA protocol with Taq polymerase mix (MBI Fermentas). 3′RACE outer PCR was performed under the following conditions: 3 min at 95°C, followed by 5 cycles of 30 sec at 94°C and 1 min at 72°C; 5 cycles of 30 sec at 94°C, 30 sec at 70°C, and 1 min at 72°C; 30 cycles of 30 sec at 94°C, 30 sec at 68°C, and 1 min at 72°C, and 3′RACE inner PCR were performed in the following conditions: 3 min at 95°C, followed by 30

cycles of 30 sec at 94°C and 1 min at 72°C; 5 cycles of 30 sec at 94°C, 30 sec at 70°C, and 1 min at 72°C; 30 cycles of 30 sec at 94°C, 30 sec at 68°C, and 1 min at 72°C.

5′RACE-PCR 5′RACE amplifications were conducted on 2 μl of *P. xylostella* 5′RACE-ready cDNA, with sense gene-specific primers deduced from the sequences obtained following 3′RACE outer and inner PCR amplifications of GOBP1 (GOBP1 5′RACE outer primer: 5′-GCCCAGCAG GTTGAAGTAGC-3′ and GOBP1 5′RACE inner primer: 5′-GCTGCGACTGCTCCCGACAA-3′); GOBP2 (GOBP2 5′RACE outer primer: 5′-GATGTCGTCGTACTT CTTCTCA-3′ and GOBP2 5′RACE inner primer: 5′-AAG CTCTTGATGTAGTCGTGCA-3′) and with antisense 5′ RACE outer and inner primers (TaKaRa). The 50-μl amplification mix was prepared according to the TaKaRa cDNA protocol with Taq polymerase mix (MBI Fermentas). PCRs were performed as described for the 3′RACE-PCR.

Cloning and Sequencing After gel extraction (Sunny Biotechnologies), amplified cDNAs were cloned into a pMD-18T vector (TaKaRa). Recombinant plasmids were isolated by using the Plasmid Mini kit (Sunny Biotechnologies), and custom sequenced. Database searches were performed with the BLAST program (NCBI), protein analyses with MWCALC (Infobiogen) and SignalP (Nielsen et al. 1997), and sequence alignment with CLUSTALW (NPS@IBCP).

Phylogenetic Analysis with Other Lepidoptera GOBPs Several Lepidoptera GOBP sequences were retrieved from GenBank for phylogenetic analysis. Amino acid sequences of GOBPs without the signal peptide sequence were aligned by using the Multalin program (Corpet 1988). Maximum parsimony was used to build a strict consensus tree with MEGA4.0 software. Branch support was assessed by bootstrap analysis based on 1,000 replications.

Tissue Specificity of PxylGOBPs Tissue specificity was assessed by reverse transcription (RT)-PCR. RT-PCR templates were the cDNA from antennae and other tissues of male and female moths. Specific primer pairs (PxylGOBP1-forward: 5′-CACCATGACAACACGCACAAG-3′, PxylGOBP1–reverse: 5′-ACTCTGCCATCAGCATC TCCA-3′) (PxylGOBP2-forward: 5′-GAAGAATCCGGCC TATCC-3′, PxylGOBP2–reverse: 5′-CAGCCTCACCA TCGTCTC-3′) were derived from the cDNA sequences. For testing the integrity of the cDNA templates, a control primer pair (PxylActin-forward: 5′-GCGACTTGACCGA CTACC-3′, PxylActin–reverse: 5′-GGAATGAGGGCTGG AACA-3′) from the coding region of the *P. xylostella* actin gene (GenBank AB282645) was used. PCR began at 95°C for 3 min, then 35 cycles at 94°C for 30 sec, 54°C for 60 sec, and 72°C for 1 min, with a final 10 min elongation step at 72°C.

Expression Profiling of PxylGOBP1 and PxylGOBP2 Based on Real-Time PCR For the experiment examining *PxylGOBP1* and *PxylGOBP2* expression through a larval molt cycle, we used 200 eggs; 100 first instar larvae; 50 s and third instar larvae; 100 heads of male and female fourth instar larvae; and 20 male and female pupae. For expression profiling across ages of adult moths, the antennae of 0, 4, 8, and 16 h-old adult virgin and mated moths were used. To obtain mated moths, newly emerged male and females were paired individually in glass tubes and allowed to mate and were collected after 16 h. Total RNA from all of the above material from 100 moths was extracted, and cDNA was synthesized according the methods described above. Specific primer pairs for cloning *PxylGOBP1*, *PxylGOBP2*, and *Pxylactin* were the same as the primer pairs for RT-PCR, and were expected to amplify 209 bp, 219 bp, and 252 bp fragments, respectively. Real-time PCR was performed in an ABI Prism 7000 Sequence Detection System (Applied Biosystems) by using SYBR green dye bound to double strand DNA at the end of each elongation cycle (QuantiTect SBGR Green PCR kit; Qiagenn, Beijing, China).

The thermal cycling conditions for real-time PCR were 15 min at 95°C, followed by 40 cycles of 15 sec at 94°C, 30 sec at 55°C, and 30 sec at 72°C. PCR reactions were performed in triplicate, and data were processed by using the relative quantification method. The cDNA sample from male *P. xylostella* antenna was diluted to C0 (1, 4, 16, 64, and 256) times, and the CT values of *PxylGOBP*s and *PxylActin* were measured by real-time PCR. The standard curve was performed by CT and logC0 (the slope K and intercept B), and the relative values were measured as $10^{\Delta CT}$ (where ΔCT = CTPxylGOBPs[-(CT-B)/K] – CTPxylActin[-(CT-B)/K)]. Background data for this quantification have been provided (Rn vs Cycle of Real-time PCR and standard curve in Supplemental Data Figs. 1, 2, 3, 4, 5, 6).

Results

Molecular Cloning and cDNA Sequencing of P. xylostella GOBP1 and GOBP2 The RT-PCR approach performed with two pairs of degenerate primers identified two cDNA fragments 317 bp (*GOBP1*) and 260 bp (*GOBP2*), respectively. By RACE-PCR strategies, two full-length cDNAs, encoding potential GOBPs, were cloned from *P. xylostella*. They both contained an open-reading frame encoding two putative proteins of 168 and 163 amino acids, which we have named PxylGOBP1 and PxylGOBP2, respectively. The names were assigned according to the high identity of these proteins with proteins from these

classes in BLAST searches. The sequences for PxylGOBP1 and PxylGOBP2 have been deposited in GenBank under the accession numbers ABY71034, and ABY71035, respectively. The deduced amino acid sequences for both proteins possess a putative signal sequence of 24 (PxylGOBP1) and 22 (PxylGOBP2) amino acids (Fig. 1). Mature predicted PxylGOBP1 protein consisted of 144 amino acids with a molecular mass of 16,922 Da and a pI of 4.92, whereas PxylGOBP2 consisted of 141 amino acids with a molecular mass of 16,356 Da and a pI of 5.03. Thus, the two predicted mature proteins are small, likely soluble, likely secreted, and both have an acidic isoelectric point. Moreover, both contained six cysteines in conserved positions when aligned with other known GOBPs: positions C^{19}, C^{50}, C^{54}, C^{97}, C^{108}, and C^{117} (Fig. 2).

We aligned the mature amino acid sequences of PxylGOBPs with GOBPs from *Bombyx mori* (Lepidoptera: Bombycidae) and 14 other species of Lepidoptera (Figs. 2 and 3). PxylGOBPs have conserved motifs characteristic of Lepidoptera GOBPs, including the six cysteine residues that form three disulfide bridges, and the hydrophobic domains. The two PxylGOBPs can be classified into different GOBP groups (group1 and group 2) by phylogenetic analysis, and PxylGOBP1 was closest phlylogenetically to the corresponding GOBP from *B. mori* (Fig. 4). Similarity analysis on the amino acid sequences of GOBPs further confirmed the phylogenetic result. The two PxylGOBPs share only 50% identity, but are more identical to GOBPs of the same group from other moth species. PxylGOBP1 displays high identities with BmorGOBP1 (61.18%), HassGOBP1 (59.76%), AsegGOBP1 (59.76%), and SlitGOBP1 (63.31%), whereas PxylGOBP2 is more identical with BmorGOBP2 (65.06%), HassGOBP2 (72.29%), AsegGOBP2 (65.66%), and SlitGOBP2 (70.48%).

Tissue Specificity of PxylGOBPs RT-PCR experiments were performed by using specific primers to determine the tissue distribution of *PxylGOBP1* and *PxylGOBP2* (Fig. 4). RT-PCR products of the predicted size were observed exclusively in reactions with antennal cDNA of both sexes. No specific product was observed with head (without antennae), leg, abdomen, or wing. The integrity of the cDNA templates prepared from different tissues was verified by primers specific for the actin gene. In all cDNA preparations, an Actin amplification product of the correct size was amplified. Therefore, *PxylGOBPs* are only expressed in antennae.

GOBPs Expression Patterns in P. xylostella Real-time PCR was performed to compare the transcript levels of *PxylGOBPs* from antennae of male to female moths and through a larval molt cycle. For each sex and each time, cDNA was synthesized from mRNA isolated from pools of 200 antennae.

PxylGOBPs were expressed throughout the life cycle of *P. xylostella* (including egg, larva, pupa, and adult) (Figs. 5 and 6, CT data shown Supplemental Data Tables 1 and 2). The transcription levels of both *PxylGOBP1* and *PxylGOBP2* were very low in egg, larval, and pupa stages compared to adult moth, just about 0.1‰ (Figs. 5 and 6). The transcription levels of both *PxylGOBP1* and *PxylGOBP2* were lowest in eggs of whole period; which in first

Fig. 1 Nucleotide and deduced amino acid sequences of pxylGOBP1 (*left*) and pxylGOBP2 (*right*) cDNAs from antennae of the diamondback moth, *Plutella xylostella* (GenBank: ABY71034 and ABY71035). The stop codons are indicated by an *asterisk*. Putative signal peptides at the N-termini are *underlined*

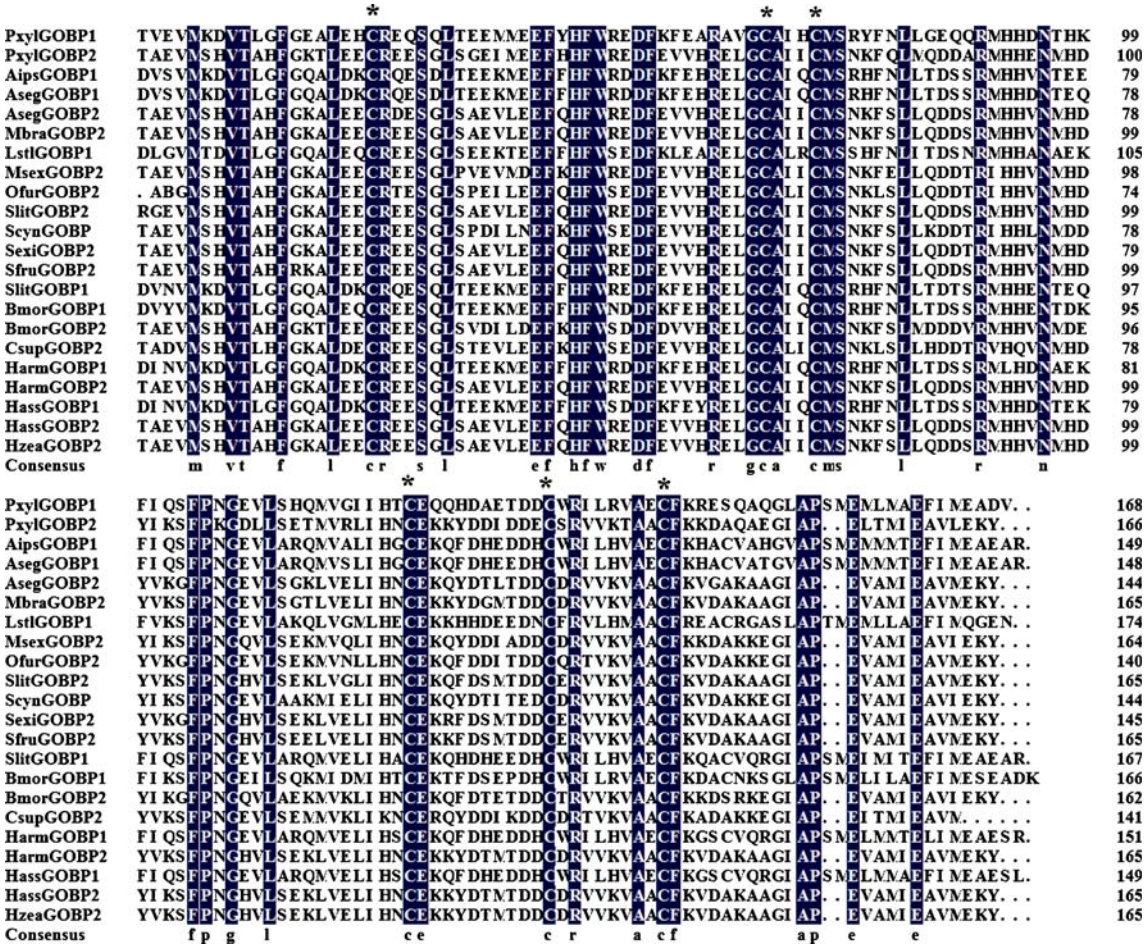

Fig. 2 Comparison of the predicted amino acid sequences of PxylGOBP1 and PxylGOBP2 from antennae of male *Plutella xylostella* with GOBPs from other Lepidoptera. The six conserved cysteines are marked by an asterisk. GenBank accession numbers—PxylGOBP1: ABY71034; PxylGOBP2: ABY71035; AipsGOBP1: ABI24160; AsegGOBP1: ABI24159; AsegGOBP2: ABI24161; BmorGOBP1: NP_001037496; BmorGOBP2: NP_001037498; CsupGOBP2: ABD98823; HarmGOBP1: AAL09821; HarmGOBP2: CAC08211; HassGOBP1: AAW65076; HassGOBP2: AAQ54909; HzeaGOBP2: AAG54078; LstiGOBP1: ACB47481; MbraGOBP2: AAC05703; MsexGOBP2: AAG50015; OfurGOBP2: ABG66419; ScynGOBP: BAF91328; SexiGOBP2: CAC12831; SfruGOBP2: AAT74555; SlitGOBP1: ABM54823; and SlitGOBP2: ABV32167

instar were highest of whole larval period, and the transcription level of *PxylGOBP1* was about double that of other larval periods; the transcription levels of *PxylGOBP1* in male pupa were higher than in female pupa; the transcription levels of *PxylGOBP2* decreased after pupation. The transcription levels of *PxylGOBPs* increased sharply after eclosion. The transcription levels of *PxylGOBPs* in male antenna were higher than those in female antenna. Mated individuals showed much higher levels of *PxylGOBPs* expression at 16 h post emergence than their unmated counterparts. The transcription levels of *PxylGOBPs* in 4 h-old moth antenna were the lowest in males, whereas they were highest in females. The transcription levels of *PxylGOBP1* from antennae were lower than *PxylGOBP2* in both male and female moths, and the amounts of *PxylGOBP1* mRNA were about 20% of *PxylGOBP2* mRNA (Fig. 6).

Discussion

In *P. xylostella*, no GOBPs had been described prior to our study. Deciphering the GOBP repertoire in this species provides the opportunity to relate GOBP expression with the functional types of sensilla. Here, we have cloned two cDNAs that encode proteins that can be classified in the lepidopteran GOBP family. Indeed, the deduced amino acid sequences present all of the typical features of OBPs: (1) they are small hydrophilic proteins with acidic isoelectric points; (2) they are destined for secretion, as demonstrated by the occurrence of a signal peptide at the N-termini; (3) they possess six cysteines in positions conserved across OBPs (Pelosi et al. 2006). The deduced proteins were grouped in the GOBP families, according to sequence homologies with lepidopteran GOBPs and phylogenetic

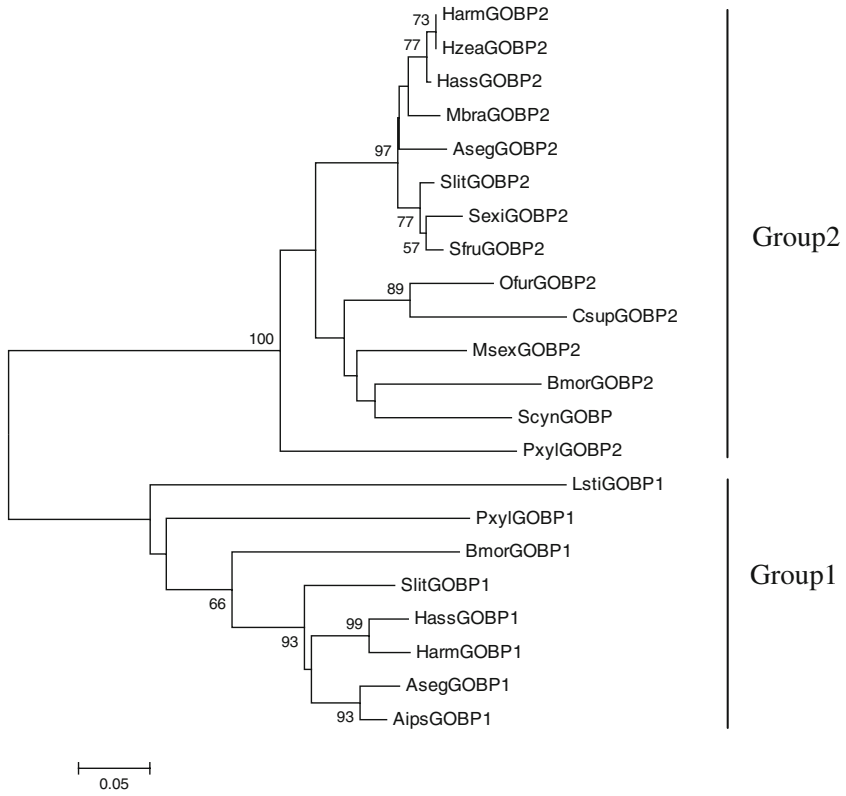

Fig. 3 Phylogenetic analysis of PxylGOBPs amino acid sequences with various lepidopteran GOBPs. GenBank accession numbers are listed in Fig. 2. Bootstrap support values (in percent) based on 1,000 replicates are indicated. Analysis indicates two groups (Grp1 and Grp2), as defined by Picimbon and Gadenne (2002)

analyses, and thus have been named PxylGOBP1 and PxylGOBP2.

Phylogenetic analysis showed that Lepidoptera GOBPs are classified into two distinct groups (Fig. 3): PxylGOBP1 belongs to group1 and PxylGOBP2 belongs to group 2. Group 1 contains PxylGOBP1, bmorGOBP1, HassGOBP1, slitGOBP1 etc.; group 2 includes PxylGOBP2, bmorGOBP2, HassGOBP2, slitGOBP2, etc. A more meaningful phylogenetic tree of insect GOBPs can be constructed when more GOBPs become available from a larger number of species. Insect OBPs have also been classified into long chain (~160 aa), medium chain (~120 aa), and short chain (~110 aa) classes, which relates to their potential structure and function (Pesenti et al. 2008). According to this hypothesis, PxylGOBP1 (168 aa) and PxylGOBP2 (163 aa) belong to the long chain class, and this is useful to know for future functional studies of these proteins.

OBPs are presumed to mediate the delivery of odorants to specific receptor proteins embedded in the dendritic membrane (Vogt et al. 1999). Steinbrecht (1998) proposed that OBPs function to solubilize and carry olfactory signal molecules, but the physiological function of OBPs is still

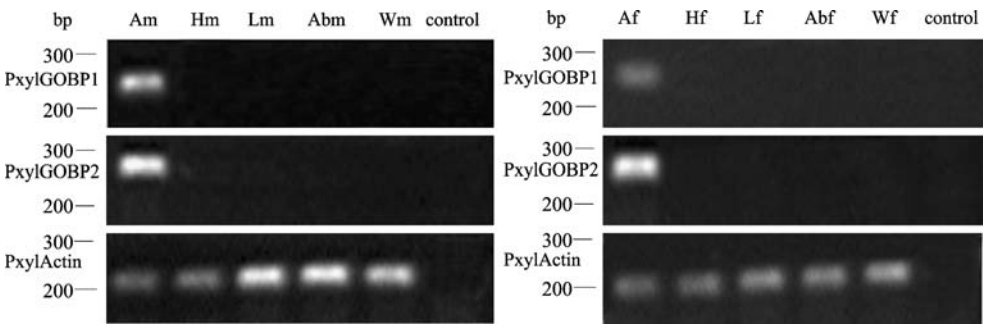

Fig. 4 Tissue-specific expression of *PxylGOBPs*. RT-PCRs were performed by using RNAs isolated from the different tissues. Amplification products were analyzed on agarose gels and visualized by UV illumination after staining with ethidium bromide. Based on the primer design, the sizes of the expected PCR-products were 209 bp for *PxylGOBP1*, 219 bp for *PxylGOBP2*, and 252 bp for *Actin* (control). *Am*: Male antenna, *Af*: female antenna, *Hm*: male head (without antenna), *Hf*: female head (without antenna), *Abm*: male abdomen, *Abf*: female abdomen, *Lm*: male leg, *Lf*: female leg, *Wm*: male wings, *Wf*: female wings, control: no-template (negative control) ensures the specificity of the amplifications. The position of molecular weight markers (*bp*) is indicated on the *left* side

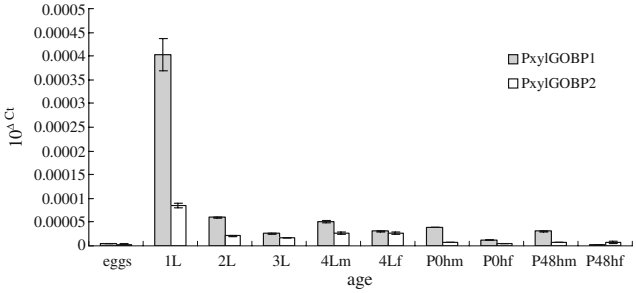

Fig. 5 Relative quantification of expression of *PxylGOBP1* and *PxylGOBP2* amplified through a larval molt cycle by real-time PCR. 1 L: first larval instar; 2 L: second larval instar; 3 L: third larval instar; 4 L: fourth larval instar; P0hm: 0 hr male pupa; P0hf: 0 hr female pupa; P48hm: 48 hr male pupa; and P48hf: 48 hr female pupa

under investigation. There are several studies that support the role of PBP's in pheromone detection (Ljungberg et al. 1993; Schneider et al. 1998; Fan et al. 2003; Xu et al. 2005), but the functional role of GOBPs is still unclear. GOBPs were first presumed to mediate the delivery of plant volatiles, since they are localized in *B. mori* and *A. polyphemus* in sensilla basiconica (Laue et al. 1994; Heinbockel and Kaissling 1996), which respond to food or host-plant odors (Priesner 1979). Surprisingly, binding properties of GOBP2 were only shown for the major pheromonal compound in *A. polyphemus* (Vogt and Riddiford 1981). Recombinant GOBP2 from *Manduca sexta* also showed strong affinity for the major pheromonal compound of this species, *trans*-6, *cis*-11-hexadecenyl acetate [(*E*)-6-(*Z*)-11-16:Ac], binding of which is only displaced by very high concentrations of plant odors (Feng and Prestwich 1997). In *Mamestra brassicae*, a recombinant GOBP2 was expressed in *Escherichia coli* and gave positive binding with three tritiated pheromone analogs (Maíbèche-Coisné et al. 1998). However, the native form of this protein (purified from male antennae) did not show affinity for the pheromone components, but displayed high specific affinity for *cis*-11-hexadecenol, an antagonist to pheromone-mediated male attraction (Jacquin-Joly et al. 2000).

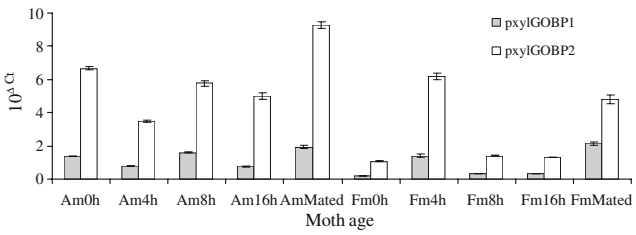

Fig. 6 Relative quantification of expression of *PxylGOBP1* and *PxylGOBP2* amplified at separate times by real-time PCR. *Am*: Male antenna; *Af*: female antenna; 0 hr, 4 hr, 8 hr, and 16 hr and mated refers to the adult at 0 hr, 4 hr, 8 hr, and 16 hr after eclosion and mating

The transcription levels of *P. xylostella* GOBP genes differed among mated and unmated male and female moths, and also correlated by age. This result agrees with the report that mated females were more responsive to three green leaf volatiles (GLVs) viz., (*Z*)-3-hexenyl acetate, (*E*)-2-hexenal, and (*Z*)-3-hexene-1-ol than males or virgin females (Reddy and Guerrero 2000). In fact, many moths have showed a plasticity of olfactory-guided behavior not only dependent on the nature of the chemical, but that might change with the physiological status (e.g., age/hormone or mating status) of the individual (Anton et al. 2007). For example, mated females, but not virgin females, of *Amyelois transitella* (Walker) flew upwind in an odor plume containing almond volatiles (Phelan and Baker 1987). In female *Lobesia botrana*, wind tunnel experiments with various grapevine plant parts as odor sources, demonstrated that only mated females were attracted. Virgin females never showed any upwind flight behavior in response to any of the plant parts used (Masante-Roca et al. 2007). Similar phenomena were found in adult female *Manduca sexta* (Mechaber et al. 2002). Gypsy moth, Lymantria dispar, PBPs discriminate among structurally related odorants (Plettner et al. 2000; Kowcun et al. 2001). Laughlin et al. (2008) also found that OBP-ligand complexes of a very specific conformation activate the receptor and that "locking" the OBP (through a mutation) into the conformation can cause the receptor and sensillum activation without the presence of a ligand. However the electrophysiological responses to a specific ligand do not correlate with the binding affinity of the gypsy moth PBPs for that ligand (Honson et al. 2003). In the future, we plan to investigate the relationship between the transcription of GOBP genes and behavioral plasticity in *P. xylostella*.

pest control and for basic research of species-specific pheromonal communication. We report here the identification of compounds in pheromone gland extracts of female *S. haitangvora*, and the male responses to blends of different components and ratios in the field.

Methods and Materials

Insects Late stage larvae of *S. haitangvora* were collected by excavating them from infested trunks of apple trees during May and June of 2008 at Suwon (37.2°N,127.1°E), Korea. They were individually reared in capped plastic cups (30 ml) on artificial diet (Bio-serv, Frenchtown, NJ, USA) and maintained at 23°C under a 16L:8D photoperiod. After eclosion, the sexes were separated based on distinctive hair tufts (Arita et al. 2004). Moths were provided with a cotton pad soaked with a 5% (*w*/*v*) sucrose solution as food.

Chemicals Synthetic pheromone standards used were purchased from Pherobank (Wageningen, The Netherlands). Isomeric purity of these compounds exceeded 99%. C23–C28 straight-chain hydrocarbons were obtained from Sigma-Aldrich (Missouri, USA).

Pheromone Extraction As female *S. haitangvora* exhibited calling behavior (extending their ovipositors) during photophase, pheromone gland extracts were taken from 1- to 2-d-old females at 4 h into the photophase. The pheromone gland of each female was extruded by applying gentle pressure to the abdomen, excised with fine forceps, and extracted in 10 μl hexane containing 10 ng of tridecyl acetate (13:OAc) as an internal standard into a 0.3-ml conical vial (Wheaton, Millville, NJ, USA) for 10 min at room temperature. The extract was transferred to a new vial and stored at −80°C until analysis.

Chemical Analysis Pheromone gland extracts were analyzed on an Agilent 6890N GC interfaced to an Agilent 5973 mass-selective detector. Samples were run on DB-23 and DB-Wax columns (30 m×0.25 mm ID, 0.25 μm film thickness, J&W Scientific, Folsom, CA, USA) in the splitless mode. Injector and detector temperature were 250°C. Helium was used as carrier gas (1 ml/min). The GC oven temperature was programmed from 80°C (1 min hold) to 220°C at 10°C/min and held for 10 min. The ionization voltage was 70 eV. The ion source temperature was 230°C. Components in gland extracts were identified tentatively by comparison of their mass spectra with the mass spectra library (Wiley-NIST, Hoboken, NJ, USA); and identifications were confirmed by comparison of retention indices (RI; relative to alkane standards, Van den Dool and Kratz 1963), and mass spectra with those of authentic standards on two different columns. The quantity of each component was estimated by comparing its GC peak area with that of the internal standard (13:OAc).

Field Experiments Field experiments were conducted during August–September of 2008 in apple orchards at Suwon, Korea. Sticky delta traps (Green Agro Tech, Korea) baited with rubber septa (Aldrich Chemical Co., Milwaukee, WI, USA) impregnated with test chemicals in hexane were hung on branches 1–1.5 m above ground level. All field tests employed a complete randomized block design with four replicate blocks. The distance between traps within a block was at least 10 m. Trapped moths were counted and removed daily.

Experiment 1 investigated the attraction of *S. haitangvora* males to the two major components *Z*3,*Z*13-18:OAc and *E*2,*Z*13-18:OAc singly and in binary blends. Experiment 2 was conducted to test the individual effects of seven minor components identified in female gland extracts; *Z*9-16:OAc, *Z*11-16:OAc, *Z*9-18:OAc, *Z*13-18:OAc, *E*3,*Z*13-18:OAc, *Z*3,*Z*13-18:OH, and *E*2,*Z*13-18:OH as possible synergists, by using standard baits of the two major components. Finally, experiment 3 compared the relative attractiveness of different doses of a 1:1 blend of *Z*3,*Z*13-18:OAc and *E*2,*Z*13-18:OAc. Trap catch data (x) were transformed to log (x+1) and submitted to one-way analysis of variance. Means were compared by Tukey's test at α=0.05 (SAS Institute Inc. 2004).

Results

Chemical Analysis GC-MS analysis of pheromone gland extracts of female *S. haitangvora* revealed the two major and seven minor components, as well as henicosane, tricosane, pentacosane, and heptacosane (Fig. 1). The mass spectrum of peaks 1 and 2 had diagnostic fragment ions *m/z* 282 (M^+), 222 (M^+-CH_3COOH), and 61 ($CH_3COOH_2^+$), suggesting hexadecenyl acetate. Peaks 3 and 4 showed diagnostic ions *m/z* 310 (M^+), 250 (M^+-CH_3COOH), and 61 suggestive of octadecenyl acetate. For identification of the monoene acetates, the retention indices (RIs) of the *E* and *Z* isomers of hexadecenyl and octadecenyl acetates in which the double bond position ranged from carbon 7 to 13 were calculated on the two GC columns. The RIs of peak 1 and the *Z*9-16:OAc standard were the same on the DB-Wax and DB-23 columns (RIs of 2,342 and 2,386, respectively), and peak 2 coincided with *Z*11-16:OAc in GC retention times on both columns (RIs of 2,354 and 2,400, respectively). The calculated RIs of peak 3 and the *Z*9-18:OAc standard were the same on the DB-Wax and DB-23 columns (RIs of 2,529 and 2,594, respectively), and peak 4 had RIs of 2,555 and 2,620, respectively, the same as those of *Z*13-18:OAc standard.

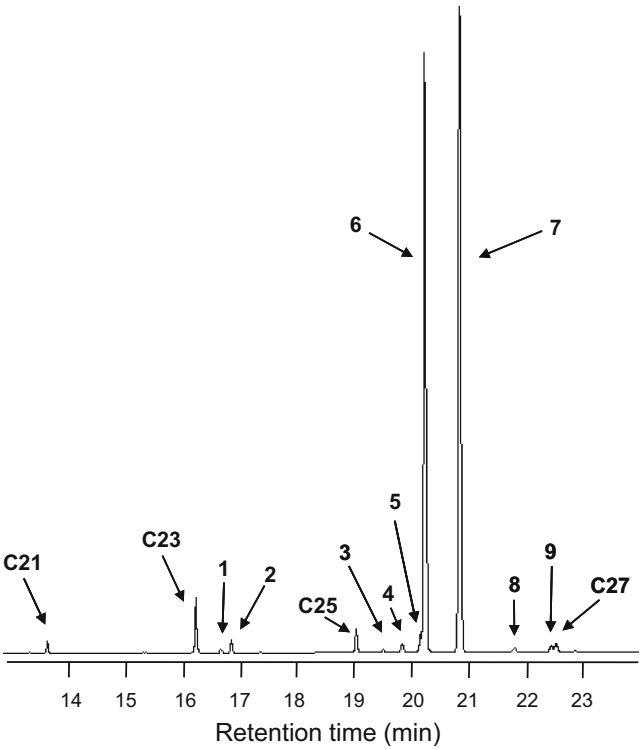

Fig. 1 Total ion chromatogram of GC-MS analysis of pheromone gland extract from female *Synanthedon haitangvora* on DB-Wax column. 1 (*Z*)-9-hexadecenyl acetate, 2 (*Z*)-11-hexadecenyl acetate, 3 (*Z*)-9-octadecenyl acetate, 4 (*Z*)-13-octadecenyl acetate, 5 (*E*,*Z*)-3,13-octadecadienyl acetate, 6 (*Z*,*Z*)-3,13-octadecadienyl acetate, 7 (*E*,*Z*)-2,13-octadecadienyl acetate, 8 (*Z*,*Z*)-3,13-octadecadien-1-ol, 9 (*E*,*Z*)-2,13-octadecadien-1-ol, C21 heneicosane, C23 tricosane, C25 pentacosane, C27 heptacosane

The mass spectra of peaks 5, 6, and 7 were similar and had diagnostic ions at *m/z* 308 (M^+), 248 (M^+-CH_3COOH), 219, 205, 191, and 61. This suggested that all three compounds were octadecadienyl acetates. Comparison of RIs of the natural compounds with the 3,13 and 2,13 isomers of octadecadienyl acetates on both columns confirmed that compounds 5, 6, and 7 were *E*3,*Z*13-18:OAc, *Z*3,*Z*13-18:OAc, and *E*2,*Z*13-18:OAc, respectively (Table 1). The mass spectrum of peaks 8 and 9 showed diagnostic fragment ions of octadecadien-1-ol at *m/z* 266 (M^+), 248 (loss of H_2O), 219, 205, and 191. The calculated RIs of peak 8 and the *Z*3,*Z*13-18:OH standard were the same on the DB-Wax and DB-23 columns (RIs of 2,669 and 2,673, respectively), and peak 9 coincided with *E*2,*Z*13-18:OH in GC retention times on both columns (RIs of 2,694 and 2,687, respectively). The amount of the major component *E*2,*Z*13-18:OAc present in the gland extract was estimated as 21.5 ng per female (N=15), and the relative ratio of compounds 1–9 in gland extracts was 0.2:1.5:0.4:3:2:87:100:1:1.5.

Field Experiments A total of 37 *S. haitangvora* males were trapped in field experiment 1, with no catch in control traps. *Z*3,*Z*13-18:OAc as a single component was attractive to males, while *E*2,*Z*13-18:OAc was unattractive alone (Fig. 2). Traps baited with a two-component blend of *Z*3,*Z*13-18:OAc and *E*2,*Z*13-18:OAc in a 1:1 ratio enhanced catches compared with traps baited with *Z*3,*Z*13-18:OAc alone or other blend ratios of the two components. In a subsequent experiment, a total of 394 moths were caught during the 4 days. Addition of *Z*3,*Z*13-18:OH to the binary blend of *Z*3,*Z*13-18:OAc and *E*2,*Z*13-18:OAc strongly inhibited attraction of *S. haitangvora* males (Fig. 3). Minor components identified in gland extracts showed no synergistic effect. Moreover, the full nine-component blend did not increase trap catches compared with traps baited with the primary binary blend. A total of 98 moths were captured in the final experiment that tested different doses of pheromone. Increasing loadings of the optimum pheromone blend in the lures from 0.1 mg to 2.0 mg resulted in increasing attractiveness of the lure (Fig. 4). There was a strong positive correlation between dose and catch, within the range of exposures tested (r^2=0.91, P<0.01).

Table 1 Retention indices of octadecadienyl compounds (peaks 5, 6, 7, 8 and 9) present in gland extracts of female *Synanthedon haitangvora* and synthetic 3,13- and 2,13-octadecadienyl compounds on DB-Wax and DB-23 columns

Compound	DB-Wax	DB-23
Female extract		
Peak 5	2,576	2,620

(*Z*,*Z*)-2,13-octadecadien-1-ol	2,694	2,705

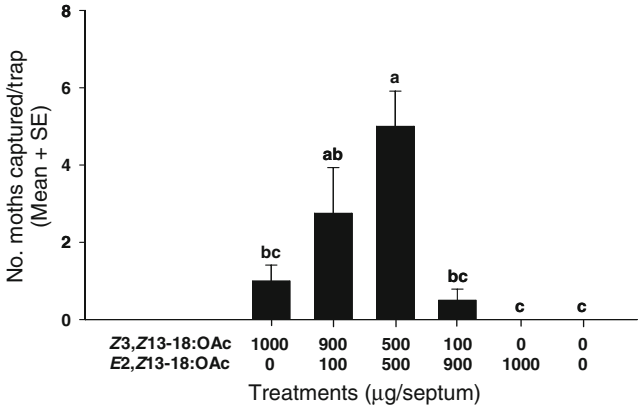

Fig. 2 Number of *Synanthedon haitangvora* males captured in traps baited with lures containing different ratios of *Z*3,*Z*13-18:OAc and *E*2,*Z*13-18:OAc at apple orchards in Suwon, Korea, 27–30 August 2008 (N=4). *Bars* with the same letter are not significantly different (Tukey's test: $P>0.05$)

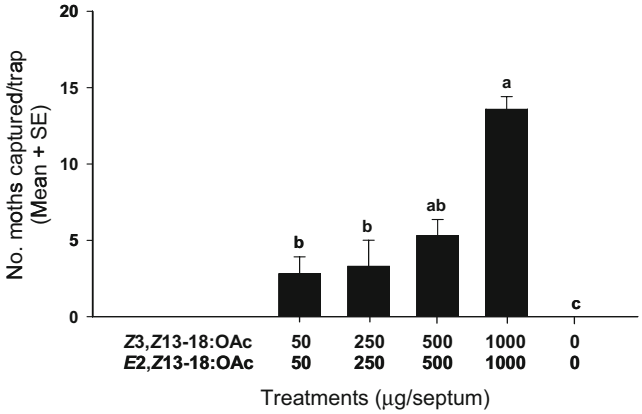

Fig. 4 Number of *Synanthedon haitangvora* males captured in traps baited with different doses of *Z*3,*Z*13-18:OAc and *E*2,*Z*13-18:OAc at apple orchards in Suwon, Korea, 7–10 September 2008 (N=4). *Bars* with the same letter are not significantly different (Tukey's test: $P>0.05$)

Discussion

GC-MS analyses of female *S. haitangvora* pheromone gland extract showed that two major octadecadienyl acetates were present at an approximately 1:1 ratio. To determine the double-bond positions of these diene acetates, dimethyl disulfide (DMDS) derivatization of the female extracts was performed as described by Vincenti et al. (1987). However, as in the study by Naka et al. (2006), the mass spectrum of the DMDS adducts did not show diagnostic ions indicating the double-bond positions of the dienes. In most of the known cases, moths in the family Sesiidae utilize octadecadienyl compounds with 3,13 or 2,13 positions of unsaturation as major components of their female sex pheromones (El-Sayed 2009). Based on this information, the two major compounds, *Z*3,*Z*13-18:OAc and *E*2,*Z*13-18:OAc, were identified by comparison of retention indices on two GC columns with authentic standards of all four isomers of the 3,13- and 2,13-octadecadienyl acetates.

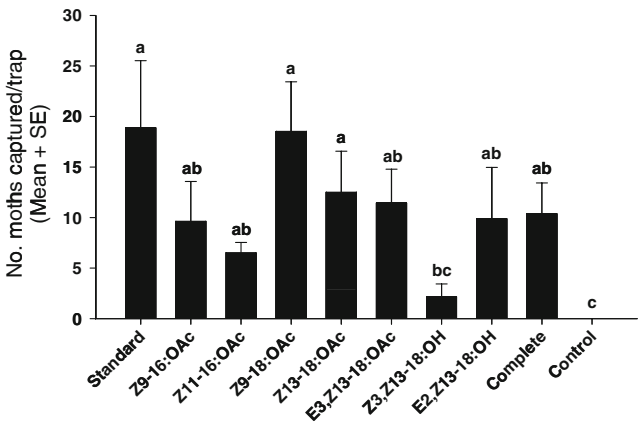

Fig. 3 The effect of adding 2% of different minor components to standard baits with 1 mg/septum of *Z*3,*Z*13-18:OAc and *E*2,*Z*13-18:OAc on captures of male *Synanthedon haitangvora* at apple orchards in Suwon, Korea, 2–5 September 2008 (N=4). The complete blend consisted of nine components in a ratio found in the pheromone gland extract. *Bars* with the same letter are not significantly different (Tukey's test: $P>0.05$)

Field trapping experiments showed that *Z*3,*Z*13-18:OAc and *E*2,*Z*13-18:OAc were necessary for optimal attraction of male *S. haitangvora*, and males were preferentially attracted to the blend found in gland extracts. Conversely, none of the other geometrical isomers of major components were attractive to male moths (data not shown). During the course of this study, no other sesiid species were attracted to a 1:1 mixture of *Z*3,*Z*13-18:OAc and *E*2,*Z*13-18:OAc. Thus, we suggest that this blend is a specific and effective attractant for monitoring *S. haitangvora*.

*Z*3,*Z*13-18:OAc and *E*2,*Z*13-18:OAc have been reported as either sex pheromone components or attractants in many species of Sesiidae (El-Sayed 2009). Like *S. haitangvora*, *Synanthedon scitula* and *Melittia cucurbitae* utilize mixtures of *Z*3,*Z*13-18:OAc and *E*2,*Z*13-18:OAc in their sex pheromones (Klun et al. 1990; Zhang et al. 2005). *Z*3,*Z*13-18:OAc is the major component of the pheromone blend of *S. scitula*, whereas *E*2,*Z*13-18:OAc constitutes the major component for *M. cucurbitae*. Therefore, species-specific pheromone signals by using different ratios might play a role in reproductive isolation if *S. haitangvora* is sympatric with *S. scitula* and *M. cucurbitae* in other areas of the world.

The effects of minor glandular components on field trap catches varied. The addition of *Z*3,*Z*13-18:OH to the binary blend of *Z*3,*Z*13-18:OAc and *E*2,*Z*13-18:OAc significantly decreased attraction for *S. haitangvora* males. This result suggests that *S. haitangvora* males may be not attracted to *Nokona pernix* and *Paranthrene tabaniformis* females that

emit *Z*3,*Z*13-18:OH as their pheromone (Naka et al. 2006; Mozûraitis and Karalius 2007). On the other hand, addition of *E*3,*Z*13-18:OAc did not affect male attraction of *S. haitangvora* males to the standard bait. In field screenings of attractants for *Synanthedon tenuis*, Tamaki et al. (1977) confirmed an antagonistic effect of *E*3,*Z*13-18:OAc on male attraction when it was mixed with the major component, *Z*3,*Z*13-18:OAc, in a very low ratio. Therefore, *E*3, *Z*13-18:OAc may prevent cross-attraction between *S. haitangvora* and *S. tenuis* where they occur sympatrically in Korea and China. However, it is not known whether *Z*3, *Z*13-18:OH and *E*3,*Z*13-18:OAc are actually released from the female glands during calling. Further research is required to compare the attractiveness of pheromone blends actually emitted with those found in female gland extracts.

In addition, four monounsaturated acetates, *Z*9-16:OAc, *Z*11-16:OAc, *Z*9-18:OAc, and *Z*13-18:OAc, were identified as minor components of female *S. haitangvora* gland extracts, but the behavioral roles of these components remain unclear. Addition of monounsaturated acetates to two major components in biologically relevant rates had no significant effect on attraction of conspecific males in the present study. Previous studies with other sesiid species have shown that monounsaturated acetates are present in female pheromone glands, but no biological activity was observed in the field trials (Klun et al. 1990; Mozûraitis et al. 2006). These results suggest that monounsaturated acetates found in gland extracts from sesiid moths may just be by-products of the biosynthesis of octadecadienyl acetates. Further studies are necessary to determine the biosynthetic pathway for producing the sex pheromone components in sesiid moths.

Acknowledgements The authors thank Prof. Yang Seop Bae for identification of *S. haitangvora* and two anonymous reviewers for invaluable comments.

walking up the tree bole. They suggested that the female initiates courtship by walking close to a male on the upper branches of the canopy. The male follows the female, tapping her body with the forelegs and the antennae. This description by Morgan and Stewart (1966) strongly suggested the presence of a contact signal on the female cuticle.

In a preliminary study in the laboratory, *Sirex noctilio* males, when presented with freeze-killed females, responded with abdominal bending but did not do so after the cuticular coating of the dead females was removed by dipping the female in hexane (D.J.C., unpublished data). These preliminary results indicated the relevance of female cuticular compounds in the mating behavior. This is further supported by the work of Crook et al. (2008), who reported a high abundance of contact chemoreceptors on the antennae of *S. noctilio*.

Cuticular lipids are key compounds involved in the recognition of mates, caste, and kin, in a number of insect species (Howard 1993; Wyatt 2003). Hydrocarbons of the epicuticle, in particular, have been described as recognition cues, kairomones, chemical mimicry agents, and sex pheromone components throughout the insect taxa (Blomquist et al. 1993; Howard and Blomquist 2005). While semiochemicals of hymenopterans in the sub order Apocrita frequently are reported, we know much less about the chemical ecology of insects in the other sub order, Symphyta, in which the family Siricidae belongs (Ayasse et al. 2001; Keeling et al. 2004). The primary focus of this study was to analyze the cuticular lipid coating of male and female *S. noctilio*, and to identify the contact pheromone that induces males to attempt copulation with females.

Methods and Materials

Insects Adults were reared out of Scots pine logs harvested near Syracuse, NY, USA. The first batch of infested trees were taken down in December 2007 and cut into approximately 60 cm-long logs. The logs were kept in barrels with a mesh lid at 25°C at the USDA PPQ rearing facility in Syracuse. Emergence of males started at the end of February 2008, followed thereafter by the emergence of females in March. A second batch of logs was taken into the rearing facility in May 2008. Emergence started in July and lasted until the beginning of August. Barrels were checked twice a week, and emerging insects were identified and separated by sex. Males and females were kept individually in screw cap glass jars, with a piece of paper towel inside, until used.

Solvent Dipping For the analysis of cuticular lipids, insects were freeze killed at age 1–6 days. On the day of analysis, bodies were thawed for 30 min at room temperature. Each wasp was placed individually into a 10 ml screw cap vial and extracted × 3, for 2 min, with 3 ml of hexane (Burdick & Jackson, 95%, Morristown, NJ, USA). The extracts were combined in a separate 10-ml screw cap vial. Solutions were held at 4°C until subsequent fractionation or analysis. For analysis, the body wash was evaporated under a gentle stream of nitrogen. The residue was redissolved in 300 µl of a 50 ng/µl solution of 16-methyl hexatriacontane in hexane.

For the bioassay experiments, 1 to 6-d-old females were freeze killed the night before the experiment. The bodies were thawed for 30 min at room temperature. Extraction was performed as described above. The extracts were combined in a 10-ml screw cap vial, and the body wash was evaporated under a gentle stream of nitrogen. Samples were redissolved with the appropriate amount of hexane to give body wash solutions of 1/3, 1, or 3 female equivalents (FE) per 100 µl. Washed females were dried in a fume hood for 30 min before application of any treatment.

Analysis of the Cuticular Washes Amounts of compounds were quantified with an Agilent 6890 gas chromatograph-flame ionization detector (GC-FID) system equipped with an Equity-5 column (30 m×0.2 mm×0.2 µm; Supelco, Bellefonte, PA, USA). Quantification of compounds was based on their peak area values obtained from the data acquisition and analysis software (Chemstation D.01.00, Agilent). The output values were corrected with the relative response factors to calculate percentage composition and amounts of the identified compounds (Böröczky et al. 2008). For identification, selected samples were injected into an Agilent 6890N GC, equipped with an identical Equity-5 column, coupled with a 5973N Mass Selective Detector (MSD) in EI mode (+70 eV). For all the analyses, the oven temperature program was initially 50°C (held for 1 min) then programmed to 210°C at 20°C min^{-1}, then to 320°C at 3°C min^{-1} (and held for 25 min). The injector temperature was 280°C, in both systems, and the FID (in the GC) and transfer line (in the GC-MS) temperatures were 300°C. Samples were injected splitless (purge set at 0.75 min), and the carrier gas was helium at an average linear flow velocity of 25 cm s^{-1}.

Identification of the compounds was based primarily on their EI mass spectra (NIST05, Masslib) and their Kovats indices on the Equity-5 column (Van Den Dool and Kratz 1963; Kovats 1965). Position of the methyl branching of mono-, and dimethylalkanes was determined by using characteristic even- and odd-mass fragments of their respective mass spectra (Nelson, 2001) as well as by calculated retention indices (Carlson et al., 1998). Position of double bonds was determined by examining the mass spectral fragmentation of the dimethyl disulfide (DMDS)

adducts of the alkenes (Francis and Veland 1981; Vincenti et al. 1987). Identification of wax esters is tentative based on their molecular weight and the weight of the $[RCO\text{-}1]^+$ and $RCOOH_2^+$ fragments from their mass spectra. High resolution MS (HR-MS) analysis of the natural and synthetic compounds was performed at the Proteomics and Mass Spectrometry Core Facility at The Huck Institutes of the Life Sciences of The Pennsylvania State University.

Contact Behavioral Assay Behavioral experiments were performed between March 20 and April 18, and between July 16 and August 1, 2008. Live males used in the assays were 1-6-d-old. Treatments were prepared fresh each morning. Dead females (unwashed and hexane washed) were mounted, at the thorax, on a piece of wire. Treatment solutions were applied to previously washed dead females with a 10 µl syringe, thus ensuring that the solution covered the bodies evenly. Treated females were placed in a fume hood for 10 min to allow evaporation of the solvent. In the bioassay, the responses of males were tested by presenting a female 1–2 cm away from the males. The typical sequence of responses to an active treatment was, walking up to the treated dead female, antennation of the abdomen and/or grabbing the dead female with the forelegs, mounting, and either abdominal bending or a copulation attempt. Each observation lasted 20–25 sec or was terminated earlier if the male attempted copulation or flew away. We counted copulation attempts as being a positive response. Each morning a new group of males was tested with an unwashed dead female (UDF), and only the positively responding males were used on that day in the bioassay (6–12 males per day). Each set of treatments was replicated 17–24 times over 3–4 d. The order in which the treatments were presented varied each day. A treatment was presented to all the males before switching to the next treatment, with males allowed to rest half an hour between treatments. Each set of treatments included a negative and a positive control. The negative control (C) was prepared by evaporating 9 ml hexane and redissolving the residue in 100 µl of hexane. For the positive control, an unwashed dead female (UDF) or a female with reapplied whole body wash (WB) was used. The sets of treatments tested were the following: a) Whole body wash reapplied at three concentrations: 1/3, 1, and 3FE (WB1/3, WB, and WB3, respectively); and the controls C and UDF. b) Fractions of the female body wash at 1FE: alkanes (A), monoalkenes (MA), dialkenes (DA), and more polar lipids (P) (see below); and the controls C and WB. c) Synthesized components of MA at 1FE: (*Z*)-7-heptacosene (Z7C27), (*Z*)-9-heptacosene (Z9C27), (*Z*)-7-nonacosene (Z7C29), and (*Z*)-9-nonacosene (Z9C29) individually (see below), a mix of all four (Mix4), MA; and the controls C and UDF. d) Binary combinations of the three most active components at 1FE: Z7C27+Z7C29, Z7C27+Z9C29, and Z7C29+Z9C29, a mix of the three components (Mix3), Mix4, MA; and the controls C and UDF.

For each treatment within a set, the significance of difference from the positive control was determined by using the 2-tail values of the Fisher's exact test.

Fractionation of the Female Body Wash Body washes of ten females were combined and evaporated to dryness, which resulted in approximately 4 mg solid material. This was redissolved in 50 µl of hexane and loaded onto a small flash chromatography column, consisting of a Pasteur pipette, with a ball of glass wool as a plug and approximately 300 mg of silica gel (Sigma-Aldrich, 230–400 mesh, 60 Å). Compounds were eluted with hexane in two 1-ml fractions, followed by three 1-ml fractions of diethyl-ether. The hexane fractions were combined to provide a hydrocarbon mix, while the combined diethyl-ether fractions gave a mixture of more polar lipids. The latter was evaporated to dryness and redissolved in 1 ml of hexane resulting in a 1FE/100 µl solution (P).

The hydrocarbon fraction was further separated on 300 mg of silver nitrate-treated silica (Li et al. 1995). The fraction, in hexane, was loaded onto the column, and the alkanes were eluted with hexane (two 1-ml fractions), the monoalkenes with dichloromethane (B&J, High Purity Solvent; five 1-ml fractions), and the dialkenes with acetonitrile (EMD, Omnisolv, High Purity Solvent; two 1-ml fractions). Fractions containing compounds of the same class were combined and evaporated to dryness. Residues were redissolved in 1 ml of hexane, resulting in the following 1FE /100 µl solutions: alkanes (A), monoalkenes (MA), and dialkenes (DA).

Syntheses Z9C27 was prepared as the main geometric isomer from the Wittig reaction of nonyltriphenyl phosphonium bromide and octadecanal. A significant amount of the (*E*)-isomer was formed by this route and required additional chromatography for purification. Partial hydrogenation of the appropriate alkynes was used to provide alkenes Z7C27, Z7C29, and Z9C29. The corresponding alkanes were produced in 3–5% as a result of over-reduction, but they were easily removed by flash chromatography. The alkynes were conveniently prepared by condensing the appropriate alkyl iodides with either 1-decynyl lithium or 1-octynyl lithium in the presence of 1, 3-dimethyl-3,4,5,6-tetrahydro-2(1H)-pyrimidinone (DMPU) (Bengtsson and Liljefors 1988). The identity of the compounds was confirmed by their mass spectra and the exact mass of the molecular ion determined by HR-MS. Melting points are uncorrected.

Preparation of 7-Heptacosyne A solution containing 0.33 g (2 mmol) of distilled 1-octyne in 10 ml of tetrahydrofuran

(THF) was cooled to −70°C and treated with 2 ml of 1.6 M *n*-BuLi. After 45 min, a solution containing 0.39 g (1 mmol) of 1-iodononadecane (Marukawa et al., 2001) in 3 ml of DMPU was added dropwise, and the mixture was allowed to warm to room temperature overnight. The mixture was treated with 5 ml of saturated NH_4Cl and taken up in 70 ml of petroleum ether. The organic layer was washed × 3 with 10 ml of water, and dried over anhydrous $MgSO_4$. After filtration, the solvent was removed in vacuum, and the residue was purified by flash chromatography (hexane/silica gel) to provide 0.19 g of 7-heptacosyne as a waxy solid: mp 35–37°C, EI-MS *m/z* 376 [M^+](2), 292(1), 291(2), 278(2), 277(1), 250(1), 222(1), 208(1), 207(2), 194(1), 180(2), 179(2), 166(10), 165(10), 152(5), 151(7), 138(9), 137(11), 124(15), 123(24), 111(15), 110(30), 109(58), 97(37), 96(82), 95(88), 83(48), 82(83), 81(100), 80(12), 79(16), 71(14), 69(40), 68(30), 67(73), 57(41), 55(56), 54(32), 43(57), 41(39). HR-MS *m/z* 376.4080; calculated for $C_{27}H_{52}$, 376.4069.

Preparation of 7-Nonacosyne Coupling 1-octyne and 1-iodoheneicosane (Mori and Wu, 1992), as described for 7-heptacosyne, provided 0.18 g of 7-nonacosyne as a waxy solid: mp 41–43°C, EI-MS *m/z* 404 [M^+](2), 320(1), 319 (2), 306(2), 305(1), 207(1), 180(3), 179(2), 166(11), 165 (11), 152(6), 151(7), 138(11), 137(12), 124(17), 123(25), 111(18), 110(33), 109(60), 97(41), 96(90), 95(89), 85(10), 83(51), 82(87), 81(100), 80(12), 79(15), 71(18), 69(44), 68(32), 67(74), 57(45), 55(56), 54(30), 43(59), 41(36). HR-MS *m/z* 404.4369; calculated for $C_{29}H_{56}$, 404.4382.

Preparation of 9-Nonacosyne Coupling 1-decyne and 1-iodononadecane (Marukawa et al., 2001), as described for 7-heptacosyne, provided 0.3 g of 9-nonacosyne as a waxy solid: mp 35–37°C, EI-MS *m/z* 404 [M^+](2), 347(1), 278 (2), 277(1), 264(1), 222(1), 208(2), 207(2), 195(1), 194(5), 193(5), 152(5), 151(6), 138(14), 137(22), 124(23), 123(26), 111(16), 110(20), 109(38), 97(40), 96(74), 95(72), 83(49), 82(93), 81(100), 80(12), 79(15), 71(15), 69(38), 68(25), 67(64), 57(46), 56(10), 55(58), 54(26), 43(52), 41(33). HR-MS *m/z* 404.4382; calculated for $C_{29}H_{56}$, 404.4382.

Preparation of Z7C27 A solution containing 100 mg of 7-heptacosyne, 2 drops of quinoline, and 75 mg of Lindlar catalyst (Aldrich Chemical Co.), in 25 ml of ethanol and 2 ml of ethyl acetate, was cooled to 10°C and hydrogenated at atmospheric pressure. The reaction products were followed by GC-MS analysis; this indicated the absence of starting alkyne after 3 h. The mixture was filtered through celite, and after the solvent was removed *in vacuo*, flash chromatography (hexane/silica gel) provided 85 mg of Z7C27, EI-MS *m/z* 378 [M^+](5), 237(1), 223(1), 222(1), 210(1), 209(2), 208(1), 196(1), 195(2), 194(1), 182(2), 181(3), 180(2), 167(6), 153(9), 139(15), 125(30), 112(12), 111(54), 110(10), 99(11), 98(17), 97(91), 96(22), 85(37), 84(27), 83(88), 82(29), 81(15), 71(50), 70(35), 69(68), 68(13), 67(17), 57(100), 56(39), 55(81), 54(14), 43(68), 41(39). HR-MS *m/z* 378.4232; calculated for $C_{27}H_{54}$, 378.4226.

Preparation of Z7C29 Hydrogenation of 7-nonacosyne, as described above, provided Z7C29, EI-MS *m/z* 406 [M^+](4), 251(1), 250(1), 237(1), 236(1), 224(1), 223(2), 222(1), 210(1), 209(2), 208(1), 196(1), 195(3), 194(1), 183(1), 182(2), 181(4), 180(2), 167(6), 153(11), 139(18), 125(34), 112(12), 111(58), 110(10), 99(13), 98(18), 97(96), 96(25), 95(10), 85(39), 84(26), 83(90), 82(30), 81(16), 71(54), 70(35), 69(69), 68(15), 67(20), 57(100), 56(34), 55(71), 54(13), 43(74), 41(37). HR-MS *m/z* 406.4522, calculated for $C_{29}H_{58}$, 406.4539.

Preparation of Z9C29 Hydrogenation of 9-nonacosyne, as described above, provided Z9C29, EI-MS *m/z* 406 [M^+](4), 251(1), 250(1), 237(1), 236(1), 224(1), 223(2), 222(1), 210(1), 209(2), 208(1), 196(1), 195(3), 194(1), 183(1), 182(2), 181(4), 180(2), 167(6), 153(11), 139(18), 125(34), 112(12), 111(58), 110(10), 99(13), 98(18), 97(96), 96(25), 95(10), 85(39), 84(26), 83(90), 82(30), 81(16), 71(54), 70(35), 69(69), 68(15), 67(20), 57(100), 56(34), 55(71), 54(13), 43(74), 41(37). HR-MS *m/z* 406.4544; calculated for $C_{29}H_{58}$, 406.4539.

After purification, compounds Z7C27, Z7C29, and Z9C29 were at least 99% pure (*Z*)-isomers based on the peak area values by GC.

Preparation of Z9C27 A suspension of 0.86 g (2 mmol) of nonyltriphenylphosphonium bromide in 10 ml THF was cooled to −10°C under argon and treated with 1.5 ml of 1.6 M butyl lithium in hexanes to provide an orange mixture. After 30 min, a solution containing 0.54 g of octadecanal in 5 ml THF was added dropwise, and the mixture was stirred overnight and allowed to warm to room temperature. The mixture was partitioned between diethyl ether and aqueous NH_4Cl. The ether layer was dried over anhydrous $MgSO_4$, filtered, and the solvent removed *in vacuo*. The residue was taken up in petroleum ether and filtered through celite, and the fitrate concentrated *in vacuo*. Flash chromatography (hexane/silica gel) provided 200 mg of a 5:1 mixture of (*Z*)- and (*E*)-isomers; EI-MS *m/z* 378 [M^+](2), 237(1), 210(1), 209(2), 208(1), 196(1), 195(2), 194(1), 182(2), 181(3), 180(2), 167(6), 153(9), 139(15), 125(30), 112(12), 111(54), 110(10), 99(11), 98(17), 97(91), 96(22), 85(37), 84(27), 83(88), 82(29), 81(15), 71(50), 70(35), 69(68), 68(13), 67(17), 57(100), 56(39), 55(81), 54(14), 43(68), 41(39). HR-MS *m/z* 378.4232, calculated for $C_{27}H_{54}$, 378.4226. A small portion (4 mg) of the 5:1 (*Z*)/(*E*)-mix was purified further on a silver nitrate treated silica

column (400 mg) by sequential elution with hexane, 5% dichloromethane in hexane, 10% dichloromethane in hexane, and 50% dichloromethane in hexane, all in 1-ml fractions. Fractions 2–6, in 10% dichloromethane in hexane, and fractions 1–3, in 50% dichloromethane in hexane, were combined, which resulted in 3 mg of Z9C27, 98% pure (*Z*)-isomer based on the peak area values by GC.

Results

Cuticular Lipids of S. noctilio The hexane-extractable cuticular lipids of *S. noctilio* consisted predominantly of alkanes (C21-C33), mono- and dimethyl alkanes (C23-C37), mono- and dialkenes (C23-C31), and wax esters (C36-C44). (Fig. 1, Table 1). The hydrocarbon components of the cuticle were sexually dimorphic. While *n*-alkenes were one of the major groups of the hexane body wash of females (29% in females, 4% in males), methyl-branched alkanes were more abundant in the male body wash (28% in males, 2% in females). Additonally, a few lower molecular-weight (C23-C25) monoalkenes were present on the male cuticle. Wax esters and *n*-alkanes were abundant in both sexes (37% and 31% in males, and 38% and 31% in females, respectively).

Activity-Guided Bioassay UDF and WB positive controls, respectively, elicited copulation attempts in 65% and 60% of males (not significantly different, Fisher's exact test). However, WB controls at one-third the amount (1/3WB) elicited a significantly weaker response from males than when the same treatment was tested at 1 FE (Fig. 2a). Negative C controls did not elicit copulation attempts in any of the males tested across all experiments (Fig. 2), thus demonstrating that hexane washing removed the cuticular signals.

The A fraction did not elicit a positive response in any of the males (N=17) tested, whereas a weak response was observed to the DA and more polar P fractions. The response to the MA fraction was not different statistically

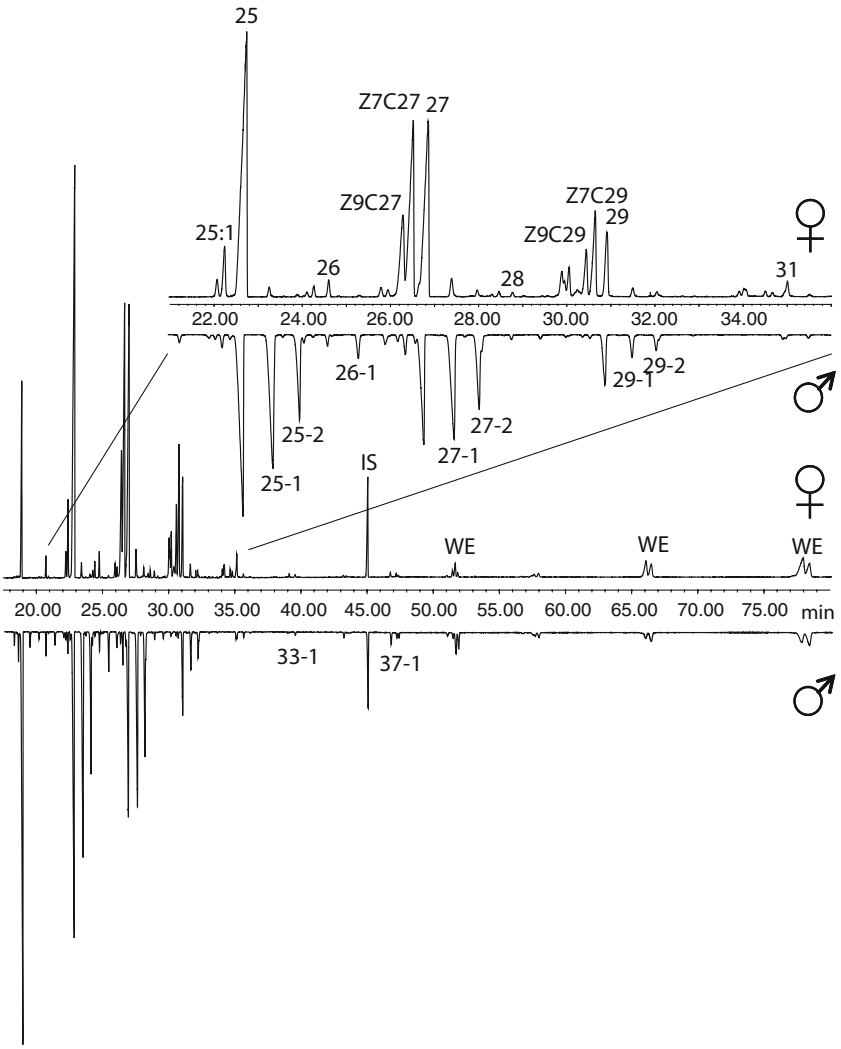

Fig. 1 Representative gas chromatograms of the whole body wash of female (*top*) and male (*bottom*) *Sirex noctilio*. Each sample is a hexane extract of one individual with 50 ng/μl 16-methyl hexatriacontane as internal standard. Coding is the same as in Table 1, for example, pentacosane (25), pentacosene (25:1), (*Z*)-9-nonacosene (Z9C29), methyl heptacosane (27-1), dimethyl pentacosane (25-2), and wax ester (WE), etc.

[d] All averages are means of four.

[e] 'nd': not detected, 'tr': <0.10 μg/wasp.

from the response to WB (Fig. 2b), hence, we investigated that fraction further. The major components of MA were identified as pentacosenes, heptacosenes, and nonacosenes based on their retention indices and mass spectra. The position of the double bond of the most abundant compounds was shown to be 7 and 9, based on the mass spectra of the DMDS adducts. Additional isomers in lower amounts were nonacosenes with the double bond being more toward the middle of the chain (Table 1). The four most abundant components of MA, 7- and 9-heptacosene, and 7- and 9-nonacosene, were synthesized, and the geometries of the double bonds in the natural compounds were determined by comparison of the retention times on the Equity-5 column. For all four monoalkenes, the natural compounds were the (*Z*)-isomers. Purification of the crude synthetic products by flash chromatography on silica and silver nitrate-treated silica led to 98–99% pure (*Z*)-isomers, which were tested in our bioassay at 1FE (for amounts see Table 1). One of the compounds, Z9C27, did not elicit significant responses from males (N=24), while the other

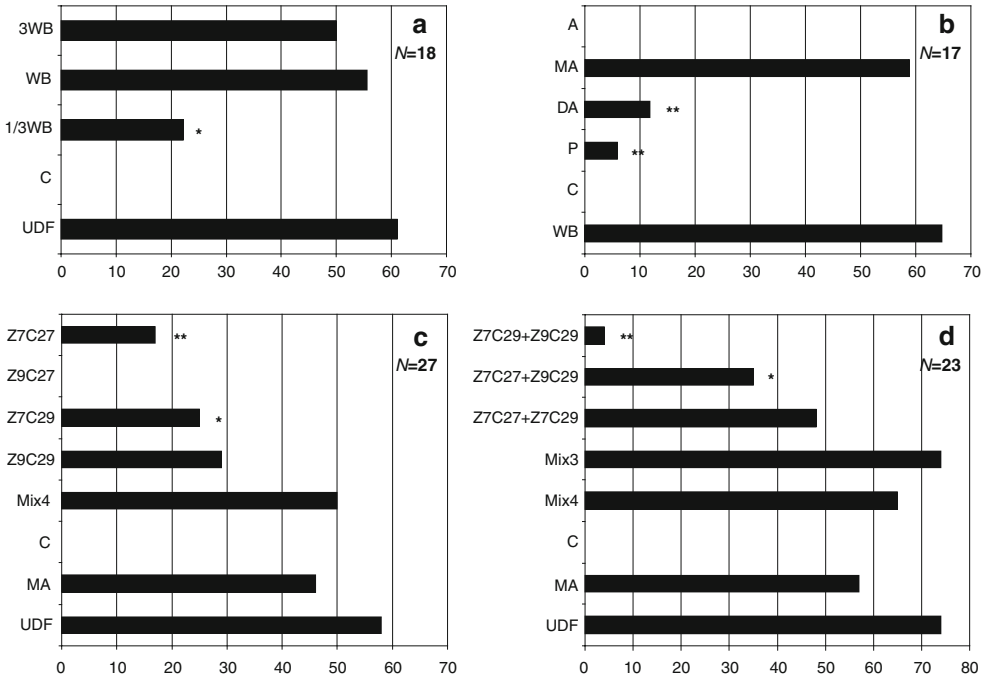

Fig. 2 Percentages of males that attempted copulation with dead females having various treatments applied in four sets of treatments. (**a**) Three concentrations of the female whole body wash: 3 female equivalents (FE) (3WB), one FE (WB), and one third FE (1/3WB). (**b**) Fractions of the body wash at one FE: alkane fraction (A), monoalkene fraction (MA), dialkene fraction (DA), and the fraction of more polar cuticular lipids (P). (**c**) Four synthetic components of MA: (*Z*)-7-heptacosene (Z7C27), (*Z*)-9-heptacosene (Z9C27), (*Z*)-7-nonacosene (Z7C29), and (*Z*)-9-nonacosene (Z9C29). (**d**) Binary combinations of the active synthesized monoalkenes. Positive control was either an unwashed dead female (UDF; **a**, **c**, and **d**) or whole body wash reapplied (WB; **b**). Negative control was hexane reapplied (C). Within each set the statistical significance of the difference of a treatment from the positive control was calculated using Fisher's exact test; *: $P<0.05$, **; $P<0.01$

three did (Fig. 2c). The mixture of the three active components at 1 FE (Mix3), and also the binary mixture of Z7C27 and Z7C29, elicited activity from males not different statistically from that elicited by UDF. The results of testing binary combinations of the three active monoalkenes indicated that Z7C27 was an essential component of the blend (Fig. 2d).

Discussion

We identified three major components, Z7C27, Z7C29, and Z9C29, of the cuticular lipids of female *S. noctilio* that elicited copulation attempts in conspecific males. The responses of males to a binary mixture of synthetic Z7C27 and Z7C29 or to a mixture of these three compounds were not different statistically from the responses to unwashed dead females, indicating that these compounds accounted for most, if not all, the cuticular activity. When Z7C27 was not present in the blend, the responses of males dropped significantly (Fig. 2d, $P<0.01$). Further work on these compounds should test more rigorously for possible additive and/or synergistic effects in mixtures of these compounds.

Cuticular monoalkenes are well-known to act as contact sex pheromone components and sex recognition compounds in some cerambicid beetle (Ginzel et al. 2003, 2006) and *Drosophila* species (Howard 1993; Howard and Blomquist 2005). These compounds are odd chain-length alkenes, ranging in chain length from 25 to 33 carbons, with (*Z*) geometry across the double bond. Among hymenopterans, various parasitic wasps are reported to use a mix of cuticular alkenes and, more often, alkadienes as volatile sex pheromones (Keeling et al. 2004). In the suborder Symphyta, the family Diprionidae (conifer sawflies) is the most extensively studied. Many of the species use female-produced volatile sex pheromones that are methyl-branched secondary alcohols and esters thereof (Keeling et al. 2004). However, no reports are available on the role of cuticular compounds in mating behavior. To our knowledge this is the first description of cuticular hydrocarbons that serve as contact sex pheromone components in this ancient hymenopteran suborder.

In our bioassays, 65% of males attempted copulation with UDF controls, although all males tested had responded positively during the selection process earlier in the day. That we did not observe 100% positive responses to our positive control treatment is likely due to some males being

affected by frequent handling. Also, defrosted females sometimes had their wings in a twisted position, which restricted the movements of the male; males can copulate with a live female only after pressing down the wings of the female tight to her body (unpublished observation). Moreover, we only counted attempted copulation, the clearest behavioral response, as a positive response for our observations, and we did not include other positive responses, such as agitated wing-flapping and abdominal bending. Other variation observed in responses of males to UDF across treatment sets is likely due to differences in age (1-6-d-old males were used), changes in barometric pressure, relative humidity, temperature, and light conditions.

Our laboratory bioassay tested only contact cuticular chemicals for activity in mating. It seems likely that other factors (olfactory, visual, tactile, and auditory) may provide additional cues to males during mate location and selection. To date no evidence has been found for the existence of a long-range sex pheromone component in the Siricidae. Some hymenopterans are hill-topping insects and use rendezvous sites to find their mate (Alcock and Dodson 2008). Similar behavior has not been observed with *S. noctilio*. Although females may fly into male swarms, there are no behavioral data published that investigate the cause of such behavior; it is difficult to determine in a laboratory bioassay what type of cue (olfactory, visual, and/or auditory) may be used in such behavior. After emergence, both sexes are positively phototactic (Morgan and Stewart 1966), and it is likely that both sexes are attracted by host volatiles to the same area since their antennae are responsive to volatile terpenes produced by pines (Simpson 1976). Indeed, females can be caught using girdled pine trees as lures; however, males are not found in the same traps that are usually placed way under the canopy. Thus, it remains to be investigated how the two sexes locate each other.

Acknowledgements This research was supported by USDA APHIS PPQ. We thank Robert D. Minard at the Proteomics and Mass Spectrometry Core Facility at The Huck Institutes of the Life Sciences of The Pennsylvania State University very kindly for providing the high resolution mass spectrometry data.

behavioral steps performed mainly by males (Rojas et al. 1990; Manrique and Lazzari 1994; Pires et al. 2004; Vitta and Lorenzo 2009). In addition, female receptivity to male copulatory attempts has been shown to affect mating success in *Triatoma infestans*, *Panstrongylus megistus*, and *T. brasiliensis* (Manrique and Lazzari 1994; Pires et al. 2004; Vitta and Lorenzo 2009). Few studies have been conducted on the effect of chemical cues on mating behavior in triatomines. Electrophysiological studies have shown that copulating pairs of *T. infestans* release odors that elicit responses from the antennae of males (De Brito Sánchez et al. 1995). Several authors have suggested that chemical signals are released by copulating pairs, leading to the aggregation of surrounding males (Baldwin et al. 1971; Manrique and Lazzari 1995).

Triatoma brasiliensis adults have a pair of metasternal glands (MGs) that open to the ventral metathorax (Brindley 1930), but their functions, as well as the composition of their secretion, are unknown for this species. All triatomine species studied to date also possess a pair of Brindley's glands, opening dorso-laterally between the thorax and abdomen, which secrete isobutyric acid as the most abundant compound; this secretion probably plays a role in alarm and/or defense (Ward 1981; Cruz López et al. 1995; Manrique et al. 2006). Other reports for several triatomine species suggest that the compounds produced by Brindley's glands are involved in the sexual communication (Fontán et al. 2002; Rojas et al. 2002; Guerenstein and Guerin 2004). Recently, Manrique et al. (2006) and Pontes et al. (2008) suggested that the MG secretion of *T. infestans* and *R. prolixus* is involved in sexual communication. These authors identified several highly volatile ketones and alcohols that are produced by MGs of these species, and showed that the contents are emitted by adults during copulation. Moreover, Crespo and Manrique (2007) and Pontes et al. (2008) have shown that MG volatiles are relevant for mating success. However, odor-mediated orientation mechanisms that could promote encounters between adults of triatomines are not known. Therefore, we analyzed the behavior of adult *T. brasiliensis* in the presence of air currents laden with volatiles emitted by both sexes, searching for oriented responses. Additionally, we tested whether the compounds emitted by the MGs of females are necessary for the expression of orientation responses by males. Moreover, the ability of these compounds to elicit responses from the antennae of males was studied by means of gas chromatography-electroantennographic detection (GC-EAD) assays. Finally, the full identities of 14 of the most abundant volatile compounds produced by the MGs of *T. brasiliensis* females and males are reported, with special attention to those compounds with GC-EAD activity.

Methods and Materials

Insects T. brasiliensis were reared in the laboratory at 26± 2°C and 60±10% RH, and fed on live chickens. The insects were sorted by sex as fifth instar larvae (Espínola 1966), and maintained apart until the experiments were carried out. Adults were fed weekly and kept in plastic containers, which had a piece of folded filter paper as substrate. Identification of volatiles and behavioral assays were performed with 30 d old virgin adults starved for 2 wk. All insects used for this study were exposed to 12:12 hL/D cycle at least 3 d before experiments.

Olfactometer Bioassays A two-choice "T" olfactometer was used to test orientation responses of adult insects (Fig. 1). The olfactometer was made of acrylic (two 21.5 cm arms and a 33.5 cm common stem, arm section 24.0 cm^2). The apparatus was positioned horizontally in an experimental room under the same temperature conditions as described for rearing insects. All experiments were performed during the first half of scotophase. A piece of filter paper covered the base of the olfactometer in order to allow the insects to walk easily. Filtered air was drawn through the olfactometer by a fan connected to the release chamber. Air was purified by using charcoal filters located before the stimulus chamber of each arm of the olfactometer. The filters consisted of 10-ml glass pipettes filled with granular activated charcoal (4–8 mesh, Sigma, USA). The air-flow was maintained at a speed of 10 cm/s as measured by an anemometer (Testo, Germany) at the end of each arm, which was connected to a small polyacrylic chamber (6×6×3.5 cm) used for presenting the odor sources.

Filter papers were changed after each test to avoid bias due to chemical contamination left from walking insects. The stimuli associated with each olfactometer arm were alternated after three repetitions to avoid directional bias effects. The olfactometer was washed with distilled water and dried with tissue paper before each experiment.

Bioassay Calibration Tests were performed to evaluate whether the olfactometer constructed *ad hoc* presented any intrinsic bias. For this, *T. brasiliensis* adults were tested under two conditions: a) no air currents associated, and b) both arms associated with clean air currents.

Olfactometer Tests The olfactometer was used to test whether adult *T. brasiliensis* showed orientation responses when exposed to air currents associated with volatiles from adult males or females. The orientation of insects of both sexes was tested by offering individual bugs a choice between an arm associated with volatiles from two adult insects of the same gender or another that presented a clean air current. For each series, 30 individuals were tested

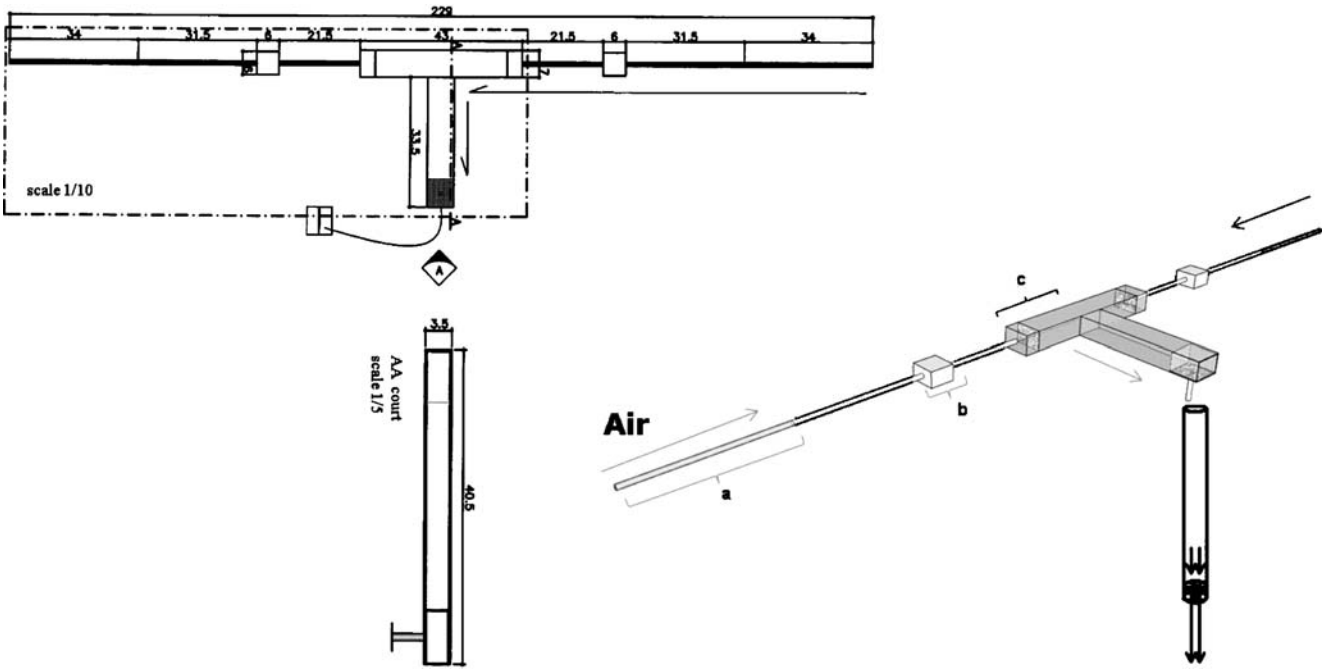

Fig. 1 Schematic drawing of the T-olfactometer used to test orientation responses in adults of *Triatoma brasiliensis*. **a** activated charcoal filter, **b** stimulus chamber, and, **c** arm. Dimensions are given in cm

against odor-laden or clean air currents. A single *T. brasiliensis* adult was introduced gently into the release chamber and kept there for acclimatization for 10 min. Subsequently, the entrance door of this compartment was opened, and the behavior of the insect was recorded for 15 min. Insects that did not express a choice after 15 min from the beginning of the assay were discounted. Test and stimulus insects were used only once.

To determine preferences, the first choice of each insect, i.e., which arm of the olfactometer that was chosen, was recorded. For this, we adopted the following criterion: an insect made a choice every time that its whole body passed the boundary between the main trunk and the corresponding arm of the olfactometer. Choices were statistically analyzed by means of a binomial test.

The following experimental series were performed to investigate whether male or female *T. brasiliensis* adults orientate to conspecific odor-laden air currents: a) female bugs exposed to male odor-laden air currents; b) female bugs exposed to female odor-laden air currents; c) male bugs exposed to female odor-laden air currents; d) male bugs exposed to male odor-laden air currents; and e) male bugs exposed to nymph odor-laden air currents.

Because of the positive response of males towards female and male odors, two complementary series of assays were conducted to elucidate further aspects of their behavior. The series tested were: f) male bugs confronted with an air current laden with volatiles from two males with the orifices of their MGs occluded with paraffin; and g) male bugs confronted with an air current laden with volatiles from two females with the orifices of their MGs occluded with paraffin. In order to test whether the response of males was due to the occlusion manipulation, two additional control assay series were performed, as follows: h) male bugs were confronted with an air current laden with volatiles from two sham-treated males to which paraffin was applied without occluding their MG orifices; and i) male bugs were confronted with an air current laden with volatiles from two sham-treated females to which paraffin was applied without occluding their MG orifices. Because of the absence of significant orientation by females in response to volatiles from adults, a positive control was performed to confirm that this apparatus was adequate for testing orientation by female bugs. In this experimental series, the females had to choose between one arm associated with mouse odors from two laboratory-reared *Mus musculus* newborns vs. a clean air current.

Identification of Compounds Produced by Metasternal Glands In order to obtain glands for the sampling of volatiles, insects were first kept at −18°C for 7 min to avoid disturbance during the dissection. They were then secured with flour-based modeling dough (Faber-Castell, Brazil), leaving their thorax and abdomen exposed. These preparations were placed into an ice-cold phosphate buffer solution to minimize volatilization of MG secretions. Immediately after mounting the insects, a microsurgical knife was used to remove the MG together with its reservoir and a piece of

cuticle surrounding the gland opening (ca. 0.25 mm^2). Samples of 10 glands were stored in 2-ml vials closed with Teflon®/silicone-lined caps and kept in an ice bath until the end of the subsequent dissections. To exclude any compounds that were not found exclusively in the MGs, we prepared control samples with pieces of tissue and cuticle from other parts of the thorax. Female and male samples were stored in a freezer at −18ºC for not more than 10 d for subsequent analysis. No change of the chemical profile was observed after storage, compared with freshly prepared samples.

Gland samples were sonicated (40 kHz, Thorton, Inpec Eletrônica, Brazil) for 5 min and then heated at 50°C for 30 min. A solid phase microextraction (SPME) fiber (2 cm, DVB/CAR/PDMS-50/30 µm, SUPELCO, USA) was exposed to the headspace of the samples for 10 min at 50°C prior to analysis by gas chromatography with mass-spectrometric detection (GC-MS Shimadzu 17A coupled to a Shimadzu 5050A). The desorption time in the injection port of the GC was 1 min. Helium was used as carrier gas (30 cm/s), and injections were splitless for 1 min. GC injector and transfer line temperatures were 230°C and 250°C, respectively. The ionization energy was 70 eV. The oven program was 40°C for 5 min, 3°C/min to 120°C, and 15°C/min to 200°C using a SupelcoWax-10 column (30 m×0.25 mm i.d.×0.25 µm film; Supelco, USA). Tentative identification of volatiles was based on the comparison of retention index (RI, Kováts 1965) and mass spectra with data from the literature and a spectral library (NIST-02). All tentative identifications were confirmed by peak enhancement in co-injections with authentic synthetic samples (Pontes et al. 2008).

The configuration of chiral compounds was determined by GC with flame-ionization detection (FID; Shimadzu 17A) analysis and GC-MS analysis (Shimadzu 17A coupled to a Shimadzu 5050A). Gland samples were heated at 50°C for 30 min. An SPME fiber (2 cm, DVB/CAR/PDMS-50/30 µm) was exposed to the headspace of the glands for a varying time interval depending on the abundance of compounds. The desorption time in the injection port of the GC was 1 min. For the GC-FID, the following settings were used: helium was used as the carrier gas (31 cm/s), and injections were splitless for 1 min. Injector and detector temperatures were 225°C. All enantioselective GC was performed isothermally using a CYCLOSILB column (30 m×0.25 mm i.d.×0.25 µm film, J & W Scientific, USA). The column temperature varied from 30°C for 2-butanol to 110°C for 1-phenylethanol. Because of the occurrence of overlapping peaks of different compounds when using the enantioselective GC-FID set-up described above, additional enantioselective GC-MS analysis was carried out according to the protocol for achiral analysis, but with a GammaDex 225 column (30 m×0.25 mm i.d.× 0.25 µm film, Supelco USA). As for the CYCLOSILB column, isothermal conditions were applied, with column temperatures varying from 30°C to 110°C. The retention times were compared with synthetic standards, and co-injections with peak enhancement were carried out to confirm the configuration of all chiral compounds.

Chemicals 2-butanone, 3-pentanone, (2*R*)-butanol, (2*S*)-butanol, 2-methyl-1-propanol, 3-pentanol, (2*S*)-pentanol, 3-hexanol, (2*S*)-methyl-1-butanol, 1-heptanol, and (1*R*)-phenylethanol were purchased from Sigma-Aldrich (Sweden and Brazil). The remaining compounds were synthesized as described below:

For all synthesized compounds ^{1}H-NMR and ^{13}C-NMR spectra of $CDCl_3$ solutions were recorded at 500 MHz and 125 MHz, using a Varian Unity spectrometer. Chemical shifts were expressed in ppm in relation to tetramethylsilane, multiplicity (s, singlet; d, doublet; t, triplet; and m, multiplet), coupling constants (Hz) and number of protons. The starting materials employed were obtained from commercial suppliers and used without further purification. Mass spectra (70 eV, EI) of synthetic compounds were obtained with an HP 6890 GC interfaced to an HP 5973 mass selective detector (Hewlett Packard, Palo Alto, CA, USA), using helium as the carrier gas. The GC was equipped with a BPX-70 column (30 m×0.25 mm, ID 0.25 µm, SGE, Australia). Enantioselective GC was performed with an HP 5890 GC (Hewlett Packard, Palo Alto, CA, USA) fitted with a CYCLOSILB column (30 m× 0.25 mm, ID 0.25 µm, J & W Scientific, USA). Chromatography on silica gel was carried out using a medium pressure liquid chromatography (Baeckström et al. 1987). All chemicals used as starting materials in the syntheses were used as delivered from Sigma-Aldrich (Sweden) and Alfa Aesar (Germany). Anhydrous solvents were used, and reactions were carried out under nitrogen when appropriate.

(2R)-Pentanol This chiral alcohol was obtained by resolution of racemic 2-pentanol with the use of *Candida antarctica* B lipase.

Racemic 2-pentanol (20 g, 0.23 mol), vinyl acetate (70 g, 0.81 mol), and *Candida antarctica* B lipase (300 mg) were added to dichloromethane (*ca*. 150 ml). After 160 min, the enzymes were removed by filtration, the solvent removed *in vacuo*, and pentane was added. The unreacted (2*S*)-pentanol was separated from the formed (2*R*)-pentyl acetate by chromatography. A fraction containing 1.66 g of the acetate was isolated. A solution of (2*R*)-pentyl acetate (1.50 g, 11.5 mmol), KOH (1.0 g, 18 mmol) and MeOH/water (20 and 3 ml, resp.) was stirred at room temperature (RT) over night. Most of the methanol was removed *in vacuo*, water was added, and the product was extracted ×3 with diethyl ether, washed with brine, dried over $MgSO_4$, and the diethyl ether was removed on an ice bath *in vacuo*

to yield 710 mg (8.1 mmol) of a slightly yellow product. Chemical and enantiomeric purities were 99%.

3-Methyl-2-hexanol This alcohol was prepared by a Grignard reaction between 2-bromopentane and acetaldehyde. Since all isomers were present in similar amounts in the glands, no stereospecific synthesis was carried out:

A round-bottomed flask was charged with magnesium (3.5 g, 0.144 mol), iodine (1 crystal), and diethyl ether (50 ml). To the mixture, 2-bromopentane (15.9 g, 0.10 mol, 13.0 ml dropwise addition via syringe) was added, maintaining spontaneous reflux to form the Grignard reagent. Thereafter, the reflux was continued for 20 min. After cooling to 0°C, acetaldehyde (6.16 g, 0.14 mol, 10.0 ml) was added to the mixture by syringe. After reflux for 20 min, the reaction was quenched by addition of ice-water followed by HCl (10%, aq.) until all precipitate was dissolved. The product was extracted ×4 with diethyl ether and washed twice with bicarbonate (sat, aq.) and brine, dried over $MgSO_4$ and concentrated *in vacuo* to yield 7.73 g of a slightly yellow oil. Some 3-methyl-2-hexanone had been formed, and to remove this impurity, the crude product was treated with sodium borohydride (0.30 g, 8 mmol) dissolved in aqueous ethanol (50%, 25 ml). The crude product (7.73 g) was added dropwise at 0°C while stirring. Stirring was continued at RT over night. Potassium carbonate was added until the mixture became transparent and saturated. The product was extracted ×3 with diethyl ether, washed twice with brine, dried over $MgSO_4$ and solvents were removed *in vacuo* to yield 5.60 g (48%) of a slightly yellow oil, which was purified by chromatography. A sample of 3.38 g product of 99% purity (diastereomeric ratio ca. 2:3) was isolated. MS: 39(5), 41(11), 42(5), 43(24), 44(9), 45(100), 55(16), 56 (4), 57(5), 59(3), 69(4), 70(29), 71(5), 83(6), 98(3), 101(4). ^{1}HNMR: δ: 3.65-3.70 (m, 1 H), 1.0-1.6 (m, 5H), 1.12-115 (d, 3H, J=6.3 Hz) 0.85-0.92 (m, 6H) (the peaks of two diastereomers overlapped to a large extent and that made the NMRs difficult to interpret.) ^{13}CNMR: δ: 72.0, 71.7, 40.0, 39.7, 35.1, 35.0, 20.6, 20.6, 20.5, 19.5, 14.7, 14.6, 14.3 ppm (one overlapping signal).

6-Methyl-1-heptanol This achiral alcohol was synthesized from 3-methyl-1-butylbromide via a Grignard reaction with oxetane (Bestmann and Vostrowsky 1974). MS and NMR data corresponded with literature data (Reiter et al. 2003; Tang et al. 1995).

(4R)-Methyl-1-hexanol The reaction of (3*S*)-citronellyl bromide in a modified Lemieux-von Rudloff periodate-permanganate oxidation (Lemieux and Rudloff 1955; Overberger and Kaye 1967; Higashimura et al. 1983; Chen et al. 2008) followed by an lithium aluminum hydride (LAH) reduction yielded the product in 99% enantiomeric purity.

(3*S*)-Citronellyl bromide (1.50 g, 6.84 mmol) was dissolved in 50% acetone in water (50 ml). $NaIO_4$ (5.0 g, 20.7 mmol) and $KMnO_4$ (0.2 g, cat) were dissolved in water (50 ml) and added slowly to the solution of (3*S*)-citronellyl bromide at 0°C. The mixture was stirred at RT overnight (16 h). After confirming full conversion (GCMS), the product mixture was filtered *in vacuo*. Most of the acetone was removed *in vacuo*, and the remaining pink solution was acidified to pH≈2 by HCl (10%, aq.). The acidic solution was stirred at RT for 30 min. The orange solution was extracted ×3 with diethyl ether, washed twice with brine, dried over $MgSO_4$, and concentrated *in vacuo* to give a copper-colored oil: 1.45 g (101%). The crude (4*S*)-6-bromo-4-methylhexanoic acid (1.45 g) was dissolved in diethyl ether (40 ml) and was added dropwise to a solution of LAH (1.9 g, 50 mmol) in diethyl ether (50 ml) at steady reflux. The mixture was refluxed for 1 h, and then quenched by addition of Baeckström's reagent (sodium sulfate deca-hydrate/celite, Baeckström et al. 1991). When the suspension had changed from grey to white, the solids were removed by filtration *in vacuo*. The solvents were removed *in vacuo* to yield a colorless oil of 63% purity (612 mg, 49%). After purification by chromatography a fraction of 99% purity (257 mg, 99% enantiomeric purity) was obtained. Spectroscopic data correlated well with literature data (NIST 2002; Larsson et al. 2001).

(4R)-Methyl-1-heptanol This chiral alcohol was synthesized from (2*R*)-methyl-1-pentanol by malonate ester synthesis (Barth and Effenberger 1993; Hedenström et al. 2002; Tai et al. 2002).

Racemic 2-methyl-1-pentanol (16.0 g, 0.16 mol) and vinyl acetate (56.0 g, 0.65 mol) were dissolved in dichloromethane (250 ml) at RT. Amano PS-D lipase (800 mg) was added while stirring. The reaction was monitored hourly by enantioselective GC. When the (2*R*)-methyl-1-pentanol remaining in the mixture had an *e.e.* of 96% (at ca. 75% conversion), the lipase was filtered off. The mixture was concentrated *in vacuo*, and the alcohol (4.0 g, 50%) was isolated by chromatography.

(2*R*)-Methyl-1-pentanol (3.40 g, 33.3 mmol) was dissolved in a mixture of p-toluene sulfonyl chloride (6.8 g, 35.7 mmol) in dry pyridine (20 ml). The mixture was stirred at RT for 6 h and then quenched by pouring into ice-water (40 ml). The product was extracted ×3 with diethyl ether, the organic phase was washed with copper sulfate solution (10%, aq.), bicarbonate (sat., aq.), and brine, dried over $MgSO_4$, and concentrated *in vacuo* to yield a pale yellow oil of 79% purity (6.74 g). MS: 39(6), 41(11), 42(5), 43(19), 55(11), 56(28), 63(4), 65(23), 69(28), 71(4), 77(4), 83(4), 84(100), 85(8), 89(8), 90(5), 91(93), 92(27), 93(4), 107(8), 108(5), 139(5), 155(100), 156(18), 157(21), 172 (13), 173(43), 174(4).

The crude (2*R*)-methyl-1-pentyl tosylate (6.6 g, 25.8 mmol) was added to a solution of lithium bromide (12.7 g, 146 mmol) in acetone (100 ml). The mixture was refluxed overnight and then concentrated. Water was added, and the mixture was extracted ×4 with pentane, the organic phases washed twice with water and dried over $MgSO_4$. The solvent was removed *in vacuo* to yield a pale yellow oil of 57% purity (6.6 g, 89%). After chromatography, a fraction of 2.89 g was used as such in the next step. MS: 39(13), 41(35), 42(12), 43(7), 55(16), 56(10), 57(9), 69(12), 71(21), 84(8), 85(100), 86(10), 121(7).

Diethyl malonate (2.84 g, 17.7 mmol) was added to a solution of sodium ethoxide (1.15 g in 10 ml ethanol), and the mixture was refluxed for 15 min. 2-Methylpentyl bromide (2.80 g, 17.1 mmol) was added dropwise at RT while stirring, whereafter the mixture was refluxed for 1 h. The solution was acidified at RT by acetic acid (3 drops), and then diluted by water (10 ml) and diethyl ether (10 ml). The organic phase was separated, and the water phase was extracted ×4 with diethyl ether. The organic phases were washed twice with brine, dried over $MgSO_4$, and the diethyl ether was removed *in vacuo*. The copper-colored residue (1.76 g) was added to a solution of potassium hydroxide in ethanol (30 ml, 0.14 g/ml), and the mixture was refluxed for 4 h. After removal of most of the ethanol *in vacuo*, water was added, and the solution was washed twice with diethyl ether, acidified to pH≈1 (HCl, conc.), extracted ×3 with diethyl ether, washed with water and brine, concentrated *in vacuo*, and heated at 180° C for 2 h. A solution of sodium carbonate (sat., aq.) was added at RT, and the aqueous solution was washed with diethyl ether, acidified (HCl, conc.), extracted with diethyl ether, washed with water and brine, dried over $MgSO_4$, and concentrated *in vacuo* to yield a pale brown oil (203 mg). The carboxylic acid intermediate (203 mg, 1.4 mmol) was added in diethyl ether (5 ml) by syringe to a solution of LAH (65 mg, 1.7 mmol) in diethyl ether (5 ml). The mixture was stirred for 1 h, whereafter Baeckström's reagent was added. When the reaction mixture turned white, the precipitate was removed by filtration *in vacuo* and the solvent removed *in vacuo*. The yield of a colorless oil of 99% purity was 141 mg (6%, 98% enantiomeric purity). Spectroscopic data correlated well with literature data (NIST 2002; Tai et al. 2002). MS: 39(10), 40(2), 41(46), 42(17), 43(44), 44(3), 45(3), 53(4), 54(1), 55(44), 56(56), 57(12), 60(1), 67(5), 68(5), 69 (100), 70(54), 71(16), 82(3), 83(13), 84(81), 85(6), 87(3), 97(5), 112(1). ^{1}HNMR: δ: 3.63 (m, 2H), 1.1-1.6 (m, 9H), 0.87 (m, 6H), ^{13}CNMR: δ: 63.7, 39.5, 33.1, 32.6, 30.6, 20.3, 19.8, 14.6 ppm. Total yield from (2*R*)-methyl-1-pentanol was 4%.

Gas Chromatography Coupled to Electroantennographic Detection

Headspace collections were made over 8 excised MGs of females by means of SPME, using the same fiber type as described for the chemical analyses. The volatiles collected were analyzed by GC-EAD using the same GC-setup as for GC-FID analyses, fitted with a SupelcoWax-10 column (30 m×0.25 mm ID; 0.25 μm film), and coupled to an electroantennographic setup (Syntech, Hilversum, The Netherlands). Recordings of responses to volatiles eluting from the GC column were obtained from the antennae of 8 different males in separate experiments. An antenna was isolated from the head by cutting at the antennal base. The proximal end of the isolated antenna was inserted into a borosilicate glass micropipette containing 0.1 M KCl solution, serving as the reference electrode. The distal end of the antenna was inserted into another glass micropipette filled with 0.1 M KCl solution after the tip of the segment was cut off. Ag-AgCl wire was used to maintain electrical continuity between the electrodes, and a high input impedance headstage preamplifier (Syntech, Kirchzarten, Germany). The EAG signals through the preamplifier were further amplified and processed with a PC-based signal processing system (Syntech, Kirchzarten, Germany). The digitized signals from the FID and antenna were analyzed by means of the EAD2000 software (ver. 2.3, Syntech, Hilversum, The Netherlands).

Results

Olfactometer Bioassays In the negative control experiments, neither male nor female insects showed significant orientation to either arm of the olfactometer when no air current or two clean air currents were presented. Female insects did not show a significant preference for male or female odor-laden air currents (Fig. 2) but were significantly attracted to the odor emitted by mice (Fig. 2, $P<0.001$) in the positive control experiments, showing that the apparatus is capable of evincing orientation responses by these bugs. *T. brasiliensis* males, in contrast to females, significantly preferred the arm of the olfactometer associated with male or female odors (Fig. 3, $P<0.01$ and $P<0.001$, respectively). When the MGs of the female insects used as stimuli were occluded, males did not show a significant orientation (Fig. 4). However, sham-treated females promoted the orientation of males in the olfactometer (Fig. 4, $P<0.01$). The occlusion of the MGs of males used as sources of stimuli did not promote a change in the orientation of males in the olfactometer (Fig. 4, $P<0.01$).

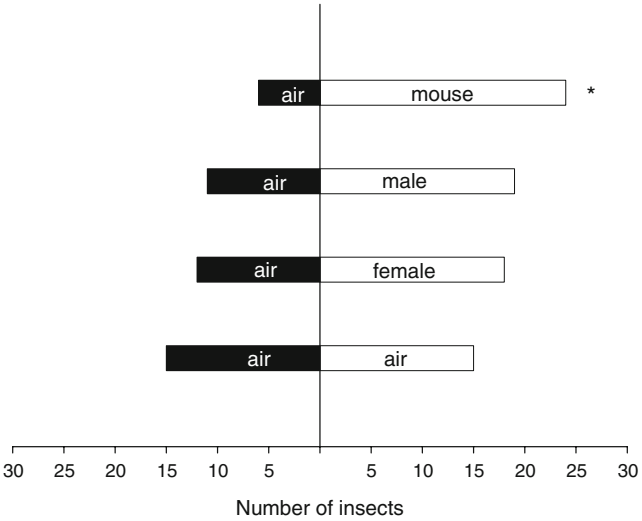

Fig. 2 Response of *Triatoma brasiliensis* females to different stimuli in an olfactometer. Significant differences between treatments were determined by a binomial test (*$P<0.001$)

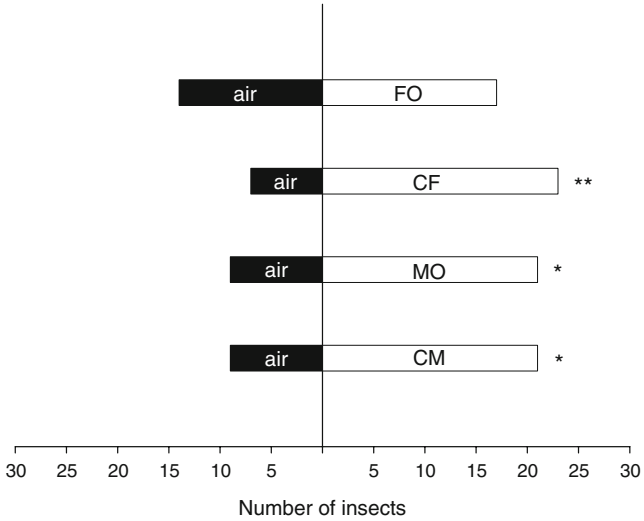

Fig. 4 Responses of *Triatoma brasiliensis* males to different stimuli in an olfactometer. MO=males with occluded metasternal glands (MGs), CM=control males treated with paraffin on a different part of their body surface, FO=females with occluded MGs and, CF=control females treated with paraffin on a different part of their body surface. Significant differences between treatments were determined by a binomial test (*$P<0.01$ and **$P<0.001$)

Identification of Compounds Produced by MGs The MGs of *T. brasiliensis* are the sources of a complex mixture of volatiles. In total, sixteen compounds were identified, with the most abundant compounds being 3-pentanone, 3-pentanol, and (4*R*)-methyl-1-heptanol (Table 1). The configurations of the chiral compounds varied; 2-methyl-1-butanol was present as the *S*-enantiomer, 4-methyl-1-hexanol, 4-methyl-1-heptanol, and 1-phenylethanol were present as the *R*-enantiomers, while 3-hexanol and 3-methyl-2-hexanol were present in all isomeric forms. For 2-butanol and 2-pentanol, problems with co-elution and/or low abundance of the compounds prevented us from confirming the configuration.

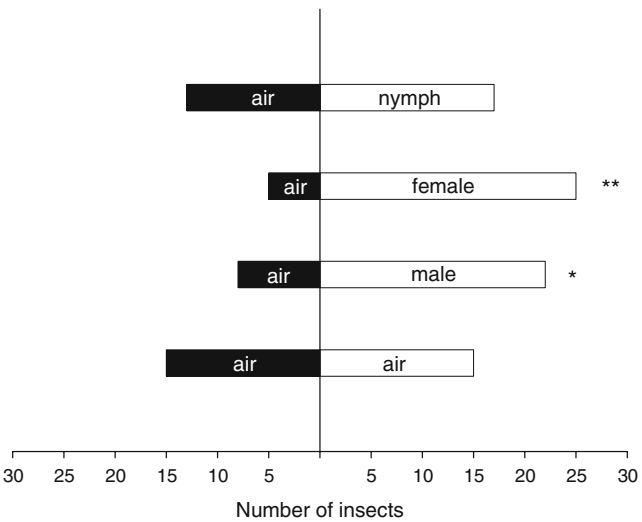

Fig. 3 Response of *Triatoma brasiliensis* males to different stimuli in an olfactometer. Significant differences between treatments were determined by a binomial test (*$P<0.01$ and **$P<0.001$)

Gas Chromatography Coupled to Electroantennographic Detection Our GC-EAD recordings showed that the antennae of males of *T. brasiliensis* respond to a series of volatile compounds produced by the MGs of females (Fig. 5). Responses to 3-pentanone were consistently observed in all recordings and were normally the strongest. In addition, 75% of the recordings presented strong responses to 4-methyl-1-heptanol, and responses also were observed for 2-methyl-1-butanol and 1-phenylethanol. It is worth highlighting that one of the compounds reported here as unknown (RI=1,156) was capable of promoting responses from 3 out of 8 antennae tested (Fig. 5).

Discussion

Orientation in response to odor-laden air currents is a widespread mechanism that mediates sexual encounters between male and female insects. However, no cases of anemotactic orientation to sexually related signals are known to date for triatomine bugs. Our report presents significant evidence showing that *T. brasiliensis* males express oriented responses to air currents associated with volatiles from conspecific adults. These anemotactic responses are apparently stronger when males are con-

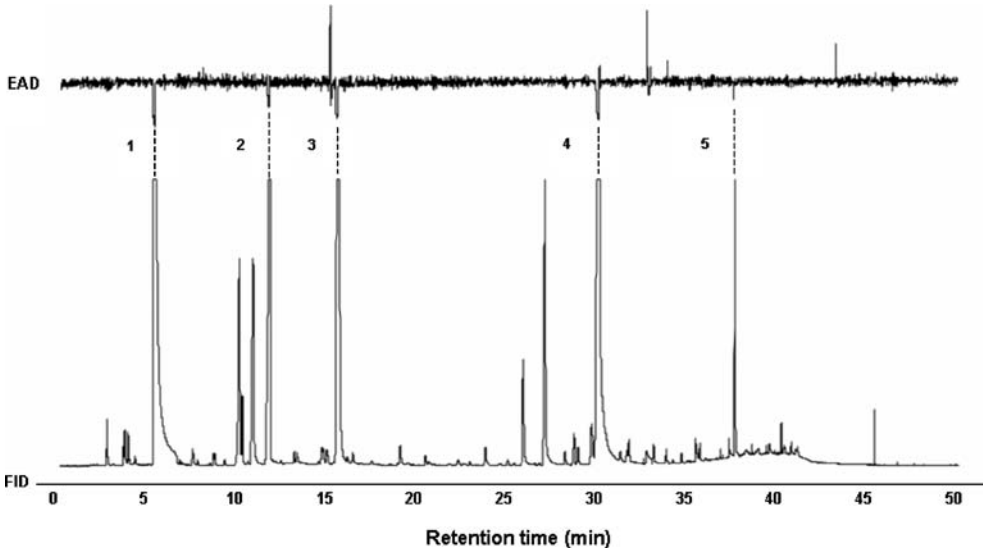

Fig. 5 Gas chromatogram (FID) and corresponding electroantennogram (EAD) traces from one antenna of a *Triatoma brasiliensis* male, in response to a headspace collection of metasternal gland (MG) volatiles. Active compounds are represented with numbers: 1) 3-pentanone, 2) unknown, 3) 2-methyl-1-butanol, 4) 4-methyl-1-heptanol, and 5) 1-phenylethanol

fronted by air currents laden with female volatiles rather than with male odors. This finding suggests that males are attracted by odors emitted by distant females, and exploit air currents to define the direction of their responses. This may represent a putative mechanism to mediate encounters between adults of different gender, and suggests that a sexual pheromone is produced by females.

Our results showed that MGs of females emit a volatile signal that is necessary to mediate the orientation expressed by males. On the other hand, the preference observed when male insects were confronted with male odor was not affected by the occlusion of MGs. Therefore, male to male orientation is apparently not mediated by signals produced by these glands. As females did not show oriented responses to air currents laden with odors from adult bugs, we propose that *T. brasiliensis* males are the only gender attracted to sexual signals.

The use of antennae of male insects as detectors for electrophysiologically active compounds made it possible to demonstrate that several substances produced by MGs stimulate male receptors. Specifically, 3-pentanone and (4*R*)-methyl-1-heptanol, elicited strong responses in most preparations, while (2*S*)-methyl-1-butanol, (1*R*)-phenylethanol and two unknown compounds (RI=1,156 and RI=1,548, Table 1) elicited weaker responses from antennae of males. Whether or not other components of the female MG secretion are capable of stimulating antennal receptors needs to be determined. It is worth mentioning that while the secretions produced in the MGs of females and males were similar according to our GC-MS analyses, the responses observed when males were tested in olfactometers suggest that the products of male and female MGs are different. This is supported by the two occlusion experiments, as the occlusion of male MGs did not affect the orientation of males to the air currents laden with volatiles from other males.

It has been proposed that the secretion of the MGs of triatomines is involved in mediating sexual communication (Manrique et al. 2006; Pontes et al. 2008). The identification of the volatile compounds detected over the headspace of *T. brasiliensis* MGs corroborated that these glands produce ketones and alcohols in triatomines. The fact that 3-pentanone is the most abundant compound produced by MGs is coincident with the results presented by Manrique et al. (2006) for *T. infestans*. The relatively less volatile 4-methyl-1-heptanol, that appears to be characteristic of the

latter species, is reported here for the first time. Our GC-EAD results suggest that both substances could be involved in mediating behavioral responses of the kind described in this study. Several other compounds reported here (2-butanone, 2-pentanone, (2*S*)-butanol, 3-methyl-2-butanol, 3-pentanol, (2*S*)-pentanol, and (3*S*)-hexanol) were previously detected in the MGs of other blood-sucking bugs (Manrique et al. 2006; Pontes et al. 2008). All compounds found in the MGs except 4-methyl-1-hexanol, 6-methyl-1-heptanol, and 4-methyl-1-heptanol have been reported previously in other insect species (El-Sayed 2008). It is relevant to highlight that capturing volatile compounds by means of SPME allowed us to perform successful GC-EAD recordings, confirming that this odor extraction technique is adequate for the preparation of odor samples for electrophysiological studies.

Baldwin et al. (1971), as well as Manrique and Lazzari (1995), have shown that *R. prolixus* and *T. infestans* males aggregate around mating pairs, and suggested that this behavior is mediated by chemical signals. In addition, Vitta and Lorenzo (2009) have shown recently that *T. brasiliensis* males react to the presence of competitors by showing increased mate-guarding responses. Furthermore, these authors described that mating duration can be shortened if males copulate with previously mated females. Whether these changes in male behavior are triggered by chemical signals is not known. Crespo and Manrique (2007) and Pontes et al. (2008) have demonstrated that the occlusion of the MGs of *T. infestans* and *R. prolixus* affects mating success in a dramatic manner. In addition, it has been suggested that the secretion from Brindley's glands is involved in sexual communication of triatomines (Fontán et al. 2002; Rojas et al. 2002; Guerenstein and Guerin 2004). Nevertheless, no behavioral evidence has been reported associating compounds from Brindley's glands with behavioral responses specifically related to sex.

Baits and traps for triatomine bugs are necessary for the early detection of reinvasion of houses after insecticide treatments, in order to avoid contact between triatomines and humans. Whether the compounds and behavioral responses described here can be exploited for the development of control tools will depend on further work testing synthetic compounds in dose-response electrophysiological and behavioral bioassays.

Acknowledgements The authors are grateful to FAPEMIG, CNPq and FIOCRUZ for financial support. This work was also supported by the Swedish International Development Cooperation Agency (SIDA), and by the University of Kalmar (Sweden). The New Zealand Institute for Plant & Food Research Limited, Lincoln, New Zealand provided some research facilities for BB and CRU. ACRV wishes to thank Mr. Arnaldo Aroeira for his kind support on drawing the olfactometer scheme.

changes as host colonization proceeds (Birgersson and Bergström 1989). Both males and females may contribute unique components to the pheromone blend, whereas only one sex initiates colonization (Borden 1982); hence pheromone components from the pioneer sex are emitted prior to those of the joining sex, but as multiple families accumulate at an aggregation, signaling by the pioneering and joining sexes overlaps. Additionally, either sex may produce a succession of different compounds during host colonization (Birgersson et al. 1984; Byers et al. 1984). Attacks on individual trees begin frequently at a specific height on the bole and then spread to adjacent portions over the course of a few days, and adjacent trees within infestations are typically attacked successively rather than simultaneously (Gara and Coster 1968; Berryman 1982; Schlyter et al. 1987a). Hence, at any one time, the composition and release rate of the emitted pheromone blend will vary spatially, both along the length of the infested bole as well as among adjacent, attacked trees. Pheromones arising from adjacent rather than identical points in space may send a distinctly different message to host-seeking beetles, and thus they might differently influence the location where a beetle ultimately lands. However, few studies of bark beetles have examined the effect of separating the release points of aggregation pheromone components (Byers 1987).

The southern pine beetle, *Dendroctonus frontalis* Zimmermann (Coleoptera: Scolytidae), is an aggressive bark beetle that is native to the southeastern United States, Arizona, Mexico, and parts of Central America (Payne 1980). Infestations typically occur across the landscape in spatially discrete, rapidly expanding "spots" in which adjacent trees are attacked in succession by beetles arriving from the surrounding forest as well as by re-emerging parent and brood adults from within the infestation (Gara 1967; Gara and Coster 1968). Aggregation is mediated by a complex of semiochemicals: initially-attacking females release the attractive pheromone component frontalin, which is enhanced synergistically both by monoterpene kairomones (particularly α-pinene) released by the host pine and (+)-*endo*-brevicomin from secondarily-arriving males (Smith et al. 1993; Sullivan et al. 2007). Additionally, the female-produced pheromone component *trans*-verbenol may substitute for host monoterpenes when the latter are at low levels, and may play an important role in initiating host colonization (Renwick and Vité 1969; Payne et al. 1978a). *Dendroctonus frontalis* also produces several compounds (such as verbenone and myrtenol) that inhibit response to attractants, and one or more of these may function as antiaggregation pheromones for this species (Smith et al. 1993; Sullivan 2005).

There are divergent data sets on the behavioral activity of *endo*-brevicomin with *D. frontalis*. Studies performed with racemic *endo*-brevicomin indicated that this compound acts as an attractant antagonist (Vité and Renwick 1971; Payne et al. 1978a; Salom et al. 1992). In contrast, baits composed of pure (+)-*endo*-brevicomin (only enantiomer produced by the species) strongly enhanced attraction to combinations of frontalin and host odors (Vité et al. 1985; Sullivan et al. 2007), and led these authors to conclude that this compound was a component of the *D. frontalis* aggregation pheromone. (+)-*endo*-Brevicomin alone does not attract *D. frontalis* into traps (Sullivan et al. 2007).

Observations during trapping trials with *D. frontalis* suggested that trap spacing alone might determine whether the addition of (+)-*endo*-brevicomin increased, reduced, or did not alter catch in attractant-baited traps relative to attractant-only control traps (authors' unpublished data). We hypothesized that interacting pheromone components of bark beetles (i.e., synergists, antagonists) might convey unique information and elicit different behaviors when their sources are separated by a short distance (i.e., a few meters) rather than being either collocated or widely separated. We therefore performed tests to determine if point sources of *endo*-brevicomin could influence catch in distant traps and whether varying the distance between such point sources and attractant-baited traps could reverse the apparent activity of this pheromone component. We also performed initial studies to elucidate interactions of *endo*-brevicomin release rate with trap spacing and contrast the spatial dynamics of *endo*-brevicomin to other aggregation-mediating semiochemicals for *D. frontalis*.

Methods and Materials

Location, General Design, and Materials Trapping experiments were performed by using 12-unit funnel traps (Chemtica International, San Jose, Costa Rica) placed in mature, mixed pine/hardwood stands of the Homochitto National Forest in southwestern Mississippi (31.43° N, 91.19° W). The pine component was dominated by loblolly pine, *Pinus taeda* L., interspersed with shortleaf pine, *Pinus echinata* Mill. Adjacent pine forests were experiencing moderate levels of *D. frontalis* infestation, but according to aerial surveys no multiple-tree beetle infestations were within 1 km of the trap locations. Traps were positioned >10 m from the nearest pine and suspended (with the bottom of the trap cup 1–1.5 m above the ground) from vertical standards consisting of 1.7 cm dia. pieces of electrical conduit staked into the ground. Trap cups contained several centimeters of aqueous propylene glycol to preserve captured insects, and catch was collected at intervals of 6–18 d (longer intervals were used during periods when flying beetles were less abundant). Frontalin baits consisted of a pair of capped 400 µl-capacity LDPE

microcentrifuge tubes each loaded with 200–300 µl racemic frontalin [>95% chemical purity (contaminants with no known behavioral activity), Chemtica International]. Turpentine baits consisted of a single 250 ml-capacity brown glass bottle with a piece of 1 cm dia. cotton dental wick immersed in the liquid (200–250 ml, steam distilled from *P. taeda*; Hercules Inc., Brunswick, GA, USA) and protruding 2.5 cm through the cap. *endo*-Brevicomin was released either from glass capillaries with one heat-sealed end or from open, 100 µl-capacity glass autosampler vial inserts; these were secured open-end-up inside of an uncapped, inverted 4 or 8 ml-capacity glass screw-cap vial (Table 1). The capillaries and autosampler vial inserts were secured in the vial with a silicone GC septum that was pressed sideways into the vial mouth; the sealed end of each capillary (or the tapered tip of each insert) was inserted into a pinhole in the interior-facing edge of the septum. (+)-*endo*-Brevicomin was synthesized as described elsewhere (Sullivan et al. 2007) and was >99% enantiomerically and 95% chemically pure by GC (contaminants with no known behavioral activity). Racemic *endo*-brevicomin [PheroTech (now ConTech Inc.), Delta, BC, Canada] was 95% chemically pure (<1% *exo*-brevicomin contamination). Bait release rates were measured in a fume hood at 23±2°C, either gravimetrically for turpentine (7 g/d) and frontalin (5 mg/d) or by volume loss for *endo*-brevicomin (Table 1). Frontalin and *endo*-brevicomin baits were attached at the fourth funnel from the bottom of the trap, whereas the turpentine bottle was placed within the funnel immediately below the trap top to protect the wick from rain. During experiments, pines adjacent to traps were checked regularly for the presence of pitch tubes and other evidence of *D. frontalis* attack. If attacked pines were apparently not under mass attack (Payne 1980), traps were moved an additional 10-20 m from these trees thereby stopping further attacks; if a mass attack was observed (as occurred twice), traps were moved at least 100 m away. In both cases, data from the moved trap was used in the analyses.

Experiment 1: Displacement of (+)-endo-Brevicomin Bait from an Attractant-Baited Trap Single funnel traps were spaced >130 m apart, baited uniformly with frontalin and turpentine, and assigned one of six experimental treatments (Fig. 1a): A single (+)-*endo*-brevicomin bait was either attached directly to the trap (i.e., at 0 m), or positioned 4, 8, 16, or 32 m away, or no *endo*-brevicomin bait was assigned to the trap (in this case the closest source of *endo*-brevicomin was associated with adjacent traps and thus was >100 m away). Three lines of six traps each were established, and the six treatments were assigned initially at random to the six traps of each line and then re-randomized without replacement to any previous position for each of six successive trap collections. Thus, the experimental design was three complete Latin squares with each square consisting of six traps (columns) and six successive trapping intervals (rows). The displaced *endo*-brevicomin release devices were suspended 1.5 m above the ground on plastic garden stakes and the direction that each release device was located relative to its treatment trap (0°, 60°, 120°, 180°, 240°, or 300° from north) was assigned at random and without duplication among the six traps of each line. This directional assignment remained the same for each trap position for the duration of the experiment. The experiment was conducted 8 February–12 April 2006. Trap catches of *D. frontalis* were cube root transformed and analyzed with a mixed-model ANOVA in which treatment, date, and treatment by date effects were considered fixed, whereas square, trap within square, and treatment by square effects were regarded as random (SAS 9.0, SAS Institute Inc., Cary, NC). The cube-root transformation was used for analysis of this and all following ANOVAs of total *D. frontalis* catches because it was generally better at normalizing residuals than the weaker square root or the stronger $\log_{10}$ transformation (based on examination of residual plots), and in all comparisons the residuals from the transformed data sets did not fail the Kolmogorov-Smirnov test for a normal distribution (α=0.05). Treatment means

Table 1 Construction and elution rate of *endo*-brevicomin release devices[a]

Experiment number (release rate)	Glass insert/capillary characteristics				Elution rate[c] (mg/d ± s.d.)
	Diameter (i.d.)	Length	Height filled	Number per device	
1, 2[b], 4	1.2 mm	20 mm	10 mm	1	0.23±0.01
3 (low rate)	0.6 mm	32 mm	10 mm	1	0.045±0.007
3 (medium rate)	1.2 mm	32 mm	10 mm	3	0.52±0.03
3 (high rate)	3.7 mm	30 mm	8 mm	3	2.8±0.6

[a] Each device consisted of 1–3 glass autosampler vial inserts or glass capillaries secured open-end-up inside of an inverted, uncapped 4 ml (8 ml for the high release rate device) capacity screw-capped vial.

[b] In experiment 2, a single device was used for (+)-*endo*-brevicomin, but two devices were used for racemic *endo*-brevicomin.

[c] Measured in a fume hood at 23±2°C (N=3).

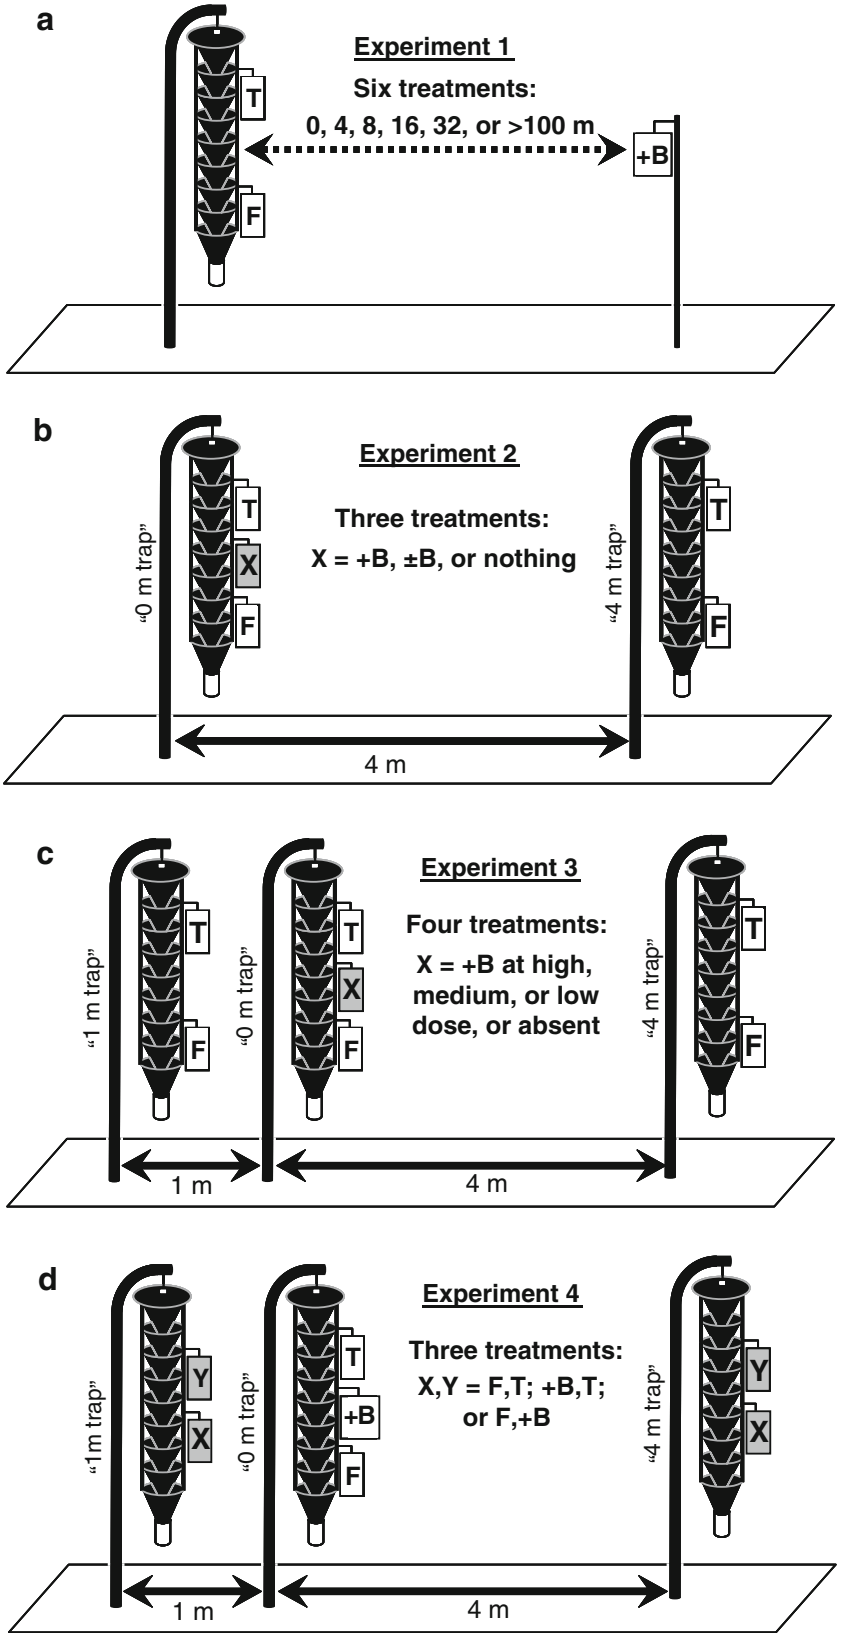

Fig. 1 Trap and bait arrangements for experiments 1–4. Rectangles represent release devices of either frontalin (F), turpentine (T), (+)-*endo*-brevicomin (+B), racemic *endo*-brevicomin (±B), or an experimentally variable bait (shaded X and Y). For the 4, 8, 16, and 32 m-distances in experiment 1, the "+B" release device was attached to the top of a plastic garden stake; for the >100 m treatment, no+B device was assigned to the trap and the closest such device was associated with an adjacent treatment. Otherwise, release devices were attached directly to traps

were compared by using Tukey's test for all pairwise comparisons (α=0.05) with treatment by square as the error term. In this and the other trapping experiments, catches for some traps and intervals were very low or zero, hence use of the above ANOVA for analysis of treatment effects on sex ratio was not possible due to the excessive numbers of missing values and/or the highly non-normal distributions of residuals. Therefore, the proportion of female *D. frontalis* trapped in each treatment was pooled within a square and subjected to a two-way ANOVA with square and treatment as factors. Proportions of females trapped were not transformed for this or other experiments since the pooled data never failed the Kolmogorov-Smirnov test (α=0.05).

Experiment 2: Pairs of Adjacent Traps Differing in endo-Brevicomin Pairs of funnel traps spaced 4 m apart and baited identically with frontalin and turpentine were established at locations separated by >100 m (Fig. 1b). One trap of each pair (the "0 m trap;" chosen by a coin toss), received either a single (+)-*endo*-brevicomin bait, two racemic *endo*-brevicomin baits, or no additional bait (three experimental treatments). The opposite trap (the "4 m trap") received no additional bait. Four lines, each with three trap pair locations, were established, and the treatments were assigned initially at random to the three pairs of each line and then re-randomized without replacement to any previous pair for each of three successive trap collections. Thus, the experimental design was four complete Latin squares with each square consisting of three adjacent trap pairs (columns) and three successive trapping intervals (rows). The experiment was run 13 December 2005–17 January 2006. The summed *D. frontalis* catch per trap pair ($\Sigma_x = X_{4m} + X_{0m}$, transformed $\sqrt[3]{\Sigma_x}$) and the difference in catch ($D_x = X_{4m}-X_{0m}$, transformed $\sqrt[3]{D_x}$), were analyzed with the mixed-model ANOVA of experiment 1. Treatment effects on the proportion of females trapped per pair and the difference in proportion of females between members of each pair were analyzed with a two-way ANOVA (as in experiment 1). Additionally, beetle responses to the two traps of each pair (X_{4m} vs. X_{0m}) were compared within each treatment by a paired *t*-test (α=0.05).

Experiment 3: Trios of Adjacent Traps with Varying endo-Brevicomin Release Rate At locations separated by >100 m, groups of three traps were erected in a straight line with the outside traps spaced 1 m and 4 m away from the middle trap (Fig. 1c). The outside traps were erected first, and then the location of the middle trap respective to either outside trap (i.e., the assignment of 4 m and 1 m-distant traps) was chosen by a coin toss. All three traps were baited with frontalin and turpentine, and the middle trap (the "0 m trap") either received no additional bait or was baited additionally with a device releasing either a low, medium, or high rate (Table 1) of (+)-*endo*-brevicomin (four experimental treatments). Two lines, each with four trap trio locations, were established, and the treatments were assigned initially at random to the four trios of each line and then re-randomized without replacement to any previous trio for each of four successive trap collections. After these initial four collections (after every treatment had been at every trio location once), the middle trap was moved 3 m in order to reverse the designation of the 1- and 4 m-distant traps within each trio. Then treatment assignments were re-randomized among trios within lines, and a second set of four successive collections was performed similar to the first. Thus, the experimental design was four complete Latin squares with each square consisting of four adjacent trap trios (columns) and four successive trapping intervals (rows). The experiment was run 16 August–23 October 2005. Total catch of *D. frontalis* per trap trio ($\Sigma_x = X_{4m} + X_{1m} + X_{0m}$; transformed $\sqrt[3]{\Sigma_x}$) as well as the differences in catch between the outside and middle traps ($D_1 = X_{4m}-X_{0m}$, $D_2 = X_{1m}-X_{0m}$; transformed $\sqrt[3]{D_x}$) were analyzed with a mixed model ANOVA in which treatment and date within square were considered fixed, and square, trio within square, and treatment by square were regarded as random effects (SAS 9.0). Date was included in the model as a fixed effect nested within square to account for replication of squares in time. Tukey's all-pairwise comparisons (α=0.05) utilized treatment by square as the error term. Treatment effects on the proportion of females trapped per trio, and the differences in proportion of females between the outer and middle traps, were analyzed with a two-way ANOVA (as in experiment 1).

Experiment 4: Trios of Adjacent Traps with Variable Baits Trap trios were established identically as in experiment 3, however, the 0 m trap was baited consistently with frontalin, turpentine, and (+)-*endo*-brevicomin, whereas the 4- and 1 m-distant traps were both baited identically with just two of these bait components and thus lacked one of (+)-*endo*-brevicomin, frontalin, or turpentine (i.e., three treatments, Fig. 1d). Three lines, each with three trap trio locations were established, and treatments were assigned initially at random to the three trios of each line and then re-randomized without replacement to any previous position for each of three successive trap collections. Thus, the experimental design was three complete Latin squares, with each square consisting of three adjacent trap trios (columns) and three successive trapping intervals (rows). The experiment was run 17 October–14 November 2005. Differences in catch between the outside and middle traps ($D_1 = X_{4m}-X_{0m}$, $D_2 = X_{1m}-X_{0m}$; transformed $\sqrt[3]{D_x}$) were compared among treatments by using the mixed-model ANOVA of experiment 1. Differences in proportion of females trapped between the outer and middle traps were subjected to a two-way ANOVA (as in experiment 1).

A corollary data set was collected to determine whether catch in the outside and middle traps differed when all three traps in each trio were baited identically. Trios as described above were established at 14 different sites, all three baits were placed at all three traps, and catch during a single 7–18 d interval was collected from each on 7 November 2005–17 January 2006. For all bait configurations, the transformed differences in catch between the outside and middle traps ($^3\sqrt{D_1}$, $^3\sqrt{D_2}$) were each tested against the null hypothesis of equality to zero with a one-sample *t*-test (two-tailed, α=0.05).

Results

Experiment 1: Displacement of (+)-endo-Brevicomin Bait from an Attractant-Baited Trap Catch of *D. frontalis* in traps baited with frontalin and turpentine was significantly influenced by trap distance from a (+)-*endo*-brevicomin release device (F=85.8; df=5, 10; P<0.001). Traps caught significantly more beetles when the (+)-*endo*-brevicomin releaser was 0–32 m distant rather than >100 m away (Fig. 2). Furthermore, catch was significantly greater when the (+)-*endo*-brevicomin release device was 4, 8, or 16 m away from the trap rather than attached directly to it. Distance of the *endo*-brevicomin releaser from the trap did not significantly alter the proportion (0.40±0.01, mean ± s.d.) of females responding (F=0.37; df=5, 10; P=0.86).

Experiment 2: Pairs of Adjacent Traps Differing in endo-Brevicomin Pairs of traps spaced 4 m apart and baited identically with frontalin and turpentine caught significantly more *D. frontalis* when one of the two traps was baited additionally with either (+)- or racemic *endo*-brevicomin (F=94.6; df=2, 6; P<0.001; Fig. 3). Trap pairs with either (+)- or racemic *endo*-brevicomin did not differ significantly in total catch (Tukey test, P>0.05). Furthermore, the disparity in catch between traps within pairs was significantly altered by the addition of either (+)- or racemic *endo*-brevicomin to one of the traps (F=26.0; df=2,6; P=0.001). Within *endo*-brevicomin-treated trap pairs, the trap that lacked *endo*-brevicomin caught significantly more beetles than its *endo*-brevicomin-baited twin [for (+)-*endo*-brevicomin: t=3.78, df=11, P=0.003; for racemic *endo*-brevicomin: t=3.2, df=11, P=0.008], whereas there was no significant difference in catch between traps within pairs when *endo*-brevicomin was not added to either of the two traps (t=0.86, df=11, P=0.41) (Fig. 3). There were no significant treatment effects on the proportions of females trapped [either total catch per trap pair (F=0.38; df=2,6; P=0.70) or difference between the traps in proportion of females caught (F=0.71; df=2,6; P=0.53)]. The overall proportion of females trapped was 0.42±0.03 (mean ± s.d.).

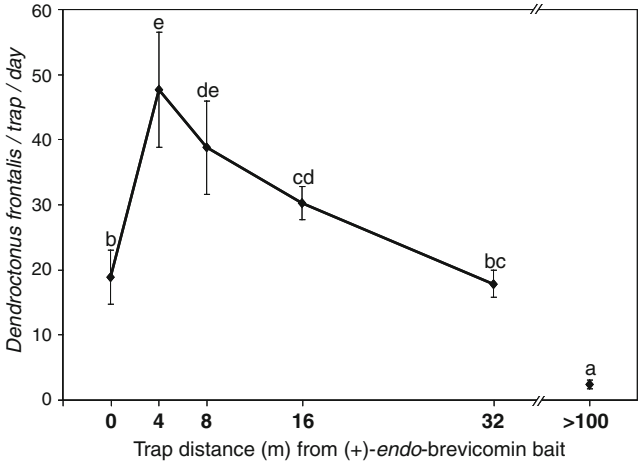

Fig. 2 Experiment 1: Mean (± s.e.) daily catch of *Dendroctonus frontalis* in individual multiple-funnel traps baited with frontalin and turpentine. Traps were positioned >130 m apart, and each trap either had a single release device of (+)-*endo*-brevicomin placed a specified distance (0, 4, 8, 16, 32 m) away from it or had no (+)-*endo*-brevicomin bait assigned [i.e., the closest (+)-*endo*-brevicomin bait was in an adjacent treatment or >100 m away)]. Means associated with the same letter were not significantly different (Tukey test on cube root transformed data, α=0.05). Means and s.e.'s were calculated from the untransformed data with six observations averaged within each Latin square (N=3)

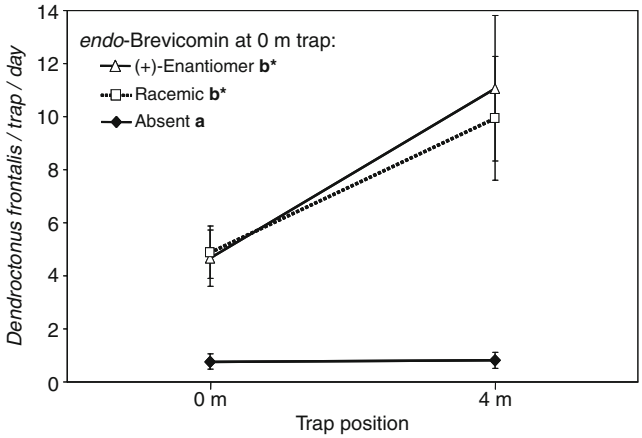

Fig. 3 Experiment 2: Mean (± s.e.) daily catch of *Dendroctonus frontalis* in traps arranged in pairs with 4 m spacing between traps and >100 m spacing among pairs. All traps were baited with frontalin and turpentine, and one randomly-chosen trap per pair (the "0 m trap") was baited additionally with racemic *endo*-brevicomin, (+)-*endo*-brevicomin, or nothing. Treatment names in legend inset associated with the same letter did not differ significantly in summed beetle catch per pair (Tukey test on cube root transformed data, α=0.05); those with an asterisk had a significant difference in catch between the two traps within the pair (paired *t*-test; α=0.05). Means and s.e.'s were calculated from the untransformed data with three observations averaged within each Latin square (N=4)

Experiment 3: Trios of Adjacent Traps with Varying endo-Brevicomin Release Rate Total catch of *D. frontalis* by trios of frontalin/turpentine-baited traps was significantly affected by the rate of (+)-*endo*-brevicomin released from the middle trap (F=34.3; df=3,9; P<0.001; Table 2). The disparity in catch between the outer and middle traps was likewise influenced by the release rate of (+)-*endo*-brevicomin (for X_{4m}-X_{0m}: F=10.3; df=3,9; P=0.003; for X_{1m}-X_{0m}: F=16.9; df=3,9; P<0.001) . In general, increasing the release rate of (+)-*endo*-brevicomin at the middle trap enhanced total catch by the trios, and it caused a relatively greater increase in catch at the two outer traps than at the middle trap (Table 2). Release rate of (+)-*endo*-brevicomin from the middle trap had no effect on the proportions of females trapped [either total catch per trio of traps (F=0.73; df=3,9; P=0.56) or difference between outer and middle traps (F<0. 28; df=3,9; P>0.84)]. The overall proportion of females trapped was 0.48±0.04 (mean ± s.d.).

Experiment 4: Trios of Adjacent Traps with Variable Baits The disparity in catch between the outer and middle traps of trap trios was significantly influenced by altering the bait component that was removed in the outer trap treatments (for X_{4m}-X_{0m}: F=13.0; df=2,4; P=0.018; for X_{1m}-X_{0m}: F=8.41; df=2,4; P=0.037). When (+)-*endo*-brevicomin was absent from the outer traps, catch in each outer trap was greater than in the middle trap, whereas the reverse occurred when frontalin was absent (Table 3). The arrangement of baits had no significant effect on the difference in proportions of females trapped by the outer and middle traps (F<2.36; df=2,4; P>0.21). The overall proportion of females trapped was 0.45±0.06 (mean ± s.d.). When trap trios were established with all three baits at all three traps (Table 3, corollary data set), catch in the outer traps did not differ from catch in the middle trap (for X_{4m}-X_{0m}: t=0.099; df=13; P=0.92; for X_{1m}-X_{0m}: t=0.127; df=13; P=0.90).

Discussion

Horizontal displacement of the release point of a single release rate of the male-produced pheromone component *endo*-brevicomin significantly enhanced its synergistic effect on *D. frontalis* attraction to sources of female-produced frontalin and host odors (experiment 1, Fig. 2). We are not aware of previous reports in which separation of the release points of synergistic insect pheromone components caused enhanced attraction. Incremental separation of a pair of traps each baited with different synergistic components of the aggregation pheromone of the western pine beetle, *Dendroctonus brevicomis* LeConte, caused a rapid, logarithmic decline in attraction of this bark beetle (Byers 1987). For two moth species [cabbage looper, *Trichoplusia ni* (Hübner), and the spotted stem borer, *Chilo partellus* (Swinhoe)], separation of the release points of two sex pheromone components by mere centimeters significantly reduced the percentage of males reaching the sources (Linn and Gaston 1981; Lux et al. 1994).

Of the three major components of the aggregation attractant for *D. frontalis* (i.e., frontalin, (+)-*endo*-brevico-

Table 2 Experiment 3. Effect of varying release rate of (+)-*endo*-brevicomin on catch of *Dendroctonus frontalis* by trios of adjacent funnel traps[a]

Release rate of (+)-*endo*-brevicomin at 0 m trap[b]	Trap position within trio	Catch (No./trap/d)[c]	Total catch (No./trio/d)[c,d]	Difference in catch between 4 m and 0 m trap[c,d]	Difference in catch between 1m and 0 m trap[c,d]
Absent	0 m	0.70±0.35	2.42±1.46a	0.33±0.37ab	0.00±0.05a
	1 m	0.70±0.40			
	4 m	1.03±0.71

	1 m	0.40±0.16		
	4 m	0.14±0.05		
Turpentine	0 m	1.69±0.39	−0.50±0.34a	−0.07±0.25ab
	1 m	1.62±0.46		
	4 m	1.19±0.33		
Corollary data set[f]				
None (all three baits at all three traps)	0 m	7.24±1.68	0.44±0.81	0.40±0.71
	1 m	7.64±1.96		
	4 m	7.69±2.09		

[a] Three traps were arranged in a straight line with the outer traps located either 1 m or 4 m from the middle ("0 m") trap. The 0 m trap received all three bait components, whereas the 1 and 4 m traps were baited identically and each lacked a single component.

[b] See Table 1.

[c] Mean ± s.e.

[d] Means within a column associated with the same letter were not significantly different (Tukey test on cube root transformed data, $\alpha=0.05$). Asterisk denotes rejection of the hypothesis that the difference equaled zero (one sample *t*-test, df=8, $P<0.05$)

[e] Treatments compared in a Latin square experimental design. Means and s.e.'s calculated from untransformed data with three observations averaged within each Latin square ($N=3$)

[f] Descriptive data set collected separately from 14 trap trios with all three traps baited identically with all three bait components. Data excluded from statistical comparisons among treatments. Means and s.e.'s calculated with each trio as the unit of replication ($N=14$)

min, and host monoterpenes; Sullivan et al. 2007), only (+)-*endo*-brevicomin and frontalin appeared to mediate beetle discrimination among closely-spaced traps (experiment 4, Table 3). Beetle captures were concentrated in traps that were relatively closer to a frontalin source, but relatively more distant from a (+)-*endo*-brevicomin source (Table 3). This tendency of *D. frontalis* to be trapped close to the source of frontalin is consistent with its proposed function as a releaser of landing behavior for this species (Hughes 1976) and likely reflects the general tendency of bark beetle aggregation pheromones to concentrate beetle flight and landings near their release point (Coster and Gara 1968; Tilden et al. 1979; Laidlaw and Wieser 2003). In contrast, *endo*-brevicomin does not appear to direct landings close to its point of release. Although its release rate was varied across three orders of magnitude, catch was never higher in a trap amended with (+)-*endo*-brevicomin than in unamended traps positioned 1 and 4 m distant (experiment 3, Table 2), and the synergistic effect of (+)-*endo*-brevicomin was the same whether the release device was placed directly on a frontalin/turpentine-baited trap or 32 m away from it (Fig. 2). Thus, *endo*-brevicomin appears to function as a synergist on an area-wide scale, enhancing attraction and landing of beetles to any sources of frontalin/host odors within a radius of tens of meters.

With the exception of the highest release rate used in experiment 3, the *endo*-brevicomin release rates in our experiments (Table 1) were within the range that we estimate is produced by a single pine undergoing mass attack by *D. frontalis*. Based on calculations and data reported in Coulson et al. (1976) and Fargo et al. (1978), approximately $0.4–1.8\times10^3$ *D. frontalis* pairs per day infest a 25–40 cm diameter loblolly pine in the first 4 d following initiation of mass attack, whereas an individual male *D. frontalis* paired for <1 d with a female produces 291±55 ng *endo*-brevicomin in an 18±2 hr period (Sullivan et al. 2007). Thus, during the first days of a mass attack, we conservatively estimate that a single mass-attacked tree yields 0.12–0.52 mg *endo*-brevicomin/d. Our estimate is also in agreement with that of Browne et al. (1979) for the release rate of frontalin (the male-produced bicyclic acetal aggregation pheromone component of the sibling species, *D. brevicomis*). These authors reported the collection of 0.4 and 3.3 μg frontalin per m of bole per hr from two different infested ponderosa pines. When extrapolated over 24 hr and 5 m of infested bole their measurement represents a release rate of 0.048 and 0.40 mg/d/tree. Since stand densities recommended for host species of *D. frontalis* produce an average 4–10 m spacing among trees of susceptible ages (Nebeker et al. 1985), we deduce that *endo*-brevicomin

arising from a single infested tree could synergize attraction of beetles to attacks on potentially dozens or hundreds of neighboring trees.

Additionally, at an adequately high release of *endo*-brevicomin, this synergy would evidently be stronger at adjacent trees than the tree of pheromone origin. Thus, elevated (+)-*endo*-brevicomin concentrations associated with high densities of beetle pairs should disproportionately enhance beetle responses to neighboring trees that are in the early stages of colonization by solitary, frontalin-releasing females. Pheromones are believed to play an important role in shifting the focus of bark beetle attack from fully-colonized trees to neighboring trees that are either in the initial stages of colonization or not yet attacked (Renwick and Vité 1970; Borden 1989). Furthermore, synchronization of such host "switching" by the beetle population is evidently critical to the sustained growth of *D. frontalis* infestations (Gara and Coster 1968). Several authors have proposed that host switching in *D. frontalis* and other bark beetles is mediated by the compounded effects of pheromones of opposing activities: long-range attractants from both the old and new attack foci draw beetles into the area while simultaneously short-range inhibitors deter landings on old attack foci (Johnson and Coster 1978; Payne 1980; Berryman 1982; Schlyter et al. 1987a). In contrast, *endo*-brevicomin may promote host switching by *D. frontalis* through a single principle, namely, the disproportionate enhancement of attraction to relatively more distant sources of frontalin/host odors.

Bark beetle semiochemicals have been classified as either synergists or inhibitors typically with "attractant-challenge"-type experiments in which a bait of undetermined activity is attached to a randomly-selected, attractant-baited trap, and catch is compared to a simultaneously-operated, attractant-only control trap (Reeve and Strom 2004; Fettig et al. 2006). If catch in the challenged trap is significantly lower than the control, the test bait is concluded to be inhibitory; if catch is significantly higher than the control, the test bait is concluded to be a synergist or attraction enhancer (Payne et al. 1978a; Bedard et al. 1980; Bakke 1981; Pureswaran and Borden 2004; Sullivan 2005). Our data demonstrate how such attractant-challenge tests might generate misleading or inconsistent conclusions regarding the activity of a compound. In experiment 2 (Fig. 3), catch in the randomly chosen, *endo*-brevicomin-challenged trap of a pair was significantly lower than in its 4 m-distant, attractant-only baited twin (the latter being equivalent to a control in an attractant-challenge type experiment employing 4 m trap spacing). Thus, according to the traditional interpretation of such data, *endo*-brevicomin inhibited catch at the experimental trap. However, since catch by both traps of the pair was much lower in the absence of *endo*-brevicomin, the difference within the pair was apparently due to greater enhancement of catch in the control trap than the challenged trap and not to inhibition in the challenged trap.

Theoretically, any synergist possessing the property displayed by *endo*-brevicomin in experiment 1 (i.e., maximizing beetle response to an attractant when displaced a short distance from it, what we shall hereafter call "displacement-enhanced synergism") could be interpreted in a challenge test to be either a synergist or an inhibitor depending solely upon the trap spacing used (Fig. 4). This is because challenge experiments employing a simultaneously-operated control trap cannot distinguish whether the test bait alters catch in the challenged trap rather than (or simultaneously with) the control trap. The ability to conclude enhancement or inhibitory activity in such tests relies on the assumption that traps are adequately spaced to assure that they cannot influence one another. However, the minimum separation required to assure trap independence is difficult to determine experimentally and has rarely been sought in research on bark beetle flight behavior (Dodds and Ross 2002). It should be noted that many of the interpretations of the results from the present study rely on the assumption that the minimum 100 m distance between adjacent experimental subjects (i.e., individual traps in experiment 1, pairs in experiment 2, and trios in experiments 3–4) was adequately large to prevent mutual interference.

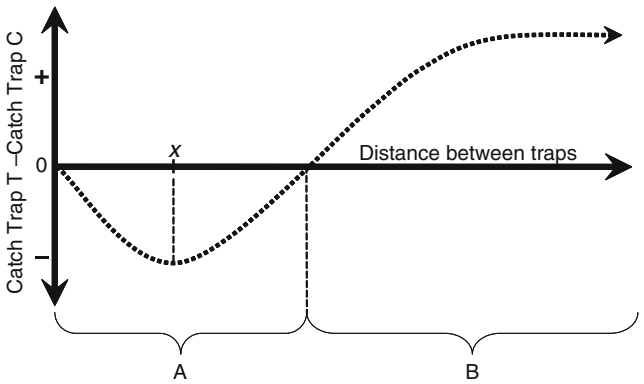

Fig. 4 Hypothetical responses of insects to two adjacent traps baited identically with an attractant where one trap chosen at random (treatment trap, "trap T") is baited additionally with a compound possessing the properties exhibited for (+)-*endo*-brevicomin in experiment 1 (Fig. 2), namely, it has (1) synergistic activity when attached directly to the trap and (2) maximum synergistic activity when displaced distance *x* from the trap (i.e., displacement-enhanced synergism). The opposite trap ("trap C") is baited only with the attractant, and is thus equivalent to the control trap in a classic "attractant-challenge"-type trapping bioassay (see text). The Y-axis represents the arithmetic difference in catch between the two traps; the X-axis represents the distance between the two traps. Within distance range A, catch is greater in the control trap than the trap holding the experimental bait, and thus the "apparent" effect of the bait is inhibition. However, at greater distances (range B), catch is less in the control trap than the experimental trap, and the apparent effect of the bait is enhancement

We suspect that interference among adjacent experimental traps compounded with *endo*-brevicomin's capacity for displacement-enhanced synergism may explain why many earlier studies failed to detect *endo*-brevicomin's synergistic activity. Intertrap spacing of less than 30 m is typical for studies evaluating bark beetle semiochemicals (Payne et al. 1978b; Bedard et al. 1980; Bakke 1981; Borden et al. 1987; Miller and Borden 1992; Sullivan 2005) and was 25 and 15–20 m in the only two trapping studies that both observed *endo*-brevicomin inhibition for *D. frontalis* and reported these experimental parameters (Payne et al. 1978a; Salom et al. 1992). Catch in the control traps of these tests was possibly enhanced by the nearby *endo*-brevicomin baits (i.e., attached to experimental traps) leading to the conclusion that the *endo*-brevicomin was reducing catch in the experimental trap to which it was attached. Experiment 1 demonstrated that *endo*-brevicomin can have synergistic effects on attractant-baited traps as far as 32 m away, hence greater trap spacing than this would be necessary to assure absence of intertrap effects. The two aforementioned studies were also performed within the limits of an active *D. frontalis* infestation, and *endo*-brevicomin released from naturally-infested trees within these infestations could likewise have altered responses to traps. One highly significant implication of our results is the possibility that additional bark beetle species possess pheromone components whose attractive activity has been overlooked due to the use of experimental procedures that concealed this activity.

Vité et al. (1985) demonstrated that the antipodes of *endo*-brevicomin elicited conflicting behavioral responses from *D. frontalis*, and they hypothesized that the inhibitory activity reported for *endo*-brevicomin in previous studies was due to the use of high release, racemic baits in which the antagonistic (–)-enantiomer overwhelmed the attractive (+)-enantiomer. In our experiment 2, baits consisting either of two capillaries of racemic *endo*-brevicomin or of a single capillary of (+)-*endo*-brevicomin [and thus having an identical dose of (+)-*endo*-brevicomin but a differing dose of (–)] exhibited essentially identical activity (experiment 2, Fig. 3). Thus, the (–)-enantiomer did not diminish the synergistic activity of the (+)-enantiomer at the release rates that we tested. Rather, experiment 2 demonstrated that both pure (+) and racemic baits could induce greater catches in more distant traps, and thus either might appear to behave as an attractant synergist or inhibitor under appropriate experimental conditions (Fig. 4).

The mechanism that underlies displacement-enhanced synergism likely involves the concentration of the relevant components in the behavioral chemical plume, and displacement of a modifier compound (i.e., a synergist or an inhibitor) from an attractant-baited trap should influence pheromone concentrations within the plume downwind of the trap in predictable ways. These include: 1) the average concentration of the modifier within the attractant plume will be reduced, causing the active space of the combination (i.e., the zone in which both the attractant and modifier exceed the response threshold of the insect) to be smaller; 2) the relative proportions of the attractant and modifier will vary greatly within the overlapping portions of the plumes; and 3) the concentration of modifier at the attractant-baited trap and close to it will drop to zero unless the modifier is released directly upwind from the attractant (adapted from Byers 1987). Thus, reducing the modifier's release rate should at least partially duplicate the effects of displacing the modifier, particularly regarding effects 1 and 3 above. In support of this inference, spatial displacement of a modifier (either a synergist or an inhibitor) from the release point of an insect semiochemical generally produces the same outcome as reducing the dose of or eliminating the modifier: displacement of inhibitors increases (McLaughlin et al. 1974; Witzgall and Priesner 1991; Liu and Haynes 1992; Rumbo et al. 1993; Potting et al. 1999), whereas displacement of synergists reduces insect responses to a semiochemical (Linn and Gaston 1981; Byers 1987; Lux et al. 1994). However, in experiment 3, reducing the dose of (+)-*endo*-brevicomin at the center trap caused a reduction in *D. frontalis* catches at both the center and the adjacent traps, not an increase in catch at the center trap as would be predicted if the relatively higher catch in the outer traps was attributable simply to a relatively lower concentration of (+)-*endo*-brevicomin at these locations. Thus our data are not consistent with the hypothesis of an entirely dose-driven mechanism for the displacement-enhanced synergism of *endo*-brevicomin.

In addition to synergists and inhibitors, bark beetles may also utilize "multifunctional" semiochemicals that are attractive or synergistic at low release rates but inhibitory at high ones (Rudinsky 1973; Borden et al. 1987; Schlyter et al. 1987a; Seybold et al. 1992; Erbilgin et al. 2003). Furthermore, bark beetle responses to certain attractive semiochemicals decline at very high release rates (Seybold et al. 1992; Ross and Daterman 1998; Miller et al. 2005). Semiochemicals possessing such a parabolic dose-response curve should possess a single, optimally-attractive release rate; therefore the attractive activity of a bait exceeding this optimum dose could conceivably be enhanced by displacing it from the target (e.g., a trap), thereby effectively reducing its dose both at and downwind of the target. Additional experiments would be necessary to determine whether the (+)-enantiomer of *endo*-brevicomin produced by *D. frontalis* (Sullivan et al. 2007) has the parabolic dose-response of a multifunctional pheromone, however evidence suggests that at least racemic *endo*-brevicomin possesses this dynamic (Vité et al. 1985). Results of previous studies suggest that elevated doses of multifunctional pheromones may enhance insect attraction to or landing at distant locations. When

Rabaglia and Lanier (1983) increased the rate that the multifunctional pheromone α-multistriatin was released from the bole of host trees, landings by the European elm bark beetle, *Scolytus multistriatus* (Marsham), switched from the bole to the crown. Elevating the release rate of the multifunctional pheromone ipsdienol at a trap baited with aggregation pheromone increased the relative proportion of *Ips typographus* (L.) trapped in 3 m-distant, unbaited traps while it increased the summed catch for all traps (Schlyter et al. 1987b). The possibility that displacement-enhanced synergism is a common property of multifunctional semiochemicals is worthy of further investigation. Enhanced knowledge of semiochemical plume dynamics in heterogeneous environments integrated with data from further studies that vary both the release rate and displacement of attraction modifiers will help to elucidate the mechanism underlying displacement-enhanced synergism.

Acknowledgments We thank Brad Hoosier, Joanne Barrett, Erich Vallery, Tessa Bauman, and Chris Young for technical assistance; Cavell Brownie for guidance on statistical analyses and addressing reviewers' comments; Drs. K. Fuhshuku and Y. Masuda of RIKEN, Japan, for help with the synthesis of (+)-*endo*-brevicomin; Lee Dunnam, Homochitto National Forest, MS, for assistance and cooperation in field studies; Rhonda Tam and Jessica Norris for administrative assistance; and Steve Clarke, Darrell Ross, and Will Shepherd for critical readings of earlier versions of this manuscript.

the lack of temperature effects on pheromone production can be found (e.g., Pandey and Pandey 1990). Certain insects exhibit pheromone-releasing behaviors that increase in frequency with increasing temperature, leading to periodicity in pheromone release that can be both circadian and seasonally controlled (e.g., Sower et al. 1971; Pope et al. 1982). In all vertebrates studied to date with described or putative pheromones, pheromone production and expression are thought to be controlled almost exclusively by hormones (e.g., amphibians, Yamamoto et al. 1996; Iwata et al. 2000a; Kikuyama et al. 2005; reptiles, Mendonça and Crews 1996; birds, Rajchard 2007; rodents, Bruce 1965; Thiessen et al. 1968; Mugford and Nowell 1971; primates, Michael 1975; goats, Iwata et al. 2000b). However, in at least one vertebrate, the red-bellied newt, *Cynops pyrrhogaster*, pheromone production may be promoted by low temperature (Iwata et al. 2000a; Takahashi et al. 2001).

Our focal species, the red-sided garter snake, *Thamnophis sirtalis parietalis*, is a reptilian model for understanding the relationship between seasonality, behavior, and sex pheromones. After a prolonged winter dormancy (8 mo, Gregory 1976), these animals emerge from limestone hibernacula by the thousands in the interlake region of Manitoba, Canada. At this time, males vigorously court and compete for females, leading to large mating balls of males courting single females (Aleksiuk and Gregory 1974). Courtship behavior in male red-sided garter snakes is affected by changes in temperature, with prolonged, low temperature dormancy (12 wk, 4°C) enabling robust, stereotypical courtship behavior in the laboratory after simulated emergence from hibernation (Hawley and Aleksiuk 1975; Garstka et al. 1982). Because the snakes hibernate several meters underground, there is no light, and photoperiodic cues have been shown to have no effect on the induction of spring mating behavior (Whittier et al. 1987; Lutterschmidt et al. 2006). Instead, the one seasonal signal, low temperature dormancy, causes changes in aromatase activity in the sexually dimorphic nuclei of the brain of males (hypothalamic pre-optic area, HPOA; Krohmer et al. 2002). The HPOA hypertrophies by the time of emergence, and is the neural center for the control of courtship behavior in this species (Krohmer et al. 2002). Laboratory-simulated hibernation conditions induce changes in the secretion patterns of melatonin in males, suggesting that this hormone may play a role in the regulation of courtship behavior as well (Lutterschmidt 2006). Thus, male red-sided garter snakes have evolved a behavioral response to a specific, relevant environmental cue: temperature (Crews and Moore 1986).

Female red-sided garter snakes exhibit seasonal changes in two components of female reproduction: receptivity and attractivity (Beach 1976). Sexual receptivity is controlled primarily by estrogen, with ovariectomy abolishing receptivity and estrogen replacement in castrated females reinstating receptivity (Crews 1976). Attractivity is determined by using bioassays of male courtship behavior, and both the quantity and quality of the female sexual attractiveness pheromone blend can be determined easily with chemical analyses (Mason et al. 1989, 1990). The female sex pheromone of the red-sided garter snake is a series of nonvolatile, long-chain (C_{29}–C_{37}) saturated and monounsaturated methyl ketones ranging from 394 to 532 Da (Mason et al. 1989). Individual pheromone components, when presented singly, elicit much lower levels of courtship from males compared to the complete blend; however, the longest, unsaturated components can elicit significant courtship behavior when presented alone (Mason et al. 1989). More recent work has shown that the ratio of the abundances of unsaturated to saturated components relays information about female reproductive condition. Long and/or fat females produce more offspring and elicit more vigorous courtship from males when compared to females of lesser condition (LeMaster and Mason 2002; Shine et al. 2003). Sex pheromone blends from large females consist primarily of the long-chain, unsaturated components, specifically those with masses of 476, 504, and 532 Da, whereas sex pheromone blends from small females are composed equally of saturated and unsaturated methyl ketones that span the entire range (394-532 Da; LeMaster and Mason 2002). Males prefer isolated pheromone extracts from large females compared to small females, suggesting that they choose females based solely on differences in the composition of the pheromone, namely the ratio of unsaturated to saturated components (LeMaster and Mason 2002; Shine et al. 2003). Thus, the female sex pheromone is an honest signal that relays information about reproductive condition.

Early laboratory studies on garter snakes have shown that males display increased interest in females during the time of shedding (as evidenced by increased tongue-flicking and chin-rubbing behavior), and this may be attributed to changes in the quantity of the pheromone produced by the skin (Noble 1937; Kubie et al. 1978). The quality of the pheromone differs between the breeding (spring) and nonbreeding (fall) seasons in the red-sided garter snake, suggesting that the pheromone relays information about season as well as sex (Mason et al. 1987; LeMaster and Mason 2001). However, pheromone profiles for this species are complex: there are at least 16 unique methyl ketone molecules comprising a single female pheromone profile (Mason et al. 1989). To fully understand this complexity, analyses are needed of pheromone profiles from individual red-sided garter snakes, however, this was not done in the previous two studies on pheromone seasonality in this species (Mason et al. 1987; LeMaster and Mason 2001).

The purpose of this study was to examine changes in the pheromone profiles from individual female garter snakes that may be affected by the process of hibernation. Initiation of sexual behavior in males is dependent on exposure to prolonged low temperature, and it may be that female attractivity also is affected by the low temperature dormancy that this species experiences annually. In the field, it is impossible to gather pheromone samples from females during hibernation because they are several meters below ground (Lutterschmidt et al. 2006). Thus, our laboratory study utilized simulated hibernation to determine how both the quantity and quality of the female sexual attractiveness pheromone may change during winter dormancy.

Methods and Materials

Animals Female red-sided garter snakes, *Thamnophis sirtalis parietalis,* (N=24) were captured at the hibernaculum in the fall of 2005 (Inwood, Manitoba, Canada). Pheromones were extracted from subsets of these snakes (N=8 each) at three different times: fall, winter (during hibernation), and spring. The fall sample was collected at the hibernaculum, whereas the remaining snakes were transported back to the laboratory at Oregon State University and placed into artificial hibernation approximating natural conditions (4°C; 0:24 h L:D; 85% RH). Pheromones were collected from the winter group after 12 wk in winter hibernation (January), and those for the spring group were collected 12 wk later (April) after 1 wk of simulated emergence (12°C, 10 h:6°C, 14 h, L:D). All procedures involving the use of live animals were approved by the Institutional Animal Care and Use Committee at Oregon State University (ACUP 3120) and were in compliance with guidelines established by the National Institutes of Health Guide for the Care and Use of Laboratory Animals. The collection and use of these animals was approved by Manitoba Conservation (Manitoba Wildlife Scientific Permit WB02024).

Pheromone Collection and Isolation We followed previously published methods for collection and analysis of pheromone extracts (Mason et al. 1989). Snakes were sacrificed with a lethal overdose of brevital sodium (6 mg/kg) prior to collection of skin lipids from individual snakes by immersion in hexane for 12 h. The snakes were then removed from the solvent, and snake mass (g), snout-vent length (SVL, cm), and midbody circumference (cm) were recorded. The volume of the skin lipid extracts was reduced under vacuum with a rotary evaporator, and the total skin lipid yield of the dry product was determined (mg) before fractionation. The pheromone was isolated by using alumina columns [activity III (Sigma-Aldrich, St. Louis, MO, USA); pooled fractions 4-6 (2% diethyl ether:98% hexane as mobile phase)]. The pooled fractions containing pheromone were reduced to dryness by using a rotary evaporator and weighed to determine the mass (mg; termed "pheromone fraction mass" hereafter). The combined pheromone fractions are composed almost solely of female sex pheromone methyl ketones (>99% of fraction mass) and have been demonstrated to elicit courtship behavior from males that is as intense as courtship directed to live females in the den in the spring (Mason et al. 1989). The pooled pheromone fractions were resuspended in a pheromone:hexane mixture (1 mg:1 ml) before analysis by gas chromatography-mass spectrometry.

Gas Chromatography-Mass Spectrometry Individual pheromone samples were analyzed with a Hewlett Packard 5890 Series II gas chromatograph fitted with a split injector (280°C) and an HP 5971 Series mass selective detector. Aliquots (1 µl) of the 1:1 samples (1 mg pheromone:1 ml hexane) were injected onto the fused-silica capillary column (RTX-1; 15 m×0.25 mm i.d., 0.25 µm film thickness; Restek Corporation, Bellefonte, PA, USA) with helium as the carrier gas (5 cm/sec). All injections were made in the splitless mode with the split valve closed for 60 sec. Oven temperature was held initially at 70°C for 1 min, increased to 210°C at 30°C/min, held at 210°C for 1 min, increased to 310°C at 5°C/min, and held at 310°C for 5 min. Individual compounds were identified by using mass spectral data and ion chromatograms comparing our spectra to published data and authentic standards (Mason et al. 1990). By using the peak integration function in ChemStation software (Agilent) interfaced with the GC-MS, we determined relative contributions of each component of the pheromone to the overall profile of each snake.

Data Processing and Statistical Analysis We tested for global differences in total skin lipid mass, pheromone fraction mass, pheromone concentration, unsaturated to saturated component ratio, individual unsaturated and saturated component mass, and low and high molecular weight contributions to profiles by using one-way and two-way ANOVAs (time, component type as factors) followed by pairwise comparisons (Tukey Tests; SigmaStat v.3.1). Total skin lipid mass and pheromone fraction mass were arcsine transformed after correcting for snake mass before analyses. Pheromone fraction mass was used to derive pheromone concentration (µg/cm^2) by using previously published methods and log-transformed before analysis (Mason et al. 1990; LeMaster and Mason 2002). Briefly, the circumference (cm) at midbody was measured and then multiplied by the snout-to-vent length (cm) to get total surface area (cm^2), and pheromone fraction mass (mg) was converted to µg and divided by total surface area to yield pheromone concentration (µg/cm^2). By using an internal

standard (methyl stearate, 10 μg/ml hexane; LeMaster et al. 2008), we were able to derive individual component mass (μg) for all of the 16 methyl ketones comprising the pheromone. Global differences in pheromone structure were analyzed by using the Multi-Response Permutation Procedure in the vegan package for R (v.1.8-8; McCune et al. 2002). Pairwise comparisons for pheromone structure were run by using the same procedure but by excluding a new group each time. Coordinates for a non-metric multidimensional scaling plot to represent differences in individual pheromone profiles also were generated with the vegan package, and all graphics were created in SigmaPlot (v.8.0).

Results

Total skin lipid and pheromone fraction masses increased from fall to spring ($F_{2,\ 21}$=95.471, P< 0.001; $F_{2,\ 21}$=9.196, P= 0.001; Fig. 1). Total skin lipid mass was higher in both spring and winter than in fall (q= 17.893, P< 0.001; q= 15.750, P< 0.001, respectively). Pheromone fraction mass was higher in spring than in fall (q= 6.065, P= 0.001). No other differences were found in skin lipid or pheromone fraction masses. Pheromone concentration (μg pheromone/cm^2 of skin) also increased over time (H=14.791, P< 0.001), with the pheromone concentration being higher in spring and winter than in fall (q=4.850, P=0.005; q= 4.525, P=0.006, respectively; Fig. 2).

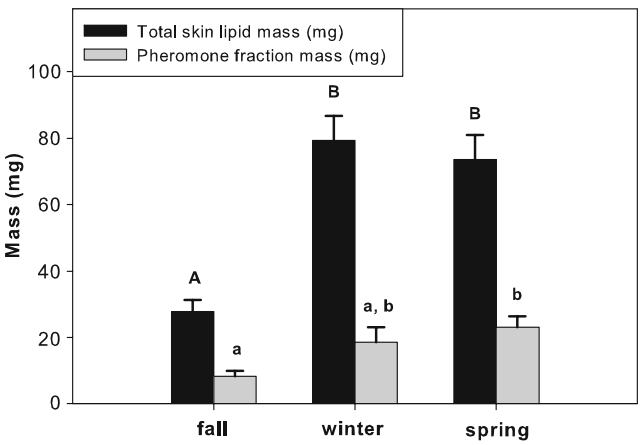

Fig. 1 Change in mass (mg; mean + s.e.; N=8 for each bar) of both total skin lipids (black bars) and pooled fractions containing only the nonvolatile methyl ketones that comprise the pheromone (pheromone fraction mass; gray bars) of female red-sided garter snakes. Pheromones were collected from individual females in the fall at the snake den, during winter in laboratory-simulated hibernation, and in the spring in the laboratory after simulated emergence. Different letters of the same case (e.g., "a" vs. "b") represent significant differences (P< 0.05) in mass for those sampling periods

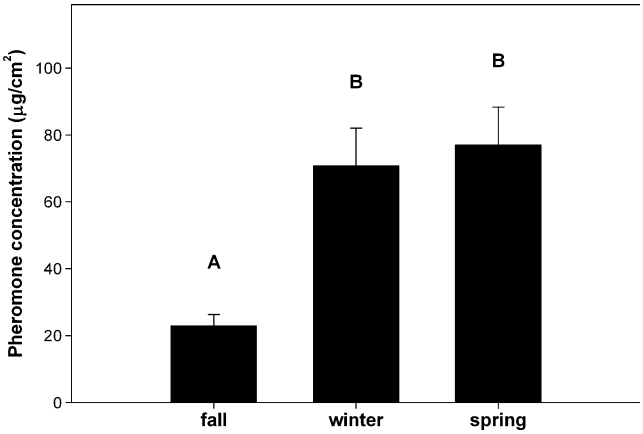

Fig. 2 Sex pheromone concentration (μg pheromone/cm^2 skin; mean + s.e.; N=8 for each bar) extracted from female red-sided garter snakes in the field and during laboratory-simulated hibernation and emergence. Different letters represent significant differences (P<0.05) in pheromone concentration for those sampling periods

Following the GC-MS analysis, we found that the composition of the pheromone blends changed over time (A= 0.07672, P= 0.016). Spring profiles were different than fall profiles (A= 0.1089, P= 0.012), but no other differences were significant (Fig. 3). We then tested the pheromone profile characteristics that may have contributed to these global differences. We found no difference in the ratios of the abundances of unsaturated to saturated components within the pheromone profiles over time ($F_{2,\ 18}$=0.301, P> 0.05). Both main effects (season, component type [saturated, unsaturated]) were significant when we analyzed the masses of pheromone components ($F_{2,\ 47}$=8.703, P< 0.001; $F_{1,47}$=18.329, P< 0.001, respectively). There was no season x component type interaction ($F_{2,\ 47}$=2.010, P= 0.147). Within season, the mass of unsaturated components was greater than the mass of saturated components for fall (q=3.004, P=0.04), winter (q= 3.772, P=0.011), and spring (q= 3.218, P=0.028; Fig. 4). Within component type, the mass of saturated components was greatest in spring compared to fall (q=4.561, P=0.007), but no other differences were detected. The mass of unsaturated components was greater in spring than in fall (q= 4.774, P= 0.005), and winter than in fall (q= 3.706, P=0.032; Fig. 4). The compounds contributing most to the overall makeup of the pheromone blend were the 504 (unsaturated), 476 (unsaturated), 450 (saturated), and 448 (unsaturated) Da molecules (Fig. 3).

Components within each pheromone profile were arbitrarily split into two molecular weight classes: low molecular weight (LMW; <463 Da) and high molecular weight (HMW; >463 Da). Previous work has demonstrated that the attractivity of female red-sided garter snakes increases with increasing molecular weight and unsaturation of individual components of the pheromone, suggest-

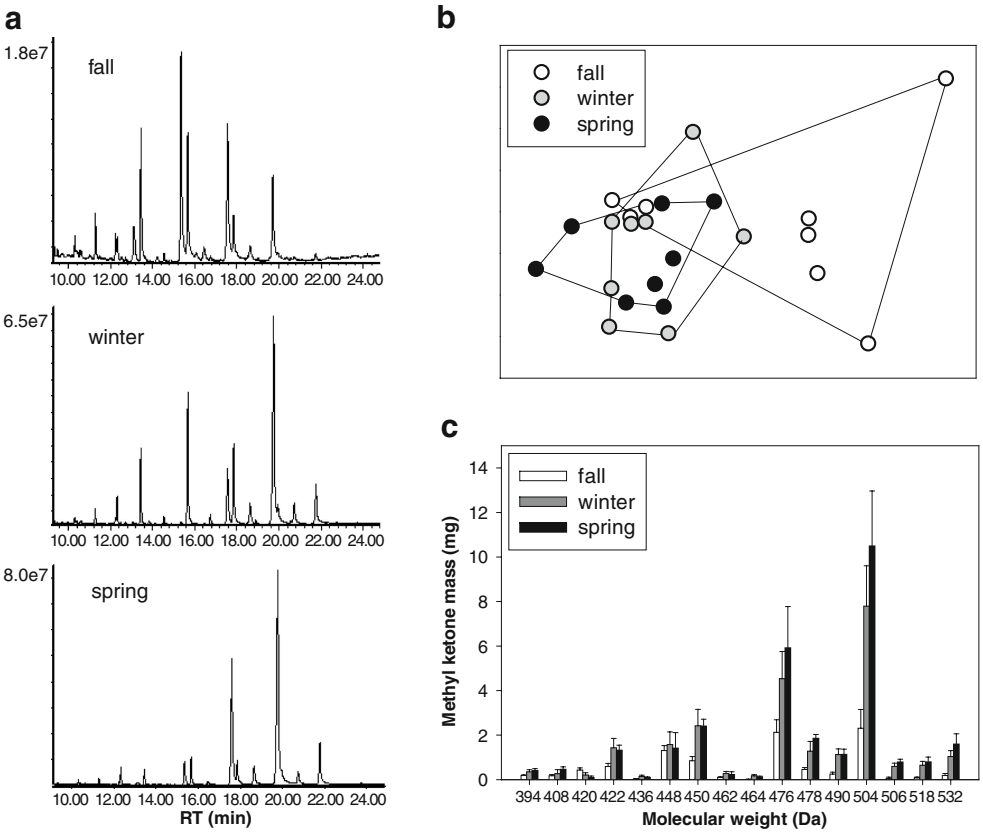

Fig. 3 Changes in the female sexual attractiveness pheromone blend of red-sided garter snakes from three sampling periods (fall, winter, spring). **a** Representative total ion chromatograms of sex pheromone blends from individual females from the three sampling periods. **b** Non-metric multidimensional scaling plot showing individual pheromone profiles. Minimal convex polygons are drawn for each group to show how the area of similarity for pheromone profiles shifts and contracts from fall to spring, with individual profiles being most similar (most tightly clustered) in spring. The fall (white circles) and spring (black circles) were significantly different ($P<0.05$). **c** Masses (mg; mean + s.e.; $N=8$ for each bar) of prospective individual components (categorized by molecular mass; Da) of the female sex pheromone blend over the three sampling periods. The most abundant compounds were the 504 (unsaturated), 476 (unsaturated), 450 (saturated), and 448 (unsaturated) Da methyl ketones

ing that changes observed in the molecular weight of pheromone constituents over time have biological consequences in nature (Mason et al. 1989). Thus, we analyzed the ratio of HMW:LMW proportions over time (log-transformed) and found a significant time effect ($F_{2,\ 21}=5.362$, $P=0.013$). Pheromone profiles were dominated by HMW compounds in spring compared to fall ($q=4.365$, $P=0.015$), but no other differences were significant (winter vs. fall, $q=3.522$, $P>0.05$).

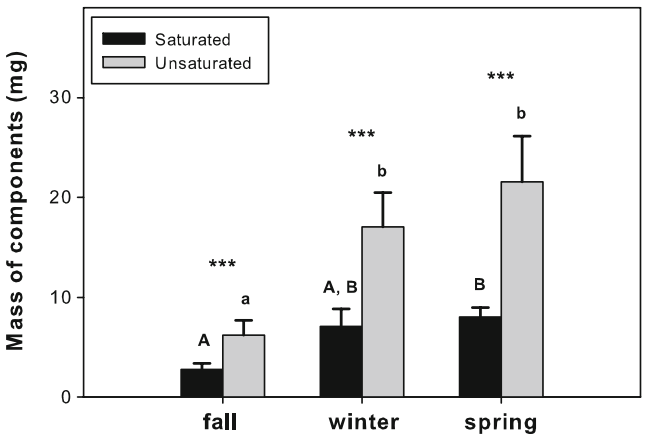

Fig. 4 Mass of components (mg; mean + s.e. ; $N=8$ for each bar) comprising the female sex pheromone blend of red-sided garter snakes from three sampling periods (fall, winter, spring) grouped by methyl ketone type (saturated, unsaturated). At all three sampling periods, unsaturated components were significantly more abundant ($P<0.05$; asterisks) than saturated components, especially in the spring. Within each class, both types of components reached peak mass in the spring. Different letters of the same case represent significant differences ($P<0.05$) within a class

Discussion

We have shown that the process of hibernation induces quantitative and qualitative changes in the female sexual attractiveness pheromone of the red-sided garter snake. Both total skin lipid mass and pheromone fraction mass increased from fall to spring as did the concentration of pheromone present on the skin. The quality of the pheromone also appeared to change concomitant with the changes in amount and concentration, with females producing pheromones dominated by unsaturated, high molecular weight (HMW) methyl ketones by the winter and into spring. Thus, hibernation is critical in the regulation of one of the two components of female reproduction in this species: attractivity.

Temperature has numerous effects on sexual signals, both in vertebrates and invertebrates. For instance, ambient temperature affects the length and color of the manes of lions, an information-rich sexual signal (West and Packer

2002). Vertebrates and invertebrates exhibit fluctuating asymmetry in sexually selected traits that reflect changes in ambient temperature and photoperiod (e.g., tail length in swallows, Møller and Szep 2005; sex combs in flies, Polak and Starmer 2005). Further, many animals use sex-specific sounds to attract and evaluate mates, and both the production and perception of these signals can be altered significantly by changes in temperature (e.g., flies, Ritchie et al. 2001; frogs, Gerhardt 1978; Shimizu and Barth 1996). Our results suggest that a powerful sexual signal, the female attractiveness pheromone of garter snakes, changes significantly as a result of low temperature dormancy (i.e., hibernation).

Sex pheromone production is known to be affected by temperature in red-bellied newts, *Cynops pyrrhogaster*, where low temperatures (8–12°C) induce increased synthesis of prolactin mRNA, and prolactin, in conjunction with androgens, can induce hypertrophy of the secretory capacity of the newt pheromone (sodefrin) gland and stimulate production of sodefrin (Toyoda et al. 1994; Yamamoto et al. 1996; Iwata et al. 2000a; Takahashi et al. 2001). Sodefrin is a peptide pheromone, thus the mechanisms controlling its synthesis and expression will differ from those acting in garter snakes to produce the relatively small methyl ketone molecules that act as pheromones in our system. However, both systems are responsive, at least in part, to changes in temperature, and they warrant further study. Our study is the first in a reptile to demonstrate the effects of hibernation on female attractivity at the level of pheromone production.

Female receptivity and male courtship behavior in both amphibians and reptiles are known to be affected by changes in temperature. Low temperatures are critical for either initiating or maintaining expression of both male courtship and female receptivity in a number of salamanders, newts, and frogs (Duellman and Trueb 1994). In reptiles, the effects of temperature on sexual behavior in males have been studied more extensively than in females (Whittier and Tokarz 1992). Male red-sided garter snakes do not express typical courtship behavior in the spring unless they experience an extended (8–17 wk) low temperature dormancy (4°C, 0 h:24 h L:D; Camazine et al. 1980; Garstka et al. 1982). Female receptivity in garter snakes is influenced by low temperature dormancy, but hormonal priming (estrogen) before hibernation exerts a much stronger effect, as evidenced by abolished receptivity in ovariectomized females and only reduced receptivity resulting from exposure to warmer temperatures during winter dormancy (Bona-Gallo and Licht 1983; Mendonça and Crews 1996). Our results suggest that female attractivity is optimized by low temperature dormancy, though our study did not include a warm hibernation control group due to the high rate of female mortality demonstrated in previous studies (16%, Whittier et al. 1987).

Collectively, research on this system has shown that maximal, coordinated sexual behavior in the red-sided garter snake (male courtship and female attractivity and receptivity) is contingent upon sustained, low temperature dormancy. This species overwinters in large, communal dens, and snakes emerge en masse in the tens of thousands to engage in spectacular displays of scramble mating as males search for and court singly-emerging females (Aleksiuk and Gregory 1974; Gregory 1976). In an evolutionary sense, this species has adapted to maximally express sexual characteristics (behavior, pheromones) at a time when population densities are highest and precision in identifying and selecting mates is critical.

The role of skin and gland-derived compounds as pheromones in sauropsids (birds and reptiles) may have arisen from the modification of phospholipids originally derived for waterproofing the integument (adapted from Maderson 1986). In another sauropsid (mallard, *Anas platyrhynchos*), the waterproofing gland (uropygial) produces sex pheromones, and pheromone synthesis occurs from lysosomal modification (lengthening, esterification) of monoester waxes, and ultimately is regulated by female sex steroid hormones (Jacob et al. 1979; Kolattukudy and Rogers 1987; Bohnet et al. 1991). Thus, skin waxes generated primarily for waterproofing have been co-opted into a secondary role as sexual signals in this species. The pheromone of red-sided garter snakes may be similarly derived. First, the skin may increase its lipid production to retard transcutaneous water loss during low temperature dormancy, which is a common process in sauropsids during cold acclimation (e.g., turtles, Willard et al. 2000; pigeons, Peltonen et al. 2000). Second, as is the case in mallards, the lipids would be modified by enzymes that are activated by cold temperatures. The data presented in this paper show that the pheromone of female red-sided garter snakes becomes dominated by longer, unsaturated molecules, the most sexually attractive components of the female pheromone, as a result of low temperature dormancy (Mason et al. 1989; LeMaster and Mason 2002; Shine et al. 2003). Several enzymes are activated by cold temperatures in vertebrates that either synthesize or lengthen long-chain lipids (C16 or greater; Jakobsson et al. 2005, 2006). Other enzymes, such as desaturases, play a critical role in maintenance of the phospholipid bilayer by desaturating lipid chains to increase membrane fluidity and prevent damage from freezing (reviewed in Hazel and Williams 1990; Tiku et al. 1996). Such temperature-induced mechanisms (elongation, desaturation) may exist in the pheromone synthesis of red-sided garter snakes and warrant further study.

We have shown that female pheromone content is altered during hibernation in this species, and that the pheromone present at emergence is composed primarily of long-chain,

unsaturated methyl ketones, which in other studies have been shown to elicit the strongest behavioral response from males (Mason et al. 1989; LeMaster and Mason 2002; Shine et al. 2003). The red-sided garter snake serves as a robust model for testing hypotheses on the seasonality of sexual signal production, and it also represents a point of evolutionary divergence in vertebrate sexual signals. Rather than plumage and pelage to reflect sex, condition and season, the skin lipids of the female red-sided garter snake are modified to signal condition and fecundity so as to be optimally honest at a time when mate density is highest and the odds of mating are virtually certain. In the future, we plan to examine skin lipid production by male garter snakes to determine if they may also display the same seasonal pattern we have shown in females of this species.

other signals such as pH. However, the diversity of sources of CO_2 in the rhizosphere and the imperfect correlation between regions of the root with high CO_2 and those with highest attraction suggest that CO_2 may not be a specific signal (Bird 1960). In the soil, CO_2 efflux is the result of root and rhizospheric respiration and organic matter decomposition. *Meloidogyne incognita* is repelled by ammonia and several nitrogenous salts released from decaying material (Castro et al. 1991) possibly further modulating its response. For the free-living nematode *Caenorhabditis elegans*, CO_2 has been described both as an attractant and a repellant (Dusenbery 1983; Bretscher et al. 2008; Hallem and Sternberg 2008). Recent studies with *C. elegans* suggest that the degree of CO_2 avoidance depends on strain and nutritional status (Hallem and Sternberg 2008).

Pluronic F-127 (PF-127) has been used by our group to study plant-nematode interactions and nematode behavior (Wang et al. 2009). A 23% PF-127 solution forms a semisolid gel at room temperature but is liquid at 15°C and below. The gel is highly transparent and generally has low toxicity or is non-toxic, depending on the organism and gel concentration used (Gardener and Jones 1984; Ko and Van Gundy 1988). Nematodes can be mixed in PF-127 solution at 15°C. As the solution warms to room temperature, nematodes become suspended in the gel. They can move freely in 3 dimensions through the gel, allowing examination of behavior in response to various treatments. Nematodes dispersed in PF-127 gel are highly attracted to roots, aggregating mainly at the zone of elongation (Wang et al. 2009). In the absence of roots, nematodes aggregate into tight balls containing most of the nematodes that were distributed in PF-127 gel. We have postulated that this aggregation is due to a preference for low oxygen concentration, a response to anhydrobiotic stress, and/or inter-nematode chemical signals (pheromones). The ability to form aggregates differs among RKN species and strains (Wang et al. 2009; Wang and Williamson, unpublished).

Here, we tested the utility of PF-127 gels for examining root-knot nematode movement in gradients of pH and CO_2. Because the genetic map and genome sequence for *Meloidogyne hapla* strain VW9 are available (Opperman et al. 2008), thus opening the potential to explore genes involved in signal recognition and behavior by the nematode, we focused on this nematode in the current work. We have, however, compared the behavior to isolates of other agronomically important species, including *M. incognita*, for which the genome sequence is also available (Abad et al. 2008).

Methods and Materials

Nematodes and Materials *Meloidogyne hapla* strains used were VW9 (Liu and Williamson 2006), NCS (from C. Opperman, North Carolina State University) and LM (from P. Roberts, University of California, Riverside; Chen and Roberts 2003). *M. javanica* strains VW4 and VW5 are a pair of nearly isogenic strains that differ in ability to reproduce on tomato bearing the resistance gene *Mi-1* (Gleason et al. 2008). *M. incognita* strains used were 557R (Yaghoobi et al. 2005), W1(inbred from nematodes isolated from a Woodland, CA tomato field), Beltran (P. Roberts), Harmony (H. Ferris, University of California, Davis), and VW6 (inbred from a field isolate obtained by H. Ferris). All *M. hapla* strains, *M. javanica* strain VW5, and *M. incognita* strains 557R and W1 were maintained on tomato cultivar VFNT, which carries the gene *Mi-1*. The remaining strains were maintained on the nematode-susceptible tomato cultivar UC82. Eggs were collected and axenic J2s produced as described by Branch et al. (2004) with minor modifications (Wang et al. 2009), then rinsed four times with sterile water; larvae hatched at room temperature.

Methanesulfonic acid and pyridine, both 99%, were from Acros Organics (Geel, Belgium). Bromocresol purple was the sodium salt from National Analine Division, New York, NY, U.S.A.. Other chemicals were A.C.S. grade.

Gel Preparation and Attraction Assay PF-127 (Sigma, St. Louis, MO, U.S.A.) solution was 23% w/v in 10 mM Tris, 10 mM morpholino-ethanesulfonic acid (MES), pH 7.1, unless otherwise indicated. Suspended PF-127 was dissolved by stirring for 24 h at 4°C (Wang et al. 2009). Where noted, the pH indicator bromocresol purple was included. The solution was stored at 15°C. Twenty ml of PF-127 solution containing freshly-hatched J2 (6000 J2 per plate unless otherwise indicated) were poured into each Petri dish (nominal 100×15 mm) at 15°C.

"Chemical dispensers" were prepared by cutting standard 5 cm, 200 µl pipette tips (USA Scientific Inc.) 5 mm from the small end and 20 mm from the large end. The test chemical solutions were prepared in 23% PF-127 and maintained on ice. Approximately 100 µl of the test solution were pipetted into each chemical dispenser, which was held horizontally while the solution was allowed to gel at room temperature. The Petri dish with the PF-127 solution and dispersed nematodes was placed at room temperature, and two dispensers were placed anti-parallel with ends not closer than 3 cm from the Petri plate edge, before the gel formed and before bubbles could develop at the dispenser ends. Dispensers rested on the bottom of the plate, and the top of the large opening of the dispenser was approximately at the surface of the gel in the Petri dish when 20 ml of PF-127 solution were used (i.e., 3.4 mm deep gel). At the indicated time after initiation of the assay, the number of nematodes was counted within the 5 mm diam. circle centered at the small end of pipette tip. Control dispensers containing 23% PF-127 in water were used as checks. The

different sizes of the two dispenser openings allowed us to examine two different concentration gradients simultaneously, and the paired dispensers in each plate provided duplicate analyses. At least three plates were included in each experiment, and each experiment was repeated at least twice. Micrographs were captured with a Nikon SMZ-U dissecting microscope by using SimplePCI High Performance Imaging System (Compix Inc, Sewickley, PA, USA). To obtain a broader view of the nematode distribution patterns in response to chemical gradients, lower magnification photographs of Petri plates were taken with a digital camera by using edge lighting and against a black background.

pH Measurements The pH in gels was measured with a pH Meter (Denver Instrument Company, Arvada, CO, USA), by direct insertion into gel of a PHR-146 Micro Combination pH electrode (Lazar Research Laboratories, Inc., Los Angeles, CA, USA). pH meter calibration was performed by the two point standardization method (pH 7 and pH 4) according to the manufacturer's instructions. pH measurements were repeated at least twice.

Carbon Dioxide Delivery Assay A Petri dish lid was modified for delivery of CO_2 to PF-127 gel (Fig. 1). CO_2 sublimed from dry ice in a container was passed via tubing through water and delivered to a central 1.5 cm diam. circle on the gel surface. Water-saturated air was delivered to the remainder of the gel (Fig. 1), thus creating a concentric gradient of CO_2 in air in the gel from the 1.5 cm circle to the edge of the plate.

Statistical Analysis JMP software (SAS Institute Inc., Cary, NC, USA) was used for statistical analyses. Data were subjected to one-way analysis of variance (one way–ANOVA). Results are reported as significant or non-significant in Tukey's Honestly Significant Difference (Tukey HSD) Test ($P<0.05$).

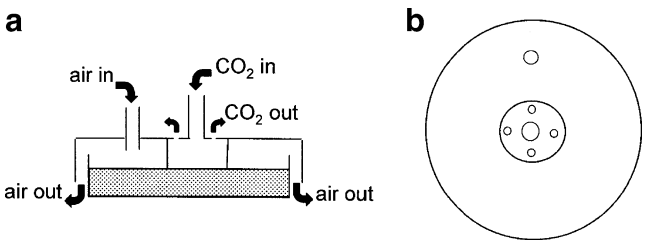

Fig. 1 Apparatus for CO_2 delivery to PF-127 gel. The lid of a standard Petri dish was modified with entry and exit ports for CO_2, and an entry port for air. Air could escape under the edge of the lid. An acrylic cylinder cemented under the lid just touched gel surface to maintain an area of water-saturated CO_2 on the gel surface. The apparatus is shown in cross section (**A**) and top view (**B**). The stippled region in A represents the gel with the nematodes

Results

Formation of pH Gradients in Gel To assess gradient formation in PF-127 gel, the pH indicator bromocresol purple was incorporated into gel in 10 mM Tris-MES buffer, pH 7.1. Two dispensers with 0.17 M acetic acid were placed into each plate. After 4 h, yellow circles were seen around the openings of the dispenser, indicating that proton diffusion occurred in a radial pattern from the openings of the dispenser. The size of the circles increased slowly over the next 20 h (Fig. 2).

Aggregation of M. hapla (Strain VW9) in pH Gradients The response of *M. hapla* strain VW9 J2 was monitored in pH gradients produced around the ends of dispensers that had been charged with 0.17, 0.34, or 0.85 M acetic acid. Nematode clustering was observed at the dispenser small end 3 h (not shown) after insertion and was maintained after 5 and 24 h (Fig. 3A and B, respectively). Five h after insertion, the gradient near the dispenser large end extended over a sufficient gel volume so that J2 responded by congregating into a halo (Fig. 3C, 0.34 M, and 0.85 M acetic acid dispensers). Presumably, the halo was generated because J2 prefer a specific low pH range to the even lower pH near the dispenser end and the pH 7.1 of the PF-127 gel in which J2 were originally suspended. Figure 4 presents J2 density related to distance from the dispenser large end for 0.34 M and 1.7 M acetic acid. The observed distributions conformed to a normal curve, and the gradient created by 0.34 M acetic acid stimulated J2 to achieve a density ten times greater than the initial density of J2 in the gel at the most dense part of the halo (Fig. 4).

By using a microelectrode, pH was measured at the boundaries of the halo of high nematode density. For both low pH and high pH boundaries, more than 50 readings were made from three plates. At 7 h after assay initiation, the pH was 4.54±0.05 for the inner boundary and 5.40±0.15 for the outer boundary. At 20 h after assay initiation, the circle was larger, but the pH values at the boundaries were similar (pH 4.58±0.17 for inner boundary and pH 5.37±0.13 for outer boundary). The experiment was repeated, and the same boundary pH values were obtained. No aggregation of nematodes was observed with any of the checks that contained dispensers with 23% PF-127 in water (not shown).

To test whether acetate from ionized acetic acid was sufficient to account for gradient-directed nematode migration, the response of *M. hapla* J2 was observed for dispensers with 10 and 50 mM sodium acetate, corresponding to the range of acetate ion expected in the previously tested acetic acid-loaded dispensers. At 24 h, no nematode aggregation was seen at the openings of the dispensers (results not shown), suggesting that protons or

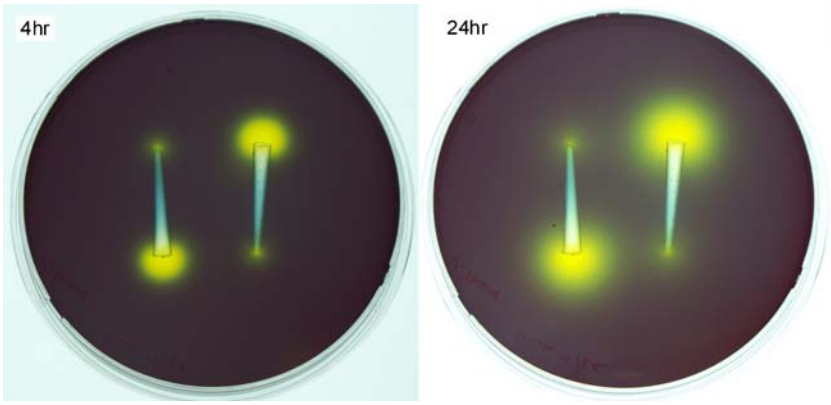

Fig. 2 pH gradient formation in PF-127 gel. The pH indicator bromocresol purple (pH 5.2–6.8, yellow to purple) was included in the gel. The dispensers initially contained 0.17 M acetic acid, and plates are shown 4 and 24 h after the dispenser was inserted into the gel

acetic acid rather than acetate ions affected the nematode aggregation.

By using the dispenser system, we tested the response of VW9 to a variety of Brønsted (proton-donating) acids, including strong acids (HCl, H_2SO_4, $HClO_4$, methanesulfonic acid), carboxylic acids (acetic, citric, formic, lactic, propionic, and succinic), pyridinium hydrochloride, and pyridinium methanesulfonate. Strong acids and three

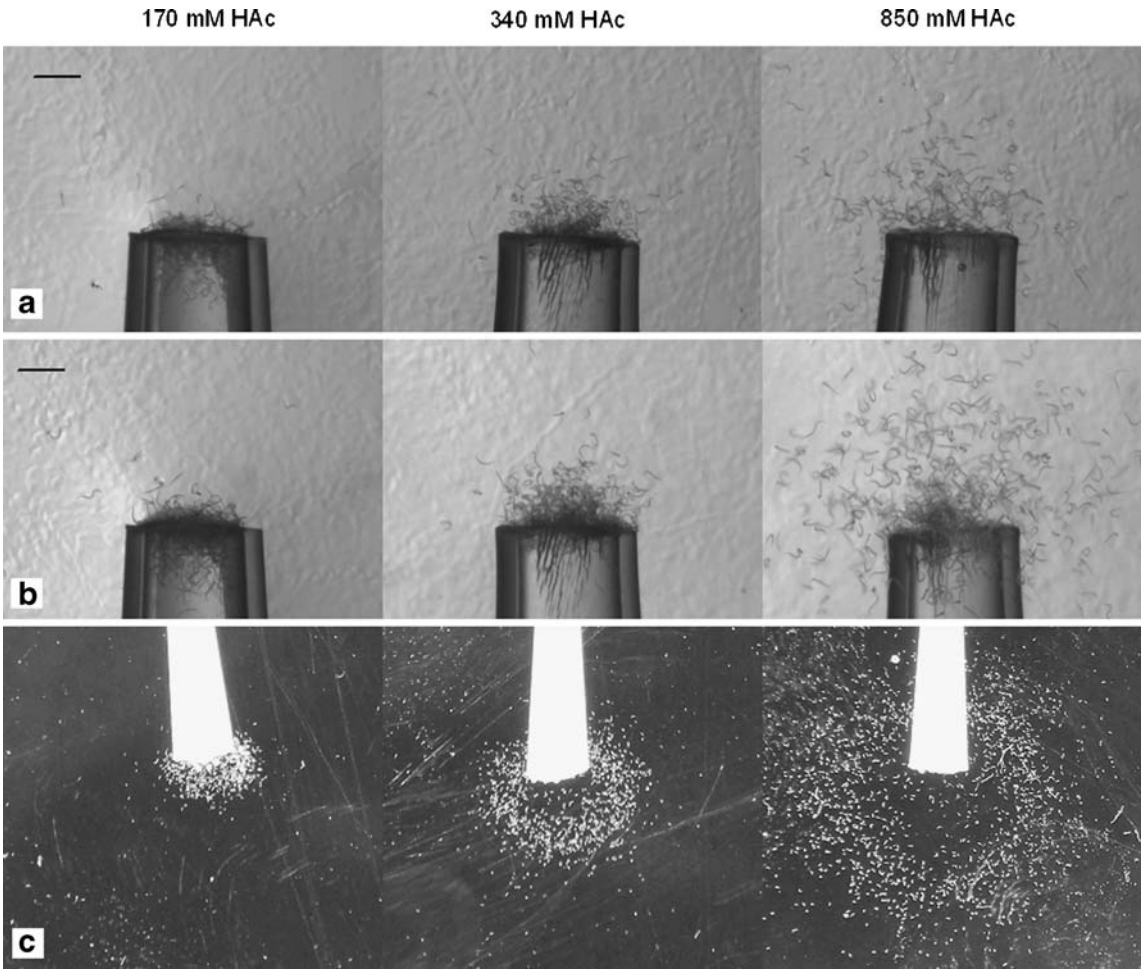

Fig. 3 Migration of *Meloidogyne hapla* VW9 J2 in acetic acid gradients in PF-127 gel. Dispensers contain 0.17 M, 0.34 M, or 0.85 M acetic acid as indicated at the top of the three columns of images. Dissecting microscope images of the dispenser small end were recorded at 5 h (**A**) and 24 h (**B**) after inserting dispensers in the gel. Scale bar = 1 mm. Lower magnification edge-lighted photographs of the dispenser large end at 24 h is shown in C. The diameter of the large end of the dispenser is~4 mm

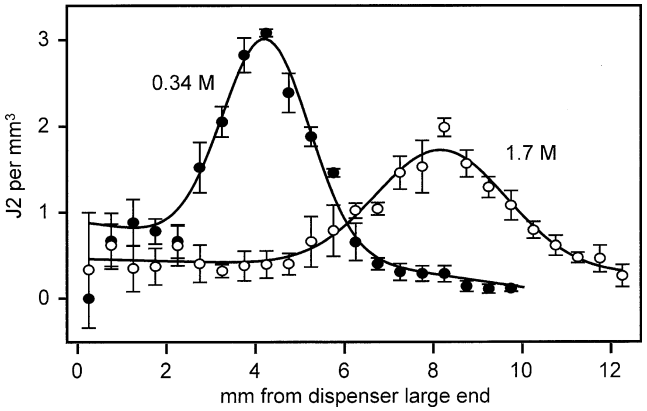

Fig. 4 Distribution of VW9 J2 in acetic acid gradients. Dispensers containing acetic acid in 23% PF-127 gel were immersed in buffered PF-127 gel containing 0.30 J2 per mm^3. After 5 h, the gel was photographed with edge lighting. Ninety degree arcs, scaled to 0.5 mm wide in the original gel, were superimposed on the enlarged photographic images with the origin of the arcs at the middle of the dispenser wide end. J2 within each arc were counted for the 0.34 M (●) and 1.7 M (○) acetic acid dispensers (four dispensers from three plates), and the data were transformed to J2 per mm^3 of gel. The average values and standard deviations are presented against distance from the dispenser large end. The standard deviation expanded at small distances from the dispenser because of the small volumes corresponding to the short arcs. Data were fit to Gaussian curves by a least-squares method

monoprotic carboxylic acids (acetic, formic, and propionic acids) induced movement of the nematodes to form a halo centered at the wide opening of the dispenser (Figs. 3C and 5A–C) and aggregation at the small opening (Figs. 3A&B, and 5G). For lactic, citric, and succinic acids, the J2 migrated to and aggregated inside the dispensers (for example, see Fig. 5E and H). The ability of citric acid and citrates to act as a J2 attractant was tested by charging dispensers with 0.40 M citrate plus citric acid buffers at pH~4.5 or ~5.5 (corresponding the observed pH values at the halo edges) and with sodium, potassium, ethanolammonium, or diethanolammonium as the cation. All of these citrate buffers, like citric acid itself, attracted J2 well into the dispensers, rather than just to the openings, suggesting that citrate/citric acid attracted J2 sufficiently to overcome any tendency to form a halo in a citric acid gradient (results not shown). Pyridinium ions were selected as another Brønsted acid because of the similarity of the pK_a (5.2) to that of acetic acid (4.8). Pyridinium methosulfonate (Fig. 5E) and pyridinium chloride (not shown) also caused aggregation of J2 inside the tip in a manner similar to that seen for citric acid.

Root-knot Nematode Species and/or Strains Differ in Responsiveness to Acetic Acid Different species and strains of root-knot nematodes differ in the rate at which they aggregated at root tips in PF-127 gel (Wang et al. 2009). Responses of different RKN species and strains to acetic acid gradients were compared 3 h after initiation of the assay (Table 1). *Meloidogyne hapla* strain VW9 had the highest aggregation at the dispenser tip of all the RKN strains tested. The nearly isogenic *M. javanica* strains VW4 and VW5, which differ in their ability to parasitize tomato with the resistance gene *Mi-1*, did not show significant differences in attraction to acetic acid. However, significant differences were seen among *M. incognita* strains derived from isolates originating from different locations and different hosts. Strains VW6, Beltran and W1 aggregated significantly less than *M. incognita* strain 577R. *M. incognita* strain Harmony, which was originally isolated from grape, aggregated much more slowly than the other strains. By 24 h and for several species and strains, the number of nematodes near the dispenser tip was too great to count with confidence, and was scored as described in Fig. 6. However, even for strain Harmony, the number of nematodes at the tip increased between 3 and 24 h, and the relative aggregation of the different strains remained the same (Table 1). The pH range of maximum aggregation was assessed at 24 h by using a microelectrode, and all were found to aggregate between pH 4.5 and 5.4. Thus, it did not appear that the strains differed in the pH range to which they were attracted, but they did differ in the rate at which they congregated in the gel region of that pH range.

Response of Nematodes to Gel Exposed to CO_2 To investigate RKN J2 response to CO_2, we delivered CO_2 to a 1.5 cm circle in the center of a PF-127 gel plate buffered with 10 mM Tris-MES, pH 7.1, in which J2 of *M. hapla* VW9 were distributed evenly. In a parallel experiment, CO_2 was delivered to a plate with the same gel, but without nematodes and with the pH indicator bromocresol purple. By two hours, the region of the gel exposed to CO_2 had acidified sufficiently to turn the indicator yellow (i.e., pH 5.2 or less), and nematodes began to aggregate outside the border of the circle. At 24 h, the yellow area remained limited to the circle area exposed to CO_2 with a gradient to blue in the 3 mm just outside the circle. Nematodes aggregated outside the circle area (Fig. 7A) whereas nematode numbers and distribution within the circle exposed to CO_2 did not noticeably change during the 24 h. The pH of the CO_2 exposed area was measured as 5.0–5.3, depending on position tested, and the pH outside the circle area was about 6.0. When delivery of CO_2 was stopped after 24 h, and the plate was examined at 48 h, nematodes were found to have aggregated within the circular area. At this time, the pH inside the circle was around 5.6, whereas that outside was around 6.0. This experiment was repeated four times with similar results. In a shorter time course, delivery of CO_2 was stopped after 4 h, and plates were observed at 24 h. In this experiment also, nematodes aggregated around the circle while CO_2

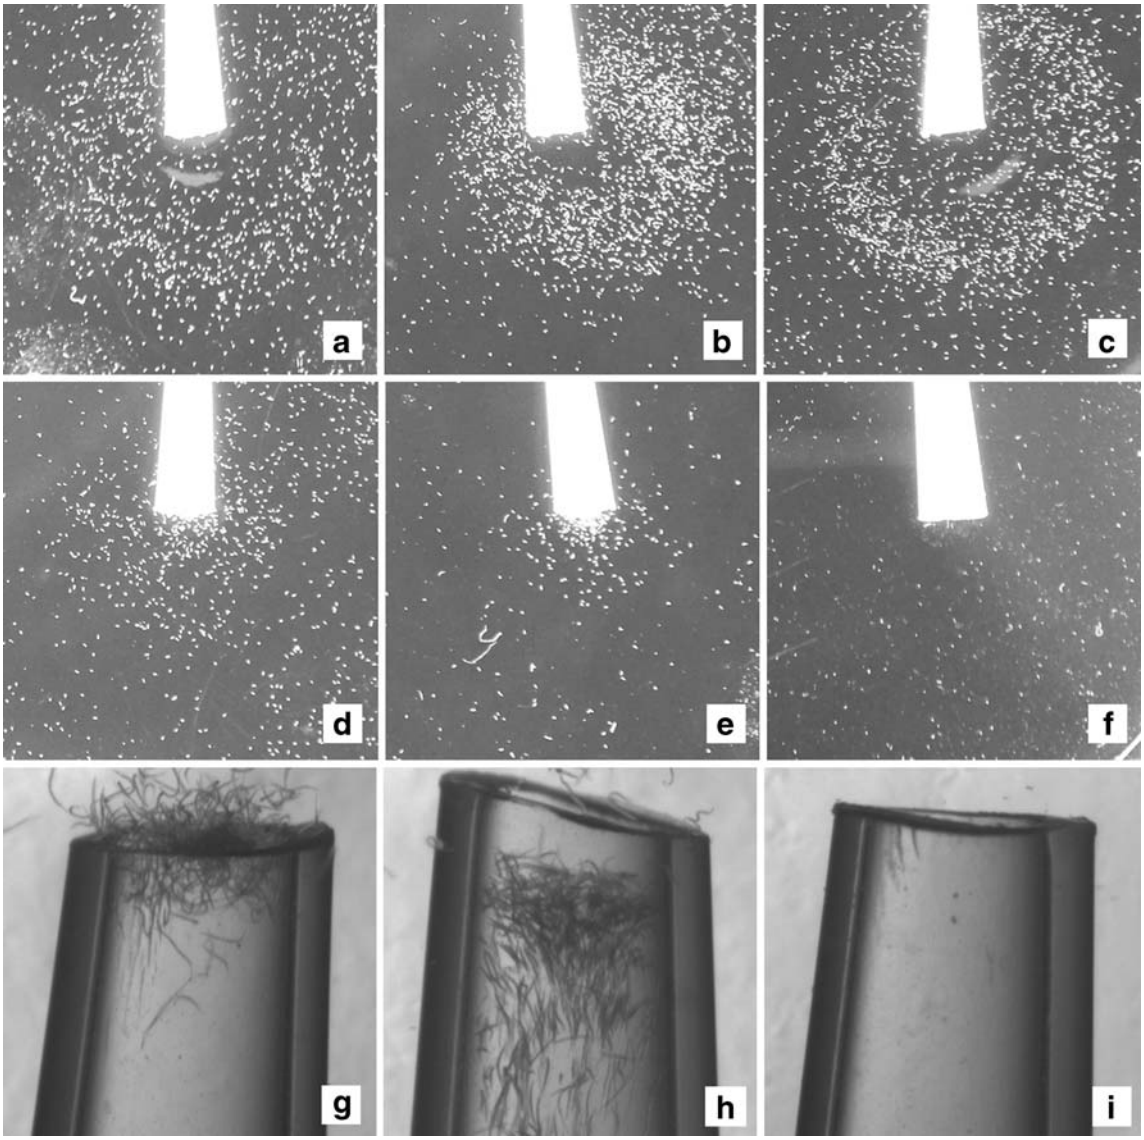

Fig. 5 Response of *Meloidogyne hapla* VW9 J2 to acid gradients in PF-127 gel. Each assay was in a Petri dish containing 6000 J2 in 20 ml of gel in 10 mM Tris-MES, pH7. Dispensers contained 0.40 M solutions of HCl (**A**), propionic acid (**B**, **G**), methane sulfonic acid (**C**), or pyridinium methanesulfonic acid (**E**), or 0.16 M citric acid (**D**, **H**), or water (**F**,**I**). All photographs were taken at 20 h after insertion of the dispensers. Panels A-F show the large end of the dispenser and were taken with edge lighting against a black background. Panels G-I show small opening of dispenser, and photomicrographs were taken under a dissecting microscope

was delivered, then moved inside during the next 24 h after the source of CO_2 was disconnected. At the latter time the pH inside the circle was ~5.8 whereas that outside was ~6.1.

To distinguish the response to CO_2 from that of reduced pH, the CO_2 experiment was repeated with gel buffered with 10 mM sodium acetate, pH 4.9. At 24 h after continuous CO_2 exposure, nematodes remained uniformly distributed throughout the gel and did not aggregate at the border of the circle (Fig. 7B). Using a microelectrode, the pH inside the circle was determined to be approximately 4.7 and that in the surrounding gel 4.9. At 24 h after removal of the CO_2 source, nematodes aggregated within the circle but to a much lesser extent than when the gel was buffered at pH 7.0.

Discussion

All tested strains of RKN J2 aggregated in a gel zone with a pH range of 4.5–5.4, e.g., from an acetic acid gradient. These species, as well as many other plant pathogens/symbionts, are strongly attracted to and invade roots in the zone of elongation. Growing root cells extrude protons, with the elongation zone being the most acidic region (Mulkey and Evans 1981; Pilet et

Table 1 Attraction to acetic acid of species and strains of root-knot nematode[a]

Species/ Strain	Isolate host and location	Nematodes within 5mm of tip	
		3h	24h
Meloidogyne hapla			
VW9	Tomato, CA	106.8A	+++
NCS	Unknown, NC	62.8B	++
LM	Unknown, France	71.5B	++
M. javanica			
VW4	Unknown, CA	57.0BC	+
VW5	Unknown, CA	50.5C	+
M. incognita			
VW6	Cotton, CA	26.8D	57A
Beltran	Lima bean, CA	37.0D	73A
Harmony	Grape, CA	4.5E	30.5B
557R	Tomato, NC	58.8BC	++
W1	Tomato, CA	28.8D	81.0A

[a] Two chemical dispensers filled with 0.17 M acetic acid were used for each plate and three plates for each treatment. At the indicated time after insertion of the dispensers, the number of nematodes within the 5 mm diam. circle, centered at the small end of pipette tip, was counted. The counts were corrected by subtracting similarly counted nematode numbers for dispensers containing gel alone. Significant differences between counts on different nematode strains at the 3 h time point are indicated with letters A-E ($P<0.05$). Nematodes continued to aggregate so that counts were not possible at 24 h for some trials, but relative nematode densities were assigned symbols +, ++, and +++ following the examples in Fig. 6. For the four strains whose numbers were assessed at the 24 h time point, significant differences are indicated by letters A and B ($P<0.05$).

al. 1983; Peters and Felle 1999). Based on pH indicator dyes, this zone was found to be less than pH 5 for maize seedlings grown on agar plates (Mulkey and Evans 1981). Using PF-127 gel and pH indicator dyes, we also found that *Medicago truncatula* and tomato seedlings produced an acid gradient around the root and could acidify the medium to pH 5 or less immediately adjacent to the root (Wang and Williamson, unpublished). The correlation of the most acidic region of the root with that which is most attractive to the nematodes is consistent with the possibility that pH gradients are signals that direct nematodes to the elongation zone of growing roots. However, while low pH is a marker for the growth zone of a wide range of host plants, the influence of the growth zone on pH in the soil is likely much less than it is in water or gels (Nichol and Silk 2001). In addition, we found that while the preferred pH range was the same for all root-knot nematode species tested, the rate of aggregation within the zone of preferred pH varied with the species and strains of root-knot nematode. *Meloidogyne hapla* VW9 aggregated most rapidly, whereas all *M. incognita* strains, except 577R, were significantly slower to aggregate than *M. javanica* and *M. hapla* species. These results cannot be reconciled directly with our previous observations of the relative migration rates of these same nematode species to host roots; i.e., movement of *M. incognita* and *M. javanica* J2 to tomato roots was much more rapid than that of *M. hapla* (Wang et al. 2009). Thus, pH is probably not the sole attractant to roots, and its relative importance may depend on the nematode strain as well as the host.

Fig. 6 Scoring aggregation of root-knot nematodes to acetic acid. The small opening of the dispenser with 170 mM acetic acid is shown at 24 h after initiation of the assay. **A**. *M. javanica* strain VW4. This sample would be scored as "+" in Table 1. **B.** *M. hapla* strain LM. This sample was scored as "++." **C.** *M. hapla* VW9 was scored as "+++." Scale bar = 1 mm

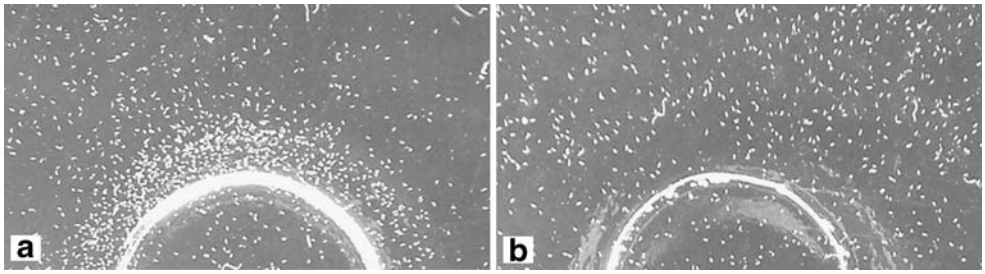

Fig. 7 Response of *Meloidogyne hapla* VW9 to CO_2 in PF-127 gel. **A**. At 16 h after continuous exposure to CO_2, nematodes aggregated just outside the area exposed to CO_2 with pluronic gel buffered with 10 mM Tris-MES, pH 7. **B**. No aggregation was observed when gel was buffered with sodium acetate, pH 4.9. At the start of the assay, 9000 J2 were dispersed in 30 ml PF-127 and poured into the Petri dish. The images show an arc of the 1.5-cm diameter circle that was exposed to CO_2. Note that the number of J2 inside the circle is similar in A and B

While all the acid solutions that we tested resulted in nematode aggregation, some appeared to be more attractive than others. For example, for citric, lactic, and succinic acids, nematodes migrated into the dispensers rather than forming a halo around the tip, suggesting that these acids may be specific attractants. In support of this, citrate salts with various cations at pH values of 4.5 or 5.5 also caused the nematodes to aggregate within the tip. Pyridinium hydrochloride and pyridinium methane sulfonate were tested because these Brønsted acids are similar to the tested carboxy acids in their acid gradient forming potential. However, the pyridinium salts proved to be strong attractants to RKN J2s; in agreement with this observation, pyridine has been reported to be an attractant for *C. elegans* (Dusenbery 1976). It is likely that nematodes respond to and integrate complex signals and/or combinations of signals in their natural environment and that perceived gradients may act in a synergistic or antagonistic manner. The assay described here has potential to identify and dissect some of these interactions.

Carbon dioxide has been widely reported to be an attractant to free-living, insect-parasitic and plant-parasitic nematodes (Pline and Dusenbery 1987; Robinson 1995; O'Halloran and Burnell 2003). However, some of these studies were carried out without buffers, and carbon dioxide can lower pH of aqueous solutions. In our assays, nematodes were attracted to just outside the CO_2-permeated central cylinder (Fig. 1) when the gel was in 10 mM Tris-MES, pH 7.1 (Fig. 7A), whereas nematodes remained uniformly distributed throughout when the gel was buffered with 10 mM sodium acetate, pH 4.9 (Fig. 7B). A pH value of 4.9 was selected because it is within the pH 4.5 to 5.4 range observed for the halos of nematodes that formed in acetic acid gradients (Fig. 3C) and because the calculated pH for water saturated with CO_2 is 4.4. That is, when the initial pH is 4.9, little perturbation of the gel pH is expected from introduction of CO_2; our gel pH measurements agreed with this expectation. Thus, for the pH 7.0 gel assay, it is likely that what attracted J2 to the region around the central cylinder was a pH gradient, not CO_2.

For either pH 7.0 or 4.9, the number of nematodes in the central cylinder of gel did not change in number while the cylinder was continuously exposed to CO_2. However, nematodes entered this area after the delivery of CO_2 was terminated. There are several possible explanations for the failure of the nematodes to enter the CO_2-exposed region. CO_2 is an anesthetic, and concentrations of CO_2 above 10% have been reported to cause a decrease in movement for *M. incognita* (Pline and Dusenbery 1987). Thus, perhaps the nematodes regained ability to move into the central region once the level of the dissolved gas had decreased sufficiently. Our pH measurements indicate that the pH remained lower in the central region compared to the periphery, possibly contributing to the attraction. In addition, it is likely that the oxygen level was lower in the region exposed to CO_2, and root knot nematodes may prefer less than ambient oxygen levels as does *C. elegans* (Gray et al. 2004). As with any in vitro assay, caution should be used in extrapolating in vitro experiments with more complex soil conditions. However, this system has the potential to provide new insights into nematode behavior in natural soil.

The method of dispenser immersion in PF-127 gel described here is simple in design and execution, and it produced steady-state pH gradients in which nematode movement was easy to visualize and document over time. Results were reproducible enough in both nematode distribution and maximum density, so that data from several plates could be combined and presented as a close approximation to a normal distribution of J2 density vs. distance from the dispenser end (Fig. 4). This system has advantages over agarose-based methods in which the test chemical is applied to a well in the agar (Wuyts et al. 2006) or on the surface of the gel (Ward 1973; Matsuura et al. 2007) to form a gradient. For agar-based assays, the volume of test substance that can be applied is limited, and sometimes a second application is needed to maintain the

gradient, whereas with our system the dispensers provided an ample reservoir of test chemical. The PF-127 assay medium in which nematodes are dispersed is three-dimensional. Therefore, the nematode is not constrained to orientations that may be sub-optimal for perception of chemical gradients by amphids and can move in any direction in response to a detected gradient. Photographs with edge lighting allowed population scale analyses of nematode behavior in response to chemical stimuli, although nematode entry into the dispensers was obscured. Under the microscope, local gatherings of nematodes, in the dispenser and elsewhere, were observed, and the clarity of the PF-127 gel allowed the examination of the behavior of individual nematodes.

Assays of this type have great potential for chemotaxis-response studies with a variety of potentially attracting substances, including root tissues (Wang et al. 2009) or small organisms, and should be suited for the study of the responses of a variety of small invertebrates, fungal zoospores, and other subjects.

Introduction

Papyriferic acid (PA; Fig. 1) is a dammarane triterpene and the principal component of the resin secreted by glandular trichomes (resin glands) produced by the current-annual-growth (CAG) twigs of the juvenile ontogenetic phase (seedlings and saplings; Kozlowski 1971) of the resinous tree birches *Betula neoalaskana* (synonym *B. resinifera*) and *B. pendula* (Reichardt 1981; Reichardt et al. 1984; Lapinjoki et al. 1991; Taipale et al. 1994; Bryant and Julkunen-Tiitto 1995; Julkunen-Tiitto et al. 1996). Several observations indicate that PA deters browsing by mammals. The intensity of browsing by the mountain hare (*Lepus timidus*; Rousi et al. 1991; Tahvanainen et al. 1991) and by the field vole (*Microtus agrestis*; Pusenius et al. 2002) on juvenile *B. pendula* correlated negatively with the density of resin glands on CAG twigs. Moose (*Alces alces*) foraging in birch provenance gardens maintained by the British Columbia Ministry of Forests severely browsed the seedlings and saplings of *B. papyrifera* but only lightly browsed the seedlings and saplings of *B. pendula* growing within a few meters (M. Carlson per. comm.). The juvenile ontogenetic phase of *B. papyrifera* produces only a trace of PA or no PA, whereas juvenile *B. pendula* produces abundant PA (Julkunen-Tiitto et al. 1996; Bryant et al. 2009). By using feeding trials with captive snowshoe hares (*L. americanus*), Reichardt et al. (1984) verified PA deterrence for this important browser of the North American boreal forest.

Reichardt et al. (1984) also demonstrated that captive snowshoe hares cannot meet their daily per capita browse requirement and maintain weight when restricted to a diet of PA-rich browse. When fed the PA-rich winter-dormant CAG twigs of *B. neoalaskana* saplings, the hares' maximum dry mass intake was 38 g/hare/d. When it is not extremely cold, the dry mass requirement for hares is about 150 g/d (Bookhout 1965), increasing as temperature declines (Pease et al. 1979) to a maximum of about 200 g/d at extremely low temperatures (Bryant unpublished data). PA toxicity is the most logical explanation for the starvation-level intake by hares of the PA-rich birch browse.

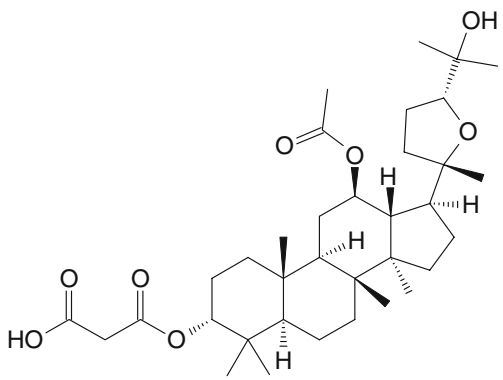

Fig. 1 Structure of papyriferic acid

This study aimed to characterize the biological effects of PA that underly its toxicity and resultant antifeedant effect in mammals. Papyriferic acid is a derivative of the triol, betulafolientriol oxide (BFTO), with a malonyl group at C-3 and acetyl group at C-12 (Fig. 1; Reichardt 1981). Malonic acid is a competitive inhibitor of succinate dehydrogenase (SDH), an enzyme in the tricarboxylic acid cycle in mitochondria that generates cellular energy by ATP production (Lehninger et al. 1993). Therefore, it seemed plausible that PA may be acting through inhibition of SDH, either after hydrolysis by esterases to release malonic acid, or by the malonate group on intact papyriferic acid interacting directly with SDH. The resulting decrease in energy production would constitute a noxious stimulus to the cell. Inhibition of mitochondrial energy production by malonate or other enzyme inhibitors leads progressively to toxicity and cell death (Wallace and Starkov 2000; Fernandez-Gomez et al. 2005). In the gastrointestinal tract, cellular damage leads to the release of serotonin (5-hydroxytryptamine or 5-HT) from enterochromaffin cells, which stimulates 5-HT_3 receptors on vagal afferents, activating neuronal pathways that leads to sensations of nausea, gastrointestinal discomfort, and pain (Spiller 2002; Costedio et al. 2007). Support for this 5-HT mechanism has come from the demonstration that the intake of food containing the *Eucalyptus* antifeedant, jensenone, can be increased in possums after administration of the 5-HT_3 receptor antagonist, ondansetron (Lawler et al. 1998).

In this paper, we report on the metabolism of PA in the rat, and the effect of PA on liver mitochondrial SDH from the rat, ox and rabbit.

Methods and Materials

Chemicals

Papyriferic acid was prepared from the ether extract of the resin of current-year-growth twigs of winter-dormant *B. neoalaskana* saplings (Reichardt 1981). Betulafolientriol oxide (BFTO) was prepared by hydrolysis of PA in alcoholic potassium hydroxide (Reichardt 1981). Other chemicals were purchased commercially and were of analytical reagent grade.

Animals

Rats (Hooded Wistar) and rabbits (New Zealand white) were obtained from the Central Animal House, University of Tasmania. Mitochondria were prepared from livers taken from these animals immediately after sacrifice, and from ox

livers obtained from freshly-killed animals at a local abbatoir. The experiments were approved by the University of Tasmania Animal Experimentation Ethics Committee in accordance with the Australian Code of Practice for the Care and Use of Animals for Scientific Purposes–2004, 7th Edition.

Dosing

Rats (about 300 g) were treated with 0.1% sodium phenobarbitone in their drinking water for 5 d, then after a washout period of 2 nights, they were gavaged with PA (100 or 500 mg/kg).The 100 mg/kg dose was suspended in mucilage of methyl cellulose, and the 500 mg/kg dose was dissolved in peanut oil (all dose volumes were 0.5 ml). Oil was used as the vehicle for the larger dose to limit possible discomfort to the animals. Food (standard laboratory chow) and water were available ad libitum. Urine and feces were collected separately for 0–24 h and 24–48 h and stored frozen (−20°C) until analyzed.

Analysis of PA and Metabolites

Aliquots of urine were diluted ten-fold with distilled water, buffered to pH 5, and incubated overnight with extract of *Helix pomatia* (β-glucuronidase plus aryl sulfatase; Boehringer Mannheim, Germany) to hydrolyse any conjugates (Boyle et al. 2000). Each 24 h collection of feces was blended with 200 ml water by using a laboratory homogenizer, then a 1 ml aliquot of the fine suspension was extracted with diethyl ether (2×5 ml), and the combined ether extracts taken to dryness at 40°C on a rotary evaporator. The residue was dissolved in 5 ml ethanol. Urine and fecal extracts were filtered (0.45 µ) before analysis by liquid chromatography-mass spectrometry (LC-MS). PA and BFTO were quantitated in fecal extracts by the addition of standards (50–250 µg in ethanol) to 1 ml of the 200 ml homogenates of control 24 h feces taken before dosing.

Metabolites were analyzed initially with a Novapak 150×3.9 mm C18 analytical column and Waters Alliance HPLC coupled to a Finnigan LCQ mass spectrometer using negative electrospray ionization (ESI) conditions as described earlier (McLean et al. 2003). The mobile phase was 85% methanol/ 15% 0.1 M ammonium acetate graded to 100% methanol over a 10 min period, with flow rate 0.8 ml/ min. Metabolites were identified as the products of expected transformations (hydrolysis and hydroxylation of PA) and verified by highly accurate mass measurements using a

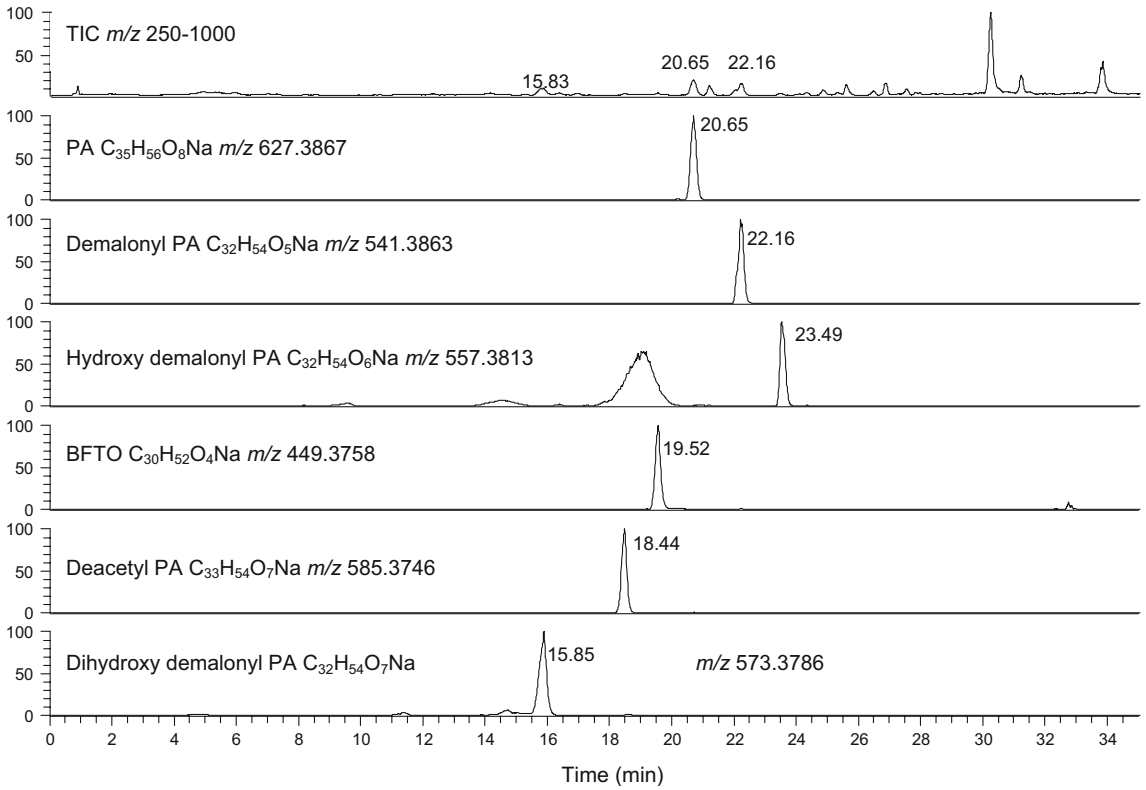

Fig. 2 Chromatograms from LC-MS analysis of rat feces showing TIC and individual mass chromatograms of papyriferic acid and metabolites. The masses are calculated values for the $[M+Na]^+$ ions. The $[M+H]^+$ ion was used in addition for betulafolientriol oxide (*m/z*=477.3957) and deacetyl papyriferic acid (*m/z*=563.3943). Chromatograms are of all measured masses within 6 ppm of the calculated exact masses

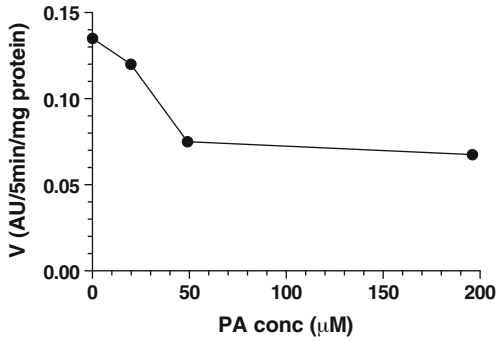

Fig. 5 Inhibition of metabolism of succinate (0.16 mM) by papyriferic acid using ox liver mitochondria

Mitochondrial Incubations

Mitochondrial particles were prepared from fresh liver of ox, rat, and rabbit using the standard method of gentle disruption of tissue and differential centrifugation (Smith 1967), and aliquots were kept frozen at -15ºC until used. The protein content of each was determined by the method of Lowry et al. (1951). Although the term 'mitochondria' is used here, the preparations were not intact but rather particles derived from disrupted mitochondria, which were used as a source of SDH and other mitochondrial enzymes.

Succinic acid was incubated with mitochondria and its oxidation by SDH was measured by the reduction of 2,6-dichlorophenol indophenol (DCPIP), which results in a decreased absorbance at 620 nm (after the method of King (1967) except that phenazine methosulfate was omitted). Reaction rates were measured in a Carey 219 spectrophotometer with cuvette chamber warmed to 25°C. Except for succinic acid, all solutions were kept on ice, and incubation mixtures were prepared at room temperature. PA solutions (20 mM) were prepared each day by dissolution of 6.05 mg in 500 μl ethanol. Incubation mixtures contained NAD^+ 50 μM (250 μl), sucrose Tris buffer 0.25 M pH 7.4 (210 μl), DCPIP 50 μM (1.5 ml), water (to make a final volume of 2.5 ml), PA (if added, 5–10 μl), mitochondria (20 or 40 μl). The spontaneous reaction rate was recorded for 5 min, then the reaction was initiated by the addition of substrate (100 μl). Potassium succinate 1 M was buffered to pH 7.4 and diluted with sucrose-Tris buffer to give the desired final concentration in the incubation mixture (0.1–40 mM). Solutions of malic and malonic acid were prepared similarly. Reaction rates were measured for 5 min, corrected by subtraction of the spontaneous reaction rate before substrate was added, and expressed as AU/5 min/mg protein.

Data Analysis

Plots of reaction velocities and enzyme kinetics were made by using Microsoft Excel and GraphPad Prism software. Plots of reaction velocity (V) vs. substrate concentration (S) were analyzed by non-linear regression to determine the Michaelis-Menten constants, V_{max} and K_m. The mechanism of inhibition was determined by Lineweaver-Burke plots of 1/V vs. 1/S and direct linear plots (DLP) of paired V and S points (Cornish-Bowden 2004). The K_i value for the enzyme-inhibitor-substrate complex (Ki_{EIS}) was determined by a secondary plot of $1/V_{max}$ vs. inhibitor concentration (I). Mean data are given±SE.

Results

Analysis of Standards

LC-MS analysis of PA and BFTO using the LCQ instrument showed single peaks with characteristic ions, as detailed under "Metabolite Identification". The lower limit of detection was well below 1 ng.

Metabolism of PA in Rats

The rats seemed unaffected after the 100 mg/kg dose, and after the 500 mg/kg dose, they were inactive and lay prone for an hour or two, but later in the day resumed normal activity. By the following day, all rats were eating well and seemed unaffected by the administration of PA. Neither PA nor its metabolites were detected in urine, using the LC-MS methods described below for fecal analyses.

Table 1 Enzyme kinetics of succinate metabolism and its inhibition by papyriferic acid in liver mitochondria from three species

	Succinate alone			Succinate with PA		
Species (N)	V_{max} AU/5 min/mg protein	K_m mM	PA μM	V_{max} AU/5 min/mg protein	K_m mM	K_{iEIS} μM

Fig. 6 Effect of papyriferic acid (40 and 80 μM) on the metabolism of succinate by ox liver mitochondria. The inset shows detail at low succinate concentrations

Metabolite Identification

PA and its metabolites were observed as $[M+H]^+$ and/or $[M+Na]^+$ ions. Figure 2 shows analysis of a rat fecal extract using the high resolution Orbitrap mass spectrometer, which gives mass measurements to better than 2 ppm. The top panel shows the Total Ion Chromatogram (TIC) monitoring all ions from *m/z* 250–1000 for up to 35 min. From this dataset, mass chromatograms were extracted by selection of the expected exact masses for PA and putative metabolites, and these are shown in the lower panels. These targeted metabolites were based on the expected hydrolysis of ester groups and/or hydroxylation of the triterpene skeleton commonly observed for other xenobiotics (Boyle et al. 2000; Parkinson and Ogilvie 2008). These chromatograms showed single peaks over the narrow mass range (± 6 ppm) selected for display where only one compound was possible. Metabolites readily observed included BFTO, demalonyl PA, deacetyl PA, several hydroxylated demalonyl PAs, and several dihydroxylated demalonyl PAs.

Since all ions had been monitored, it was possible to display the full mass spectrum for each peak, as shown in Figs. 3 and 4. PA did not show an ion at *m/z* 605 ($[M+H]^+$) but did give an intense ion for the sodium adduct $[M+Na]^+$. BFTO, however, showed both ions with approximately equal intensity (Fig. 4) and both were used for the extracted mass chromatogram (Fig. 2) and quantitation.

Tandem MS data acquired on the Finnigan LCQ instrument added further support to the assignments of these metabolites, as the three putative metabolites that retained the acetyl group showed a strong product ion for loss of acetic acid.

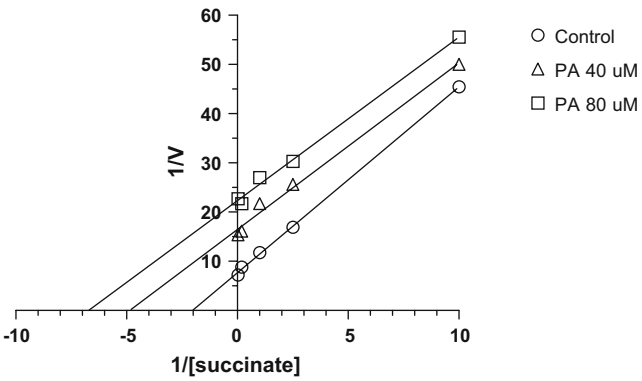

Fig. 7 Lineweaver-Burke plots of data from Fig. 6. The plot is explained in the "Results"

Quantitation of PA and BFTO

Following a dose of 150 mg PA given to two rats (500 mg/kg), the amounts of PA recovered from feces were 52 mg (rat 1) and 5 mg (rat 2) in the 0–24 h collection, and 2 mg and 0 mg, respectively, in the 24–48 h collection. The corresponding recoveries of BFTO were 2 mg and a trace in the first 24 h, and 0.2 mg and 0 mg in the second 24 h. No other metabolites were quantitated, as the standards were not available, and their amounts could not be estimated directly from the ion intensities.

Mitochondrial Incubations

Initial experiments with ox liver mitochondria showed that PA is a potent inhibitor of the mitochondrial oxidation of succinic acid. Figure 5 shows that the velocity of succinate oxidation decreased progressively as the concentration of PA increased from 0 to 200 μM, with marked inhibition at 50 μM.

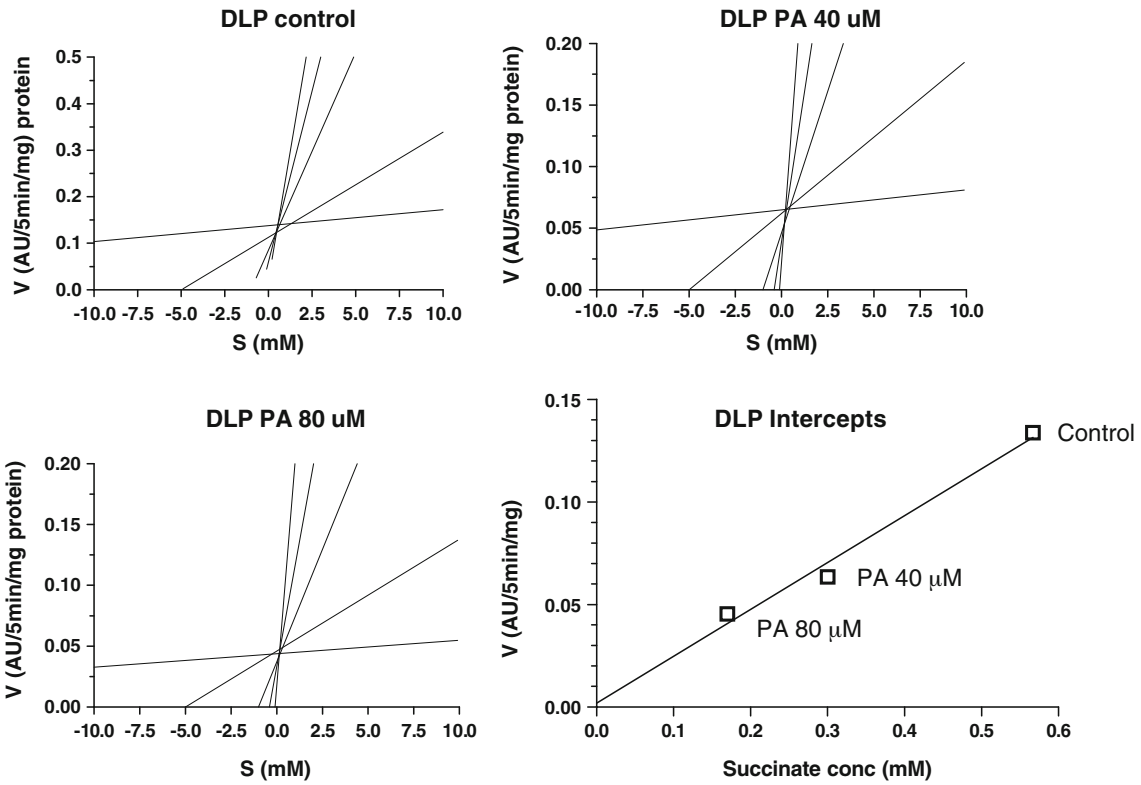

Fig. 8 Direct linear plots of data from Fig. 6 showing intercepts which regressed linearly towards the origin with increasing concentrations of papyriferic acid. The plot is explained in the "Results"

In a series of experiments with liver mitochondria from ox, rabbit, and rat, PA was found to act as an uncompetitive inhibitor of SDH. Enzyme kinetic values for the three species are shown in Table 1. V_{max} is expressed per mg protein to enable comparison between preparations. In all species, both V_{max} and K_m were decreased in the presence of PA. However, rat mitochondria required a higher concentration of PA (80 μM) to show this effect.

Figure 6 shows an example of the V vs. S plot for ox liver mitochondria where PA (40 μM) reduced the maximum reaction rate by more than 50%. At low succinate concentrations (Fig. 6 inset), the inhibition was relatively less complete. The Michaelis-Menten constants calculated from these data are also given in Fig. 6. The Lineweaver-Burke regression lines of these data (Fig. 7)

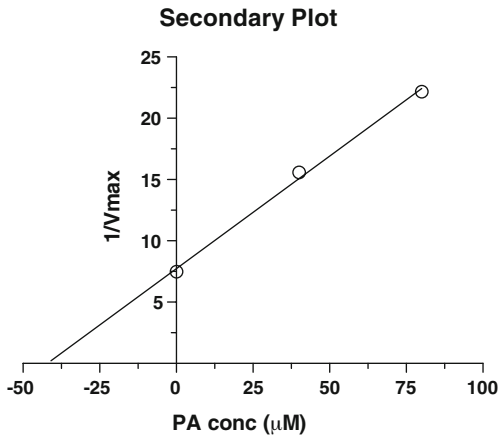

Fig. 9 Secondary plot of data from Fig. 6, showing 1/Vmax vs. concentration of papyriferic acid. The intercept at −42.1 μM gives the K_{iEIS}

	Control	PA 40 uM	BFTO 40 uM	BFTO 80 uM
VMAX	0.1171	0.06019	0.1155	0.1184
KM	0.3966	0.1878	0.3881	0.4117

Fig. 10 Lack of effect of BFTO (betulafolientriol oxide, the hydrolysis product of papyriferic acid) on the metabolism of succinate by ox liver mitochondria. At the highest concentration (200 μM), BFTO was only tested at 40 mM succinate. The inhibitory effect of papyriferic acid is shown as a positive control

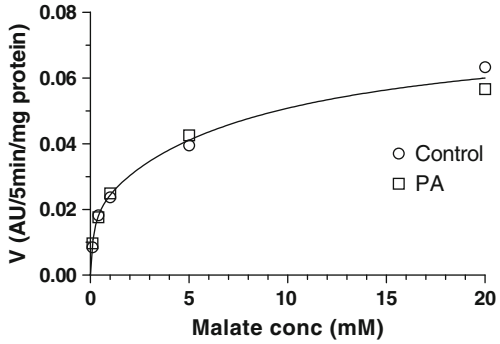

Fig. 11 Lack of effect of papyriferic acid (160 μM) on the metabolism of malate by rabbit liver mitochondria. Similar data were obtained for ox liver (data not shown)

show that PA produced a concentration-dependent parallel shift from the control line, indicating that the mechanism of inhibition was uncompetitive (Cornish-Bowden 2004). This was confirmed by direct linear plots in which paired values of V and S are connected by straight lines (Fig. 8). Each plot (control and two concentrations of PA) produced an intercept of these lines, and a separate plot of these intercept values (Fig. 8: DLP Intercepts) showed a linear regression to the origin with increasing concentration of PA. This is another indication that PA inhibits by an uncompetitive mechanism. A secondary plot of $1/V_{max}$ vs. concentration of PA using the same data (Fig. 9) showed a linear regression with an intercept on the PA concentration axis which gave the value of K_{iEIS} (42.1 μM).

The inhibitory activity was lost when PA was hydrolyzed to BFTO (Fig. 10), indicating that the malonyl group, and possibly the acetyl group, was required for activity. The inhibition was selective for SDH as PA, at an even higher concentration (160 μM), had no effect on malate metabolism (Fig. 11). This shows that malate dehydrogenase was unaffected by PA.

Malonic acid is known to be a competitive inhibitor of SDH, and this was confirmed in mitochondria from each of the species used. Figure 12 shows this for ox liver mitochondria. The Lineweaver Burke plot shows the characteristic pattern for competitive inhibition, with an intercept at $1/V_{max}$. Nonlinear regression analysis of the V vs. S data showed that V_{max} values were similar for control (0.154 AU/5 min/mg protein) and in the presence of 50 μM malonate (0.123 AU/5 min/mg protein) while, as expected for competitive antagonism, the K_m values for succinate differed for control (0.097 mM) and malonate incubations (0.226 mM).

Discussion

The results show that PA is a potent and selective inhibitor of mitochondrial SDH, and that it acts by an uncompetitive mechanism. PA had similar effects in mitochondria from ox, rabbit, and rat, indicating that this is a general effect to be expected in other mammals, including the snowshoe hare and other animals that browse on twigs of birch that produce PA (e.g., the juveniles of *B. neoalaskana* and *B. pendula*, Reichardt et al. 1984; Rousi et al. 1991; Tahvanainen et al. 1991; Julkunen-Tiitto et al. 1996; Pusenius et al. 2002; Bryant et al. 2009). This study does not prove that inhibition of SDH underlies the anti-feedant effect of PA, but this mechanism seems likely. As discussed in the "Introduction", noxious stimuli, such as those produced by inhibition of mitochondial energy supply, can release serotonin in the gut leading to sensations such as nausea, which would suppress feeding (Spiller 2002; Costedio et al. 2007). In vivo, mitochondria are protected by membrane barriers of the host cell and the organelle itself, but PA is a lipophilic substance and would be expected to readily permeate biological membranes.

Although the lack of urinary metabolites indicates that PA is poorly absorbed into the bloodstream from the gut, its potency in the in vitro experiments suggests that only a small amount would need to enter the gut cells to inhibit mitochondrial activity and elicit an antifeedant response.

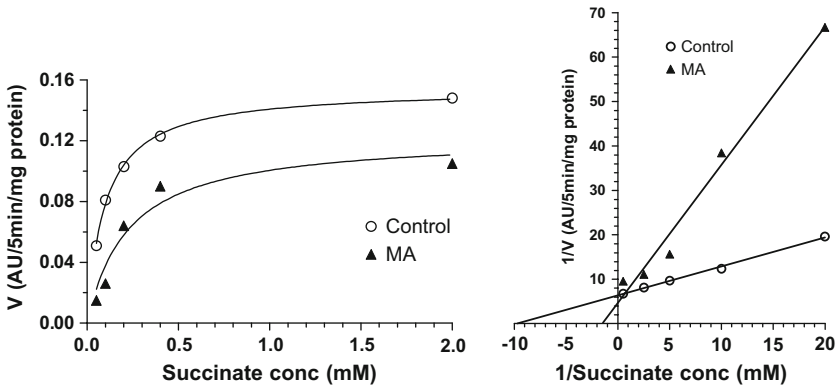

Fig. 12 Effect of malonic acid (MA, 50 μM) on the metabolism of succinate by ox liver mitochondria

Poor absorption may also explain why, despite its potency in vitro as an enzyme inhibitor, hares can ingest relatively large doses of PA before ceasing feeding (Reichardt et al. 1984; Bryant et al. 1994, 2009).

The intestinal epithelium possesses the P-glycoprotein efflux transporters that are expressed at the apical surface of enterocytes (Kullak-Ublick and Becker 2003) and can regulate the systemic absorption of plant secondary metabolites (Sorensen and Dearing 2006). However, the cycle of diffusion into the enterocyte and transport back into the lumen of the intestine effectively prolongs the cellular residence time and increases the extent of interaction with cellular enzymes (Johnson et al. 2001). This would promote both the inhibition of SDH by PA, and the possible metabolism of PA by cellular enzymes.

PA also is a steroid and is, therefore, a possible substrate for the hepatic organic anion transporter, which takes bile acids, endogenous steroid hormones, and plant steroids (e.g., digoxin) from the blood into bile (Kullak-Ublick and Becker 2003). This would also act to decrease the systemic absorption of PA while exposing it to the xenobiotic metabolizing enzymes of the liver. A full pharmacokinetic study is required to resolve these questions.

Although the metabolic study found that in vivo at least some of the PA loses its malonyl group by hydrolysis, it seems likely that PA acts as the intact molecule rather than by releasing malonic acid. First, as shown in this study, PA and malonate inhibit SDH by two different mechanisms (uncompetitive and competitive, respectively). Second, the inhibition of ox liver SDH by 50 μM malonate was less than that by 40 μM PA, and even if all of the PA were hydrolyzed (an unlikely event given the chemical stability of PA to hydrolysis and absence of appropriate enzymes in mitochondria), the concentration of malonate could not exceed 40 μM.

The uncompetitive mechanism of action, in which the inhibitor binds to the enzyme-substrate complex, has the consequence that inhibition is relatively greater at high substrate concentrations, and that even at high concentrations of inhibitor the reaction is not completely inhibited (as shown in Fig. 5). Similarly, at low succinate concentrations, inhibition is not complete (Fig. 6, inset). This suggests that, unlike malonate, which causes dose-dependent neurotoxicity (Fernandez-Gomez et al. 2005), PA will not produce irreversible toxic effects. This is supported by the observations in rats given high oral doses of PA, which showed temporary discomfort followed by a full recovery the next day.

The original hypothesis that PA, like malonate, interacts with the succinate binding site on SDH must be discarded, since the mechanistic evidence indicates that PA does not bind in place of the substrate but to the enzyme-substrate complex. Recent evidence suggests where this site may be. α-Tocopherol succinate (TOS) is a selective inducer of apoptosis in cancer cells, and now has been shown to act through the inhibition of SDH activity of complex II by interacting with the ubiquinone binding sites (Dong et al. 2008). Like PA, TOS has a lipophilic (C_{29}) region, which is esterified with a dicarboxylic acid, and in both cases activity is lost after hydrolysis. Further study will be required to determine whether PA acts through binding to the ubiquinone sites, and this could be commenced by using molecular modeling since the crystal structure of complex II has been described (Sun et al. 2005).

Although data are presented on three species, this study was not designed to compare the effects of PA in different species, which requires more rigorous preparation and characterization of mitochondria (Hulbert et al. 2006). There can be dramatic differences among species in the susceptibility of their mitochondrial enzymes to inhibition (Krueger et al. 1995). If these differences also occur as variations among geographically separated congeners or conspecifics, then this would be an important topic for future study, for it would provide a biochemical test of Thompson's (2005) geographic mosaic of selection hypothesis.

A geographic mosaic of birch-hare coevolution may exist across the vast boreal forest and north temperate forest of North America (Bryant et al. 2009). This suggests that a transcontinental comparison of the PA tolerance of snowshoe hares from regions home to birches with PA concentrations ranging from high to low is warranted, especially given the unprecedented spatial scale at which these terrestrial mosaics could operate relative to other previously documented consumer-resource mosaics (e.g., Thompson 2005; Thompson and Fernandez 2006; Toju and Sota 2006; Siepielski and Benkman 2007; Toju 2008). The comparison would be a transcontinental test of Thompson's (2005) geographic mosaic of coevolution hypothesis.

Acknowledgments We are grateful to Debbie Orchard for assistance in preparation of mitochondria, Lai K. Wong for undertaking the initial incubations, and Edwin Lowe for Orbitrap LC-MS data. We also thank Jennifer Forbey for helpful comments on the manuscript.

which is a very different from the emissions of healthy plants (Kännaste et al. 2008). In the present study, we compared the volatile blends released by a Norway spruce clone infested either by *Nalepella* sp. Boczek var. *Picea abietis* (Acarina, Ereophyidae) (Phytoptidae) (Löyttyniemi 1973) or by *Oligonychus ununguis* Jacobi (Acarina, Tetranychidae) (Jeppson et al. 1975). For a control, volatiles from an uninfested spruce clone also were analyzed. Both of the mite species can be serious pests of conifers in nurseries (Ehnström et al. 1974; Lehman 1982) and, due to their rapid development from larval to adult stages, five or more generations of *Nalepella.* sp. (Löyttyniemi 1973; Lehman 1982) can develop per year.

Pine weevils are attracted to weakened trees, and as the mite-infested, small plants must be regarded as highly stressed, we studied whether or not the main odors emitted by heavily infested plants were attractive to the weevils. The major compounds emitted by mite-induced spruce were tested separately and in combination with host odors in two multi-choice laboratory bioassays.

Methods and Materials

Biological Material Potted *Picea abies* plants of clone 1321, 4–5 yr-old and ca. 30 cm tall, originating from the clone archives maintained by Skogforsk (the Forestry Research Institute of Sweden), and two species of mites, identified as *Nalepella* sp. and *Oligonychus ununguis*, were used in this study. Mites of each species were fed separately for a year on the needles of a set of 8 plants. Plants were provided with artificial daylight (18 h light/6 h dark cycles, 20°C) and watered weekly. At the end of this period, both mite species completely infested the plants (approx. density: 1–5 mites /cm^2). A set of control plants was kept mite-free throughout this period.

Pine weevils (*Hylobius abietis*) of both sexes were collected during spring migration at sawmills in central Sweden. After collection, the weevils were stored in darkness at 10ºC and provided with fresh conifer bark as food. These conditions interrupted their reproductive development. They then were transferred to a chamber where they were kept for at least 10 d at 18 h light/6 h dark cycles, and 20°C prior to the bioassays. Oviposition generally commenced about a week after the transfer to the chamber. The weevils had continuous access to conifer bark as food until 24 h before use in the bioassay.

Collection of Spruce Volatiles The volatile compounds released by 4 plants infested by a mite species and 4 controls were collected by solid-phase microextraction (SPME) as follows. Each plant was enclosed in a plastic bag (polyethylene terephthalate, Toppits Melitta, 35× 43 cm). A fused silica fiber coated with a 65 μm film of polydimethylsiloxane/divinylbenzene (Supelco, Bellefonte, PA, USA) was inserted into the bag to collect the volatiles emitted from the living plant. Volatiles were collected over a 24 h period for GC-MS analysis and a 5 h period for 2D-GC-analysis (see below).

Separation and Identification of Volatiles The chemical composition of the volatiles in each headspace was analyzed using a Varian 3400 gas chromatograph (GC) connected to a Finnigan SSQ 7000 mass spectrometer (MS) operated in electron ionization, full-scan mode (ionization energy, 70 eV; injector temperature, 215°C; ion source temperature, 150°C; 30 s splitless injections; mass range 33–400 m/z). The GC was equipped with a CB1 column (Supelco, 30 m, 0.25 mm id and 0.25 μm film thickness). Analytes were eluted using the following temperature program: 40°C held for 1 min, followed by a 4°C/min gradient to 190°C, held for 0.01 min, then a 20°C/min gradient to 220°C, held for 10 min; helium (pressure 10 psi) was used as the carrier gas. Spectra in the NIST (National Institute of Standards and Technology) and MassFinder 3.06 reference libraries were used in conjunction with published retention indexes (RIs) and mass spectra of available reference samples for identifying the spruce volatiles (Davies 1990; Ruther 2000).

In addition, the enantiomeric compositions of the chiral terpenes that strongly affect the pine weevil's behavior were analyzed by 2D-GC (Borg-Karlson et al. 1993). In the first GC, a DB-wax column (J&W Scientific™, 30 m, 0.25 mm id, 0.25 μm film thickness) was used with an injector temperature of 215°C (30 s splitless injections), and the following temperature program: 40°C held for 2 min followed by a 4°C/min increase to 130°C, held for 12 min, a further 4°C/min rise to 150°C, held for 0.01 min, then a final 10°C/min gradient to 220°C, held for 10 min. In the second GC, an HP Chiral-20 β 19091G-B233 (J&W, 30 m×0.25 mm×0.25 μm, 20%) was used to separate the chiral constituents using a temperature program of 55°C for 11 min, followed by a 1°C/min increase to 75°C, held for 65 min, and finally a 1°C/min rise from 75°C to 90°C, held for 60 min. Helium was used as the carrier gas at a pressure of 34 psi for the first and 22 psi for the second GC. Both GCs were equipped with a flame ionization detector (FID), and the temperature of the FIDs during the analyses was 250°C.

Chemicals Standards that were not already available in our laboratories were purchased, at the highest purity offered (>98%) from Lancaster Synthesis or Sigma-Aldrich.

Preparation of Dispensers Capped polyethylene tubes (1.5 ml, 1 mm thick walls) were used for dispensing (-)-

linalool and (*E*)-β-farnesene, while 1 ml tubes with 2 mm walls were loaded with MeSA for the bioassays with the pine weevil. Due to the poor emission of (*E*)-β-farnesene, a metal needle (0.5 mm diam.) was used to puncture 10 holes in the walls of each dispenser. In each tube, 10 µl of a single compound were added.

Emissions from Loaded Dispensers The emission rates from the dispensers loaded with (-)-linalool, (*E*)-β-farnesene, and MeSA in dynamic conditions were checked before use in the bioassays by hanging one dispenser containing each of the three substances in a 1.8 liter glass jar, and pumping air into the jar using a 224-PCXR7 SKC universal pump (SKC) at room temperature through a Porapak Q filter with a flow rate of 450 ml/min. After 2 d of stabilization, a fused silica fiber with a 65 µm coating of polydimethylsiloxane/divinylbenzene (Supelco, Bellefonte, PA, USA) was inserted into the jar to trap the volatiles released during 1 h.

Laboratory Bioassay with H. abietis The behavioral response of *H. abietis* to three mite-induced compounds (linalool, (*E*)-β-farnesene, and MeSA) was examined in two experiments in a multi-choice arena with 24 pitfall traps. The first experimental set-up included 18 traps that contained one dispenser each (six for each compound) and six control traps with no odor dispenser. The second experiment differed from the first in that a freshly cut piece of Norway spruce twig (0.5 cm diam., length 2 cm) was suspended in each of the 24 traps. Thus, the second experiment measured the response of *H. abietis* to each of the three compounds in combination with a blend of attractive host volatiles, mainly monoterpenes. Each of the two experiments was run four times, twice with 50 males and twice with 50 females. Each run lasted 24 h, after which the numbers of weevils that had entered each of the 24 traps were counted.

The arena was made of black Perspex and covered an area of 100×70 cm, with 14 cm high sides painted with Fluon RAD 1090 (AG Fluoropolymers, Thornton, Lancashire, UK) to prevent weevils from climbing up. We uniformly distributed 24 conical plastic jars into holes (65 mm) on the bottom of the arena. Each jar was capped with a plastic lid under which the dispenser (and the piece of spruce in experiment 2) was suspended, out of reach of the weevils. The jar extended 30 mm above the arena floor. Eight holes (14 mm diam.) with their lower edge 5 mm above the floor of the arena were equally spaced around each jar. Thus, the weevils in the arena had to actively climb up 5 mm to enter a hole and fall into the trap. The beetles entering a trap fell through a funnel attached to the open bottom of the jar and into a container 40 cm below the arena. According to results of separate tests, these captured weevils did not affect the likelihood of additional weevils entering the traps.

In each of the two bioassays with *H. abietis,* the significance of differences in the data obtained for the males and females was tested by heterogeneity *chi-square* analysis, and it was found that these data could be validly pooled. The *chi-square* goodness of fit of the pooled data was then calculated with the null hypothesis of equal numbers of weevils entering the differently baited traps.

Results

Emissions from Healthy and Infested Spruces Large differences in the composition of emitted volatiles were found between the healthy and heavily mite-infested spruces (Table 1, Fig. 1). Limonene was the dominant monoterpene in the emissions of healthy spruces, especially the (-)-enantiomer, which accounted for 80% of the limonene content (Table 1). Feeding by both species of mites induced the release of several compounds, not detected in the emissions from the uninfested controls, including the terpenes (*Z*)-β-ocimene, 2,6-dimethyl-2,6-octadiene, 4,8-dimethylnona-1,3,7-triene (DMNT), *cis*- and *trans*-linalooloxides (furane type), neral, geraniol, geranial, *trans*-α- and *trans*-β-bergamotene, (*Z*)-β-and (*Z*,*E*)-α-farnesene (Table 1). MeSA and (*E*,*E*)-α-farnesene were the main compounds in the bouquet of *Oligonychus ununguis*-infested spruces, while (*E*)-β- and (*E*,*E*)-α-farnesene dominated the emissions of *Nalepella* sp.-attacked spruce plants (Table 1, Fig. 1). In addition, both mite infested spruce specimens released linalool with similar enantiomeric composition; the (-)-enantiomer accounting for ca. 95% of the total linalool released.

Among many other compounds, spruces attacked by the mites released several green leaf volatiles (GLV:s), e.g., (3*Z*)-hexenol, (3*Z*)-hexenyl acetate and hexyl acetate, and various aromatic compounds, e.g., benzaldehyde, benzylalcohol, benzyl acetate, 1,3-dimethoxybenzene, benzoic acid, estragole, and vanillin (Table 1).

Comparison of the Emissions from Spruces Infested by the Two Mite Species Only grafts infested with mites of *Nalepella* sp. emitted: (3*Z*)-hexenol, (3*Z*)-hexenyl acetate, and hexyl acetate; the oxygenated monoterpenes *cis*-linalool (furanoid) and linalyl acetate; and the sesquiterpenes (*Z*)-β-farnesene, *trans*-α-bergamotene, and *trans*-β-bergamotene. Neral was emitted only from *O. ununguis*-infested spruces (Table 1). The spruces were infested for a year before the experiment, and the infestation was regarded to be in a steady state, with a fairly even density of mites. Nevertheless, there were substantial between-plant variations in the

relative amounts of volatiles induced by the mites. Despite this variation, certain compounds could be regarded as being mite-specific (Table 1, Fig. 1).

The profiles of the emissions of aromatic compounds from infested plants seemed to be related to the species of mite. Vanillin was present in small amounts in the emissions from both types of infested spruces. Feeding by *O. ununguis* and *Nalepella* sp. mites triggered increases in the emissions of MeSA compared to healthy spruce. However, MeSA was present in larger amounts in the emissions of spruce attacked by *Naplepella.* sp.

Release Rate of Volatiles by Dispensers In dynamic air conditions, stabilization time was required to allow the rate of release of compounds from the dispensers to reach a steady state (Fig. 2). After this time, according to the calibration, the dispensers emitted on average 20 ng of the test compound per h. These dispensers were used in the laboratory bioassays to assess the effects (attraction/repellence) of the compounds on the behavior of pine weevils. Under similar conditions, we estimated that the *Nalepella* sp.-infested spruces released approximately 1, 11, and 8 ng per h (-)-linalool, (*E*)-β-farnesene, and MeSA, respectively.

Results of Laboratory Bioassays with H. abietis The *Chi-square* analysis of the pooled data for each of the two experiments showed that the distribution of captured weevils differed significantly from an even distribution between the differently baited traps (*Chi-square*=23.9, *df*=3, $P<0.001$ for experiment 1 and *Chi-square*=19.7, *df*=3, $P<0.001$ for experiment 2) (Fig. 3). In the first experiment, when the three substances were presented without the addition of host volatiles, (*E*)-β-farnesene attracted both male and female *H. abietis*. A similar tendency was found for (-)-linalool, but MeSA did not appear to elicit any behavioral response. When the compounds were presented together with spruce odor, both sexes were attracted less strongly to the traps with both MeSA and (-)-linalool than they were to the control traps with host plant odor alone. (*E*)-β-farnesene did not affect the attraction of *H. abietis* to host odor.

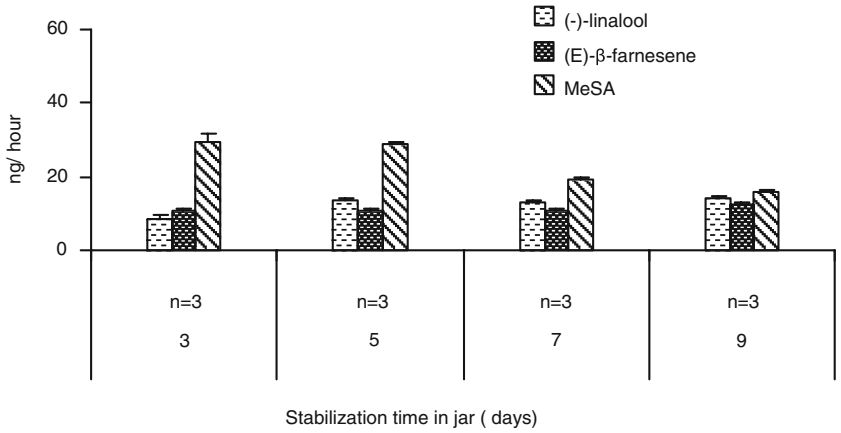

Fig. 2 Release rates (mean±SD) of (-)-linalool, (*E*)-β-farnesene, and MeSA from dispensers in flowing air. The mean emission rates of the compounds were obtained from three measurements. Capped polyethylene tubes, with 1 mm thick walls were used with (-)-linalool and (*E*)-β-farnesene, while tubes with 2 mm thick walls were loaded with methyl salicylate. Release of (*E*)-β-farnesene was increased by perforating the walls of the tubes containing it

Discussion

We have previously shown that clones of small conifer plants infested by mites release many kinds of compounds, especially terpenes (Kännaste et al. 2008). Arimura et al. (2000a, b) showed that DMNT and (*E*)-β-ocimene released by bean plants attacked by the spider mite *Tetranychus urticae* activate genes involved in the induced defense reaction of intact plants. Moreover, green leaf volatiles, (3*Z*)-hexenol and (3*Z*)-hexenyl acetate, which are also released during ozone damage, have been claimed to activate the defense genes of neighboring intact plants (Arimura et al. 2001; Heiden et al. 2003). In addition, Shulaev et al. (1997) postulated that methyl salicylate (MeSA) is involved in plant — plant communication, and recent studies have proved its involvement in systemic acquired resistance in plants (Park et al. 2007).

Effects of plant volatiles on the behavior of forest pests are of both fundamental interest to biologists and great practical interest to foresters (Tominaga et al. 1984; Nordlander 1990, 1991; Byers 1992; Wibe et al. 1997; Thiery and Marion-Poll 1998; Byers et al. 2000; Huber et al. 2000; Bichão et al. 2003; Miller et al. 2003; Asaro et al. 2004). Our results show that some of the volatiles released by mite-infested spruces significantly decreased the attraction of the pine weevil *H. abietis* to host volatiles from spruce. Thus, the biosynthesis of (-)- linalool and MeSA might prevent the trees from being damaged. (*E*)-β-Farnesene was attractive to *H. abietis* when tested alone, but did not affect the attraction of weevils to wounded spruce odor when large amounts of the attractive α-pinene (Nordlander 1990) were released. (*E*)-β-farnesene released from pine has been shown to attract egg parasitoids (Mumm and Hilker 2005), and it might attract *H. abietis* to trees infested by sucking insects. Thus, further tests in the field are needed to determine whether conifer seedlings naturally infested with mites are more or less attractive to the pine weevils than the healthy seedlings.

Minor amounts of aromatic compounds such as benzaldehyde, benzyl alcohol, 1,2- and 1,3-dimethoxybenzene, benzyl acetate, benzoic acid, vanillin, and estragole were detected in the emissions of the mite-infested spruces. The biosynthesis of aromatic compounds related to the scents of many flowering plants has been intensively investigated

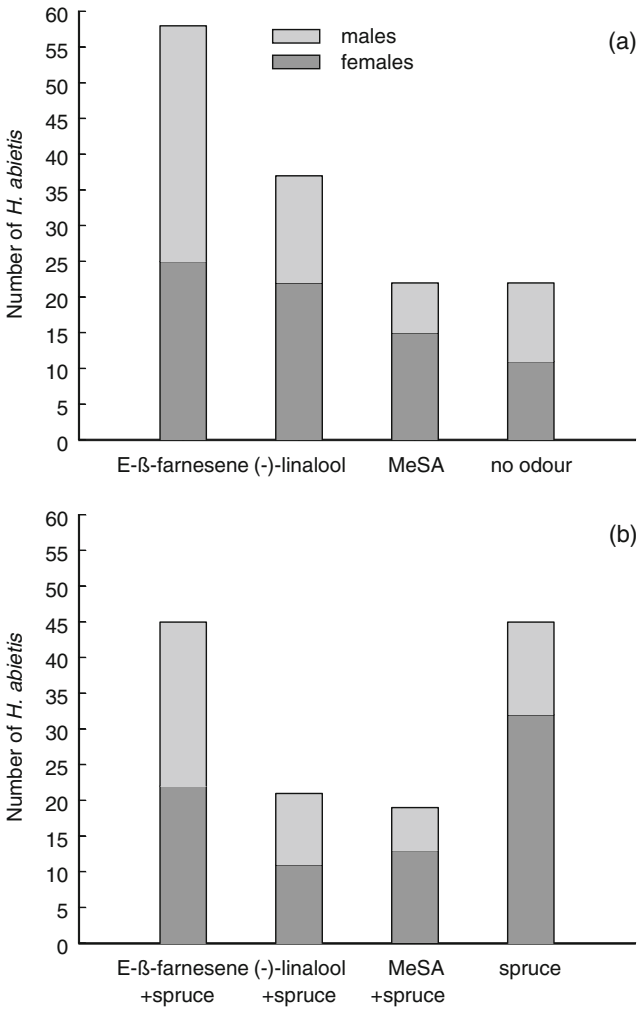

Fig. 3 Number of *Hylobius abietis* weevils entering traps baited with stress-related compounds alone (**a**) or in combination with host odor from Norway spruce twigs (**b**)

(Dudareva et al. 1998, 2000; Dudareva and Pichersky 2000; Guterman et al. 2006; Koeduka et al. 2006). The presence of vanillin, benzaldehyde, benzoic acid, and several unknown aromatic compounds in the spruce volatiles is probably related to lignin biosynthesis or precursors (Schultz 1987; Gang et al. 2001; Dudareva et al. 2006; Jourdes et al. 2007). Similar induction of phenolic compounds by pathogens or fungi, in both pines and spruces, has been observed by several authors (e.g., Campbell and Ellis 1992; Cvikrová et al. 2006). The induced production of small amounts of dimethoxybenzenes is interesting since these compounds are antifeedants for the pine weevil (Borg-Karlson et al. 2006), as are MeSA and structurally related aromatic compounds in sufficiently large concentrations (Legrand et al. 2004; Borg-Karlson et al. 2006). Furthermore, in our recent investigation (Kännaste et al. 2008) we showed that large amounts of MeSA are released from a pine weevil-susceptible spruce clone, and we observed a clear dose-dependent antifeedant effect of MeSA on *H. abietis* in previous studies (unpublished data).

Several biosynthetic pathways are involved in the production of herbivore-induced plant volatiles. The co-occurrence of myrcene and (-)-limonene is consistent with the results of studies by Martin et al. (2004), in which myrcene was identified as a by-product of MeJA-activated limonene synthases. Geraniol and the corresponding aldehyde, geranial, were both found in the emissions. Geranial and neral could be released by the mites (Morita et al. 2004), since in several species they act as alarm pheromones or attractants (Nishimura et al. 2002; Hiraoka et al. 2003).

The diversity in volatiles emitted from the mite-stressed plants reflects the diversity in induced synthase activities. There were no clear differences in the emissions of some terpenes induced by the two mite species, but as shown in the representative chromatograms, the release of (*E*)-β-farnesene seems to be mite specific (Table 1, Fig. 1). The induced terpenes, such as the farnesenes and linalool, and the aromatic compounds like MeSA, indicate that "cross talk" occurs between biosynthetic pathways (Dudareva et al. 2006), especially in the spruces infested with *O. ununguis*, which released larger amounts of MeSA. In the present study, we showed that induced (*E*)-β-farnesene is attractive to pine weevils in the absence of host monoterpenes, while linalool and MeSA are deterrents. However, further studies on the relevance of these compounds as resistance markers are required, using clones with known resistance and susceptibility to various infestations.

Acknowledgements We are grateful to Mariusz Lewandowski who identified (using photos) one of the mites as belonging to the genus *Nalepella*. The photos are present at the Department of Chemistry, Ecological Chemistry group, KTH. We are also grateful to Lars Lundqvist for identifying the spinning mite *Oligonychus ununguis*. This study was financially supported by FORMAS (Swedish Research Council for Environment, Agricultural Sciences and Spatial Planning), the Carl Trygger Foundation and an Archimedes stipend from Estonia to Astrid Kännaste.

different groups of *Oxytropis* exist, with one group containing swainsonine and the other containing no detectable swainsonine or concentrations that are near the detection threshold.

The objective of this research was three fold: (1) to determine if there are two groups of *O. sericea,* and, if so, the amounts of endophyte in each; (2) to determine the concentration of swainsonine and amount of endophyte in the different plant parts of *O. sericea* at a single developmental stage from a single population; and (3) to compare the concentration of swainsonine and the amount of endophyte from the same plant when separated into stalks (leaves, scape(s), and flowers/pods).

Methods and Materials

Plant Materials Twenty four plants of *O. sericea* Nuttall (Whitepoint locoweed) were collected in July 2007 from the Raft River Mountains, Utah (N 41º 54′ 15.4″ W 113º 20′ 54.9″). Plants collected were in full flower/early pod and divided into their corresponding parts representing the root (tap root), crown (non-photosynthetic woody tissue extending from ground level to tap root), leaves (odd-pinnate with leaflets being opposite), scapes (flowering stem), and flowers/pods. *Oxytropis sericea* has no stem material, and leaves and scapes arise from the crown. These plants were used to investigate objectives 1 and 2. In addition, 10 plants were collected at the same location and time but the plants were divided into 5 equal stalks where each stalk contained leaves, scape(s), and flowers/pods. These plants were used to investigate objective 3. A control sample, representing a composite of a single plant, was extracted to determine the range, mean, and relative standard deviation associated with the method of extraction and analysis as part of objective 3. Immediately after collection, all plant material was bagged and frozen on dry ice. Upon return to the laboratory, plants were freeze-dried and ground through a 2 mm screen in a Wiley mill. Swainsonine and DNA were extracted from this plant material for analyses.

DNA Extraction DNA was extracted from freeze-dried, ground plant material (~20 mg) by using the DNEasy Plant Mini Kit (Qiagen Inc., Valencia, CA, USA). All extractions were performed according to the manufacturer's instructions. DNA was quantified with the ND-1000 spectrophotometer (Nanodrop Technologies, Wilmington, DE, USA).

PCR Primer Design The PCR primers used have successfully detected the presence of the fungal endophyte, *U. oxytropis* in *Oxytropis* and *Astragalus* species (Ralphs et al. 2008). The primers used were ITS 5 (5' GGA AGT AAA AGT CGT AAC AAG G) (White et al. 1990) and OR1 with an additional base pair at the 3' end (5' GTC AAA AGT TGA AAA TGT GGC TTG G 3'), which amplify the internal transcribed spacer (ITS) region. Primers were synthesized by Integrated DNA Technologies, Inc. (Coralville, IA, USA).

Quantification of the Fungal Endophyte For the quantification of the fungal endophyte, a standard curve (30, 10, 3, 1, 0.3, 0.1, 0.03, 0.01 ng fungal DNA) was prepared from DNA extracted from a pure culture of the endophytic fungus (Cook et al. 2009b). Each analysis included three replicate reactions (25 µl) for each DNA quantity. Each analysis also included a non-template control reaction, in which water was substituted for the DNA to confirm that the reagents were free from contaminating template DNA. The equation derived from the standard curve was $y=-3.54x+17.9$, $R^2=0.996$.

Endophyte samples for the standard curves were prepared by analyzing three replicate 25 µl reactions that contained the amount of DNA (0.01–30 ng fungal DNA) indicated on the standard curve. Plant samples were analyzed in three replicate 25 µl reactions that contained 50 ng (5 µl of a 10 ng / µl stock) of total DNA. Each reaction contained 12.5 µl of the QuantiFast SYBR Green PCR Kit master mix (Qiagen Inc., Valencia, CA, USA) and 500 nM each of the forward and reverse primer. Endophyte content (per 50 ng total DNA) was estimated from the endophyte standard curve. Endophyte amounts were expressed as picograms/nanogram total DNA. Samples with endophyte amounts below the quantitative limit of detection of the standard curve were assigned values of 0.2 pg/ng total DNA.

Amplification and detection of fluorescence were performed by using a Bio-Rad CHROMO4 quantitative PCR detector (Bio-Rad Laboratories Inc., Hercules, CA, USA). Thermal cycling conditions comprised an initial denaturation step for 7 min at 95°C, followed by 40 cycles of 15 sec at 95°C, 30 sec at 58°C, 40 sec at 72°C, and a plate read at the end of each cycle. This was followed by a melting profile, to determine the purity of the reaction products, where the temperature was raised from 55°C to 90°C in 0.2°C increments, held for 2 sec at each temperature, and a plate read at each temperature.

PCR products were resolved on a 1% agarose gel containing ethidium bromide at 118 volts for 20 min and visualized under UV illumination. The amplified PCR product was approximately 580 base pairs (bp). PCR products were digested with the restriction enzyme *Ava*II as a diagnostic check since this primer set may also amplify *Alternaria* species, a closely related genus. *Alternaria* species do not contain the restriction site, therefore, a digested product indicates the presence of the locoweed

endophyte, *U. oxytropis*. Restriction enzyme digests contained 5 µl of PCR product, 0.5 µl *Ava*II (New England Biolabs Inc., Ipswich, MA, USA), 1 µl NEB Buffer 4 supplied with the enzyme, and 3.5 µl sterile water for a total volume of 10 µl. Digests were incubated at 37°C for 1.5 h after which the digest was heat inactivated at 65°C for 20 min. Restriction fragments were separated by gel electrophoresis according to the conditions above. A result of two fragments with lengths of 380 bp and 200 bp confirmed the positive amplification of the locoweed endophyte, *U. oxytropis*.

Swainsonine Analysis Samples were analyzed for swainsonine following the procedure described by Gardner et al. 2001. In brief, 100 mg of plant material were extracted with chloroform and acetic acid. The acetic acid portion was passed through a cation exchange resin to retain the swainsonine, which was subsequently eluted with a weak ammonium hydroxide solution. A portion of the final extract then was quantitatively analyzed for swainsonine by LC-MS. The detection limit of swainsonine was 0.001% of dry weight.

Data Analysis Swainsonine and endophyte concentrations were examined in plant parts by using a general linear model of SAS (PROC GLM) (SAS Institute, Cary, NC, USA). Mean comparisons among plant parts after a significant ($P<0.05$) F test was done with preplanned comparisons using the PDIFF procedure in SAS. Initial data analysis revealed two potential groups of *Oxytropis*, one containing readily detectable concentrations of swainsonine and another with little or no swainsonine. Therefore, plants from these two groups were compared for endophyte and swainsonine concentration by using the GLM procedure with least square means for unbalanced sample sizes. Means were compared by using the PDIFF procedure in SAS. The variation in swainsonine concentration among stalks was determined by using descriptive statistics, including the relative standard deviation (RSD, %), which is the absolute value of the coefficient of variation.

Results

Swainsonine in Plant Parts Swainsonine was detected in all plant parts of *O. sericea*. Mean swainsonine concentrations ranged from 0.002% in roots to 0.062% in leaves of *O. sericea* ($N=24$ plants) (Fig. 1). Above ground tissues had higher ($P<0.001$) concentrations of swainsonine than below ground tissues. Swainsonine concentrations did not differ ($P>0.05$) in the leaves, scapes, and flowers/pod or between the root and crown tissues. *Oxytropis sericea*

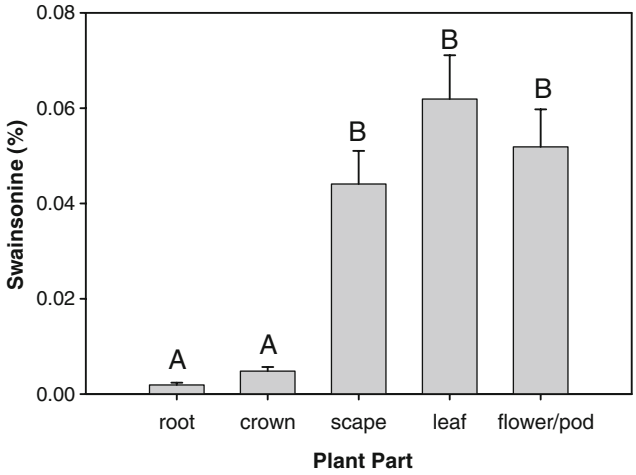

Fig. 1 Swainsonine concentrations (%) differentially accumulate within below ground and above ground parts of *Oxytropis sericea*. Mean swainsonine concentrations±the standard error of parts (root, crown, scape, leaf, and flower/pod) from 24 individual plants. Different letters above each bar represents significance at $P<0.05$

plants appeared to group into two categories, plants ($N=17$) that contained swainsonine in leaves (>0.01%), and plants ($N=7$) where swainsonine was not detected or concentrations that were near the detection threshold in leaves (<0.005%). For further comparison, *O. sericea* plant parts were separated into two categories, group 1 and group 2.

These two apparent groups of *Oxytropis* contained differing concentrations of swainsonine. There was a group x part interaction ($P<0.001$). In group 1 plants, swainsonine was not detected in the root, crown, scapes, and flowers/pods but was detected at a mean concentration of 0.001% in the leaves (Fig. 2). Group 2 plants contained more swainsonine than group 1 plants in all above ground parts ($P<0.001$). Mean swainsonine concentrations in group 2 plants ranged from 0.003% in roots to 0.087% in leaves (Fig. 2). In group 2 plants, above ground tissues had higher concentrations of swainsonine than below ground tissues ($P<0.001$). In addition, in group 2 plants, leaves had greater swainsonine concentrations than flowers/pods and scapes ($P<0.05$).

Endophyte Content in Plant Parts A newly developed qPCR method for *U. oxytropis* allowed determination of endophyte amounts in each of the tissues (Cook et al. 2009b). Endophyte amounts are expressed as pg endophyte DNA/ng total DNA. The endophyte was detected in all plant parts. Mean endophyte amounts ranged from 0.7 pg/ng in the roots to 21.2 pg/ng in the scapes ($N=24$ plants) (Fig. 3). In some instances, endophyte amounts did not mirror swainsonine concentrations in the corresponding tissue type. For example, the crown contained much greater amounts of endophyte compared to its swainonsine content.

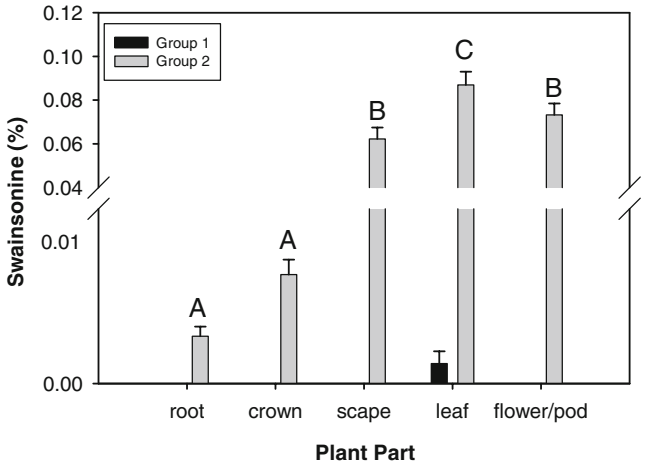

Fig. 2 Swainsonine concentrations (%) differentially accumulate within plant parts and within two groups of *Oxytropis sericea*. Mean swainsonine concentrations±the standard error of parts (root, crown, scape, leaf, and flower/pod) from two groups of *O. sericea* plants that differentially accumulate swainsonine. Group 1=plants that accumulate <0.005% swainsonine in leaves (N=7), Group 2=plants that accumulate >0.01% swainsonine in leaves (N=17). Different letters above each bar represents significance at P<0.05

The apparent groups of *Oxytropis* showed very different concentrations of endophyte (Fig. 4). There was a group x part interaction (P<0.001), as group 1 plants contained less endophyte than group 2 plants in all plant parts but the root. In group 2 plants, the mean endophyte content in the leaves, crown, scapes, and flowers/pods was similar, ranging from 12.1 pg/ng to 29.9 pg/ng. The root was the most different from any tissue type in group 2 plants and contained an average of 0.9 pg/ng endophyte (P<0.001). In group 1 plants, the endophyte was detected in all tissue types; however, the mean endophyte amount ranged from 0.2 pg/ng in the crown to 0.4 pg/ng in leaves (Fig. 4).

Swainsonine in Stalks Five aliquots from a control sample, representing a composite of a single plant, were extracted to determine the range, mean, and relative standard deviation associated with the method of extraction and analysis. The control sample had a mean swainsonine concentration of 0.051% ±0.003 (Relative Standard Deviation (RSD)=6%) (Table 1). To determine if the distribution of swainsonine was uniform within individual plants, five stalks per plant from 10 different plants were analyzed for swainsonine. Swainsonine was detected in 9 of 10 plants (Table 1). Swainsonine was detected in each stalk (N=5 stalks/plant) of the 9 plants that contained swainsonine (Table 1). Based on the results of the control sample analysis, an RSD for swainsonine concentration greater than 6 % for the stalks representing individual plants would suggest that swainsonine is not uniformly distributed throughout the plant. The RSD was greater than 6 % in all plants analyzed, thus swainsonine was not equally distributed within these plants (Table 1).

Endophyte Content in Stalks Five DNA samples were extracted from aliquots of the control sample described in the previous section to determine the range, mean,

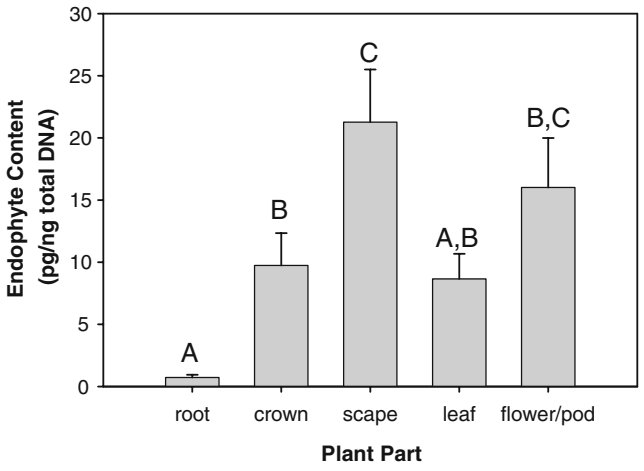

Fig. 3 Endophyte amounts (pg/ng total DNA) differentially accumulate in different plant parts of *Oxytropis sericea*. Mean endophyte amounts±the standard error of parts (root, crown, scape, leaf, and flower/pod) from 24 individual plants. Different letters above each bar represents significance at P<0.05

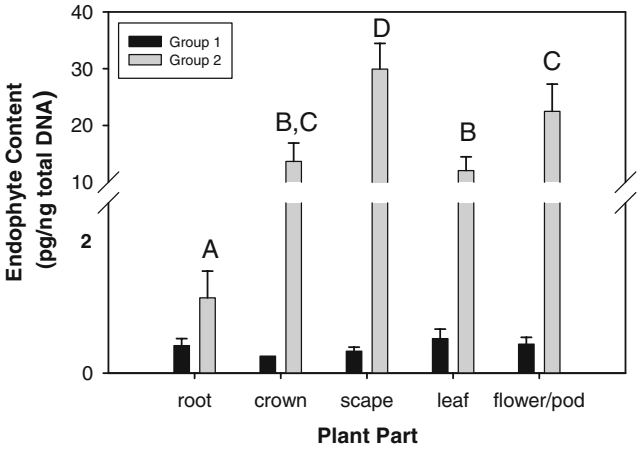

Fig. 4 Endophyte amounts are quantitatively different in two groups of *Oxytropis sericea* plants that accumulate different concentrations of swainsonine. Mean endophyte amounts±the standard error of parts (root, crown, scape, leaf, and flower/pod) from Groups 1 and 2 in Fig. 2. Different letters above each bar represents significance at P<0.05

Table 1 Swainsonine and endophyte distribution within stalks of *Oxytropis sericea* plants

Plant	Swainsonine (%)				Endophyte (pg/ng total DNA)			
	Mean	Range	S	RSD[a] (%)	Mean	Range	S	RSD[a] (%)
1	0.066	0.053–0.082	0.012	18	31.8	26.5–41.6	6.2	19

10	n.d.				0.2			
Mean (1–9)	0.073		0.013	18	18.4		6.2	34
Control[b]	0.051	0.047–0.54	0.003	6	29.6	23.8–35.8	5.2	17

[a] RSD(%)-Relative Standard Deviation was calculated by dividing the standard deviation by the mean and multiplying by 100

[b] The control, representing a composite of a single plant, represents 5 aliquots that were extracted to determine the range, mean, and relative standard deviation associated with the method of extraction and analysis for swainsonine concentration and endophyte amount

and relative standard deviation associated with the method of extraction and analysis. The control sample had a mean endophyte amount of 29.6 pg/ng±5.2 (RSD=17%). To determine if the distribution of the endophyte was uniform within a plant, 5 stalks per plant representing 10 plants were sampled and analyzed for endophyte amounts. The endophyte was detected in all 10 plants. In addition, the endophyte was detected in every stalk from all ten plants (Table 1). Plant No. 10 was a plant with no detectable swainsonine, and it contained endophyte amounts near or below the quantitative detection limit of 0.2 pg/ng total DNA. Based on the results of the control sample analyses, an RSD for endophyte amount greater than 17 % for the stalks representing individual plants would suggest that the endophyte is not uniformly distributed throughout the plant. The RSD was greater than 17 percent in 8 of the 9 plants. Thus like swainsonine, the endophyte was not equally distributed in the analyzed plants (Table 1).

Discussion

It has long been known that *O. sericea* contains swainsonine (Molyneux and James 1982), and more recent research has shown that swainsonine accumulates to highly variable amounts within any single *O. sericea* population, ranging from not being detected to approximately 0.08% (Gardner et al. 2001). Furthermore, it has been shown that a fungal endophyte, *Undifilum oxytropis*, is responsible for the synthesis of swainsonine (Braun et al. 2003; Pryor et al. 2009). The results of this study confirm these previous observations in addition to: (1) identifying two groups of *O. sericea* and quantifying the amounts of endophyte in each; (2) measuring the concentration of swainsonine and amount of endophyte in the different plant parts of *O. sericea* at a single developmental stage; and (3) determining if the concentration of swainsonine and the amount of endophyte from the same plant were uniformly distributed in individual stalks of the same plant.

By using methods previously developed to quantify swainsonine and a newly developed quantitative PCR method to quantify the endophyte, the concentration of swainsonine and amount of endophyte in the different plant parts of *O. sericea* were investigated at a single developmental stage. Swainsonine and the endophyte were found in all plant parts. Swainsonine concentrations were approximately 10 times greater in above ground tissues than below ground tissues (Fig. 1). Endophyte amounts differed among plant parts and in some instances did not mirror the concentrations of swainsonine in the corresponding tissues (Fig. 3). For instance, the crown contained a comparable amount of endophyte to above ground tissues of the plant, but did not contain a comparable amount of swainsonine. This discrepancy may be explained by swainsonine acting as a mobile secondary compound, and thus being better mobilized, or there is the possibility that the endophyte in the crown tissue is not producing swainsonine. However, irrespective of the low swainsonine concentration, the large amount of

endophyte in the crown may serve as a reservoir for the endophyte for subsequent growth in the following year.

Plants were classified into two groups based upon swainsonine concentration in leaves (Fig. 2). Plants, where swainsonine was not detected or concentrations that were near the detection threshold, occurred at a frequency of approximately 30% within the sampled population of *O. sericea*. Analysis of the qPCR data showed that amounts of endophyte differed between these two groups (Fig. 4). The endophyte, *U. oxytropis*, has been shown to produce swainsonine in *O. sericea*, therefore, these quantitative differences in endophyte amount probably explain the difference in swainsonine concentrations between these two groups of plants. We hypothesize that the observations made for this population of *O. sericea* in regard to endophyte amounts can be applied to other populations of *O. sericea* in Colorado and New Mexico where plants within the same population have been observed to differentially accumulate swainsonine (Gardner et al. 2001; Ralphs et al. 2008).

By using methods to quantify swainsonine and the endophyte, swainsonine concentrations and endophyte amounts were investigated in five stalks from ten plants of *O. sericea*. The mean endophyte content in above ground parts of *O. sericea* containing swainsonine was approximately 18.4 pg/ng total DNA, or a relative endophyte biomass of 1.84% with a range 0.5 to 4.0% (Table 1). In addition, the results show that the concentration of swainsonine and amount of endophyte are not equally distributed within stalks from the same plant (Table 1). These results have implications in regard to sampling techniques for future studies, mainly that sampling the same plant multiple times over a growing season may lead to erroneous conclusions. We recommend that for any sampling regime, the whole plant or all above ground parts be harvested, thus enabling one to make meaningful conclusions in regard to swainsonine and endophyte content.

The perennial ryegrass / fescue endophyte relationship is agronomically important and ecologically important in shaping ecosystems (Rudgers and Clay 2007; Cheplick and Faeth 2009). Our results highlight some similarities and differences between the perennial ryegrass / fescue endophyte relationship and the *O. sericea* endophyte relationship. First, the relative endophyte biomass (0.5 to 4.0%) in *O. sericea* was similar to the relative endophyte biomass in an *Epichloe*/*Neotyphodium* symbiotic assocatiation with perennial ryegrass, estimated to be between 0.3% to 1.9% (Young et al. 2005). Second, the distribution of the endophyte in *O. sericea* plant parts was similar to those reported for tall fescue by Dombrowski et al. (2006) except that, unlike *O. sericea,* the endophyte was not detected in the roots of tall fescue. Third and most critical, in perennial ryegrass and tall fescue, plants are either endophyte positive, thus alkaloid positive, or endophyte minus, thus alkaloid minus. Whereas in *O. sericea*, plants are either endophyte positive, thus swainsonine positive, or the endophyte is detected, but amounts are below a critical threshold, and swainsonine is not detected, or concentrations are near the detection threshold.

The difference in accumulation of swainsonine between the two groups of *O. sericea* leads to the question of the relative toxicity posed by each group. Molyneux et al. (1994) suggested a conservative threshold toxicity of 0.001%. Stegelmeier et al. (1999) showed that doses at or above 0.2 mg/kg body weight/day for at least 21 days produced irreversible neurological disease. Much less is known about lower doses over longer periods of time; however, it has been suggested that it may lead to weight loss and biochemical lesions (Stegelmeier et al. 1999). Swainsonine concentrations of 0.001%, the concentration found in leaves of group 1 plants, would produce a dose of 0.2 mg/kg body weight/day only when locoweed consumption was 100% of their diet at an intake of 2% of their body weight. Therefore, it is unlikely that locoweed plants with swainsonine concentrations of 0.001% would pose a significant risk of causing irreversible neurologic disease; however, grazing animals may incur other reversible negative consequences such as loss of weight.

In summary, *O. sericea* has two groups that differ in their swainsonine accumulation, most likely because of the differences in endophyte amounts between the two groups. These results lead us to hypothesize that *Oxytropis* species in which plants within the same population differ in their swainsonine accumulation also will have differing amounts of endophyte, and we hypothesize that similar results will be found with *Astragalus*. Furthermore, we hypothesize that plants having low or non-detectable swainsonine concentrations may have arisen due to imperfect transmission of a critical amount of the endophyte to the seed or seedling (Afkhami and Rudgers 2008) that is required for effective colonization by the endophyte. Alternatively, low swainsonine-containing plants may suppress endophyte growth due to a plant genotype by endophyte interaction (Adcock et al. 1997; Roylance r. 1994). These hypotheses merit further investigation. In addition, future research is necessary to determine if there are differences in fitness, as observed in grass-endophyte relationships (Rudgers and Clay 2007; Cheplick and Faeth 2009), between plants belonging to these two groups of *O. sericea*.

tion), and PDMS tubing. The PDMS sorbents were placed in the pots at planting and removed at harvests 29, 55, and 88 days after planting. As analyzed by HPLC, the amount of sorgoleone recovered increased with time. Barto and Cipollini (2009) used 10 cm lengths of PDMS tubing (buried in soil, then recovered and extracted) in an attempt to measure allelochemicals beneath garlic mustard, *Alliaria petiolata*, and were able to detect low amounts of one flavonoid, isovitexin-6″-O-β-D-glucopyranoside. Weidenhamer et al. (2009) used solid phase root zone extraction (SPRE) probes constructed by inserting stainless steel wire into PDMS tubing to recover nano- to microgram quantities of thiophenes from soil beneath growing marigolds, using a 24 hour sampling time.

PDMS-based materials are used widely for trace analysis of anthropogenic contaminants. They are used as stationary phase in capillary columns for the analyte separation in gas chromatography, and as enrichment material in several analytical techniques that include solid phase microextraction (Arthur and Pawliszyn 1990), stir bar sorptive extraction (Baltussen et al. 1999), and thin-film microextraction (Bruheim et al. 2003). PDMS also has been applied for diffusive sampling in sediment and soil (Mayer et al. 2000; Weidenhamer 2005; Weidenhamer et al. 2009) and for passive sampling in the aquatic environment (e.g., Cornelissen et al. 2008). Recently developed techniques are based on the permeation of non-polar analytes through the wall of PDMS microtubing: Ooki and Yokouchi (2008) constructed a silicone membrane tube equilibrator from PDMS tubing for the sea water to gas equilibration of volatile organic compounds; Mayer et al. (2009) used 6 m PDMS microtubes as silicone membrane equilibrator to measure polycyclic aromatic hydrocarbons directly in tissue and oil samples. The tubing was immersed in the sample, and compounds were extracted by pushing a plug of methanol through the tubing and collecting it in an HPLC vial for analysis. In the present study we apply PDMS microtubing for the in situ sampling of root exudates and the subsequent elution into methanol while keeping the tubing in place.

The objective of the experiments described in this paper was to compare the ability of three PDMS-based techniques to measure the spatial and temporal dynamics of thiophenes in the root zone of African marigold, *Tagetes erecta* L. Solid phase root zone extraction probes were used to monitor thiophene concentrations at different depths beneath marigolds grown in PVC pipes. Marigolds were grown between foil-lined glass plates, and thiophene distributions in the soil were measured by two techniques: (a) PDMS sheets were press-applied to the roots and analyzed after 24 h; and (b) PDMS microtubing (1 m lengths) was placed over the roots and sampled at 24 h intervals by flushing 95% methanol through the tubing. Because PDMS selectively sorbs lipophilic compounds (Baltussen et al. 1999), marigold was considered to be a good model species for these studies due to the highly lipophilic character of the thiophenes produced by marigold roots (Fig. 1, Bohlmann et al. 1973; Downum and Towers 1983). In addition, these thiophenes have high biological activity against a number of organisms (Bakker et al. 1979; Campbell et al. 1982), and have been reported to be released into the marigold root zone (Campbell et al. 1982; Tang et al. 1987; Martin and Weidenhamer 1995; Weidenhamer et al. 2009).

Methods and Materials

Growth Media and Plant Cultivation Conditions Plants were grown in a greenhouse under natural sunlight during June – July 2009. In general, daytime temperatures ranged from 21–32° C and nighttime temperatures from 16–22° C. A 1:1 (v:v) mixture of sand and a peat/vermiculite-based growth medium (Redi-earth® plug and seedling mix) was used for all experiments. Plants (*Tagetes erecta* cv. 'Crackerjack mix' and *Tagetes patula* cv. 'Janie primrose') were watered as needed, and received weekly applications of a general purpose fertilizer solution (Peters Professional® all purpose plant food, 24-8-16 plus B, Cu, Fe, Mn, Mo, and Zn). Fertilization was not done immediately before or during sampling.

SPRE Probe Study Marigolds (*T. erecta* cv. 'Crackerjack mix', thinned to 3 plants per pipe) were grown in four 7.5 cm ID, 44 cm tall PVC pipes. The pipes were mounted on a flat, circular base. A 10 cm layer of gravel at the base and three drainage holes drilled at the bottom kept the pots well-drained. Three evenly spaced holes (1.5 mm diam, 5 cm apart) were drilled at eight depths (2.5 cm intervals, from 2.5–20 cm below soil surface) to allow access for sampling. Pipes were wrapped with polyethylene film to

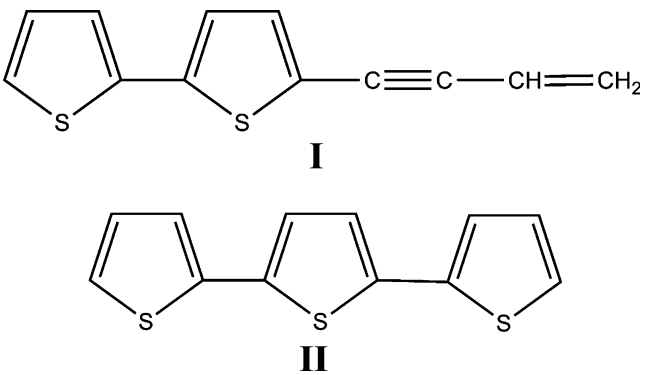

Fig. 1 Structures of 5-(3-buten-1-ynyl)-2,2′-bithienyl (BBT, I) and α-terthienyl (2,2′:5′,2″-terthiophene, α-T, II)

prevent the drainage of water through the probe access holes.

SPRE probes were prepared as described in Weidenhamer et al. (2009). Stainless steel wire (22-gauge) was inserted into 5 cm lengths of hexane-swelled Silastic® tubing (0.64 mm ID×1.19 mm OD, Fisher Scientific catalog no. 11-189-15B). The probes were sequentially cleaned with hexanes, dichloromethane, methanol, and water by soaking for 10 min in each, and then dried in an oven at 70°C. Once the probes were dried, they were stored in tightly capped vials until use.

At 3, 4, and 5 wk after planting, SPRE probes were inserted into the 96 probe access holes (3 access holes× 8 depths×4 pipes) and left in place for 24 h. The 3 probes at each depth were pooled, and thiophenes were extracted from the probes by first rinsing with water to remove adhering soil particles, blotting dry, stripping the tubing from the wire support, and sonication in an amber autosampler vial with 700 µl of 95% methanol (methanol: water 95:5, v:v) for 12 min.

Glass Box PDMS Sheet Study Glass boxes were constructed by using two 20x20 cm glass plates (0.3 cm thickness). Four bottle caps were glued in the corners of one plate to maintain a 1 cm spacing between the plates. Plates were covered with non-stick aluminum foil (to protect light-sensitive thiophenes from degradation), sealed with polyethylene film on three sides, and held together with clamps before filling with growth medium. Drainage holes allowed removal of excess water. Marigolds (*T. erecta* cv. 'Crackerjack mix') were thinned to two seedlings per box.

Three-five wk after planting, boxes were unclamped and a 17.5×20 cm sheet of clear PDMS (0.8 mm thickness, obtained from Specialty Silicone Products, Ballston Spa, NY, USA) was press-applied to the root zone. To insure that PDMS sheets were clean, they were soaked in methanol for at least 24 h and then dried at 70° C before application. The glass plate was replaced, the box clamped, and the sheet was left in place for 24 h. PDMS sheets were then washed to remove adhering soil and immediately cut into fifty-six 2.5×2.5 cm segments. Each segment was placed in a vial with 3 ml of 95% methanol and sonicated for 12 min to extract thiophenes.

Glass Box Microtubing Study A glass box with established marigolds (*T. erecta* cv. 'Crackerjack mix') was sampled by using five replicate 1 m lengths of PDMS Silastic® microtubing (0.30 mm ID×0.64 mm OD, Fisher Scientific catalog no. 11-189-14). Prior to use, microtubing was cleaned by soaking in methanol for 24 h and dried at 70° C. One piece of microtubing was coiled over a 4 cm width× 17.5 cm depth section of the root zone (a total of 5 pieces over the 20 cm wide box), with the ends of the tubing left exposed above the soil surface to allow repeated sampling (Fig. 2). Microtubing was sampled by pushing 500 µl of 95% methanol through each tube at a rate of 1 ml/min followed by a 500 µl bolus of air to extrude any residual solvent. The resulting extract was collected for HPLC analysis as it exited the tubing.

The operative range of the silicone tube microextraction method was tested by preparing 1:1 sand:growth medium mixtures spiked with known concentrations of α-Terthienyl (2,2′:5′,2″-terthiophene) (α-T) (Sigma Aldrich). α-Terthienyl was applied in hexane to sand, the hexane allowed to evaporate, and the spiked sand used to prepare sand:growth medium mixtures containing concentrations of 0–10 µg g^{-1}. In a Petri dish, one microtube was coiled over 10 g sand: growth medium, covered, and a second microtube was coiled and then covered with sand:growth medium. A total of 43 g of 1:1 sand:growth medium was used per dish. Holes were drilled in the top of the Petri dish to provide access for sampling. Water was added to bring the dishes to 20% moisture content, and microtubing was sampled at 24, 48, and 72 h (using separate dishes for each sampling time).

Root Dissection In order to gain insight into the possible reasons for the tremendous heterogeneity of measured thiophene concentrations seen in the SPRE probe and glass box PDMS sheet studies, roots of several *T. erecta* and *T. patula* seedlings were dissected and analyzed for thiophene content. Primary and secondary roots and root tips of several seedlings grown in a 1:1 mixture of sand and growth medium were analyzed by extraction in methanol. Two week old plants (5–6 cm in length from root cap to cotyledon) were separated from the soil by submersion in

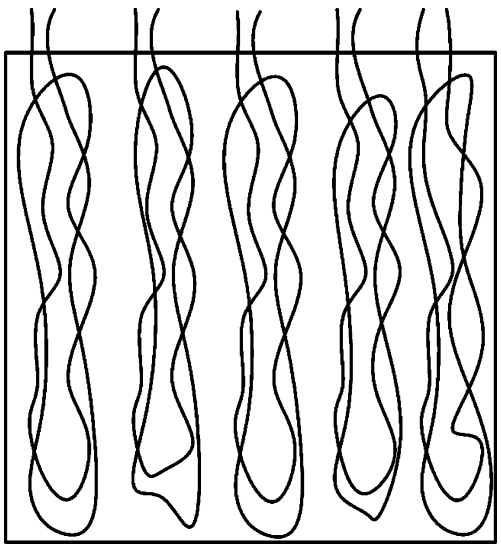

Fig. 2 Schematic diagram showing placement of five 1 m length of PDMS microtubing across the marigold root zone in a 20 cm wide glass box

distilled water. Growth medium was carefully washed from the roots. Root hairs (secondary roots) were separated from the main root with a scalpel and forceps. Roots were transferred to a Petri dish that contained distilled water, blotted dry on KimWipes®, and weighed on a microbalance to obtain a fresh root mass.

Diffusion Studies For the diffusion studies, SPRE probes loaded with known amounts of α-T were prepared by taking freshly prepared probes and placing them in sand spiked with a known amount of α-T (20–100 ppm) and moistened to 12.5% moisture content. Probes were incubated for 1, 2, 4, or 7 d, and 4 probes were analyzed at each time point to determine the amount of loading. The amount of α-T loaded on the probes increased with concentration and time (data not shown) up to a maximum of 29 μg after 7 d incubation in 100 ppm sand. In subsequent studies, a loading time of 4 d typically was used, and several probes from each batch were analyzed to verify the α-T content.

Loaded SPRE probes (containing 22 μg α-T) were used to measure the diffusion of α-T through sand and a 1:1 mixture of sand and growth medium. A loaded probe was placed in a Petri dish containing the sand or growth medium maintained at 12.5% moisture content, and a blank probe placed 1–5 cm away. After 7 d, both probes were extracted and analyzed for α-T content.

HPLC Methods A standard sample of α-T was obtained from Sigma Aldrich. 5-(3-buten-1-ynyl)-2,2′-bithienyl (BBT) was obtained by bulk extraction of marigold roots and preparative TLC following methods of Downum and Towers (1983), and its identification confirmed by GC-MS (data not shown). The HPLC system was an Agilent 1100 Series equipped with a binary gradient pump, autosampler, and diode array detector. Separation was carried out on an Ultra C18 5 μm particle size column (150×4.6 mm), with detection at 360 nm. BBT and α-T were identified based on both retention time and UV spectra using the diode array detector. Analysis of unused PDMS materials verified that these were free from contaminants when extracted and analyzed by HPLC. BBT was quantified based on the ratio of the molar absorptivity of BBT to that of α-T at 360 nm. Detector response was linear for α-T over a concentration range of 0.05–50 mg L^{-1}. The quantitation limit was below 2 ng thiophene injected. The mobile phase was 95:5 methanol: water (v:v), at a flow rate of 1 mL min^{-1}. All PDMS extracts were analyzed within 24 h of extraction, and were stored in amber autosampler vials to prevent degradation from light exposure. PDMS samples that could not be analyzed immediately were stored in a freezer (−20° C) until extraction and analysis. All samples were syringe filtered (0.22 μm nylon filter) prior to analysis, and injected in duplicate with the two runs averaged. Typical run to run variation was less than 1%. The injection volume was 25 or 75 μL depending on sample size.

Results and Discussion

SPRE Probe Study Results of analyses of SPRE probes placed at varying depths beneath marigolds grown in PVC pipes are shown in Tables 1 and 2. There was tremendous variability in the amounts of α-T and BBT recovered. Table 1 shows recovery as a function of depth at 3 weeks after planting, and it can be seen that the standard deviations approach or exceed the means for all values. High probe to probe variability also was seen in studies with *Tagetes patula*, in which SPRE probes were inserted into soil around marigolds growing in outdoor garden beds (Weidenhamer et al. 2009). This variability was reduced somewhat by pooling multiple probes to obtain a more integrated sample, but standard deviations in the previous study still were above 50% of the mean values measured even when three probes were combined (Weidenhamer et al. 2009).

When the total amounts of α-T and BBT recovered from each pipe at the three samplings are compared, high variability is also seen (Table 2). For example, at the first sampling 3 weeks after planting, the total amount of α-T recovered (from 24 SPRE probes) ranged from 280 to 3,170 ng, and the total amount of BBT recovered ranged from 870 to 8,150 ng. There also was variability from one sampling to another, as seen by the fact that pipe 1 yielded the most α-T at the first sampling, but the least α-T at the next sampling. While overall the average amount of BBT found was four times that of α-T, the amounts found in individual pipes at a given sampling sometimes deviated

Table 1 Recovery of thiophenes as a function of depth at 3 weeks after planting, using SPRE probes to sample marigolds grown in PVC pipes at depths of 2.5–20 cm. Mean thiophene recovery is expressed in ng per SPRE probe ± standard deviation

Thiophene content as function of depth at 3 weeks after planting		
Depth, cm	α-T, ng per probe ± SD	BBT, ng per probe ± SD
2.5	277±385	87±107
5	72±72	44±37
7.5	37±54	29±25

4	1110	5610	6720
Overall mean per pipe±s.d.	1030±1090	4150±2990	5180±3240

α-T = α-Terthienyl (2,2′:5′,2″-terthiophene)

BBT = 5-(3-Buten-1-ynyl)-2,2′-bithienyl

widely from that proportion, as seen with pipes 1 and 3 at the first sampling.

Glass Box PDMS Sheet Study PDMS sheets successfully recovered both α-T and BBT, but the amounts found were highly variable as found in the PVC pipe study (Table 3). Two boxes were sampled once approximately 3 weeks after planting. Immediately after sampling, the soil in each box was sectioned into a grid corresponding to the 2.5×2.5 cm^2 sections of the PDMS sheet, and analyzed for either total thiophene content (box 1) or total root mass (box 2). No correlation was found between either total thiophene content or root mass and the amounts of thiophenes measured per PDMS section (data not shown). A third box was sampled twice, at 4 and 5 weeks after planting. As can be seen from the results summarized in Table 3, very different overall results were obtained at each sampling. The maximum amount of α-T recovered on one of the 2.5×2.5 cm^2 sections was 5,990 ng (bordered by sections all yielding less than 40 ng), while BBT concentrations were less extreme in their variation, with a maximum amount of 260 ng recovered (bordered by sections containing 85–216 ng).

Glass Box Microtubing Study The final approach used to measure thiophenes in the marigold root zone was to place several 1 m long coiled PDMS microtubes over portions of the marigold root zone. The silicone tube microextraction approach allows repeated sampling of root exudates without further disturbance of the soil, and experimentally is quite simple, with samples collected directly for HPLC analysis by passing 95% methanol through the microtube. The results of our first applications of silicone tube microextraction to measure thiophenes were remarkably different from those seen with other sampling methods (Fig. 3). The amounts of both BBT and α-T recovered both were highest at the initial sampling, and BBT was higher in the middle and one side of the plate, while α-T recovery was uniform across the plate (Fig. 3). Recovery of BBT slowly dropped from days 2–6, while amounts of α-T recovered and stabilized quickly at approximately 11–14 ng. While the recovery of BBT remained fairly variable among replicate microtubing extractors, with relative standard deviations of 63–87% of the mean values, recovery of α-T with the microtubing was more uniform, with relative standard deviations of 4.0–8.4% of the mean values (Table 4).

The operative range of the silicone tube microextraction was tested for α-T by spiking 1:1 sand:growth medium mixtures with known amounts of α-T and incubating microtubing in the spiked soil for 24 h. This yielded a highly linear response over the range of 0–10 ppm α-T (Fig. 4), and additional measurements (data not shown) show that response was linear to 800 ppm. These data imply that recoveries of 11–42 ng α-T from silicone tube microextractors in the marigold root zone correspond to soil concentrations well below 1 ppm α-T. Separate spiked Petri dishes sampled at 48 and 72 h also yielded linear responses, with slightly increased slopes for each 24 h period. However, repeat sampling of the 24 h dishes at 48 h yielded a lower slope, suggesting that the α-T removed by sampling at 24 h was not completely replaced by diffusion over the next 24 h. Given that sorption to different soil components will vary with time and affect the partitioning behavior of thiophenes, calibration to actual soil concen-

Table 3 Recovery of thiophenes from PDMS membranes press-applied to soil of marigolds grown in glass boxes. Analyses were performed 3, 4 and 5 weeks after planting (WAP). Membranes were analyzed in 2.5×2.5 cm^2 segments, and total thiophene content of the 17.5 cm×20 cm membrane is reported here

Glass Box	α-T, ng per membrane	BBT, ng per membrane	BBT/α-T ratio
1 (3 WAP)	9087	88.8	0.010
2 (3 WAP)	1057	4325	3.09
3 (4 WAP)	517	1965	3.80
3 (5 WAP)	2982	329	0.11

α-T = α-Terthienyl (2,2′:5′,2″-terthiophene)

BBT = 5-(3-Buten-1-ynyl)-2,2′-bithienyl

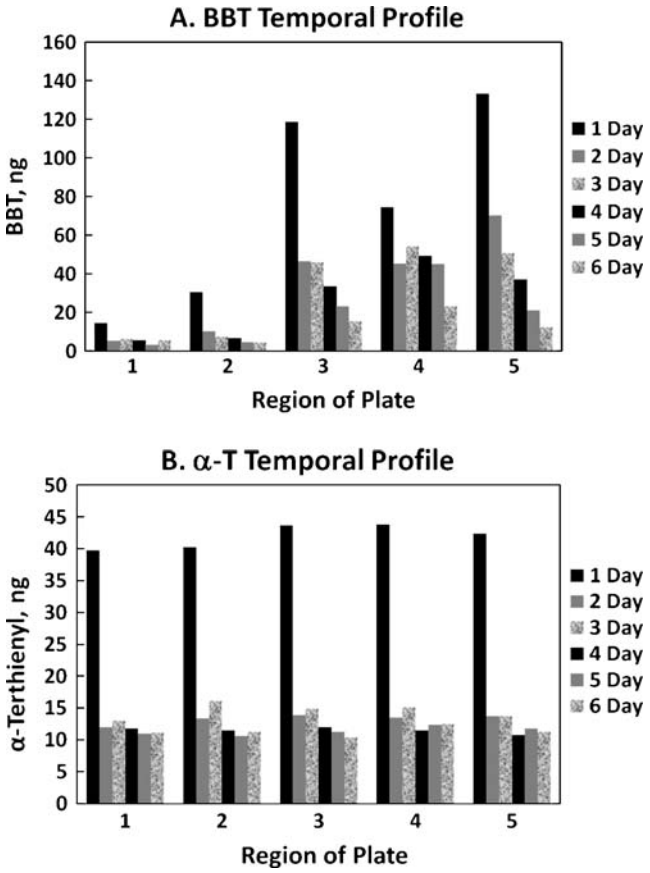

Fig. 3 Amounts of (**a**) 5-(3-buten-1-ynyl)-2,2′-bithienyl (BBT) and (**b**) α-terthienyl (2,2′:5′,2″-terthiophene) (α-T) recovered from five replicate 1 m lengths of PDMS microtubing coiled over successive 4 cm wide×17.5 cm deep sections of marigold root zone across a 20 cm wide glass box. Samples were taken daily for six days. Means and standard deviations for each day are presented in Table 4

trations would be difficult. We envisage two strategies for the calibration of the silicone tube microextraction. (1) The silicone tube can be equilibrated following the principles of equilibrium sampling devices (Mayer et al. 2003), and will then yield measurements of freely dissolved concentrations, chemical activities, or fugacities (Reichenberg and Mayer 2006). This approach will require high surface to volume ratios of the microtubing, and it will be suited for analytes that can be equilibrated within minutes, hours, and possibly days, which appears difficult to achieve for the thiophenes of the present study. (2) Alternatively, the extraction can be operated in the kinetic mode, and it will then yield measurements of the diffusive flux into the silicone similar to the principles of Diffusive Gradients in Thin Films (DGT) that is well established for the sampling of cationic metals (Zhang et al. 1995, 2001).

In follow-up experiments, the effectiveness of the methanol extraction of the tubing was tested by pushing ten 500 µl portions of 95% methanol through tubing incubated in a spiked sand:growth medium mixture, and then extracting remaining α-T from the tubing by sonication in excess 95% methanol. The first wash recovered approximately 40% of the total α-T on the tube, and amounts recovered by subsequent washes followed an exponential decrease, with less than 1% recovered on the tenth wash. After ten washes, less than 5% of the total α-T remained on the tubing. Further work will be required to optimize the methanol extraction procedure and there again are two different strategies. (1) The methanol volume can be minimized to e.g., 100 µl in order to avoid analyte depletion of the silicone, and this will yield the highest possible analyte concentrations in the methanol ($C_{MeOH} = C_{PDMS} * K_{MeOH,PDMS}$) (Mayer et al. 2009). (2) Alternatively, the methanol volume can be increased to several ml aiming for a complete extraction of the PDMS. Optimization of both the sampling step (soil to silicone) and of the extraction step (silicone to methanol) should be feasible, and further studies aiming at a well defined calibration of silicone tube microextraction are underway.

Root Dissection and Diffusion Studies Thiophene content of roots was variable, with no clear pattern in variation from primary to secondary roots (data not shown). Concentrations of BBT and α-T in *T. patula* roots ranged from 0.22–1.38 µmol g^{-1} fresh weight and 0.01–0.04 µmol g^{-1} fresh weight, respectively. Concentrations of BBT and α-T in *T. erecta* roots were lower, ranging from 0.09–0.17 µmol g^{-1} fresh weight and 0.01–0.02 µmol g^{-1} fresh weight, respectively. These data are similar in magnitude to literature reports of thiophene concentrations in marigold roots. Croes et al. (1989) reported total thiophene concentrations of 0.22–0.41 µmol g^{-1} in attached *T. patula* roots, while Croes et al. (1994) found 0.77 µmol thiophenes g^{-1} in roots of six-day-old seedlings of *T. patula*. Jacobs et al. (1994) found total thiophene concentrations in *T. patula* roots to be consistently higher than those of *T. erecta*, which they reported to range from 0.14–0.21 µmol g^{-1}.

Table 4 Mean amounts (± SD) of α-T and BBT measured over six days from five replicate 1 m lengths of PDMS microtubing placed over 4 cm×17.5 cm sections of marigold root zone in a 20 cm wide glass box. Values of individual replicates are presented in Fig. 3

Day	α-T, ng per microtube	BBT, ng per microtube	BBT/α-T ratio
1	42.0±1.9	74.4±52.3	1.77
2	13.3±0.8	35.6±27.2	2.67
3	14.6±1.2	33.0±24.1	2.26
4	11.5±0.5	26.4±19.4	2.29
5	11.4±0.7	19.5±17.0	1.71
6	11.3±0.8	12.2±7.7	1.08

α-T = α-Terthienyl (2,2′:5′,2″-terthiophene)

BBT = 5-(3-Buten-1-ynyl)-2,2′-bithienyl

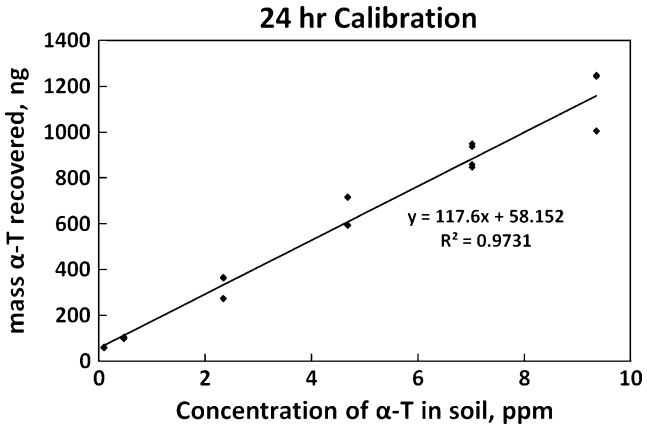

Fig. 4 External calibration of silicone microtubing prepared by spiking 1:1 sand:growth medium with known concentrations of α-terthienyl (2,2′:5′,2″-terthiophene) and incubating 1 m lengths of microtubing for 24 hr

The amounts of BBT found in roots are in general much higher than α-T. For *T. erecta*, the ratio of BBT to α-T ranged from 3.7:1 to more than 20:1 depending on the sample, considerably higher than the typical ratio of BBT to α-T recovered with the various PDMS extraction methods (Tables 3 and 4), suggesting that α-T is either preferentially exuded by roots or is more stable in soil than BBT. Further study will be required to answer this question.

Over seven days, limited diffusion of α-T was observed in sand, with ng quantities of the thiophene detected up to 4 cm from the source probe (Fig. 5a). Slightly greater diffusion was observed in the sand:growth medium mixture, but was still in the ng range compared to the 22 μg loading on the probes (Fig. 5b). Such a result was expected for these highly lipophilic compounds. The limited ability of α-T to diffuse in soil implies that it will tend to stay where it is produced, and indicates that direct contact with marigold roots or rhizosphere soil will be necessary for thiophenes to be available to target plants or organisms.

Taken together, our results provide some evidence for continued release of thiophenes from marigold roots. The limited ability of α-T to diffuse in soil, combined with the decreased amount of α-T recovered when spiked soils were resampled in the microtubing calibration study, implies that the stable concentrations of α-T measured over days 2–6 with the microtubing reflect continued release of α-T into the root zone. However, further studies will be required to verify this.

Comparison of PDMS Sampling Methods The three PDMS-based methods gave markedly divergent results, with much lower variability in amounts recovered seen with the microtubing, especially for α-T. The three techniques are not equivalent in their potential for measuring thiophene distributions in the marigold root zone. The SPRE probes (5 cm length, 1.19 mm outer diam) have an exposed surface area of approximately 1.9 cm^2, and gather data for specific, separate regions of the root zone. The PDMS sheet provides data on a vertical slice of the root zone, providing an average value over each 2.5 cm square (= 6.25 cm^2) segment. The PDMS microtubing (1 m length, 0.64 mm outer diam) has an exposed surface area of approximately 19 cm^2 (accounting for 2 cm at each end of the tube not in contact with soil), and thus averages thiophene concentrations over a larger region of soil than the other two methods. The question of whether the heterogeneity of thiophene distributions observed with the SPRE probe and PDMS sheet methods is real or an artifact of the sampling methods is crucial, given that such variation in the soil could have profound impacts on biological activities of these compounds.

We interpret our data to support the conclusion that the extreme heterogeneity of thiophene concentrations observed with the SPRE probes and PDMS sheets is an artifact of the sampling method and probably due to root

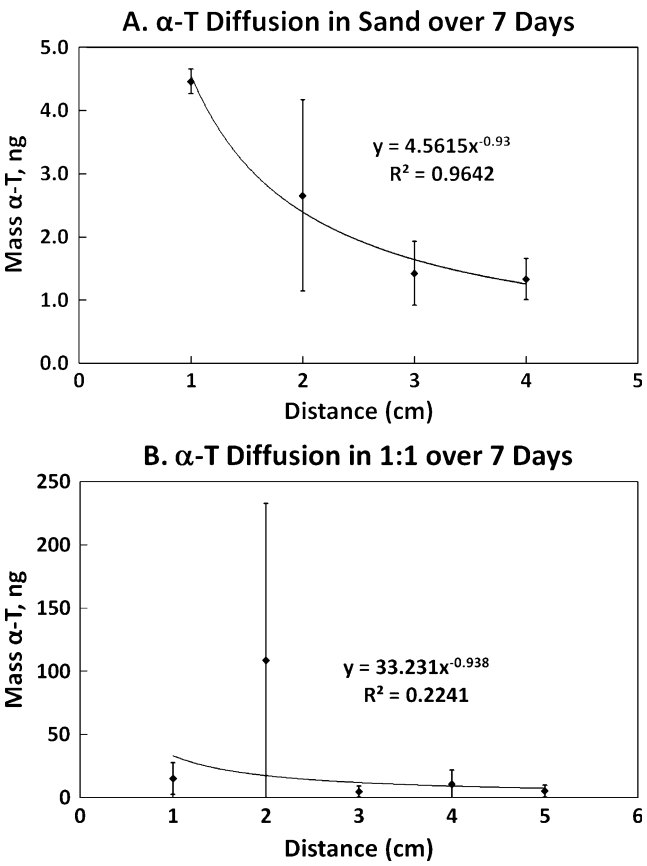

Fig. 5 Diffusion of α-terthienyl (2,2′:5′,2″-terthiophene) α-T from loaded SPRE probes in (**a**) sand and (**b**) a 1:1 sand:growth medium mixture over seven days

injury and/or disturbance by these methods. We base this conclusion on several observations: (a) Variability of the SPRE probe method was extremely high even if the amount of thiophenes found on all 24 probes per sampling was summed (Table 2). The total exposed surface area of 24 SPRE probes is 45.6 cm^2, more than double that of the 1 m microtubes, yet variability was very high for the SPRE method in comparison to the microtubes; (b) Heterogeneity of soil concentrations could be due to localized interactions of roots with soil microbes and microfauna, but as noted above there was no correlation between thiophene recovery and marigold root mass in the PDMS sheet study; (c) The higher recovery of thiophenes on the initial day following application of the microtubing, which was less disruptive than the press-application of PDMS sheets, also seems to underscore the importance of minimizing soil disturbance during sampling, at least for this system. A crucial requirement for obtaining accurate data on allelochemical concentrations in soil is that those dynamics not be altered by the attempt to measure them.

Finally, while PDMS in the form of SPRE probes may not be useful as originally envisioned for measurement of allelochemical dynamics (Weidenhamer et al. 2009), loaded probes may prove useful as a means to deliver known amounts of lipophilic compounds for bioassay (e.g., Mayer and Holmstrup 2008; Kwon et al. 2009).

Advantages and Potential Applications of the Silicone Tube Microextraction Method The silicone tube microextraction method is a further development of the silicone membrane equilibrator technique, which was developed and applied for measurements of volatile organic compounds in seawater (Ooki and Yokouchi 2008) and of polycyclic aromatic hydrocarbons in vegetable and fish oils and mussel tissue (Mayer et al. 2009). In this paper, we call this method silicone tube microextraction as a more descriptive name for placing silicone microtubing for sampling in the root zone. This method has several key advantages for studies of root exudates: (a) Once microtubing is in place, the root zone can be repeatedly sampled without further disturbance; (b) the sampling method is quite simple, and the materials are inexpensive; (c) the method is sensitive to daily and spatial variations in allelochemical content; and (d) calibration of results to available analyte concentrations seems feasible, though this requires further research. The technique should be broadly applicable to the measurement of non-polar root exudates, providing a means to test hypotheses about the role of root exudates in plant-plant and other interactions. It should be possible to place microtubing in pots prior to seeding plants to monitor allelochemical dynamics over time or plant response to treatments such as herbivory, nutrient stress, or competition. Applications of microtubing for field studies also should be possible. Further explorations of the potential of this method for allelochemical analysis in soil are underway.

Acknowledgments This research was supported by a grant from the National Science Foundation (DEB 0515826) and from the European Commission (MODELPROBE, no. 213161). Philip Boes assisted with isolation and characterization of BBT. Udo Blum and two anonymous reviewers provided helpful comments on the manuscript. Kelly Harrison assisted with greenhouse cultivation of plants.

produced by a great variety of plant species. In addition, considerable diversity is often observed in the structure and concentration of chemical constituents within exudates of various species or cultivars (Bertin et al. 2003a).

Root exudates and the allelochemicals they contain generally are thought to degrade fairly rapidly within the soil rhizosphere, through the activity of soil microbes, chemical breakdown and immobilization caused by irreversible binding to organic matter and lignin (Blum et al. 1991; Weston and Duke 2003; Weidenhamer 2004). To further characterize allelochemical interference in the rhizosphere, the accumulation of allelochemicals at phytotoxic levels and their fate, persistence, and interactions in soil, are important to examine. For example, the allelopathic activity of black walnut (*Juglans nigra* L.) has been observed for years (Massy 1925; Davis 1928). Some believe that because juglone is sensitive to biotic and abiotic degradation in soil, it is improbable that it persists at phytotoxic concentrations high enough to result in growth inhibition (Schmidt 1988, 1990). Others have argued that the allelopathic potential of juglone is due to its existing concentration in the soil suspension, its renewal rate by release from living roots, and the sensitivity of surrounding species that are impacted by juglone itself (Williamson and Weidenhamer 1990). As allelochemicals undergo chemical and biological degradation upon soil entrance, their accumulation and concentration may likely change rapidly over time in soil settings. Hence, many researchers have expressed their concerns regarding the relative unpredictability of laboratory bioassays in terms of explaining field observations (Inderjit and Dakshini 1995, 1999; Inderjit and Weston 2000).

We have shown in recent studies that m-tyrosine, an analogue non-protein amino acid, is exuded by the living root system of certain fine leaf fescue species. Interestingly, it possesses potent weed suppressive activity and appears to impact plant growth mainly from initial inhibition of plant root growth or radicle elongation at very low concentrations (Bertin et al. 2003a, b, 2007). The laboratory bioassays we utilized for our initial isolation and characterization of *m*-tyrosine were simple assays that evaluated seed germination and radicle elongation in soil-less Petri dishes, with a variety of indicator species. In an attempt to examine further its activity under controlled laboratory conditions before studying its release in rhizospheres of living roots under field conditions, we evaluated its effect upon plant growth in a series of soil-based bioassays, using lettuce (*Lactuca sativa*) L. as a sensitive indicator species. Here, we report on the effects of soil texture upon allelochemical activity as well as soil amendment with nitrogen and activated carbon, in an attempt to determine if *m*-tyrosine activity in soil is impacted by availability in these soil conditions. We also evaluated the relative soil persistence of *m*-tyrosine in different soil media over time. One key objective was to demonstrate that laboratory bioassays that evaluate allelochemical activity and soil persistence can be utilized to generate useful preliminary data, in an attempt to predict allelochemical activity under field conditions, and to design more appropriate field-based studies to evaluate allelochemical persistence in the rhizosphere environment.

Methods and Materials

General Procedures Soil (Arkport fine sandy loam: psamentic Hapludlafs, coarse loamy mixed mesic, pH 6.2) was collected from a field situated at the Bluegrass Lane Research Farm at Cornell University in Ithaca, NY. Soil was allowed to dry at room temperature and was sieved (1.8 mm sieve) and mixed with dried field or patio sand at a ratio of 1:1 to allow for enhanced permeability and reduced soil puddling in laboratory based experiments with small receptacles. The soil mixture had an organic matter content of less than 2.0%. In addition, a peat-based growth medium with higher organic matter (MetroMix 360, Scotts Company, Maryville, OH, USA, organic matter content >4%; pH 6.4) was utilized for experimentation to assess impact of high organic growth media upon *m*-tryosine activity (Roberts 2006). Soils were not autoclaved but were dried at room temperatures before utilization. DL *m*-Tyrosine was purchased from Sigma/Aldrich and was utilized in all experiments. In experiments performed to evaluate activity of synthetic *m*-tyrosine and *o, p*, and purified *m*-tyrosine, synthetic DL *m*-tyrosine showed nearly identical activity to that evaluated in purified root exudates of fine leaf fescue cv. Intrigue (Bertin et al. 2007). A stock solution was prepared (6 mg*m*-tyrosine/L) from which other concentrations of *m*-tyrosine dissolved in purified water were formulated for use in experiments outlined below. The pH of all *m*-tyrosine solutions and purified laboratory water (Waters Millipore Corporation, Billerica MA, USA) was within a neutral pH range (6.2–6.7) during the course of this experiment.

Soil Texture Study Soil sand media (40 g) was amended with 25 ml each of aqueous solution containing m-tyrosine in various concentrations to provide a final concentration in each Petri dish of 20, 40, 80, and 160 μM*m*-tyrosine per dish. Soil that was amended with 25 ml untreated purified water served as a control so that each dish was moistened with an equal volume of water before an experiment was conducted. All dishes were closed with lids after seeding with indicator species, and placed in an controlled environment incubator until experiment termination. A similar experiment was performed with MetroMix 360 growth medium (described above) utilizing an identical protocol.

Soil Amendment Studies MetroMix 360 (15 g) growth medium was amended with 0, 0.25, 0.5, and 1 g of activated carbon (Sigma Corporation, St Louis MO, USA) and with *m*-tyrosine solutions at a concentration of 160 µM. The experiment was replicated three times for each activated carbon treatment and was repeated over time.

An additional experiment was designed where MetroMix 360 (15 g) was amended with *m*-tyrosine to formulate concentrations of 20, 40, 80, 160 µM *m*-tyrosine in soil media. For each *m*-tyrosine concentration, 0, 0.25, 0.5, and 1 g/dish of activated charcoal treatments were evaluated. Soil that was amended only with distilled water or activated charcoal alone served as a control. Appropriate amounts of ammonium nitrate (NH_4NO_3) were dissolved in water and added to soil to provide final concentrations of 0.25, 0.5, 0.75, and 1.0 mM ammonium nitrate per dish. In addition, *m*-tyrosine was added to soil at a concentration of 160 µM.

Soil Persistence Study MetroMix media (15 g) was amended with 25 ml of appropriate aqueous solutions to provide 160 µM *m*-tyrosine per dish. Lettuce seeds (Johnny's Select Seed; Winslow, ME, USA) were sown at d 0, 2, 5, 7, and 15 d after the aqueous solution of *m*-tyrosine was mixed with the soil media. Lettuce radicle length was measured for each seedling 7 d after seeding, and percent inhibition of radicle growth was recorded.

Growth Analyses In all experiments described above, lettuce was selected as the assay species of choice because it exhibited rapid and uniform germination. Large crabgrass (*Digitaria sanguinalis*) also was assessed in the first two experiments because it is a common monocotyledonous weed in turf settings and exhibits reasonably uniform and fast germination. Prior experiments have shown that *m*-tyrosine is a potent inhibitor of root growth of both large crabgrass and lettuce (Bertin et al. 2003b). Soil or MetroMix 360, was placed in 9-cm petri dishes, and 15 lettuce or crabgrass seeds were sown on the soil surface of each dish following amendment with m-tyrosine, ammonium nitrate, or activated carbon. Root and shoot length of lettuce and large crabgrass were recorded after 7 d of growth in an incubator at a temperature of 25ºC and lighting of 46 µmol photon $m^{-2}s^{-1}$. Each treatment was replicated three times, and was arranged in a completely randomized design. All experiments were repeated over time.

Statistical Analyses Each data set was analyzed statistically by using the general linear model (GLM) procedure (SAS Inst. 1998) for completely randomized design experiments. Means were separated by LSD at the $a=0.05$ level. Standard errors were calculated for each treatment mean where appropriate.

Results and Discussion

Soils Amended with m-Tyrosine A sand/soil mix with low organic matter content amended with *m*-tyrosine significantly suppressed both the radicle and hypocotyl growth of lettuce, and increasing concentrations exhibited greater inhibition of growth, with radicle elongation especially impacted (Fig. 1). *m*-Tyrosine was dissolved easily in aqueous solutions, and was applied to soil that was then thoroughly mixed to ensure uniform distribution. Application was made in a manner similar to commercial herbicide formulations that are used in turf and landscape settings, and were evaluated in past laboratory experiments for comparative toxicity purposes. *m*-Tyrosine at these concentrations was approximately 2–4 times higher in concentration than comparable labeled field application rates of soil applied pendimethalin, which currently is used widely for commercial control of weeds in established turf (data not presented). Treated lettuce initially was able to germinate under the conditions provided, but further growth at higher concentrations of *m*-tyrosine up to 160 µM was significantly reduced, indicating that *m*-tyrosine was available in the soil solution at these concentrations in quantities sufficient to control seedling growth of lettuce during the evaluation period.

Compared with previous Petri-dish bioassays performed on filter paper, the concentration of *m*-tyrosine required for growth inhibition in soil media was higher. The concentration of *m*-tyrosine required for 50% inhibition of root growth of lettuce (I_{50}) in soil is approximately 30 µM, whereas in a soilless assay, the I_{50} is approximately 8 µM. For large crabgrass (data not presented), the I_{50} value in soil media was approximately 25 µM. It is likely that in these

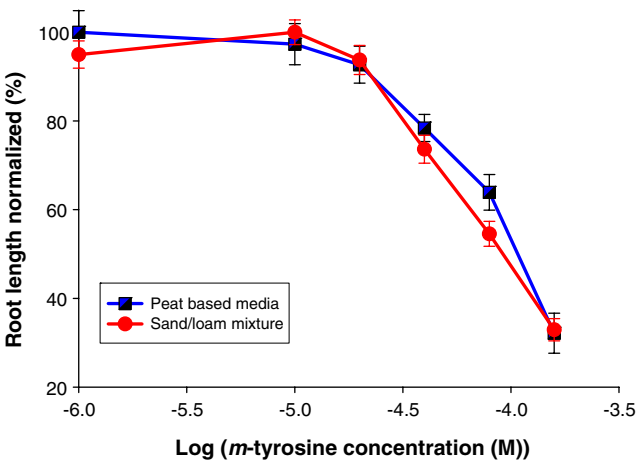

Fig. 1 Impact of *m*-tyrosine on root length of lettuce seedlings in an amended sand and loam soil mixture and MetroMix 360, a peat-based growth medium. Standard error bars are presented for each treatment and treatment means were calculated on the basis of 6 replicates per treatment and 90 seedlings per treatment unit

simulated soil experiments in the laboratory, *m*-tyrosine interacts by adsorption to soil particles or organic matter, resulting in reduced specific activity in soil or organic-based media because less is available in the soil water solution. Soil composition and texture often impact the activity of herbicides in a field environment, with higher concentrations of herbicide required in higher organic matter soils (Cobb and Kirkwood 2000). However, in the case of *m*-tyrosine, inhibition of lettuce radicle elongation was similar in both the higher organic matter growth medium and in the sand/soil mixture (Fig. 1). One might suspect that significant soil sorption, both reversible and irreversible, are associated with reduced activity or availability of *m*-tyrosine in soil media (Blum 1998) in comparison to toxicity observed in soilless growth media experiments performed on filter paper or agar media (Bertin et al. 2007).

Nitrogen Fertility Various levels of ammonium nitrate dissolved in water were added to soil amended with and without *m*-tyrosine. In the absence of *m*-tyrosine, nitrogen application did not significantly affect the growth of lettuce seedlings over a 7 day period, even at high concentrations of fertilizer N (1 mM). In the presence of *m*-tyrosine, it appeared that the addition of fertilizer N impacted root growth to some extent by reducing toxicity, especially at higher concentrations of soil N; however, toxicity was never overcome even at the highest N concentration (Table 1). Inhibition of radicle elongation was reduced by approximately 25% in the presence of *m*-tyrosine and 1 mM NH_4NO_3 in comparison to *m*-tyrosine applied without soil NH_4NO_3 (Table 1). We did not measure soil microbial activity in these assays, but higher microbial activity due to additional nitrogen fertilization might be suspected (Novak et al. 1995), thus resulting in significantly reduced availability of *m*-tyrosine due to enhanced microbial degradation. The presence or bioavailability of organic compounds as substrates for microbial growth generally influences microbial activity. However, additional experiments with various pasteurized or sterilized soil types and specific microbial communities will be useful to develop a better understanding of the role of soil microfauna on *m*-tyrosine toxicity, especially in field vs. laboratory conditions.

Table 1 Effect of *m*-tyrosine in peat based growth medium amended withsoluble ammonium nitrate solutions on root growth of 7 day old lettuce seedlings

Ammonium nitrate concentration (mM)	Root length of lettuce seedlings (cm) with *m*-tyrosine at 160 µM	Root length of untreated lettuce seedlings (SE=±1)
0	2.07 (0.02)	6.48 (0.37)
0.125	3.56 (0.07)	6.79 (0.32)
0.25	4.82 (0.1)	7.00 (0.29)
0.5	4.8 (0.09)	7.13 (0.35)
1.0	4.8 (0.12)	6.88 (0.47)

Numbers in parentheses refer to standard errors calculated for each treatment. Treatment means were calculated on the basis of 6 replications per treatment and 90 seedlings per treatment unit.

Soil Amended with Activated Carbon Activated carbon often is used to trap or eliminate the interference or inhibition caused by organic molecules in soil-based systems (Mahall and Callaway 1992; Inderjit and Foy 1999). By sequestering water-soluble organic constituents, the presence of activated carbon can remove allelochemicals from the soil in situ (Inderjit and Nilsen 2003). Activated carbon usually is used in field settings to remove residual herbicidal activity. Therefore, in this study, we assessed the activity of charcoal upon plant growth inhibition due to *m*-tyrosine. We compared the effect of *m*-tyrosine on lettuce seedling root elongation grown in soil bioassays supplemented with or without activated carbon. Compared to the control, soil amended with different amounts of charcoal clearly exhibited reduced toxicity of *m*-tyrosine on radicle elongation of lettuce (Figs. 2 and 3). Carbon itself had only limited effect on plant growth in untreated lettuce seedlings, and resulted in some apparent stimulation of growth that was not statistically significant. Inhibition of radicle elongation, however, was still observed at low concentrations of activated carbon (0–0.25 g/dish) in m-tyrosine treated seedlings. At the highest concentration of m-tyrosine and activated carbon (1.0 g/dish), inhibition

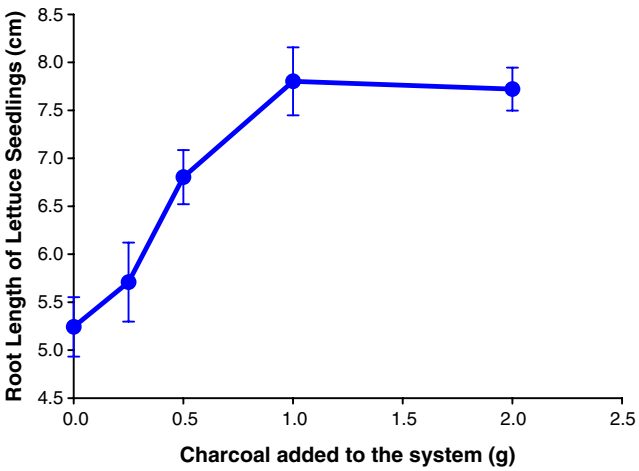

Fig. 2 Effect of increasing amount of activated carbon or charcoal upon root growth of *m*–tyrosine treated lettuce seedlings in peat based growth medium. M-tyrosine was applied at a rate of 160 µM to activated charcoal treated soils. Standard error bars are presented for each treatment mean and means were calculated on the basis of 6 replicates per treatment and 90 seedlings per treatment unit

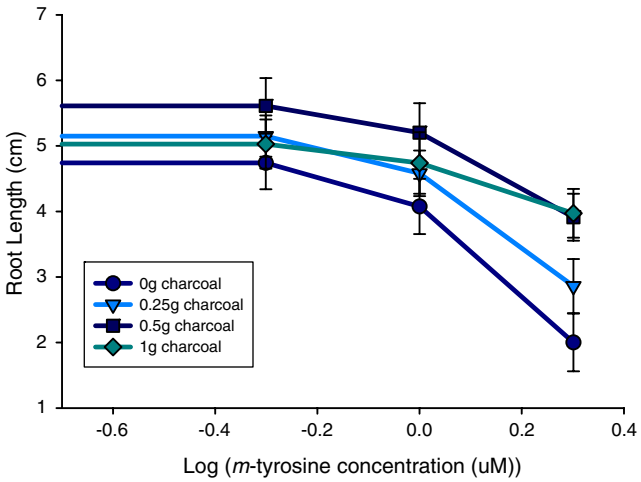

Fig. 3 Effect of increasing activated carbon or charcoal amendment and *m*-tyrosine concentration in peat based growth medium on root growth of lettuce seedlings. Standard error bars are presented for each treatment mean and means were calculated on the basis of 6 replicates per treatment and 90 seedlings per treatment unit

of root growth was much reduced in comparison to the m-tyrosine treatments without activated charcoal, suggesting that *m*- tyrosine was inactivated by high soil concentrations of activated carbon. This experiment suggests that *m*-tyrosine can bind to organic soil constituents such as carbon, thus resulting in reduced bioavailability and phytotoxicity, if these organic constituents are of fine texture and have available binding sites. In recent literature, it has been suggested that addition of activated carbon can cause increases in plant growth not because of reduced bioavailability of toxic constituents, but because of additional available nitrogen provided by the carbon itself (Lau et al. 2007). Although we did not assess available N from activated carbon in our growth media, we did show that additional N provided to the growth media in the form of ammonium nitrate impacted phytoxicity by causing reductions in toxicity. It may be that activated carbon may act in multiple ways to reduce toxicity of m-tyrosine, by reducing availability of the compound and also by providing additional soil N that might in turn stimulate microbial degradation. It is likely that significant levels of *m*-tyrosine remained available in the soil solution at high concentrations of m-tyrosine and were not completely sorbed even at higher carbon incorporation rates, given that we still observed considerable toxicity at these higher rates of incorporation (Fig. 3).

Soil Persistence Once allelochemicals are released into the environment, they are susceptible to decomposition or inactivation by microorganisms and also to chemical interactions that do not involve microorganisms (Rice 1984). Many environmental factors influence the persistence of allelochemicals in the soil (Blum 1998, 1999). A supplemental study was performed to evaluate the persistence of *m*-tyrosine in soil- based growth media over time (Fig. 4). When lettuce seeds were seeded in MetroMix 360 amended with *m*-tyrosine and resided at ambient temperature just prior to seeding, significant root and shoot growth inhibition were observed (Fig. 1). However, longer residence time in soil of 2 days or greater resulted in no significant soil toxicity in comparison to the untreated control. Our data indicate a half life of *m*-tryosine of less than 2 days and likely less than 24 hours after soil incorporation. Further experiments are required to determine the exact half life in these conditions. In the case of perennial species such as *Festuca* spp., consistent production and release of allelochemicals at phytotoxic levels is possible as the mass of living fibrous roots that exist within a perennial turf sod is large, and new root growth and continous root exudation is likely. Although rapid degradation of *m*-tyrosine is likely in both laboratory and also field settings, continuous release of root exudates over time by the extensive living root system of fine fescues may result in continual replenishment, especially in the rhizosphere where germinating weed seeds are likely to be located. In comparison to other phenolics, which are degraded within hours after application to soil settings, *m*-tyrosine appears to exhibit similar low levels of soil persistence (Blum et al. 1991).

In summary, we demonstrated that *m*-tyrosine is active in a number of soil settings when present in significant concentrations for uptake by seedlings from the soil solution. *m*-Tyrosine causes significant growth inhibition, in particular inhibition of radicle elongation of both

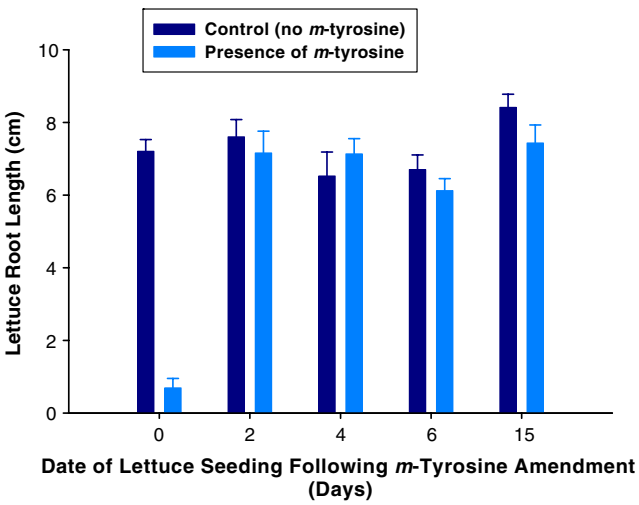

Fig. 4 Persistence of *m*-tyrosine in peat based growth medium as measured by lettuce seedling growth over time. *m*-Tyrosine was added to the soil media at time 0 and lettuce seeds were seeded after 0, 2, 4, 8, and 15 days following m-tyrosine amendment. Standard error bars are presented for each treatment mean and means were calculated on the basis of 6 replicates per treatment and 90 seedlings per treatment unit

monocots and dicots. Phytotoxicity is impacted by the addition of soluble nitrogen to the soil media, perhaps by stimulation of enhanced microbial degradation of *m*-tyrosine but apparently generally is unaffected by soil organic matter content or textural alteration. However, the toxicity of *m*-tyrosine was impacted by the presence of activated carbon in soil media, which likely results in decreased bioavailability and a subsequent reduction in phytotoxicity. It is also possible that additional N provided by presence of activated carbon also impacts availability and activity of *m*-tyrosine. In sand/loam soils, the persistence of *m*-tyrosine is limited to less than 48 hours or less, with an estimated half life of less than 24 hours.

While it is possible that *m*-tyrosine plays an important role in allelopathic interactions observed in fine fescue species, further experimentation in actual field settings is needed to assess accurately its rate of release and relative persistence in rhizosphere settings. *m*-Tyrosine may have potential to be utilized as a natural or organic herbicide if bioavailability in field soil can be significantly increased by reformulation to allow for enhanced soil persistence over time.

A recent paper by Kaur et al. 2009, suggests that microbial degradation of *m*-tyrosine is high, and half life of *m*-tyrosine was estimated as less than 24 hours in laboratory experimentation. The authors challenged the ability of *m*-tyrosine to act as an allelochemical inhibitor in microbially active soils. As their results also were conducted under conditions optimal for microbial growth in a laboratory setting, we believe that additional studies performed in a field setting with living root systems present and field microbial populations will better predict residence times of m-tyrosine in natural settings and determine whether continual production and release of a molecule such as m-tryosine will in certain cases and soils, lead to an allelopathic interaction. The common example of black walnut juglone indicates that degradation of this phenolic occurs in a matter of hours in laboratory persistence experiments. These findings, however, conflict with actual field observations where black walnut toxicity is clearly observed in infested soils in long term experiments. In the case of a perennial sod such as that formed by fine leaf fescues, the potential exists for nearly continual production during the growing season and a localized release of root exudates within the rhizosphere to germinating weed seeds. Additionally, we have observed weed suppression by certain fine leaf fescues over multiple locations and years and have determined that this suppression is cultivar dependent (Bertin et al. 2009). Further studies are now underway to directly assess m-tyrosine release rates and to evaluate toxicity within the rhizosphere of living fine fescue roots.

Acknowledgements We thank Dr. F. C. Schroeder for assistance in the design of the soil bioassays and Prof. U. Blum for critical review of the manuscript.

the cultured broth of this strain was not successful. Instead, the co-culturing of *Microcystis* with the *Brevibacillus* sp. enhanced the production of two volatile compounds, β-cyclocitral (Fig. 1) (Jüttner 1984; Jüttner and Höflacher 1985) and 3-methyl-1-butanol (Wright et al. 1991). The former had a characteristic lytic activity (Ozaki et al. 2008). It was confirmed that these volatile compounds were derived from the cyanobacteria themselves. Further, β-ionone (Fig. 1), geosmin, and 2-methylisoborneol (2-MIB) derived from cyanobacteria and similar volatile compounds, i.e., terpenoids, produced by plants, also had lytic activity. Although the minimum inhibition concentration (MIC) values of the cyanobacterial metabolites were estimated to be higher generally than those of compounds from plants, their local concentrations around a cluster of cyanobacteria might reach a sufficient concentration to cause auto-lysis, because they are intrinsic metabolites (Ozaki et al. 2008).

Among these volatile compounds, β-cyclocitral caused a characteristic color change in the culture broth from green to blue during the lysis process (see Supplementary Material Fig. 1). In the past, a similar color change had been found several times in the natural environment and was recently observed in Lake Tsukui (see Supplementary Material Figs. 2, 3, 4). Because it was hypothesized that β-cyclocitral is critical for the regulation of cyanobacteria in a freshwater ecosystem, the blue color formation of cyanobacteria with β-cyclocitral was investigated. This study focuses on the lytic behavior of various cyanobacteria with β-cyclocitral and its mechanism involving the blue color formation.

Methods and Material

Chemicals β-Cyclocitral was purchased from Wako Pure Chemical Industries (Kyoto, Japan), β-ionone was obtained from Kanto Chemical (Tokyo, Japan), and citral, cinnamaldehyde, perillaldehyde, and vanillin were purchased from Sigma-Aldrich (St. Louis, MO, U.S.A.). Methanol was purchased from Nacalai Tesque (Kyoto, Japan).

Cyanobacteria Cultures Axenic strains NIES-73, -102, -103, -112 and -298 belonged to *Microcystis,* NIES-611 was a *Phormidium*, and NIES-808 was an *Anabaena*. They were

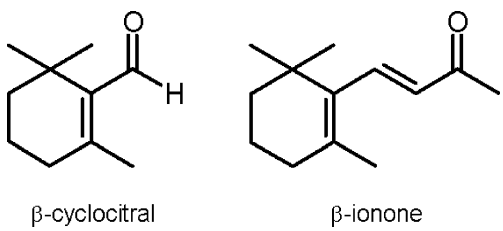

Fig. 1 Structures of β-cyclocitral and β-ionone

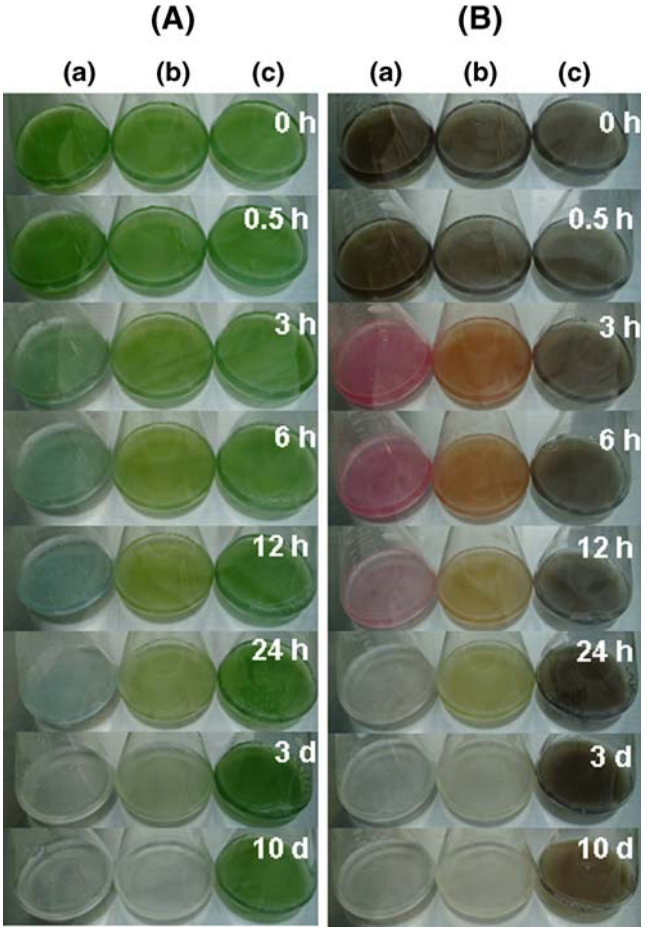

Fig. 2 The color change in lysed cyanobacteria; (A) NIES-102, (B) NIES-611, (a) β-cyclocitral, (b) β-ionone and (c) water

obtained from the National Institute for Environmental Studies (NIES), Tsukuba, Japan. PCC6803 was a *Synechocystis* sp. obtained from the Pasteur Culture Collection of Cyanobacteria (PCC), Paris, France. These strains were cultured in 1 liter Erlenmeyer flasks, each containing a modified MA medium (300 ml) at 25°C for 8 d under a 28 $\mu Em^{-2}s^{-1}$ continuous illumination. The MA medium consisted of a mixture of bicine (500 mg); $Ca(NO_3)_2{\cdot}4H_2O$ (50 mg); KNO_3 (100 mg); $NaNO_3$ (50 mg); Na_2SO_4 (40 mg); $MgCl_2{\cdot}6H_2O$ (50 mg); β-Na_2glycerophosphate (100 mg); a mixed metal solution (1 ml; composed of 1 mg of Na_2EDTA, 0.1 mg of $FeCl_3{\cdot}6H_2O$, 1 mg of $MnCl_3{\cdot}4H_2O$, 0.1 mg of $ZnCl_2$, 1 mg of $CoCl_2{\cdot}6H_2O$, 0.16 mg of $Na_2MoO_4{\cdot}2H_2O$ and 4 mg of H_3BO_3 in 200 ml of distilled water), and the resulting solution was adjusted to pH 8.6.

Collection of Cyanobacterial Blooms A bloom sample was collected from Lake Suwa on August 6, 2007, and another from Lake Tsukui on August 24, 2007 in Japan.

Measurement of Anticyanobacterial Activity The anticyanobacterial activity also was determined by measuring the

absorbance of chlorophyll-a (Uchida et al. 1998). Briefly, the final concentrations (6.5 mM) of the volatile compounds (β-cyclocitral, β-ionone, citral, cinnamaldehyde, perillaldehyde, and vanillin) were added to 100 ml of the cultured cyanobacteria (8 d) and natural blooms, and incubated at 25°C with shaking for 1 and 10 d under a 28 $\mu Em^{-2}s^{-1}$ continuous illumination. Water was used as the control. Five ml aliquots of the culture medium were withdrawn according to the color change during the first day, and then once per day until the 10th day. Simultaneously, the culture broth was photographed. The pH of the withdrawn samples was measured with a pH meter Navi F-52 (Horiba Ltd., Kyoto, Japan) and filtered through a GF/A filter (Whatman International, Ltd., Maidstone, England). The cyanobacteria on the filters were soaked in 2.5 ml of methanol, and the resulting mixture was stored at 4°C in the dark overnight. A 200 μl aliquot of the supernatant was placed on a 96-well microplate well (Kartell, Milan, Italy), and the optical density was measured at 665 nm with an MPR-A4iII microplate reader (TOSOH, Tokyo, Japan). The anticyanobacterial activity was determined as a decrease in absorbance (see Supplementary Material Fig. 6).

Acidification of MA medium by the Volatile Compounds β-Cyclocitral and β-ionone were added to 100 ml of the MA medium or water to the final concentrations (6.5 mM), and incubated at 25°C with shaking for 1 and 20 h under a 28 $\mu Em^{-2}s^{-1}$ continuous illumination. Water and ethanol were used as the negative control. Aliquots of 5 ml of the MA medium or water were withdrawn during the first, 0.5, 3, and 18 h. The pH of withdrawn samples was measured with a Navi F-52 pH meter.

Absorption Spectra of Culture Broths β-Cyclocitral and β-ionone were added to 100 ml of the *Microcystis* NIES-102 or *Phormidium* NIES-611 cultured for 8 d at the final concentrations (6.5 mM), and incubated at 25°C with shaking for 1 and 10 d under a 28 $\mu Em^{-2}s^{-1}$ continuous illumination. Water was used as the control. Aliquots of 5 ml of the culture medium were withdrawn according to the color change during the first day, and then once per day for 10 d. Absorption spectra were recorded at 800–190 nm using a Jasco V-560 UV/VIS spectrophotometer (Jasco Int. Co., Tokyo, Japan).

Isolation of an Acidic Compound β-Cyclocitral was added to water with shaking for 20 h, and the produced acidic compounds were collected by liquid-liquid separation with ether. The main compound was isolated by using a preparative HPLC whose system consisted of a pair of CCPS pumps, an SD-8022 degasser, a CO-8020 column oven, a UV-8020 detector, and a PX-8020 system controller (TOSOH, Tokyo, Japan). The sample was filtered by using an Ultrafree-MC membrane centrifuge filtration unit (hydrophilic PTFE, 0.2 mm, Millipore, Bedford, MA, U.S.A.) and loaded onto a Cosmosil $5C_{18}$-AR-300 column (250×10 mm ID, particle size 5 mm, TOSOH, Tokyo, Japan). The mobile phase was methanol/water containing 0.1%(v/v) formic acid. The methanol concentration was increased from 60 to 90% for 25 min in

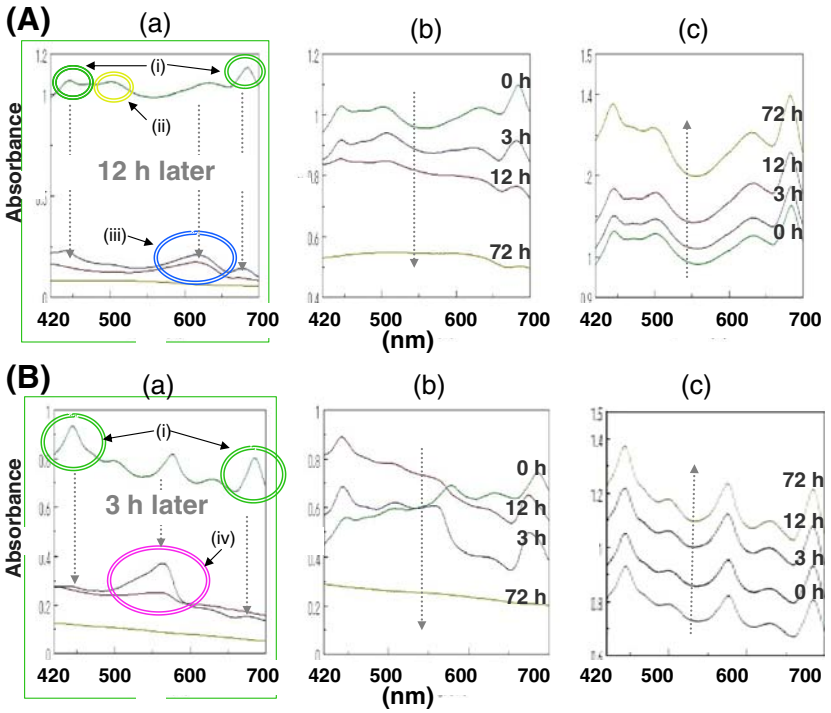

Fig. 3 The visible spectra of lysed NIES-102 and -611; (A) NIES-102, (B) NIES-611, (a) β-cyclocitral, (b) β-ionone, and (c) water. The circles of (i), (ii), (iii) and (iv) indicate the absorption maxima of chlorophyll-a (420 and 680 nm), β-carotene (500 nm), phycocyanin (620 nm) and phycoerythrin (560 nm), respectively. The absorbances of these characteristic absorption maxima changed with the growth of the cyanobacterium as indicated by the arrows

the linear gradient mode. The column temperature was 40°C and the flow rate was 3 ml/min.

LC/MS Five μl of the sample were filtered using an Ultrafree-MC membrane centrifuge filtration unit (hydrophilic PTFE, 0.2 mm, Millipore, Bedford, MA, U.S.A.). The acidic compound analysis was carried out by LC/MS. The LC separation was performed with an Agilent 1100 HPLC system (Agilent Technologies, Palo Alto, CA, U.S.A.). The compound was monitored at 254 nm using a variable wavelength UV detector. The column was a TSK-gel Super-ODS column (100×2 mm ID, particle size 2 mm, TOSOH, Tokyo, Japan). The mobile phase was acetonitrile/water containing 0.1% formic acid. The acetonitrile concentration was increased from 10 to 80% for 20 min in the linear gradient mode. The column temperature was 40°C, and the flow rate was 0.2 ml/min. The MS analysis was accomplished with a Finnigan LCQ Deca XP plus mass spectrometer (Thermo Fisher Scientific, San Jose, CA, U.S.A.), equipped with an electrospray ionization (ESI) interface. The ESI conditions in the positive ion mode were as follows: capillary temperature, 350°C; sheath gas flow rate, 40 (arbitrary unit); ESI source voltage, 5000 V; capillary voltage, 46 V; tube lens offset, 30 V.

NMR Spectroscopy The isolated acidic compound was dissolved in chloroform-d_1. The ^{1}H- and ^{13}C-NMR spectra were measured by a JNM-ECA500 spectrometer (JEOL Tokyo, Japan) at 500.16 MHz and 125.77 MHz, respectively. The obtained signals are summarized as follows: $\delta^{1}H$ (ppm), 1.14 (6H, s); 1.44 (2H, m); 1.65 (2H, m); 1.77 (3H, s); 2.01 (2H, t). $\delta^{13}C$ (ppm), 18. 6; 21.6; 28.3; 31.7; 33.0; 38.6; 134.0; 136.5: 175.5.

Results and Discussion

Observation of the Blue Color Formation with β-Cyclocitral Figure 2(A) shows the effect of β-cyclocitral (a), β-ionone (b), and water (c) on the lysis of *Microcystis* NIES-102 after its addition. In contrast to the case with the water control (c), β-cyclocitral (a) and β-ionone (b) caused a lysis of the cyanobacteria as measured by a decrease in chlorophyll-a absorbance. While β-ionone gradually reduced the green color to provide a colorless solution mixed with white precipitates after 10 d, β-cyclocitral began to cause the characteristic color change from green to blue after 6 h, and the resulting blue color continued for about 1 d. The blue color change also was observed in *Microcystis* NIES-73, -103, -112, and -298, *Anabaena* NIES-808, and *Synechocystis* PCC6803 strains with β-cyclocitral. The *Phormidium* (NIES-611) strain originally provided a dark brown cultivated broth as shown in Fig. 2(B). Whereas the addition of β-ionone induced a gradual change from the original color to a colorless solution mixed with white precipitates via a diluted brown color [Fig. 2(B-b)], β-cyclocitral provided a characteristic pink color after 3 h, and this color continued for 12 h [Fig. 2(B-a)].

β-Cyclocitral and β-ionone were added to natural bloom samples from Lake Tsukui (see Supplementary Material Fig. 5). Generally, bloom samples of cyanobacteria have a sheath outside of the cells (Amemiya and Nakayama 1989; Amemiya et al. 1988) and we were interested in whether similar results were obtained when β-cyclocitral was applied to the bloom samples. Although the collected samples from Lake Tsukui were very dense, they were used without dilution. While the blue color formation was also observed after 4 d due to the addition of β-cyclocitral (see Supplementary Material Fig. 5), such behavior was not found in the case of β-ionone as stated above (see Supplementary Material Fig. 5). Therefore, β-ionone did not affect the chlorophyll-a concentration in the cells, and this behavior was different from that of the laboratory strains [Fig. 2(A-b) and (B-b)]. These results indicate that there was a difference between β-cyclocitral and β-ionone in the lytic activity against bloom samples composed of several cyanobacteria due to the presence of the sheath, and

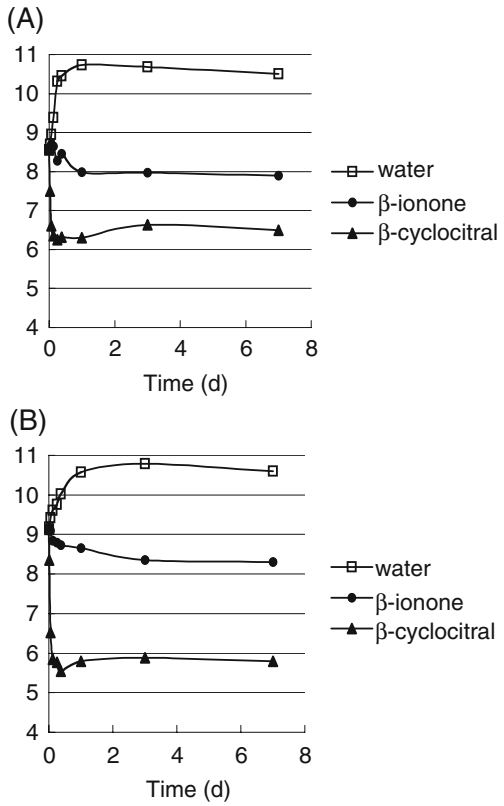

Fig. 4 Change in pH during lysis of cultured strain broths; (A) NIES-102, (B) NIES-611

that β-cyclocitral can lyse the laboratory strains of any genera and bloom samples, including many species of cyanobacteria, and can cause the characteristic color change from green to blue.

Visible Spectral Observation of Photosynthetic Pigments in Lysed Cyanobacteria In this experiment, we observed the visible spectra of the cultured broths affected by β-cyclocitral and β-ionone. Figure 3(A-c) shows the visible spectra of *Microcystis* NIES-102 with water as the negative control, and the absorbances of the characteristic absorption maxima increased with growth of cyanobacterium. These absorption maxima at 420 and 680 nm, 500 nm, and 620 nm can be assigned to those of chlorophyll-a, β-carotene, and phycocyanin, respectively. The addition of β-ionone uniformly reduced these absorption maxima to complete disappearance after 72 h [Fig. 3(A-b)]. In contrast, β-cyclocitral provided characteristic behavior in which the absorption maxima of chlorophyll-a and β-carotene disappeared, but that of phycocyanin remained after 12 h [Fig. 3(A-a)], indicating that the resulting blue color was derived from phycocyanin after the disappearance of the remaining pigments due to β-cyclocitral. This observation corresponded exactly to the phenomena shown in Fig. 2(A). An additional experiment using a *Phormidium* (NIES-611) strain, whose photosynthetic pigments are chrolophyll-a, β-carotene, and phycoerythrin instead of phycocyanin, which showed a pink color [Fig. 2(B-a)], supported the above conclusion [Fig. 3(B)]. That is, the addition of β-cyclocitral showed behavior similar to that of the absorption maxima disappearance of chrolophyll-a and β-carotene, but that of phycoerythrin at 560 nm still remained after 3 h (data not shown). This was consistent with the behavior shown in Fig. 2(B). These findings indicate that β-cyclocitral rapidly decomposed chlorophyll-a and β-carotene, so that the inherent colors from the tolerant water-soluble pigments became observable in the cultured broth.

Acidification of Cultured Broth and Bloom Sample with β-Cyclocitral The changes in pH of the cultivated broth of NIES-102 and -298 with the addition of β-cyclocitral and β-ionone are shown in Fig. 4. Thirty min after the addition of β-cyclocitral, the pH of both cultured broths decreased quickly to around 6, and it was maintained for several hours. However, such behavior was not observed in the case of β-ionone, in which the pH changed to around 8 over several hours. A dramatic pH change also was found in the bloom samples. As shown in Fig. 5, the pH decreased immediately to 4.5 after the addition of β-cyclocitral, and the pH then was slightly elevated for several hours in the case of the bloom sample from Lake Suwa. The bloom sample from Lake Tsukui showed nearly similar behavior. However, the pH changed to around 7 after the addition of β-ionone (Fig. 5).

We also investigated the pH-lowering effect of a volatile compound with an aldehyde group such as citral, cinnamaldehyde, perillaldehyde, and vanillin from plants, together with β-cyclocitral. Figure 6 shows the pH change due to the addition of these volatile compounds in water (A) and MA medium (B), in which water and ethanol were used as the negative control. The pH of a water solution of perillaldehyde gradually decreased to 4 in 20 h, and that of cinnamaldehyde decreased immediately to 4.5 in a manner similar to that of β-cyclocitral [Fig. 6(A)]. However, this behavior was not observed in the MA medium with buffer action [Fig. 6(B)]. In contrast, the solution decreased promptly to pH 4.5 after the addition of β-cyclocitral as already described.

Conversion of β-Cyclocitral to Corresponding Acidic Compound Twenty hours after the addition of β-cyclocitral to water, the reaction mixture was separated into the neutral and acidic fractions by liquid-liquid extraction. While a large amount of β-cyclocitral was still present in the former fraction, the acidic fraction contained several components as shown in Fig. 7. Because peaks No. 1 and No. 2 were not stable, it was impossible to isolate them. However, preparative HPLC could separate the main peak (No. 3) in a pure state, and the structural characterization was carried out as follows: the molecular weight

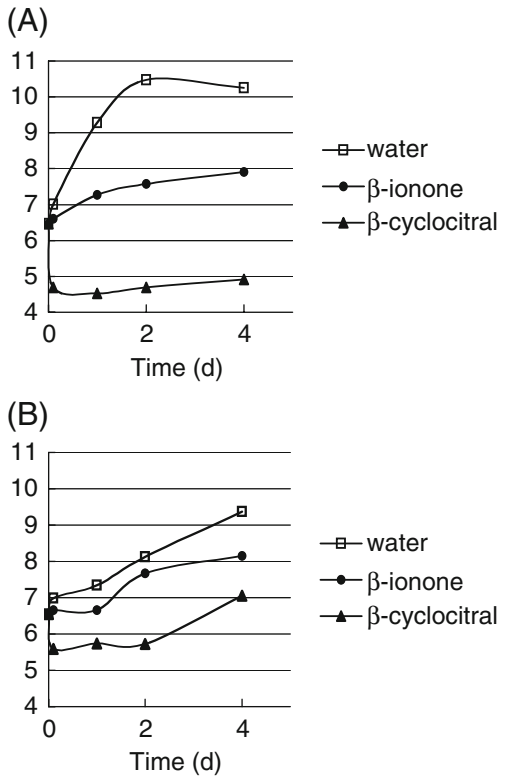

Fig. 5 Change in pH during lysis of bloom samples; (A) Lake Suwa and (B) Lake Tsukui

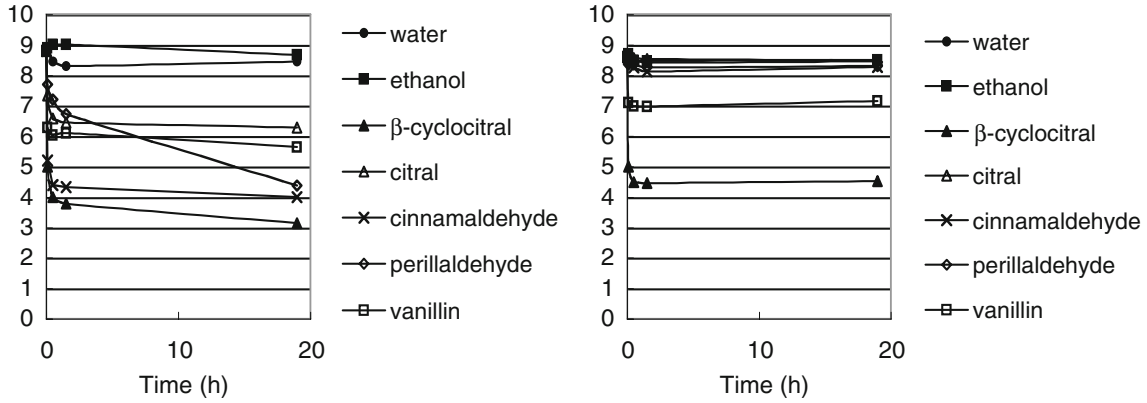

Fig. 6 Chang in pH with β-cyclocitral and terpenoids; (A) water and (B) MA medium

was determined to be 168 by LC/MS by using electrospray ionization (ESI), and the ^{1}H- and ^{13}C-NMR spectra were almost identical to those of β-cyclocitral except for an exchangeable proton, which was not observed in $CDCl_3$. From these data, we concluded that β-cyclocitral was converted to the corresponding carboxylic compound (2,6,6-trimethylcyclohexene-1- carboxylic acid) in a water solution. Similar results were obtained in MA medium. As mentioned above, β-cyclocitral showed the remarkable pH change in MA medium, but such behavior was not observed in the case of several other volatile compounds with an aldehyde group as shown in Fig. 6, thus suggesting that the pH-lowering effect was due to oxidation of an aldehyde group to a carboxylic acid. The solubility of the free acid was poor in water. One mg of the sample was not completely soluble in 1 ml of water in a short time period, and it took a few days to change to a clear solution, which resulted in a pH of about 3.3. Huang et al. (2002) reported that the blue color formation of a cyanobacterium (*Synechocystis* sp. PCC 6308) may be due to acid stress. They used hydrochloric acid for acidification, and the blue color was formed below pH 3.6. Probably, the acid formed from β-cyclocitral contributed to the pH-lowering effect to thus provide the characteristic blue color, although our resulting pH was higher than pH 3.6.

In summary, according to reports by Jüttner (1984), Jüttner and Höflacher (1985), and Watson (2003), β-cyclocitral is derived from β-carotene in *Microcystis* sp. Recently, it was found that β-carotene in cyanobacteria is cleaved by a specific enzyme (carotenoid cleavage dioxygenase, CCD) to provide retinal and related compounds (Kloer and Schulz 2006; Marasco et al. 2006). Probably, β-cyclocitral is formed together with 3-methyl-1-butanol by CCD in cyanobacteria and shows lytic activity against cyanobacteria. Because β-cyclocitral is more easily oxidized compared to similar aldehyde compounds, it is an interesting question whether β-cyclocitral or its acid contributes to the lytic activity. In a natural environment, cyanobacteria grow intensively during the summer season and gradually disappear in the autumn, and a sudden decline in the cyanobacteria has been observed in some cases (Fallon and Brock 1979). We observed a similar phenomenon together with blue color formation (Supplementary Material Figs. 2, 3, 4) in a lake. The present study provides support that β-cyclocitral plays an important role in this phenomenon. In a subsequent study, the dynamics of β-cyclocitral in cyanobacteria and the environment will be investigated in more detail.

tsugae, and *Fomes fomentarius*—each of which may be found within the same local area of forest.

Bolitotherus cornutus' primary defensive response is a death feint (Liles 1956), but, like many other tenebrionid beetles, it can produce volatile defensive chemical secretions (Tschinkel 1975a). The defensive secretions are stored in eversible glands at the tip of the abdomen (Tschinkel 1975b). When the beetle is disturbed, the glands are everted and stroked rapidly with the hindlegs, thus spreading the secretion (Conner et al. 1985). Although other species of tenebrionids secrete or spray defensive chemicals in response to attack by other insects (Peschke and Eisner 1987), *B. cornutus* reliably produces defensive secretions only in response to the warmth, humidity, and pulse—but not to the carbon dioxide content—of mammalian breath (Conner et al. 1985). Even mechanical injury by using artificial jaws does not usually result in eversion of the glands (Conner et al. 1985).

Early investigation of the chemical composition of *B. cornutus* defensive secretions was accomplished by directly "milking" the glands of the beetles and analyzing the product with packed-column gas chromatography (Tschinkel 1975a). With this older instrumentation, two large peaks were observed and identified as methyl-*p*-benzoquinone and ethyl-*p*-benzoquinone. Although other quinones and alkenes were detected in other tenebrionids, they were not detected in *B. cornutus* (Tschinkel 1975a). Solid phase microextraction, in combination with capillary gas chromatography-mass spectrometry (SPME-GC-MS) now provides an improved method for collecting, separating, and detecting volatile species. Recent applications of this technique to the detection of the quinone secretions of beetles include analysis of the defensive secretions of the red flour beetle, *Tribolium castaneum* (Herbst) (Villaverde et al. 2007) by using a carboxen/polydimethylsiloxane fiber, and analysis of the sex pheromones of a desert tenebrionid beetle by using a polydimethylsiloxane fiber (Geiselhardt et al. 2008).

Fieldwork on *B. cornutus* behavior suggested that beetles found on different species of fungus have slightly different scents to human observers. By using SPME-GC-MS, we compared the volatile secretions of male and female beetles collected from two species of fungus, *Ganoderma applanatum* and *Fomes fomentarius*, in the southern Appalachian Mountains.

Methods and Materials

Beetle Collection and Maintenance Forked fungus beetles were wild-caught as adults in the immediate vicinity of Mountain Lake Biology Station in Giles County, Virginia, USA in early August. Specimens were collected during the day from the surfaces of fungus brackets. They were placed immediately in containers that contained a fungal fruiting body harvested from that particular log, and shipped live to the laboratory for chemical analysis. Twelve individuals were collected from 6 colonies of *Ganoderma applanatum*, and 6 individuals from 6 colonies of *Fomes fomentarius* within an area of 0.05 ha. The sex of adults was determined easily by the large horns and ventral hair patches present only on males (Liles 1956). Analysis commenced 2 d after beetles arrived in the laboratory. The majority of beetles was analyzed within 1 wk of arrival; three beetles were not analyzed until over 1 wk later.

Chemicals Standards of *p*-benzoquinone (CAS 106-51-4), methyl-*p*-benzoquinone (CAS 553-97-9), 3-methylphenol (CAS 108-39-4), 3-ethylphenol (CAS 620-17-7), 2-methylhydroquinone (CAS 95-71-6), and 4-ethylresorcinol (CAS 2896-60-8) were obtained from Sigma-Aldrich (St. Louis, MO, USA).

Instrumentation A Varian (Walnut Creek, CA) Saturn 2100T gas chromatography—mass spectrometer (GC-MS), equipped with a FactorFour VF-5ms column (5% phenyl-methyl, 30 m, 0.25 mm i.d., 0.25-µm, Varian, Walnut Creek, CA, USA) was used for the analysis**.** Two cm dual-layered solid phase microextraction (SPME) fibers coated with highly cross-linked 50/30-µm divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS) were purchased from Supelco (Bellefonte, PA, USA). Before use, fibers were cleaned by leaving them in the GC-MS injector port at 250°C for 30 min.

Sample Collection All sampling was done at room temperature by using headspace solid phase microextraction (HS-SPME). The amount of a compound collected by HS-SPME depends on both its gas-phase concentration and its affinity to the fiber (Zhang and Pawliszyn 1993); however, the maintenance of constant sampling conditions allows comparisons among samples. Before each run, a beetle was placed gently into a clean 10 ml glass vial and allowed to settle for several minutes. Then, by using a straw, human breath was blown onto the beetle for 5 sec. Gland eversion was observed in all cases. The vial was sealed immediately with a septum cap, and the SPME fiber was pierced through and exposed. After 3 min of collection, the fiber was removed and inserted into the GC/MS injection port, where it was desorbed for 30 sec at 250°C. In between runs, the SPME fiber was cleaned for 90 sec at 250°C to ensure that there was no carry-over from one beetle to the next.

A baseline measurement was performed each day by following the above procedure with an empty vial. Similarly, runs were performed by following the same protocol with a beetle present, but without exposure to breath.

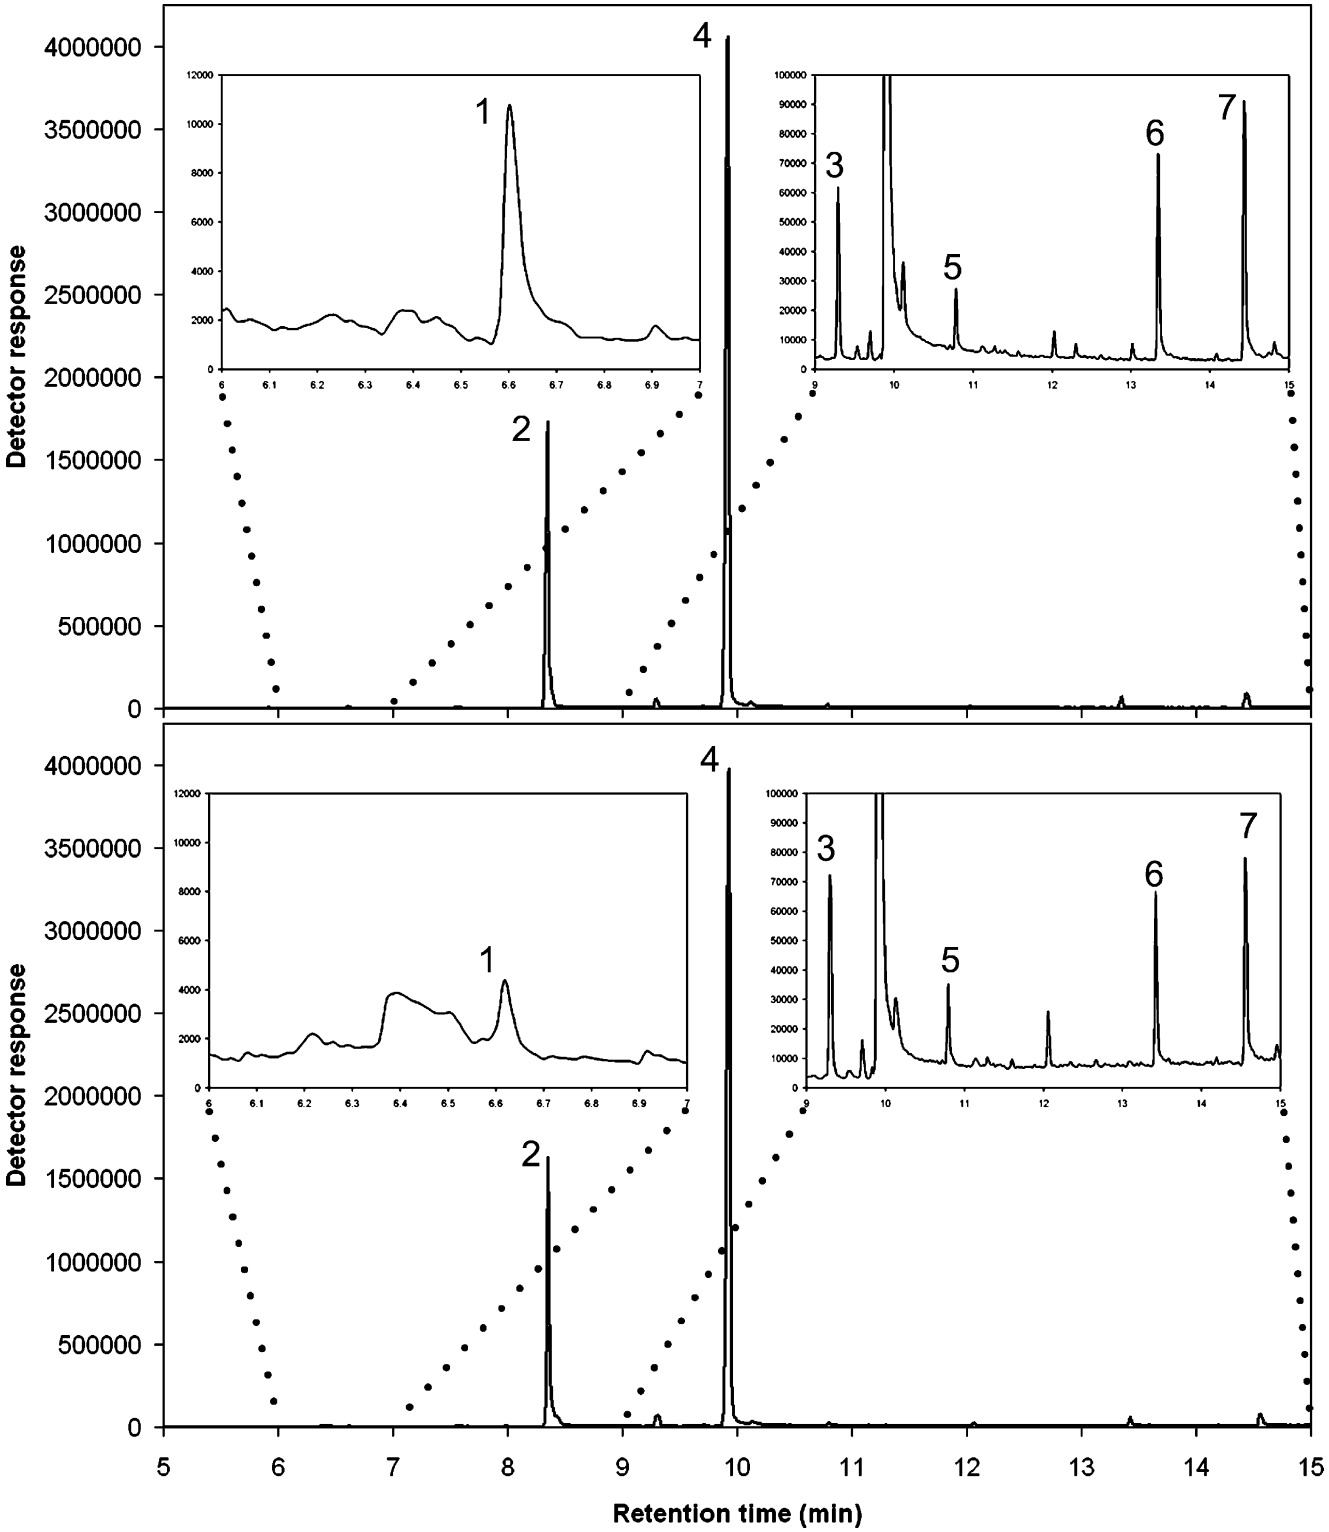

Fig. 1 Gas chromatogram of volatiles collected with solid phase microextraction from (*top*): a male *Bolitotherus cornutus* beetle collected from *Fomes fomentarius*; (*bottom*): a female *Bolitotherus cornutus* beetle collected from *Ganoderma applanatum.* 1: *p*-benzoquinone; 2: methyl-*p*-benzoquinone; 3: 3-methylphenol; 4: ethyl-*p*-benzoquinone; 5: 3-ethylphenol; 6: 2-methylhydroquinone; 7: 2-ethylhydroquinone. The scales for each portion of the graph are identical in the top and bottom pane

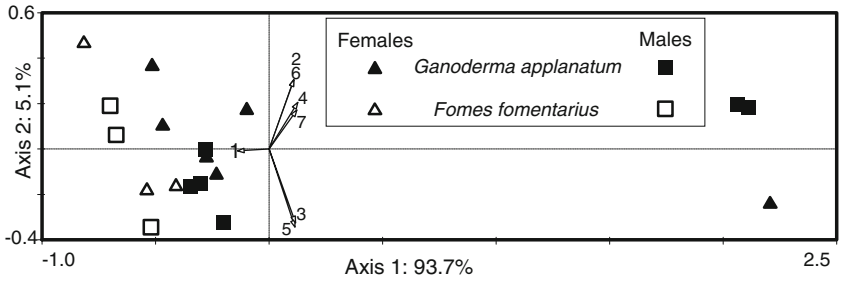

Fig. 2 Principal component analysis of centered log ratio transformed relative peak areas. 1: *p*-benzoquinone; 2: methyl-*p*-benzoquinone; 3: 3-methylphenol; 4: ethyl-*p*-benzoquinone; 5: 3-ethylphenol; 6: 2-methylhydroquinone; 7: 2-ethylhydroquinone

Gas chromatography-mass spectrometry A 20:1 split injection (column flow, He = 1.2 ml/min) into an injection port held at 250°C was used. Temperature programming: hold at 50°C for 3 min, ramp to 250°C at 10°C/min, and hold for 2 min.

With the exception of ethyl-*p*-benzoquinone and 2-ethylhydroquinone, all volatiles were identified by comparison of mass spectra and retention times with those of standards. Ethyl-*p*-benzoquinone (CAS 4754-26-1) was positively identified from its mass spectrum (NIST database), as well as by reference to prior identification of high concentrations of it in the defensive secretions of *B. cornutus* (Tschinkel 1975a). 2-ethylhydroquinone (CAS 2349-70-4) was identified tentatively by comparison of the mass spectrum to published data (Wahrendorf and Wink 2006), and by comparison of the retention time and mass spectrum to that of its structural isomer (with hydroxyl substituted at a different position on the ring), 4-ethylresorcinol.

Data Analysis As different beetles produced different absolute amounts of volatiles (statistically determined to be unconnected to sex or food source), a relative peak area was computed for each peak by dividing its area by the total area of the seven major, identified peaks for that beetle. Ordination analysis thus was done on fractional compositions that sum to unity, and for which the proportions of the different chemical compounds are not independent within a sample. Accordingly, a centered log ratio transformation (Aitchison 1984; Pawlosky-Glahn and Egozcue 2006) was employed prior to principal components analysis and its canonical equivalent, redundancy analysis, performed using CANOCO 4.5 (ter Braak and Smilauer 2002). In the case where a component was not detected, "0.00000001" was used in place of "0" as the relative peak area for that component in the calculation of centered log ratios (Aitchison and Egozcue 2005).

Results

The two major components of the beetles' volatile secretions were methyl-*p*-benzoquinone and ethyl-*p*-benzoquinone. However, smaller amounts of *p*-benzoquinone, 3-methylphenol, 3-ethylphenol, 2-methylhydroquinone, and 2-ethylhydroquinone also were detected (Fig. 1).

By using the chemical composition of the beetles' volatile defensive secretions, it is possible to differentiate beetles collected from *G. applanatum* from those collected from *F. fomentarius* (Fig. 2). The most important factor was the level of *p*-benzoquinone expressed. Three beetles collected from *G. applanatum* did not produce any detectable *p*-benzoquinone, and points for these beetles appear at the far right of axis 1 in Fig. 2. The points could, through their leverage, have a distorting or compressing effect on the rest of the ordination, thus inflating the effect of the *p*-benzoquinone. However, separation of beetles based on their fungal diet also was evident when the three points with high leverage were removed (Fig. 3). When fungal food source was used to constrain axis 1 of a redundancy analysis, the constrained axis explained 18.7% of the variance among beetles, and Monte Carlo permutations showed this axis to be significant (P=0.032). With the three beetles with no detectable *p*-benzoquinone excluded, the constrained axis was responsible for 23.8% of the

Table 1 Chemical composition of volatile secretions of male and female forked fungus beetles collected from two species of fungus. Values are given as mean relative peak areas, expressed as a percent, with associated standard errors

Food		N	*p*-benzoquinone	Methyl-*p*-benzoquinone	3-methylphenol	Ethyl-*p*-benzoquinone	3-ethylphenol	2-methyl-hydroquinone	2-ethyl-hydroquinone
Ganoderma applanatum	Female	6	0.03±0.01	29±2	1.4±0.4	67±2	0.5±0.2	0.8±0.2	1.1±0.2
	Male	6	0.03±0.01	23±2	1.8±0.4	73±2	0.6±0.2	0.9±0.1	1.3±0.2
	All	12	0.033±0.007	26±2	1.6±0.3	70±2	0.5±0.1	0.9±0.1	1.2±0.1
Fomes fomentarius	Female	3	0.16±0.03	28±2	1.9±0.8	67±2	0.5±0.2	1.2±0.2	1.7±0.3
	Male	3	0.19±0.01	26±1	2±1	68.3±0.3	0.5±0.3	1.1±0.1	1.63±0.06
	All	6	0.18±0.02	27±1	1.9±0.6	68±1	0.5±0.2	1.2±0.1	1.7±0.1

variance among beetles, with $P=0.028$. Whether or not the three beetles with no *p*-benzoquinone were included, there was no evidence from the ordinations of differences in volatiles associated with beetle sex.

Although *p*-benzoquinone was a minor component of the detected volatile species, beetles that were collected from *F. fomentarius* produced, proportionally, a much greater amount than those that were collected from *G. applanatum* (Table 1). The lowest producing *F. fomentarius*-fed beetle still produced 1.4 times as much *p*-benzoquinone as the highest producing *G. applanatum*-fed beetle (as a proportion of the total volatiles detected for the beetle). The relative peak area for *p*-benzoquinone was significantly different for beetles collected from the two fungal food sources (Two sample *t* test: $t=8.94$, $d.f. = 16$, $P<0.001$).

Several significant relationships were observed among the components. As seen in Fig. 4, the relative peak areas of 3-methylphenol and 3-ethylphenol are positively linearly correlated ($r=0.95$, $N=18$, Bonferroni-corrected $P<0.001$), and methyl-*p*-benzoquinone and ethyl-*p*-benzoquinone are negatively linearly correlated ($r=-0.94$, $N=18$, $P<0.001$). 2-Methylhydroquinone and 2-ethylhydroquinone also have a positive association, although the trend is not as clear as in the other two examples ($r=0.71$, $N=18$, $P=0.02$). No significant correlation was observed between the phenols and the quinones, or between *p*-benzoquinone and any other compound.

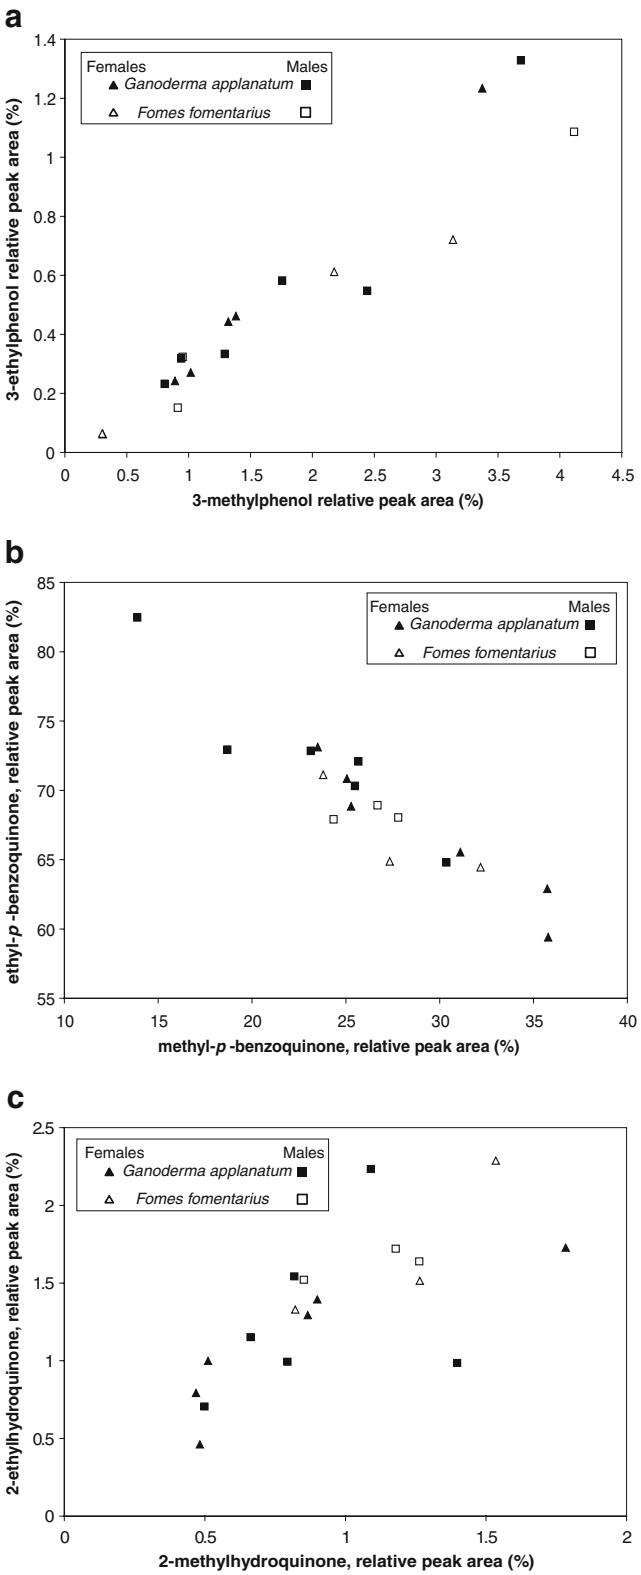
Discussion

Quinones are common in the defensive secretions of tenebrionid beetles (Tschinkel 1975a). Both methyl-*p*-benzoquinone and ethyl-*p*-benzoquinone previously were detected in the defensive secretions of *B. cornutus*, but the unalkylated *p*-benzoquinone was not (Tschinkel 1975a). Indeed, the lack of *p*-benzoquinone was seen as a distinguishing feature for *B. cornutus* among other tenebrionids that secrete quinones but not hydrocarbons (Tschinkel 1975a). We showed here that *p*-benzoquinone is produced, albeit in very small quantities, and that differences in diet and habitat may influence levels of this compound.

At first glance, it is surprising that *p*-benzoquinone has a much greater differentiating effect than similarly structured alkylated benzoquinones. However, this may be due to the presence of different biosynthetic pathways for the creation of alkylated benzoquinones (Meinwald et al. 1966). In *Eleodes longicollis* Lec., another tenebrionid beetle, Meinwald et al. (1966) demonstrated that *p*-benzoquinone was synthesized using the aromatic ring from either tyrosine or phenylalanine, whereas the alkylated benzoquinones were derived from acetate units. Therefore, differences in food sources may affect one pathway but not the other. *G. applanatum* fungus might have less bioavailable tyrosine or phenylalanine than *F. fomentarius*. Interestingly, some food source preferences have been observed in controlled observations of *B. cornutus* (Heatwole and Heatwole 1968), with *G. applanatum* being less preferred when another fungus species was available (*F. fomentarius* was not tested).

The three beetles collected from *G. applanatum* that did not produce any detectable *p*-benzoquinone were those that were sampled over a week later than the other beetles; perhaps some variation in living conditions caused the difference. However, these extremes of *p*-benzoquinone concentration did not enhance the separation between beetles collected from the two species of fungus, despite *p*-benzoquinone being the major distinguishing species between the two groups. In all other cases, a mixture of male and female beetles collected from *G. applanatum* and *F. fomentarius* were sampled on the same day.

3-Methylphenol (Tschinkel 1969; Attygalle et al. 1991; Villaverde et al. 2007; Geiselhardt et al. 2009;), 3-ethylphenol (Tschinkel 1969; Geiselhardt et al. 2009), 2-methylhydroquinone (Happ 1968; Wahrendorf and Wink 2006; Villaverde et al. 2007; Geiselhardt et al. 2009), and 2-ethylhydroquinone (Happ 1968; Hodges et al. 1996; Wahrendorf and Wink 2006; Geiselhardt et al. 2009) have all been detected in the defensive secretions of other tenebrionid beetles, although quinones are more ubiquitous



◀ **Fig. 4** Correlations between volatile components (relative peak areas, in percent) found for male and female *Bolitotherus cornutus* beetles collected from *Ganoderma applanatum* or *Fomes fomentarius*. **A** 3-ethylphenol as a function of 3-methylphenol. **B** ethyl-*p*-benzoquinone as a function of methyl-*p*-benzoquinone. **C** 2-ethylhydroquinone as a function of 2-methylhydroquinone

in tenebrionids. The presence of all of these chemical compounds emphasizes the likelihood that the alkylated benzoquinones found in *B. cornutus* are synthesized from acetate units.

3-Methylphenol, 2-methylhydroquinone, and methyl-*p*-benzoquinone are thought to be sequential members of a biosynthetic pathway that originates with 6-methylsalicylic acid (Gnanasunderam et al. 1984), itself formed from acetate (or malonate) units (Birch et al. 1955). Similarly, 3-ethylphenol, 2-ethylhydroquinone, and ethyl-*p*-benzoquinone are likely derived from 6-ethylsalicylic acid (Gnanasunderam et al. 1984), which differs in its synthesis by the use of a propionate unit in place of an acetate (or malonate) unit, as evidenced by isotope tracing experiments on ethyl-*p*-benzoquinone (Meinwald et al. 1966). We did not detect any salicylic acids in the defensive secretions of *B. cornutus*, but their methyl esters have been found in the secretions of another tenebrionid beetle (Gnanasunderam et al. 1984).

In view of this pathway, one way to explain the positive correlation between the relative peak areas of the phenols (or hydroquinones) is by attributing their relationship to a coupled series of biochemical reactions in which the formation of one leads to favorable conditions for the production of the other. The negative correlation observed between the relative peak areas of the alkylated quinones might be explained by a competitive inhibition of the oxidase used to form quinones from hydroquinones (Happ 1968). It is interesting that correlations were seen only between methyl and ethyl analogs at each structural level; no correlations were found between members of a biosynthetic pathway. The lack of correlation between either alkylated benzoquinone and *p*-benzoquinone further emphasizes its different biosynthetic origins.

No significant differences were seen between the sexes. Therefore, although both phenols (Geiselhardt et al. 2008) and quinones (Ruther et al. 2001; Geiselhardt et al. 2008) are used as sex pheromones in other beetle species, this does not appear to be the case for *B. cornutus*. This is not unexpected, as the volatiles are emitted in response to a specific threat stimulus.

The ecological effect of the observed differences in chemical blends is unclear. Although, in comparison to *p*-benzoquinone, the alkylated benzoquinones have been shown to have greater repellant effects against ants and induce greater topical irritation in cockroaches (Peschke and Eisner 1987). *Bolitotherus cornutus* emits these compounds only in response to detected threats from mammalian predators. Some human observers can detect qualitative odor differences in the blends, but do not notice differences in overall repugnance, although *p*-benzoquinone is known to be a powerful irritant (Eisner and Aneshansley

1999). Further experiments with isolated *p*-benzoquinone or blends of quinones that vary in relative ratios of *p*-benzoquinone will elucidate the importance of dietary differences to anti-predator function.

Acknowledgements We thank Neil J. Holliday for statistics advice and Swarthmore College for support of this research. Mountain Lake Biological Station provided support for the field component. Corlett Wood, Eileen Butterfield, and Mollie Barnard assisted with fieldwork, and Lisa Schumacher assisted with laboratory analysis.

deterrent properties of primary chemistry could evolve in response to selection from insect herbivory (Berenbaum 1995). Even in the absence of a direct functional role in deterrence, the ecological implications of primary nutrient and chemistry variation are significant. Numerous studies have demonstrated that primary nutrients can influence host plant selection by herbivorous insects, insect foraging behavior, growth and performance, the composition of insect communities, and possibly the evolution of host plant specialization in herbivorous insects (reviewed in Berenbaum 1995).

One especially significant primary nutrient for herbivorous insects is sterols. Sterols are triterpenoid steroid alcohols that are used by eukaryotic organisms to maintain cell membrane integrity, permeability, and fluidity. Furthermore, they are precursors for steroid hormones and are directly involved in developmental gene regulation (Behmer and Nes 2003). For most insects studied to date, cholesterol (Fig. 1) is the primary sterol incorporated into cell membranes and a necessary precursor to steroid hormones (e.g., ecdysteroids in arthropods). However, unlike many other organisms, insects are unable to synthesize the steroid nucleus *de novo* and must obtain sterols (i.e., cholesterol) either directly or indirectly from their diets (Clayton 1964). For example, carnivorous insects can absorb and directly utilize the cholesterol contained in their prey's tissues. For herbivorous insects, however, obtaining cholesterol poses a challenge. Plants synthesize hundreds of different sterol molecules (collectively known as phytosterols), but often

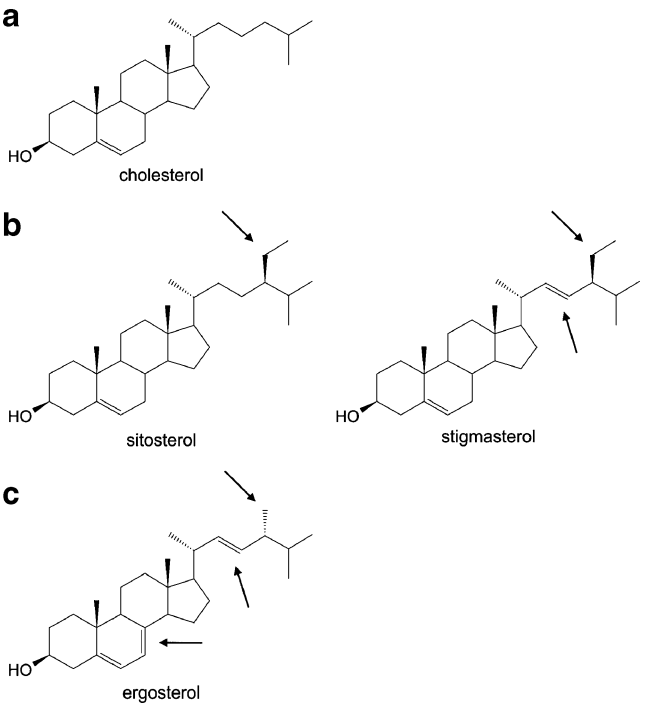

Fig. 1 The chemical structures of the most common (**a**) animal, (**b**) plant, and (**c**) fungal sterols. The black arrows highlight structural differences of plant and fungal sterols relative to cholesterol

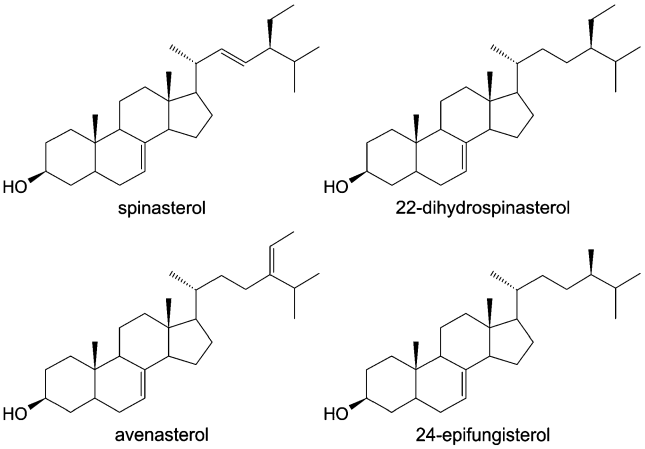

Fig. 2 The chemical structures of the sterols detected in the vegetative tissues of *Solidago altissima*

synthesize little or no cholesterol (Svoboda and Thompson 1985). Instead, the two most common phytosterols are sitosterol and stigmasterol (Fig. 1). Spinasterol also is prevalent, but relatively less common (Fig. 2). Phytosterols share gross structural similarities with cholesterol, but often have ethyl- or methyl groups at carbon position 24 and/or double bonds at positions other than five in the tetracyclic nucleus (B-ring) (Figs. 1, and 2). Consequently, in order to obtain cholesterol from their diet, most herbivorous insects must metabolize ingested phytosterols into cholesterol or other cholesterol-like molecules.

Two key factors complicate cholesterol acquisition for herbivorous insects. First, some species are unable to convert certain structural classes of phytosterols into cholesterol. Grasshoppers (Orthoptera: Acrididae), for example, are unable to convert sterols that contain Δ^7 and/or Δ^{22} double bonds into cholesterol (see Figs. 1, and 2 for examples) (Behmer and Elias 1999a; Behmer et al. 1999b). Like grasshoppers, a number of insects are unable to dealkylate the hydrocarbon side chain, and/or to remove double bonds on the side chain or within the tetracyclic nucleus (B-ring) of the sterol molecule (e.g., Svoboda et al. 1977, 1989; Kircher et al. 1984; Ritter 1984; Rees 1985; MacDonald et al. 1990). The inability of some insects to utilize and/or efficiently metabolize entire suites of phytosterols suggests that, in addition to their dietary necessity, the sterol physiology of plants could mediate a myriad of plant—insect interactions. Second, for reasons that are not entirely clear, plants frequently maintain a portion of their sterols in a conjugated form (Wojciechowski 1991; Moreau et al. 2002). Conjugated sterols are virtually identical to free sterols, except that they are covalently bonded at the 3β-OH group to either fatty acids (steryl esters) or carbohydrates (steryl glycosides or acylated steryl glycosides; Moreau et al. 2002). The relative amount of conjugated sterols varies among plant species, and even within species and individuals under

different environmental conditions, over time, or in different tissues (cf. Moreau et al. 2002). Conjugating phytosterols also may interfere with an insect's ability to absorb and/or metabolize those sterols, but relatively little is known about the ecological consequences of sterol conjugation.

Remarkably, despite decades of research on insect sterol metabolism, little is known about the ecology of plant-insect sterol physiology and metabolism. In particular, it is unknown how a community of herbivorous insects metabolizes the sterols found in their common host plant. Do communities of herbivores specializing on a host plant converge on a common sterol metabolic strategy? Or, does host plant variation along with variation in insect host breadth offer a variety of "sterol niches"? Are particular insect species constrained for their metabolism strategies and, if so, what patterns are evident? Here, we analyzed the sterol profile of the tall goldenrod, *Solidago altissima* L., and six of its common insect herbivores, including two gall-formers, and the fungal symbiont associated with one of the gall-formers. Specifically, we attempted to elucidate how insects from distinct taxonomic groups, with different phylogenetic histories, and with different ways of obtaining nutrients (feeding guilds) metabolize the phytosterols in their shared diet. We ask how much these insects vary in the metabolic translation of host plant phytosterols, and what the observed variation reveals about the contribution of plant primary nutrients to plant—insect ecology. We predicted that insects that were phylogenetically related would exhibit similar metabolic capabilities, but that insects could diverge in sterol metabolic strategies as they diverge more generally in dietary strategies.

Methods and Materials

Collection Sites All collections were made in August to October, 2007 and 2008, at a site in Tennessee and another one in Ohio, USA. The site in Tennessee was Shelby Bottoms Greenway and Nature Park in Davidson County (36.168°, −86.718°). This site is a protected 810 acre stretch of alluvial floodplain that runs parallel to the Cumberland River. It is characterized by large stands of open prairie and wetlands surrounded by light forest. The plant community throughout the open prairies is dominated by various grasses and *S. altissima*, but also includes other asteraceous species, such as *Ambrosia*, *Bidens*, *Cirsium, Eupatorium*, and *Rudbeckia*. Some of the common non-asteraceous genera include *Asclepias*, *Daucus*, *Desmodium*, *Rubus*, *Solanum*, and *Vitis*.

The second site was Beaver Creek Wildlife Area North in Greene County, Ohio (39.765°, −84.002°). Beaver Creek Wetland Wildlife Area North is a 380 acre portion of the protected Beaver Creek Wetland, specifically designated for hunting and fishing. This site includes sections of open prairie, marshland, and lightly wooded areas. The open prairie is dominated by various grasses and *S. altissima*, but also includes numerous other herbaceous asteraceous genera, including *Ambrosia*, *Aster*, *Bidens*, *Conyza*, *Erigeron*, *Eupatorium*, *Euthamia*, *Rudbeckia*, and *Symphyotrichum*. Some of the common non-asteraceous genera include *Asclepias*, *Daucus*, *Desmodium*, *Rubus*, *Solanum*, and *Vitis*.

Study Taxa This study focused on the plant *S. altissima*, a subset of insects observed on it, and a fungus found associated with one of the insects. A brief description of each taxon follows.

The Plant Solidago altissima (Asteraceae) is an herbaceous, rhizomatous perennial that inhabits old fields and disturbed habitats throughout a large portion of North America. Its range extends from southwestern Canada, south through the eastern Rocky Mountains to southeastern Texas, and east to the Atlantic seaboard and coastal plains of the Gulf of Mexico. *Solidago altissima* ramets emerge from a mother rhizome in late spring, grow throughout the summer, and flower from late August to early October. *Solidago altissima* prefers dryer, more circum-neutral soils, but is relatively tolerant of a wide variety of environmental conditions and is a dominant disturbed habitat species through a large portion of its range. *Solidago altissima* is attacked by over 100 species of herbivorous insects, including numerous non-specialists and a handful of *Solidago*/*Aster* specialists (Abrahamson and Weis 1997).

The Insects We focused on six locally abundant species that represented a range of feeding guilds, including a leaf-chewer, three phloem-feeders, and two gallers—one stem galler and one leaf galler. Our target insects also were taxonomically diverse, representing three orders and five families.

The leaf chewer was *Trirhabda virgata* LeConte (Coleoptera: Chrysomelidae). This beetle specializes on plants in the genus *Solidago,* including the species *S. canadensis* L., *S. altissima*, *S. gigantea* Ait., *S. rugosa* Mill., *S. juncea* Ait., and *S. missouriensis* Nutt. (Swigoňová and Kjer 2004). It also has been recorded feeding on *Euthamia graminifolia* (L.) Nutt. and *Aster* spp., although these plants are unlikely to be consumed regularly (Messina and Root 1980). This beetle has a broad geographic range that extends from southern Canada through the United States east of the Great Plains.

We collected three phloem-feeders. The first was *Acutalis tartarea* Say (Hemiptera: Auchenorrhyncha: Membracidae). This treehopper specializes on species in the Asteraceae, including several *Solidago* species, *Ambrosia* spp. (putative preferred host), *Helianthus* spp., *Bidens bipinnata* L., and *Callistephus chinensis* (L.) Nees (Tsai

and Kopp 1980). Records of it feeding on locust (*Robinia* spp.) also exist, but these records may be based on misidentifications (C. Dietrich, pers. comm.). It geographic range is broad, extending from southeastern Canada, throughout the eastern and southeastern US, and west to the Great Plains.

The other two phloem-feeders used were aphids in the genus *Uroleucon* (Hemiptera: Sternorrhyncha: Aphididae). The first of these, *U. luteolum* Willams, specializes on species in the Asteraceae, with *Solidago* spp. as its preferred hosts. It attacks several *Solidago* species and may attack species in the genera *Erigeron*, *Conyza*, and *Aster* (Blackman and Eastop 2006). Its range extends from southeastern Canada, throughout the eastern and southeastern USA, and west to Kansas and Nebraska.

The second aphid *U. nigrotuberculatum* Olive also appears to be an Asteraceae specialist, with *Solidago* spp. as its preferred hosts (Richards 1972). It also may occasionally attack *Zigadenus* spp. (Melanthiaceae) (Robinson 1985). Records from Japan, where it is invasive, indicate that it can feed on other members of the Asteraceae, including *Aster*, *Callistephus*, *Chrysanthemum*, and *Rudbeckia*, plus two other non-Asteraceae, *Zigadenus* spp. (Melanthiaceae) and *Oenothera erythrosepala* Borbás (Onagraceae) (Blackman and Eastop 2006). It is broadly distributed in North America, extending throughout much of southeastern Canada, the eastern USA into the midsouth, and as far west as Colorado.

Finally, two galling flies were collected. The first was *Eurosta solidaginis* subp. *solidaginis* (Diptera: Brachycera: Tephritidae), a stem-galling fly that specializes on only two *Solidago* species: *S. altissima* and *S. gigantea*. Rarely, *E. solidaginis* galls also have been recorded on *S. canadensis* and *S. rugosa* (Abrahamson and Weis 1997). *Eurosta solidaginis*' range extends from southeastern Canada throughout most of the eastern USA, which includes New England west to North Dakota, south through northern Texas, and throughout the southeast to northern Florida.

The second fly was the leaf-galling midge *Asteromyia carbonifera* (Diptera: Nematocera: Cecidomyiidae). It too specializes on the genus *Solidago*, but has been collected on dozens of different goldenrod species (Gagné 1968; J.O. Stireman, T.G. Carr, pers. comm.). Like a number of other gall midges in the family Cecidomyiidae, *A. carbonifera* maintains a symbiotic association with a fungus (see below) (Bissett and Borkent 1988), which females actively transport to oviposition sites in specialized structure called the mycangium (Bissett and Borkent 1988). Unlike many other plant galling insects, the galls of *A. carbonifera* are not composed of plant tissue, but rather are made up almost entirely of fungal mycelium. Many of the biological details of the *Asteromyia*-fungus symbiosis are not well characterized, including any nutritional relationships between *A. carbonifera* and the fungus (Gagné 1968; Bissett and Borkent 1988). Its range extends throughout southern Canada, south through the United States into Mexico, and from coast to coast in the United States, but it is most common in northeastern North America.

The Fungus Botryosphaeria dothidea (Moug.) Ces. & De Not. (Ascomycota: Botryosphaeriales: Botryosphaeriaceae) has been identified as the fungal symbiont of *Asteromyia carbonifera* (Bissett and Borkent 1988; E. M. Janson, J. O. Stireman, and P. Abbot, unpublished manuscript). It is a generalist, cosmopolitan plant pathogen and endophyte, that has been isolated from hundreds of plant genera in numerous families throughout the world (Farr et al. 1989; Smith et al. 1996). In addition to being associated with *A. carbonifera*, *Botryosphaeria* species/lineages appear to be associated with many cecidomyiids, and thus may represent a long evolutionary association with gall midges (Bissett and Borkent 1988).

Tissue Collection for Sterol Analysis Plant, insect and fungus were collected in the field and processed according to the following protocols. *Solidago altissima* leaves were hand removed directly from ramets, placed in sealable plastic bags, and transported in a chilled cooler. Leaves of all ages were picked, except those that had started to senesce. Leaves were immediately frozen whole at −80°C until analysis upon arrival at the laboratory.

The beetles, treehoppers, and aphids were collected directly from *S. altissima* plants in the field and killed by placing them into separate 50 ml plastic centrifuge tubes filled with 100% ethanol. Beetles and treehoppers were allowed to drop directly from the plants into the tubes, while aphids were removed with soft forceps. We collected insects without regard to their sex. For the beetles and treehoppers, only adults were available. For aphids, we collected both nymphs and adults. The specimens were stored at 4°C in 100% ethanol until analysis.

We collected *E. solidaginis* galls by clipping them from *S. altissima* stems and transporting them in a chilled cooler. Galls then were dissected, and larvae were killed and stored by placing them in a −80°C freezer until analysis. Entire leaves containing galls of *A. carbonifera* were collected directly from *Solidago* ramets and transported in a chilled cooler. Galls were dissected, and larvae/pupae were killed and stored by placing them in a −80°C freezer until analysis. No adult flies were analyzed.

In order to obtain enough tissue for analysis and to obtain uncontaminated sterol profiles for the fungal symbiont of *A. carbonifera*, sterol analysis was performed on mycelia from plated fungal cultures. *Asteromyia carbonifera* galls were excised from *S. altissima* leaves and surfaced sterilized with a sequential sterilization procedure

(10 sec in 95% ethanol, followed by 2 min in 10% bleach solution, and finally 2 min in 70% ethanol) and then placed on 2% malt extract agar until evidence of mycelial growth. Mycelia then were isolated using sterile technique and subcultured to obtain pure cultures. The identity of each fungal isolate analyzed was confirmed by phylogenetic reconstruction of the nrITS region (data not shown). Briefly, genomic DNA was extracted using the method of Arnold and Lutzoni (2007). The nrITS region was amplified in 20 μl PCR reactions (1x NEB standard PCR buffer, 1.5 mM $MgCl_2$, 0.25 mM dNTPs, 0.5 μM each primer, 1 M betaine, and 1 U NEB *Taq* DNA polymerase) using primers ITS4 and ITS5 (White et al. 1990) with a thermal cycler program that included 2 min at 96°C, followed by 30 cycles of 30 sec at 94°C, 45 sec at 52°C, and 45 sec at 72°C, finishing with a 10 min extension at 72°C. Amplicons were treated with SAP/EXOI to remove residual dNTPs and primers, and then sequenced at the Vanderbilt University DNA Sequencing Core Facility (Nashville, TN, USA) or the University of Arizona Genetics Core (Tucson, AZ, USA). Phylogenetic reconstruction was performed in MEGA 4.02 (Tamura et al. 2007). Reconstruction was performed using maximum parsimony with the close-neighbor-interchange (CNI) algorithm where initial trees were obtained by random addition of sequences (10 replicates). Clade support was estimated by1,000 bootstrap replications. The reconstruction included several *Botryosphaeria* spp. samples publically available on NCBI's GenBank, including sequences from the epitype specimen for *B. dothidea* (isolate CMW 8000). We employed a phylogenetic species concept and considered all isolates that belonged to the same monophyletic clade as the *B. dothidea* epitype sequence to be *B. dothidea* isolates. Only those isolates that met these criteria were used in sterol analysis.

Sterol Extraction and Analysis Samples used for insect sterol extraction and analysis were comprised of hundreds to thousands of individual collected in the same geographic location at the same time of year (although in two separate calendar years). The qualitative sterol profile of each study species did not vary significantly across space or time, so the reported sterol profiles are an average (numerous individuals, two geographic locations, different calendar years) sterol profile for the species in question. This approach was necessitated in part by the relatively small size of the study insects and the goal of the study, which was to characterize broad patterns of sterol metabolism in an insect herbivore community. The free-alcohol and conjugated sterol profiles for *S. altissima* were obtained from hundreds of leaves across numerous plants, and the fungal sterol profile was obtained from 20 different fungal isolates.

Fresh frozen plant material, fresh fungal material, or ethanol preserved insect carcasses were extracted by obliteration using 8, #5 glass beads (Sigma, St. Louis, MO, USA) and a modified paint shaker. The obliteration was repeated 3 times for each sample in a 50 ml centrifuge tube, with constant shaking for 30 min in 30 ml of 95% ethanol. Ethanol fractions were removed, combined, evaporated to dryness, and the residue was resuspended in 70% methanol:water. Steroids were extracted from the 70% methanol:water phase with water equilibrated hexane. The steroid fraction was evaporated to dryness under nitrogen and subsequently resuspended in a minimal volume of hexane for subsequent concentration and cleaning by thin layer chromatography (TLC) on Silica G (Alltech, Nicholasville, KY, USA—250 micron plate thickness) developed with toluene: ethyl acetate (9:1). The bands that co-migrated with sterol standards were scraped from the TLC plate and extracted from the silica in anhydrous ethyl ether. The ether fraction was evaporated to dryness under nitrogen, and the resulting film was resuspended in hexane. Sterols were concentrated by repeated injections and collection of sterol containing fractions from a reverse-phase liquid chromatography (RP-HPLC) column. This was accomplished by eight, 50 μl injections per sample on an Apollo C18 high efficiency column (Alltech, Nicholasville, KY, USA) and eluted with acetonitrile:MeOH (9:1, 1 ml/min) at 38°C.

Next, sterol fractions were collected, combined, and evaporated to dryness under nitrogen and resuspended in 50 μl of hexane for subsequent injection on a gas chromatograph—mass spectrometer (GC-MS) for conclusive identification. Steroids were identified and quantified by GC-MS using previously produced standard curves for all steroids. Authentic sterol standards were purchased commercially (Sigma, St. Louis, MO, USA) or in the case of the Δ^7 sterols, isolated and purified from spinach. Steroids were analyzed by GC-MS on a 6850 networked gas chromatograph (Technologies, Inc., Santa Clara, CA, USA) and a 5973 mass selective detector (Technologies, Inc., Santa Clara, CA, USA) by using the following conditions: Inlet temp 260°C, transfer line temp of 280°C, and column oven temperature programmed from 80 to 300°C with the initial temperature maintained for 1 min and the final one for 20 min (ramp rate: 30°C/min). The column used was a glass capillary MS-5 column (30 m) (Restek, Bellefonte, PA, USA) with a film thickness of 0.25 mm. Helium at a flow rate of 1.25 ml/min served as carrier gas. The Agilent 5973 mass selective detector maintained an ion source temperature of 250°C and a quadrupole temperature of 180°C. All steroids were in agreement with authentic sterol standards at each of the separation, concentration, and identification steps. We report (1) cholesterol, (2) spinasterol, (3) 22-dihydrospinasterol, (4) avenasterol, (5) ergosterol, (6) brassicasterol (ergosta-5, 22-dien-3β-ol), (7) ergosta-7,22-dien-3β-ol, (8) 7-dehydrodesmosterol (cholesta-5,7,24-trien-3β-ol, (9) desmosterol, (10) lathos-

terol, (11) stigmasterol, (12) sitosterol, and (13) 24-epifungisterol within insect, fungi, or higher plant tissues. The mass spectrum for each of the sterols was consistent with previous studies. The prominent mass ions for all sterols are as follows: cholesterol *m/z* 386 [98%], 371 [50%], 368 [60%], 301 [56], 275 [100%], and 255 [50%]; spinasterol: *m/z* 412 [35%], 397 [25%], 369 [30%], 271 [95%] and 255 [100%]; 22-dihydrospinasterol: *m/z* 414 [99%], 399 [75%], 273 [75%], and 255 [100%]; avenasterol: *m/z* 412 [25%], 397 [25%], 314 [90%], 271 [100%], and 255 [80%]; ergosterol: *m/z* 396 [60%], 363 [100%], 271 [30%], and 253 [60%]; brassicasterol: *m/z* 398 [100%], 383 [16%], 380 [20%], 271 [65%], and 255 [194%]; ergosta-7,22-dien-3-β-ol: *m/z* 398 [25%], 383 [15%], 355 [10%], 271 [100%], and 255 [30%]; 7-dehydrodesmosterol: *m/z* 382 [80%], 349 [100%], 323 [40%], 271 [10%], and 253 [30%]; lathosterol: *m/z* 386 [100%], 371 [29%], 368 [3%], 273 [20%], and 255 [80%]; stigmasterol: *m/z* 412 [60%], 397 [15%], 379 [10%], 271 [80%], and 255 [100%]; sitosterol: *m/z* 414 [90%], 399 [60%], 396 [40%], 273 [60%], and 255 [100%]; 24-epifungisterol: *m/z* 400 [50%], 385 [25%], 367 [10%], 273 [5%], and 255 [100%].

Throughout the paper, free steroids are those identifiable in the tissue without further processing following ethanol extraction, while steryl-ester pools were reported following a subsequent base or acid hydrolysis step. Base saponification included the treatment of ethanol extracted sterols with a 5% ethanolic KOH solution at 70°C for 12 h, while acid hydrolysis included the treatment of ethanol extracted sterols with 0.5% H_2SO_4 in 95% ethanol at 50°C for 12 h. Subsequently, the freed steroids were extracted with hexane, backwashed to neutrality, and processed as described above for free sterols. Internal standard (100 μg cholestane) was added to select samples to determine extraction efficiency of the sterol extraction and concentration procedure. All data are presented as relative percentages of the total sterol profile identified within the given organism because no organismal weights were recorded. Where there is no report of sterol conjugates, the limited starting mass of material prevented us from dividing the sample for conjugate analysis.

Results

Solidago Leaf Sterol Profile In nature, sterols can exist in either a free- or conjugated form, and in the majority of plants the dominant form is the free-form. In the leaves of *Solidago altissima*, however, approximately 85% of the total sterol profile was in the conjugated form (Table 1), with the remaining 15% in the free-alcohol form. In terms of the composition of the free sterol pool, spinasterol (C-29 $\Delta^{7,22}$-sterol) was by far the dominant sterol (94%) (Table 1; Fig. 2). Three other free sterols were present, but at a low proportion of the total pool (Table 1; Fig. 2). In terms of the conjugated sterol pool, it consisted entirely of spinasterol. In this pool, approx. 63% of the spinasterol was conjugated to fatty acids/acetate, with the remaining fraction being conjugated to carbohydrates.

Externally Feeding Insects' Sterol Profiles The sterol profiles of the four external feeders showed tremendous variation in tissue sterol profile (Table 2; Figs. 1, 2, and 3), even though they were all collected directly from *S. altissima* plants.

Almost 60% of the sterol profile of the chrysomelid beetle *Trirhabda virgata* consisted of unmetabolized *S. altissima* sterols, with spinasterol comprising almost 50% of the total tissue sterol profile. Lathosterol (C-27 Δ^7-sterol), a potential metabolite of any *S. altissima* sterol following dealkylation, made up 40% of this beetle's tissue sterol profile. Only a small amount of cholesterol (1%) was detected.

We also observed multiple sterols in the tissues of the membracid treehopper *Acutalis tartarea*. Cholesterol (C-27 Δ^5-sterol) was the most abundant sterol (40%), but three unmetabolized plant sterols—stigmasterol (C-29 $\Delta^{5,22}$-sterol), spinasterol, and 22-dihydrospinasterol (C-29 Δ^7-sterol)—also were observed, at 30, 20, and 10%, respectively.

Interestingly, the two aphids showed marked differences in sterol profile, even though they are congeners and were feeding on the same plant part. *Uroleucon luteolum* showed a high cholesterol profile (90%), with the remaining 10% being divided equally among lathosterol, sitosterol (C-29 Δ^5-sterol), and stigmasterol. In contrast, *U. nigrotuberculatum* had much lower cholesterol content (just over 16%),

Table 1 Identification and relative percentages of sterols detected in the leaf tissue of *Solidago altissima*

	Sterol type (as relative % of specified sterol pool)			
Sterol form	Spinasterol	22-dihydrospinasterol	Avenasterol	24-epifungisterol
Free-alcohol (15[a])	94	4	1	1
Conjugated (85[a])	100	–	–	–

[a] these numbers represent the relative percentages of the total sterol pool that were in the free-alcohol or conjugated form.

1) cholesterol, (2) spinasterol, (3) 22-dihydrospinasterol, (4) avenasterol, (5) lathosterol, (6) sitosterol, (7) stigmasterol, and (8) 22-dihydrobrassicasterol. Sterols with asterisks were found in *Solidago altissima* (see Table 1). Values may not sum precisely to 100% because of rounding.

and almost half of its tissue sterol profile was unmetabolized spinasterol. Four other sterols were observed in *U. nigrotuberculatum*. One was lathosterol (15%), which is likely generated by the aphid dealkylating spinasterol or other *S. altissima* sterols. The remaining three were plant sterols (sitosterol, stigmasterol, and 22-dihydrobrassicasterol), but none was observed to exceed 10%.

Fungus Sterol Profile The dominant sterol in *Botryosphaeria. dothidea* was ergosterol at 95%. The other recorded sterol (ergosta-7,22-dien-3β-ol (5%)) may be a stable component of *B. dothidea*'s sterol biosynthesis pathway (Table 3; Figs. 1, and 3).

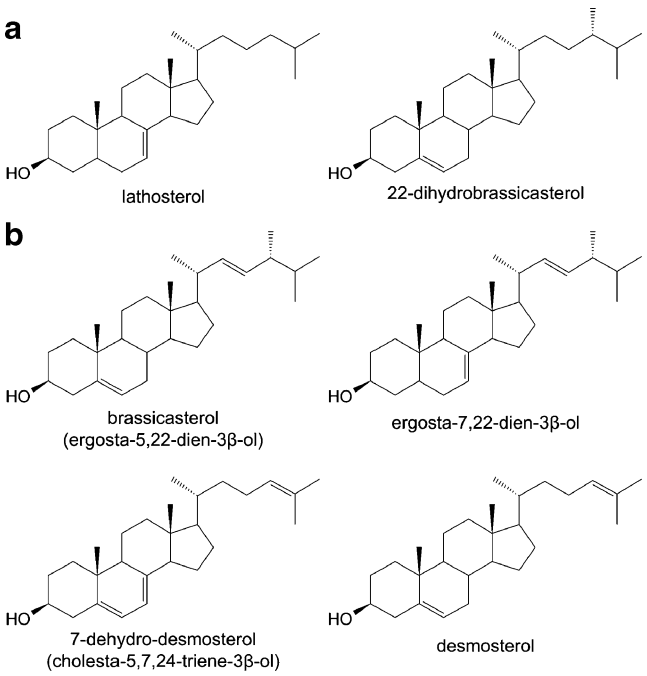

Fig. 3 The chemical structures of the additional sterols detected in the tissues of the insects associated with *Solidago altissima*. The two sterols shown in panel (**a**) are sterol products derived from phytosterols, while those shown in panel (**b**) are sterol products derived from fungal sterols

Internally Feeding Insects' Sterol Profiles The sterol profile of the leaf-galling midge *Asteromyia carbonifera* was completely free of any of the phytosterols detected in *S. altissima*. Instead, the profile contained ergosterol (C-28 $\Delta^{5,7,22}$) and ergosterol precursors/metabolites. This latter group of sterols included the C-27 ergosterol metabolite 7-dehydrodesmosterol (cholesta-5,7,24-trien-3β-ol), plus brassicasterol (ergosta-5,22-dien-3β-ol) and ergosta-7,22-dien-3β-ol (both are C-28 sterols). No detectable levels of cholesterol or 24-epifungisterol were found in *A. carbonifera*, although the common cholesterol precursor desmosterol (a C-27 $\Delta^{5,24}$-sterol) was found at low levels (3%).

In complete contrast to the leaf-galling *A. carbonifera*, the sterol profile of the stem-galling fly *Eurosta solidaginis* contained only phytosterols and phytosterol metabolites (Table 3; Figs. 2, 3). The majority (95%) of its tissue sterol profile was unmetabolized plant sterols, including spinasterol, 22-dihydrospinasterol, and avenasterol. The remaining 5% was mostly an unidentified sterol, plus a small amount of lathosterol. No 24-epifungisterol or cholesterol was detected in *E. solidaginis* tissue.

Discussion

Because insects must acquire sterols exogenously, their acquisition and metabolism may play important roles in insect ecology and community processes. Previous studies have demonstrated variation in sterol metabolism in insects, but have provided little ecological context. We characterized the sterol profiles of a natural insect herbivore community on the ecological model plant, the goldenrod *S. altissima*. Our data show that, despite sharing a host plant and a common sterol source, these insects exhibit marked variation in their sterol profiles, even between congeneric species. Part of this diversity likely is due to variation in host breadth and feeding guild among species. However, our data also highlight the likelihood of significant constraints on the evolution of sterol metabolism in

Table 3 Identification and relative percentages of sterols detected in two galling insect species and a fungal symbiont collected from *Solidago altissima*

(1) cholesterol, (2) spinasterol, (3) 22-dihydrospinasterol, (4) avenasterol, (5) ergosterol, (6) brassicasterol (ergosta-5,22-dien-3β-ol), (7) ergosta-7,22-dien-3β-ol, and (8) 7-dehydrodesmosterol (cholesta-5,7,24-trien-3β-ol). Column 9 represents a consolidation of other sterols found in smaller amounts (≤ 5%). Sterols with asterisks were found in *Solidago altissima* (see table 1)

insects: most species, even *Solidago* specialists, were inefficient at metabolizing or were unable to use *S. altissima* sterols. Finally, our results underscore the importance of fungi as sterol sources for plant-associated insects, as witnessed in a number of other species (Kok et al. 1970; Mondy and Corio-Costet 2000; Noda and Koizumi 2003).

Compared to most species in the Asteraceae, which typically produce Δ^5-sterols (Nes and McKean 1977), *S. altissima* appears somewhat unusual in producing Δ^7-sterols as its principal sterols. However, this result is consistent with results from a previous pollen study of *Solidago* spp. where the principal sterol detected was 22-dihydrospinasterol (as Δ^7-stigmasten-3β-ol) (Svoboda et al. 1983). Here, it appears that specific subclades within the Asteraceae may contain plant species that synthesize primarily Δ^7-sterols, while other clades contain species that synthesize both Δ^7- and Δ^5-sterols, or Δ^5-sterols exclusively. For example, *S. altissima* belongs to the subfamily Asteroideae (Panero and Funk 2008), and in the Asteroideae sterol profiles from at least one species from seven different tribes have been recorded. The principal sterols in four of these (Anthemideae, Eupatorieae, Gnaphalieae, and Senecioneae) appear to be Δ^5-sterols. In contrast, two of the seven (the Calenduleae and Heliantheae alliance) contain species that synthesize both Δ^5- and Δ^7-sterols (Nes and McKean 1977). Finally, *Aster scaber*, which like *Solidago* belongs to the tribe Astereae, appears to synthesize Δ^7-sterols (spinasterol) exclusively (Tada et al. 1974). Thus, in clades that are basal to Astereae (e.g., Calenduleae), species that synthesize Δ^5:Δ^7-sterol mixes or only Δ^5-sterols may be common, while within the more derived Astereae, Δ^7-sterols (e.g., spinasterol) may be more common.

Many plants have independently converged on Δ^7 sterol profiles (e.g., Salt et al. 1991), yet the ecological and evolutionary significance of this convergence remains unclear. Δ^7-Sterols may confer important biochemical functions to the plant, and act in physiological adaptation to particular habitats (for example dry, saline environments; Salt et al. 1991; Behmer and Nes 2003). They also may act in defense against insects (Behmer and Nes 2003). Many insects cannot efficiently metabolize/utilize Δ^7-sterols, (Clark and Bloch 1959; Ritter and Nes 1981; Ritter 1984; Behmer and Elias 2000), and some insect herbivores learn to avoid foods that contain large amounts of unsuitable sterols (Behmer and Elias 1999b; Behmer et al. 1999a). Convergence could, therefore, be a result of (a) a history of intense selection from common insect herbivores that are unable to metabolize Δ^7-sterols (e.g., grasshoppers) and/or (b) biochemical adaptation to novel habitats and/or niches.

A surprising finding was that *S. altissima* contained mostly conjugated sterols. Most plants conjugate free sterols, but only a relatively small percentage of them (Wojciechowski 1991; Moreau et al. 2002). The function of conjugated sterols in plants and the ways insects metabolize them are unknown (Behmer and Nes 2003; Schaller 2003). Conjugation of plant sterols may be considered a form of plant defense. Possibly, conjugation may prevent some insects from accessing needed sterols since conjugated sterols may be "difficult-to-metabolize" forms. Further work is necessary to determine if conjugated sterols are an effective insect defense.

One of the most significant results is the remarkable variation observed in cholesterol content among insect herbivores. The virtual lack of cholesterol in the beetle (*T. virgata*) is somewhat surprising, but this is consistent with work done on the alfalfa weevil, *Hypera postica* Gyllenahl, which also specializes on plants (alfalfa) that contain only Δ^7-sterols (MacDonald et al. 1990). That a relatively large amount of lathosterol was recovered from *T. virgata* tissue demonstrates that side-chain dealkyalation likely occurs. Moreover, the fact that 99% of the tissue sterols recovered from *T. virgata* had a double bond at position seven (Δ^7) is consistent with the notion that many herbivorous insects lack the enzymes (specifically isomerases) necessary to completely convert Δ^7-sterols to Δ^5-sterols (Ritter 1984; Rees 1985; MacDonald et al. 1990). The detection of low levels of cholesterol raises the possibility that *T. virgata* can convert a small amount of Δ^7-sterol to cholesterol, or that an undetected Δ^5-sterol could have been dealkylated and converted to cholesterol. However, further work is necessary to differentiate metabolism from contamination (e.g., prior to

sampling, *T. virgata* may have ingested some material (e.g. pollen) that contained a small amount of cholesterol).

The high percentage of Δ^7-sterols in *T. virgata* suggests that Δ^5-sterols (like cholesterol) are not necessarily the primary sterol required for growth and development, as seen in some grasshopper (Behmer and Elias 2000) and leaf-cutter ant species (Ritter et al. 1982). For insects that regularly encounter Δ^7-sterols, such as *S. altissima* specialists, it may be more metabolically efficient to forego metabolism to cholesterol and instead use dealkylated Δ^7-sterols (e.g., lathosterol) and/or unmetabolized Δ^7-sterols for biological functions. However, for some generalist insects, the inability to metabolize Δ^7-sterols from host-plants has an adverse effect on growth and development, likely due to difficulties associated with ecdysteroid biosynthesis (Ritter and Nes 1981; Behmer and Elias 1999a, 2000). A puzzling issue remains for specialist insects that feed on plants with Δ^7-sterols and cannot introduce Δ^5 double bonds, in that most insect ecdysteroid biosynthesis pathways appear to require $\Delta^{5,7}$ sterol intermediates (Rees 1985), which these species would be unable to synthesize.

Given the significant amounts of cholesterol and lathosterol recovered in the two aphid species, our results indicate that aphids are capable of phytosterol dealkylation. However, the relatively small amount of cholesterol and lathosterol, and high amounts of spinasterol and other phytosterols suggests that, in *U. nigrotuberculatum,* dealkylation capabilities may be relatively inefficient. Similar results were observed in another aphid species (*Schizaphis gramimum* Rondani) fed Δ^5-sterols (Campbell and Nes 1983). The distinct difference in sterol profiles observed in the two *Uroleucon* species is notable, but the precise reasons behind the difference cannot be determined by this study. *Uroleucon* is a large genus that includes species that vary widely in their host-plant specificity and life histories. *Uroleucon luteolum* may simply be more efficient than *U. nigrotuberculatum* at converting phytosterols to cholesterol. One previous study hinted that phytosterol metabolism can show minor variability within a species (Behmer and Grebenok 1998). Thus, it is even more likely that substantial metabolic variation can exist between congeneric species.

Both *Uroleucon* species also contained detectable, albeit relatively low amounts of the Δ^5-sterols sitosterol and stigmasterol, neither of which was detected in *S. altissima* leaf tissue. Two possibilities may explain this result. First, recent evidence has shown that phloem phytosterol profiles do not always identically match that of the leaf tissue (Spencer T. Behmer, Robert J. Grebenok, and Angela E. Douglas, unpublished data), and *Solidago* may synthesize some Δ^5-sterols that are more highly concentrated in the phloem (see also Svoboda et al. 1983). Sap-feeders like aphids may be particularly likely to sequester 'whole plant' nutrients, vitamins, and sterols not immediately present at the feeding site. The second explanation is that aphids collected for analysis may have been feeding recently on plants that contained Δ^5-sterols, stored those sterols in a conjugated (esterified) form for later metabolism, and passed a fraction of those on to their offspring. Approximately 20% of the individuals in aphid samples were winged alates, which could have been migrants from other host plant species.

Interestingly, similar patterns were observed in the treehopper *A. tartarea*. *Acutalis tartarea* adults are phloem-feeders and highly mobile, so it is possible that the stigmasterol detected in their tissues was either transported by the *S. altissima* vascular tissues or obtained from a non-*S. altissima* plant species. A previous study of a planthopper (*Laodelphax striatellus* Fallen) suggests that some Auchenorrhyncha can dealkylate sterols (Noda and Koizumi 2003). It appears that *A. tartarea* may be inefficient at or incapable of metabolizing sterols with Δ^7 and/or Δ^{22} double bonds, given the lack of lathosterol and detectable levels of stigmasterol, spinasterol, and 22-dihydrospinasterol detected in its tissues. Further work, including direct sterol analysis of phloem itself and manipulative field experiments on confined insects, will provide insights into the unusual sterol variability in the phloem-feeders.

The sterol profiles of the two dipteran gall-formers were dramatically different. *Eurosta solidaginis* belongs to the family Tephrititdae, a large family of primarily herbivorous brachyceran flies. In addition to unmetabolized plant sterols, only trace levels of C-27 sterol were detected in larval tissues, suggesting that *E. solidaginis* is unable to dealkylate phytosterols. All brachyceran species studied to date are incapable of dealkylating C-28/C-29 sterols (Robbins 1963; Kircher et al. 1984; Svoboda et al. 1989). Lack of dealkylation is somewhat surprising, because species in herbivorous brachyceran families frequently may encounter low to non-existent levels of C-27 sterols in their plant-based diet. Moreover, fly larvae, especially the galling or leaf mining species common to the Brachycera, are relatively immobile, preventing them from incorporating behavioral mechanisms such as dietary mixing to cope with sterol inadequacies (e.g., Behmer and Elias 2000). Trace amounts of lathosterol in *E. solidaginis* may be transient components of the ecdysteroid biosynthesis pathway of *S. altissima* that were concentrated to detectable levels in *E. solidaginis* tissue. Other Brachycera (i.e., *Musca* and *Drosophila*) selectively absorb minute amounts of C-27 sterols from their diets for use in ecdysteroid production, as long as other sterols are present to act in structural roles (a phenomenon known as sterol sparing; Clark and Bloch 1959; Robbins 1963; Kircher et al. 1984; Feldhaufer et al. 1995). The capacity to successfully use C-28/29 phytosterols as membrane inserts may have been crucial for the shift that some brachyceran species have made from basal feeding modes such as

saprophagy/predation/parasitism/blood feeding (where C-27 sterols are abundant) to more derived herbivory (where C-27 sterols are relatively rare).

By contrast, *A. carbonifera*, a member of the midge family Cecidomyiidae, lacked plant-derived sterols altogether suggesting that it does not consume *S. altissima* tissue at all. Instead, it appears to acquire its sterols by consuming its fungal ectosymbiont. The presence of the C-27 ergosterol metabolite 7-dehydrodesmosterol (cholesta-5,7,24-trien-3β-ol) and the C-27 sterol desmosterol indicates that, like other Nematocera, *A. carbonifera* can dealkylate sterol side-chains (Svoboda et al. 1982). The dependency of *A. carbonifera* on its nutritional mutualist for dietary sterols adds to growing evidence that fungal mutualists can act as sources of dietary nutrients for plant-associated insects (Kok et al. 1970; Mondy and Corio-Costet 2000; Noda and Koizumi 2003). Indeed, many other cecidomyiids consume fungus as their principal food source (Bissett and Borkent 1988). Because *A. carbonifera* actively transports a single species of fungus for consumption (Bissett and Borkent 1988; E.M. Janson, unpublished manuscript), this interaction demonstrates how fungal symbioses could potentially circumvent some level of "nutritional mismatching" between an insect and its host plant (Janson et al. 2008). Here, the phytosterol metabolic capacity of *A. carbonifera* is irrelevant, because it can simply metabolize the sterols provided by its symbiont on all plants that it is able to gall.

The physiology and biochemistry of plant and insect sterol synthesis and metabolism has been characterized in great detail over the past 50 years. What has been largely ignored is how plant sterol physiology and the limitations of insect sterol metabolism affect the ecology of plant-insect interactions. What are the proximate and ultimate causes for the marked variation we observe in phytosterol physiology and insect sterol metabolism? Are phytosterols important in structuring insect communities? Do sterols shape how insects compete on their host plants or act as chemical defenses, and, if so, how often and under what ecological and evolutionary circumstances? To address such questions, a deeper understanding of the functional significance of the variation in phytosterol profiles among many plant species is necessary (e.g., Omoloye and Vidal 2007). These questions might best be addressed by correlating environmental conditions with particular phytosterol profiles across numerous phylogenetically independent plant groups, and determining the sterol metabolic capabilities of insect herbivores that co-occur with these plants. Such an approach would provide clues as to how important phytosterols act as defense against herbivores. Trade-offs associated with sterol specialization may affect host plant specificity. Furthermore, it is an open question as to how frequently and at what rate sterol metabolic capabilities are gained or lost. Insect taxa such as beetles, which have so far shown extreme variation in side-chain dealkylation, but consistency in B-ring metabolism (they are unable to introduce Δ^5 double bonds), may be especially amenable to such studies.

In summary, our results show that: 1) Several insect species were unable to fully metabolize *S. altissima* sterols into cholesterol, despite many of them specializing or feeding regularly on *Solidago*. Thus, there appears to be significant constraint on the evolution of sterol metabolism in insects in that many species appeared to be unable to convert or are inefficient at converting phytosterols with Δ^7 double bonds to Δ^5 sterols. 2) Closely related species and those occupying the same feeding guild differed dramatically in sterol metabolism. 3) Fungal symbionts can provide a source of dietary sterols for their insect hosts.

Acknowledgements We thank Emily Peeden for gall dissection efforts. John Stireman aided with plant community characterization at Beaver Creek Wildlife Area. Denise Weyer assisted with plant community characterization at Shelby Bottoms. Dean Della Penna provided laboratory space and financial support for some of the sterol extraction, sterol sample preparation and analysis. Chris Dietrich provided information about the host range of *A. tartarea*. Two anonymous reviewers provided helpful criticisms. This work was supported by a National Science Foundation grant (DEB 0614433) awarded to P. Abbot, and by a CSREES NRI-USDA grant (2007-35302-18185) awarded to S.T. Behmer and R.J. Grebenok.

and unsaturated hydrocarbons (Schmitt 1990; Oldham et al. 1994), mostly the same odd-numbered C21 to C31 ones (Schmitt 1990; Goulson et al. 2000; Saleh et al. 2007), suggesting that lipids from diverse body parts mix on the cuticle surface (Oldham et al. 1994). While probing for nectar, foraging bees touch flower corollae with various body parts, including the tarsi, and, thus, traces of cuticular lipids may pass onto the flower surface. Eltz (2006) speculated that the epicuticular wax of flower corollae could retain a record of past bumblebee visits. In a controlled garden experiment, flowers of the deadnettle, *Lamium maculatum*, with different numbers of visits by worker bumblebees (*Bombus pascuorum*), were analyzed by gas chromatography/mass spectrometry (GC/MS). Several odd-numbered alkenes, in addition to the plants' own cuticular lipids (mostly saturated alkanes), were identified. Pentacosenes (C25:1) were the clearest *B. pascuorum* markers. The quantity of pentacosenes in corolla washes increased positively and linearly with the number of visits that a flower had received. Furthermore, the amount of pentacosenes left on corollae did not change for two hours following the last bumblebee visit (Eltz 2006), thus suggesting that these bee lipids could serve as a long-term information store of bee visits.

In the present study, we further investigated this phenomenon by extending the time scale over which footprint retention is measured and by investigating the extent that retention is affected by environmental variables. We also conducted a field survey that tested the hypothesis that the amount of bumblebee footprint chemicals obtained from corollae of wild comfrey (*Symphytum officinale*) is indicative of the number of bumblebee visits. We show that the alkene amount on flower corollae can be used as a predictor of visit frequency, even in a natural, dynamic foraging environment.

Methods and Materials

All laboratory experiments were conducted in a climate chamber at the Department of Sensory Ecology at the University of Düsseldorf. *Bombus terrestris* colonies (Koppert Biological Systems) were maintained in a nest box (30×30×20 cm), which was connected to a feeding box (40×40×80 cm) via a Plexiglas tunnel (75 cm long). The colonies were fed with 20 ml sugar syrup (ApiInvert®) each day, provided in plastic syringes (5 ml). Pollen was supplied *ad libitum* directly into the nest box. The observation of bumblebee visits on flowers of wild comfrey (*S. officinale*) took place on the 29th July 2007 in pastures and meadows near Himmelgeist and Urdenbach, south of Düsseldorf.

Footprint Accumulation and Retention Under Different Ambient Temperatures Worker *B. terrestris* were allowed to forage on flowers of potted foxglove (*Digitalis grandiflora*; in 2007) or cowslip (*Primula veris;* in 2008) placed in the feeding box. Visits to individual flowers were recorded with the help of a computer and the software clbehave (Compulights 2005). To maintain high attractiveness of the flowers, small amounts of ApiInvert® were pipetted into the corollae at regular intervals.

The number of visits to individual flowers of *D. grandiflora* (2007) was manipulated and varied gradually between 31 and 51, whereas flowers of *P. veris* (2008) were allowed fixed numbers of 0, 20, or 40 visits. In both years, we tested how long the visited flowers retained deposited alkenes by taking corolla samples after 0, 6, and 24 h following the last bumblebee visit. The experiment was replicated under two different ambient temperatures (15 and 25°C) in both years, to test for effect of temperature on alkene retention. Individual flower corollae were removed from the receptacle with clean forceps, and anthers cut off at the base with scissors. Each corolla was extracted for 30 sec. in 500 µl *n*-hexane (p.a., Merck) containing 10 µg of 2-undecanone as an internal standard. The extracts were stored at 2°C until GC/MS analysis (see below). We also analyzed samples of bumblebee cuticular lipids. For this, we randomly sampled workers from the experimental colonies and cut off their tarsi at the proximal end of the femur. All six tarsi of an individual were combined and extracted in the same way as corollae.

We tested for effects of time since the last visit and ambient temperature on the amount of bumblebee-derived nonacosenes (C29:1) in corolla washes. For *D. grandiflora* (2007), in which the flowers had received varying numbers of visits, we performed an analysis of covariance (ANCOVA) in SPSS 15. Time (0, 6, and 24 h) and temperature (15 and 25°C) were specified as factors, and the number of visits received per flower (31–51) was the covariate. For *P. veris* (2008), we used an analysis of variance (ANOVA) and tested for effects of the factors, time (0, 6, and 24 h), temperature (15 and 25°C) and number of visits (0, 20, and 40), on the amount of nonacosenes.

Retention of Synthetic (Z)-9-Tricosene on Flowers Tricosenes are among the most dominant components in the cuticular lipids of bumblebees (e.g., Goulson et al. 2000). The (Z)-9-isomer has, among other hydrocarbons, been detected in footprint deposits of bumblebee workers (Schmitt et al. 1991; S. Witjes, unpublished data). Potted deadnettles were introduced into a climate chamber and habituated to an ambient temperature of 25°C. We applied 0.1 µl of (*Z*)-9-tricosene (Aldrich, Milwaukee, WI, USA), as a model compound, to unvisited flower corollae using a 5 µl Hamilton syringe. The syringe was connected to an assembly micrometer gauge (Holex, Munich, Germany) to facilitate adjustment of the exact volume. Corolla samples

either were taken immediately (0 h treatment), or after 24 or 48 h following application. Individual corollae were extracted for 30 sec. in 1.5 ml *n*-hexane. We performed ANOVA to test for effect of storage time on the amount of (*Z*)-9-tricosene in corolla extracts.

Footprint Accumulation on Flowers of Wild Comfrey Comfrey is a common perennial plant in pastures and meadows along the river Rhine, where it is frequently visited by local bumblebees for nectar and pollen. On the 29th July 2007, we recorded insect visits to flowers of 63 individual plants in 10-min.-intervals distributed evenly over the day from 800 to 1600 h (on average 5.5 intervals per plant, or 55 min of observation). Individual plants were chosen from a total of sixteen patches, and visit data were recorded synchronously by eight teams of two observers, each team switching back and forth regularly between patches and individual plants, so as to reduce the effects of time of day on counts per plant. Bumblebees were the only regular flower visitors (99% of visits), and the occasional visits by other insects (unidentified syrphid flies and solitary bees) were excluded from further analysis. We recorded the species of visiting bumblebee and calculated the average number of bumblebee visits received in 10-min observation intervals per flower and plant for each bumblebee species. At the end of the observation period, we randomly picked 5 flowers from each observed plant with clean forceps and extracted the corollae in 1 ml *n*-hexane (p.a., Merck) containing 10 µg of 2-undecanone as an internal standard for GC/MS analysis. We performed a linear regression analysis to test for an effect of the number of bumblebee visits on the amount of retained alkenes on flower corollae.

Chemical Analysis GC/MS analysis was performed with an HP 5890 II GC, equipped with a 30-m non-polar DB-5 column, connected to a HP 5972 mass selective detector, and an HP 7673 autoinjector (in splitless mode). The column oven was heated from 60 to 300°C at 3°C min^{-1}. Hydrocarbons were characterized by comparison of their mass spectra and retention times with that of authentic reference samples. For the purpose of the present study we did not differentiate between different alkene isomers, but pooled all alkene peaks of a given chain length.

Results

Footprint Accumulation and Retention under Different Ambient Temperatures Tarsal extracts of *B. terrestris* (*N*=10) contained *n*-alkanes and alkenes with chain length from 21 to 31, while corolla extracts of unvisited *D. grandiflora* (*N*=10) and *P. veris* (*N*=10) contained saturated alkanes, but no detectable amounts of unsaturated alkenes (Fig. 1). Nonacosenes (C29:1) were the most abundant class of alkenes on the tarsal cuticle of *B. terrestris* (Fig. 1) and, therefore, these chemicals were quantified as an indicator of bumblebee footprints. There were significant positive effects of the number of bumblebee visits on the amount of nonacosenes in corolla extracts of *D. grandiflora* in 2007 (ANCOVA: $N=77$; $df=1$; $F=9.664$; $P<0.05$) and of *P. veris* in 2008 (ANOVA: $N=180$; $df=2$; $F=69.018$; $P<0.001$) (Fig. 2). In neither case was there an effect of ambient temperature on the amount of nonacosenes in corolla extracts (*D. grandiflora*, $N=77$; $df=1$; $F<0.001$; N.S; *P. veris,* $N=180$; $df=1$; $F=1.074$; N.S) (Fig. 2). The amount of nonacosenes was not significantly affected by the time elapsed since the last visit to *P. veris* ($N=180$; $df=2$; $F=0.69$; N.S) (Fig. 2). In *D. grandiflora*, there was a marginal effect of time ($N=77$: $df=2$; $F=3.126$; $P=0.05$), with the amount of nonacosenes being, on average, reduced by 14% on corollae extracted 24 h, compared to 0 h, after the last visit.

Retention of Synthetic (Z)-9-Tricosene On Flowers No (*Z*)-9-tricosene was detected in extracts of unmanipulated control corollae of *L. maculatum* ($N=24$). In contrast, all treated corollae contained (*Z*)-9-tricosene (Fig. 3). There was no significant effect of the time since application on the amount of (*Z*)-9-tricosene on treated corollae (*ANOVA*: $N=57$; $df=2$; $F=0.358$; N.S.) (Fig. 3).

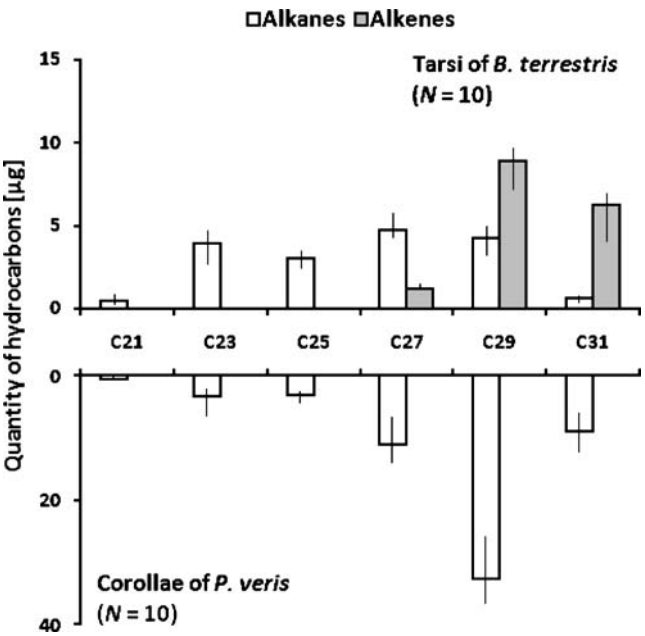

Fig. 1 Quantities of odd-numbered hydrocarbons in extracts of *Bombus terrestris* tarsi (µg/insect; $N=10$) and unvisited corollae (µg/corolla) of *Primula veris* ($N=10$), shown as medians with quartile ranges

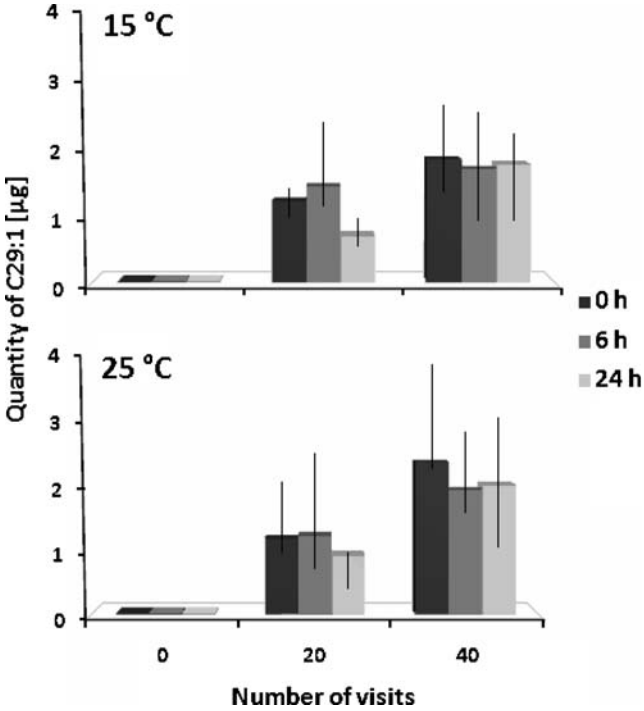

Fig. 2 Quantities (µg/corolla) of nonacosenes from *Primula veris* corollae, extracted 0, 6, or 24 h following the last bumblebee visit. The experiment was carried out at 15°C (*top*) or 25°C (*bottom*) ambient temperature. Corollae received 0, 20, or 40 visits by workers of *Bombus terrestris*. Median amounts with quartile ranges are shown

Footprint Accumulation on Flowers of Wild Comfrey The corollae of unvisited flowers of comfrey contained no detectable quantity of alkenes (S. Witjes, unpublished data). Workers of *B. pascuorum* were the most abundant visitors of comfrey at the time and contributed roughly 80% of all observed flower visits. The remaining 20% of visits were by *B. hortorum* (13 %), *B. terrestris* (4 %) and *B. pratorum* (3 %). The extracts of visited comfrey corollae contained alkenes of chain lengths from 21 to 31, corresponding well with that found in tarsal extracts of the visiting species of bumblebees (Goulson et al. 2000, Eltz 2006, S. Witjes, unpublished data). There was a significant positive relationship between the number of bumblebee visits observed per flower for a given plant during the observation intervals and the overall amount of alkenes on corollae of those plants (Fig. 4; Linear Regression: N=63; dF=62; F=32.83; P<0.001).

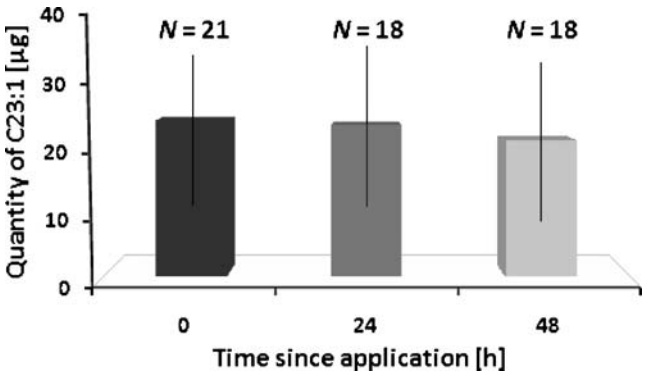

Fig. 3 Quantities (µg/corolla) of (*Z*)-9-tricosene from corollae of *Lamium maculatum* 0, 24, or 48 h after application. Data are shown as mean values with standard deviation

Discussion

This study provides further evidence that flowers retain a long-term chemical record of bumblebee visits. First, the amount of *B. terrestris*-derived nonacosenes washed from corollae was closely related to the number of bumblebee visits to the respective corollae in laboratory experiments. Second, the amount of marker alkenes remained unchanged over periods of 24 (footprint nonacosenes) to 48 (synthetic (*Z*)-9-tricosene) hours after the visits/manipulations, indicating that flower petals retain a quantitative record of bumblebee visits for a period similar to the lifetime of individual flowers of many temperate bee-pollinated plant species (Molisch 1929; Stead 1992). Third, the laboratory results were confirmed by our survey of wild comfrey plants, in which the amount of alkenes on flower corollae was closely related to the number of visits flowers of those plants received during the previous eight hours. Overall, our results indicate that alkene footprints on flower corollae can serve as an information source of bumblebee visits in natural populations of plants, especially since unsaturated alkenes seem to be absent or rare in epicuticular waxes of unvisited flowers (Griffiths et al. 1999, 2000; Goodwin et al. 2003; Eltz 2006). The alkene footprint, due to its cumulative nature, effectively integrates visitation dynamics over the entire exposure time of a flower, possibly providing a more accurate measure of bumblebee visits than an observational method, especially in studies with multiple replicates and limited observers.

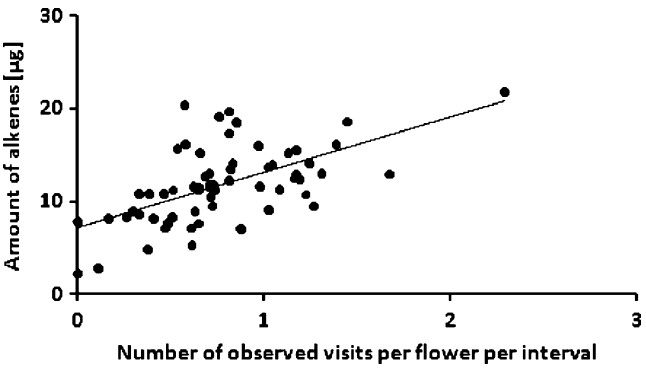

Fig. 4 Quantities of total alkenes on corollae of wild *Symphytum officinale* plants (N=63) in relation to the mean number of bumblebee visits the plants had received per flower in 10-minute observation-intervals during the day

Cuticular hydrocarbons are typically of low volatility, a point illustrated by a study that used combinations of synthetic alkanes (C24 to C31) to mark the elytra of milkweed beetles; these alkane profiles remained unchanged in quality and quantity over weeks despite exposure to direct sun and rain (Ginzel and Hanks 2002). The long-term retention of bee footprints on flowers may be promoted by the physicochemical characteristics of plant surfaces. Following deposition, bee hydrocarbons probably are integrated into the semi-liquid layer of plant cuticular waxes (Jetter et al. 2000; Eltz 2006), reducing their susceptibility to evaporation.

In agreement with Ginzel and Hanks (2002), bumblebee alkene retention was not influenced by changes in ambient temperature, at least over the temperatures (15 or 25°C) used in the experiments. The effects of more extreme temperature regimes or variation in exposure to direct sun were not investigated in detail in the present study. However, preliminary tests in an incubator oven suggest that evaporative losses of (*Z*)-9-tricosene droplets from filter paper are small even at 60°C (7.2 % over 24 h; S. Witjes, unpublished data). This suggests that variability of hydrocarbon retention should be low across a broad range of climatic conditions, thus allowing for comparisons among samples taken at different dates within the same general season/region.

It should be emphasized that the amount of hydrocarbons deposited on corollae of different plant species may vary substantially due to differences in flower morphology and in the way visitors contact corolla surfaces. Thus, each species of plant is likely to require calibration for determination of the number of visits. We currently are testing the applicability of footprint quantification as a tool to retrace the composition of the flower-visiting bumblebee community in wild populations of comfrey. Bumblebees show species-specific differences in hydrocarbon profiles (Goulson et al. 2000; Eltz 2006), and preliminary data indicate that those differences can be used to reconstruct the visiting bumblebee community (Witjes and Eltz, unpublished).

Quantification of hydrocarbon footprints on flowers may represent a cheap and reliable tool to quantify bumblebee visits in pollination studies, thus helping to reduce the problem of insufficient temporal and spatial replication in studies of pollinator decline.

Acknowledgements We thank Klaus Lunau and the members of the Sensory Ecology Group for discussions and comments on the manuscript, and the participants of the 2007 Sensory Ecology course for their help and endurance during the wild comfrey survey. A special thanks to Andreas Fischbach and Wilhelm Rogmann of the Botanical Garden of the University of Düsseldorf for maintaining the plants, as well as Waldemar Seidel of the Feinmechanikerwerkstatt of the University of Düsseldorf for the production of the bumblebees´ nest- and feeding boxes. This study was funded by the DFG grant EL249/3 and the University of Düsseldorf.

to produce latex, which serves as a physical barrier and a source of concentrated toxins effective against chewing herbivores (Dussourd and Eisner 1987; Zalucki and Malcolm 1999; Zalucki et al. 2001b; Agrawal 2005; Agrawal and Konno 2009). Latex accumulates under pressure in special cells (laticifers), which quickly release the sticky substance upon damage. By partially severing a leaf's petiole or cutting the midrib, the flow of latex to distal tissues in that leaf essentially can be stopped. This treatment substantially improved the performance of monarch caterpillars on four latex-rich milkweed species, but had relatively minimal effect on caterpillars feeding on four milkweed species that produce less latex (Zalucki and Malcolm 1999; Zalucki et al. 2001a, b). In addition, genetic families of *Asclepias syriaca* L. that exude more latex also have enhanced resistance to several insect species in feeding assays and in the field (Agrawal and Van Zandt 2003; Van Zandt and Agrawal 2004; Agrawal 2005).

All milkweed species also contain cardenolides, with concentrations varying over several orders of magnitude across species and among organs. Cardenolides inhibit Na^+/K^+-ATPases, which are important for maintenance of membrane potential in most animal cells. Cardenolides are toxic to a wide array of animals (Malcolm 1991). Differences in structure and polarity have been linked to differential absorption by animals, resulting in differential toxicity (Seiber et al. 1980; Malcolm 1991; Frick and Wink 1995). For example, the non-polar compound digitoxin is almost completely absorbed, irrespective of how it is administered to insects; conversely, ouabain, a highly polar cardenolide, is absorbed slowly from the gastrointestinal tract (Malcolm 1991). The Na^+/K^+ ATPase from specialist herbivores, such as the monarch butterfly (*Danaus plexippus*) has a slightly modified cardenolide binding site, thus reducing cardenolide toxicity (Holzinger and Wink 1996). Specialist herbivores of milkweed also may sequester cardenolides that are used for their own defense (Brower et al. 1972; Malcolm et al. 1989).

Other secondary metabolites that occur in milkweeds are cysteine proteases. Proteases, found in all living organisms, cleave proteins. Various types are found in the latex of plants that belong to a diversity of phylogenetic clades. For example, cysteine proteases are reported in latex of families such as Caricaceae, Moraceae, and Apocynaceae (Light et al. 1964; Sgarbieri et al. 1964; Arribére et al. 1998), and serine protease in Moraceae, Euphorbiaceae, Apocynaceae, Convolvulaceae (Arima et al. 2000; Tomar et al. 2008). Direct evidence for the involvement of cysteine proteases in plant resistance against herbivores came from experiments in which the toxicity of wild fig (*Ficus virgata*) against two generalist herbivores disappeared when E-64, a specific cysteine protease inhibitor, was painted on leaf surfaces (Konno et al. 2004). In previous work, we found that cysteine protease activity showed a 24-fold variation across the latex of 36 milkweed species (Agrawal et al. 2008).

It has been proposed that the carbon/nitrogen ratio (C/N ratio) of plant tissues is a significant regulator of susceptibility to leaf-eating insects (Behmer 2009). In particular, nitrogen may be the limiting factor for herbivores (Mattson 1980). Changes in C/N ratios in leaves might, therefore, be seen as an additional line of defense against folivorous insects.

The orchestration of multiple types of defenses in response to herbivore attack seems to be the key to 'plant immunity' (Howe and Jander 2008). Jasmonic acid plays a central role in coordinating the induction of the multivariate responses (Chini et al. 2007; Thines et al. 2007). Yet, we still know remarkably little about how different defensive traits are altered by herbivory, which traits are the most important for resistance, or how trait expression is coordinated. Closely related species that show divergent defensive strategies are especially interesting to compare because they can give us insight into how traits and their importance in resistance vary and potentially how they evolve.

In this study, we assessed variation of three plant defense related traits (latex, cardenolides, and proteases), one primary metabolism trait (C/N ratio), and one measure of resistance (larval growth of specialist monarch butterfly caterpillars) among three milkweeds (*Asclepias spp.*). We examined induction by monarch larvae or by treatment with jasmonic acid. Additionally, we sought to disentangle the impacts of two potentially potent resistance components, latex and cardenolides, on larval growth.

Methods and Materials

Plants and Growth Milkweeds of the genus *Asclepias* include about 130 species in North America, including Mesoamerica and the Caribbean, and six additional species endemic to South America (Woodson 1954; Fishbein et al. 2009). Within *Asclepias* is a monophyletic clade, series Incarnatae, with about 21 species (Fishbein et al. 2009) that we have been studying with regard to the evolution of latex and cardenolides (Rasmann et al. 2009). Preliminary experiments within this clade permitted us to choose three species (*A. angustifolia, A. fascicularis*, and *A. barjoniifolia*) that vary in their latex production, cardenolide production, and inducibility (Rasmann et al. 2009; Agrawal et al. 2009). *Asclepias angustifolia*, found mainly in Arizona (USA) and northern Mexico, and *A. fascicularis,* found throughout the west coast of the United States and Northern Mexico (Woodson 1954), exude relatively little latex and produce low levels of cardenolides. Latex production is induced in the latter following monarch herbivory. *A. barjoniifolia*, principally found on hot dry slopes in inter-Andean

valleys of Bolivia and Northern Argentina (David 2007), produces more latex and higher levels of cardenolides constitutively. Cardenolides (Rasmann et al. 2009), but not latex (S.C. Cook et al., unpublished) are induced by monarch herbivory.

For all experiments, seeds were germinated at room temperature after being stratified at 4°C on moist filter paper for 2 wk. Seedlings were randomized and grown in potting soil (10 cm diam pots) in a growth chamber (14 h daylight, 26°C day: 20°C night). Plants were fertilized (N:P:K 21:5:20, 150 ppm N [μg/g]) once, 1 week after planting.

We used larvae of the monarch butteriflies *Danaus plexippus plexippus*, a species that feeds almost exclusively on *Asclepias* spp. Monarchs are native to North and South America, and are split into a subspecies in South America, *D. plexippus erippus* (Ackery and Vane-Wright 1984). We assume that the three *Asclepias* spp. that we studied are experiencing herbivory from these two subspecies of monarchs regularly.

Induction Experiments After 4 wk of growth, plants from the 3 species were divided equally into 3 groups: 1) controls, 2) plants induced by addition of one first instar monarch caterpillar, and 3) plants sprayed with roughly 1.5 ml of 0.5 mM jasmonic acid (N=16 plants per treatment, per species). After 4 d, all larvae used for induction were removed from the treated plants, and half of the plants (N=8 plants per treatment, and per species) were sampled to determine latex exudation and chemical composition (see below). The remaining plants were left untouched for 5 d before inoculating each with one first instar monarch caterpillar. This set of larvae was weighed (fresh weight) after 5 d of feeding to obtain a measure of larval growth rate.

Latex Exudation We measured the amount of latex exuded onto a 1 cm diam pre-weighted filter paper, after cutting the first 5 mm off the tip of the youngest fully expanded and intact leaf. Latex stopped flowing after ≈10 s, and all latex was absorbed on the filter paper. This disc was placed in a pre-weighed microcentrifuge tube and weighed to estimate wet latex exudation per plant. Our method is a reproducible assay for determining latex exudation.

Cysteine Protease Activity To measure protease activity, we prepared a 0.6% latex solution by removing 1–3 leaves at the petiole of each plant to collect 1.5 μl of latex, which was mixed with 250 μl of 50 mM sodium phosphate buffer (pH 7). We employed a modification of the spectrophotometric protocol developed by Konno et al. (2004). Briefly, a reaction buffer with casein (Sigma, St. Louis, MO, USA) as the substrate was incubated for 30 min and stopped with trichloroacetic acid. After precipitating the undigested casein, absorbance of the supernatant at 280 nm was recorded.

HPLC Analysis of Cardenolides After collecting latex, we harvested all aboveground plant tissue and immediately froze it at −80°C. Collected plant material was oven-dried at 50°C for 3 d and ground. Fifty milligrams of ground material, spiked with 20 μg of digitoxin (Sigma) as internal standard, was extracted with 1.9 ml of 95% ethanol in a sonicating water bath at 55°C for 20 min. Ethanol was evaporated, and the residue was dissolved in 0.5 ml methanol. Samples were analyzed by HPLC using a Gemini C18 reversed phase column (3 μm, 150×4.6 mm, Phenomenex, Torrance, CA, USA) and an Agilent 1,100 series instrument with diode array detection. The 15 ul injection was eluted at a constant flow of 0.7 ml/min with a gradient of acetronile and 0.25% phosphoric acid in water as follows: 0–5 min 20% acetonitrile; 20 min 70% acetonitrile; 20–25 min 70% acetonitrile; 30 min 95% acetonitrile; 30–35 min 95 % acetonitrile. Peaks were detected by a diode array detector at 218 nm, and absorbance spectra were recorded from 200 to 400 nm. Peaks showing a characteristic symmetrical absorption band with a maximum between 217 and 222 nm were recorded as cardenolides (Malcolm and Zalucki 1996). Concentrations were calculated and standardized by using a standard curve that related peak areas to known digitoxin concentrations.

Above-ground tissue C/N was assessed with ≈3 mg of dried and powdered material at the Cornell University Stable Isotope Laboratory.

All statistical analyses were conducted by using JMP (Version 7. SAS Institute Inc., Cary, NC, 2007). First, we performed an overall MANOVA on the four response variables together (latex, cardenolides, C/N ratio, and proteases). Then, we performed a two-way ANOVA on each of the responses to assess effects of species, treatment, and their interaction.

Artificial Diet Experiment To test specifically for the impacts of latex and cardenolides, we focused on one species (*A. angustifolia*). This species was chosen because it exudes comparatively small amounts of latex and has low levels of cardenolides. The species is relatively poorly induced by herbivory (Rasmann et al. 2009). We investigated the role of latex by comparing monarch larval weight gain on 5–wk-old plants grown as described above (treatment *Intact*) to weight gain of larvae fed on cut leaves (treatment *Cut*) (i.e., no latex exudation). All cut leaves were placed on moist filter paper in 10 cm diam plastic boxes, with the petiole in moistened foam to reduce desiccation. Moreover, we tested the effect of two cardenolides (digitoxin and ouabain) on larval growth by placing one first instar monarch larva on a cut leaf that was painted with either 0.5% dry weight (DW) digitoxin (Sigma) in a methanolic solution (treatment *Digitoxin*), or 0.5% DW ouabain (Sigma) in a methanolic solution (treatment *Ouabain*), or pure

methanol (treatment *Methanol*). All five treatments were randomized on a laboratory bench. Larvae were allowed to feed for 2 d before recording their mass. To assess the amount of leaf tissue eaten during the trial, we scanned the leaves and quantified the area of tissue consumed using ImageJ 1.41 software (http://rsbweb.nih.gov/ij/). Area was plotted against a known leaf mass per area regression curve (r^2=0.969, leaf mass=0.027* leaf area—0.01, P<0.001) to obtain the fresh leaf mass eaten by the insect. The effect of different treatments was assessed with one-way ANOVA. We assessed differences within species and treatments using Student's *t post-hoc* tests.

Results

Induction Experiment Overall, we found strong variability across the four plant traits (latex, cardenolides, C/N ratio, and proteases) measured across three species, and three treatments (Fig. 1, Table 1, MANOVA, species: Wilks' λ=, $F_{16,263.37}$=31.618, P<0.001; treatment: Wilks' λ=, $F_{8,172}$= 3.979, P<0. 001, interaction: Wilks' λ=, $F_{32,318.75}$=1.877, P<0.001). *Asclepias angustifolia* was the best host plant for monarch larvae, supporting an average growth rate (over 3 treatments) that was five-fold higher than the average rate on *A. barjoniifolia*, and three-fold higher than the average rate on *A. fascicularis*. Of the three species, only *A. fascicularis* showed increased resistance after induction by monarchs or jasmonic acid, and larvae on induced plants grew 68 and 74% less, respectively, compared to larvae on controls. In contrast, on *A. angustifolia* we found induced susceptibility; larvae grown on monarch-treated plants were 61% heavier compared to control plants. This effect was not mirrored in the jasmonic acid treatment, which had no effect (Fig. 1, Table 1). *Asclepias barjoniifolia* was uniformly of poor quality, and larval growth rate was not affected by either type of induction.

Latex exudation largely mirrored the effects of treatments and species on larval mass. *Asclepias barjoniifolia* and *A. fascicularis* produced the same amount of latex, while *A. angustifolia* produced four-fold less. *Asclepias barjoniifolia* increased latex production 32% following the jasmonic acid treatment, but production diminished more than 90% after monarch herbivory. Interestingly, after monarch damage, *A. barjoniifolia* latex production was essentially the same as *A. angustifolia*. Induction of latex also was found for *A. fascicularis,* with plants exuding 30% more following jasmonic acid or monarch induction.

Cardenolides were two and five times more abundant in *A. fascicularis* and *A. barjoniifolia,* respectively, than in *A. angustifolia.* A significant (30%) increase in cardenolide prosecution was induced in *A. barjoniifolia* by either induction treatment Overall the level of cardenolides was correlated with the number of individual cardenolide peaks found in our HPLC analysis (Pearson correlation: N=9, r^2=0.997, P<0.001). We found more peaks in *A. barjoniifolia* (8-10) than in *A. angustifolia* (4-6) or *A. fascicularis* (4-6) (Fig. 2). More cardenolide peaks were recorded after jasmonic acid or monarch treatments in all species. Across species, cardenolide peaks eluted between 15 and 20 minutes. Only *A. barjoniifolia* produced more polar cardenolides that eluted before 15 minutes (Fig. 2).

The C/N ratio was different across species, with *A. barjoniifolia* and *A. fascicularis* having a 22 and 14% higher ratio, respectively, than *A. angustifolia* (Fig. 1). Interestingly, jasmonic acid treatments decreased the ratio by 11%; but overall, monarch treatment increased it by 8%, resulting in a significant difference between these two treatments. Monarch treatment increased the ratio in *A. barjoniifolia* by 27%.

Proteases showed a significant species effect with *A. fascicularis* having almost twice the level found in *A. angustifolia,* and *A. barjoniifolia* having intermediate levels. (Fig. 1, Table 1). Jasmonic acid or monarch treatments generally decreased protease activity, with a dramatic 80% decrease in either jasmonic acid- or monarch-induced *A. barjoniifolia* compared to controls.

Artificial Diet Experiment Larval weight gain after two days of feeding was differentially affected by treatments ($F_{4,75}$= 4.68; P =0.002, Fig. 3a). Larvae were 1.7 times heavier on cut leaves, compared to those feeding on intact plants, indicating a role for latex in resistance to monarchs. However, larvae feeding on cut leaves painted with digitoxin performed as poorly as those feeding on intact plants. There was no effect of ouabain or the methanol control when painted on leaves, compared to control cut leaves.

The weight gain per amount of leaf mass eaten (food conversion efficiency) on digitoxin and on ouabain painted leaves was 38 and 36% lower than on control cut leaves, respectively ($F_{3,40}$=2.857, P=0.049, Fig. 3b). In other words, although conversion efficiency was decreased substantially for monarchs that consumed ouabain, they apparently were able to compensate for this reduction by consuming 53 % more tissue than larvae feeding on digitoxin.

Discussion

Variability of Responses Within plant taxa and across our three treatments, there was substantial variation in the constitutive and induced levels of several putative defense traits. Latex and cardenolides levels were species specific, and induction by monarchs and jasmonic acid had overlapping and distinct effects. Latex and cardenolides showed some correlation with larval performance. For instance, the

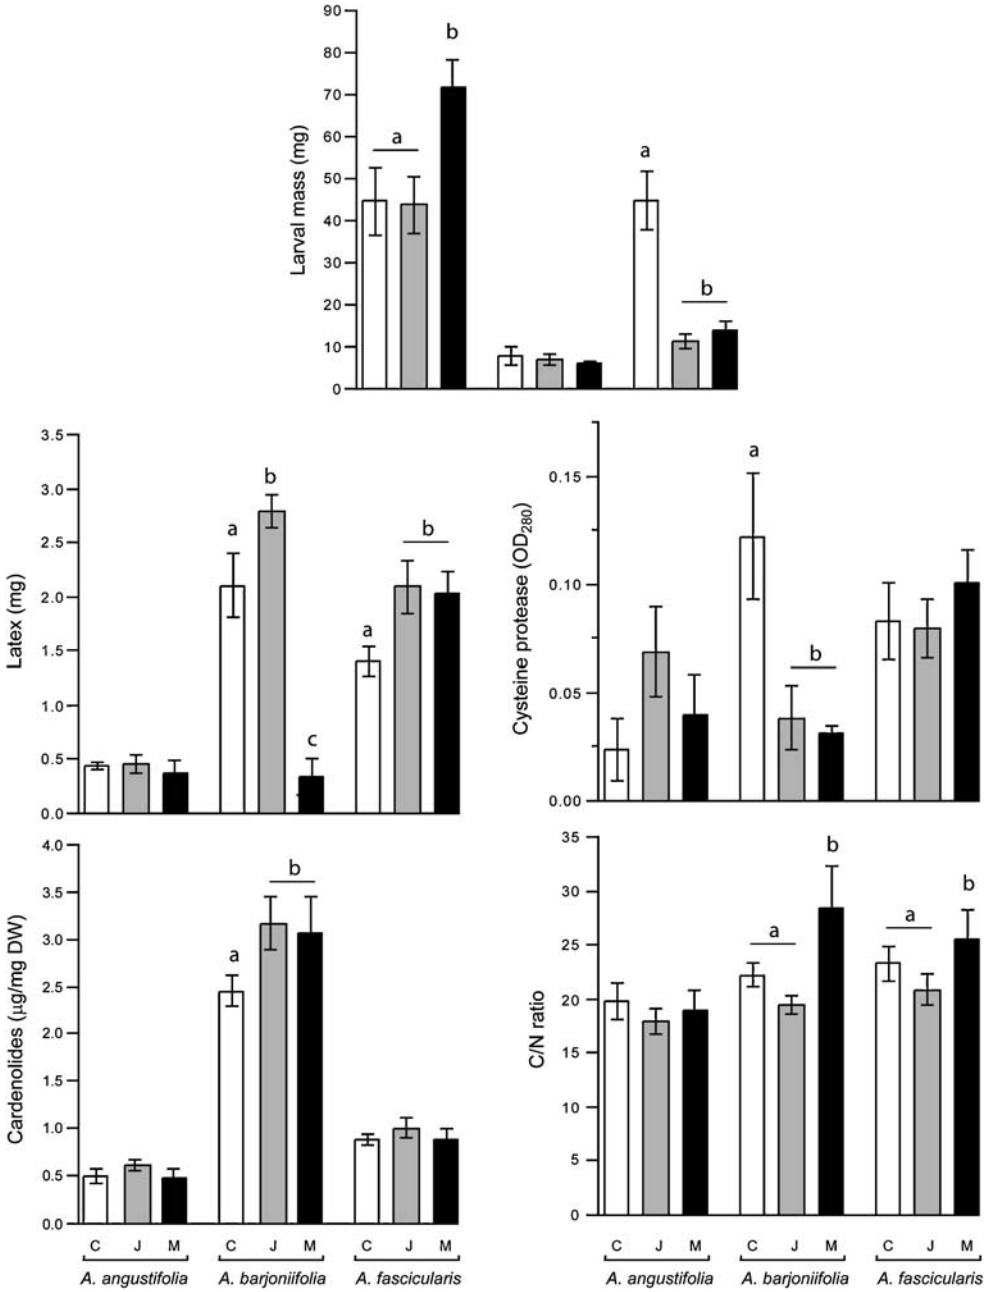

Fig. 1 Means ± SE of larval mass, latex, cardenolides, C/N ratio and proteases, in *Asclepias angustifolia*, *A. barjoniifolia*, and *A. fascicularis* and across the control (C), jasmonic acid (J), and monarch (M) treatments. Different letters above bars indicate significant differences among treatments within plant species ($P<0.05$)

low latex and low cardenolide species *A. angustifolia* supported more larval weight gain compared to high latex (*A. barjoniifolia* and *A. fascicularis*) or high cardenolide (*A. barjoniifolia*) species. The induction of latex but not cardenolides in *A. fascicularis* was accompanied by a decrease in larval weight gain (Fig. 1). In *A. barjoniifolia*, monarch induction did not alter larval growth because although cardenolides were higher after induction, latex production was diminished.

A high carbon to nitrogen ratio (C/N) could be caused by low levels of nitrogen or high levels of carbon-based compounds in the leaves, and in general indicates poor leaf quality. If a leaf is of a poor nutritive quality, it is predicted to be less defended than a high quality leaf (Coley 1983). In our case, we found species differences in the constitutive C/N ratios, but these were not mirrored by cardenolide levels. These differences in C/N may be more influenced by abiotic factors that shape plant ecophysiology (Agrawal et al. 2009) than by a response to herbivory. Matsuki and Koike (2006) showed that across seven species of deciduous broad-leaved trees that differed in their leaf life span, C/N correlated negatively with total N and herbivore survival, revealing that older leaves with low nitrogen content were less suitable for caterpillar growth. Following monarch feeding on *A. barjoniifolia* and *A. fascicularis*, C/N increased; this could be a result of metabolite reallocation and changes in

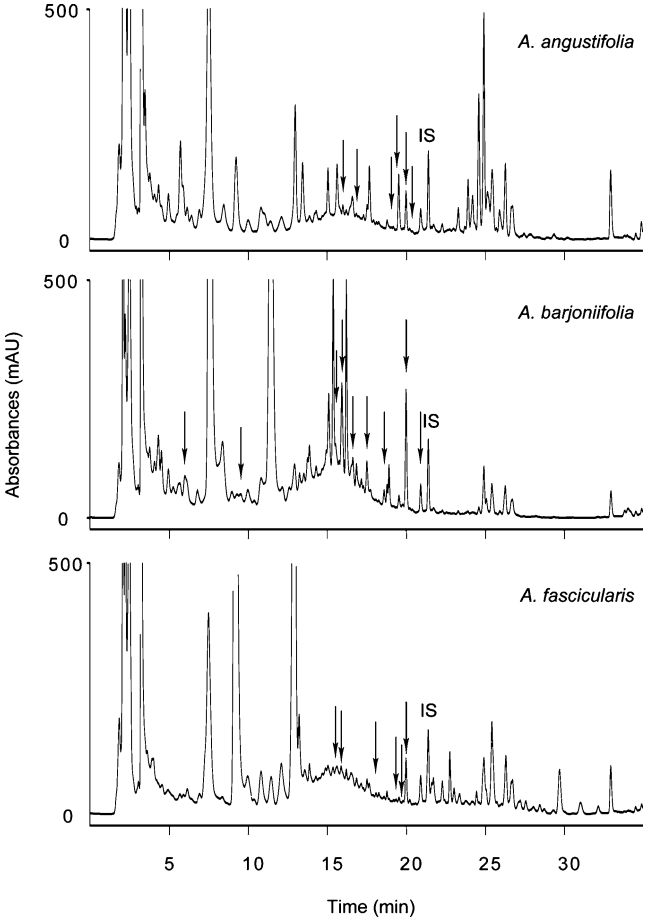

Fig. 2 Sample HPLC chromatograms of peak absorbance at 218 nm of leaf extracts for the three species of *Asclepias* studied. Scale is truncated at 500 mAU for better visualization of cardenolide peaks. Arrows mark all cardenolides found in undamaged plants. IS marks the internal standard (digitoxin)

photosynthesis. Consistent with the current findings, Agrawal and Fishbein (2006) showed that across 24 species of *Asclepias,* C/N correlated with leaf toughness, but not with qualitative defenses such as latex, cardenolides, or trichomes.

Cysteine proteases in latex drastically reduce herbivore growth (Konno et al. 2004). Across 36 species of *Asclepias,* Agrawal et al. (2008) showed that cysteine proteases in latex correlated positively with the amount of latex produced by the plant, but traded off with cardenolide concentration in latex. Here, the species with the highest leaf cardenolide level, *A. barjoniifolia*, also had the highest protease activity. We speculate that the consistently poor quality of *A. barjoniifolia,* irrespective of induced plant responses, was due to the high cardenolide, high latex, and high protease content of the species.

In the swamp milkweed *A. incarnata,* there was no influence of reduced latex flow on growth rates or survival of first-instar monarchs (Zalucki and Malcolm 1999). This is both a low latex and low cardenolide plant species, with smooth, soft, lanceolate leaves. The lack of a response to reduced latex flow in a low-latex and low-cardenolide milkweed lends credence to hypothesis that both latex and cardenolides are integrated defenses against early-stage monarch larvae. Similarly, Zalucki et al. (2001b) found that monarch larvae on nine *Asclepias* species generally grew faster and survived better on leaves when latex flow was reduced by partial severance of the leaf petiole. The outcome depended on milkweed species, and was related to the amount of latex and cardenolides produced, as well as to other plant characters, such as leaf hairs and microclimate. They concluded that several other parameters of plant quality/defense must play an important role in larval performance. We agree with this conclusion based on the three *Asclepias* species studied here.

Specificity of Induction Jasmonic acid now is widely accepted to be a key intracellular signal in mediating responses to insect attack (de Bruxelles and Roberts 2001), eliciting both direct and indirect defenses resulting in lower herbivore performance (Thaler et al. 2002). Here, we showed that exogenous application of jasmonic acid resulted in species- and trait-specific responses, which were often different from the responses plants produced after caterpillar feeding (Fig. 1). For example, latex induction

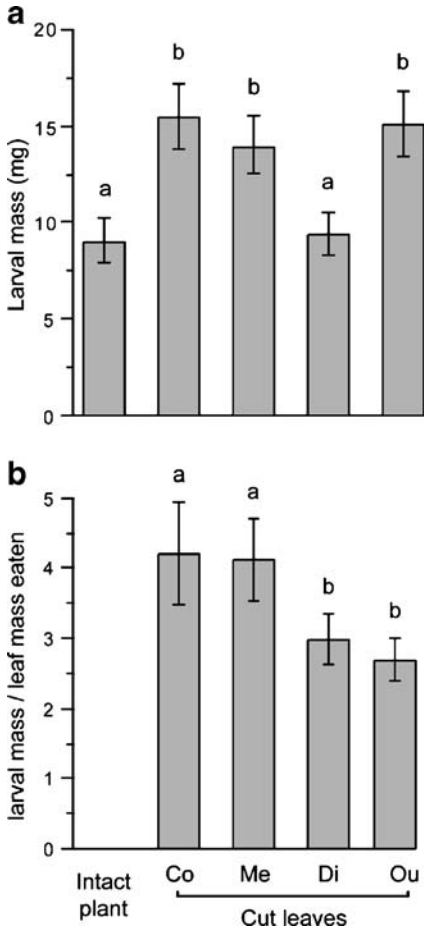

Fig. 3 **a**) Mean ± SE larval mass after 2 days feeding on *Asclepias angustifolia* intact plants, cut leaves (Co), cut leaves painted with methanol (Me), cut leaves painted with digitoxin (Di), or on cut leaves painted with ouabain (Ou). **b**) Mean ± SE conversion efficiency for each treatment other than the intact plant. Different letters above bars indicate significant differences among treatments ($P<0.05$)

was the same after jasmonic acid or monarch herbivory in *A. fascicularis*, but not for *A. barjoniifolia*.

One might think that the "sabotaging" behavior of monarch caterpillars, which notch veins and cut small moats through the leaves that reduce latex exudation at the feeding sites (Dussourd and Denno 1991; Zalucki and Brower 1992), was the cause of the reduced latex flow in *A. barjoniifolia.* However, in this species, latex was collected from healthy leaves, often opposite to the damaged one. Additionally, reduced latex production has been noted in other experiments with *A. barjoniifolia* when latex was collected several days after monarch feeding had ceased (S.C. Cook et al., unpublished data). Thus, the decrease in latex production in *A. barjoniifolia* following herbivory suggests that there may be other factors than mechanical sabotage that are involved in reducing latex production. Jasmonic acid, on the other hand, increased latex in the same species. This leads us to speculate that monarch larvae can impede or even disrupt some aspects of jasmonic acid induction in *A. barjoniifolia*.

Separating the Effects of Different Defense Components

Latex and cardenolides have detrimental effects on the growth rate of first-instar monarch larvae (Zalucki et al. 2001a, b; Agrawal 2005). Our results confirm this observation as we found that larvae fed on cut leaves perform better than larvae fed on cut leaves painted with digitoxin, or on intact plants. Based on field observations of naturally laid eggs, Zalucki et al. (1990) showed that survival in the first instars was weakly negatively correlated with plant cardenolide concentration in *A. humistrata*. Zalucki and Brower (1992) subsequently confirmed this observation experimentally and suggested that some of the high mortality in instars might be related to the cardenolide concentration in latex, or to the latex itself. This was confirmed by manipulative experiments in the field. By notching the basal side of the mid-vein of a leaf, Zalucki et al. (2001a) reduced latex flow and increased monarch larval growth rate. In our experiment, by removing the leaf from the plant, we similarly reduced latex exudation, thus also favoring larval growth. Here, however, we cannot completely exclude alterative explanations for the reduced resistance, such as the lack of responses that involves changes in systemic resource allocation.

Various levels of several cardenolides are found in latex and all other parts of the plant (Malcolm 1991), Fig. 2). Malcolm (1991) suggested that different types of cardenolides, having different polarities, are absorbed at different rates from the insect gut (Frick and Wink 1995). We compared the impacts of two cardenolides with different polarities. Larvae feeding on cut leaves painted with digitoxin (less polar) grew more poorly then larvae growing on leaves painted with ouabain (more polar). Although our conclusions regarding cardenolide toxicity to monarchs based on digitoxin and ouabain are tentative (digitoxin is only found in *Digitalis* sp.), our results are consistent with the prediction that non-polar compounds are more readily absorbed than polar ones (Wright 1960; Duffey and Scudder 1974; Malcolm 1991). The species studied here have cardenolides that may have polarities similar to digitoxin, based on elution time on reversed phase HPLC. *Asclepias barjoniifolia* also had some cardenolides that may have been more polar (Fig. 2).

In summary, although it is convenient to consider plant defense as a single trait, plants typically utilize a broad arsenal of defensive traits against herbivores (Duffey and Stout 1996; Romeo et al. 1996). Even when a plant species apparently is defended by a single type or class of defense chemical (like latex or cardenolides in our case), typically there are many specific forms of those compounds (Berenbaum et al. 1986; Malcolm 1991; Bennett and

Wallsgrove 1994). Thus, it is more useful to think about plant defense as a suite of traits, which might include aspects of a plant's nutritional quality, physical characteristics, toxicity, phenology, regrowth capacity, and indirect defense (Agrawal and Fishbein 2006). Synergistic interactions between multiple traits are particularly important in providing a greater level of defense than would be possible if the traits were present independently (Broadway et al. 1986; Berenbaum et al. 1991; Rasmann and Agrawal 2009).

By studying closely related species, we have taken account of similarities due to shared ancestry, and have attempted to identify important differences in defensive features (Agrawal and Fishbein 2006). Interestingly, our closely related species were substantially different in defensive traits, suggesting that they may have evolved under dramatically different habitats and herbivory regimes. An additional dimension to the plant defense syndrome hypothesis would be to incorporate induction and repression of defensive traits following herbivore attack. We found that *A. angustifolia* is nearly defenseless, so we suggest that for this species induction would not be helpful because herbivores generally have high performance on this species. On the contrary, *A. barjoniifolia* is extremely toxic and induced responses seem to be redundant, not providing additional protection. Finally, *A. fascicularis* had intermediate traits, with inducible latex, which in coordination with the other components of the defensive system, promoted reduced larval growth.

Acknowledgments We thank Amy Hastings for laboratory assistance, Rayko Halitschke for help with chemical analysis, Jennifer Thaler for providing jasmonic acid, Susan Cook, Rayko Halitschke and Mike Stastny for comments on the manuscript, and Steve Malcolm for providing seeds of *A. barjoniifolia*. Chemical analyses were conducted in the Cornell Chemical Ecology Core Facility, with support from Paul Feeny, New Life Sciences Initiative, College of Agriculture and Life Sciences, Center for a Sustainable Future, Boyce Thompson Institute, and Departments of Ecology & Evolutionary Biology, Neurobiology & Behavior, Entomology, Plant Biology, and Horticulture. Our research was supported by NSF-DEB 0447550 to AAA, and postdoctoral fellowship from Swiss National Science Foundation PA0033-121483 to SR.

pollinators and seed dispersers (Dudareva et al. 2004). Herbivore-induced plant volatiles (HIPVs) currently are the most intensively studied VOCs in the field of chemical ecology. A wide range of plant species has been shown to emit new VOCs or increased amounts of constitutive VOCs following herbivore damage (Dicke et al. 2003; Unsicker et al. 2009). Nevertheless, whether or not these volatiles are a result of co-evolutionary processes among plants, herbivores, and their natural enemies remains unclear (Holopainen 2004). This is because most studies have been performed on agriculturally important plant species under greenhouse or laboratory conditions, thus making it difficult to derive direct conclusions on the evolutionary role of HIPVs (Arimura et al. 2005). Although greenhouse and laboratory studies provide useful information on individual interactions among plants, herbivores, and natural enemies, they often fail to include various biotic and abiotic stresses that influence volatile production under natural conditions. Plants in the field often are attacked by multiple insect herbivores and diseases at the same time, in contrast to the situation in the laboratory where plant damage is carefully controlled and usually restricted to one attacking species. Abiotic stresses, such as high light and drought also have been shown to influence plant VOC production although these are rarely studied in the laboratory (Gouinguene and Turlings 2002; Blanch et al. 2007). There are only a few studies that report the volatile bouquets for the vegetative parts of naturally growing plants, for instance those on *Nicotiana attenuata* (Kessler and Baldwin 2001), wild lima bean (Heil 2004), or *Solidago altissima* (Tooker et al. 2008).

In the present study, we investigated HIPV emission from the legume *Trifolium pratense* L. (red clover), under both laboratory and field conditions. Red clover is a common forb in many Central European and North American grassland ecosystems. Although it is cultivated as a forage crop and used to increase soil nitrogen in many parts of the world, it remains a common species of natural meadow plant communities (Hoghjensen and Schjoerring 1994; Andrews et al. 2007). The nitrogen-fixing function of nodules found on red clover plays a key role in natural grassland ecosystems where other plant species growing near such legumes benefit from the nitrogen released from root exudates or upon plant death (Spehn et al. 2002; Temperton et al. 2007). Considered one of the key species in grassland ecosystems, red clover provides a useful basis for looking at multiple ecological roles of HIPVs since it is attacked by various herbivores. In cultivated stands, the root borer *Hylastinus obscurus* (Marsham) and the clover root weevil (*Sitona lepidus* Gyllenhal) both have been reported to cause extensive damage in pastures (Tapia et al. 2005; Murray et al. 2007). In natural grasslands, the level of damage on *T. pratense* was reported to be affected by multiple factors including plant community biomass, plant species richness, and plant species composition (Scherber et al. 2006; Unsicker et al. 2006).

Early studies on the induced defenses of *T. pratense* focused on defense against pathogens. Several authors showed that *T. pratense* produces various secondary metabolites such as pterocarpanoid phytoalexins and amides in response to fungi (Macfoy and Smith 1979; Mcmurchy and Higgins 1984). Jasmonic acid (JA) was shown to induce the production of caffeoyl DOPA (clovamide) in the roots but not in the shoots of *T. pratense* (Tebayashi et al. 2000). Later studies focused on the attraction of root herbivores to root volatiles in *T. pratense* from root extracts (Tapia et al. 2007). Other research on the volatile organic compounds of *T. pratense* has used dried or fresh leaf extracts to determine the quality of the hay produced (Figueiredo et al. 2007).

In the present study, we investigated: 1) the VOCs emitted by *T. pratense* under laboratory conditions after caterpillar herbivory and mechanical wounding; 2) the effects of temperature and sampling duration on VOC composition in the laboratory; and 3) the emission of herbivore-induced volatiles under field conditions.

Methods and Materials

VOC Production of *T. pratense* Under Laboratory Conditions

Plants and Insects Ramets of *T. pratense* were transplanted from the field in April 2007 when plants were still small (<10 cm in height). Plants were trimmed back to 3 cm, potted in 16 cm pots with a mixture of compost soil and sand (2:1), and allowed to grow under greenhouse conditions (day:night temperatures of 22–25°C: 18–20°C, 16/8 h L/D cycle, photosynthetically active radiation ca. 180 µmol m^{-2} s^{-1}, and 30–55% relative humidity). Measurements of volatiles were performed as soon as plants reached an average height of 15 cm (14 days after they were trimmed).

Caterpillars of Spodoptera littoralis Boisd (Lepidoptera: Noctuidae), a generalist leaf-chewing herbivore, were hatched from eggs obtained from Syngenta (Basel, Switzerland) and reared on agar-based artificial media (Fontana et al. 2009) at 23–25°C with a 16/8 h L/D cycle until they reached the 3rd instar.

Herbivory and Temperature Manipulations To determine the effect of herbivory on *T. pratense,* we compared volatile emissions of plants damaged by *S. littoralis* to emissions of control plants and plants subjected to mechanical damage. In total, there were 6 treatments: mechanical wounding, herbivore feeding (4 treatments) and a control. Control

plants were undamaged and not exposed to leaf herbivores prior to the experiment. Mechanical wounding was induced 15 min before the start of volatile collection using a commercially available fabric pattern wheel (McCloud and Baldwin 1997). Four tracks were made on the leaf lamina parallel to the mid-rib on 4–6 leaves of the plant depending on its size. For the feeding treatments, plants were exposed to three *S. littoralis* larvae previously starved for 8 h for a period of: a) 30 min; b) 2 h; c) 8 h; and d) 24 h before the start of volatile collection. The larvae were removed from the plants at the end of each feeding treatment immediately before volatiles were collected.

The effects of temperature on VOC emission were tested by performing experiments at both 20°C and at 30°C. We used three replicates for each temperature-herbivory treatment combinations so that 36 plants were measured in total (6 treatments x 2 temperatures x 3 replicates)

We also were interested in determining the effect of sampling time on volatile detection. Consequently, for each temperature-herbivory treatment combination, three measurements were performed: 15 min, 30 min, and 4 h. These sampling time tests were carried out consecutively; entrainment vials were opened at each time point to change the traps. This gave a total of 3 pseudo-replicates per temperature-herbivory combination.

Volatile Collection in the Laboratory VOCs were collected using a dynamic headspace sampling system that was installed in a climate chamber under controlled conditions (70% relative humidity and 150 μmol m^{-2} s^{-1} PAR) as described previously (Chen et al. 2003). The plants were placed inside 3 l glass desiccators (Schott, Jena, Germany). Each desiccator was closed tightly with a glass lid and equipped with a valve through which charcoal-purified air entered the system at 4 l min^{-1}. Volatiles were collected from the plants by passing the outlet air through a super-Q filter (containing 50 mg Super-Q absorbent) (Analytical Research Systems, Gainesville, FL, USA) at a rate of 2 l min^{-1}; the excess was released through vents at the top of the glass jars. VOCs from 6 *T. pratense* plants were collected simultaneously in the volatile collection chamber. Replicates were made on different days but at the same time of day, from 0900 to 1500 h. After each collection, the volatiles were eluted from the traps with 150 µl hexane and 10 µl of an internal standard (n-nonylacetate; Sigma-Aldrich, Seelze, Germany) at a concentration of 4 ng μl^{-1}. At the end of each VOC collection, the leaves per plant were counted and percent herbivory was estimated.

Volatile Analysis Sample analysis was conducted using an Agilent 6890 Series gas chromatograph, with helium as the carrier gas; the outlet of the column (DB-5MS 30 m× 0.25 mm×0.25 µm film) was coupled to a mass spectrometer (Agilent 5973 N quadrupole detector). Parameters for electron impact sample ionization were as follows: interface temperature, 280°C; repeller, 30 V; emission, 34.6µA; electron energy, 70 eV; source temperature, 230°C. The gas chromatographic conditions were as follows: splitless injection at 220°C, initial oven temperature, 40°C for 3 min, increased at 5°C min^{-1} to 210°C followed by an increase of 60°C min^{-1} to 300°C and held for 2 min. To identify compounds, the mass spectra were compared with those in the commercially available mass spectra libraries NIST and Wiley. Individual compounds were quantified by calculating the peak area relative to the peak area for the internal standard. Reference factors were determined using a mixture of pure standards (where available, see Tables 1, 2 and 3). For statistical analysis, all volatile emissions were standardized to the amount of compounds released per leaf (ng $leaf^{-1}$ h^{-1}). Dry weight (DW) of leaves of *T. pratense* was in later experiments found to range between 0.01–0.04 g $leaf^{-1}$.

VOC Production of *T. pratense* Under Field Conditions

Design of Field Sampling Field measurements were carried out in plots of "The Jena Experiment" (a long term grassland biodiversity experiment established in 2002 in Jena, Germany; for details, see Roscher et al. 2004). The plant communities were established from seeds in 2002 from a pool of nine plant species (the so-called dominance experiment, Roscher et al. 2004): *Trifolium pratense*, *Trifolium repens*, *Anthriscus sylvestris*, *Geranium pratense*, *Alopecurus pratensis*, *Arrhenatherum elatius*, *Dactylis glomerata*, *Phleum pratense*, and *Poa trivialis*. Plant species composition has been maintained by weeding since the establishment of the plots in 2002. We randomly selected seven 3.5×3.5 m plots, all with three-species mixtures, in which to perform plant volatile measurements on the target species, *T. pratense*. Two *T. pratense* plants were selected from each plot, one with high levels of leaf herbivory (based on a visual estimate of leaf area loss due to chewing insects) and one with low levels of herbivory. VOCs from both plants were collected simultaneously, after which the plants were harvested and the leaf area consumed by herbivores was immediately assessed visually on five randomly selected leaves per plant to the nearest 5% for each leaflet. The mean percent damage value of the 5 leaves was used as the percent damage of the plant for further analysis. Finally, leaf dry weight was determined after plants were dried for 48 h at 70°C.

Volatile Collection and Analysis The volatile collection consisted of a push-pull system (Tholl et al. 2006). Plants in the field were enclosed in a 30×50 cm polyethylene terephthalate (PET) cooking bag (Toppits® Bratschlauch,

Table 1 Volatile emission from *Trifolium pratense* in the laboratory experiment (mean ± SE amount, ng leaf^{-1} h^{-1}) emitted after 4 hours of sampling at *20°C*

Melitta, Minden, Germany) which is free of detectable amounts of volatiles (Kost and Heil 2005). The bags enclosed 4 stems of the target plant and were supported by a stainless steel rod on their outsides (Fig. 1). Compressed air (compressor: Schneider Druckluft GmbH, Reutlingen, Germany) entered the system after passing through an activated charcoal filter on the lower side of the plant and was pulled out at the top through an adsorbent super-Q filter by using a vacuum pump (Thomas Products, Memmingen, Germany) at the rate of 1.6±0.5 l min^{-1} for 30 min (Fig. 1). Before the initiation of volatile sampling, charcoal-filtered clean air was flushed though the collection system for 15 min; this was found to be sufficient in preliminary experiments to remove volatiles resulting from plant handling during the set-up of the enclosure. Umbrellas were employed to provide shade in order to moderate the temperature inside the bags on sunny days. Collections were made at the same time of day starting at 0900 h and continuing to 1500 h.

Throughout the volatile collection, temperature was measured inside each bag with temperature sensors; mean temperatures ranged from 20°C to 30°C. Radiation and temperature data also were recorded daily at the weather station at the "Jena Experiment" every 10 min. All temperature and light sensors were obtained from Campbell Scientific (Bremen, Germany).

To estimate the light reduction by the umbrellas, light under the umbrella was measured using a solar meter after the VOC sampling had been completed. Measurements were made continuously from 0900 to 1500 h for 3 consecutive days. The levels of radiation under the umbrella during the actual VOC sampling then were extrapolated by plotting a regression of measurements made under the umbrella to the weather station measurements on these 3 d. The equation

was: radiation under umbrella = 130.04+0.045 * radiation at weather station. For all analyses, the mean temperature and radiation during each collection interval was used.

Statistical Analysis

Emission data were log-transformed and analyzed using repeated measures analysis of variance with the open source software R 2.8.1 (http://www.r-project.org/; Crawley 2007). First, the interaction effects of herbivory treatments with temperature and sampling time were tested as main effects with plant as the random effect. The models were simplified to obtain the simplest models with highest explanatory power. Comparisons between feeding treatments were done after model simplification using factor level reduction.

For field data, the effect of radiation, temperature and herbivory were analyzed using a linear regression analysis. The emission data (ng g^{-1} h^{-1}) were square root transformed because this provided the best normality of errors and constancy of variance (Crawley 2007). DMNT, limonene, and myrcene occurred only a few times and were therefore converted to binomial data and analyzed using a generalized linear model.

For comparisons between the field and the laboratory experiments, proportions (percentages of total amounts) of 10 plant volatiles found to occur in both field and laboratory experiments were used. For the laboratory collections, only data from the 30 min sampling time were used, as it was similar to the sampling duration in the field study. After a *t*-test was performed to compare the composition of laboratory and field blends, a principal

components analysis (PCA) was carried out to determine the correlations between low damage and high damage classes in the field and laboratory plants using CANOCO 4.5 (Ter Braak and Šmilauer 2002).

Results

VOC Emission by T. pratense Under Laboratory Conditions From headspace collections of *T. pratense* in the laboratory, 24 volatile compounds were identified by gas chromatography-mass spectrometry. The majority were terpenes: eight monoterpenes, four sequiterpenes and the homoterpene 4,8-dimethyl-1,3,7-nonatriene (DMNT). The remainder included eight aliphatic compounds and the aromatics, indole, methyl salicylate (MeSA) and benzyl alcohol (Tables 1, 2).

Effect of Herbivory Feeding by *S. littoralis* resulted in 2–30% damage on the experimental plants. This herbivory significantly increased both the total amount of volatiles released and the number of volatile compounds emitted (Tables 1, 2). A comparison across all treatments showed that herbivore feeding had a significant effect on emission of *(E)*-β-ocimene ($F_{5,30}$ = 9.09; P<0.01), *(Z)*-β-ocimene ($F_{5,30}$ = 4.52; P<0.01), DMNT ($F_{5,30}$ = 4.75; P<0.01), (*E,E*)-α-farnesene ($F_{5,30}$ = 4.00; P<0.01), (*E*)-β-caryophyllene ($F_{5,30}$ = 2.00; P<0.05), linalool ($F_{5,30}$ = 3.07; P<0.05) and MeSA ($F_{5,30}$ = 2.72; P<0.05) (Tables 1, 2). These seven compounds can, therefore, be considered herbivore-induced plant volatiles (HIPVs). There was no significant difference in emissions between mechanical wounding and control treatments for the six HIPVs based on factor level reduction (Tables 1, 2). The 30 min feeding treatment showed an increased emission in total volatiles from the control, but this increase was significantly different for only two specific compounds, (*E*)-β-caryophyllene and *(E)*-β-ocimene (P<0.05, Tables 1, 2). Plants exposed to 8 h and 24 h feeding emitted the highest amount of *(Z)*-β-ocimene, *(E)*-β-ocimene, and DMNT with no significant difference between the two feeding times. However, for (*E,E*)-α-farnesene, emission peaked at 8 h and then was lower after 24 h of feeding (Tables 1, 2). For the compounds *(Z)*-β-ocimene, MeSA and (*E*)-β-caryophyllene, the 2, 8, and 24 h feeding treatments did not differ significantly in emission (Tables 1, 2).

Effect of Temperature and Sampling Time Across all treatments, temperature had the strongest effect on emission of limonene ($F_{1,34}$ = 8.30; P<0.01). The amount of limonene emitted at 30°C was higher than that emitted at 20°C (P< 0.01, Fig. 2). Among the herbivore-induced volatiles, only (*E,E*)-α-farnesene emissions increased when temperature increased ($F_{1,24}$ = 5.93; P<0.05). There was an interaction between feeding treatment, temperature, and sampling time on the emission of (*E,E*)-α-farnesene ($F_{10,48}$ = 4.72; P< 0.01). Emission was higher after the 8 h feeding at 30°C and 4 h of sampling than after other treatments (P<0.01; Tables 1, 2).

Sampling time had an effect on the amounts of the terpenes α-pinene ($F_{2,70}$ = 4.75; P<0.05), β-pinene ($F_{9,70}$ = 9.33; P<0.01), 1,8-cineole ($F_{9,70}$ = 3.53; P<0.05), and (*Z*)-

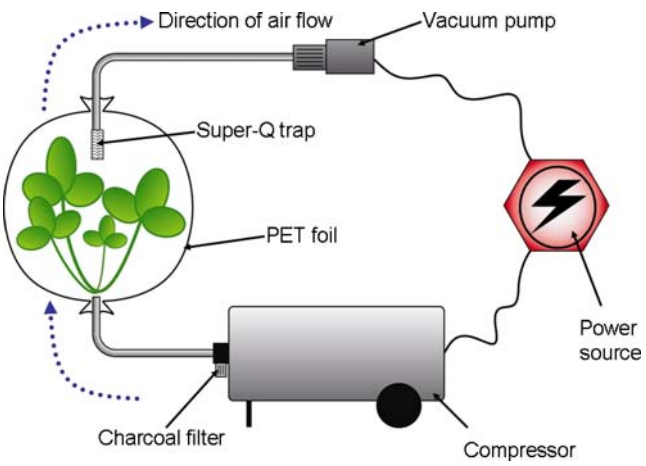

Fig. 1 Diagram of the VOC sampling system used in field collections

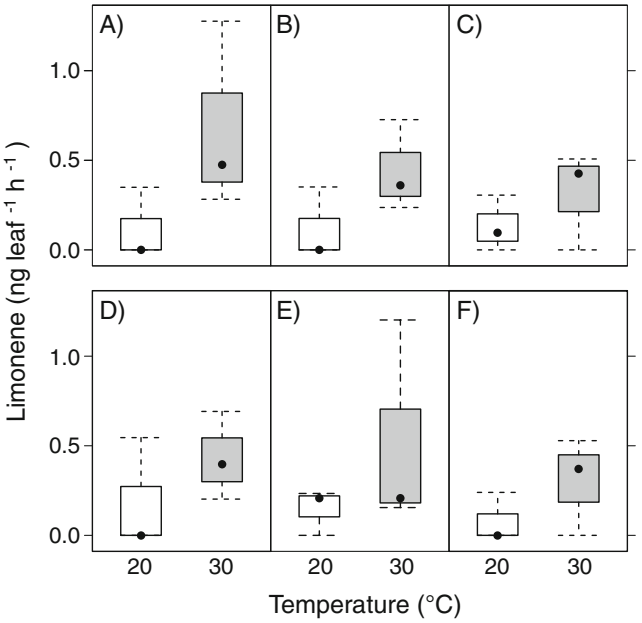

Fig. 2 Effect of temperature on the amount (ng leaf^{-1} h^{-1}) of limonene emitted from *Trifolium pratense* in the laboratory experiment. Panels show different treatments: (**A**) control, (**B**) mechanical wounding, (**C**) 30 min feeding, (**D**) 2 h feeding, (**E**) 8 h feeding, and (F) 24 h feeding. Dots in the boxes are the median values, while the bottom and top of the box show 25th and 75th percentiles respectively. Dashed vertical lines show either the maximum value or 1.5 times the interquartile range of the data (whichever is smaller). Open boxes depict data for 20°C and shaded boxes for 30°C

jasmone ($F_{9,70}$ = 8.35; P<0.01). These compounds were detected only after 4 h collection. Sampling time also had an interaction effect with feeding treatment on the emission of 1-octen-3-ol ($F_{10,60}$ = 2.08; P<0.05) where the effect of herbivory was detected after 4 h, but not after the 15 and 30 min sampling times. Thus, 1-octen-3-ol can also be regarded as an HIPV bringing the total number of such compounds in this study to eight.

The amounts of benzyl alcohol ($F_{2,70}$ = 3.00; P<0.05), (*Z*)-3-hexenyl acetate ($F_{2,70}$ = 47.4; P<0.01), decanal ($F_{2,70}$ = 4.75; P<0.05), dodecane ($F_{2,70}$ = 3.7; P<0.02) and undecane ($F_{2,68}$ = 86.95; P<0.01) all significantly decreased with increase in sampling time, while indole and octylaldehyde did not show variation with sampling time.

VOC Emission of T. pratense Under Field Conditions Under field conditions, eleven compounds were identified (Table 3), all of which were also detected in the laboratory. Levels of invertebrate herbivory measured as % leaf area loss ranged from 3–15%. Five compounds showed a significant response to herbivory in a multiple regression. The emission of α-pinene (T=4.06, P<0.01), *(Z)*-β-ocimene (T=5.21, P<0.01), *(E)*-β-ocimene (T=4.63, P<0.01), and nonanal (T=2.86, P<0.05) declined with increased herbivory (Table 3), while decanal increased (T=2.3, P=0.04), and undecane and dodecane were not significantly influenced by herbivory. The compound DMNT also was negatively correlated with herbivory but the correlation was not significant (T=2.1, P=0.6) There was no effect of herbivory on the emission of limonene and myrcene (T=1.9, P=0.2; T=1.6, P=0.2).

Effect of Temperature and Radiation Both radiation and temperature had significant effects on volatile emission in the field. An increase in radiation was negatively correlated with the emission of *(E)*-β-ocimene and nonanal (Fig. 3A, C), while α-pinene and decanal emissions appeared to increase with radiation,. although this increase was not significant (Fig. 3B, D). Similarly, undecane and dodecane emission were not significantly influenced by radiation (results not shown). Elevated temperature enhanced the emission of (*Z*)-3-hexenyl acetate (T=3.79, P<0.01), α-pinene (T=3.15, p=0.02), *(E)*-β-ocimene (T=3.05, P<0.05), and *(Z)*-β-ocimene (T=2.78, P<0.05). There were interactions between temperature and herbivory for *(E)*-β-ocimene (T=2.15, P<0.05) and between radiation and herbivory for α-pinene (T=4.06, P<0.05). *(E)*-β-Ocimene declined with an increase in herbivory at high temperature, while α-pinene emission decreased with herbivory at low radiation.

Comparison of Laboratory and Field Experiments Comparing field and laboratory data, herbivore-induced compounds usually were detected in lower relative amounts (% total compounds) in the field compared to the laboratory. The relative amounts of (Z)-β-ocimene and (E)-β-ocimene and limonene were lower in the field (T = −2.9, P=0.01; T = −3.374, P<0.01, and T = −3.45, P<0.01, respectively), while the amounts of α-pinene, decanal, and undecane were higher (T=3.35, P<0.01; T=2.09, P=0.05, and T=4.94, P<0.01, respectively). DMNT, nonanal, and (Z)-3-hexenyl acetate did not vary significantly in relative amount between field and laboratory conditions.

Principal components analysis of the relative amounts of volatiles emitted showed that the first axis (Principal factor 1) explained 60% of the variation in both field and laboratory experiments. The herbivore induced compounds, *(Z)*-β-ocimene and *(E)*-β-ocimene, were positively correlated with this axis, while decanal and undecane were negatively correlated with this axis (Fig. 4). In the laboratory, the more heavily damaged plants (>10% leaf damage) were positively correlated with herbivore-induced compounds (Fig. 4A), while in the field experiment, the less damaged plants (<10% leaf damage) were positively correlated with herbivore-induced compounds (Fig. 4B).

For (*E*)-β-ocimene, the dominant herbivore-induced compound in *T. pratense,* the proportion as a percentage of the total volatile blend generally increased with amount

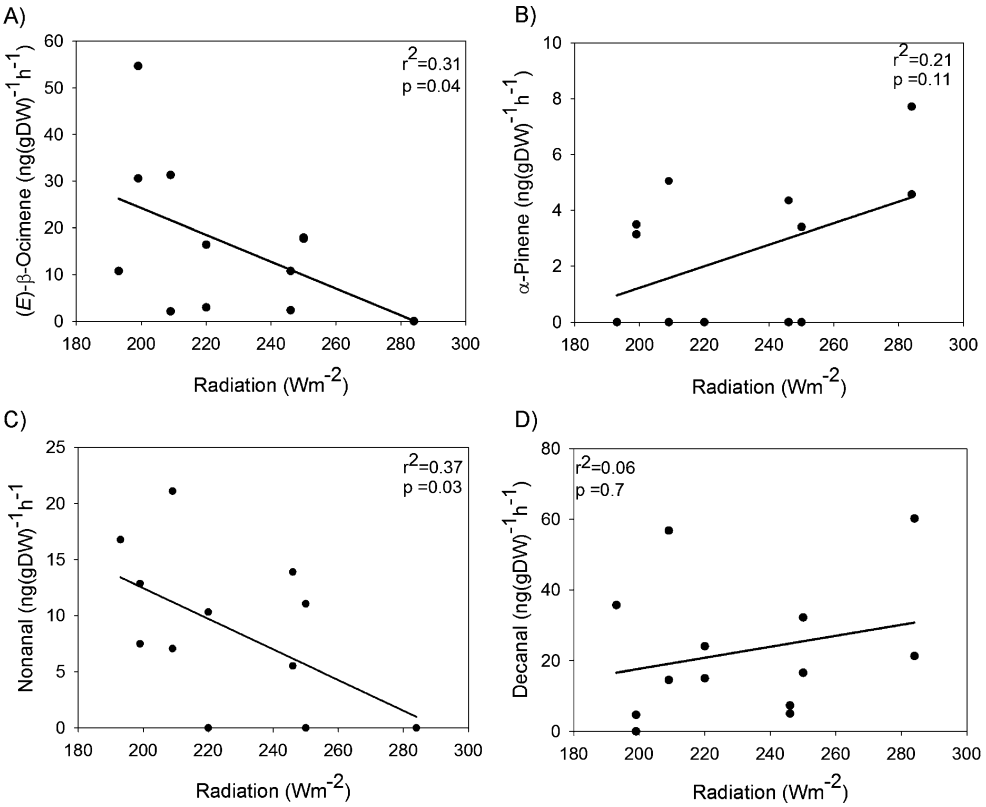

Fig. 3 Dependence of volatile emissions (ng (g DW)$^{-1}$h^{-1}) from *Trifolium pretense* on radiation measured in the field experiment. (**A**) (*E*)-β-ocimene (**B**) α-pinene, (**C**) nonanal, and (**D**) decanal

of damage under laboratory conditions (Fig. 5A), while in the field, intermediate levels of damage were associated with the greatest proportion of (*E*)-β-ocimene (Fig. 5B). To try and resolve this apparent contradiction, we reanalyzed the field emission data by removing the effects of radiation. (*E*)-β-Ocimene continued to show a decline with increased herbivory (Fig. 6A). Similarly, the emission of nonanal decreased with herbivory (Fig. 6C). However, amounts of α-pinene showed no trend in this regard (Fig. 6B), while the amounts of decanal increased with herbivory (Fig. 6D).

Discussion

Trifolium pratense is cultivated as forage and is found growing wild in a variety of grassland and ruderal habitats. Here, we report on the volatile compounds emitted by *T. pratense* growing under laboratory and field conditions. In the laboratory, feeding by the generalist lepidopteran *Spodoptera littoralis* significantly increased the amount of volatile organic compounds (VOCs) released, while elevated temperature did not significantly influence total emission. The release of eight individual compounds was herbivore-induced, of which the major compound, the monoterpene (*E*)-β-ocimene, made up 30–50% of the total. The other principal herbivore-induced plant volatiles (HIPVs) of this species were the isomeric monoterpene, (*Z*)-β-ocimene, the monoterpene linalool, the sesquiterpene (*E*)-β-caryophyllene, the sesquiterpene-derived homoterpene 4,8-dimethyl-1,3,7-nonatriene (DMNT) and methyl salicylate. Only three of these HIPVs were detected in the field. Surprisingly, their emission did not increase in relation to an increase in naturally-occurring levels of invertebrate herbivory, but rather decreased. Temperature and radiation significantly influenced the emission of all volatiles in the field except the aliphatic hydrocarbons.

The VOCs of *T. pratense* also have been reported from other plant species. DMNT, for example, has been detected frequently as an HIPV from plant species, such as maize, cotton, and cabbage. Such widespread HIPVs are suggested to be useful in attracting generalist natural enemies of herbivores (Turlings et al. 1998; De Boer and Dicke 2004). However, the low abundance HIPV, 1-octen-3-ol, so far has been documented from only a few plant species, including *Phaseolus lanatus* (lima bean) *Medicago truncatula*, and *Lotus japonicus* (Arimura et al. 2000; Ozawa et al. 2000; Leitner et al. 2005), all of which belong to the family Fabaceae. Interestingly, high amounts of 1-octen-3-ol also have been reported from mushrooms where they have anti-feeding effects on slugs (Wood et al. 2001). This compound could serve as an anti-feedant in *T. pratense* and other Fabaceae, but not much is known on the direct defense properties of HIPVs (Unsicker et al. 2009).

Among the volatiles of *T. pratense* are some that have been reported as HIPVs in other species, but were not induced in *T. pratense*. Indole, for example, was measured

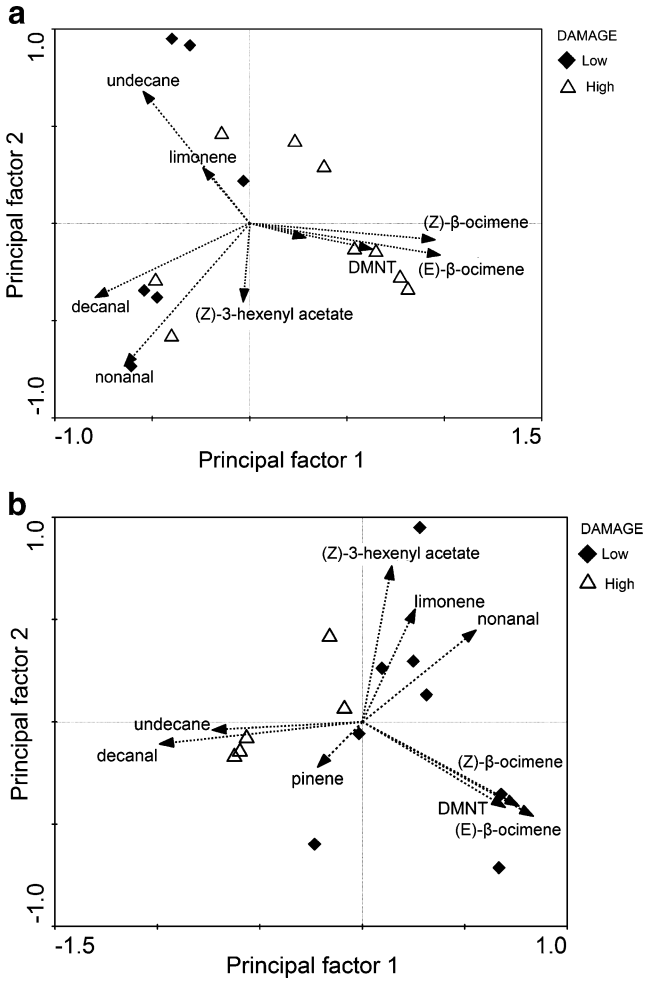

Fig. 4 Principal components analysis of the volatile emission of *Trifolium pratense* (**A**) in the laboratory experiment, and (**B**) in the field experiment based on the relative proportions of compounds in the headspace. Damage classes were allocated based on the percent damage to the leaf in both laboratory and field experiment. For the laboratory experiment, this ignored the effect of feeding duration. Damage was classified as high if it was more than 10%. Compounds are represented by arrows, each pointing in the direction of greatest increase. Smaller angles between arrows show higher correlation. Plant samples are indicated by symbols. Samples that cluster together are highly correlated, and samples and arrows that are in the same area are also correlated

only after herbivore attack in cotton and maize (Röse and Tumlinson 2004) but was constitutively emitted by *T. pratense*. (*Z*)-Jasmone also was not significantly induced in *T. pratense*, though it has been reported to be induced by feeding or by applying oral secretions in *Nicotiana attenuata*, maize, and cotton (Loughrin et al. 1994; Lou and Baldwin 2003; Röse and Tumlinson 2004). Another important feature of the HIPV composition of *T. pratense* is the dominance of (*E*)-β-ocimene (30–50%, Table 2). In other plant species, other HIPVs dominate the odor bouquet. For example, (*E*)-β-caryophyllene was the most dominant compound in several of the ecotypes of *Datura wrightii* in response to induction by methyl jasmonate or leaf beetle herbivory (Hare 2007), while *(Z)*-α-bergamotene was the main volatile compound in *Nicotiana attenuata* (Halitschke et al. 2000). Thus, volatile bouquets often are species specific. In the case of *T. pratense*, specificity may arise from the mixture of certain widespread volatiles, such as (*E*)-β-ocimene (*E*)-β-caryophyllene, DMNT, linalool, and MeSA with the Fabaceae-specific 1-octen-3-ol.

Herbivore-induced volatiles usually are reported to be first emitted 12–24 h after herbivory (Turlings et al. 1998; Heil 2008). However, a very rapid response to herbivory was exhibited by *T. pratense* in the laboratory where the HIPVs (*Z*)-β-ocimene, (*E*)-β- ocimene, DMNT, and MeSA were detected in the first 45 minutes after feeding was initiated (Table 2). This rapid release may be relevant to the proposed role of volatiles as within-plant or between-plant signals (Karban et al. 2000; Kessler et al. 2006; Heil and Silva Bueno 2007). To date, only green-leaf volatiles (GLVs) and MeSA have been shown to induce chemical defenses when applied to plants (Heil and Silva Bueno 2007; Park et al. 2007; Kost and Heil 2008), but the role of terpenes like *(E)*-β-ocimene needs further investigation in this regard (Gershenzon 2007). Besides the rapidly emitted compounds, *T. pratense* showed significant increases in the emission of some substances, including linalool, 1-octen-3-ol, (*E*)-β-caryophyllene, and (*E,E*)-α-farnesene, only after the plants were exposed to herbivory for more than 2 h. These compounds may be useful in attracting herbivore enemies, as has been shown for other species of plants, even though they are produced in relatively low amounts (less than 2 ng leaf^{-1} h^{-1}) (Table 2). Insects have been shown to detect relatively low amounts of VOCs, and higher emissions do not always correspond with increased response (Bruce et al. 2005).

There are only a few studies that directly compare herbivore-induced volatile production in the field and laboratory (Heil 2008; Dicke 2009). In our work, many compounds identified in the laboratory, such as indole, were not detected in the field. This discrepancy could be due to differences in growth conditions. Indole, for example, is often produced as a result of physiological stress (Dudareva et al. 2004). This compound may have been produced in the growth chamber used for the laboratory experiments, since many climate chambers are known to be oxygen-rich. Other compounds identified in laboratory collections, such as sabinene, 1,8-cineole, β-pinene, germacrene D, (*Z*)-jasmone (*E,E*)-α-farnesene, and (*E*)-β-farnesene, were not detected possibly due to the shorter collection time of 30 min used in the field. These compounds also were not detected under laboratory conditions within a 30 min collection. A short collection time was deemed necessary in the field to minimize physical stress on plants and to allow sampling of many plants.

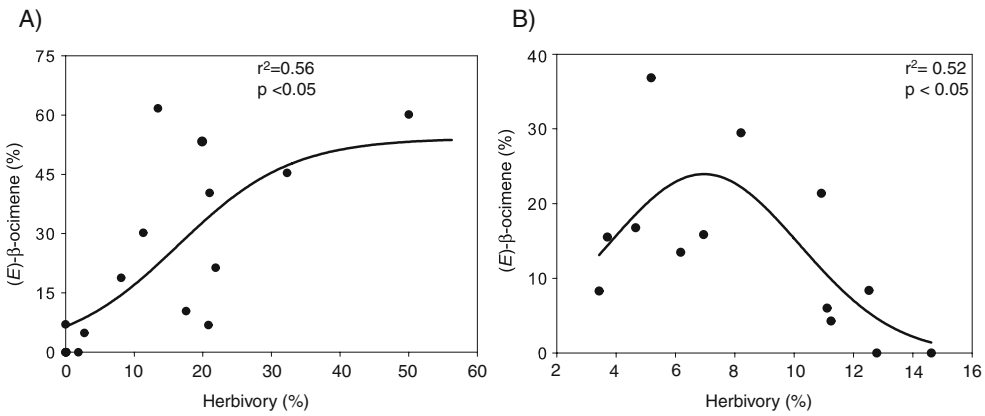

Fig. 5 Effect of herbivory on emission of (*E*)-β-ocimene (expressed as percentage of total blend) from *Trifolium pratense* under (**A**) laboratory and (**B**) field conditions

The differences in volatile composition observed between laboratory and field collections also might be attributed to differences in the apparatus used. Plants were enclosed in glass jars in the lab and in polyethylene terephthalate (PET) bags in the field. However, volatile recovery rates between glass vials and PET bags should not differ. Comparison of the recovery rates of VOCs from mixtures of standard compounds in glass vessels vs. PET bags showed no significant differences for limonene, linalool, MeSA, and (*E*)-β-caryophyllene (Stewart-Jones and Poppy 2006). Ambient air may contain ozone, which breaks down many volatile compounds Pinto et al. (2007). Contamination of the airflow in the PET bags was avoided by using over-pressure push-pull system (Fig. 1).

The main cause of differences between field and laboratory volatile collections thus is likely to be differences in the environmental conditions, such as light, atmospheric composition, and water supply that plants were growing under, although it is difficult to identify specific factors without further investigation. A similar reduction in the number of volatile compounds detected under field conditions compared to controlled laboratory

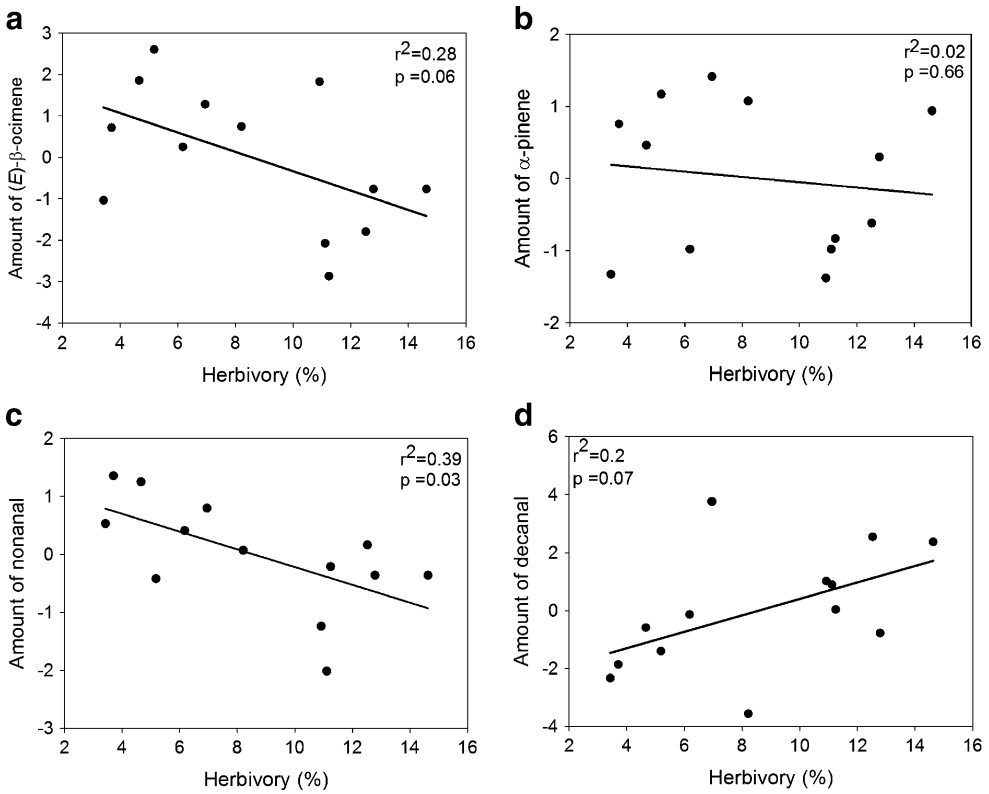

Fig. 6 Dependence of volatile emissions (ng (g DW)$^{-1}$h^{-1}) from *Trifolium pretense* on measured herbivory rates in the field experiment. (**A**) (*E*)-β-ocimene, (**B**) α-pinene, (**C**) nonanal, and (**D**) decanal after removing the effect of radiation. Amount of each compound is expressed as a residual

conditions also has been reported by Tooker et al. (2008) for *Solidago altissima*.

High levels of damage in the field were unexpectedly negatively correlated with herbivore-induced volatiles, unlike in the laboratory where damage led to an increase in volatile emission with eventual saturation (Table 3, Figs. 4 and 5). The plants selected for volatile collection in the field already had been damaged by herbivores at unknown time points prior to sampling, while in the laboratory induced volatile measurements were all performed within 24 h after herbivory was stopped. Laboratory measurements thus represent a snapshot taken right at the beginning of the time course of volatile emission following herbivory, while measurements in the field may have been made many days after herbivory.

The negative correlation of herbivory to volatile emission in the field (Fig. 4) also may be rationalized in several other ways. First, field plants that are attacked by herbivores may not allocate resources directly to defensive compounds, but to regrowth capabilities instead. *T. pratense* is a perennial plant that often behaves like a biennial with the ability to re-grow rapidly (Taylor and Quesenberry 1996). High herbivory may have induced a re-translocation of carbon and nitrogen to the roots in order to allow better re-growth in the later phases of development (Schwachtje and Baldwin 2008). Alternatively, resources that could have been invested in volatile formation instead may have been allocated to the formation of other chemical defenses. *T. pratense* has been shown to produce other secondary metabolites like clovamides in response to diseases or herbivory (Macfoy and Smith 1979; McMurchy and Higgins 1984; Tebayashi et al. 2000). Analysis of other induced defense compounds would provide more information on how this species responds in nature to herbivory.

Second, herbivory in the field may not be positively correlated to herbivory in the laboratory because of differences in the species of herbivore causing damage in the field as well as to the presence of pathogens. Different herbivores are known to induce different volatiles due to differences in elicitors present in their saliva (Turlings et al. 1993;Geervliet et al. 1997; De Moraes et al. 1998). For example, Geervliet et al. (1997) reported both qualitative and quantitative differences in the volatiles emitted by plants when fed on by two different caterpillar species. At the time of sampling in our study, the main observable herbivores on *T. pratense* were beetles and grasshoppers. Grasshoppers like the generalist species *Chorthippus parallelus* have also been shown to feed on *Trifolium pratense* in food choice experiments (Unsicker et al. 2008; Franzke et al. 2009). Grasshoppers contain different elicitors from *S. littoralis* (Alborn et al. 1997, 2007) that result in differences in the volatiles emitted by plants (Turlings et al. 1993). Since herbivory in the laboratory was induced with *S littoralis*, the differences in herbivores in the field may have caused the differences in quality and quantity of the volatile blend. In addition, beetle larvae, which have been reported to feed on *T. pratense* roots (Tapia et al. 2007), may have affected volatile emission. Thus it is possible that the plant measured may have had beetle larvae feeding on the roots. Such multiple agents of herbivory, plus pathogen infestations, which were also observed in the field, may have altered and even suppressed VOC production (Maddox and Root 1990; Tooker et al. 2008).

A third reason why herbivory in the field might have been associated with lower volatile emission is that a lower level of emission may have resulted in fewer visits from natural enemies and thus a higher rate of herbivory (Halitschke et al. 2000; Heil 2008). Finally, our experimental plants in the field grew together with other species (Appendix 1), which may have influenced volatiles, although it is still unclear how species composition of communities affects volatile emission. However, other induced defense compounds are affected by neighboring species mainly through competitive interactions (Van Dam and Baldwin 2001; Marak et al. 2003; Barton and Bowers 2006). For example, Barton and Bowers (2006) reported an increase in iridoid glycosides in the presence of competitors, and this increase was dependent on neighbor identity.

The influence of temperature and radiation on the emission of specific volatiles was consistent with trends previously reported in the literature with elevated temperature and radiation generally increasing emission (Gouinguene and Turlings 2002; Kuhn et al. 2002; Blanch et al. 2007). Monoterpenes are especially light and temperature sensitive (Guenther et al. 1993; Kesselmeier and Staudt 1999). In the laboratory experiment, limonene, and the herbivore-induced compound (*E,E*)-α-farnesene exhibited increased emission upon raising the temperature from 20°C to 30°C (Tables 1, 2, Fig 2). In the field, increased temperature was correlated with increased emission of (*Z*)-3-hexenyl acetate, and the terpenes, (*E*)-β-ocimene, (*Z*)-β-ocimene, and α-pinene, with the remainder of compounds showing no significant increases or decreases with temperature. Meanwhile, increased radiation in the field apparently correlated with increased α-pinene and decanal but was not statistically significant, (Fig. 3). Counter to these trends, is the unexpected decline in the emission of the principal volatiles, (*E*)-β-ocimene and nonanal with increased radiation. This may have been due to the use of umbrellas for field collection on the warmer, sunny days. The resulting lower radiation on such days would be associated with higher temperatures, with the net result being a positive correlation between lower radiation and higher emission.

In summary, our results emphasize the need for caution in extrapolating the volatile emission profiles observed in laboratory experiments to plants growing in the field. Many of the compounds measured in the laboratory were not

detected in the field, and many compounds observed to be induced by herbivory in the laboratory were not positively associated with herbivore damage in the field. The changes in light and temperature conditions between the lab and field could not account for these differences. Perhaps other abiotic factors not measured in this study were responsible for the variation, such as atmospheric gas composition, light quality, or water supply. Or, perhaps the combined influence of many biotic factors in the field, including multiple herbivores (both shoot and root), pathogens, and competing plants shape a vastly different emission profile. The damage observed in the field may have been too old to have an influence on volatile emission.

Future studies need to take into account biotic and abiotic factors that may influence emission in the field especially those, such as the presence of multiple herbivores and competing plants, which cannot be easily simulated in the laboratory. Such work preferably should manipulate herbivory directly on field-grown plants and use this as a basis to make comparisons with emission from plants with previously existing herbivore damage. More complete and accurate knowledge of the range of volatiles emitted from field plants is essential if we are to make progress in understanding the physiological and ecological functions of these compounds.

Acknowledgments We thank Daniel Veit who assisted in the design and construction of the field volatile collection system. Sylvia Creutzburg, Rebecca Wagner, Andreas Weber, and the gardeners of the MPICÖ assisted in various other aspects of this work. We also thank The Max Planck Society and the International Max Planck Research School for funding this project.

are implicated in a large number of physiological functions, such as plant pollination (Raguso 2008), attraction of seed dispersers (Borges et al. 2008), and defense against biotic and abiotic stresses (Pichersky and Gershenzon 2002; Vickers et al. 2009). VOCs may have a direct deterrent or cytotoxic effect against herbivores and pathogens (De Moraes et al. 2001; Pichersky and Gershenzon 2002; Heil 2004), or indirect effects through the attraction of herbivore enemies as predators or parasitoids (Turlings and Wäckers 2004; Heil 2008). The defensive function of VOCs has been studied intensively in some model plant species (Turlings and Wäckers 2004) but not much is known about importance in complex plant communities such as tropical forests.

Some compounds are common in both reproductive and vegetative plant tissues. In a review on floral scents, Knudsen et al. (2006) emphasized the importance of twelve compounds that occur in over 50% of the 90 plant families investigated. They highlighted six monoterpenes (D-limonene, (E)-β-ocimene, β-myrcene, linalool, α-pinene, β-pinene), one irregular terpene (6-methyl-5-hepten-2-one), four shikimic acid pathway by-products (benzaldehyde, methyl-2-hydroxybenzoate, benzyl alcohol, 2-phenyl ethanol), and one sesquiterpene (β-caryophyllene). Aside from their likely role in plant pollination, most of these have toxic or deterrent activity against microbes and herbivores (De Moraes et al. 2001; Mumm and Hilker 2006; Bakkali et al. 2008). It has been proposed that the widespread distribution of these compounds and their emission by both reproductive and vegetative parts of the plant reflect their importance in chemical defense (Knudsen et al. 2006). We expect that they also will be widespread among tropical tree species, as a response to high predation pressure.

Aside from the common compounds, one of the striking characteristics of plant volatile terpenes is their diversity and the large number of compounds in blends (Gershenzon and Dudareva 2007). The "screening hypothesis" proposes that the ability to produce a large array of defensive compounds increases the probability of possessing active compounds (Jones and Firn 1991; Firn and Jones 2003). A high chemical diversity should help increase the plant's protection against attacks from a wide range of enemies in changing environments (Agrawal and Fishbein 2006; Gershenzon and Dudareva 2007). Moreover, diverse compounds may act synergistically to provide greater toxicity or deterrence (Berenbaum and Neal 1985), or to maintain activity for a longer period of time (Akhtar and Isman 2003). Complex VOC blends also may be involved in making the information sent to parasitoids in tritrophic interactions species-specific (Gershenzon and Dudareva 2007). Thus, the diversity of VOCs in a species may be at least in part related to defensive roles. Studying patterns of VOC diversity and variability across species may shed light on their importance in long-lived species such as tropical trees.

Both the density and diversity of insects are higher in the tropics than in temperate zones (Novotny et al. 2006; Lewinsohn and Roslin 2008). This leads to higher predation pressure on tropical plants compared with their temperate counterparts (Janzen 1970; Coley and Aide 1991). Consequently, tropical plants may have enhanced defenses compared to temperate plants, including more diversity and variability in chemical defenses (Coley and Aide 1991). We postulated that many different VOCs would be released by tropical tree species, reflecting a diverse array of predatory pressure. Moreover, the use of VOCs in defense may not be uniform among species, and this should lead to mixtures of varying complexities.

We sampled the vegetative parts (bark and leaves) of a wide array of tropical plants in natural forests in French Guiana (South America), and identified the blend of constitutive VOCs released immediately in response to physical damage. We used this dataset to determine patterns of VOC diversity among tropical tree species with three objectives: (1) What is the relative frequency of VOCs across species? (2) Are mixtures of VOCs species specific? (3) Is the complexity of the mixtures variable across species?

Methods and Materials

Study Sites Field work was conducted at three sites of old-growth rainforest in French Guiana, namely the Paracou Research Station (5°18′N, 52°53′W), the Nouragues Research Station (4°05′N, 52°40′W), and Montagne Tortue (4°18′N, 52°22′W). Annual rainfall is 2,990 mm for Nouragues, 3,160 mm for Paracou, and ca. 3,500 mm for Montagne Tortue. We worked on five plots of one hectare each: two were at the Paracou site (N=643 and 487 trees), two at Nouragues (N=537 and 567 trees), and one at Montagne Tortue (N = 536 trees). In these plots, each tree with a diameter at breast height (dbh) greater than 10 cm was climbed by professional tree climbers (Baraloto et al. 2009) to collect leaves in order to create a voucher specimen for taxonomic determination. Over 98% of the trees were identified to species or morphospecies, and the species richness ranged from 148 to 210 species per hectare. Sampling was conducted in June 2007 for Paracou, September 2007 for Nouragues, and in November 2007 for Montagne Tortue.

Field Sampling We sampled species belonging to the most common tree families across sites and for which our plots had more than one individual per species. Overall, 2–6 individuals of the most common species were chosen,

depending on the individuals available, totaling 195 individuals from 55 species. Table 1 lists the sampled species and sampling size. Sampling a large number of species requires a rapid technique and appropriate storage for subsequent analysis (Wajs et al. 2006). For each tree, we cut about 20 mg of tissue from a young leaf. Young leaves were chosen because they are better chemically defended than older ones (McKey 1979). We also sampled a 1-cm^2 piece of bark at 1 m above ground, using a leather punch. Each sample was put immediately into a glass vial (10 ml) and sealed with a screw cap containing a Teflon-lined septum (Varian Instruments, Sunnyvale, CA, USA). In the field, sealed vials were maintained at −4°C in a portable freezer. Samples were transferred to the laboratory where they were stored at −20°C until analysis.

By using four taxa representative of our dataset (*Protium sp.* Burseraceae, *Inga sp.* Mimosaceae, *Guarea sp*. Meliaceae, *Spondias mombin* Anacardiaceae), we verified that the VOC composition as measured with our protocol was consistent with the blend released following mechanical damage of the tissue (either bark or leaves). For 3 individuals per species, we trapped VOCs directly in the field by sealing mechanically damaged tissue in a Teflon bag, and then introducing a Solid Phase Micro Extraction (SPME) fiber into the bag for 5 to 15 min (Bouvier-Brown et al. 2007). For the same tissue, we collected VOCs from frozen samples as described below.

Laboratory Analyses VOCs from the headspace of the samples were adsorbed onto SPME fibers, allowing analysis without solvent extraction (Lord and Pawliszyn 2000). Originally developed for the analysis of pollutants, this technique is suitable for detecting VOCs emitted by plants (Tholl et al. 2006; Mayer et al. 2008). We used fused silica fibers coated with PDMS/DVB (Polydimethylsiloxane/Divinylbenzene) 65 µm (Supelco, Bellefonte, PA, USA), since this coating is an effective trap for plant VOCs (Guo et al. 2006; Bouvier-Brown et al. 2007). Fibers were conditioned before the first use for 30 min at 250°C, following instructions from the manufacturer. Before extraction, the glass vials containing the tissue samples were maintained at room temperature for at least 1 h. The SPME fiber was placed into the vial with the tissue sample (bark or leaf) for 5 to 60 min at ambient temperature (25° C). The exposure time was optimized for each species to maximize the extraction without saturating the analytical column (Appendix 1). The fiber was inserted immediately into the 250°C inlet of a Varian 3800 Gas Chromatograph (GC) fitted with a Saturn 2000 ion-trap Mass Spectrometer (MS; Varian Instruments, Sunnyvale, CA, USA). The GC was run with a non-polar Varian DB-5 column (30 m× 0.25 mm ID, 0.25 µm film) commonly used for the analysis of VOCs (Tholl et al. 2006). Helium was the carrier gas at a constant flow of 1 ml/min. The oven temperature program of the GC started at 50°C, with 6°C/min temperature increase up to 140°C, and then with 4°C/min increments up to 160°C. This temperature was held for 1 min and increased finally to 200°C at 10°C/min. The MS was operated in electronimpact (EI) mode at 70 eV, with a scan range of 30–450 m/z. After each analysis, the fibers were cleaned in the injector port for 10 min at 250°C, and each fiber was reused no more than 100 times, as recommended by Tholl et al. (2006). Control analyses (blanks) were performed every ten analyses to check for contamination of the fiber.

Post-Processing of the GC-MS data Since the SPME technique does not ensure quantitative recovery, only presence/absence data are reported. VOC presence/absence was inferred by using a novel statistical approach (Nicole et al., unpublished). This procedure is both more efficient and more accurate than visual classification procedures for a large number of analyses. All routines were developed in the R statistical software (http://cran.r-project.org/). Here, we review briefly the major steps in the procedure.

A typical GC-MS output is represented by two components. The chromatogram displays the mixture as separated by the GC, and each peak corresponds to the elution of a distinct molecule, characterized by retention time. For each point on the GC chromatogram (N=1,500), a mass spectrum is obtained by fragmentation in the MS chamber. A mass spectrum is represented by a histogram displaying the intensity of each fragment (the mass-to-charge ratio, m/z).

The GC-MS output was saved into a raw text file by using the *GC and GCMS File Translator*™ (ChemSW, http://www.chemsw.com/12149.htm). Peaks were identified automatically in each chromatogram as a 3-point increase followed by a 3-point decrease around a peak intensity of at least 5 kcounts. Each detected peak in the course of the analysis was then defined by the mass spectrum that corresponded to the apex of the peak. The mass spectra corresponding to all peaks in all analysis were grouped into a single matrix in which each row represented the mass spectrum associated with a selected GC peak. A distance matrix was computed by using the pairwise Euclidian distance between any two spectra. An agglomerative clustering algorithm was used to cluster the spectra based on this distance matrix (Ward 1963), and the optimal number of clusters was inferred from a variance analysis (Rousseeuw 1987).

The Kováts Retention Index (RI, Kovats 1958) for each peak were defined as follows

$$RI(i) = 100 \times \left(\frac{\ln(RT(i)) - \ln(RT_{\inf}(i))}{\ln(RT_{\sup}(i)) - \ln(RT_{\inf}(i))} \right) + 100n$$

where $RT(i)$ is the retention time of the i^{th} peak (in minutes), $RT_{inf}(i)$ is the retention time of a reference n-alkane that eluted immediately before the i^{th} peak, and $RT_{sup}(i)$, the retention time of (n+1)-alkane that eluted immediately after the i^{th} peak. In the above equation, n is the number of carbon atoms in the n-alkane that eluted immediately before the i^{th} peak. Together with the mass spectrum, RI is used for the identification. The consistency of the clusters generated automatically was tested by computing the intra-cluster variance of RI. Ambiguous clusters were examined separately and found to correspond either to very similar compounds that can be distinguished with RI or to several co-eluted compounds. Clusters were identified based on comparison to authentic mass spectral standards or to the NIST 98 MS library, the ADAMS library, and to RI reported in the literature (ADAMS). Using these techniques we were able to assign 78% of the compounds as known molecular structures (Appendix 2). For unidentified molecules, we defined them as unknown molecules characterized by their mass spectra and their RI.

Validation of the Protocol We verified our methods by comparing the VOCs obtained from SPME fibers exposed to freshly harvested tissue in the field to those obtained with our lab techniques that used frozen tissue. The qualitative blend of VOCs was the same with the two methods for four different species tested (Fig. 1). During the period of analysis, we confirmed that storage of tissue samples at −20°C did not alter VOC composition by repeating the analyses on three samples at monthly intervals (data not shown). We concluded that the methods were an effective way to sample VOCs from the large number of samples collected in the field study.

Statistical Analyses For each individual tree, the VOC composition was defined as the composite of all compounds found in the leaves, in the bark or in both tissues. The resulting dataset was characterized by a presence/absence matrix, where each row represented the compounds found in an individual tree, and each column represented a single compound. We calculated the chemical richness (number of distinct compounds) for each individual, each species, and each plant order. The significance of differences in mean VOC diversity (the number of compounds)

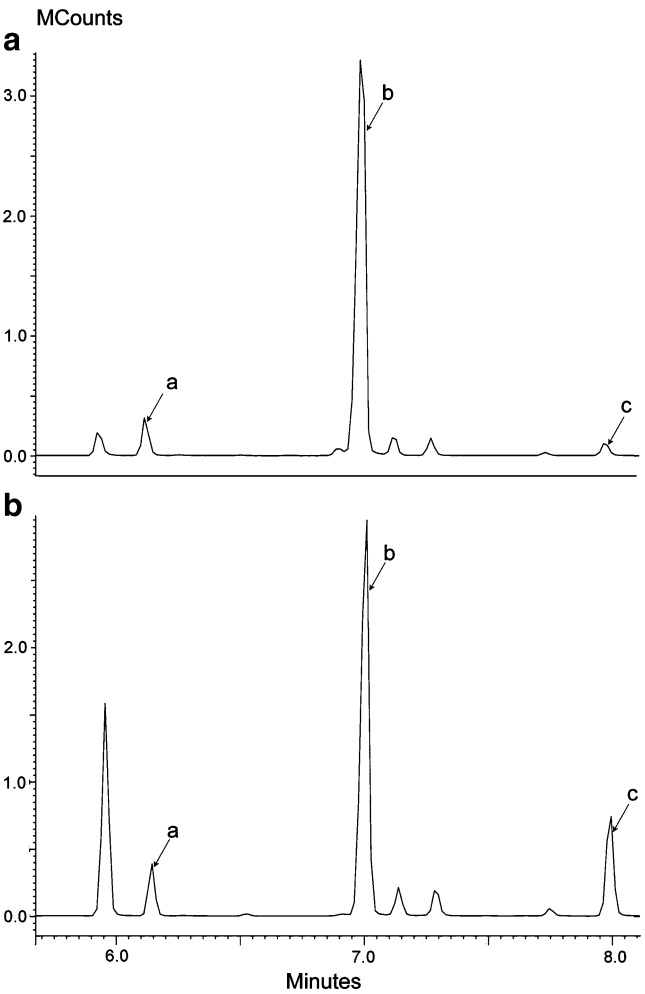

Fig. 1 Comparison of the composition in monoterpenes for the leaves of one individual of *Protium sp.*, for **a** extraction in the field and **b** extraction in glass vials from frozen samples. Similar results were obtained for the other species. Compounds shown are: **a** α-pinene, **b** sabinene, **c** γ-terpinene

among species and orders were tested with the non parametric *Kruskal-Wallis* test.

To assess whether our dataset could be used to discriminate among species, we constructed a matrix of chemical dissimilarity between pairs of individuals using the Manhattan distance $D_{x,y} = \sum_{i=1}^{N_m} |x_i - y_i|$, where x and y are two distinct individuals, and N_m is the total number of compounds in our dataset. We then constructed a hierarchical dendrogram with the Ward clustering algorithm (Ward 1963). Dendrogam node support was assessed based on approximately unbiased (AU) p-values computed from 10,000 bootstraps (pvclust package; Suzuki and Shimodaira 2006).

Results

A total of 264 compounds was found in the 55 sampled species. This included one nitrogen-containing compound, three compounds from the shikimic acid pathway, 34 compounds from the lipoxygenase pathway (or green leaf volatiles), 57 monoterpenes, and 169 sesquiterpenes. We were able to assign names to 206 of the 264 compounds (78%). The 58 unidentified compounds are mostly sesquiterpenes, and many of them may be previously unreported.

Four terpenes were released by over 90% of the species (Fig. 2): α-pinene (all species) and D-limonene (96% of the species) in the monoterpene group, and β-caryophyllene (94% of species) and α-copaene (92% of species) in the sesquiterpene group. About 23% of the compounds were present in the VOC blend of only a single species (Fig. 2).

For 43 of the 55 sampled species, the clustering analysis grouped all individuals of the same species in well-supported clusters (AU *P*-value greater than 0.80; Fig. 3). Above the species level, this clustering analysis did not show any pattern of chemical similarities within genera or families (Fig. 3). Similar results were obtained by considering only monoterpenes and sesquiterpenes.

The complexity of the VOC profile varied significantly both across all species and within each plant order

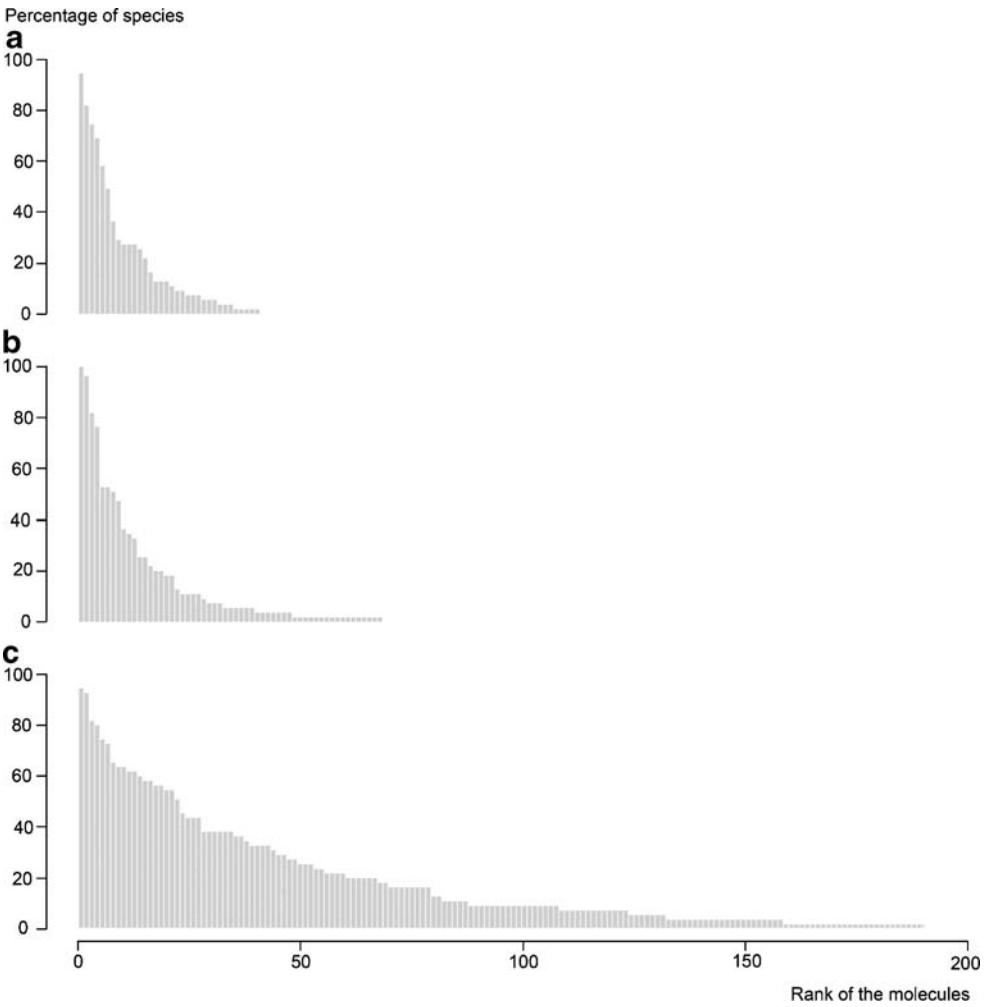

Fig. 2 Distribution of the VOCs isolated in the dataset with the percentage of species emitting each molecule for the three most common groups: **a** green leaf volatiles, **b** monoterpenes, and **c** sesquiterpenes

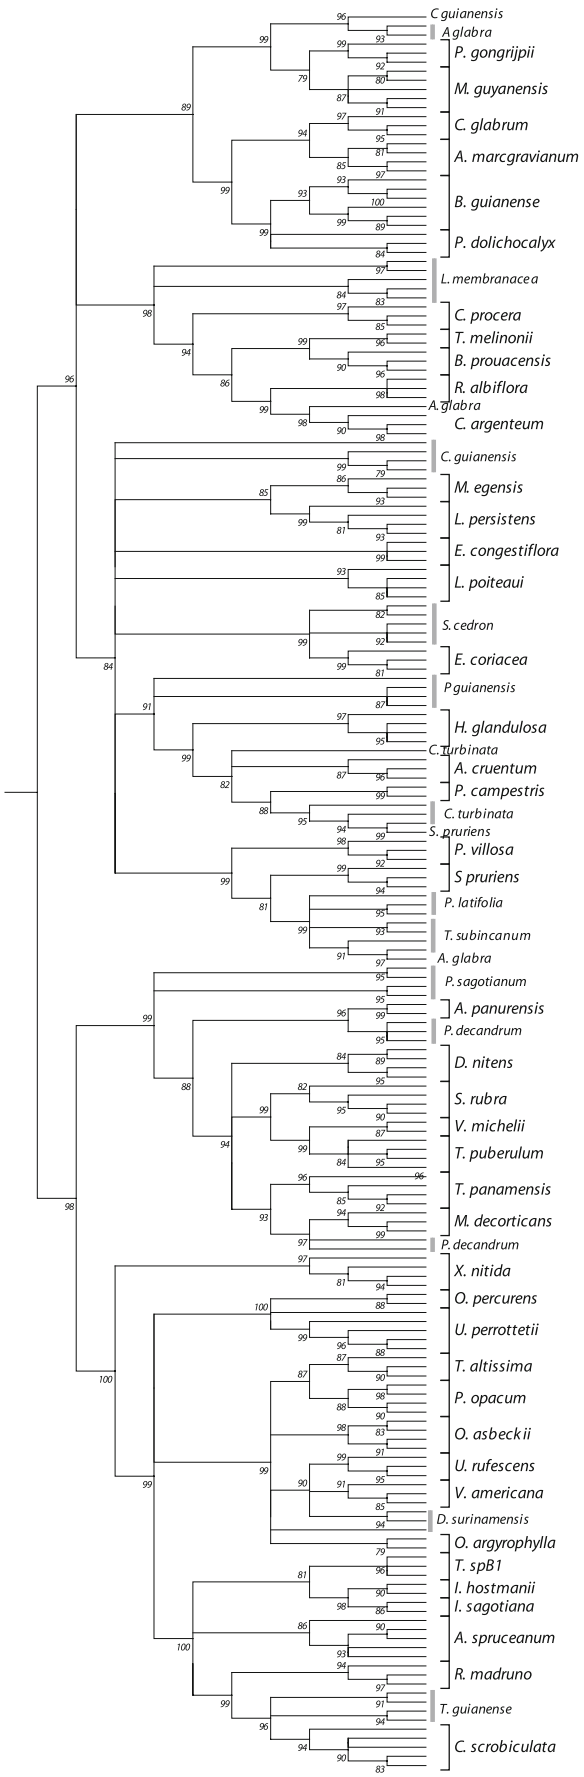

Fig. 3 Dendrogram displaying the dissimilarities in VOC composition among individuals, based on Ward clustering and Manhattan distance. Bootstrap support values greater than 80% on the nodes are reported on the tree. Species with names indicated in *grey* did not group into single clusters with a bootstrap value greater than 80%

(Kruskal-Wallis test, $P<0.001$). The mean number of VOCs per individual was 36.8 (Fig. 4). Chemical diversity was higher for species belonging to the Laurales, Sapindales, or Magnoliales (Fig. 4a), mean number of compounds per species in each order 43.8, 48.7, and 58.5, respectively). Two exceptions to this general trend were *Simaba cedron,* a member of the Simaroubaceae, and *Sextonia rubra*, in the Lauraceae. Both species had lower chemical diversity relative to other members of their families (Fig. 4a), mean number of compounds 17.4 and 33.5, respectively). Species belonging to the Ericales, Gentianales, and Malvales emitted less diverse mixtures of VOCs (21.3, 22.6, and 24.6, respectively). These differences were mainly due to differences in the number of sesquiterpenes (Fig. 4b).

Discussion

The most prevalent compounds that were identified in this study have defensive roles in model plant species, and they are among the most common compounds identified in floral scents (Knudsen et al. 2006). Within the monoterpenes, both α-pinene and limonene are toxic to fungi, bacteria, and insects (Miresmailli et al. 2006; Bakkali et al. 2008). These two compounds are known to be emitted in large quantities by tropical trees, as atmospheric chemists have previously detected them in high concentration in the atmosphere above Amazonian forests (Greenberg et al. 2004). Here, we demonstrated that a large array of species emit them. The other monoterpenes ((E)-β-ocimene, β-myrcene, linalool, β-pinene) and the irregular terpene (6-methyl-5-hepten-2-one), common in floral scents, are also found in vegetative emissions (Appendix 1). The sesquiterpenes caryophyllene and α-copaene have been implicated in direct and indirect responses against herbivores and pathogens (Heil 2004; Gols et al. 2008; Köllner et al. 2008), and they were distributed widely in the studied tree species.

The blend of VOCs is largely species-specific, as most species formed single clusters based on their VOC profiles. Taxa above the species level (genus, family, or order) usually were not characterized by a distinct profile. This result is in agreement with the pattern observed in floral scents where VOCs are consistent within a species but usually differ among closely related ones (Knudsen et al. 2006).

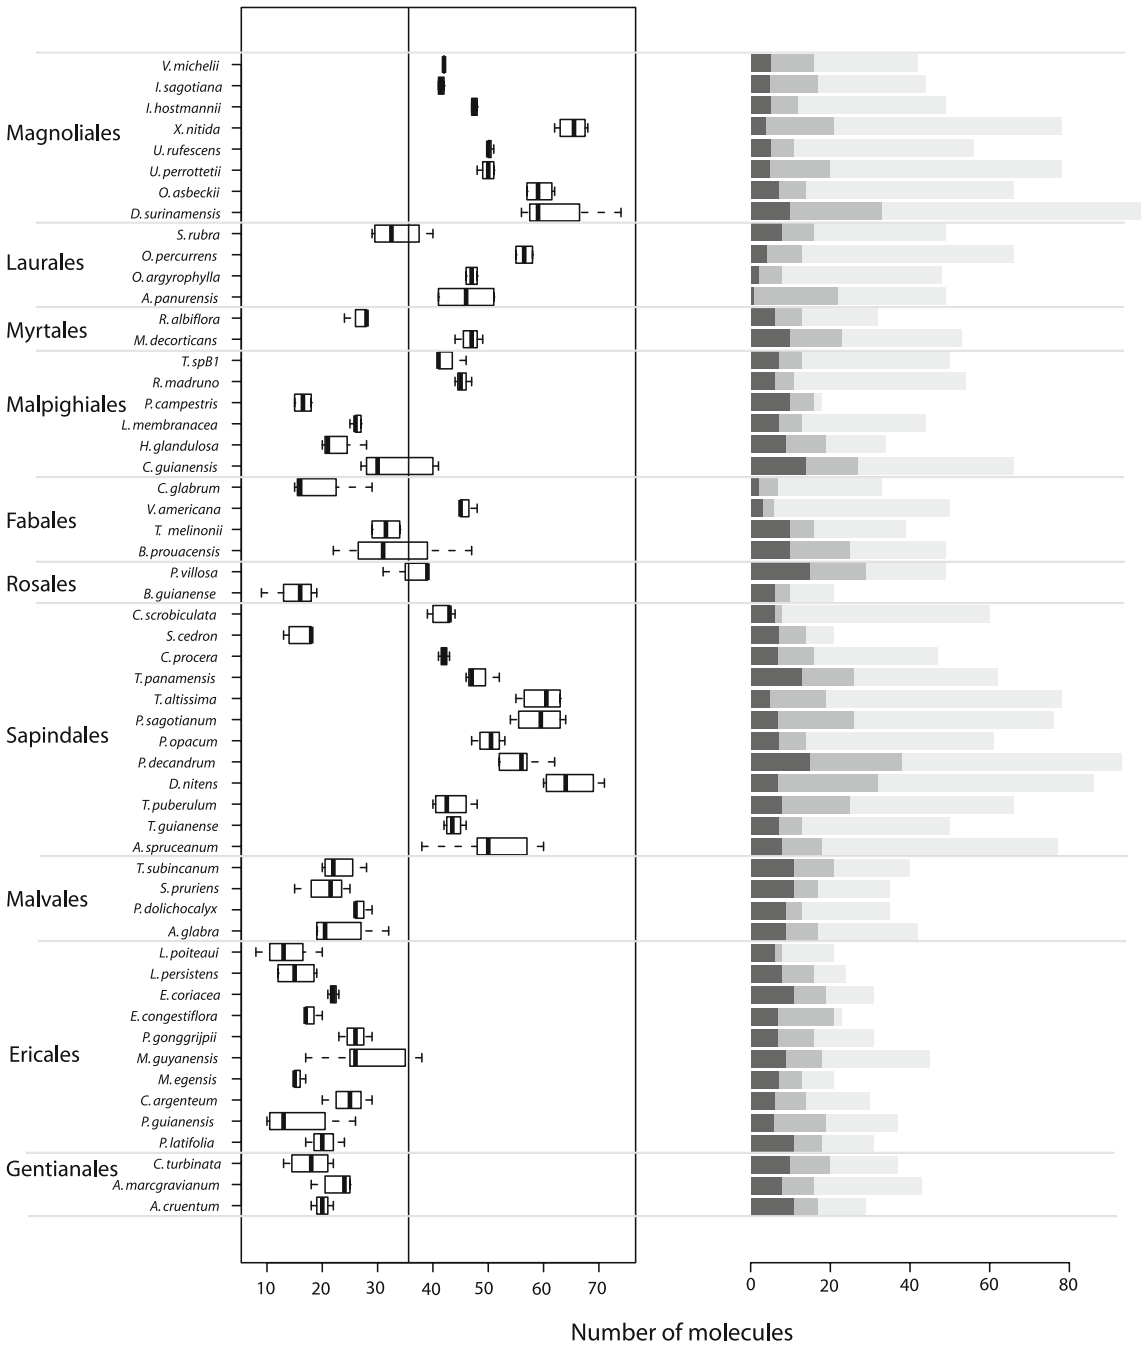

Fig. 4 **a** Mean number of compounds and the variation observed among conspecific individuals. For each box, *leftmost point* represents the 5% quantile and the *rightmost point*, the 95% quantile. The *rectangular box* represents the 25% quantile to 75% quantile ranges. The *dark line* shows the median of the distribution. The *vertical line* represents the mean number of compounds in the dataset (36.8) **b** contribution of the three more common class of compounds to the mean number of compounds for each species with green leaf volatiles in black, monoterpenes in *dark grey* and sesquiterpenes in *light grey*. *Horizontal lines* separate the distinct order in the dataset

The total diversity of VOCs varied greatly across species. Species in the Sapindales, Magnoliales, and Laurales generally released a more diverse blend than species in other orders. Exceptions were *Simaba cedron* (Simaroubaceae, Sapindales), and *Sextonia rubra* (Lauraceae, Laurales), which emit simpler mixtures of VOCs than other species in their respective families. *Simaba cedron* is actively defended by quassinoids, oxygenated triterpenes that are not detected by GC-MS (Ozeki et al. 1998). A non-volatile defensive compound has been isolated in great quantity from *S. rubra* wood (D. Stien, unpublished results). These specific examples suggest that plants

defended by other compounds may have simpler VOC profiles than plants that rely mainly on VOC defense.

Terpenoids made up the majority of the observed chemical diversity, consistent with our current knowledge on plant VOC synthesis (Wink 2003). Sesquiterpenes were more diverse than monoterpenes in tropical trees, with many compounds produced by only a few species. Diverse sesquiterpene composition is not the rule for all tree species: conifers emit mostly monoterpenes and only a few sesquiterpenes (Keeling and Bohlmann 2006). Our data suggest that production of sesquiterpenes may be more important than previously thought for tropical plants. In previous studies, VOC emissions from tropical forests have been quantified mostly in atmospheric studies of air pollutants (Guenther 2002). Generally, sesquiterpenes are difficult to detect in the air, due to their short lifetime in the atmosphere (Kesselmeier and Staudt 1999; Guenther 2002). Understanding the importance of sesquiterpene emissions by tropical forests remains an important challenge (Bouvier-Brown et al. 2007), and the present work provides a reference database for future investigations in this direction.

We hypothesize that plant defense by VOCs depends not only on the abundance of the various emitted VOCs, but also on the diversity of the blend. Fine et al. (2006) recently compared the investment in the production of monoterpenes and sesquiterpenes in tropical tree species to test the hypothesis that species under a higher herbivory pressure are better defended chemically. This hypothesis was not supported for the genus *Oxandra* (Annonaceae, Magnoliales). Our analysis may provides an explanation for their result: Fine et al. (2006) only compared overall concentration of terpenes and did not look at the diversity of the blend.

An assumption of our study is that, to measure the chemical diversity of VOC blends, we considered each compound as an independent unit. However, VOCs are linked by their biosynthetic pathways, especially in the sesquiterpene and monoterpene groups where terpene synthases often are involved in the synthesis of multiple products. An important challenge is to determine whether biosynthetic pathways may be partially elucidated by data from large-scale surveys.

One important limitation of our analysis is that we characterized the blend of VOCs released immediately after inflicting mechanical damage and not after an herbivory event. We assumed that this blend is representative of the constitutive VOCs released immediately after herbivore attack (see also Banchio et al. 2005; Mithöfer et al. 2005). However, VOC emissions are often modulated by factors such as elicitors released by herbivores (Mattiacci et al. 1995). In some species, VOCs are stored in specialized cells and volatilized immediately after wounding, whereas in others, synthesis is triggered by herbivory (Turlings and Wäckers 2004). Our study was designed to detect general pattern of constitutive VOCs among numerous long-lived species. Detailed studies will be necessary to understand fully the relative role of constitutive and induced VOCs in the defensive strategies of tropical trees.

In summary, our analysis highlights three major aspects of VOC emissions by tropical tree species. First, for most species, the intraspecific variation of the VOC blend is low, suggesting that VOC composition is species-specific. Second, sesquiterpenes are a key constituent of the VOC blend. Future studies should link pathogens and herbivore occurrence as well as herbivory rates with the quantity and diversity of sesquiterpenes in leaves and bark. Third, the complexity of the VOC mixtures varies significantly among species, indicating large differences in VOCs production among species. Future studies will need to relate this observation to our understanding of the evolution of plant defenses and to the herbivores and pathogens community associated with each species.

Acknowledgements We thank all participants of the BRIDGE project, Antoine Stevens and the Institut Pasteur of French Guiana in Cayenne for providing laboratory facilities, Pascal Petronelli for help in the field, Julien Engel for help in the validation of the protocol, Bruno Buatois for providing the alkane blend, and Martine Hossaert-McKey, Kyle G. Dexter, A. E. Hagerman and two anonymous reviewers for useful comments at several stages of the writing of this manuscript. This work is a contribution of the BRIDGE project, funded by the Agence Nationale pour la Recherche (ANR-Biodiversité program).

Appendix 2

Compounds tentatively identified. For each compound, the Kovats RI and the number of species that emits the compound is indicated. The compounds authenticated with standards are indicated by *.

classe	compound	RI	# species
N_compound	2-isopropyl-3-methoxypyrazine	1091	1
shikimic pathway	unknown S 1	1206	15
	methyl salicylate	1206	5
	1,4-dimethoxybenzene	1249	1
lipidic pathway (LP)	hexanal	813	52
	n-hexanol	872	45
	(*E*)-2-hexenal	863	41
	penten-3-ol	741	38
	2-ethyl furan	749	32
	(*Z*)-3-hexenol	864	27
	unknown LP 1	733	20
	isopentyl alcohol	768	16
	unknown LP 2	735	15
	octen-3-ol	984	15
	3-octanone	989	15
	unknown LP 3	854	14
	2-pentanone	743	12
	penten-1-ol	791	9
	3-pentanone	749	7
	heptanal	905	7
	hexyl hexanoate	1386	7
	(*E*)-3-hexenol	857	6
	1-pentanol	769	5
	hexenyl acetate	1014	5
	3-methyl-3-buten-1-ol	757	4
	3-octanol	1000	4
	hexenyl-3-methylbutanoate	1231	4
	(*Z*)-2-hexenol	872	3
	octanone	989	3
	hexenyl butanoate	1186	3
	octene	800	2
	(E)-2-octen-1-al	1066	2
	hexyl butanoate	1192	2
	unknown LP 4	805	1
	unknown LP 5	909	1
	unknown LP 6	970	1
	hexenyl isobutanoate	1142	1
	hexenyl isovalerate	1236	1
irregular terpene	6-methyl-5-hepten-2-one	989	1
monoterpene	α-pinene *	940	55
	limonene *	1034	53
	p-cymene	1030	45
	β-pinene	985	42
	3-carene	1014	29
	β-myrcene *	992	29
	α-phellandrene	1011	28
	camphene	958	26
	linalool *	1103	20
	p-xylene	881	19
	α-thujene	932	18
	β-phellandrene	1036	14
	β-terpinolene	1089	14
	1,8-cineole	1038	12

	α-terpinene	1022	11
	γ-terpinene	1062	11
	β-ocimene	1049	10
	sabinene	978	10
	o-xylene	905	7
	iso-methoxythymol	1241	6
	o-cymene	1025	6
	Perilene	1114	6
	tricyclene	930	6
	delta-2-carene	1002	5
	α-terpinolene	1083	4
	cis-sabinene-hydrate	1075	4
	terpinene-4-ol	1188	4
	allo-ocimene	1119	3
	linalool-oxide-trans	1075	3
	unknown monoterpene 1	1173	3
	mentha-1-7(8)-diene	1010	3
	p-cymenene	1096	3
	verbenene	986	3
	3p-menthene	1000	2
	camphor	1156	2
	carvacrol-methyl-ether	1232	2
	(*E*)-β-ocimene	1047	2
	mentha-2,8-diene	1001	2
	thuja-2,4(10)-diene	961	2
	thymol-methyl-ether	1227	2
	(4*E*,6*Z*)-allo-ocimene	1131	1
	α-terpineol	1202	1
	campholenal	1133	1
	cymen-8-ol	1194	1
	linalool-oxide-cis	1180	1
	linalool-oxide-dihydroxy	1112	1
	unknown monoterpene 2	1047	1
	mentha-2,8-dienol	1123	1
	myrtenal	1204	1
	pinocarvone	1170	1
	rose-furan-oxide	1197	1
	trans-sabinene-hydrate	1108	1
	sylvestrene	1021	1
	trans-pinocarveol	1149	1
	trans-verbenol	1152	1
	(*Z*)-β-ocimene	1035	1
sesquiterpene	β-caryophyllene *	1427	52
	α-copaene	1381	51
	α-humulene	1462	45
	δ-cadinene	1521	44
	germacrene D	1487	41
	cyperene	1412	40
	bicyclogermacrene	1502	36
	allo-aromadendrene	1467	35
	sesquithujene	1393	35
	α-ylangene	1375	34
	di-exo-T-cadinol	1479	34
	γ-cadinene	1518	33
	calarene	1436	32
	unknown sesquiterpene 1	1393	32
	aromadendrene	1445	31
	unknown sesquiterpene 2	1503	31
	α-cubebene	1349	30
	unknown sesquiterpene 3	1502	30
	trans-calamenene	1526	28
	δ-elemene	1338	25
	β-humulene *	1433	24
	bicyclo-elemene	1335	24
	eremophyladiene	1541	24
	α-selinene	1496	21
	caryophyllene-oxide	1592	21
	cis-cadina-1,4-diene	1498	21
	γ-elemene	1432	21
	unknown sesquiterpene 4	1350	21
	unknown sesquiterpene 5	1439	21
	α-cadinene	1536	20
	β-bazzanene	1529	20
	(*Z*)-α-bisabolene	1509	19
	α-muurolene	1507	18
	unknown sesquiterpene 6	1399	18
	unknown sesquiterpene 7	1435	18
	sesquithujene-7-epi	1389	18

levels in *Nicotiana sylvestris* Spegazzini and Comes through wounding and removal of leaves varying in age (young, mature, and old) and found that changes in nicotine distribution and concentration were consistent with ODT.

Iridoid glycosides are secondary metabolites that have been isolated and identified from a large number of plant species, but relatively little is known of their distribution and function within plants. A body of previous work focused on the defensive function of iridoids from narrow-leaved plantain (*Plantago lanceolata* L.), which has two major iridoids, catalpol, and aucubin (Bowers and Puttick 1986, 1988; Puttick and Bowers 1988). More recent work on *P. lanceolata* has shown that catalpol is the predominant iridoid in young to intermediate aged leaves, with older leaves containing mainly aucubin (Bowers and Stamp 1992; Klockars et al. 1993; Fuchs and Bowers 2004). Catalpol was found to be a more potent growth inhibitor of larval *Spodoptera eridania* (Stoll) than aucubin (Puttick and Bowers 1988), and its high concentration in younger leaves is consistent with ODT. The structural similarity and defensive function of catalpol in *P. lanceolata* as compared to antirrhinoside of *Antirrhinum majus* L. has been described by Beninger et al. (2008).

Antirrhinum majus (snapdragon) is native to the Mediterranean region (Sutton 1988), and based on genetic analyses recently has been placed in the family Plantaginaceae along with *Linaria vulgaris* Mill. (yellow toadflax) (Albach et al. 2005). According to one of the most parsimonious trees of the combined analysis of common genes, *Antirrhinum* and *Linaria* are placed in the subfamily Antirrhineae (Albach et al. 2005). *Linaria vulgaris* is native to Eurasia but was introduced into North America over 300 yr ago. It escaped cultivation and has since become well established as a noxious weed (Saner et al. 1995). *Antirrhinum majus* reproduces solely through the production and dispersal of seed. *Linaria vulgaris* reproduces through seed but also asexually by means of radical shoots produced from buds that arise endogenously from the main, or long, horizontal roots (Bakshi and Coupland 1960; Charlton 1966; Sutton 1988). Vegetative propagation becomes an important mode of reproduction for *L. vulgaris* seasonally and at high latitudes (Nadeau and King 1991; Nadeau et al. 1992). For example, *L. vulgaris* plants that were introduced in grain shipments to a sub-arctic habitat (Churchill, Manitoba, Canada, 58° 46′ L.N), have become frequent and persistent, but they do not produce viable fruit, and they spread exclusively through radical shoots (Staniforth and Scott 1991).

Iridoid glucosides are common to both *A. majus* and *L. vulgaris* (Scarpati et al. 1968; Guiso and Scarpati 1969; Scarpati and Guiso 1969; Sticher 1971; Ilieva et al. 1992, 1993). However, for *A. majus*, we have found that antirrhinoside is the predominant iridoid in all plant tissues except for older leaves that contain mainly antirrhide (Beninger et al. 2007). Similarly, for *L. vulgaris*, antirrhinoside is the major iridoid found in all plant tissues (this paper). Antirrhinoside, is known to be phloem mobile in *Asarina scandens* (Cav.) Penn. (Gowan et al. 1995), and recent research has shown that this also is likely the case for antirrhinoside in *A. majus* (Beninger et al. 2007). Other possible defensive secondary metabolites such as the alkaloids choline (Harkiss 1974) and linarinic acid (Hua et al. 2002) have been found in *A. majus* and *L. vulgaris*, but their concentrations are extremely low (9.7×10^{-4} % and 2.5×10^{-6} %, respectively). Whether they have biological activity at these concentrations is unknown. However, antirrhinoside, can be found in concentrations ranging from 5 to 23% dry weight of plant tissue in *A. majus* (Beninger et al. 2007), and is known to inhibit growth of larval gypsy moth significantly at a concentration of only 3.3% in artificial diet (Beninger et al. 2008).

The importance of sexual reproduction to *A. majus* and of both sexual and asexual reproduction for *L. vulgaris* led to the generation of questions that could best be framed in the context of ODT. For example, constitutive levels of antirrhinoside are known to vary with time in organs of *A. majus*; young leaves and flowers contain the highest levels of antirrhinoside, and roots the lowest. How do these patterns of distribution compare to a species such as *L. vulgaris*, which also has antirrhinoside as its predominant iridoid, but for which sexual or asexual reproduction may differ in importance throughout ontogeny? Specifically, are new leaves of *L. vulgaris* protected with levels of antirrhinoside comparable to *A. majus*, and do these levels change in a similar manner during ontogeny? Since roots are a reproductive organ for *L. vulgaris*, how do root levels of antirrhinoside compare to *A. majus*, and do these levels change with time? How does allocation of antirrhinoside to flowers, the only reproductive organs for *A. majus*, compare to *L. vulgaris* which has both flowers and radical shoots as reproductive organs?

Methods and Materials

Seed Reproduction of A. majus and L. vulgaris The average seed production per capsule of the *A. majus* cv. Maryland White Ivory used in this study is 47 with ca. 73–85% germination rate (*pers. comm.* Linda Laughner, plant breeder, PanAmerican Seed™, Chicago, IL, USA). For *L. vulgaris*, seed production is poor due to pollinator limitation (Arnold 1982), predation (McClay 1992), and resource limitation (Clements and Cavers 1990). Average numbers of seed per capsule in field collections varied between 24.5 and 38.6 (Clements and Cavers 1990) with seed germination of only 8±1% to 53±19% (Nadeau and

King 1991). Seed dispersal also is poor (Nadeau and King 1991), and seed can have strong dormancy (Andersen 1968).

Plant Material and Environmental Conditions Seeds of *A. majus* Maryland Ivory White cultivar provided by Pan-American Seed™ (Chicago, IL, USA) were sown in 128 cavity plug trays (Landmark Co. Plastic, Akron, OH, USA) Sept. 21, 2005 in soil-less growth medium (Pro-Mix®, Premier Horticulture Ltée/LTD Rivière du Loup, QC, Canada) and grown until Nov. 04 2005, initially in a glass greenhouse (University of Guelph, ON, Canada, 43.3° 15′ L.N.) under ambient light at a temperature of 22/15 °C (day/night). *Linaria vulgaris* seeds purchased from Chiltern Seeds (Cat.No.813E; Cumbria, UK) were sown Nov. 17, 2006 and grown until Jan. 09, 2007 under the same temperature and greenhouse conditions described for *A. majus*, except that when selecting seedlings for transplant into hydroponic solution, those with one or two initial stems were chosen preferentially over those with more stems. The second stem (ramet), if present, was smaller, and was pinched off to ensure uniformity before the plants were grown hydroponically in the growth chambers. The removal of the small ramet is similar to defoliation of one of a pair of ramets, and when this was done for *L. vulgaris*, there was no difference in the total amount of ^{13}C labeled in the two ramets (Hellström et al. 2006). It is, therefore, unlikely that pinching of the small ramet had any effect on antirrhinoside concentration in the remaining stem.

Both species were removed from the growth medium, roots washed with distilled water, and then grown hydroponically in environmental chambers as described in Beninger et al. (2007). Briefly, seedlings of both species were transplanted to 1.8 liter containers filled with aerated nutrient solution as described by Johnstone et al. (2005). To exclude light from the nutrient solution, which could promote the growth of algae, the containers were inserted into a larger black plastic container, and its lid was covered with black-on-white plastic sheeting, white side upwards. Hydroponic single-plant units were positioned in a growth chamber with a 12-h photoperiod and provided 350±50 μmol $m^{-2}s^{-1}$of photosynthetically active radiation (PAR) at plant canopy height. Day/night temperatures were approximately 23.5/18°C. Plants were fertilized with a commercial hydroponic formulation (1.15 g of 6-11-35 N:P:K supplemented with 0.85 g of $CaNO_3$ per liter, Plant Products Ltd., Brampton, ON, CA), with a pH of 6.0, and electrical conductivity (EC) of 1.9 mS/cm. Each main stem was supported by a galvanized wire stake (gauge 12). Seedlings received a half strength nutrient solution for 5 d after transplant. Thereafter, seedlings received full strength nutrient solution, and the solution level was maintained during the experiment. *Antirrhinum majus* cultivars have been grown hydroponically in our laboratory to commercial flower maturity previously (Ortiz-Uribe et al. 2005), but this is the first time that *L. vulgaris* has been grown successfully in hydroponics.

For the sampling of leaf tissue, there are two types of leaves in *A. majus* and *L. vulgaris*, axillary and lateral. Axillary leaves are first to develop and are attached directly to the main stem. Lateral leaves are attached to lateral stems that branch from the main stem above the axillary leaves (Figs. 1 and 2). Axillary leaves and lateral stems originate from slightly enlarged areas of the main stem, defined as nodes. Axillary leaves were harvested from the 4th, 8th, and 12–14th node from the base. Lateral leaves harvested were the 1st pair of leaves on the lateral stem at the 4th and 8th node of the main stem (see Fig. 3 in Beninger et al. 2007 for a diagram). Sampling the leaves at different nodes was done to obtain leaves from youngest (12th–14th node) to oldest (4th node) parts of the plants.

Plant organs for *A. majus* were harvested between 1300–1430 h 44, 54, 61, 68, 75, 82, and 89 days after sowing (DAS). Harvests for *L. vulgaris* occurred between 1330–1500 h at the following DAS: 53, 61, 68, 75, 82, 89, and 94. Harvesting of *A. majus* was ended at 89 DAS because the flower spike was fully developed and plants had reached commercial maturity. Harvesting of *L. vulgaris* was terminated at 94 DAS because some of the flowers at the lower portions of the inflorescence had begun to senesce. Three replicate plants per species were harvested at each of the above time periods. Leaves were removed at the stem, wrapped in aluminum foil, immediately frozen in liquid N_2, stored in a −80°C freezer, and freeze-dried. Non-leaf tissue was separated according to organ type (i.e. stem, root, etc.) and then treated as the leaves. Prior to HPLC analysis,

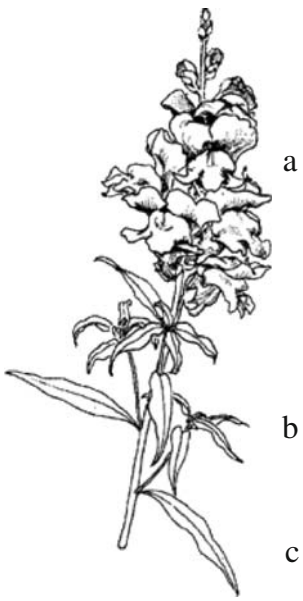

Fig. 1 Growth habit and flower morphology of *Antirrhinum majus.* **a.** Flower **b.** Lateral Leaves **c.** Young axillary leaf. Drawing modified from University of Florida Fact Sheet FPS-44

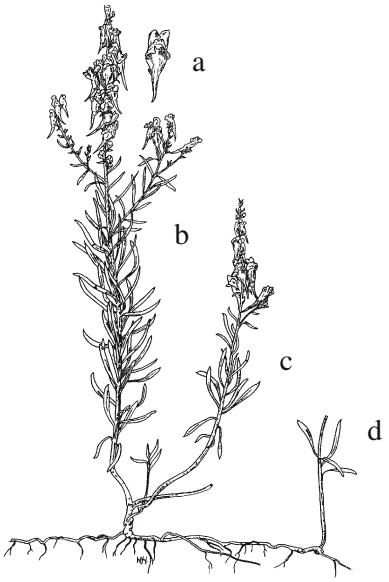

Fig. 2 Growth habit and flower morphology of *Linaria vulgaris*. **a.** Flower **b.** Lateral Leaves **c.** Clonal Growth from Main Root **d.** Clonal Growth from Lateral Root. Drawing modified from Saner et al. (1995)

freeze dried tissue of *L. vulgaris* was prepared and extracted as described for *A. majus* in Beninger et al. (2007).

HPLC Instrument and Conditions Instruments and conditions for analysis of *A. majus* extracts were as described in Beninger et al. (2007). Briefly, an Agilent model 1100 HPLC equipped with a degasser, quad pump, autosampler, and diode array display (DAD) (Agilent Technologies Canada Inc., Mississauga, ON, CA) was used. The column used was a CapCell Pak AG 120 C18 (4.6×250 mm, 5μ particle size) (Shiseido Co. Ltd. Japan), and the HPLC had ChemStation software. For quantification of the iridoids, the solvent system was isocratic employing 6% acetonitrile in water with a flow rate of 1.0 ml/min and sample elution periods of 10 min for *A. majus*. However, for *L. vulgaris*, the solvent composition was changed to 8% acetonitrile in water to decrease run times, since there was no closely eluting antirrhide to interfere with the separation and quantification of antirrhinoside. Water and acetonitrile were both HPLC grade.

Statistical Analyses All data were analyzed using the SAS® (2005) statistical software package. The data for antirrhinoside concentrations for both species was square-root transformed, and the total data set passed normality tests. Data were analyzed by using regression analysis in Figs. 3 and 4 with r^2 and P values given for the regression lines on the graphs. However, when divided into species, organ, and harvest, and analyzed separately for normality, there were three cases in which the data were not distributed normally, and univariate ANOVA analysis would not be appropriate. Therefore, in order to determine significant differences in antirrhinoside concentration between the two species for individual plant organs at each harvest, non-parametric Wilcoxon rank-sum tests were used. Significant differences at $P<0.05$ are indicated by stars above the points at different harvests on the graphs in Figs. 3 and 4. The data presented in Table 1 passed normality tests and was analyzed by using 1-way ANOVAs. Although the data were analyzed using the square-root transformed values, actual means and standard errors are depicted in the figures and table.

Results

Comparison of Antirrhinoside Levels in Organs of *A. majus* and *L. vulgaris*

Axillary Leaves. For node 4 (oldest leaves), the concentration of antirrhinoside at harvest 0 (at time of transplant to hydroponics) was high and not significantly different between the two species (Fig. 3a). However, by the second harvest and until the final harvest, the concentrations of antirrhinoside in *L. vulgaris* for leaves at this node were significantly higher (Fig. 3a). The regression analysis showed that the decline in antirrhinoside was only marginally significant for *L. vulgaris* but highly significant for *A. majus* (Fig. 3a). For node 8 (Fig. 3b), the only significant difference at a given harvest between the two species was at harvest 3 where *A. majus* had significantly more antirrhinoside than *L. vulgaris*. Regression analysis showed no significant decline in antirrhinoside for *L. vulgaris* but a significant decline for *A. majus* (Fig. 3b). At node 12-14, significantly higher amounts of antirrhinoside were found for *A. majus* at all harvests (Fig. 3c). Similar to leaves at node 8, regression analysis for leaves at node 12-14 showed no significant reduction in antirrhinoside for *L. vulgaris* but the decline for *A. majus* was significant (Fig. 3c).

Stems, Lateral Stems, Roots and Flowers The pattern of accumulation of antirrhinoside in the main stems is similar between the two species, but at harvests 4, 5, and 6, *A. majus* had significantly more antirrhinoside (Fig. 4a). The lateral stems of both species began with relatively high concentrations of antirrhinoside at the second harvest, and then both gradually declined with time (Fig. 4b). There was no significant difference in antirrhinoside concentration in the lateral stems between the two species at a given harvest, but the regression analysis showed that the decline for both was significant. The antirrhinoside concentration in the roots of *L. vulgaris* was significantly higher than *A. majus*

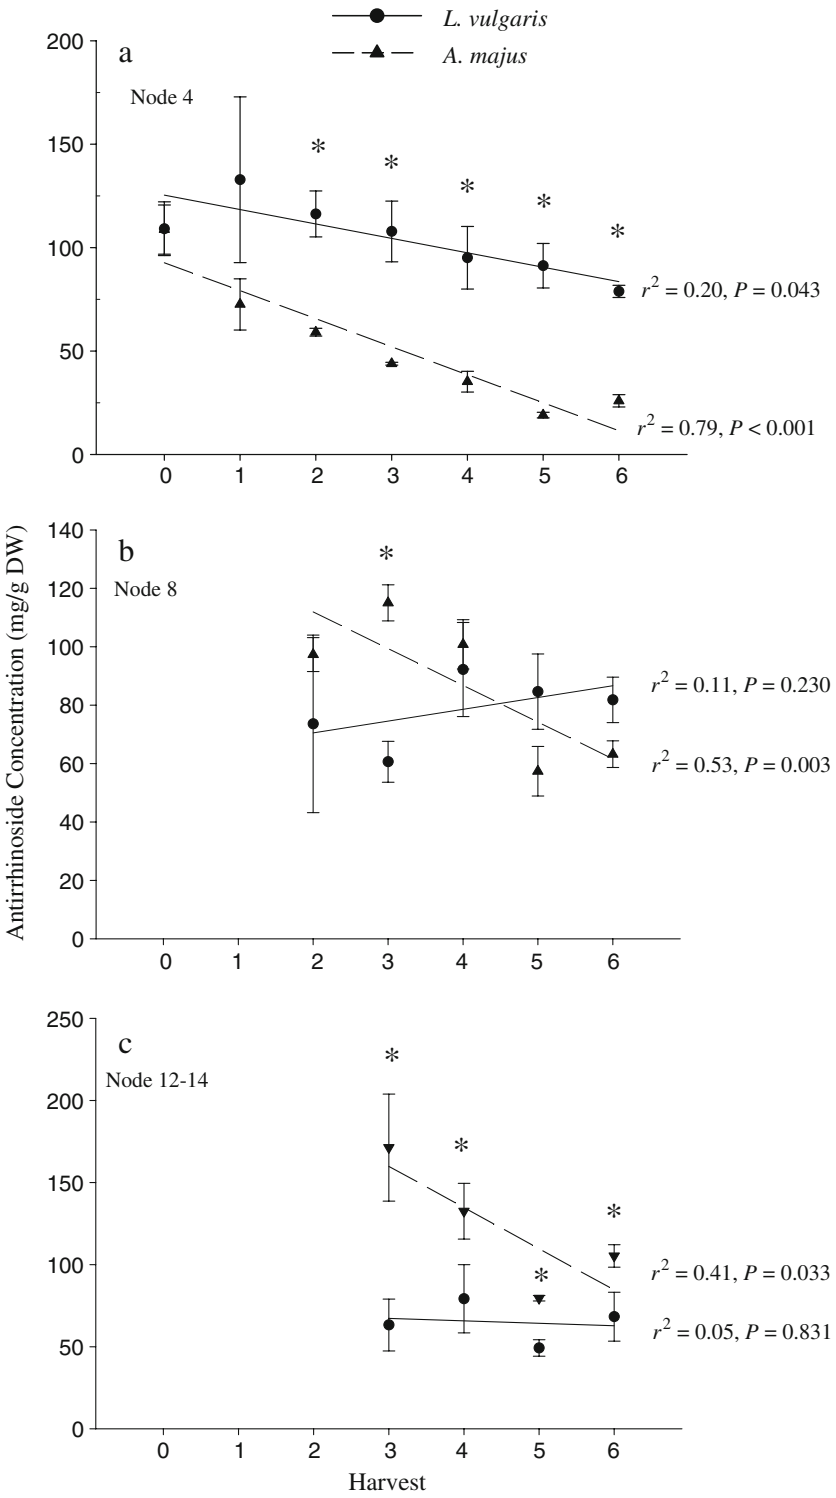

Fig. 3 **a.** Comparison of antirrhinoside concentrations for leaves of *Antirrhinum majus* and *Linaria vulgaris* at node 4 (oldest leaves) over the experimental period. Stars indicate significant differences between the two species ($P<0.05$). **b.** Same as for **a**, except means are for leaves at node 8 (intermediate aged leaves). **c.** Same as for **a** and **b**, except means are for leaves at node 12-14

at all harvests except for the initial one when the plants were removed from the growth medium (Fig. 4c) (Note: initial data points open circle and open triangle were not used in the regression analysis since these roots were analyzed immediately after removal from the soil-less growth medium, and may not give an accurate indication of antirrhinoside amounts in roots for that medium compared to roots grown in the hydroponic system). *Linaria vulgaris* still had over twice as much antirrhinoside as *A. majus* in this tissue by harvest 6. Antirrhinoside concentrations were very high in the buds of both species, but there was no significant difference between them. During the flowering

Stars indicate significant differences observed between the two species ($P < 0.05$). **b.** Same as for **a** except that means are for the lateral stems. **c.** Comparison of antirrhinoside concentrations for roots of *A. majus* and *L. vulgaris* over the experimental period

Table 1 Comparison between species in the levels of antirrhinoside (mg/g DW), in different organs of *Antirrhinum majus* and *Linaria vulgaris* over the flowering period

	Buds	Roots	Flowers
A. majus	195.42 (26.90)	22.71 (2.18)	142.10 (5.20)
L. vulgaris	169.69 (9.09)	49.17 (4.04)	96.93 (10.63)
P – value	0.5127	<0.001	<0.01

Actual means with SE in brackets are shown whereas the square root-transformed means were compared and significant differences between species indicated at $P<0.05$.

stage, *A. majus* had significantly higher concentrations of antirrhinoside in the flowers than *L. vulgaris* (Table 1).

Comparison of Biomass Allocation During the vegetative stage, *L. vulgaris* allocated significantly more relative biomass to axillary leaves than *A. majus*, but there was no difference between the species at the flowering stage (Fig. 5a). There was no difference between the two species in the amount of relative biomass allocated to lateral leaves at the vegetative stage, but at the flowering stage *L. vulgaris* allocated a significantly larger percentage to those leaves (Fig. 5b). During vegetative and flowering stages, *A. majus* allocated significantly more relative biomass to the main stem than *L. vulgaris*. In contrast, *L. vulgaris* allocated more to lateral stems at both stages than *A. majus*. There was an almost equal allocation of biomass for both species to root tissues at the two stages of development. Finally, *A. majus* allocated over two times the proportional amount of biomass to flowers as *L. vulgaris*.

Discussion

Antirrhinoside is structurally similar to catalpol found in *Plantago lanceolata*, which has been shown to reduce the growth of the generalist insect *Spodoptera eridania* (Puttick and Bowers 1988). We have shown that antirrhinoside reduces the growth of another generalist, gypsy moth, at concentrations in artificial diet well below those found in leaves (Beninger et al. 2008). Antirrhinoside, therefore, can be classified as a defensive compound, and predictions can be made about its distribution and concentration within plants according to ODT. Young, expanding leaves are most likely to be attacked by herbivores because of their higher nutritional value (Coley 1983), yet these are more valuable to the plant than older leaves due to their higher photosynthetic rates (Harper 1989), and according to ODT should contain higher levels of defensive compounds (Zangerl and Rutledge 1996). For *A. majus*, initial constitutive concentrations of antirrhinoside for all axillary leaves were high when young, and then tended to decline significantly with age (Fig. 3) consistent with ODT predictions. High concentrations of defensive compounds in young leaves also have been reported for terpenoid aldehydes in cotton (*Gossypium hirsutum* L.) (Anderson and Agrell 2005), pyrrolizidine alkaloids in *Cynoglossum officinale* L. (Van Dam et al. 1996), and phenolics in three tropical species (Read et al. 2003).

For *L. vulgaris*, a marginally significant decline in antirrhinoside over time was apparent only for leaves at node 4, and there was no significant reduction in this compound for the other axillary leaves (Fig. 3a–c). Even though the decline in antirrhinoside is significant for the oldest leaves of *L. vulgaris*, it is still significantly less than the decline in leaves of *A. majus* removed from the same

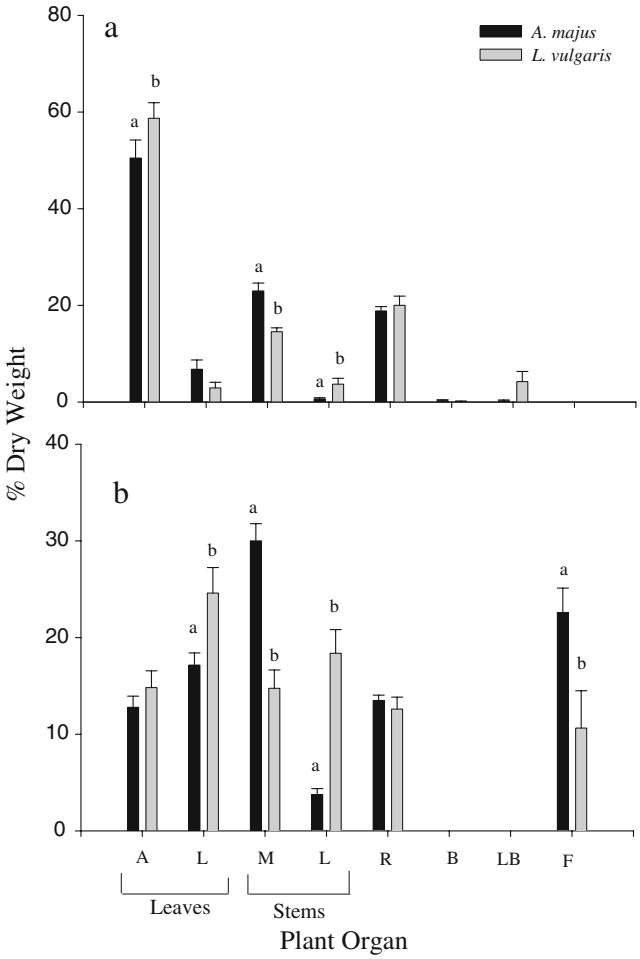

Fig. 5 a. Comparison between species of the % dry weight of different organs for *Antirrhinum majus* and *Linaria vulgaris* averaged over the vegetative period. Different letters above bars indicate significant differences between species at $P<0.05$. A = Axillary; L = Lateral; M = Main; R = Roots; B = Buds; LB = Lateral Buds; F = Flowers **b.** Same as for **a** except comparison is averaged over the flowering period

node. It is uncertain why the same pattern of defense allocation in young leaves of *L .vulgaris* generally is not seen, but species differences in leaf size and shape and plant architecture may affect the amount of light that is received by old vs. young leaves. It has been shown for a number of plant species that there is a decrease in net production with leaf age due both to senescence and to the over shading of older leaves by young leaves (Mooney and Gulman 1982; Harper 1989), which makes older leaves less valuable to the plant. Leaves of *L. vulgaris* are much smaller and narrower than leaves of *A. majus* and generally the same (homoblastic), regardless of where they are in the canopy. Axillary leaves of *A. majus*, are larger and heteroblastic; near the top of the plant, leaves are narrow but increase in width towards the bottom of the canopy. These differences in leaf morphologies and growth habits (architecture) of the two species (Figs. 1 and 2) would likely affect the amount of light older leaves receive, and this then would affect photosynthesis and the relative value of leaf tissue. In our study, however, we did not measure the amount of light received by leaves of different ages, and further research is needed to resolve this issue.

Accumulation of antirrhinoside in the main stem was remarkably similar between the two species with amounts peaking at bud-break for *L. vulgaris* or flowering for *A. majus* (Fig. 4a). Antirrhinoside has been shown to be phloem mobile when it occurs in other species (Gowan et al. 1995; Voitsekhovskaja et al. 2006), and we have shown through steady-state $^{14}CO_2$ labeling that it also is phloem mobile in *A. majus* as well (Beninger et al. 2007). There are no data on whether antirrhinoside is phloem mobile in *L. vulgaris*, but given the similar pattern of accumulation in the main stem it seems likely that it also is transported in the phloem. The ability to move antirrhinoside through the phloem has important implications in terms of its distribution as a defensive compound. For example, increases in leaf concentrations in antirrhinoside may not be solely a result of local induction, but rather reallocation from undamaged leaves or other parts of the plant. If the iridoid catalpol in *P. lanceolata* is also phloem mobile, this may be one of the reasons why local induction of iridoids is difficult to detect (Fuchs and Bowers 2004).

The lateral stems of both species (Fig. 4b) have a pattern of accumulation different from the main stems with initial high concentrations of antirrhinoside declining to less than half these values by the end of the experimental period. Antirrhinoside concentration in the lateral stems is high initially, perhaps because lateral leaf growth for both species declines with time. Since there were not enough lateral leaves of either species to analyze chemically over the experimental period, we do not know if the concentration of antirrhinoside in young lateral leaves of either species is high. However, lateral growth may be more important for *L. vulgaris* because it allocates more biomass on a relative basis to lateral stems and leaves during the flowering period (Fig. 5).

Root tissue is important for vegetative reproduction of *L. vulgaris* and if antirrhinoside is effective against root herbivores, then antirrhinoside concentrations in root tissue of *L. vulgaris* would be expected to have higher concentrations than *A. majus* root tissue. According to ODT the value of root tissue is higher for *L. vulgaris* than *A. majus* since its loss would have greater impact on the fitness of the former. However, for *L. vulgaris*, during flowering, the value of root tissue may decline and levels of root antirrhinoside also would be expected to decline as the flowers develop and become important for reproduction. This seems to be true for *L. vulgaris*, as root concentrations of antirrhinoside are initially about five times as high compared to *A. majus* and then steadily decline, whereas the concentration of antirrhinoside for *A. majus* remains low and constant throughout growth (Fig. 4c). It is noteworthy that the growth of these two plant species in a hydroponic medium is unique in that it allows for sampling of the root systems without the problems of accessibility and damage that results from removal of plants grown in a soil medium. On the other hand, hydroponic growth is artificial, and while clonal growth was observed for *L. vulgaris*, it may have been restricted by experimental conditions (pot size, shading) when compared to soil-grown plants.

There are, to our knowledge, no studies that have quantified root concentrations of antirrhinoside or other iridoids with the exception of a recent one by De Deyn et al. (2009). These authors examined iridoid distribution in *P. lanceolata* genotypes selected for high and low leaf concentrations of catalpol and aucubin, and their effects on root colonization by arbuscular mycorrhizal fungi (AMF). Concentrations in leaves and roots of the two iridoids were found to be positively correlated, and growth of AMF was negatively correlated with the concentration of root aucubin. These data do not support our previous suggestion that aucubin of *P. lanceolata* may be similar to antirrhide of *L. vulgaris*, i.e. it is not phloem mobile and found only in leaves (Beninger et al. 2007, 2008). De Deyn et al. (2009) reported the presence of aucubin in roots at concentrations of 0.05–0.93% DW depending on whether the plant was a high or low iridoid genotype. Further work on the distribution of catalpol and aucubin in *P. lanceolata* is needed to confirm these findings, but if aucubin is indeed in roots of *P. lanceolata*, it may function in defense.

According to ODT, flowers should be constitutively well defended, but not as inducible as other, less expendable tissues, such as older leaves. This has been shown to be the case for a toxic furanocoumarin in wild parsnip (*Pastinaca sativa*) (Zangerl and Rutledge, 1996) and to some extent for

glucosinolates in wild radish (Strauss et al. 2004, but see also Pavia et al. 2002). In our study, we did not test whether antirrhinoside was inducible in flowers or any other tissues, but we did measure the constitutive concentrations over plant ontogeny. During the flowering period of both species, allocation of antirrhinoside was significantly higher in flowers of *A. majus* (Table 1) compared to those of *L. vulgaris*. Since flowers are the only reproductive organ in *A. majus*, it is expected, according to ODT, that they would have higher levels of constitutive protection, whereas *L. vulgaris* would have lower levels, as it may still also reproduce vegetatively through adventitious roots even while flowering. In addition, on a proportional dry weight basis, *L. vulgaris* allocated less than half as much relative biomass to flowers than *A. majus*, yet had the same allocation to root tissue (Fig. 5).

In summary, our results demonstrate that the constitutive distribution and concentration of antirrhinoside in two related plant species with different reproductive strategies is generally consistent with ODT, although other explanations are possible. Our research provides a basis for further work on iridoid distribution among organs in other related plant species, as well as the potential effect of insect herbivores on plant fitness.

zation of anti-aphrodisiacs may incur fitness costs to both females and males when natural enemies exploit them. Parasitic wasps, including egg parasitoids, often exploit the sexual communication system of their hosts during foraging (reviewed by Vinson 1984; Stowe et al. 1995; Powell 1999; Fatouros et al. 2008b).

Recently, we showed that *Trichogramma* egg parasitoids utilize the anti-aphrodisiac of one of their hosts, the gregarious large cabbage white butterfly, *Pieris brassicae* L. (Fatouros et al. 2005b; Huigens et al. 2009). Male *P. brassicae* induce female refractoriness for mating by transferring the anti-aphrodisiac, benzyl cyanide (BC), within the ejaculate (Andersson et al. 2003). Benzyl cyanide acts as a kairomone for *Trichogramma brassicae* Bezdenko and *T. evanescens* Westwood by attracting the wasps to mated *P. brassicae* females, thus facilitating phoretic transport to host oviposition sites (Fatouros et al. 2005b; Huigens et al. 2009). In addition, BC incurs another indirect cost on *P. brassicae* by triggering the release of plant compounds that arrest *T. brassicae* wasps, egg parasitoids of the butterfly (Fatouros et al. 2005a, 2008a).

Plants fed or oviposited upon by herbivores often release chemical cues (i.e., plant synomones) that attract predators and/or parasitoids, enemies of the herbivorous attackers (Hilker and Meiners 2002, 2006; Turlings and Wäckers 2004; Dicke 2009; Dicke et al. 2009). In cases known thus far, the plant's response is triggered by compounds present either in the regurgitant or in the egg-associated secretion of the herbivore (Mattiacci et al. 1995; Alborn et al. 1997; Halitschke et al. 2001; Colazza et al. 2004a; Hilker et al. 2005; Felton and Tumlinson 2008). Brussels sprouts plants respond to *P. brassicae* eggs by modifying the leaf surface, which arrests *T. brassicae* wasps three days after egg deposition when the host eggs are most suitable for parasitism (Fatouros et al. 2005b). The leaf surface changes could be of a chemical nature, but remain unknown. However, genome-wide transcriptional analysis has provided molecular evidence that confirms oviposition- and BC-induced changes in the plant (Fatouros et al. 2008a). In female *P. brassicae*, traces of BC (the male anti-aphrodisiac) were detected in the secretion from the accessory reproductive gland (ARG), which is released with eggs onto the plant surface (Fatouros et al. 2008a).

Whereas *P. brassicae* deposits egg clutches consisting of 20–50 eggs (Feltwell 1982), the closely related small cabbage white, *P. rapae* L., lays single eggs on wild and cultivated Brassicaceae (Richards 1940). Male *P. rapae* butterflies transfer methyl salicylate (MeSA) and indole with their ejaculate to the females. Mated *P. rapae* females emitting MeSA and indole were unattractive to conspecific males, thus showing that both compounds function as an anti-aphrodisiac blend (Andersson et al. 2003). The aim of this study was to investigate whether singly laid eggs of *P. rapae* induce the production of a plant synomone in Brussels sprouts that arrests *T. brassicae* wasps, and, if so, whether this plant response is triggered by male-derived compounds transferred within the ejaculate during mating, specifically, the anti-aphrodisiac compounds indole and/or methyl salicylate.

Methods and Materials

Plants and Insects Brussels sprouts plants (*Brassica oleracea* L. var. *gemmifera* cv. Cyrus) were grown in a greenhouse (18±5°C, 50–70% rh, L16:D8). *Pieris rapae* was reared on Brussels sprouts in a climate room (21±1°C, 50–70% rh, L16:D8). Virgin females were obtained by separating sexes in the pupal phase, and keeping them separately from males after eclosion until dissection. Three days after eclosion, the ARGs were dissected from females. Mated females were obtained by adding a virgin male to a virgin female one day after eclosion. As soon as a butterfly couple was observed to mate, it was isolated in a separate cage to obtain females for dissection that had mated for the first time. Two days after mating, the ARG were dissected from females.

Trichogramma brassicae (Hymenoptera: Trichogrammatidae) was reared in irradiated eggs of the moth *Ephestia kuehniella* Zeller (Lepidoptera: Pyralidae), received from Koppert B.V., The Netherlands, at 25±1°C, 50–70% RH, L16:D8 in a climate chamber. *Ephestia kuehniella* eggs were glued on paper cards and offered to the wasps in glass vials for parasitization. *Trichogramma* wasps are known to be capable of developing successfully in *Ephestia* eggs (Brower 1983). Only mated, 2-5-d-old, oviposition-experienced female wasps were used for the experiments. An oviposition experience was given for a period of 18 h prior to the experiment with ≤3-d-old *P. rapae* eggs deposited on Brussels sprouts leaves. Eggs older than 3 d are unsuitable for parasitization because of sclerotization of the caterpillar's head capsule.

Preparation of ARG Homogenates To obtain samples for bioassays, ARGs were dissected from 3 gravid or virgin *P. rapae* females (3-d-old) in phosphate buffered saline (PBS; pH 7.2), transferred to a vial with 100 µl PBS, and homogenized. Then, after addition of another 100 µl of PBS, the homogenate was centrifuged, and 100 µl of the supernatant were applied with a brush to the edge of a cabbage leaf as described below (an equivalent of 1.5 extracted glands per leaf). For chemical analysis, 1 ARG of either a mated or a virgin *P. rapae* female (3-d-old) was dissected and transferred to a vial containing 50 µl of dichloromethane (DCM) with ethyl salicylate (EtSA) as internal standard (0.25 ng/µl). In total, 7 samples of each gland type were analyzed by GC-MS.

Plant Treatments For bioassays with egg-infested plants, test plants were placed into a cage with more than 100 *P. rapae* adults to allow deposition of eggs, wing scales, and host odors onto the plants. Plants were exposed for about 1–2 h to the butterflies, with a maximum of 20 eggs deposited per leaf. Up to 20 *P. rapae* eggs have been observed on a single *Brassica oleracea* plant in nature (N.E. Fatouros, personal observations). After this exposure time, the egg-infested plants were tested immediately or were kept in a climate chamber (21±2°C, 70% rh, L16:D8) either overnight (24 h) or 48 to 72 h after the day of egg deposition. Thus, the period during which eggs or butterfly deposits could affect the cabbage plant was in total 6, 24, 48, 72, or 96 h. Control plants were grown under the same conditions as treated plants, but were never in contact with *P. rapae* or other insects.

For bioassays with ARG homogenate-treated plants, a sample of ARG homogenate of mated *P. rapae* females was applied to the edge of a Brussels sprouts leaf in a stretch of about 2 cm on the abaxial leaf side. As a control, a sample of ARG homogenate of virgin *P. rapae* females was applied to the plants in the same way. After treatment, all plants were kept for either 24 or 72 h in a climate chamber (21±1°C, 50–70% RH, L16:D8).

For bioassays with ARG homogenate and indole treated plants, 30 µl of methanolic indole solution (10 ng indole (Sigma-Aldrich) in 100 µl MeOH) were added to 170 µl of ARG homogenate from virgin females, and 100 µl of this mixture were applied to a leaf as above (i.e., 1.5 ng indole, plus ARG homogenate from virgin females equivalents 1.5 ARGs from mated females). Test leaf squares were cut from the plant 72 h after application of the mixture. Control leaf squares were obtained from leaves treated with ARG homogenate of virgin females in PBS and MeOH.

For bioassays with indole treated plants, 100 µl of 0.005 or 0.5 ng indole/µl MeOH solutions were applied to leaves as described above. Control plants were treated with 100 µl MeOH only. Leaf squares adjacent to the indole treatment were tested against leaf squares adjacent to the solvent treatment in a two-choice bioassay.

Two-chamber Olfactometer Bioassays The experiments were carried out in a two-chamber olfactometer described in detail by Fatouros et al. (2005a). Time spent by wasps in one of the two odor fields was measured for 300 s. The 4th or 5th leaf from the top of a plant was excised, and kept with its petiole in a vial with water during the bioassay. A total of 10 *T. brassicae* wasps were tested per day per plant. In total, 50 wasps per treatment were tested, and 5 plants per treatment were used. To avoid biased results due to positional preferences of the parasitoids, the olfactometer was rotated 180° after every third insect tested. The response of *T. brassicae* was tested to odors of plants infested with *P. rapae* eggs in the following two-choice combinations: a) plants with eggs 24 h after deposition vs. clean air and, b) plants with eggs 72 h after egg deposition vs. clean air. All two-chamber olfactometer bioassays were statistically analyzed using *Wilcoxon matched pairs test* by using SPSS for Windows 15.0 Software.

Two-choice Contact Bioassays All contact bioassays were conducted with egg-free or untreated leaf squares (in Fatouros et al. 2005a, 2008a, denoted as 'locally induced') cut close to a treated leaf part, i.e., single eggs, applied ARG homogenate and/or indole/MeOH solution. A female wasp was released in a glass Petri dish (5.5 cm diam) halfway between a test, and control leaf squares (1.5 cm^2) directly cut from the plants immediately prior to the bioassay. The total time spent (i.e., residence time) on each of the leaf squares was observed for a period of 300 s by using The Observer software v. 4.0 (Noldus Information Technology, Wageningen, The Netherlands). A detailed description of the bioassay method is given elsewhere (Fatouros et al. 2005a). Test and control squares were taken from leaves of corresponding size and position on the plants. In total, 50 wasps per treatment were tested, and 5 plants per treatment were used. A maximum of 10 wasps per experimental day were tested. Leaf squares were renewed and repositioned randomly after every third wasp tested. All two-choice contact bioassays were analyzed using *Wilcoxon matched pairs test* by using SPSS 15.0 for Windows Software.

Chemical Analysis ARG extracts were analyzed by coupled gas chromatography—mass spectrometry (GC-MS) using a gas chromatograph (Agilent 7890A) equipped with a 30-m Zebron ZB-5 ms column (0.25 mm i.d., 0.25-µm film thickness; Phenomenex, Torrance, CA, USA) and an inert mass selective detector (model 5975C with triple axis detector, Agilent). A 5 m Guardian™ pre-column (deactivated fused silica tubing without stationary phase; Phenomenex, Torrance, USA), was permanently attached to the analytical column. The GC was programmed from 45°C for 1 min, to 200°C at 10°C min^{-1}, then to 280°C at 30°C min^{-1}, and held 3.5 min. The sample volume (1 µl) was injected in splitless mode. The injection port and interface temperature were 250°C and 280°C, respectively, and the helium inlet pressure was controlled electronically to achieve a constant column flow of 1.0 ml min^{-1}. A solvent delay was set to 4 min. The ionization potential was set at 70 eV, and scanning was performed from 33 to 200 atomic mass units. Identification of MeSA, indole and the internal standard EtSA was based on the injection of authentic reference standards (>98% purity, Sigma-Aldrich). Quantification of MeSA and indole was based on comparison with the internal standard. A calibration

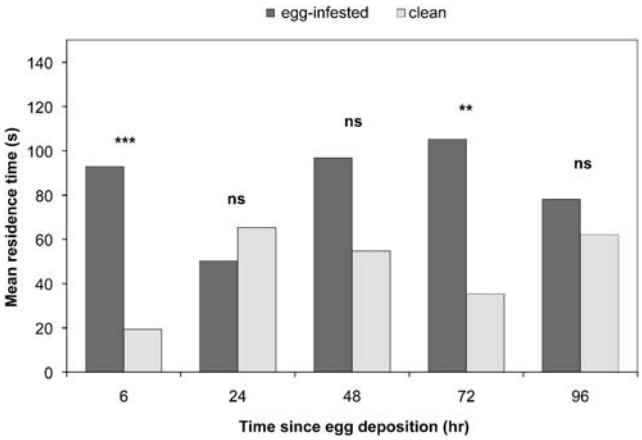

Fig. 1 Mean residence time of *Trichogramma brassicae* females on Brussels sprouts leaves infested with *Pieris rapae* eggs (egg-infested) tested against leaves of uninfested plants (clean). Egg-free leaf squares adjacent to eggs that had been deposited 6-96 h prior to the bioassay (dark grey columns) were simultaneously offered against leaf squares from uninfested plants (light grey columns) in a two-choice contact bioassay in a Petri dish. Number of tested females per treatment, N=50. Abbreviations: ns—not significant; **P<0.01; ***P<0.001 (*Wilcoxon matched pairs test*)

series of MeSA, indole, and EtSA, injected from a concentration of 0.05–50 ng/µl DCM, showed similar linear response factors of all three compounds within this concentration range (data not shown). Differences in quantities of anti-aphrodisiac compounds were analyzed using *Mann-Whitney U test* by using SPSS 15.0 for Windows Software.

Results

Olfactory Response of Trichogramma to Leaves Infested with P. rapae Eggs Trichogramma brassicae did not discriminate between volatiles from an egg-laden leaf and clean air (24 h: P=0.426, 72 h: P=0.903, *Wilcoxon matched pairs test*).

Arrestment of Trichogramma by Leaves Infested with P. rapae Eggs Leaf squares from plants, on which eggs had been deposited 6 h prior to the assay arrested *T. brassicae* when tested vs. leaf squares from uninfested plants (Fig. 1, P<0.001, *Wilcoxon matched pairs test*). However, leaf squares from plants on which eggs had been deposited 24 h prior to the assay did not arrest the wasps (Fig. 1, P=0.494, *Wilcoxon matched pairs test*). The wasps tended to prefer leaf squares cut from an egg-carrying leaf on which eggs had been deposited 48 h prior to the assay when tested vs. leaf squares from uninfested plants (Fig. 1a, P=0.058, *Wilcoxon matched pairs test*). Wasps stayed longer on leaf squares of plants with eggs deposited 72 h prior to the bioassay (Fig. 1, P=0.004, *Wilcoxon matched pairs test*). Four days after egg deposition, wasps did not discriminate between leaf squares of egg-infested plants when tested vs. leaf squares of uninfested plants (Fig. 1a, P=0.427, *Wilcoxon-matched pairs test*).

Arrestment of Trichogramma by Leaves Treated with ARG Untreated leaf squares obtained from leaves treated with ARG homogenates of mated females were tested against

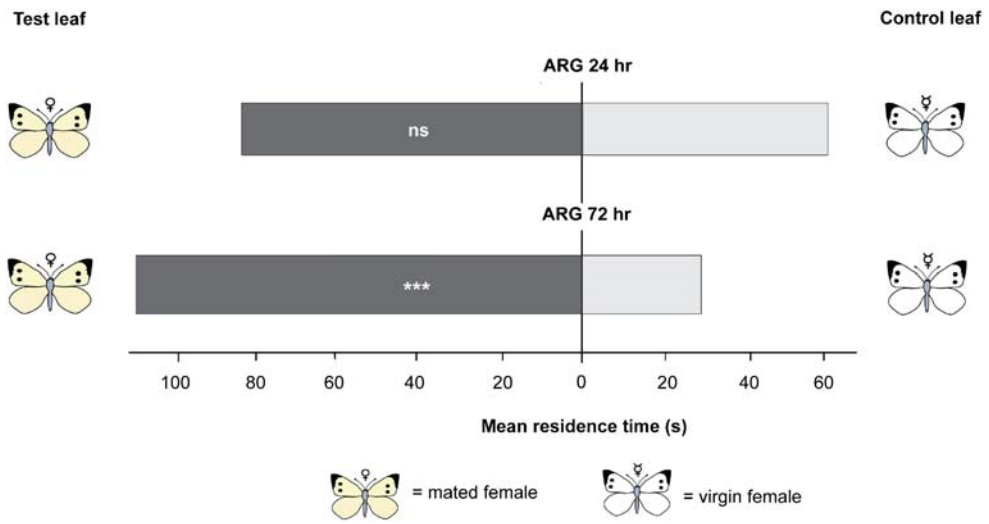

Fig. 2 Mean residence time of *Trichogramma brassicae* females on Brussels sprouts leaves treated with accessory reproductive gland (ARG) homogenate of *Pieris rapae* females. Leaves were treated either with ARG homogenate from virgin females (light grey bars) or ARG homogenate from mated females (dark grey bars) a) 24 h or b) 72 h prior to the bioassay. Untreated leaf squares, adjacent to a site on the same leaf that was treated with ARG homogenate, were simultaneously offered to the wasps in a two-choice contact bioassay in a Petri dish. Number of tested females wasps per bioassay combination, N=50. Abbreviations: ARG—accessory reproductive gland; ns—not significant; ***P<0.001 (*Wilcoxon matched pairs test*)

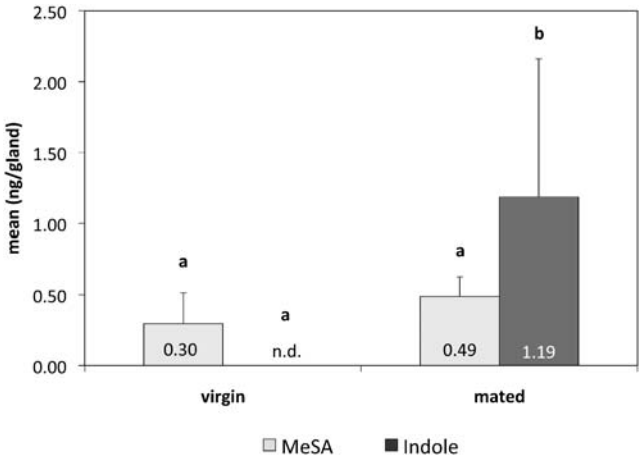

Fig. 3 Quantities of anti-aphrodisiac compounds detected by GC-MS in accessory reproductive gland (ARG) extracts from virgin or mated *Pieris rapae* females. Mean (± s.d.) amount of methyl salicylate (grey columns) and indole (dark grey column) per gland is shown. Number of dissected ARG, N=7 of each treatment. Different letters indicate significant differences in quantity within the same compound between the ARG extracts from virgin and mated females (*Mann-Whitney U test*). Abbreviations: ARG—accessory reproductive gland; MeSA—methyl salicylate; n.d.—not detected

untreated leaf squares from leaves treated with ARG homogenate of virgin females 24 h after treatment. The wasps did not discriminate between the two leaf squares cut from the vicinity of leaf area treated with the ARG homogenate (Fig. 2, P=0.184, *Wilcoxon matched pairs test*). However, 72 h after ARG application, the wasps spent significantly more time on leaf squares taken from plants treated with ARG extract of mated *P. rapae* females than on leaf squares from plants treated with ARG extract of virgin *P. rapae* females (Fig. 2, P<0.001, *Wilcoxon matched pairs test*).

Chemical Composition of ARG Extracts Chemical analysis of ARG secretion of mated females revealed the presence of the anti-aphrodisiac compounds (Andersson et al. 2003), indole and MeSA. In ARG extracts obtained from females 2 days after mating, 1.2±0.97 ng indole and 0.49±0.14 MeSA were detected (Fig. 3). In ARG extracts of virgin females, 0.30±0.22 ng MeSA / ARG was detected, whereas indole was lacking (Fig. 3, P<0.001, *Mann-Whitney U test*).

Arrestment of Trichogramma by Leaves Treated with Indole Untreated leaf squares taken from leaves treated with ARG homogenate from virgin females supplemented with 1.5 ng indole arrested the wasps 72 h after application when tested against untreated leaf squares obtained from leaves treated only with ARG homogenate from virgin females (Fig. 4, P<0.001, *Wilcoxon matched pairs test*). Leaf squares of plants treated with 50 ng indole alone did not arrest the wasps 24 h after treatment (Fig. 4, P=0.134, *Wilcoxon matched pairs test*). Leaf squares of leaves treated with indole 72 h after treatment arrested *T.*

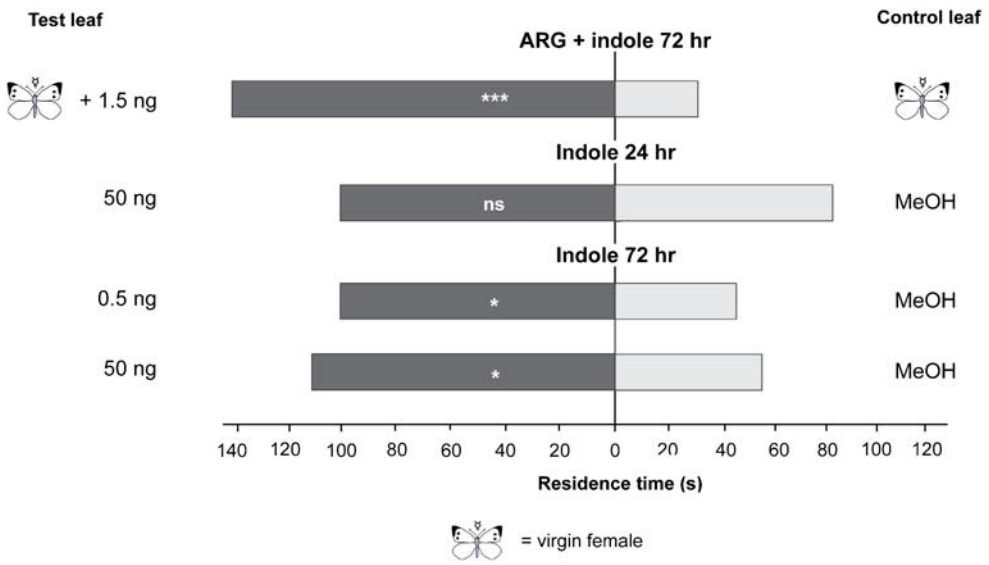

Fig. 4 Mean residence time of *Trichogramma brassicae* females on Brussels sprouts leaves treated with Accessory Reproductive Gland (ARG) homogenate of virgin females and indole or treated with indole alone (amount shown in ng). Test leaves were treated either with ARG extracts from virgin *P. rapae* females and indole or indole alone (dark grey bars) and tested against control leaves treated with ARG extracts from virgin *Pieris rapae* females or methanol only (light grey bars) a) 24 h or b) 72 h prior to the bioassay. Untreated leaf area, adjacent to a site on the same leaf that was treated with ARG homogenate and/or indole was simultaneously offered against leaf squares taken from ARG-homogenate or methanol-treated leaves in a two-choice contact bioassay in a Petri dish. Female wasps per bioassay combination, N= 50. Abbreviations: MeOH—methanol; ARG—accessory reproductive gland; ns—not significant; *P<0.05; ***P<0.001 (*Wilcoxon matched pairs test*)

brassicae wasps when tested against leaf squares of plants treated with solvent only at both tested concentrations (Fig. 4, 0.5 ng: P=0.028; 50 ng: P=0.036, *Wilcoxon matched pairs test*).

Discussion

Our data show that egg deposition of the small cabbage white butterfly, *P. rapae*, induces Brussels sprouts plants such that *T. brassicae* wasps are arrested 72 h after oviposition, whereas plants with eggs deposited 24 or 48 h before testing did not elicit this behavior (Fig. 1). Thus, we demonstrated that butterfly eggs deposited singly and spaced can trigger an indirect plant response similar to that induced by egg batches of herbivorous insects (Meiners and Hilker 2000; Hilker et al. 2002; Colazza et al. 2004a; Fatouros et al. 2005a). Most butterfly species deposit their eggs singly, and these often are cryptically colored. It is assumed that natural selection by predators and parasitoids favors this strategy. Singly laid eggs probably have lower amounts of toxins relative to the often aposematically colored eggs laid in clutches (Stamp 1980). We expected that the induced response of Brussels sprouts plants to eggs of *P. rapae* would be less detectable by *Trichogramma* wasps than the response to *P. brassicae* eggs. This contingency would have been consistent with the findings of Little et al. (2007) who showed that deposition of *P. rapae* eggs on *Arabidopsis thaliana* caused a much weaker transcriptional response of defense- and stress-related genes than did *P. brassicae* egg clutches.

When an extract from accessory reproductive glands (ARGs) of mated female butterflies was applied to plants, the wasps were arrested on treated plants 72 h after ARG treatment, but not after 24 h. This shows that the ARG secretion itself triggered the plant response and not the eggs *per se*. One known function of the ARG is the secretion of adhesive polymers to attach eggs onto the leaf surface (Gillott 2002). The ARG extract from virgin females applied onto the plant arrested the wasps neither 24 nor 72 h after application (Fig. 2). Evidently, compounds derived from the seminal fluid of the male butterfly have changed the composition of the female's ARG, ultimately playing a part in triggering the plant response.

Our evidence indicates that the male anti-aphrodisiac compound, indole, reaches the ARG of a mated *P. rapae* female. No indole was found in the ARG of virgin females (Fig. 3). Subsequently, *T. brassicae* wasps had a significant preference for leaves treated with the ARG of virgin females plus indole over leaves treated with ARG extract from virgin females. The parasitoids' response to leaves treated with indole alone (without ARG extract) 72 h after application was lower but still significant (Fig. 4). Thus, a single compound, which is part of the two-component anti-aphrodisiac blend of *P. rapae* males and transferred with the male ejaculate, is likely to trigger this plant defense in response to egg deposition. Earlier, Doss et al. (2000) showed that esters of long-chain diols (the so-called bruchins) elicit formation of callus tissue in pea pods when certain species of Bruchidae (Coleoptera) oviposit in pods. Our discoveries that anti-aphrodisiac compounds in *Pieris* spp. act similarly as elicitors add to the known instance of this type of effect (Fatouros et al. 2008a).

Interestingly, the anti-aphrodisiac compounds of *Pieris* spp. (BC, MeSA and indole) are ubiquitous phytochemicals produced, for example, as part of herbivore-induced plant volatiles (HIPV) from several plant species; e.g., Lima bean (Dicke et al. 1990; De Boer et al. 2004), tomato (Ament et al. 2004), and maize (D'Alessandro and Turlings 2005). Cultivated *Brassica* species and *Arabidopsis thaliana* emit BC, MeSA, and indole after feeding by *Pieris* caterpillars or after the application of their regurgitant (Geervliet et al. 1997; van Poecke et al. 2001; Smid et al. 2002; Fatouros et al. 2005c). The biological relevance of these HIPV components has been proven for many herbivorous and carnivorous species. Methyl salicylate and indole derivates repel parasitoids of lepidopteran larvae (D'Alessandro et al. 2006; Snoeren 2009) and ovipositing lepidopterans (De Vos et al. 2008; Ulland et al. 2008), whereas predatory arthropods are attracted (De Boer and Dicke 2004; De Boer et al. 2004; James and Price 2004; Ishiwari et al. 2007). In several plant species, the two aromatic compounds, MeSA and indole, are formed via the shikimic acid pathway (Paré and Tumlinson 1997), whereas the nitrile (BC) is a myrosinase-catalyzed hydrolysis product of glucosinolates in Brassicaceae (reviewed by Grubb and Abel 2006; Hopkins et al. 2009). However, in *Pieris*, BC, MeSA, and indole are not plant-derived; rather, males utilize the amino acids phenylalanine and tryptophan as precursors for these anti-aphrodisiac compounds (Andersson et al. 2000, 2003).

The waxy leaf surface of Brussels sprouts plants shows no apparent damage below or around eggs of *Pieris* spp. (see Chapman and Bernays 1989 and references therein; N. E. Fatouros, personal observations). All other studies of indirect plant responses against herbivore oviposition involved wounding by the ovipositing female, leading to emission of volatiles attractive to egg parasitoids (Hilker and Meiners 2006). For examples, eggs of an elm leaf beetle (*Xanthogaleruca luteola*) and a pine sawfly (*Diprion pini)* are laid on the plant surface or into tissue damaged by the egg-laying female prior to oviposition; the oviposition-associated leaf damage in these species may

provide improved attachment to the plant or protection of the eggs by the plant tissue (Meiners and Hilker 1997, 2000; Hilker et al. 2002). Eggs laid by the heteropteran, *Nezara viridula*, induced a volatile synomone for the egg parasitoid *Trissolcus basalis* in two legume species (*Vicia faba* and *Phaseolus vulgaris*), but only when oviposition and host feeding occurred together on the same plant (Colazza et al. 2004a, 2004b). Thus, we assumed that wounding of the leaf surface during or immediately preceding the egg deposition is required to induce volatile long-range cues that attract the egg parasitoids (Fatouros et al. 2005b). Yet, evidence is accumulating that in other *Brassica* species that carry less surface waxes, *Pieris* egg deposition induces volatile emissions attractive to *Trichogramma* wasps (N. E. Fatouros, unpublished data). Differences in the physical structure and/or chemical composition of the plant cuticle could play an important role in the adsorption and/or absorption of molecules into leaf cells, thus triggering certain pathways involved in plant defense against herbivores. Leaf wax microstructure and chemical composition affect herbivores, and also indirectly influence their predators and parasitoids (Eigenbrode and Espelie 1995). For example, an increased surface wax layer has been found to confer higher resistance to herbivores (see Müller and Riederer 2005 and references therein).

Egg-free leaf parts of plants on which eggs had been deposited elsewhere 6 h before testing did arrest *T. brassicae* wasps. This arrestment is probably due to host residues, such as wing scales, as Fatouros et al. (2005a) showed that *T. brassicae* responded to *P. brassicae* egg-free leaves contaminated with butterfly deposits for 24 h; however, the response disappeared after 72 h. Scales and other chemical traces of host insects frequently are used as kairomones by egg parasitoids (reviewed by Fatouros et al. 2008b). The wings of *Pieris* butterflies emit chemical cues, some of which have pheromonal activity (Arsene et al. 2002; Andersson et al. 2007). The aphrodisiacs from male scent scales of *P. rapae* and *P. brassicae* (two macrolides) recently have been identified (Yildizhan et al. 2009). Whether these macrolides arrest wasps on leaves with eggs younger than 24 h remains to be tested.

Sexual signals produced that attract mates (or that repel the competing sex as in the case of anti-aphrodisiac pheromones) potentially incur trade-offs associated with their use as kairomones by natural enemies (Stowe et al. 1995; Zuk and Kolluru 1998; Fatouros et al. 2008b . It is assumed that female sex pheromones are rarely exploited because of their high specificity, low intensity, and emission in enemy-free space and time (Zuk and Kolluru 1998). However, an increasing number of studies have shown that egg parasitoids in particular exploit adult host sex pheromones (Fatouros et al. 2008b). In contrast to sex pheromones, the release of anti-aphrodisiacs is unlikely to be under female control (Andersson et al. 2004). There should be enough time for egg parasitoids to detect and approach a mated female, in contrast to a virgin, to successfully parasitize fertilized host eggs. By triggering parasitoid-attracting plant cues, the anti-aphrodisiac compounds incur an additional cost of mating, namely, increased egg mortality and lower butterfly fitness. We postulate, therefore, that the evolution of anti-aphrodisiac compounds transferred during copulation by the males is selected against by *Trichogramma* wasps.

we trapped 86,471 subcortical insects (143 species) in baited and unbaited Lindgren funnel traps, and 500 beetles (44 species) in baited and unbaited pitfall traps. We report 23 new state collection records of subcortical insects from Minnesota. Trap catches of subcortical insects were greatest in the wind-disturbed areas 2 years after the event, and declined thereafter. Similar trends were observed for subcortical insects in the burned areas. Both wind-disturbance and burning increased the subcortical insect species richness and diversity on the landscape. The subcortical insect species compositions of the salvaged and burned forest areas differed from those of the undisturbed and wind-disturbed areas. Trap catches of subcortical insects in response to semiochemical treatments also varied with year of sampling and land-area treatment. The greatest diversity of subcortical beetle species was in traps baited with attractants for the scolytids, *Dendroctonus valens* [(+)-α-pinene and (−)-β-pinene] and *Dryocoetes* spp. [*exo*-brevicomin and (−)-α-pinene], perhaps reflecting the generic nature of the baits. The most distinct species compositions were collected in response to the woodborer and *Dendroctonus simplex* baits, whereas the species compositions in traps with the *D. valens* and *Dryocoetes* spp. baits, and the unbaited funnel trap were the most similar. The variation in trap catch with time and across landscapes suggests that the responses of subcortical insects to semiochemicals are more complex than previously appreciated.

Introduction

On 4 July 1999, a catastrophic storm with wind derechos (straight-line winds with multiple downbursts) of over 145 km hr^{-1} in the Superior National Forest (in northeastern Minnesota, USA) resulted in the wind-throw of over 193,000 ha of forestland (USDA Forest Service 2000). This long-duration and extensive wind storm originated in North Dakota, lasted less than 24 h, and traveled over 2,100 km from northern Minnesota into southern Ontario and Quebec, and northern New Hampshire, Vermont, and Maine (NOAA 2005). In Minnesota, over 85% of the most severe damage (areas with 67–100% tree mortality) occurred in the Boundary Waters Canoe Area Wilderness (BWCAW), where no forest management activity is permitted (see maps in Gandhi et al. 2005). Some damage also occurred along the Gunflint Trail Corridor, which is a heavily transited entry into the BWCAW and an access route to numerous vacation homes and service structures. Such a catastrophic storm was unique both in its extent (193,000 ha), scale of damage (>70% tree mortality in most areas), and long-interval duration (once every 1,000 yr) (Frelich and Lorimer 1991; USDA Forest Service 2000). With dead and downed trees (fuel loads) exceeding 16,000 kg/ha in some of the wind-disturbed areas (Gilmore et al. 2003), there was a strong potential for the occurrence of other natural disturbances such as wildfire, and insect and disease outbreaks. In 1999–2002, in response to these threats to remaining forest stands in this area, the USDA Forest Service reduced the fuel load along the Gunflint Trail Corridor through: (1) salvage-logging (1,100 ha), and (2) prescribed-burning (860 ha).

Subcortical (phloeophagous, xylophagous, and rhizophagous) forest insects are the first to colonize, reproduce, and increase populations in wind-disturbed forested landscapes (Connola et al. 1956; Gardiner 1975; Ayres et al. 1999). These early-successional species colonize the phloem and outer xylem of the tree tissue before it has desiccated completely (Gandhi et al. 2007). In wind-damaged forests, habitats for these species typically include uprooted trees; fallen branches and tree parts (slash); partially damaged, moribund, and living standing trees; and undamaged residual trees [collectively known as coarse-woody debris (CWD)]. Weakened, moribund, and undamaged residual standing trees, which die as a consequence of the aftermath of the storm, provide additional subcortical insect habitat for several years after the wind disturbance. The condition of CWD changes with time due to fermentation of xylem, decay of phloem, bark slough-off, breakage of stems and branches, and accumulation of additional CWD on the forest floor. The diversity and abundance of CWD created by a wind-disturbance provides excellent habitat for subcortical insects, and there is a temporal progression of species that exploit CWD with fresh phloem through those that exploit CWD with drying or decaying xylem. A large number of predators and parasites also are associated with subcortical herbivorous insects (Dahlsten 1970; Ryall 2003). Thus, as the amounts and characteristics of CWD change over time (Ryall and Smith 2005; Wilson and McComb 2005), there will be changes and turnover of associated subcortical insect communities (Weiss 1920; Blackman and Stage 1924; Savely 1939; Wallace 1953).

Historically, through rearing and collecting, workers have described the guilds of subcortical insects associated

with trees such as basswood, *Tilia americana* L. (Townsend 1886); tamarack, *Larix laricina* (Du Roi) K. Koch (Blackman and Stage 1918); shagbark hickory, *Carya ovata* (P. Mill.) K. Koch (Blackman and Stage 1924); shortleaf pine, *Pinus echinata* Mill, loblolly pine, *Pinus taeda* L., white oak, *Quercus alba* L., northern red oak, *Q. rubra* L., southern red oak, *Q. falcata* Michx., black oak, *Q. velutina* Lam., and post oak, *Q. stellata* Wangenh. (Savely 1939); and Scots pine, *Pinus sylvestris* L. (Wallace 1953). More recently, such community level taxonomic characterizations in North America have included insects associated with aspen, *Populus* spp. (Hammond 1997; Hammond et al. 2001); butternut, *Juglans cinerea* L. (Katovich and Ostry 1998); Douglas-fir, *Pseudotsuga menziesii* (Mirbel) Franco, hemlock, *Tsuga* spp. (Endlicher) Carrière, and lodgepole pine, *Pinus contorta latifolia* (Engelmann) Critchfield (Deyrup and Gara 1978); elms, *Ulmus* spp. L. (Hajek and Dahlsten 1985); loblolly and shortleaf pines, *Pinus taeda* and *P. echinata* (Dixon and Payne 1979; Berisford 1980); Monterey pine, *Pinus radiata* D. Don (Ohmart 1981; Ohmart and Voigt 1982); ponderosa pine, *Pinus ponderosa* Laws. (Dahlsten 1970; Stephen and Dahlsten 1976a, b); red pine, *Pinus resinosa* Ait. (Aukema and Raffa 2000, 2005; Aukema et al. 2000a, b, 2004, 2005; Erbilgin and Raffa 2001; Erbilgin et al. 2003); sugar pine, *Pinus lambertiana* Dougl. (Dahlsten and Stephen 1974); and white spruce, *Picea glauca* (Moench) Voss (Whitmore 1982; Gara et al. 1995; Haberkern et al. 2002). In Europe, community level work on subcortical forest insects also has been conducted in beech, *Fagus sylvatica* L. (Schiegg 2001); Norway spruce, *Picea abies* (L.) Karst, and *Pinus sylvestris* (Kaila et al. 1997); and subalpine spruce forests (Wermelinger et al. 2002, 2003; Joensuu et al. 2008).

Semiochemicals are being used increasingly to assess forest insect conservation biology and biodiversity (Svensson et al. 2004; Tolasch et al. 2007; Svensson and Larsson 2008; Larsson and Svensson 2009), and flight traps (with or without lures) are replacing hand collecting or rearing to assess the biodiversity and community ecology of subcortical insects (Ranius and Jansson 2002). Flight and pitfall traps baited with semiochemicals, such as aggregation pheromones and kairomones (Wood 1982a; Chénier and Philogène 1989), also can be used to monitor the diversity and population abundance of early successional subcortical insects following ecological disturbances (Werner 2002). In fact, semiochemicals have been a research and management tool for bark beetles for over 40 years (Wood et al. 1968), especially in western North American forests where these beetles can be devastating (Bedard and Wood 1981; Negrón et al. 2008). In many cases, semiochemicals were first identified from western North American bark beetle species (Silverstein et al. 1966, 1967; Wood et al. 1967; Furniss et al. 1972; Baker et al. 1977; Birch et al. 1980; Bowers et al. 1991; Hobson et al. 1993; Borden et al. 1996; Camacho et al. 1998; Holsten et al. 2000), and baits in other regions of the continent often are based on these research results. In addition to targeting specific species, semiochemicals also can be used to assess the diversity of predators and commensals that exploit the attractants of subcortical insects as host-finding kairomones (Dixon and Payne 1980; Phillips et al. 1988; Chénier and Philogène 1989; Seybold et al. 1992; Aukema and Raffa 2000, 2005; Erbilgin and Raffa 2001).

Presently, little is known about semiochemicals of subcortical insects and their associates in the sub-boreal forests of north-central North America. Studies on the semiochemicals of forest insects across different stand types within a landscape (such as the BWCAW) or over multiple field seasons are rare. Most semiochemical studies have been conducted over only one or two summers, either within relatively homogenous stands (e.g., single species pine stands of similar ages) (Miller and Borden 2003) or concurrently during one season across wide geographic areas (Miller et al. 1997). Finally, few studies have explored the full range of subcortical forest insects by using traps baited with semiochemicals. Most semiochemical studies have focused on either single subcortical species (e.g., Bedard et al. 1980; Borden et al. 1996); their associated predators (e.g., Seybold et al. 1992; Erbilgin and Raffa 2001); or on a small subset of subcortical insect families (e.g., Phillips et al. 1988; Chénier and Philogène 1989; Miller and Rabaglia 2009).

We studied the responses of phloeophagous, xylophagous, and rhizophagous insects and their associates to semiochemical treatments in the context of an ecological disturbance, the severe wind-disturbance event and subsequent management activities in a northeastern Minnesota sub-boreal forest. We targeted Buprestidae, Cerambycidae, and Scolytidae because they are the most economically important subcortical taxa, are early colonizers of CWD, and are crucial to CWD breakdown and nutrient cycling (Craighead et al. 1927; Craighead 1950; Furniss and Carolin 1977; Jacobs 2004). Among the primary subcortical insects, these taxa are the most species-rich and numerically abundant in sub-boreal forests (Dodge 1938; Bright 1976, 1987; Downie and Arnett 1996; Yanega 1996). Our specific research objectives were: 1) to test the efficacy of various known semiochemical treatments to monitor subcortical insects in a sub-boreal forest; and 2) to use trap-catch to document population responses of subcortical insects to a severe wind-disturbance event (>70% tree mortality) and fuel-reduction (salvaging and burning) treatments. We studied these subcortical insects for 4 years because we hypothesized that populations and assemblages of subcortical beetles would track the changing conditions of the CWD in the disturbed stands (Jacobs 2004).

Methods and Materials

Study Sites Subcortical insects and their associates were sampled from 28 sites in the BWCAW, and along the Gunflint Trail Corridor in the Superior National Forest in Cook County, MN, USA (Gandhi 2005; Gandhi et al. 2008). Mean annual temperature of the region is 1–2°C (Baker and Strub 1965), and mean annual precipitation is 65–75 cm (Baker and Kuehnast 1978). This area is located in the Laurentian mixed forest ecological province, northern Superior uplands section, and border lakes subsection of Minnesota (Minnesota Department of Natural Resources 1999). Soils along the Gunflint Trail have been classified primarily as the soil orders Inceptisols and Entisols (Anderson et al. 2001); major cover types in this area are aspen/birch/conifer (ABC) and jack pine, *Pinus banksiana* Lamb. (JP) (Table 1). In general, the ABC sites are on deeper, moist, well-drained till, outwash and lacustrine deposits, and loamy Entisols [Land Type Associations (LTA) 14, 22, 23, 37], whereas the JP sites are on shallow, well-drained till and outwash deposits, and sandy Inceptisols (LTA 21, 23) (USDA Forest Service 2000). The ABC forests originated after clear-cutting, whereas the JP forests originated after a wildfire (M. Theimer, personal communication, USDA Forest Service, Superior National Forest). Forest overstory of the ABC type is composed of trembling aspen, *Populus tremuloides* Michx., paper birch, *Betula papyrifera* Marsh., eastern white pine, *P. strobus* L., red pine, *P. resinosa*, black spruce, *Picea mariana* (P. Mill.) B. S.P., white spruce, *P. glauca*, balsam fir, *Abies balsamea* (L.) P. Mill., northern white cedar, *Thuja occidentalis* L., and tamarack, *L. laricina*. Forest overstory of the JP type is composed of jack pine, *P. banksiana*, and *B. papyrifera*. Adjoining and low-lying areas often contained *L. laricina* and *T. occidentalis* in riparian habitats. Forest understory of the two cover types is characterized by *Corylus cornuta* Marsh., *Vaccinium* spp., *P. tremuloides*, *A. balsamea*, and *P. glauca* (Gilmore et al. 2002, 2005; Johnson 2004).

Table 1 Attributes of tree species in two forest cover types in the study plots in the Superior National Forest, Cook Co., MN, USA

Stand Attributes[a]	Aspen/ Birch/ Conifer[b]	Jack Pine[b]
Soil pH	5.31±0.05	5.02±0.07
Mean Age (years)	71.33±3.62	75.29±1.64
Total Basal Area (m^2/ha)	22.10±8.24	25.37±6.70
Basal Area (m^2/ha) by Species		
Aspen, *Populus tremuloides* Michx.	10.95±2.98	2.33±1.50
Jack Pine, *Pinus banksiana* Lamb.	2.50±1.85	18.17±2.60
Balsam Fir, *Abies balsamea* (L.) P. Mill.	2.18±0.4	0.67±0.33
Paper Birch, *Betula papyrifera* Marsh.	5.12±2.23	0.83±0.37
Black Spruce, *Picea mariana* (P. Mill.) B.S.P.	1.35±0.78	3.37±1.90

Experimental Design

Land-Area Treatments During the summer of 2000, we sampled from study sites in the ABC and JP forest cover types, whereas during the summers of 2001–2003, only JP sites were sampled for logistical reasons and because results in 2000 suggested that JP sites had the greatest subcortical insect diversity. In 2000, mature *P. tremuloides* and *Pinus banksiana* trees on these sites had mean ages of 71 years and 73 years, respectively. In 2000, we sampled two sites (replicates) for each of three treatment types [(1) undisturbed forests (control); (2) severely wind-disturbed forests (>70% tree mortality); and (3) wind-disturbed-salvage-logged (salvaged) forests] in each of the two (ABC and JP) cover types for a total of 12 sites. In 2001–2003, we sampled four sites (replicates) for each of the four treatment types [(1) undisturbed, (2) severely wind-disturbed, (3) salvaged, and (4) wind-disturbed-prescribed-burned (burned) forests] in the JP cover type for a total of 16 sites (Gandhi 2005; Gandhi et al. 2008). The wind-disturbed sites were salvaged between the summer of 1999 and the spring of 2000, and burned between the fall of 2000 and the spring of 2001 (Gandhi 2005; Gandhi et al. 2008). The sites were 2–3 ha in size, and located at least 500 m (and often greater distances) away from each other. Salvaging entailed removal of all merchantable and damaged trees except for standing live *P. resinosa*, *P. strobus*, and *T. occidentalis* (USDA Forest Service 2000).

Semiochemical Treatments: Baited Pitfall Traps Rhizophagous insects and their associates were caught with baited pitfall traps that consisted of a 500 ml round plastic container (10.7 cm i.d.) inside a 1.0 l plastic liner buried in the ground (Spence and Niemelä 1994). Propylene glycol (200 ml; recreational vehicle antifreeze, Peak Co., Northbrook, IL, USA) in the plastic container served as killing agent and preservative for trapped beetles (Weeks and McIntyre 1997). The trap was covered with a 100 cm^2 plywood board suspended 4 cm above the trap to minimize flooding and disturbance by animals. Baits were hung from the plywood board and placed inside the inner cup above the level of propylene glycol. Baits included 4 host attractant solutions: 2% (−)-α-pinene, 2% (+)-α-pinene, 2% (−)-β-pinene (in ethanol), and a 100% ethanol control. The pinenes were purchased from Sigma Aldrich (St. Louis, MO, USA), and all had chemical purities of ≥99% and enantiomeric purities of >98%. The ethanol was

purchased from Aaper Alcohol Co. (Shelbyville, KY, USA).

During the summer of 2000, a total of 144 baited pitfall traps were installed in the ABC and JP cover types. There were 12 baited pitfall traps per site with three replicates of each bait treatment placed on a 6 by 2 grid, and separated by >20 m to reduce trap sampling interactions. The 12 traps were each baited with one of the four semiochemical blends. Semiochemical blends were released from wicks inserted in full 15 ml glass vials. When traps were emptied, the location of the trap and its semiochemical bait were not re-randomized within the site, and the baits were not replaced during the summer. In 2000, traps were operated from August to October and emptied every 15–30 d. For logistical reasons, the study was not initiated until August; for biological reasons, May would have been preferable.

During the summers of 2001–2003, the sampling design was changed to include 80 traps distributed over 16 sites, all located in the JP cover type. At each site, 5 pitfall traps baited with the 4 semiochemical blends in ethanol, ethanol alone, and an unbaited control were assigned to 5 sample sub-plots randomly drawn from a grid of 28 sub-plots. When the traps were emptied, the inner cups and the associated baits were re-randomized on the 5 outer cup locations (i.e., among the 5 sub-plots). In 2001 and 2002, the semiochemical blends were released from closed polyethylene bottles at an unknown low release rate (15 ml total volume) [Phero Tech. (now Contech Enterprises) Inc., Delta, BC, Canada]. In 2003, semiochemical blends were released from these polyethylene bottles with a 0.13 cm^2 hole in the side of the vial cap. The mean (± SE) release rates for 15 d in the field for each of the semiochemical blends in 2003 were as follows: (1) (−)-α-pinene: 7.98±0.23 g; (2) (+)-α-pinene: 7.64±0.26 g; (3) (−)-β-pinene: 7.24±0.20 g; and (4) 100% ethanol: 7.48± 0.20 g. Baiting started in May, and baits were replaced in July in 2001 and 2002, and every 2 wk in 2003. In 2001–2003, traps were deployed from May to October and emptied every 15–20 d.

Semiochemical Treatments: Lindgren Funnel Traps Subcortical insects were caught in flight with 16-unit Lindgren funnel traps (Lindgren 1983). The traps were baited on the 8th funnel from the top with semiochemicals that were chosen to elicit responses from the major species of scolytid and woodboring beetles known to be present in this subboreal forest (Dodge 1938; Bright 1976; University of Minnesota Insect Collection (UMIC), St. Paul, MN; K.J.K.G., personal observation) (Table 2). The selection of many of the semiochemicals was based on research data accumulated on populations of scolytid and woodboring beetles from western North America (Table 2). A bait for the spruce beetle, *Dendroctonus rufipennis* (Kirby) was employed initially in 2000 and 2001 in anticipation of potential population increases of this species, but because we trapped far more individuals of the eastern larch beetle, *Dendroctonus simplex* LeConte than *D. rufipennis* in response to this bait, we used a different bait targeting *D. simplex* in 2002 and 2003 (see Discussion for further explanation). During the summer of 2000, a total of 324 funnel traps were installed in the ABC and JP forest cover types. Twenty seven funnel traps were hung on 2.2 m tall iron rebar poles in each site so that the trap collection cup was approximately 0.1 m above the forest floor. The traps were placed on a 7 by 4 grid, separated by >20 m, and were >20 m from forest edges. Traps were each baited with 1 of 8 semiochemical blends, or left unbaited (3 replicates of each semiochemical treatment and control at each site). The collection cup of each trap contained a 4 cm^2 Dicholorvos-impregnated plastic strip to kill insects. When traps were emptied, the location of the trap and its semiochemical bait were not re-randomized within the site. In 2000, traps were deployed from August to October and emptied every 15–30 d.

During the summer of 2001, the sampling design was altered to include 160 traps distributed over 16 sites located only in the JP cover type. At each site, 10 funnel traps (baited with 9 semiochemical combinations and an unbaited control) were assigned to 10 sample sub-plots randomly drawn from a grid of 28 sub-plots. During the summers of 2002–2003, the sampling design was altered further to include 176 traps distributed over 16 sites in the JP cover type. At each site, 11 funnel traps (baited with 10 semiochemicals and an unbaited control) were assigned to 11 sample sub-plots randomly drawn from a grid of 28 sub-plots. Semiochemical treatments were altered among years 2000, 2001, and 2002–2003 after assessing the trapping efficacy of the baits. Semiochemical baits were replaced each year in July or August. In 2001–2003, when traps were emptied every 15–20 d, the location of the trap and its semiochemical bait were re-randomized among the 10 or 11 sub-plots. In 2001–2003, traps were deployed from May to October and emptied every 15–20 d.

Adult subcortical insects were identified by K.J.K.G. with taxonomic keys (Middlekauff 1960; Linsley 1962a, b, 1963, 1964; Linsley and Chemsak 1972; Nelson 1975; Bright 1976, 1987; Wood 1982b, Triplehorn 1990; Goulet 1992; Chemsak 1996; Downie and Arnett 1996; Yanega 1996; Kovarick and Caterino 2001; Bellamy and Nelson 2002; Optiz 2002; Pollack 2002; Thomas 2002; Turnbow and Thomas 2002) and with the assistance of systematists. Specifically, reference collections of buprestid, cerambycid, clerid, histerid, scolytid, and tenebrionid beetles and siricid wasps were verified by C. Bellamy (California Department of Food and Agriculture, Sacramento) and G. Nelson (College of Osteopathic Medicine, Kansas City, deceased);

Table 2 List of semiochemicals used to target subcortical beetle species in Lindgren funnel traps in 2000–2003, Superior National Forest, Cook Co., MN, USA[a]

Target Beetle Species or Families	Semiochemical	Enantiomeric Composition	Load (mg)	Release rate/d	Chemical Purity (%)
Ips grandicollis[b]	Ipsenol[c]	97%-(−)	20	240 µg[d]	97
	α-Pinene[e]	98.5%-(−)	6,413	200–300 mg[d]	99
Ips perroti[b]	Ipsenol[c]	97%-(−)	20	240 µg[d]	97
	Ipsdienol[c]	97%-(−)	20	110 µg[d]	93

J. Chemsak (University of California, Berkeley, deceased) and D. Penrose (California Department of Food and Agriculture, Sacramento); W. Barr (University of Idaho, retired) and J. Rifkind (private collector, Valley Village, California); Y. Bousquet (Agriculture Canada, Ottawa); D. Bright (Agriculture Canada, Ottawa, retired); C. Triplehorn (Ohio State University, retired); and J. Luhman (Minnesota Department of Food and Agriculture, St. Paul), respectively. All curculionid beetles were identified by S.J.K (University of Wisconsin) and D. Langor (Canadian Forest Service, Edmonton) (Blatchley and Leng 1916; Kissinger 1964; Fridrich 1965; Warner 1966; Salsbury 2000). Voucher specimens have been deposited at the UMIC, St. Paul, MN and the California Academy of Sciences, San Francisco, CA. The UMIC was also examined during this study for specimens of potential new state record insects that had not been recorded previously in the literature.

Data Handling and Statistical Analyses

Pitfall Traps Since only 500 beetles were caught in the pitfall traps during the summers of 2000–2003, no statistical analyses were performed. Instead, species-lists with a brief interpretation of trends are provided. Such small catches may represent either the inadequacy of the traps or baits or small population sizes in the forest stands.

Funnel Traps: Subcortical Insect Trap Catches Trap catches of early successional subcortical insects (=subcortical insects) were standardized to 15-d intervals [(trap catch/ total number of days that trap was operational) X 15] as the traps were emptied approximately every 2 wk. This standardization accounted for the variable number of days when the traps were operational in the plots. If funnel traps were disturbed for a particular period, catches from that period were excluded from analyses. For data collected in 2000, trap catches were pooled for all subcortical insects over the season, and three-factor analyses of variance (ANOVA) were performed first with the cover type, land-area treatment, and semiochemical treatment as factors (SAS 1999–2001). Data were checked for the required assumptions of constant variance and normality using residual and normality plots. A Goodness-of-Fit test for normal distribution (Kolmogorov-Smirnov) was conducted on the residuals to test the null hypothesis that the data were normally distributed. Data for standardized subcortical insect catches showed non-normality, and were transformed by ln (x+1), which resulted in normally distributed data. Type III Sum of Squares were used to assess the statistical significance of factors at α=0.05. The ANOVA was performed in an iterative manner in which the complete model was analyzed by successive deletions of non-significant higher-order interaction terms, two-way interaction terms, and main factors. The final model terms that were significant are presented in the tables, and all terms that were omitted as a consequence of the iterative procedure are listed as non-significant (NS). The Ryan-Einot-Gabriel-Welsch (REGW) test with α=0.05 was used for pairwise comparisons among treatment means (Day and Quinn 1989). All data were back-transformed before presentation.

For data collected in 2001–2003, split-plot analyses of variance tests were performed for: 1) all subcortical insects species combined; 2) subcortical insect families with ≥10% of total catch; and 3) subcortical insect species with ≥1% of the total beetle catch by using the PROC MIXED option (SAS 1999–2001). Split-plot analyses were performed because the traps were re-randomized every 15 d; the whole plot factor was the land-area treatment and the two split-plot factors were semiochemical treatment and year. The split-plot analysis of variance test for all subcortical insect species combined was also performed as described above, but excluding the trap catch of the most abundant subcortical insect species. This test was performed to assess the effect of the most abundant species on the total trap catches.

To determine if the responses of males and females of the four most abundant scolytid species were dependent upon the land-area treatment, selected semiochemical treatments, and year (2001–2003), a three- or a two-way ANOVA was performed on the standardized percentage of males trapped in funnel traps. These four species also were relatively easy to separate by sex. To assemble this data set, we determined the sex of 1,937 adults of *D. simplex*, 2,684 *I. grandicollis*, 7,442 *I. perroti*, and 8,811 *I. pini*. Trap catches with <10 individuals were excluded from these analyses because of the bias in sex ratio from small samples.

Funnel Traps: Subcortical Insect Species Richness Venn diagrams were used to illustrate relationships of species richness (total number of early successional species) among the ABC and JP cover types, and the land-area treatments. In the diagrams, each habitat set is represented by a circle that contains the unique numbers of species; overlapping areas depict numbers of insect species held in common with other cover type and land-area treatment combinations (Langbehn et al. 1972). Venn diagrams were constructed for species richness as follows: 1) 2000 funnel trap catches in the ABC (Fig. 4a) and JP (Fig. 4b) cover types in the three land-area treatments; and 2) 2001–2003 funnel trap catches (pooled over all three seasons) in the JP cover type in the four land-area treatments.

Funnel Traps: Subcortical Insect Species Diversity Two methods (rarefaction and Simpson's diversity index) were used to assess subcortical insect species diversity in funnel trap catches in relationship to the cover type, land-area

treatment, and semiochemical treatment. Rarefaction indices estimate the mean (± SE) subcortical insect species diversity (richness and evenness); the technique accounts for differences in trapping effort among habitats and is ideal for catches with variable trapping intervals (Magurran 2004; software developed by Holland 2003). Rarefaction analyses were performed on the following subcortical insect assemblages: 1) 2000 funnel trap catches in the ABC and JP cover types; 2) 2001–2003 funnel trap catches in 4 land-area treatments in the JP cover type; 3) 2000 funnel trap catches with 9 semiochemical treatments (including unbaited control) in the ABC and JP cover types; and 4) 2001–2003 funnel trap catches with 12 (including unbaited control) semiochemical treatments in the JP cover type.

Simpson's diversity index was used to assess species diversity and dominance for land-area and semiochemical treatments (Magurran 2004). The measure was expressed as "diversity" rather than "dominance" to ensure that species diversity increased and dominance decreased with an increasing index value (McCune and Mefford 1999; McCune and Grace 2002).

Funnel Traps: Subcortical Insect Species Composition Subcortical insect species compositions for each land-area treatment, year, and semiochemical treatment for JP stands in 2001–2003 were compared by constructing dendrograms with a similarity percentage scale that was generated by cluster analysis. In this clustering technique, standardized mean funnel trap catches within each treatment-type were analyzed by using the Bray-Curtis Distance method with the group average option (McCune and Mefford 1999; McCune and Grace 2002).

Results

Pitfall Trap Sampling During the summers of 2000–2003, 1,828 pitfall trap samples yielded 500 rhizophagous beetle adults representing 5 families, 34 genera, and 44 species (Supplemental Data Table 1). In 2000, only one species [*Dryocoetes autographus* (Ratzeburg) (Scolytidae)] was trapped in the ABC cover type. In the JP cover type, Curculionidae (73% of the total catch) was the most abundant family followed by Scolytidae (19%), and Cerambycidae (7%). Within each of these respective families, *Hylobius pales* (Herbst) (27%), *Hylurgops rugipennis pinifex* (Fitch) (8%), and *Stictoleptura canadensis canadensis* (Olivier) (2%) were the most abundant. Overall, *H. pales* (27%), *Hylobius radicis* Buchanan (16%), and *Otiorhynchus ovatus* (Linnaeus) (9%) (all Curculionidae) were the most abundant beetle species. Thirty-two rhizophagous beetle species were rare and represented ≤1% of the total beetle catch; ten rhizophagous beetle species were common and represented 1–10% of total beetle catch; and two rhizophagous beetle species were abundant and represented >10% of the total beetle catch. *Otiorhynchus ovatus* and *Polydrusus sericeus* (Schaller) are exotic species from Europe. Several species of bark beetles [e.g., *Ips grandicollis* (Eichhoff), *Ips pini* (Say), *Dr. autographus*, *Polygraphus rufipennis* (Kirby), and *Dendroctonus simplex* LeConte] generally not associated with the forest floor were caught in these traps.

In 2000–2003, 42% of the beetles were caught in the burned sites followed by lower percentages in the undisturbed (21%), salvaged (21%), and wind-disturbed (16%) sites. The species richness was also highest in the burned sites (26 species). Most of the rhizophagous beetles were caught in the traps baited with ethanol solutions of (+)-α-pinene (33%) followed by traps baited with (−)-α-pinene (26%), (−)-β-pinene (23%), ethanol (11%), and unbaited traps (7%) (Supplemental Data Table 2). The species richness (23 species) was also highest in the traps baited with ethanol solutions of (+)-α-pinene.

Funnel Trap Sampling During the summers of 2000–2003, 3,975 funnel trap samples yielded a total of 86,471 subcortical insect adults representing 12 families, 96 genera, and 143 species (Supplemental Data Tables 3, 4). The majority of subcortical insect species (126) were rare (i.e., each represented ≤1% of the total insect catch), 14 subcortical insect species were common (i.e., each represented 1–10% of the total insect catch), and three subcortical insect species were abundant (i.e., each represented >10% of the total insect catch).

Scolytidae (55% of the total catch) was the most abundant family followed by Cleridae (18%), Buprestidae (13%), and Cerambycidae (10%). Other families such as Anthribidae, Cucujidae, Curculionidae, Histeridae, Nemonchyidae, Salpingidae, Siricidae, and Tenebrionidae each represented <5% of the total catch. Within their respective families, *D. simplex* (35%) (Scolytidae), *Thanasimus dubius* (Fabricius) (65%) (Cleridae), *Buprestis maculativentris* Say (10%) (Buprestidae), and *Monochamus scutellatus scutellatus* (Say) (25%) (Cerambycidae) were the most abundant species. Overall, *D. simplex* (19%) was the most abundant beetle species followed by *T. dubius* (12%), and *I. pini* (10%).

Among families, cerambycid beetles had the greatest species diversity (43 species) followed by curculionid (34 species), scolytid (24 species), and buprestid (21 species) beetles. We also caught 10 species of clerid beetles and 5 species of siricid woodwasps. Among buprestid beetles, *Chrysobothris sexsignata* (Say), *Cypriacis striata* (Fabricius), *Cypriacis sulcicollis* (LeConte), *Phaenops aeneola* (Melsheimer), and *Phaenops drummondi drummondi* (Kirby) are new state records (Downie and Arnett 1996).

Among cerambycid beetles, *Pygoleptura nigrella nigrella* (Say) and *Xestoleptura tibialis* (LeConte) are new state records (Linsley 1962a, b, 1963, 1964; Linsley and Chemsak 1972; Downie and Arnett 1996; Yanega 1996). Among clerid beetles, *Enoclerus muttkowski* (Wolcott), *Enoclerus nigripes rufiventris* (Spinola), *Madoniella dislocatus* (Say), *Thanasimus trifasciatus* (Say), *Thanasimus nubilus* (Klug), *Thanasimus undatulus undatulus* (Say), *Trichodes nutalli* (Kirby), and *Zenodosus sanguineus* (Say) are new state records (Downie and Arnett 1996). Katovich and Ostry (1998) reported that *Z. sanguineus* was collected on the bark of butternut, *Juglans cinerea*, but it was not clear whether the species was collected from Wisconsin or Minnesota. Among histerid beetles, *Paromalus teres* LeConte, *Platysoma coarctatum* LeConte, *Platysoma deficiens* Casey, and *Platysoma lecontei* (Marseul) are new state records (Downie and Arnett 1996). Among salpingid beetles, *Boros unicolor* Say is a new state record (Downie and Arnett 1996), whereas among scolytid beetles, *Ips latidens* (LeConte) is a new regional record for the Great Lakes region in the USA (Dodge 1938; Wood 1982b; Downie and Arnett 1996). Among siricid wasps, *Sirex behrensii* (Cresson), *Urocerus gigas flavicornis* (Fabricius), and *Xeris spectrum* (Linnaeus) are new state records (Smith and Schiff 2002). Among these new records, *C. sulcicollis*, *P. aeneola, E. muttkowski*, *E. n. rufiventris, T. trifasciatus, I. latidens,* and *S. behrensii* were not present in the University of Minnesota Insect Collection, whereas the rest of the species had been collected previously from Minnesota and deposited in the museum, but not reported in the literature (Supplemental Data Table 5).

Subcortical Insect Trap Catches The three-way ANOVA for pooled trap catches of all subcortical insect species for the year 2000 showed that cover type, land-area treatment, and semiochemical treatment were significant main effects in the model (Table 3, Fig. 1). Thirty five percent more subcortical insects were caught in the JP than in the ABC cover type (Fig. 1a). Across both cover types significantly more (20–34%) insects were caught in the salvaged than in the undisturbed and wind-disturbed forests (Fig. 1a). Significantly more subcortical insects of all taxa were caught in response to the *I. pini* bait than to the other baits (Fig. 1b), and significantly more (478–559%) insects were caught in response to the *Dendroctonus rufipennis*, *I. grandicollis*, and *I. perturbatus* (Eichhoff) baits than to the unbaited traps (Fig. 1b).

For all subcortical insect species for 2001–2003, there were significant interactions between year and land-area treatment, and between year and semiochemical treatment (Table 3, Supplemental Data Fig. 1). In general, trap catches were up to 2.5 times greater in 2001 and 2002 than in 2003, except in the undisturbed forests. In 2002, the *D. simplex* bait caught more beetles than the rest of the bait-types. In 2001–2003, fifteen subcortical beetle species in order of decreasing catches from funnel traps included *D. simplex*, *T. dubius*, *I. pini*, *I. perroti*, *I. perturbatus*, *B. maculativentris*, *I. grandicollis*, *T. u. undatulus*, *T. nubilus*, *Monochamus s. scutellatus*, *M. mutator* LeConte, *Dr. autographus*, *P. rufipennis*, *Chalcophora virginiensis* (Drury), and *H. r. pinifex* (Table 3). Significant interactions between and among model factors occurred, but varied among the families (Table 3, Supplemental Data Figs. 2, 3 and 4) and species (Table 3, Supplemental Data Figs. 5, 6, 7, 8, 9, 10, 11, 12 and 13). *Ips grandicollis* and *I. perturbatus* had significant three-way interactions among model factors (Table 3), which could not be displayed graphically. In 2001 in burned forests, significantly more *B. maculativentris*, *T. nubilus*, and *P. rufipennis* were caught than in 2002 and 2003; in 2001 and 2002 in salvaged forests, significantly more *C. virginiensis* were caught than in 2003; and in 2001 in wind-disturbed forests, more *M. s. scutellatus*, *I. pini*, and *T. dubius* were caught than in 2002 and 2003. In general, significantly more *D. simplex* (Fig. 2a), *I. pini* (Fig. 2b), *I. perroti* (Fig. 2c), *I. perturbatus* (Fig. 2d), and *I. grandicollis* (Fig. 2e) were trapped in response to their respective baits than to the other semiochemical combinations, although the response of *I. grandicollis* tended to be more generic to the baits that we tested. The predaceous beetle, *T. dubius*, also tended to respond more generally to a variety of the baits that we tested (Fig. 2f), perhaps underscoring its role as a generalist bark beetle predator. *Ips perroti* responded more to the *I. perroti*-(−)-ipsdienol bait (Fig. 2c); *H. r. pinifex* (Fig. 2g) to the *D. valens*-Phero Tech and woodborer baits; *T. dubius* to the *D. rufipennis* bait (Fig. 2f); and *Dr. autographus* (Fig. 2h) to the *Dryocoetes* spp. and woodborer baits.

The grand mean percentage of male *D. simplex* trapped in 2001–2003 was 49%. Year was not used as a model factor in the analysis because of low trap catches in years 2001 and 2003. Because of the higher response of *D. simplex* (Fig. 2a), the trap catches analyzed included those responding to the baits targeting *D. simplex*, *I. pini*, and woodborers. The two-way ANOVA for the percentage of male *D. simplex* indicated no significant effect of the interactions of land-area and semiochemical treatments ($F_{(4,35)}$ = 1.89, P=0.141), or of land-area treatment alone ($F_{(2,35)}$ = 0.48, P=0.625) or semiochemical treatment alone ($F_{(2,35)}$ = 3.14, P=0.056).

The grand mean percentage of male *I. pini* trapped in 2001–2003 was 44%. Because of the higher response of *I. pini* (Fig. 2b), the trap catches analyzed included those responding to the baits targeting *I. pini* and *I. perroti*-(+)-ipsdienol. The three-way ANOVA for the percentage of male *I. pini* indicated no significant effect of any of the second or third-order interactions (P>0.5), of year alone

Table 3 ANOVA model for the pooled funnel trap catches of all subcortical beetle species, four beetle families, and fourteen species with year (YR), land-area treatment (LT), semiochemical treatment (ST), and their interactions as factors, Superior National Forest, Cook Co., MN, USA

[a] For each table entry, the top number is the *F*-value, the bottom number is the *P*-value, and the subscripts refer to the degrees of freedom for each *F*-value. *NA* Non-applicable in the model; *NS* Non-significant factor in the model

[b] The ANOVA model was as follows: $Y_{ijk} = CT_i + LT_j + ST_k + (CT*LT)_{ij} + (CT*ST)_{ik} + (LT*ST)_{jk} + (CT*LT*ST)_{ijk} + \epsilon_{ijk}$ where Y_{ijk} is the observed trap catch for cover type, land-area treatment and semiochemical treatment; $_{i,\,j,\,k}$ are the numbers of levels for each factor; and ϵ_{ijk} is the error term (unaccounted variation in the model). Cover type was significant ($F=14.53_{2,107}$, $P=0.002$); none of the second- and third-order interactions with the cover type were significant

[c] The ANOVA model was as follows: $Y_{ijk} = LT_i + \eta_i + ST_j + (LT*ST)_{ij} + YR_k + (LT*YR)_{ik} + (ST*YR)_{jk} + (LT*ST*YR)_{ikj} + \epsilon_{ijk}$ where Y_{ijk} is the observed trap catch for land-area treatment, semiochemical treatment and year; $_{i,\,j,\,k}$ are the numbers of levels for each factor; η_i is the whole plot level random error term; and ϵ_{ijk} is the split plot level random error term

[d] Data from 2001–2003

($F_{(2,106)} = 0.46$, $P=0.634$), of land-area treatment alone ($F_{(3,106)} = 1.19$, $P=0.32$), or semiochemical treatment alone ($F_{(1,106)} = 0.25$, $P=0.615$).

The grand mean percentage of male *I. perroti* trapped in 2001–2003 was 25% (Fig. 3a). Because of the higher response of *I. perroti* (Fig. 2c), the trap catches analyzed included only those from traps baited with (−)-ipsdienol and (−)-ipsenol. The two-way ANOVA for the percentage of male *I. perroti* indicated significant effects of year ($F_{(2,103)} = 5.01$, $P=0.009$) and land-area treatment ($F_{(3,103)} =$

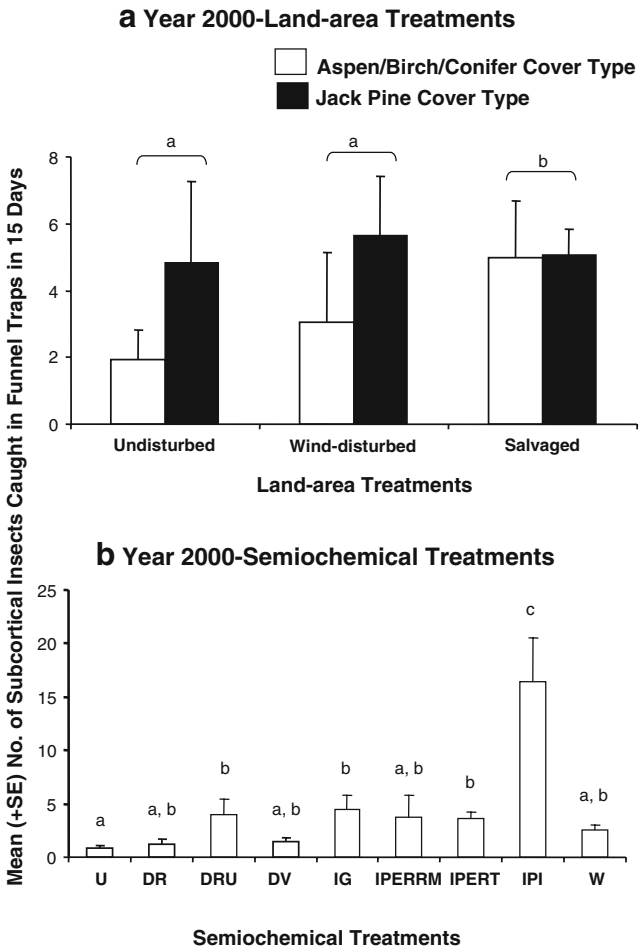

Fig. 1 Mean (+ SE) number of subcortical insects per 15 d caught during 2000 in funnel traps in the undisturbed, wind-disturbed, and salvaged plots in the aspen/birch/conifer and jack pine forest cover types (**a**). Mean (+ SE) number of subcortical insects per 15 d caught during 2000 in baited (eight semiochemical lures) or unbaited funnel traps in the aspen/birch/conifer and jack pine cover types (**b**). Key: U-Unbaited; DR-*Dryocoetes* spp.; DRU-*Dendroctonus rufipennis*; DV-*Dendroctonus valens*; IG-*Ips grandicollis*; IPERRM-*Ips perroti*; IPERT-*Ips perturbatus*; IPI-*Ips pini*; W-Woodborers (N=18). Different letters above histogram bars indicate significantly different means (Ryan-Einot-Gabriel-Welsch test, α=0.05). In (**a**) the comparisons were made among land-area treatments pooled across cover types

3.16, P=0.028) (Fig. 3a). Across most land-area treatments the percentage of males trapped was higher in 2001 than in 2002 and 2003 (38–50%). The percentage of males trapped was significantly higher in the burned sites than in the rest of the land-area treatments (Fig. 3a).

The grand mean percentage of male *I. grandicollis* trapped in 2001–2003 was 26% (Fig. 3b). Because of the higher response of *I. grandicollis* (Fig. 2e), the trap catches analyzed included only those responding to the bait targeting *I. grandicollis*. The two-way ANOVA for the percentage of male *I. grandicollis* indicated a significant effect of year ($F_{(2,49)}$ = 10.11, P<0.001) (Fig. 3b). There was no effect of land-area treatment ($F_{(3,49)}$ = 0.39, P=0.761) and no interaction between year and land-area treatment ($F_{(6,49)}$ = 0.83, P=0.554). The percentage of males trapped was significantly higher in 2003 than in 2001 and 2002 (by 50%).

Subcortical Insect Species Richness In 2000, 57 and 67 species of subcortical insects were caught in the ABC and JP cover types, respectively. A comparison of species richness among land-area treatments in the two cover types (Fig. 4) reveals that in 2000 the salvaged forests contained both the greatest total (49 and 51 species) and the most unique insect species (18 and 12 species) when compared with the undisturbed and wind-disturbed forests. In 2000, only 33% and 34% of the insect species were common to all land-area treatments in the ABC and JP cover types, respectively.

In 2001–2003, a total of 140 species of subcortical insects were caught in the JP cover type. A comparison of species richness among land-area treatments reveals that the burned (110 species) and wind-disturbed (106 species) plots contained both the greatest numbers and the most unique insect species (18 and 14 species) (Fig. 5). Fifty three percent to 58% of the subcortical insect species were shared among the four land-area treatments in the JP cover type. The greatest numbers of insect species were shared among the wind-disturbed, salvaged, and burned forests (81 species).

Subcortical Insect Species Diversity Rarefaction analyses of subcortical insect trap catches from 2000 by land-area treatment showed that at a sub-sample size of 400 individuals, the ABC and JP salvaged forests had the greatest estimated mean species diversities (Supplemental Data Fig. 14). Subcortical insect trap catches from 2001–2003 in the JP cover type by land-area treatment showed that at a sub-sample size of 14,000 individuals, the wind-disturbed and burned forests had the greatest estimated mean species diversity (Supplemental Data Fig. 15). Sub-sample sizes of 400 and 14,000 individuals were chosen for 2000 and 2001–2003, respectively, for comparisons across land-area treatments because they were the lowest sub-sample sizes at which a land-area treatment (ABC and JP undisturbed forest areas, respectively) stopped accumulating more species.

Simpson's diversity indices for subcortical insects in 2000 indicated that the salvaged forests of both cover types had the greatest species diversity (Table 4). Simpson's diversity indices for subcortical insects in 2001–2003 indicated that all land area treatments in the JP cover type had similar levels of subcortical insect species diversity, but numerically, the wind-disturbed forests had the greatest species diversity followed closely by the undisturbed, burned, and salvaged forests (Table 4).

Rarefaction analyses of subcortical insect trap catches from 2000 by semiochemical treatment showed that at a

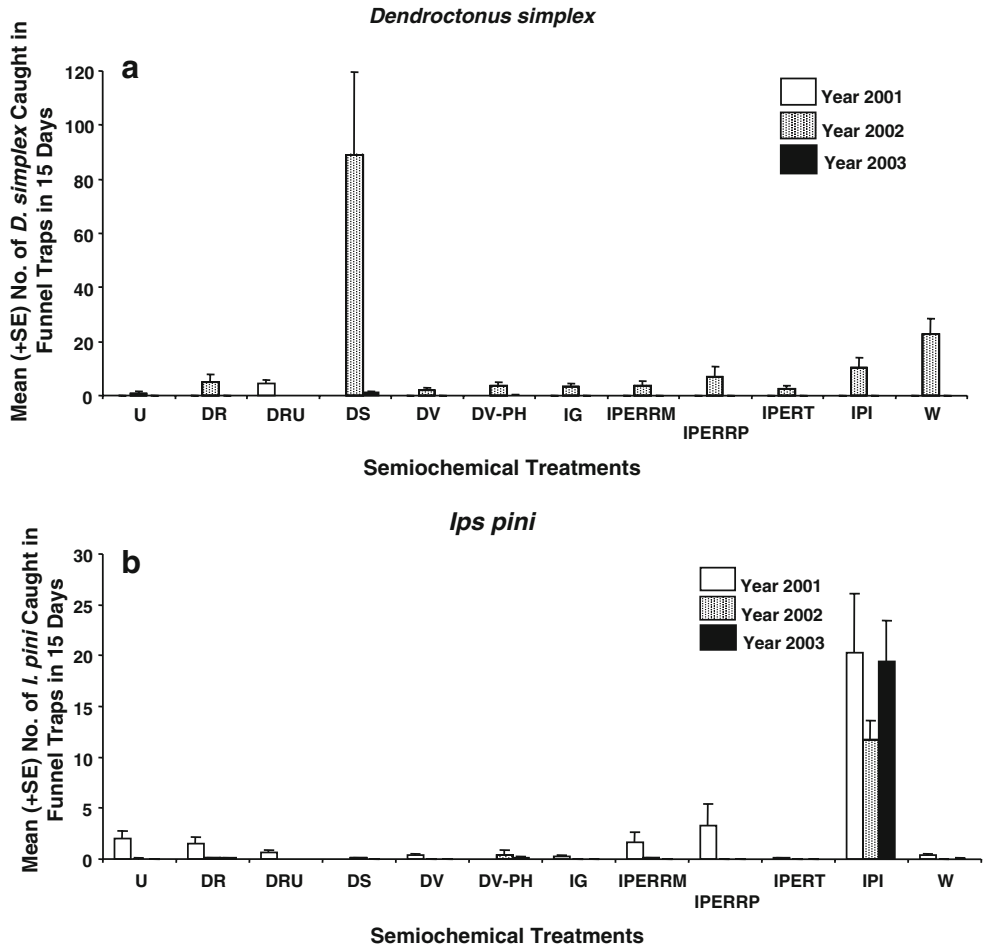

Fig. 2 Mean (+ SE) number of *Dendroctonus simplex* (**a**), *Ips pini* (**b**), *Ips perroti* (**c**), *Ips perturbatus* (**d**), *Ips grandicollis* (**e**), *Thanasimus dubius* (**f**), *Hylurgops rugipennis pinifex* (**g**), and *Dryocoetes autographus* (**h**) per 15 d caught during 2001–2003 in baited (11 semiochemical lures) or unbaited funnel traps in the jack pine cover type. Key: U- Unbaited control; DR- *Dryocoetes* spp.; DRU- *Dendroctonus rufipennis* (2001 only); DS- *Dendroctonus simplex* (2002 and 2003 only); DV- *Dendroctonus valens*; DV-PH- *Dendroctonus valens*-Phero Tech (2002 and 2003 only); IG- *Ips grandicollis*; IPERRM- *Ips perroti*-(−)-Ipsdienol; IPERRP- *Ips perroti*-(+)-Ipsdienol; IPERT- *Ips perturbatus*; IPI- *Ips pini*; W- Woodborers. For 2001, *N* ranges from 103 to 108; for 2002, *N* ranges from 100 to 109; and for 2003, *N* ranges from 86 to 93 for each semiochemical treatment. Apparent response shifts by *D. simplex* (**a**, 2001–2002); *T. dubius* (**f**, 2001–2002); and *H. r. pinifex* (**g**, 2001–2002) resulted as a consequence of the introduction to the experiment of the DS bait (2002); the removal of the DRU bait (2002); and the introduction of the DV-PH bait (2002), respectively

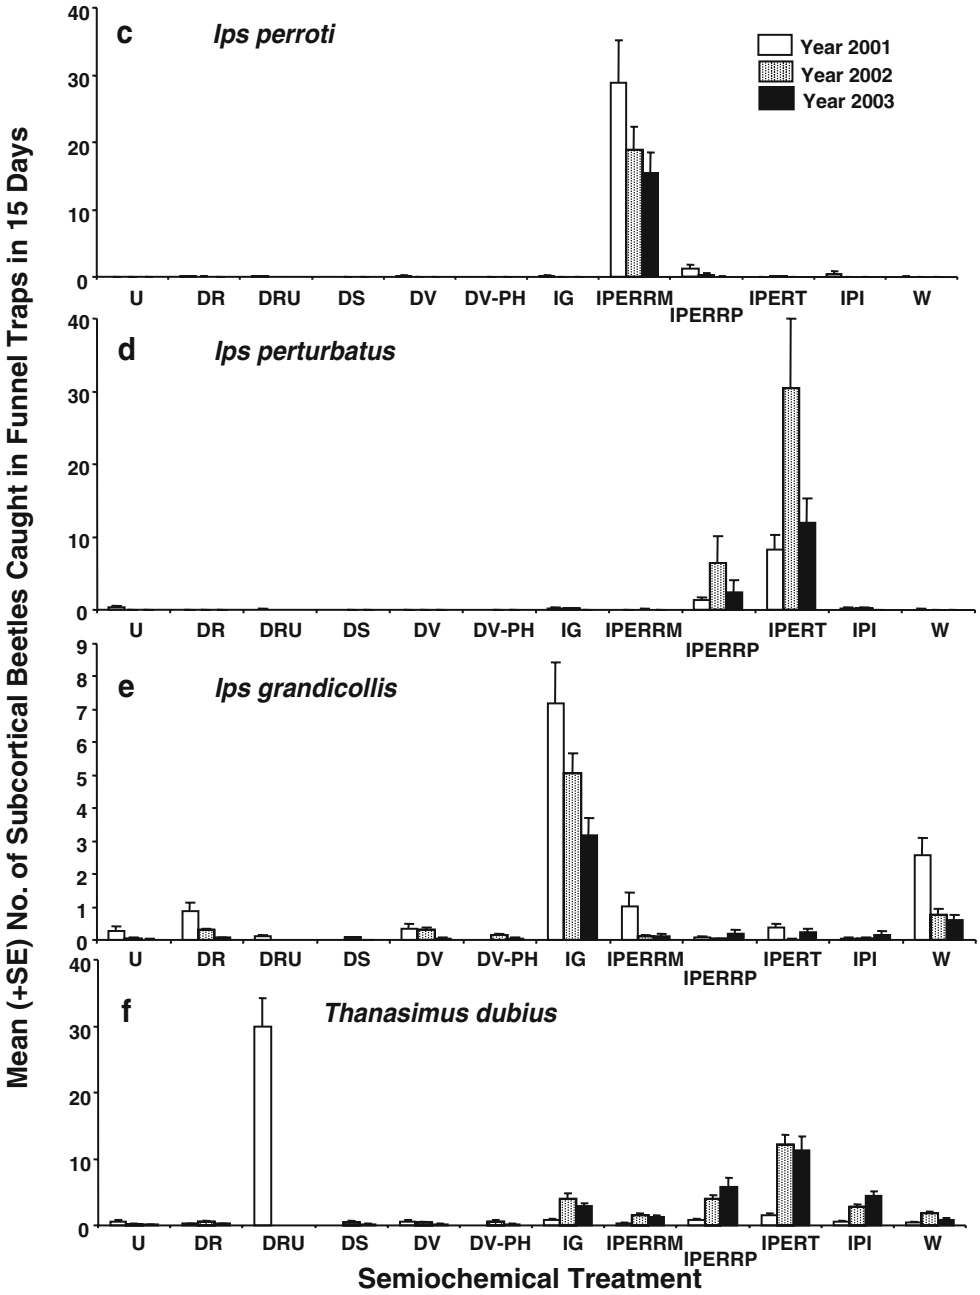
sub-sample size of 80 individuals, the *D. valens* bait elicited the numerically greatest estimated mean species diversity (Supplemental Data Fig. 16). Rarefaction analyses of subcortical insect trap catches from 2001–2003 by semiochemical treatment showed that at a sub-sample size of 1,500 individuals, the *Dryocoetes* spp. bait (Supplemental Data Fig. 17) elicited the numerically greatest estimated mean species diversity. Similar to the results from year 2000, the *I. pini* bait tended to accumulate more species with increasing sample sizes.

Simpson's diversity indices for subcortical insects in 2000–2003 indicated that the *Dryocoetes* spp. bait elicited the greatest species diversity followed by the *D. valens* and *D. valens*-Phero Tech baits, and woodborer baits, the unbaited trap, and various other baits (Table 5). The species diversities recorded from traps with the *I. pini* bait, the *I. perroti* (−)-ipsdienol bait, and the *D. simplex* bait were the lowest, likely reflecting the specificity of these baits.

Subcortical Insect Species Composition The cluster analysis of subcortical insect species composition among JP land-area treatment combinations in 2001–2003 revealed that there were two distinct groups: 1) the 2002 salvaged and burned forests with 90% similarity; and 2) the rest of the land-area treatments over the 3-year period of the study (Fig. 6). There was little similarity in species composition between the 2002 salvaged and burned forests and the rest of the groups. Within the second group, 2001 burned forests were 20%; 2003 salvaged and burned forests (with 85% similarity) and 2001 salvaged forests were 55%

Fig. 2 (continued)



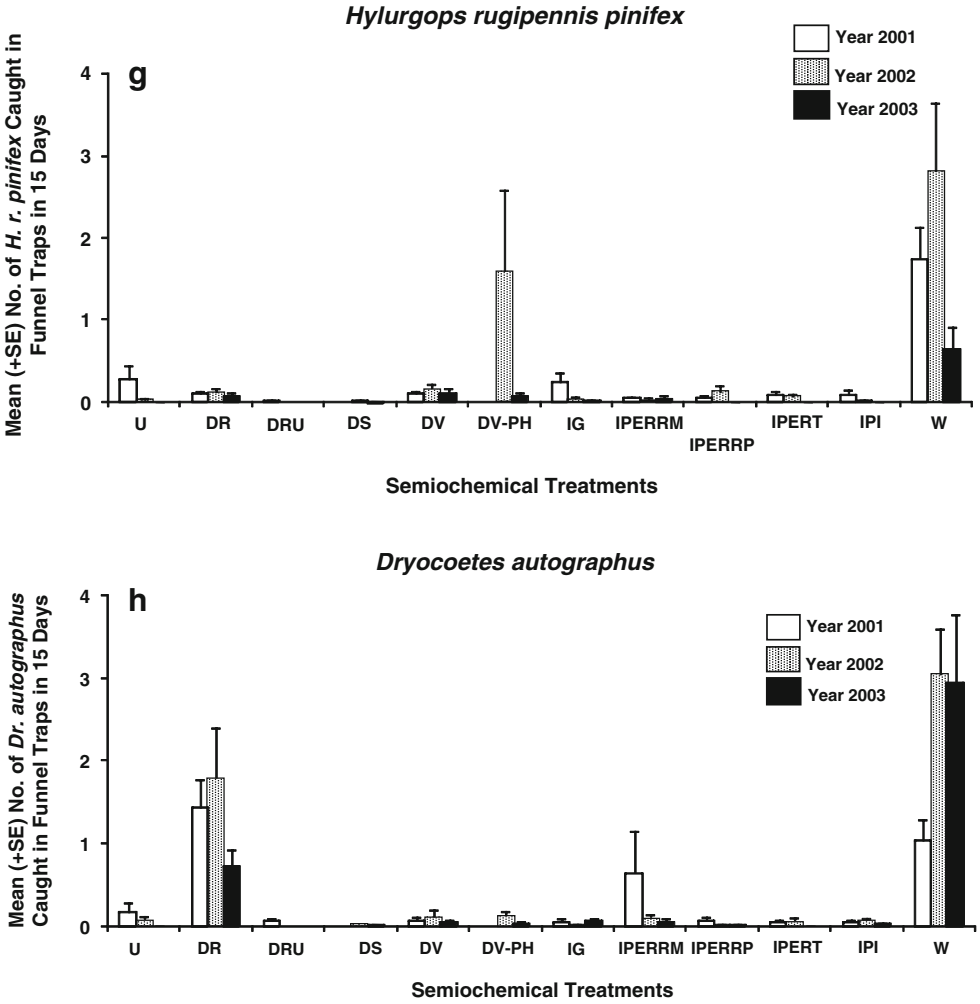
similar to the rest of the group. The undisturbed and wind-disturbed forests clustered together with >65% similarity in species composition. There was a 100% similarity between 2002 undisturbed and wind-disturbed forests.

Bray-Curtis cluster analyses of the compositions of subcortical beetle species responding to semiochemical baits in 2001–2003 revealed that the traps baited with attractants for *D. simplex* or woodborers had the most distinct species composition with only 2% similarity with the trap catches to the rest of the baits (Fig. 7). The species compositions responding to the *I. grandicollis* and *I. perroti*-(+)-ipsdienol baits were 85% similar, whereas those to the *D. valens* and *Dryocoetes* spp. baits and unbaited traps were 90% similar. There was almost 100% similarity between the trap catches to unbaited traps and the *D. valens*-baited traps.

Discussion

Our study of subcortical forest insect assemblages spanned 4 years with continuous summer trapping on a 120 km^2 stretch of sub-boreal forest landscape. We collected over 5,000 trap samples with 86,471 rhizophagous and subcortical insects represented by 143 species in baited Lindgren

Fig. 2 (continued)



funnel and pitfall traps. Other studies in North America on subcortical beetles of similar scope are by Hammond (1997) and Hammond et al. (2001) where 40,049 beetles represented by over 250 species were collected in 3 years from aspen, *Populus* spp., stands in north-central Alberta, Canada; and by Jacobs (2004) where 18,374 beetles represented by over 230 species were collected in 3 years from boreal deciduous and coniferous stands in northern Alberta. Neither of these studies used semiochemicals as baits to target key species in the trap catches. Although we caught a greater number of beetles in our traps, we had lower species richness than these other studies on subcortical insects. Possible reasons include: 1) inclusion of late-successional beetle taxa (e.g., Colydiidae, Elateridae, Passalidae, and Stapylinidae) by previous researchers in their analyses in contrast to inclusion of only early-successional taxa in our study (Savely 1939; Gibb et al. 2005); 2) the use of window-traps attached directly to the trees by previous researchers in contrast to baited Lindgren funnel traps hung from poles in our study (e.g., Sverdrup-Thygeson and Birkemoe (2008) found that window traps hung directly on aspen trees caught more beetles associated with aspen than traps hanging freely); and 3) some of the highly specific semiochemical baits that we used attracted large numbers of target species, but captured far fewer taxa than did unbaited traps or more generically baited traps.

The subcortical insect guild that we have characterized likely originated primarily from jack pine (*P. banksiana*) [e.g., *I. grandicollis*, *I. perroti, I. pini, Pityogenes plagiatus plagiatus* (LeConte) (all Scolytidae) and *M. s. scutellatus* (Cerambycidae)], with identifiable components from *L. laricina*, *Picea glauca*, *P. resinosa*, and *P. strobus*. For example, *D. simplex*, *Pityokteines sparsus* (LeConte), *P. rufipennis*, and *Scolytus piceae* (Swaine) (all Scolytidae), and *Phymatodes dimidiatus* (Kirby) and *Xylotrechus undulatus* (Say) (both Cerambycidae) have been reared or collected frequently from *L. laricina* (Blackman and Stage 1918; Dodge 1938; Linsley and Chemsak 1997). Similarly, *Crypturgus borealis* Swaine, *D. rufipennis*, *I. perturbatus*, *P. rufipennis*, and *Dryocoetes affaber* (Mannerheim) (all Scolytidae); and *Monochamus* spp. and *Tetropium cinnamopterum* Kirby (both Cerambycidae) have been reared or

collected frequently from *P. glauca* (Dodge 1938; Whitmore 1982; Gara et al. 1995; Linsley and Chemsak 1997; Haberkern et al. 2002). *Ips latidens* and *I. pini* (Scolytidae) occur in *P. strobus* (Dodge 1938; Bright 1976; Wood 1982b; Drooz 1985). Other subcortical taxa such as *D. valens* and *Trypodendron lineatum* (Olivier) (both Scolytidae), as well as most Buprestidae, Cerambycidae, and Siricidae are extremely polyphagous; rearing studies from bark samples or cut logs are needed to establish host relationships.

Compared with subcortical insects caught in funnel traps, we caught few individuals and species of rhizophagous beetles in pitfall traps in 2000–2003. Such a result is

Table 4 Species diversity estimates from Simpson's diversity index for subcortical insects caught in funnel traps by land-area treatment in 2000–2003, Superior National Forest, Cook Co., MN, USA

Year	Cover Type	Undisturbed	Wind-disturbed	Salvaged	Burned
2000	Aspen/Birch/Conifer	0.582	0.528	0.742	NA[a]
	Jack Pine	0.679	0.684	0.837	NA[a]
2001–2003	Jack Pine	0.888	0.912	0.884	0.887

[a] NA = Not Applicable

unexpected in the wind-disturbed and burned areas where large numbers of windthrown trees with exposed roots were present. This suggests that either the rhizophagous beetles persisted at much lower populations than the stem-colonizing beetles in these forests, or that the baited pitfall traps that we used may not have been the optimal trapping method. In 2000, a high release-rate device was used, and the solution evaporated within a week; in 2001–2002, we used a plastic release device from which ethanol did not elute rapidly (David Wakarchuk, Synergy Semiochemical, personal communication); and in 2003, we used the same plastic release device with a hole in the cap. None of these release devices, especially the one in 2003, seemed to attract large numbers of rhizophagous beetles. In the 2000 field season, which occurred one-year post disturbance and had the highest probability of high populations of rhizophagous insects, the high release from the devices may have rendered our traps effectively unbaited through the latter part of the sampling periods. Nonetheless, other workers have found that sampling rhizophagous insects is problematic; by using baited pitfall traps, Erbilgin et al. (2001) caught only 315 beetles in Wisconsin as compared to 2,624 beetles in Louisiana. They further reported that the baited pitfall traps were more effective than lower stem flight traps (Klepzig et al. 1991) in capturing rhizophagous beetles in Wisconsin than in Louisiana. There appear to be regional differences in both the population levels and responses of rhizophagous beetles to trap-type, which might further affect techniques for monitoring in sub-boreal forests. Rhizophagous beetles generally are difficult to sample and observe in the forest due to their cryptic life-stages. Their larvae are associated with roots and adults hide in the forest litter layer (Lynch 1984; Drooz 1985). Other possible methods to sample rhizophagous beetles include the use of insect emergence cages for infested roots, bark peeling of roots, and placement of pitfall traps directly in and around downed trees.

Effects of Semiochemical Treatments on Subcortical Insects

Overall Variability The effects of semiochemical treatments on subcortical insect flight responses generally were dependent upon the year of sampling and land-area treatments. Such high variability may be a reflection of the rapid turnover of subcortical insect communities within the disturbed habitats, and the associated large volume of semiochemical signaling by numerous species present at any given time. For example, semiochemicals of some species of scolytid beetles may interfere with the behavioral responses of related and/or competing species (e.g., allomones) (Wood et al. 1967; Birch and Wood 1975; Furniss and Livingston 1979; Borden et al. 1992; Miller and Borden 1992). Other possible reasons for the variable responses include: 1) high population levels of dominant subcortical species at the time of sampling (*see* next paragraph); and 2) the effects of local physical factors such as forest structure and weather conditions, whose effects on responses to semiochemicals are less well understood (Thistle et al. 2004). For studies conducted within a single habitat and over a short period of time, there is the potential to underestimate the variability of the responses of subcortical insects to semiochemicals.

Subcortical Insect Trap Catches Total catches of all subcortical insects were highest in response to the *D. simplex* bait, especially in 2002 in the burned areas. This trend may reflect high population levels of *D. simplex*, and

Table 5 Species diversity estimates from Simpson's diversity index for subcortical insects caught in funnel traps by semiochemical treatment in 2000–2003, Superior National Forest, Cook Co., MN, USA

Semiochemical Baits	Simpson's index
Dryocoetes spp.	0.935
Dendroctonus valens	0.929
Dendroctonus valens-Phero Tech	0.920
Woodborers	0.919
Unbaited	0.915
Ips perroti-(+)-ipsdienol	0.904
Ips grandicollis	0.873
Ips perturbatus	0.731
Dendroctonus rufipennis	0.640
Ips pini	0.613
Ips perroti-(−)-ipsdienol	0.583
Dendroctonus simplex	0.165

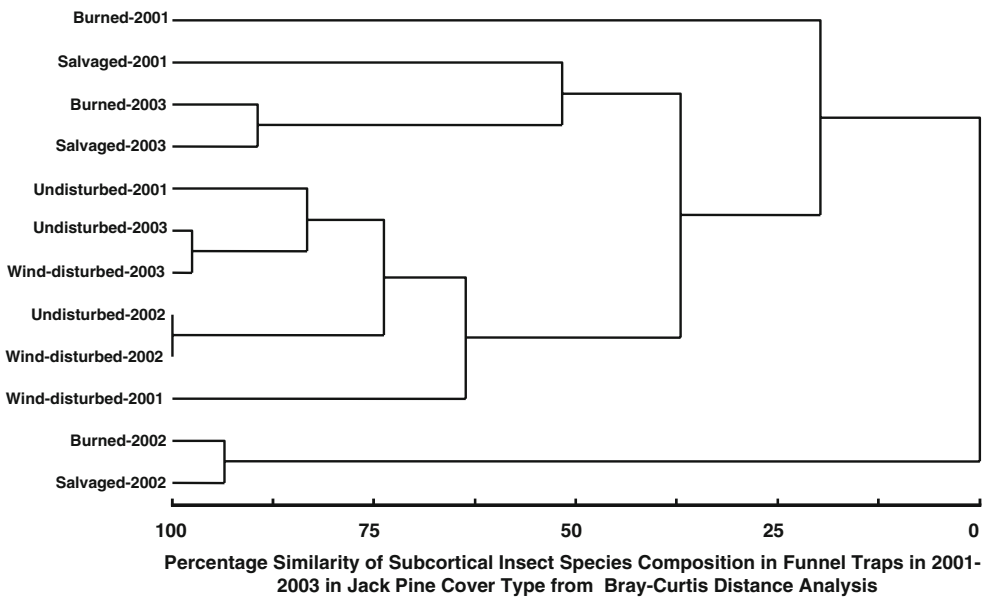

Fig. 6 Dendrogram of the percentage similarity of subcortical insect species trapped in funnel traps in 2001–2003 in the undisturbed, wind-disturbed, salvaged, and burned plots in the jack pine cover type

may account for a delayed response observed for all scolytid beetles. The greatest numbers of scolytids were also caught in response to the *D. simplex* bait in 2002 in the burned areas. This overall trend was driven by catches of *D. simplex*, which was the primary scolytid caught during this field season, and is the only native bark beetle that colonizes and kills tamarack and exotic larches in North America (Langor and Raske 1987; Seybold et al. 2002). In recent years, this species has shown an increase in activity, causing >75% mortality of tamarack trees in some areas of northern Minnesota (Albers 2005).

More predatory checkered beetles (Cleridae) were caught in response to the *D. rufipennis* bait than to the rest of the baits. This was true especially in 2001 in the wind-disturbed forests. The dominant clerid was *T. dubius*, a major predator of *I. pini* in the Great Lakes region (Schenk and Benjamin 1969), and of southern pine beetle, *Dendroctonus frontalis* Zimmermann, in the southern U.S. (Thatcher and Pickard 1966; Berisford 1980). The *D. rufipennis* bait initially was employed in 2000 and 2001 in anticipation of potential population increases of *D. rufipennis*, whose western North American populations respond to wind disturbances (Nelson 1950; Graham 1952; Schmid and Frye 1977; Holsten et al. 1999; Gandhi et al. 2007). However, the commercially available *D. rufipennis* bait was ineffective for attracting eastern populations of *D. rufipennis* in this study and in other studies in northern Minnesota (Seybold et al., unpublished data). We also

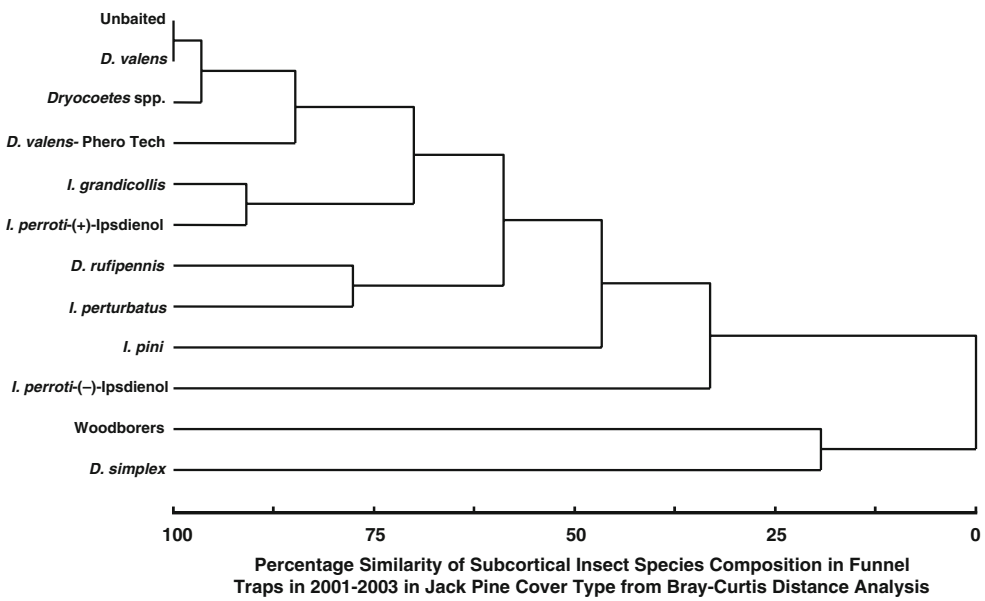

Fig. 7 Dendrogram of the percentage similarity of subcortical insect species trapped in funnel traps in 2001–2003 in response to eleven semiochemicals and an unbaited control trap in the jack pine cover type

caught more individuals of *D. simplex* than of *D. rufipennis* in response to this bait in 2001, and thus, we used the *D. simplex* bait in the subsequent years of the study. Mizell et al. (1984) found that *T. dubius* responded positively to frontalin, ipsdienol, and α-pinene. Vité and Williamson (1970) and Dixon and Payne (1980) also found that *T. dubius* was attracted to frontalin, an aggregation pheromone of *D. frontalis*. Similar results were found by Haberkern and Raffa (2003), where *T. dubius* and *Enoclerus nigrifrons* (Say) were attracted to the commercial *D. rufipennis* bait deployed in traps in *P. resinosa* stands in Wisconsin. This suggests that *T. dubius* is a generalist predator of scolytid beetles in both *Pinus* and *Picea* stands.

As expected, *I. pini* was caught in greater numbers in the *I. pini*-pheromone-baited traps, especially in the year 2002. There is geographic variation in the production and response of populations of *I. pini* to various enantiomeric blends of ipsdienol (Lanier et al. 1980; Birch et al. 1980; Seybold et al. 1995). In western populations, *I. pini* is attracted to 97% (−)-ipsdienol and is inhibited by (+)-ipsdienol (Birch et al. 1980). However, in eastern populations, *I. pini* is attracted to a racemic mixture of ipsdienol (Lanier et al. 1980). The responses of *I. pini* to the enantiomers of ipsdienol have been reported from other North American locations (Raffa and Klepzig 1989; Herms et al. 1991). In northern Minnesota, (+/−)-ipsdienol along with lanierone would be an effective pheromone to monitor the populations of *I. pini* (Teale et al. 1991; Seybold et al. 1992, 1995; Miller et al. 1997).

In 2000, we targeted *I. perroti* by using the combination of (+)-ipsdienol and (−)-ipsenol. However, this bait caught very few *I. perroti*. In 2001–2003, we also tested the combination of (−)-ipsdienol and (−)-ipsenol to target this species. Nearly twice as many *I. perroti* were caught in response to this combination, especially in the undisturbed and wind-disturbed forests. Ayres et al. (2001) reported that populations of *I. perroti* in Wisconsin red pine (*P. resinosa*) forests were attracted to a racemic mixture of ipsdienol and ipsenol. We tested only the pure enantiomers of ipsdienol (and not the racemate) in combination with ipsenol. Our results suggest that (−)-ipsdienol and (−)-ipsenol are effective baits for monitoring *I. perroti* in northern Minnesota.

In 2000, we used *endo*-brevicomin as an attractant to target species of bark beetles in the genus *Dryocoetes*, but we caught only a few specimens of *Dryocoete*s spp. Therefore, in 2001–2003, we used racemic *exo*-brevicomin and (−)-α-pinene (Camacho et al. 1998). No previous research had been conducted on *Dryocoete*s spp. pheromone biology in eastern North America, so we used these western model systems as our best-guess strategy for monitoring biodiversity. Although there was some attraction of *Dr. autographus* to the bait with *exo*-brevicomin, the greatest response by this species was to the woodboring beetle bait, especially in the wind-disturbed forests. Williams and Borden (2004) reported that *Dr. autographus* in British Columbia was most attracted to racemic and (+)-*exo*-brevicomin. Kohnle and Vité (1984) also found that European populations of *Dr. autographus* produce *exo*- and *endo*-brevicomin. The only semiochemical component common between the *Dryocoetes* spp. and woodboring beetle bait was (−)-α-pinene, which was released at an 18-fold higher rate in the latter bait. Camacho et al. (1998) reported similar results for *Dr. confusus* Swaine where (−)-α-pinene improved the response to *exo*-brevicomin in the field. (−)-α-Pinene may be more attractive to *Dr. autographus* than *exo*- or *endo*-brevicomin in our eastern sub-boreal populations.

In 2001–2003, more *Hylurgops r. pinifex* (Scolytidae) were caught in the *D. valens*-Phero Tech and woodboring beetle baits, primarily in the undisturbed and wind-disturbed forests. Very little information is available on the chemical ecology of this species. The common component between *D. valens*-Phero Tech and the woodboring beetle bait is α-pinene. The European species, *H. palliatus* Gyllenhall, was more attracted to ethanol than to host monoterpenes including (+/−)-α-pinene, (+)-3-carene, and terpinolene (Volz 1988; Byers 1992). In contrast, Schroeder and Lindelow (1989) reported that *H. palliatus* was attracted to the combination of both ethanol and α-pinene. Thus, α-pinene may be one of the attractant components for the species in the genus *Hylurgops*.

Among the most abundant subcortical beetles, *B. maculativentris*, *C. virginiensis*, and *P. rufipennis* did not show any response to semiochemical treatments. Both *B. maculativentris* and *C. virginiensis* (buprestid species) may respond to the general odors produced by dead and dying tree hosts (see also Crook et al. 2008). However, Chénier and Philogène (1989) reported a lack of response of buprestid beetles to ethanol and monoterpenes in central Ontario, and they suggest that visual cues may be more important in finding hosts. Similary, Montgomery and Wargo (1983) reported a lack of response of buprestid beetles to ethanol in Connecticut. Male *P. rufipennis* (Scolytidae) produces an aggregation pheromone while feeding on *Picea glauca* trees in British Columbia (Bowers and Borden 1990), identified as 3-methyl-3-buten-1-ol (Bowers et al. 1991). *Polygraphus rufipennis* also was attracted to a *Dryocoetes* spp. bait in *P. resinosa* stands in Wisconsin (Haberkern and Raffa 2003). In our study, it was caught in the second highest numbers in the *Dryocoetes* spp. bait, but in similar numbers in the unbaited funnel trap. These disparate regional results suggest further work on the semiochemicals of *P. rufipennis* is needed.

Overall, attractants for *I. perroti*, *I. pini*, and *D. simplex* were the most useful baits in trapping their respective target

beetles. *Ips grandicollis* and *I. perturbatus* also responded to their respective target baits at a higher level than to any other semiochemical treatments, but *I. grandicollis* and *T. dubius* tended to be semiochemical generalists when compared with the responses of *I. perroti* and *I. pini* to the spectrum of semiochemicals that we tested (Fig. 2). The *D. valens*, *D. valens*-Phero Tech, *Dryocoetes* spp., and woodboring beetle baits were the least efficient in capturing their target beetle species in the sub-boreal forests. *Dendroctonus valens* does not have a known pheromone but it is attracted to (+)-α-pinene, (−)-β-pinene, and (+)-3-carene (host kairomones) in western populations (Hobson et al. 1993; White and Hobson 1993), and to (−)-α-pinene, ipsdienol, and lanierone in eastern populations (Erbilgin and Raffa 2000). We did not find a similar attraction of *D. valens* to ipsdienol and lanierone, thus suggesting that more research needs to be conducted on the semiochemical attractants for this species.

Some species of cerambycid beetles showed a trend of greater attraction to the woodboring beetle bait. Cerambycid beetles have a general attraction to host kairomones and scolytid pheromones, although some short-range sex-pheromones also have been isolated (Allison et al. 2004). The presence of higher concentrations of plant volatiles present in the disturbed forest stands may have interrupted attraction of some beetle species to their respective baits or provided competing sources of attraction. Subcortical species with a primary attraction to host attractants may be difficult to trap and monitor with baited funnel traps in disturbed forests due to olfactory competition with large amounts of damaged and moribund trees.

Subcortical Insect Richness and Diversity The greatest diversity of subcortical insect was observed in response to the *D. valens* and *Dryocoetes* spp. baits. Both of these baits had monoterpenes that may have acted as a general attractant for subcortical insects. It also is likely that other bait types with pheromone components may have deterred non-target subcortical insect species. *Dendroctonus valens* and *Dryocoetes* spp. baits, although not as effective in capturing their target species, may have greater efficacy in capturing a broader spectrum of subcortical species in a sub-boreal forest. The lowest biodiversity was recorded from traps baited with lures for *I. pini, I. perroti*, and *D. simplex*, perhaps reflecting the specificity of these baits.

Subcortical Insect Species Composition Cluster analyses of subcortical insect species composition among the semiochemical baits in 2001–2003 revealed that woodborer and *D. simplex* baits elicited the most distinct species composition (there was only 2% similarity with the rest of the bait types). Such differences could be attributed to the efficacy of the woodborer and *D. simplex* baits in attracting their target beetles, and their associated subcortical insects (Table 5). This result also indicates that subcortical insect species that responded to the woodborer and *D. simplex* baits may differ from those that responded other bait types. The species composition of subcortical insects that responded to the *I. grandicollis* and *I. perroti* baits clustered together with 85% similarity. As these baits had (−)-ipsenol in common, this pheromone component may have the capacity to attract similar subcortical species. The species assemblages that responded to the *D. valens* and *Dryocoetes* spp. baits, and the unbaited traps clustered together with >85% similarity, which suggests that the *D. valens*- and *Dryocoetes* spp.-baited traps acted almost like unbaited funnel traps. These two baits and the unbaited trap caught both the greatest numbers of similar, though not identical, subcortical species.

Effects of Land-Area Treatments on Subcortical Insects

Subcortical Insect Trap Catches From 2000–2003, total insect catches between the wind-disturbed and undisturbed forest plots generally were similar. However, in 2001 we caught approximately 2.5-fold more subcortical insects in the wind-disturbed than in the undisturbed areas. Thus, the trap catches of subcortical insects were high 2 years after the wind storm (in 2001), but then they declined. Possible reasons for the decline of early-successional subcortical insect flight activity with time are: increasing populations of insect (Ryall 2003; Ryall et al. 2006) and avian (Baldwin 1968; Fayt et al. 2005) natural enemies (Ryall and Smith 2001); greater inter- and intra-specific competition (Robins and Reid 1997); lower availability and quality of CWD as habitat on the disturbed landscape (Wallace 1953; Wickman 1965; Jacobs 2004); and/or rapid salvaging of other downed material on the landscape (USDA Forest Service 1962, 1965). Similar results were reported for the activity of *I. pini* in ice-damaged *P. resinosa* stands in Ontario where beetle activity declined markedly 2–4 years after the storm (Ryall et al. 2006), and for the activity of *Dendroctonus brevicomis* LeConte in wind-damaged stands in California where beetle activity declined 2 years after the storm (Miller 1928). Populations of *Ips typographus* (L.) and other subcortical beetles peaked 2 years after a wind storm (Vivian) in Switzerland (Wermelinger et al. 1999) and after another wind storm (Lothar) in 1999 in France (Nageleisen 2001). In contrast, after the storm in France, ambrosia beetles (Scolytidae) in the windthrow gaps of a hardwood forest did not increase subsequently in abundance when compared to undisturbed forest areas (Bouget and Noblecourt 2005). Thus, responses of subcortical beetles to wind storms may be taxon specific, and may vary across forest types.

In 2001 and 2002, similar numbers of all subcortical insects were caught in funnel traps in the wind-disturbed and burned forests. However, in 2003, the trap catches of

subcortical insects were lower in the salvaged and burned areas as compared to the wind-disturbed sites. This suggests that although burning initially retained similar or higher numbers of insects than the wind-disturbed areas, flight activity of subcortical insects decreased 4 years after the wind storm in the areas where two disturbances were combined. One explanation for this effect is that the wind-disturbed sites continued to provide food for the beetles (i.e., residual and leaning trees continued to die into the fourth year after the storm). In the burned or logged areas, the residual trees did not die (or there were few residual trees). Alternatively, olfactory cues from the burning and/or logging may have attracted subcortical insects into these treatment sites in 2001 and 2002, but perhaps because of an absence or paucity of host material from the treatments, the insects were lured into traps rather than colonizing and reproducing in the woody debris. Werner (2002) reported that in *P. glauca* stands in Alaska, both clear-cutting and burning increased the populations of subcortical scolytid, buprestid, and cerambycid beetles during the first year after the land-area treatments. Populations of these Alaskan subcortical beetles declined to the pre-disturbance level 5–10 years later. In our study, the decline following the disturbances may have occurred on an even shorter time scale. In black spruce, *Picea mariana*, stands in Quebec, Boulanger and Sirois (2007) described two phases of subcortical insect colonization of trees after burning. The first phase occurs shortly (up to 1 year) after tree death from the fire. Insect populations decline for several years after this phase, but then increase again during the second phase when dead trees fall to the ground and are colonized by fungivorous and saprophagous subcortical insects. Our study likely did not continue long enough to capture this second phase of population increase, nor did we attempt to capture saprophages.

At the family level, flight-activity responses of subcortical insects to forest disturbances also varied with the year of sampling. In 2002, scolytid beetles responded in greater numbers in salvaged and burned as compared to undisturbed forest areas. In contrast, in 2001, clerid and buprestid beetles responded in greater numbers in all land-area treatments as compared to undisturbed forest areas. We hypothesize that the response of scolytid populations showed a lag-period because they may have originated and slowly increased in numbers from within the disturbed stands (Wermelinger et al. 2002). We also observed limited colonization of downed trees in summer 1999 and spring 2000 by scolytids (K.J.K.G. and S.J.S., personal observations). Buprestid beetles in the disturbed stands may have originated from immigration from other stands as a response to the increased amounts of CWD, and/or from within the stand as they generally take 2 years to develop (Bright 1987). Greater populations of clerid beetles present in 2001 likely were due to their strong attraction to frontalin in the *D. rufipennis* bait, which was used only in this year, and to the increased prey populations after the disturbance event (see next paragraph).

At the species level, in 2001, *I. pini*, *T. dubius*, and *M. s. scutellatus* increased their flight activity in the wind-disturbed and burned areas, and *B. maculativentris*, *T. nubilus,* and *P. rufipennis* showed similar flight activity in the burned areas. However, abundance declined 4 years after the storm. Thus, these species responded positively for a short-time to a compound disturbance on the landscape (i.e., wind followed by burning). In contrast, other species such as *C. virginiensis* and *Dr. autographus* did not increase in numbers in either the wind-disturbed or the burned areas, indicating that these species either do not always respond to the increased amounts of CWD on the landscape or that there may be greater negative pressure from competition, predators, and parasites in disturbed stands.

Among the Scolytidae, relatively more males of *I. perroti* were caught in 2001 than in 2002–2003, whereas for *I. grandicollis* relatively more males were caught in 2003 than in 2001–2002. In 2001, a greater percentage of male *I. perroti* were caught in the burned forests than in the rest of the land-area treatments. We found similar numbers of male and female *I. perroti* emerging from *P. banksiana* trees (Gandhi 2005), so we expected an equal sex-ratio in the flight response of *I. perroti* to the semiochemical-baited traps. Possible reasons for a skewed sex ratio include differential mortality of the sexes (Cameron and Borden 1967) (across land-area treatments and years) or a differential attraction of the sexes to traps in the various land-area treatments.

Subcortical Insect Richness and Diversity In Minnesota there were reportedly 23 species of buprestids (Downie and Arnett 1996), 275 species of cerambycids (Downie and Arnett 1996; Yanega 1996), one species of histerid (Downie and Arnett 1996), 64 species of scolytids (Dodge 1938; Wood 1982b), and 4 species of siricids (Smith and Schiff 2002). Our field study and concurrent museum survey established new Minnesota state records for 23 subcortical insect species in six families: *C. sexsignata*, *C. striata*, *C. sulcicollis*, *P. aeneola*, and *P. d. drummondi* (Buprestidae); *P. n. nigrella* and *X. tibialis* (Cerambycidae); *E. muttkowski*, *E. n. rufiventris*, *M. dislocatus*, *T. trifasciatus*, *T. nubilus, T. u. undatulus*, *T. nutalli*, and *Z. sanguineus* (Cleridae); *P. teres*, *P. coarctatum*, *P. deficiens*, and *P. lecontei* (Histeridae); 5) *I. latidens* (Scolytidae); and *S. behrensii*, *U. g. flavicornis*, and *X. spectrum* (Siricidae). The University of Minnesota Insect Collection specimens of previously unreported subcortical species in Minnesota were collected as early as 1894, and in the case of *T. nutalli*, were distributed in as many as 21 counties. In most cases, these specimens represented native fauna from local vegetation. In our field

study, the taxa were also derived primarily from the native fauna present in the sub-boreal Minnesotan forests. However, both *P. d. drummondi* and *P. n. nigrella* have been reported recently from western larch (*Larix occidentalis* Nutt.) logs imported to central Minnesota from Montana (Dodds et al. 2004). Regional distributions of most insects we collected suggest they are native in northeastern Minnesota. For example, *Chrysobothris sexsignata*, *E. n. rufiventris*, and *T. nutalli* occur in *P. resinosa*, *P. banksiana*, and *P. strobus* stands in the adjacent province of Ontario, Canada (Chénier and Philogène 1989), and *I. latidens* occurs in Ontario in *P. strobus* (Bright 1976). *Enoclerus muttkowski*, *E. nigripes*, *T. undatulus*, and *Z. sanguineus* occur in stands of *P. resinosa* in the adjacent state of Wisconsin (Aukema and Raffa 2000, 2005; Aukema et al. 2000a, b, 2004, 2005; Erbilgin and Raffa 2001; Erbilgin et al. 2003) and *Z. sanguineus* may be associated with a hardwood tree (butternut), *J. cinera*, in Wisconsin (Katovich and Ostry 1998).

Sirex behrensii is a woodwasp primarily found in western North America, but it was recently collected in Ohio, where it was found emerging from imported lumber (Smith and Schiff 2002; D. Smith, personal communication). Hence, either the range of this species is more extensive than previously thought, or it has also been introduced to the forests of Minnesota. It is important to note that this species erroneously has been reported to occur in Virginia and Florida (Smith and Schiff 2002: 178; D. Smith, personal communication).

In 2001–2003, the wind-disturbed forest areas in Minnesota had greater species richness and diversity than the undisturbed areas. Wind storms provide a sudden and localized increase in CWD, which may provide habitat for subcortical insect species (Bouget and Duelli 2004; Gandhi et al. 2007). After windstorm Vivian in Switzerland, there was also an increase in the species richness of scolytid and cerambycid beetles in wind-disturbed areas as compared to the cleared wind-disturbed sites (Wermelinger et al. 2002, 2003). In our study, species richness and diversity were greater in burned areas than in salvaged areas, which suggests that greater numbers of beetle species were attracted to the recently burned, larger-sized pieces of CWD (Gilmore et al. 2003), and to fire-damaged and dead residual trees. There is evidence that fire-damaged trees produce greater amounts of ethanol and, therefore, attract greater numbers of subcortical beetles than do undamaged trees (Santoro et al. 2000; Kelsey and Joseph 2003). Although burning eventually results in lowered population levels of early-successional subcortical beetles, it may actually result in a greater species richness and diversity on the sub-boreal landscape (Santoro et al. 2000). It presently is unclear whether prescribed burning will retain similar species diversity to that of naturally burned forests, as there may be inherent differences in the amounts and types of CWD in the two disturbed habitats.

Subcortical Insect Composition Analysis of our data from 2001–2003 on species composition indicated that the assemblages from undisturbed and wind-disturbed forests clustered together, whereas the assemblages from salvaged and burned forests also clustered together. Although the wind-disturbance event created regional habitats for species diversity, as has been reported for European forests (Wermelinger et al. 2002, 2003), there is a closer resemblance of the species composition of the undisturbed to the wind-disturbed forest (Bouget and Noblecourt 2005), and of the salvaged to the burned forest. This suggests that the salvaged and burned forests are being colonized by species of subcortical insects different from those that colonize the undisturbed and wind-disturbed forests. Such trends also could be attributed to the similar types (e.g., leaning trees), though different amounts, of CWD present in the undisturbed and wind-disturbed forests, and to the compounded disturbances in the salvaged and burned forests. As in the case with ground beetle assemblages (Gandhi 2005; Gandhi et al. 2008), the fuel-reduction treatments after a wind-disturbance event may have the potential to alter succession of subcortical insects. At present, it is unclear whether the species compositions of the subcortical insects in undisturbed and wind-disturbed forests will become similar to those of the salvaged and burned forests with time; longer term sampling would be necessary to address this question.

Conclusions

In summary, in 2000, we trapped one-third more subcortical insects in jack pine than in aspen/birch/conifer stands. In 2001–2003, we trapped only in the jack pine cover type, and the insect responses to land-area treatments (wind disturbance, salvage-logging, and prescribed-burning) varied with year of sampling and semiochemical treatment. Trap catches of all subcortical insects were three-times greater in 2001–2002 than in 2003, suggesting that these insects were most abundant in the wind-disturbed areas 2 years after the storm event, and then declined. In 2001, approximately 2.5-fold more subcortical insects of all taxa were trapped in wind-disturbed areas than in undisturbed areas. In 2001–2002, trap catches of beetles such as *I. pini*, *M. scutellatus scutellatus*, and *T. dubius* were similar in the wind-disturbed and burned forests. In 2003, catches of these species in the burned forests were reduced in half relative to prior years.

In 2000, salvaged forest areas had the highest species richness and diversity, whereas in 2001–2003, wind-

disturbed forest areas had the highest species richness and diversity. Both wind disturbance and burning increased the subcortical insect species richness and diversity on the landscape. We provide new state records for 23 subcortical insect species in Minnesota, which underscores the efficacy of semiochemicals as tools for determining regional biodiversity. Species compositions of subcortical insects in the undisturbed and wind-disturbed forests were distinct from those of the salvaged and burned forests. Although prescribed-burning could be an effective tool to increase species diversity in the landscape, it could result in different species composition over time.

Trap catches of subcortical insects in response to semiochemical treatments also varied with year of sampling and land-area treatment. Such variability with year has been reported before in the case of *I. pini* and *T. dubius* (see Raffa and Klepzig 1989 vs. Herms et al. 1991). During 2002, relatively high population levels of *D. simplex* dominated the response of all subcortical insects as its attractant [(+/−)-seudenol and (−)-α-pinene] elicited catches of four- to five-times more insects than the other treatments. In general, the predaceous checkered beetle, *T. dubius*, responded the most to traps baited with the attractant for *D. rufipennis* [(+/−)-frontalin, (+/−)-1-methyl-2-cyclohexenol, and (−)-α-pinene]; *I. perroti* responded most to (−)-ipsdienol and (−)-ipsenol; *I. pini* the most to (+/−)-ipsdienol and lanierone; *Dr. autographus* the most to a woodborer (i.e., buprestid, cerambycid, and siricid) attractant [ethanol and (−)-α-pinene]; and *H. rugipennis pinifex* mostly to the Phero Tech *D. valens* [(+)-α-pinene, (−)-β-pinene, and (+)-3-carene] and woodborer attractants. The greatest diversity of subcortical beetle species was in traps baited with attractants for *D. valens* [(+)-α-pinene and (−)-β-pinene] and *Dryocoetes* spp. [*exo*-brevicomin and (−)-α-pinene] perhaps reflecting the generic nature of the baits. The most distinct species compositions were collected in response to the woodborer and *D. simplex* baits, whereas the species compositions in traps with the *D. valens* and *Dryocoetes* spp. baits, and the unbaited funnel trap were the most similar. Our 4-year study across various landscapes suggests that the responses of subcortical insects to semiochemicals are more complex than previously appreciated, and that future researchers should anticipate species variation in space and time.

Acknowledgments We thank P. Anderson, D. Blackford, M. Cavaleri, L. Freund, A. Graves, J. Kyhl, and J. Koehle (University of Minnesota) for field assistance. We are also grateful to M. and J. Albers, R. Maki, B. Tiplady, and N. La Trace [Minnesota Department of Natural Resources (MN-DNR)], T. Petrice (USDA Forest Service, Michigan), and D. Neitzke, P. Johnson, T. Norman, and M. Theimer [USDA Forest Service, Superior National Forest, Gunflint Ranger District (SNF-GRD)], for assistance with field logistics. Funnel traps (provided by MN-DNR) were emptied and re-randomized with the assistance of fire suppression, silviculture, and fuel-reduction crews of the MN-DNR and SNF-GRD. R. D. Cook (University of Minnesota) and J. Baldwin (USDA Forest Service, Albany, CA) provided statistical guidance. We thank D. Langor (Canadian Forest Service, Edmonton) for species identification of *Pissodes* spp. and A. Graves for assistance with the museum survey. Funding for this project was provided by the Departments of Entomology and Forest Resources, UMN; the 2001 Dayton Natural History Fund, Bell Museum of Natural History, the 2002 Carolyn M. Crosby Graduate School Fellowship, the 2003 Alexander P. and Lydia Anderson Graduate School Fellowship, the 2004 Doctoral Dissertation Graduate School Fellowship, and the 2004 Doctoral Dissertation Research Graduate School Award, University of Minnesota all to KJKG; 2002 and 2003 Undergraduate Research Opportunity Program (UROP) Scholarships to H. Krause and L. Freund, the Minnesota Agricultural Experiment Station (Projects MN-17-070 to SJS and MIN-42-034 to DWG); two grants from the USDA Forest Service-Forest Health Monitoring, Evaluation Monitoring Program (01-GD-11244225-196, 01-DG-11244225-196) to DWG and SJS in 2001–2003; a Joint Fire Science Program Grant (00-2-23) to JCZ and DWG in 2000–2003; the USDA Forest Service Northern and Pacific Southwest Research Stations; and the Daniel B. Warnell School of Forestry and Natural Resources, University of Georgia.

known presence of moths, eggs or larvae (P. Walker unpublished data).

Polyene hydrocarbons and their epoxides constitute a second major class of lepidopteran sex pheromones that have been isolated from four major families: Geometridae, Noctuidae, Arctiidae, and Lymantriidae (Millar 2000; El-Sayed 2008). To date, C19 triene has been identified as an attractant or pheromone component in 34 other species of Geometridae, 24 of which belong to the same subfamily as *M. privata* (Ennominae) (El-Sayed 2008). In all species that use C19 triene, except *M. privata*, other bioactive compounds also have been found in pheromone extracts. The use of two or more components in a pheromone is often crucial in maintaining a discrete, species-specific chemical communication channel (Cardé and Baker 1984; Millar et al. 1990). Although *M. privata* is the only Australian geometrid in which C19 triene has been verified as a sex pheromone component, Steinbauer et al. (2004) gave indirect evidence that this compound is used for communication by other sympatric species as three species of Ennominae (two belonging to the same genus) also were caught during field trials. Therefore, it is likely that additional pheromone components are used by *M. privata*. Steinbauer et al. (2004) detected two alcohols (1-hexadecanol and 1-octadecanol) in some female *M. privata* extracts, but neither compound elicited significant antennal responses in males, nor did their addition to lures containing C19 triene enhance trap captures.

The purpose of this study was to search for other pheromone components in female *M. privata*. The response of male *M. privata* to a previously unidentified pheromone component was measured in the laboratory by an electroantennogram, and in the field by using pheromone traps in *Eucalyptus* spp. plantations in Tasmania, Western Australia, Victoria, and South Australia. We also determined the optimal ratio of the two synthetic pheromone components for attraction of male *M. privata*, compared the trapping efficacy of two types of traps, examined the effect of lure age on trap catch, and, for comparison, analyzed male *M. privata* abdominal tip extracts.

Methods and Materials

Insects A colony of *M. privata* was founded (21°C±1°C; 60–70% RH; L12: D12 photoperiod) from collections of eggs and early instar larvae infesting *Eucalyptus globulus* trees near Cornelian Bay, Hobart, Tasmania, during April and May 2005. Larvae were reared on juvenile *E. globulus* leaves placed in ventilated plastic boxes lined with paper toweling and, at the prepupal stage, were placed in boxes containing vermiculite for pupation. Pupae were sexed according the position of the genital scar, stored separately, and monitored daily for emergence. Upon emergence, moths were placed in individual 850-ml round plastic containers (Genfac Plastics Ltd, Melbourne, Australia) with a honey/sugar solution (20 g honey, 20 g sugar, and 2 g ascorbic acid in 1 l boiled water) and held until experimentation.

Extracts Abdomen tips containing the ovipositor and associated pheromone gland were excised from unmated, laboratory-reared, *M. privata* females, 1 (i.e., newly emerged), 3, 5, 7, and 9-d-old (N=10, 8, 10, and 5, respectively), and from three mated females of unknown age. Tips were removed during the first 2 h of the scotophase to increase the chance of sampling calling females. The tips from ten female *M. privata* caught in a light trap 50 km east of Albany, Western Australia, also were analyzed. After freezing females and removing the abdominal tips, each was dissected to determine its mating status. Tips from all females were placed into individual borosilicate vials with 150 µl inserts (Waters Corporation, Australia), soaked in 15 µl of CH_2Cl_2 containing 100 ng methyl stearate as an internal standard for an hour at room temperature, and then the tips were removed before storing the extract at −20°C. The solutions were allowed to reach room temperature before analysis.

Abdomen tips (the genitalia, claspers, and surrounding tissue) were excised from laboratory-reared male *M. privata* moths 1, 3, and 5-d-old (N=3 per age category), and soaked in CH_2Cl_2 as described above. All males were unmated, and had no access to females.

Gas Chromatography-Mass Spectrometry (GC-MS) Analysis GC-MS analyses were carried out on a Varian 3800 GC coupled to a Varian 1200 triple quadrupole MS using 70 eV electron ionization in single quadrupole mode. The column was a Varian 'Factor Four' VF-5 ms (30 m×0.25 mm internal diam and 0.25 micron film). Injections of 1 µl of abdominal tip extracts were made either manually or with a Varian CP-8400 autosampler in conjunction with a Varian 1177 split/splitless injector at 250°C in the splitless mode. The ion source was held at 220°C, and the transfer line at 290°C. The carrier gas was helium at 1.22 ml/min using a constant flow mode. The GC oven was held at 60°C for 1 min then ramped to 150°C at 30°/min, then to 280°C at 8°/min.

Identities of major compounds were assigned based on the previous report from Steinbauer et al. (2004) on this species, mass spectra, and Kovats retention indices relative to those reported in the NIST Chemistry WebBook (http://webbook.nist.gov/chemistry/). Lower levels of trienes were detected in moth extracts by selected ion monitoring (SIM) using characteristic ions at m/z 79 and 108, which were used for comparison of C19 and C21 triene levels. Levels of trienes were estimated in each moth from the ratio of the

response in full scan mode of the triene to the methyl stearate internal standard.

Solutions of C19 and C21 trienes for EAG and field testing were prepared in various C19/C21 proportions ranging from 3:2 to 67:1. These ratios were independently verified by GC-MS analysis of an aliquot of each solution.

Synthesis (3*Z*,6*Z*,9*Z*)-3,6,9-Nonadecatriene (>98% purity) was prepared by JAS and PPM, at the University of Tasmania, as described by Davies et al. (2007). Synthesis of (3*Z*,6*Z*,9*Z*)-3,6,9-henicosatriene (>99.7% purity) was conducted by AN, FA and EH, at Mid Sweden University, as shown in Scheme 1. Unless otherwise stated, starting materials and solvents were used as received from commercial suppliers. Dry THF (benzophenone and potassium) and Et_2O ($LiAlH_4$) were distilled from the indicated drying agents and either used immediately or stored under argon. NMR spectra were recorded on a Varian 500 instrument. GC analyses were carried out using a 30 m×0.25 mm id capillary column coated with EC-1, d_f=0.25 μm, carrier gas: N_2 (15 psi) and a split ratio of 1:20. Mass spectra were recorded on a Varian Saturn 2000 GC-MS instrument. Silica gel 60 (230–400 mesh; Merck, Sigma-Aldrich, Scandinavia) was used in preparative liquid chromatography. Thin layer chromatography (TLC) was performed on silica gel plates (Merck 60, pre-coated aluminium foil) eluted with EtOAc in cyclohexane (40%).

*(9Z,12Z,15Z)-9,12,15-Octadecatrien-1-ol (***2***)* Methyl linolenate (**1**) (1.08 g, 3.69 mmol) dissolved in Et_2O (5 ml) was added to a suspension of $LiAlH_4$ (295 mg, 7.39 mmol) in Et_2O (20 ml) at 0°C, under an argon atmosphere. After 1.75 h, the reaction was quenched with 2 M HCl (aqueous, 15 ml) at 0°C. The organic layer was separated, followed by extraction with Et_2O (3×30 ml), washing of the combined extracts with brine (30 ml), and drying ($MgSO_4$). Evaporation of solvent under reduced pressure resulted in a clear bright yellow oil that was purified by flash chromatography (silica, EtOAc/cyclohexane). Compound **2** was isolated as a clear bright yellow oil, 919 mg (3.48 mmol, 94% yield), with 100% purity according to GC. ^1H and ^{13}C NMR spectra were identical with those reported in literature (Wang and Zhang 2007).

(3Z,6Z,9Z)-Henicosa-3,6,9-triene (C21 triene) 4-Methylbenzene-1-sulfonyl chloride (1.29 g, 6.78 mmol) was added to a solution of alcohol **2** (897 mg, 3.39 mmol) and pyridine (0.80 ml, 10.2 mmol) in CH_2Cl_2 (30 ml) at 0°C, under an argon atmosphere. The reaction mixture was allowed to remain at room temperature for 4 d, after which Et_2O (50 ml) and H_2O (30 ml) were added to the mixture. The organic layer was separated, followed by extraction with Et_2O (3×30 ml), washing of the combined extracts with 2 M HCl (aqueous, 2×30 ml) and brine (2×30 ml), and drying ($MgSO_4$). Evaporation of solvent under reduced pressure resulted in a clear bright yellow oil that was purified by flash chromatography. Tosylate **3** was isolated as a clear, colorless oil, (1.56 g) containing large amounts of 4-methylbenzene-1-sulfonyl chloride. The excess of sulfonyl chloride was removed by reaction of the product mixture with 1,4-butandiol (0.70 ml) in pyridine (1.0 ml) at 5°C overnight. Et_2O (25 ml) and H_2O (25 ml) were added, and the aqueous phase was acidified with 2 M HCl. The organic layer was separated, followed by extraction with Et_2O (4×30 ml), washing of the combined extracts with brine (50 ml), and drying ($MgSO_4$). Evaporation of solvent under reduced pressure resulted in a yellow turbid oil that was purified by flash chromatography. The tosylate **3** was

Scheme 1 Synthetic schemes for (3*Z*,6*Z*,9*Z*)-3,6,9-nonadecatriene (conducted at the University of Tasmania) and (3*Z*,6*Z*,9*Z*)-3,6,9-henicosatriene (conducted at Mid Sweden University)

isolated as a clear colorless oil, 1.07 g (2.56 mmol, 76% yield, pure according to TLC), and used in the next step without further characterization.

Propyl magnesium bromide was prepared by addition of propylbromide (0.47 ml, 5.2 mmol) in THF (5 ml) to magnesium chips (256 mg, 10.5 mmol) under an argon atmosphere. The reaction started spontaneously. After 15 min, the Grignard reagent was transferred by syringe to a flask loaded with CuI (488 mg, 2.56 mmol) at −30°C under an argon atmosphere. After another 15 min, tosylate from above (1.07 g, 2.56 mmol) was added to the grey suspension. The mixture was allowed to reach room temperature slowly and turned black. After 4 d, the reaction was quenched with aqueous saturated NH_4Cl (25 ml) followed by addition of H_2O (25 ml), extraction with Et_2O (3×30 ml), washing of the combined extracts with brine (30 ml), and drying ($MgSO_4$). Evaporation of solvent under reduced pressure resulted in a yellow oil that was purified by flash chromatography. (3*Z*,6*Z*,9*Z*)-Henicosa-3,6,9-triene was isolated as a clear colorless oil, 544 mg (1.87 mmol, 73% yield), with 99.7% purity according to GC. ^{1}H and ^{13}C NMR spectra were identical with those reported in literature (Wang and Zhang 2007). MS (EI) *m/z* (relative intensity): 290 (13 %, M+), 261 (6), 247 (4), 234 (23), 219 (3), 205 (5), 191 (4), 177 (6), 163 (11), 149 (16), 135 (30), 121 (34), 108 (100), 95 (83), 81 (90), 79 (83), 67 (60), 57 (20), 55 (19), 41 (32), 39 (29).

Electrophysiology Electroantennogram (EAG) recordings were prepared by placing an antenna excised from a male between two silver wire electrodes, covered by thin glass capillaries filled with Ringers solution. Antennal responses were recorded via an Intelligent Data Acquisition Controller (IDAC-02, Syntech, Hilversum, the Netherlands) connected to a PC. Antennal preparations were exposed continuously to charcoal-filtered and moistened air with a velocity of 0.5 m/s. Test compounds (5 µl of hexane on filter paper in a Pasteur pipette) were delivered via a 1 s puff of air (5 ml/s) into an opening in the glass tube 150 mm upstream from the antenna, with the outlet 10 mm from the antenna. Stimuli were administered by that device. The solvent was allowed to evaporate from the filter paper prior to testing. The EAG responses of males to the C19 and C21 trienes, hexadecyl acetate, and 1-octadecanol (all >99% purity) were tested on the antennae of four to 12 males. EAG recordings were analyzed using 'GcEad' software, version 4.1 (Syntech, the Netherlands 2005). For data analysis, the mean solvent signal was subtracted from each mean stimulus signal. All amplitudes were normalized to the amplitude recorded in response to the reference stimulus.

GC-Electroantennogram (EAD) analysis that used combined gland extracts from three virgin females was conducted on antennae of males prepared as described above. Extracts (1 µl) were injected into a Varian Vista 6000 GC in splitless mode with an injection temperature of 220°C, and the oven was held at 60°C for 1 min and then ramped to 240°C at 20°/min, with a 5 min hold. The GC was equipped with an HP-5, (5% phenyl)-methylpolysiloxane column, 12 m×0.2 mm id, phase thickness 0.33 ìm. Nitrogen was used as carrier gas. A GC effluent splitter (split ratio 1:1) was used. One stream was directed to a flame ionization detector (FID), and the second was added through a heated transfer line to the air stream and directed over the excised antenna of a male moth, as described above. EAD signals and FID responses were recorded simultaneously by the IDAC2 connected to a PC via Syntech GcEad software.

Field Trials Field trials were carried out in commercial plantations of *Eucalyptus nitens* and *E. globulus*, 2–5-y-old, in Tasmania, Western Australia, Victoria, and South Australia in 2007 and 2008. Lures were prepared by dissolving compounds in hexane, with *ca* 1% of the antioxidant butylated hydroxytoluene, and applying 100 µl of solution into rubber septa (Sigma-Aldrich, Australia), then allowing the solvent to evaporate in a fume hood before storing at −20°C. Control septa were loaded with 100 µl of hexane. Unless otherwise stated, green Unitraps (PheroBank, the Netherlands) were used in trapping studies. The base of each trap was sprayed with a persistent surface insecticide to kill trapped moths and to prevent moths from being removed by ants and wasps. Traps were suspended within tree rows from metal poles at *ca* 1.5 m height.

Experiment 1. Field Bioactivity of C21 triene: Starting in March 2007, captures of male *M. privata* in Unitraps baited with 1 mg, 5 mg, or 10 mg C19 triene and 1 mg C19 triene + 25 µg C21 triene (40:1 ratio) were compared in commercial *Eucalyptus* plantations at various locations in southern Australia. In Tasmania, three replicates of each lure type were placed in 2–5-yr-old *E. nitens* plantations at the Surrey Hills estate, near Hampshire (NW Tasmania), three in Gould's Country (NE Tasmania), three in the Geeveston area and one near Pittwater and one near Nugent (Southern Tasmania). Three replicates of each lure type (except the 5 mg C19 triene dose) were placed in 2–5-yr-old *E. globulus* plantations near Albany, Western Australia, and four replicates were placed in the Green Triangle area on the Victoria/South Australian border. Single lines of Unitraps containing each lure type were placed 10–30 m apart at a height of 1.5 m in random order, spacing replicate rows at least 100 m apart. The position of each lure type within a replicate row was assigned randomly. Traps were checked on a weekly or fortnightly basis, and trap positions within rows were rotated in order to reduce

any positional bias in moth capture. Captured moths were identified, counted, and sexed. In Victoria/South Australia and Western Australia, trapping was terminated in May and June 2007, respectively. In Tasmania, trapping extended to February 2008, and lures were changed in December 2007 as detailed in Experiment 2.

Experiment 2. Optimal Ratio of C19 and C21 Trienes for Trapping Male M. privata: Lures loaded with blends of C19:C21 trienes at 3:2, 16:1, 33:1, 40:1, and 67:1 ratios were made by adding the required amount of C21 triene to 1 mg C19 triene. Lures loaded with 1 mg C19 triene only, 25 μg of C21 triene only (equivalent to the amount of C21 triene added to 40:1 ratio C19:C21 triene baits), and hexane only (controls) also were formulated. Single rows of randomly assigned Unitraps each containing one of the test lures were spaced 10 m apart at 1.5 m height in 2–5-yr-old *E. nitens* plantations at five locations in the Surrey Hills estate. Replicate rows of traps were spaced at least 100 m apart. The number of male *M. privata* caught was monitored 19 December 2007 to 18 March 2008, checking traps and rotating their positions about every 2 wk. Baits were not replaced over the trapping period.

Experiment 3. Comparison of Trap Design: The trapping efficiency of the green Unitraps was compared with white Delta traps in a 4-yr-old *E. nitens* plantation near Buckland, southern Tasmania. Five pairs of each trap design were placed 10 m apart, with a distance of 5 m between pairs and a trap height of 1.5 m. All traps were baited with lures containing 1 mg C19 triene + 60 μg C21 triene (16:1 ratio). The order of trap design within each pair was assigned randomly. Trap catch was checked once after a 4 d trapping period between 4 and 8 April, 2008.

Experiment 4. Effect of Lure Age on Trap Catch: The number of male *M. privata* caught in five Unitraps baited with fresh lures loaded with 1 mg C19 triene + 60 μg C21 triene (16:1 ratio) was compared with the catch for five traps baited with comparable lures that had been aged in the field for 3 mo from experiment 2. Deployment of traps was as for Experiment 3. The order of trap design within each pair was assigned randomly. Trap catch was checked twice over a 24 d trapping period between 8 April and 2 May, 2008, in the *E. nitens* plantation near Buckland, southern Tasmania.

Statistical Analysis SPSS version 16.0 for Windows (SPSS Inc. 2007) was used to analyze EAG and field trapping data. EAG responses to test compounds (mV) were normalized to the mean response to hexane as the reference stimulus (= 100%). Normalized antennal responses and pheromone trapping data from Experiments 1 and 2 were analyzed using ANOVA, while data from Experiments 3 and 4 were compared using *t*-tests. Data was checked for variance homogeneity by using Levene's homogeneity-of-variance test and transformed if necessary. If the ANOVA *F*-value was significant, differences between means were then tested for significance by the least significant difference test (LSD) at the 5% probability level.

Results

GC-MS Analysis of Solvent Extracts Twenty-one compounds were identified tentatively from gland extracts of 41 individual *M. privata* females from Tasmania by GC-MS (Table 1). Detailed examination of the mass spectra of all major and minor compounds in an individual female with relatively high levels of C19 triene revealed one compound (peak 8 in Fig. 1) that had very similar MS characteristics of a polyunsaturated compound (i.e., ions at *m/z* 67, 79, and 108). Also, the diagnostic ion at *m/z* 206 observed in the C19 triene (M- 56) was seen at *m/z* 234, consistent with an extra C_2H_4 unit (Fig. 2). Given that (3*Z*,6*Z*,9*Z*)-3,6,9-henicosatriene already had been recorded as a pheromone component in some Geometridae species (Millar 2000; El-Sayed 2008), this compound was synthesized. The synthetic C21 triene retention characteristics and mass spectrum were indistinguishable from that of the moths' compound, and the standard co-eluted with female moth component 8. Other components of interest found in female extracts were hexadecyl acetate along with the previously reported *n*-hexadecanol and *n*-octadecanol (Steinbauer et al. 2004). These three compounds were found in only a few females in variable quantities. Levels of trienes also were extremely low in some moths, and it was not possible (even by SIM-MS) to determine the C19/C21 triene ratio in all individuals. The C21 triene was below the detection limit in 23 out of 41 extracts, while the C19 triene was below detection limit in one female extract. Consequently, the calculated C19:C21 ratio is based on 15 individual females of known age and three of unknown age in which both compounds could be measured. Mean estimated titers of trienes per female (calculated as internal standard equivalents) were 30.74 ng (± 6.1 SE) (range= 604 pg to 143 ng) for C19 triene, and 1.44 ng (± 0.3 SE) (range=368 pg to 3.8 ng) for C21 triene. Estimated titers of C19 and C21 trienes were highly correlated (Pearson's correlation coefficient=0.956, $P<0.001$, $N=15$) (Fig. 3a). Mean titers of both compounds peaked in 7-d-old females and decreased markedly in 9-d-old females (Fig. 3b), but was again highly variable within age categories. The mean ratio of C19:C21 trienes in female *M. privata* from Tasmania was 33:1 (± 2.3 SE, range 8:1 to 54:1), compared to females from Western Australia which exhibited a mean C19:C21 trienes ratio of 5.7:1 (± 0.6 SE, range 3.5:1 to

Table 1 Peak number, kovats retention index and tentative. identities of the main compounds detected in abdominal tip extracts from female *Mnesampela privata*

[a] Numbers correspond to peaks in chromatogram in Fig. 1

9.7:1), which was significantly different from the ratio found for moths from Tasmania (*t-test*, t=7.614, df=26, P<0.001). Dissections revealed that all of these females had mated once.

SIM analysis of solvent extracts from the abdominal tips of nine male *M. privata* from Tasmania, detected C21 triene in six individuals, and (3*Z*,6*Z*,9*Z*)-3,6,9-tricosatriene (C23 triene) was tentatively identified in all individuals. No C19 triene was found in any of the male extracts. Levels of both trienes varied widely between males as did the ratio of C23: C21 triene. Mean estimated of C21 triene titers in extracts of males was 1.56 ng (± 0.3 SE, range=415 pg to 2.27 ng), which was not significantly different from that found in female extracts (*t-test*, t=0.24, df=19, P>0.05). Mean estimated titers of C23 triene was 7.33 ng (± 1.7 SE, range 961 pg to 16.71 ng), while the mean ratio of C23:C21 triene was 5.2:1 (± 1.1 SE, range 2.3:1 to 10.6:1).

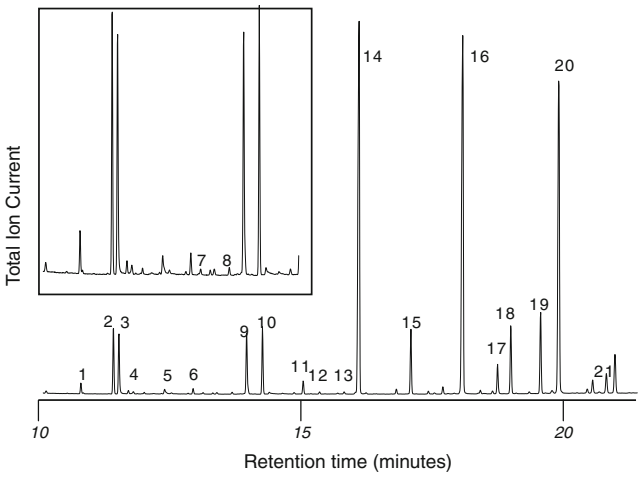

Fig. 1 Representative total ion current chromatogram of extract from a female *Mnesampela privata* abdominal tip. Number designations for peaks are as listed in Table 1. Insert shows magnified portion of chromatogram to indicate where compounds 7 (*n*-octadecanal) and 8 ((3*Z*,6*Z*,9*Z*)-3,6,9-henicosatriene), eluted

EAG and GC-EAD EAG responses of male *M. privata* antennae to C19 and C21 trienes differed (Fig. 4). Antennal responses to 5 μg of C21 triene were consistently higher than the blank stimulus, but lower than that to 5 μg C19 triene (P<0.05, LSD). EAG response to C21 triene was greater than that of 1-octadecanol and hexadecyl acetate (P<0.05, LSD), which elicited an antennal response similar to the blank stimulus. When C21 triene was added to 5 μg C19 triene at a range of ratios, including similar to that found in female extracts, there was a slightly but not significantly enhanced antennal response (P>0.05, LSD) (Fig. 4).

GC-EAD runs that used the combined abdominal extracts from three female *M. privata*, which had relatively high levels of C19 and C21 trienes as previously determined by GC-MS, elicited a weak responses (<2 mV) in antennae of males to the C19 triene. No antennal response or FID peak was detected in the region where the C21 triene was expected to elute.

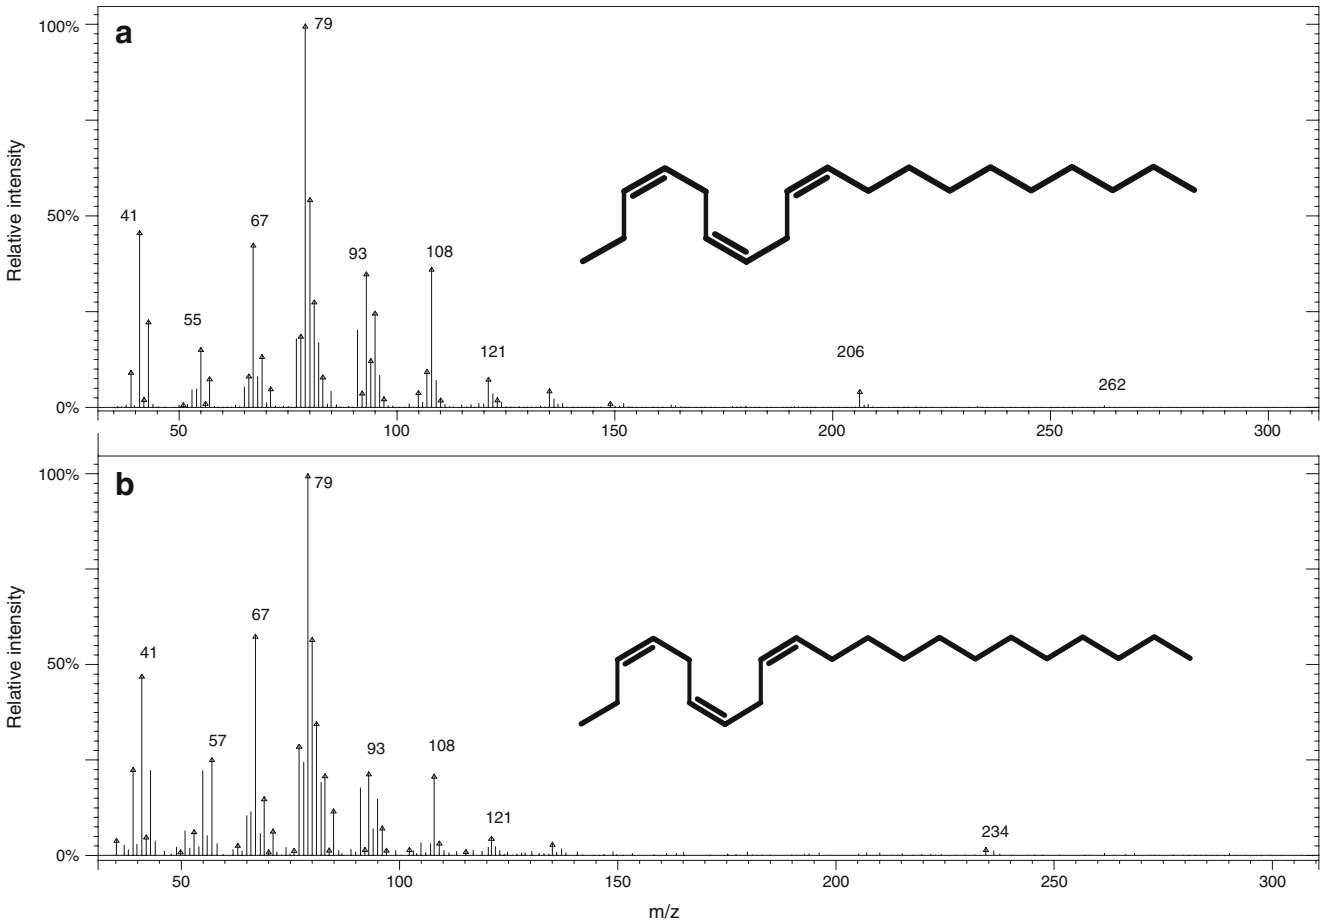

Fig. 2 EI mass spectra of C19 (**a**) and C21 (**b**) trienes from female *Mnesampela privata*

Field Trials

Experiment 1. Field Bioactivity of C19 and C21 Trienes: Significantly more *M. privata* males were caught in traps baited with a 40:1 ratio of C19:C21 trienes than in traps baited with C19 triene alone, but there was no significant difference in the number of males caught in traps baited with 1 mg, 5 mg or 10 mg C19 triene (ANOVA, $\log_{10} + 1$ transformed counts, F=4.9, df=62, P<0.05, followed by LSD test at P=0.05) (Table 2). The majority of males were caught at Surrey Hills, NW Tasmania, where a high *M. privata* population developed in late summer 2007. No *M. privata* were caught in traps placed in plantations in Victoria/South Australia, and trap captures were also low in Western Australia where trials were conducted late in the flight season. Across all plantations (N=18 locations), *M. privata* males were caught at 61.1% of locations when traps were baited with a 40:1 blend of C19:C21 trienes compared to 16.7% when traps were baited with 1 mg C19 triene only.

A large number of *Androchela smithi* McQuillan (Ennominae) also were caught in traps at Surrey Hills, north western Tasmania, during the *M. privata* flight period; 194 in 1 mg C19 triene only baited traps, and 60 in traps baited with a 40:1 ratio of C19:C21 triene. At this location, three moths of an unidentified geometrid species were also caught in C19 triene traps in March 2008. In traps placed in southern Tasmania, 12 *Mnesampela heliochrysa* (Lower) were caught in C19 triene only baited traps, but none were caught in 40:1 ratio of C19:C21 triene baited traps

Experiment 2. Optimal Ratio of C19 and C21 Trienes for Trapping M. privata: A total of 868 male *M. privata* were caught in five replicate traps of eight test baits between 19 December 2007 and 18 March 2008, at Surrey Hills, NW Tasmania. Lures containing C19 and C21 trienes in a ratio of 16:1, 33:1, and 40:1 caught significantly more *M. privata* males than those with a 3:2 and 67:1 ratio or C19 triene only (Table 3). Traps baited with C21 triene only (loaded at an amount equivalent to that in the 40:1 ratio C19:C21 triene baits) or hexane only did not catch any male *M. privata*. When trap catch was expressed as the proportion of male *M. privata* caught in each bait type at each replicate site, captures in 16:1 ratio of C19:C21 trienes were significantly higher than other blends (Fig. 5).

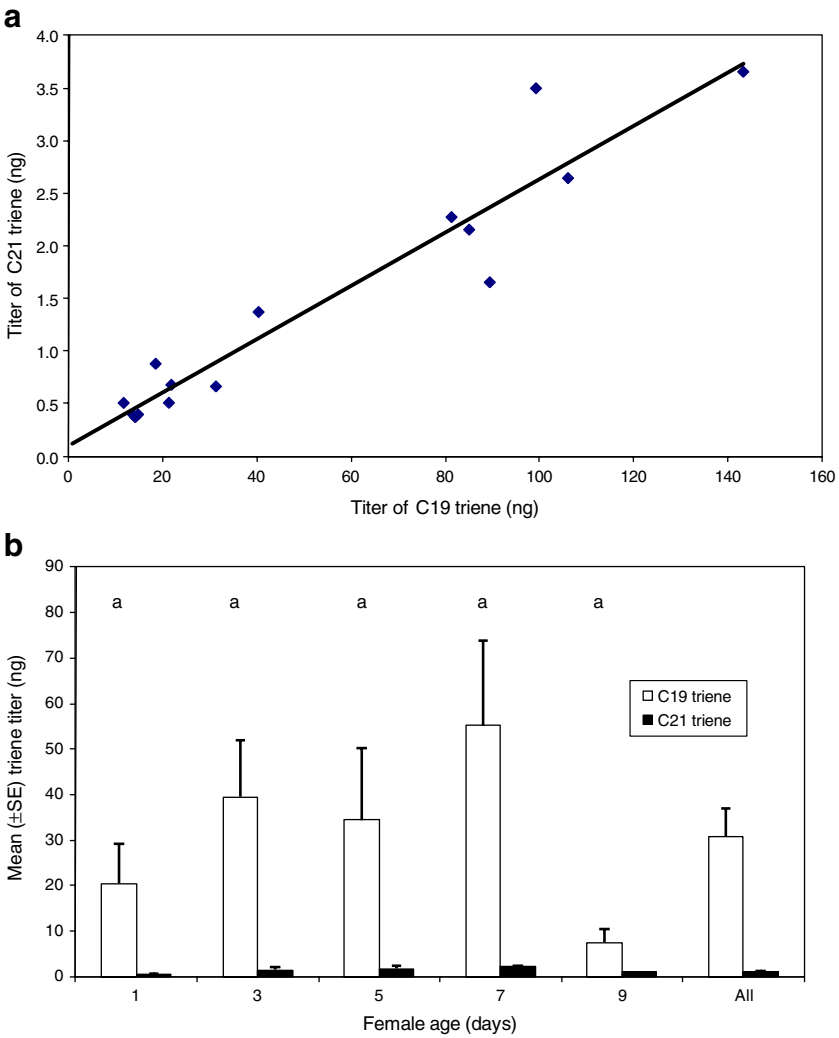

Fig. 3 **a** Correlation between estimated titers of C19 and C21 trienes in individual, unmated, female *Mnesampela privata* abdominal tip extracts, originating from Tasmania (N=15), calculated as methyl stearate equivalents (see text). Levels were positively correlated (Pearson's correlation coefficient=0.956, P<0.001). **b** Mean (± SE) estimated titers of C19 and C21 trienes (nanograms) in abdominal tip extracts of unmated female *M. privata*, originating from Tasmania 1, 3, 5, 7 and 9-d-old and for all moths analysed (C19 triene: N=10, 7, 10, 5, 5 and 37 females, respectively; C21 triene: N=2, 4, 5, 3, 1, and 15 females, respectively). Letters above C19 triene means indicate that they were not significantly different by ANOVA (F=1.4, df=36, P=0.256). C21 triene means were not statistically compared due to the small sample size in some age categories

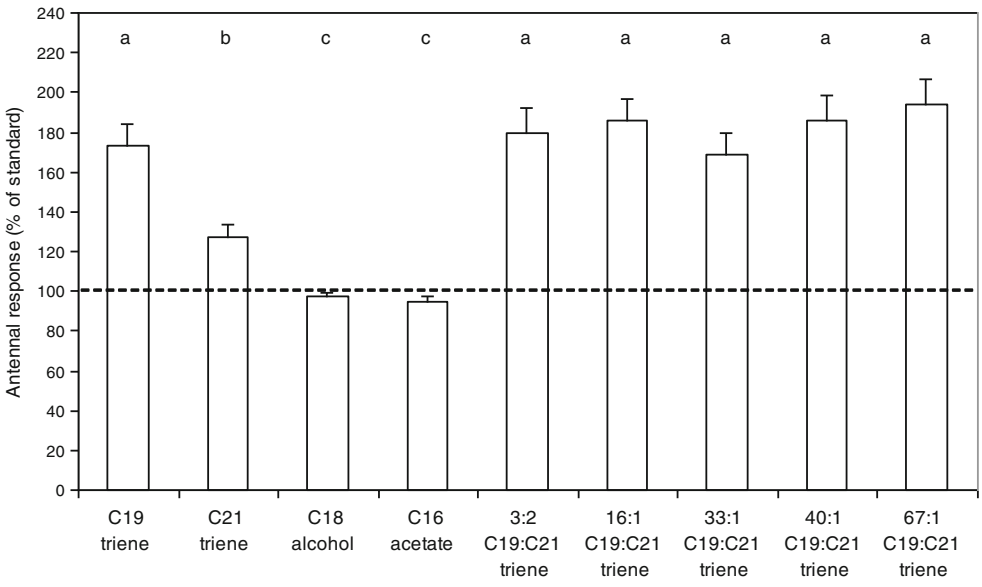

Fig. 4 Mean (± SE) EAG response of male *Mnesampela privata* antennae to 5 μg of C19 triene, C21 triene, 1-octadecanol (C18 alcohol), hexadecyl acetate (C16 acetate) and various blends of C19:C21 trienes dissolved in hexane, expressed as a percentage of the control stimulus (dashed line). Means with different letters atop bars are significantly different by one-way ANOVA (F=12.18, df=75, P<0.001) followed by the LSD test (P=0.05). Number of antennae tested: C19 and C21 trienes alone N=12, C18 alcohol and C16 acetate N=4 and triene blends N=8

Table 2 Field captures of *Mnesampela privata* in traps baited with C19 triene alone or C19 triene + C21 triene (40:1 ratio) placed in *Eucalyptus* plantations at various locations around Australia

Lure composition		Total number of males captured/location[a]				
C19 triene (mg)	C21 triene (μg)	NW Tasmania	NE Tasmania	Southern Tasmania	Victoria/South Australia	Western Australia
1	0	45	0	0	0	0
5	0	21	0	0	NT[b]	NT
10	0	22	0	0	0	1
1	25	456	25	21	0	12

[a] Traps replicated three times each location except Victoria/South Australia and Southern Tasmania where four and five replicates were employed, respectively. Trapping was conducted in Tasmania April 2007–February 2008, Victoria/South Australia March–May 2007 and Western Australia April–June 2007

[b] *NT* not tested

A total of 73 *A. smithi* were caught in traps baited with C19 triene only (mean=14.6 moths/trap) compared to 2, 5, 2, 3, and 2 *A. smithi* caught in 3:2, 16:1, 33:1, 40:1, and 67:1 ratio of C19:C21 triene, respectively (overall mean for blends=0.6 moths/trap). While no *M. privata* were caught in traps baited with C21 triene only, 1 *A. smithi* (mean=0.6 moths/trap) and 1 unidentified geometrid were caught. One unidentified species of geometrid also was caught in a trap baited with a 3:2 ratio of C19:C21 triene. No moths were caught in the control traps.

Experiment 3. Comparison of Trap Design: The mean number of male *M. privata* caught in Delta traps (33.0± 1.4 SE, range 29–36 moths per trap) was higher than in Unitraps (11.6±2.5 SE, range 7–19 moths per trap) (*t*-test, $t=7.31$, $df=8$, $P<0.001$).

Experiment 4. Effect of Lure Age on Trap Catch: There was no significant difference in the number of male *M. privata* caught in traps baited with new lures of 16:1 C19:C21 trienes (mean=19.6±1.2 SE) vs. lures aged in the field for 90 days (mean=23.4±2.1 SE) (*t*-test, $t=1.12$, $df=8$, $P>0.05$).

Discussion

We identified (3*Z*,6*Z*,9*Z*)-3,6,9- henicosatriene as a second bioactive compound in the sex pheromone of *M. privata*, in addition to the major component (3*Z*,6*Z*,9*Z*)-3,6,9-nonadecatriene. Field trials in Tasmania demonstrated that the addition of 1–6% of C21 triene to 1 mg C19 triene significantly increased the number of male *M. privata* caught in traps. Addition of C21 triene to C19 triene also increased the sensitivity of pheromone traps to detect low populations of *M. privata* in *Eucalyptus* plantations, and significantly reduced cross-attraction of other geometrid species. Essential minor pheromone components have been documented in several other geometrid species that utilize polyene hydrocarbons. For example, Szöcs et al. (2004) found that captures of male *Operophtera fagata* Scharf. increased significantly when as little as 0.1% of (1,3*Z*,6*Z*,9*Z*)-nonadecatetraene was added to the main component, (6*Z*,9*Z*)-nonadecadiene.

C19 and C21 trienes are components of the female sex pheromones in many species of Geometridae, Noctuidae, Arctiidae, and Lymantriidae (El-Sayed 2008). To our knowledge, identification of both C19 and C21 trienes in the same sex pheromone has been verified in only one other

Table 3 Field captures of M*nesampela privata* in traps baited with various blends of C19 triene and C21 triene

Traps replicated five times and placed in *E. nitens* plantations at Surrey Hills estate, NW Tasmania, from December 19, 2007 to March 18, 2008

[a] Captures followed by different letters are significantly different by ANOVA ($\log_{10}$ + 1 transformed counts), $F=20.75$, $df=39$, $P<0.001$, followed by the LDS test ($P=0.05$)

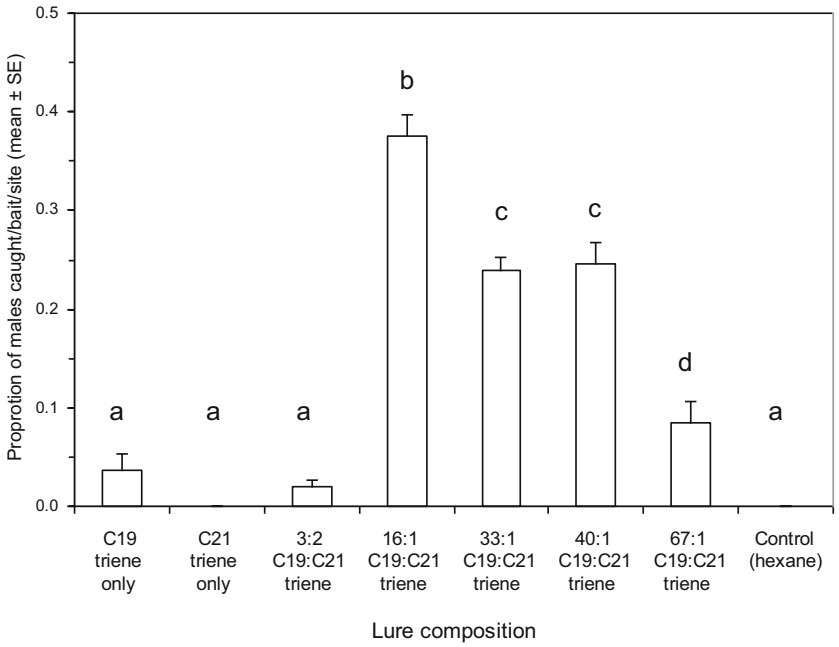

Fig. 5 Mean proportion (± SE) of *Mnesampela privata* males caught at each site (N=5) in Unitraps baited with 1 mg C19 triene alone, 0.25 µg C21 triene alone, hexane only or 1 mg C19 triene with varying amounts of C21 triene to give indicated ratios. Means with different letters atop bars are significantly different by ANOVA (F=82.54, df=39, P<0.001) followed by the LSD test (P=0.05). Trapping was conducted between 19 December 2007 and 18 March 2008 in *E. nitens* plantations at the Surrey Hills estate, NW Tasmania

species, *Colotois pennaria* L. (Szöcs et al. 1993; El-Sayed 2008), which belongs to the same subfamily as *M. privata*. Millar et al. (1992) identified both C19 and C21 trienes in pheromone gland extracts of *Epirrhoe sperryi* (H.). However, only C19 triene was attractive in the field, despite EAG activity of C21 triene in the laboratory. Wong et al. (1985) and Millar et al. (1991) reported that males of several other species of Geometridae and Noctuidae responded to both C19 and C21 trienes during electroantennogram testing, but the actual presence of these compounds in the sex pheromone was not determined, nor was the attraction to both trienes tested in the field. Several species of moths utilize blends of polyene hydrocarbons with mixed chain lengths, but usually the blend consists of compounds differing by only one carbon (Millar 2000). Therefore, *M. privata* and *C. pennaria* appear to be unique in that they use a blend of 3*Z*,6*Z*,9*Z* trienes that differ by two carbons.

While levels of the C19 and C21 trienes in individual females varied widely, the ratio of these two compounds was more constant and highly correlated (Fig. 3a). In Tasmanian *M. privata*, the mean ratio of C19:C21 trienes changed linearly from a 29:1 in 1-d-old females to 43:1 in 7-d-old females. Although this difference was not significant here, Allison and Cardé (2006) found that the ratio of pheromone components in a pyralid moth (*Cadra cautella* (Walker)) changed with female age, and suggested that males could use this to assess the reproductive value of females, which declined markedly with age. If this is the case in *M. privata*, it may explain why significantly more males were caught in traps baited with a lower ratio of C19:C21 triene (16:1) than in traps baited with a ratio closer to the average found in females (33:1) (see also: Szöcs et al. 1993; Strong et al. 2008).

GC-MS analysis of gland extracts from females caught in a light trap near Albany, Western Australia, found significant differences in the ratio of the two trienes compared to populations from Tasmania. Preliminary field trials in Western Australia suggested that increased trap sensitivity could be gained from the addition of more C21 triene to C19 triene but further research is needed to confirm the optimal ratio of these compounds to use for monitoring male *M. privata* in this and other geographical areas.

In their trapping study that used C19 triene baits, Steinbauer et al. (2004) reported catching three closely related species of geometrid: *Dolabrossa amblopa* Guest, *Mnesampela heliochrysa*, and *M. arida* McQuillan. In our study, we caught large numbers of *A. smithi* and *M. heliochrysa* in Tasmania during the flight period of *M. privata*. No *M. heliochrysa* were caught in traps baited with a blend of C19 and C21 trienes thus suggesting that the latter compound may act as a behavioral antagonist to this species. Little is known about the biology of *A. smithi*, which was described relatively recently and has been previously collected only from the Tasmanian highlands (McQuillan 1996). Captures of *A. smithi* occurred in traps baited with a range of blends of C19 and C21 trienes, but were significantly lower than in traps baited with C19 triene alone. Similarly, in field trials in Canada, Millar et al. (1992) reported the indiscriminate cross attraction of *E. sperryi* to lures containing C19 triene regardless of whatever other components were added, suggesting that other physiological or behavioral

mechanisms (e.g., closely synchronized female calling and male response) minimize male attraction to pheromone blends produced by female moths of sympatric species.

Our discovery that male *M. privata* also produce the C21 triene found in females is similar to the finding of Heath et al. (1988). They also found that abdominal tip extracts from males of the noctuid *Anticarsa gemmatalis* (Hübner) contained C21 triene, which is a major component of the female sex pheromone of this species, and suggested that it is a hairpencil compound used during courtship.

In summary, we recommend that traps used to monitor *M. privata* populations in Tasmania be baited with lures that contain both C19 and C21 trienes, at a ratio of 16:1. However, further research is needed to verify whether this is an optimal ratio of trienes to use for monitoring *M. privata* in other geographical areas. We also recommend the Delta trap design for monitoring *M. privata* in preference to the Unitrap design due to lower costs and more efficient capture rates. In the light of the recommendation to include C21 triene in the pheromone bait, the relationship between trap catch and subsequent *M. privata* egg and larval infestations needs to be re-examined as Östrand's et al. (2007) trapping studies were conducted with baits containing C19 triene only. The use of synthetic pheromone for the control of *M. privata*, through mating disruption or mass trapping, is not economically feasible at present given the high costs associated with the synthesis of the C19 and C21 trienes and the sporadic nature of this pest.

Acknowledgements This research was funded by the Australian Research Council Linkage Projects grant LP0455303. We thank Gunns Ltd, Forestry Tasmania, Timbercorp, WAPRES, and FFIC for funding and assistance. PPM is thankful to the University of Tasmania and the Thomas Crawford Foundation for a postgraduate scholarship. Thanks also to: Dr. Peter McQuillan (University of Tasmania) and Dr. Cathy Young (Tasmanian Museum and Art Gallery) for identifying geometrids, Dr. Mamoru Matsuki (IPMG, Albany) for conducting trapping trials in Western Australia and supplying moths for analysis, Mr. Ben Bradshaw (Timbercorp, Penola) for conducting trapping trials in Victoria and South Australia, and Dr. Martin Steinbauer for help with comments on the manuscript and the formulation of the original grant. We are also grateful for the financial support (for AN, FA, and EH) from the European Regional Development Fund and Länsstyrelsen i Västernorrlands län.

were analyzed initially by gas chromatography mass spectrometry to confirm the presence and Kovat's Indices of 25 cuticular hydrocarbons (CHs) identified by Rivault et al (1998). The amount of each of these CHs in extracts was determined using a Varian CP3380 gas chromatograph, fitted with a flame ionization detector, a CP-sil/5CB column (Varian Inc., 25 m×0.32 mm ID) and a split–splitless injector (split-flow=60 ml min^{-1}; opening 30 sec after injection) with helium as carrier gas (50 cm sec^{-1}). The oven was programmed from 140°C (2 min.) to 280°C at 5°C min^{-1}. CH proportions in control and spinosad-treated individuals (N=10) were compared using a t-test after arcsine transformation to normalize the data.

Statistical analyses were carried out using XLSTAT 2007 software (Addinsoft, New York, NY)

Results

The attractiveness of control female and male extracts was significantly different (Fig. 1; Chi_{15}^2=82.2; P<0.001); control female extract attracted significantly more control insects (96.7% males and 100% females) than did control male extract (90% males and 80% females).

Spinosad treatment produced several behavioral effects: (1) extract of treated females was less attractive than extract of untreated females to both control male and female cockroaches; there was no difference between attractiveness of extracts of treated and untreated males to control insects (Fig. 1a); (2) the responses of treated males to all extracts was low, although their response to control female extract was slightly higher (40%) than to all the other extracts (each 30%); (3) treated females responded similarly to extracts of males and females, whether they were from controls (50–60% for males and females) or treated (30% each from males and females) insects.

Spinosad treatment gave a significant decrease (10–30%) in the relative amounts of n-octacosane, 4-methyloctacosane, and n-nonacosane in both sexes, of 5-methylnonacosane and 3-methylnonacosane in males, and of 5,9- & 5,11-dimethylhentriacontane in females (Table 1).

Discussion

B. germanica males and females both were attracted more to female than to male cuticular extract. This confirms previous work by Tsai and Lee (1997), that showed a preference by males for female stimuli, but it contradicts their observed lack of female preference to female or male stimuli.

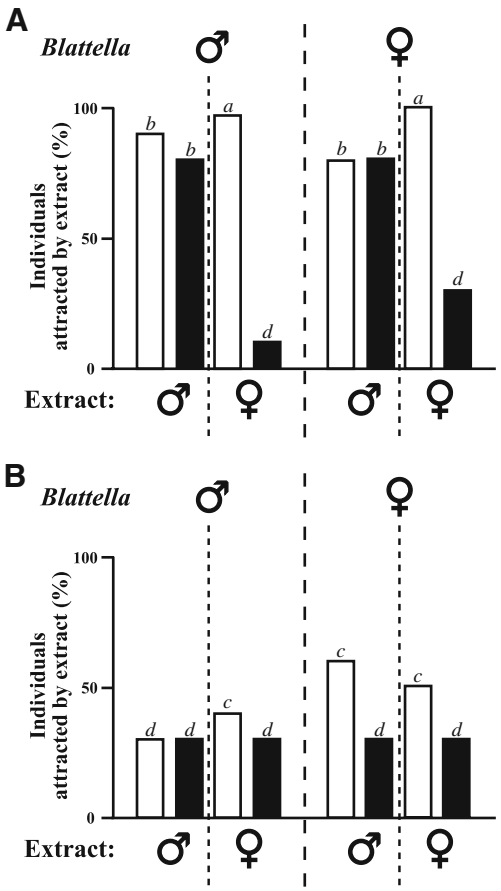

Fig. 1 Responses of control (**a**) and spinosad-treated (**b**) adult male and female *Blatella germanica* to hexane extracts of untreated (*open bars*) and spinosad-treated (*filled bars*) males and females. Cockroaches were tested in a Y-maze olfactometer. The frequencies of attracted insects were analyzed using a Chi-square test; identical *lowercase letters in italics* indicate values that were not significantly different from each other; N=10–30

We observed two effects of spinosad treatment on *B. germanica* chemical communication. First, responses of treated (male and female) adults to male or female control extracts were lower than for controls. Second, the attractiveness of extract from treated females to control adults (both male and female) was lower than that for extract of untreated females. As spinosad acts on the insect nervous system (Watson 2001), its effect on cockroach responses is not surprising. However, its effect on the attractiveness of female extracts was unexpected.

In *B. germanica*, male courtship is modulated by two pheromones: a female-produced contact pheromone (Eliyahu et al. 2008), and a female-produced volatile pheromone, blattellaquinone, which attracts males over a distance (Nojima et al. 2005). Spinosad affected quantities of four (CHs 7, 12, 15, and 17; see Table 1) of the six CHs that are described as aggregation cues in *B. germanica* (Rivault et al. 1998), which could, in turn, influence

Table 1 Proportion of the cuticular hydrocarbons (CHs) of control and spinosad-treated male and female *Blattella germanica*. In each sex, the proportion of each compound was compared between control and treated cockroaches by a bilateral *t*-test (after an *Arcsin* transformation)

t-Value (18 df) and the corresponding *P* are provided when significant.

[a] The CHs are identifed following Rivault et al. (1998).

aggregation responses to treated cockroaches. However, this would not explain why we obtained reduced attraction to treated cockroach extract in the olfactometer. Future work should investigate whether spinosad treatment affects blattellaquinone production.

We have shown previously that other insecticides affect the CH profile in *B. germanica*. A sub-lethal dose of boric acid feminized the CH profile of males but did not change female the CH profile (Kilani-Morakchi et al. 2005). Halofenozide (an ecdysteroid agonist) decreased CH levels, probably by affecting synthesis and/or transport (Kilani-Morakchi et al. in press). Work is needed to determine precisely how these chemicals influence CH production in insects.

glucose moiety and the formation of deterrent breakdown products, including nitriles, isothiocyanates, thiocyanates, oxazolidine-2-thiones, and epithionitriles (Grubb and Abel 2006; Halkier and Gershenzon 2006). More than 120 different glucosinolate side chains have been identified (Fahey et al. 2001), and at least 37 of these are found in different isolates of the well-studied model plant *Arabidopsis thaliana* (Reichelt et al. 2002).

Plutella xylostella, as a crucifer specialist, has evolved an effective detoxification system through the use of sulfatases that change the glucosinolate chemical structure to prevent the action of myrosinase enzymes on this substrate. Consequently, fewer toxic glucosinolate breakdown products are formed (Ratzka et al. 2002). With this ability to freely exploit cruciferous plants as a food source, *P. xylostella* actually uses components of the glucosinolate-myrosinase system as highly predictable oviposition cues. Glucosinolate-containing fractions of extracts of the cruciferous crop species *Brassica napus, B. juncea*, and *Sinapis alba* were found previously to attract ovipositing *P. xylostella*. These extracts contain a mixture of glucosinolates, including those with indole side chains. They were found to stimulate oviposition, but lost their activity upon *in vitro* hydrolysis by myrosinase, indicating that intact glucosinolates can function as oviposition cues for *P. xylostella* (Reed et al. 1989). However, specific fractions of glucosinolate breakdown products from cabbage leaves have been found to significantly increase oviposition by *P. xylostella* (Hughes et al. 1997). These active compounds were identified later as the aliphatic glucosinolate-derived breakdown products iberin and sulforaphane, both of which are isothiocyanates that stimulate *P. xylostella* through olfaction (Renwick et al. 2006). Whereas the *in vitro* role of aliphatic glucosinolate breakdown products and intact indole glucosinolates on oviposition by *P. xylostella* is documented, the attractive effects of these compounds have not been studied well *in vivo*.

A multitude of mutant and transgenic isolates of *A. thaliana* provide an excellent foundation for the study of the chemical attractants involved in *P. xylostella* oviposition. *Arabidopsis thaliana* with T-DNA knockout mutations of both CYP79B2 (At4g39950) and CYP79B3 (At2g22330), two cytochrome P450s that lead to the production of indole-3-acetaldoxime, are almost completely blocked in the production of indole glucosinolates (Zhao et al. 2002). The transcription factors MYB28 (At5g61420) and MYB29 (At5g07690) previously have been identified as regulators of methionine-derived glucosinolates biosynthesis (Gigolashvili et al. 2007, 2008), and the *myb28 myb29* double mutant is almost completely devoid of aliphatic glucosinolates (Sønderby et al. 2007; Beekwilder et al. 2008). The two double mutants make it possible to study the *in planta* function of these two major classes of glucosinolates, aliphatic and indole, on *P. xylostella* oviposition. Furthermore, the inactivation of TGG1 (At5g2600) and TGG2 (At5g25980), the two predominant above-ground myrosinases of *A. thaliana* largely eliminates damage-induced glucosinolate breakdown (Barth and Jander 2006). The *tgg1 tgg2* double mutant allows examination of the effect of glucosinolate breakdown on oviposition by *P. xylostella*. To determine which components of the glucosinolate-myrosinase system serve as signals for ovipositing *P. xylostella*, we performed bioassays on extracts and intact plants impaired in different aspects of this chemical defense. We demonstrated that intact indole glucosinolates and hydrolysis products of aliphatic glucosinolates function as important oviposition stimuli *in vivo*. In particular, an indole glucosinolate with secondary modifications is used as a reliable host recognition cue by *P. xylostella* females.

Methods and Materials

Plants and Insects Wildtype *A. thaliana* land race Columbia-0 (Col-0) seeds were obtained from the Arabidopsis Biological Resource Center (ABRC, www.arabidopsis.org). The Col-0 *cyp79B2 cyp79B3* (Zhao et al. 2002) and *cyp81F2* (Clay et al. 2009) mutants were kindly supplied by J. Celenza (Boston University, Boston, MA, USA) and N. Clay (Massachusetts General Hospital, Boston, MA, USA), respectively. Creation of the *tgg1-3 tgg2-1* and *myb28-1 myb29-1* double mutants by crossing the T-DNA insertion lines SAIL_786_B08 (*tgg1-3*) and SALK_038730 (*tgg2-1*), and SALK_136312 (*myb28-1*) and GABI_868E02 (*myb29-1*), respectively, has been described previously (Barth and Jander 2006; Sønderby et al. 2007). The quadruple mutant *cyp79B2 cyp79B3 tgg1 tgg2* was described previously by De Vos et al. (2008). Plants were grown in Conviron (Winnipeg, Canada) growth chambers in 20- x 40-cm nursery flats using Cornell Mix (Landry et al. 1995) with Osmocoat fertilizer (Scotts, Marysville, OH, USA) at 23°C, 60% relative humidity, with a light intensity of 180 $\mu mol^{-2}\ s^{-1}$ photosynthetic photon flux density and a 16:8 h light:dark photoperiod.

Initially, *P. xylostella* eggs were purchased from Benzon Research (Carlisle, PA, USA). Insects were reared to pupation in Petri dishes on an artificial diet (Southland Products, Lake Village, AK, USA) at 23°C. Subsequent generations of *P. xylostella* were reared in the laboratory. Eggs were deposited on aluminum foil dipped in boiled cabbage (*B. oleracea*) extract. Adult moths were placed in lidded paper cups (0.5 l, International Paper, Memphis, TN, USA) that contained aluminum foil to elicit oviposition. After several days, the foil coated in eggs was removed from the cup and placed on the artificial diet.

Generation of the cyp79B2 cyp79B3 myb28 myb29 Quadruple Knockout The *cyp79B2 cyp79B3* double mutant (Zhao et al. 2002) was manually crossed with the *myb28-1 myb29-1* double mutant (Sønderby et al. 2007). F1 plants were self-pollinated, and a total of 384 plants from the segregating F2 population were grown on soil. Theoretically, due to the independent segregation of four genes, we expected to find the quadruple mutant in one out of every 256 plants. Tissue of 3-wk-old *A. thaliana* plants was harvested into liquid nitrogen and desulfoglucosinolates were extracted using the method described previously (Hansen et al. 2007). As a preliminary screen, the 200–300 nm UV absorption spectrum of the desulfoglucosinolate extractions was measured in microplates with a Spectra-Max M5 96 microplate reader (Molecular Devices, Sunnyvale, CA, USA). Thirty samples with low absorption, presumably low in glucosinolates, were identified. Desulfoglucosinolates from these samples were extracted and run on the HPLC according to the method of Hansen et al. (2007). Eight low-glucosinolate samples, candidates for the quadruple mutant, were found. These plants were genotyped by PCR with the previously described primers detecting the wildtype and T-DNA alleles in *MYB28* and *MYB29* (Sønderby et al. 2007). The following gene specific primers for CYP79B2 (primers for *cyp79b2*: 5′-TGGACAAGTATCATGACCCAATCATCCACG-3′ and 5′-AACGGTTTAGCCAGAAACATATCGT-3’) and CYP79B3 (primers *cyp79b3*: 5-‘TGTTCTATGCATG GACTGGTGGTCAACATG-3′ and 5′-AGGAAACCGAT CACTTGACCGCTTG-3′) were used to detect the wildtype alleles. The 5′-primer was used in combination with LBa1 (5′-TGGTTCACGTAGTGGGCCATCG-3′) to verify the presence of the T-DNAs. One plant was homozygous for all four alleles except *MYB28*, another was homozygous for all alleles except *CYP79B2*. The F3 plants were grown in the subsequent generation, and the quadruple mutant was found by PCR analysis. Glucosinolate profiles were confirmed by analyzing F4 seed glucosinolate profiles from ten seeds as described previously (Hansen et al. 2007; Sønderby et al. 2007).

Plant Extraction and Fractionation Whole rosettes of 21 to 24-d-old *A. thaliana* plants were extracted by placing individual rosettes in 5 ml chloroform for 1 h. The solid plant material was then discarded, and the crude plant extract was stored at 4°C. To obtain fractions containing either intact glucosinolates or breakdown products, the chloroform extracts of 6-7 plants were pooled and evaporated to dryness. The extracts, which still contained indole glucosinolates (Supplemental Fig. 1), then were resuspended in acetonitrile for HPLC fractionation. Fractions collected before 15 min in the 35 min run were determined to contain intact glucosinolates (as compared to glucosinolate standards). Fractions collected after 15 min contained glucosinolate breakdown products. The identity of intact glucosinolates was confirmed by comparison to purified glucosinolate standards, including sinigrin as an internal control, using a Waters 2695 HPLC coupled to a Waters 2996 photodiode array detector. For HPLC analysis, the mobile phases were A, water, and B, 90% acetonitrile, at a flow rate of 1.1 ml min^{-1} at 23°C. Column linear gradients for samples were: 0–1 min, 98% A; 1–6 min 94% A; 6–8 min, 92% A; 8–16 min, 77% A; 16–20 min, 60% A; 20–25 min, 0% A; 25–27 min hold 0% A; 27–28 min, 98% A; 28–35 min, 98% A. An analytical HPLC reversed phase column (Lichrosphere 5 RP-18, ECAP 250, 4.6 mm i.d., 5 mm particle size) was used for the analysis.

Purified Glucosinolates and Breakdown Products All intact glucosinolates were purified from cabbage (*B. oleracea*) according to the protocol described by Clay et al. (2009). Indole glucosinolate breakdown products were purchased from Sigma-Aldrich (St. Louis, MO, USA), except for 3,3′-diindolylmethane that was purchased from LKT Laboratories (St. Paul, MN, USA).

Intact indole glucosinolates were dissolved in HPLC-grade water. Oviposition tests to determine relative attractiveness among indol-3-ylmethylglucosinolate (I3M), 1-methoxy-indol-3-ylmethylglucosinolate (1M-I3M), and 4-methoxy-indol-3-ylmethylglucosinolate (4M-I3M) involved 0.5 mM glucosinolate concentrations. A 1 mM glucosinolate concentration was used in tests on the effect of indole glucosinolate breakdown. I3M was treated with myrosinase (Sigma-Aldrich, St. Louis, MO, USA) to catalyze its breakdown. A myrosinase buffer solution was prepared by combining 33 mM sodium phosphate buffer (pH = 7) with 0.3 mM ascorbic acid as a cofactor (Barth and Jander 2006). Tests on commercial glucosinolate breakdown products involved 1 mM solutions in acetonitrile or methanol.

Oviposition Tests on Intact Plants and Detached Leaves For whole plant oviposition assays, 50 adult *P. xylostella* (~50% females) were allowed to oviposit on 14 to 16 plants, paired mutant and wildtype, in complete darkness in a 30×60 cm nursery flat under a dome cover. After 24 h *P. xylostella* eggs were counted. For experiments with damaged plants, each fully expended leaf was damaged across the mid-vein with a forceps.

Experiments with detached leaves were performed in the above-described 0.5 l paper cups. Petioles of wildtype and mutant leaves were cut and mounted in 1% water agar for pair-wise comparisons. Ten moths per cup were allowed to oviposit for 24 h in the dark, and the eggs were counted.

Oviposition Tests on Liquid Solutions Groups of 10 *P. xylostella* pupae (~1:1 sex ratio) were placed into lidded paper cups. These cups were placed in the dark at 23°C for

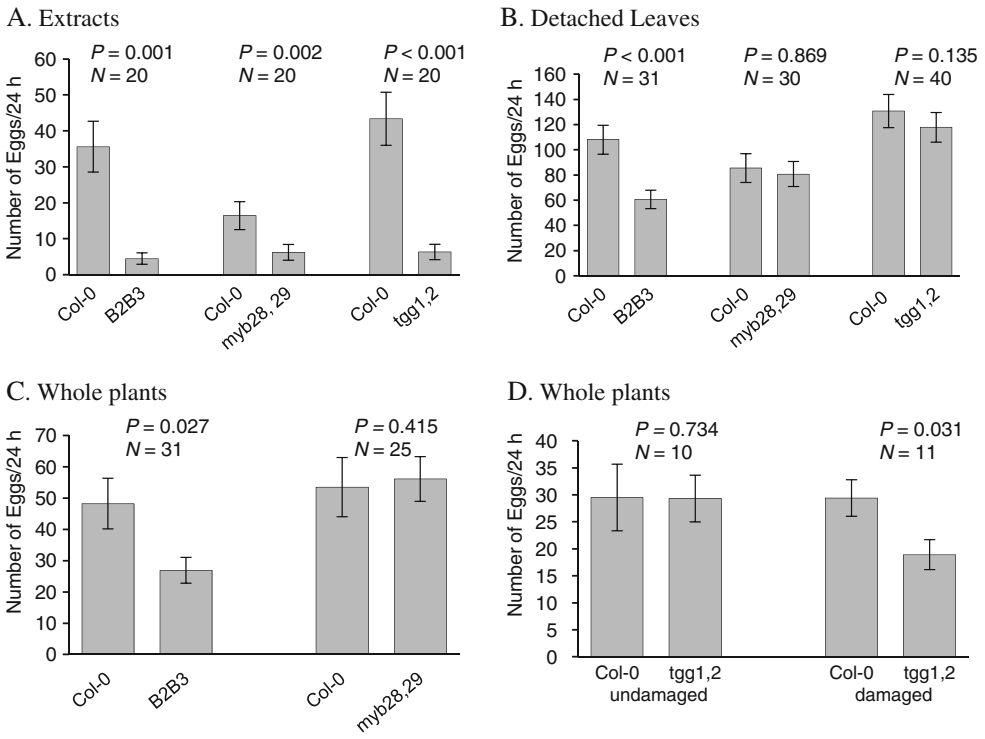

Fig. 1 *Plutella xylostella* 24 h oviposition choice tests comparing the number of eggs laid on Col-0 and double mutants containing low indole glucosinolates (*cyp79B2 cyp79B3*), myrosinase (*tgg1, tgg2*) or aliphatic glucosinolates (*myb28 myb29*), labeled as B2B3, tgg1,2 and myb28,29, respectively. **a** Oviposition tests on crude plant extracts. **b** Oviposition tests on detached leaves. **c** and **d** Oviposition tests on whole plants. (d) Leaves of intact plants were damaged across the mid-vein using a forceps to induce glucosinolate breakdown by myrosinase. Mean ± standard error. (a) and (b) significance determined by Wilcoxon signed rank tests. (c) and (d) significance determined by Mann-Whitney *U*-tests

3–5 d until the majority of the pupae had eclosed. Fifty µl of the leaf extracts were applied to paper towels (C-fold white, Kimberly-Clark, Dallas, TX, USA) and allowed to dry. The extracts were applied within 3.5 cm diam circles marked with a pencil to facilitate egg counting. Each individual paper towel contained two spots with purified glucosinolate-related chemicals in solution or plant extracts to allow for a paired oviposition test. The paper towels then were mounted underneath the lid of the previously described 0.5 l paper cups that contained 10 moths. The moths in the cups were allowed to oviposit for 24 h in the dark. After this period, the cups were placed into a cold room (4°C) to stop oviposition, and the *P. xylostella* eggs within the spots on the paper towels were counted.

Glucosinolate Analysis Glucosinolate extraction and analysis was performed on whole rosettes of 24-d-old plants. Samples were freeze-dried, weighed, and glucosinolates were extracted and analyzed according to the method described by Barth and Jander (2006). Glucosinolate concentrations are expressed as µmol per gram dry weight.

Statistical Analyses Data from oviposition tests done in cups on detached leaves, leaf extracts, or intact indole glucosinolates were analyzed by Wilcoxon signed rank tests. Data from oviposition tests on whole plants and breakdown products were analyzed by Mann-Whitney *U*-tests. All statistical analyses were performed using JMP 2007 for Windows (SAS Institute Inc., Cary, NC, USA).

Results

Oviposition of P. xylostella on A. thaliana Mutants with altered Glucosinolate Production We used *A. thaliana* mutants with altered glucosinolate profiles to determine the *in vivo* role of glucosinolates as oviposition attractants. The *A. thaliana* double mutants *cyp79B2 cyp79B3* (low indole glucosinolates), *myb28 myb29* (residual aliphatic glucosinolates) and *tgg1 tgg2* (no glucosinolate breakdown due to mutations in foliar β-glucosidases) (Table S1) offer an extremely useful tool to test the effect of glucosinolates in stimulating *P. xylostella* oviposition. The crude extracts, detached leaves, and wholes plant of *cyp79B2 cyp79B3* all experienced a significant decrease in oviposition by *P. xylostella* compared to Col-0 wildtype plants (Fig. 1a, b, c), indicating that indole glucosinolates serve as important *P. xylostella* attractants *in vivo*. Similarly, we tested the effect of aliphatic glucosinolates. Whereas elimination of aliphatic glucosinolates did not significantly affect oviposition of *P. xylostella* females in experiments with whole plants and detached leaves (Fig 1b, c), crude extracts from *myb28 myb29* received significantly fewer eggs than those from wildtype plants (Fig. 1a), thus suggesting that aliphatic glucosinolate derived breakdown products play a

role in attracting *P. xylostella* oviposition. These data confirm an earlier finding by Renwick et al. (2006) that isothiocyanates from aliphatic glucosinolates stimulate oviposition behavior. Likewise, *tgg1 tgg2* compared against Col-0 displayed no significant difference in attractiveness of either detached leaves or undamaged whole plants (Fig. 1b, d). However, crude extracts made from wildtype and *tgg1 tgg2* plants revealed a preference for wildtype (Fig. 1a). To investigate the importance of glucosinolate breakdown products, we subsequently damaged and compared oviposition on Col-0 (WT) and *tgg1 tgg2* plants. In contrast to results obtained with undamaged plants, we observed significantly more eggs deposited on damaged Col-0 plants (Fig. 1d). Thus, only damaging processes such as extraction and deliberate plant damage produced significantly different oviposition results between the wildtype and *myb28 myb29* or *tgg1 tgg2* plants. In summary, these results indicate that intact indole glucosinolates and aliphatic glucosinolate-derived glucosinolate breakdown products, most likely the previously described isothiocyanates (Renwick et al. 2006), function as oviposition attractants.

In order to investigate whether different classes of glucosinolates have additive affects on *P. xylostella* oviposition, we studied quadruple mutants that lacked multiple components of the glucosinolate-myrosinase system. Under our growth conditions, the *cyp79B2 cyp79B3 tgg1 tgg2* mutant lacks indole glucosinolates and myrosinase activity (Table S1; De Vos et al. 2008). Moreover, we crossed *cyp79B2 cyp79B3* and *myb28 myb29* to create a quadruple mutant that has no detectable production of indole glucosinolates and shows low levels of aliphatic glucosinolates residually (~6% of wildtype, Table S1). In tests using both crude extracts and whole plants, *cyp79B2 cyp79B3 tgg1 tgg2* received significantly fewer eggs than either of the progenitor double mutants (Fig. 2a, b). The same additive effect of decreased oviposition was observed for the c*yp79B2 cyp79B3 myb28 myb29* quadruple mutant, both on crude extracts and on whole plants (Fig. 2c, d). These results are in accordance with our findings that used the double mutants, suggesting that both intact indole glucosinolates and volatile aliphatic glucosinolate-derived isothiocyanates play a role in the attraction of *P. xylostella* females.

Oviposition Assays using Plant Extract Fractions To test the hypothesis that *P. xylostella* is attracted to intact indole glucosinolates for oviposition, the crude extracts of Col-0 and the *cyp79B2 cyp79B3* double mutant were separated by HPLC into two fractions that contained either intact glucosinolates or glucosinolate breakdown products. Wildtype Col-0 fractions containing intact glucosinolates received significantly more eggs than the Col-0 fraction glucosinolate breakdown products (Fig. 3a), suggesting that intact glucosinolates are more attractive to *P. xylostella* females. Moreover, despite having a similar aliphatic glucosinolate profile, the Col-0 fraction that contained intact glucosinolates received significantly more eggs when compared to the same fraction from *cyp79B2 cyp79B3* mutant plants (Fig. 3b; Table S1), indicating that intact indole glucosinolates are an important oviposition cue for *P. xylostella*.

Purified Indole Compounds In vitro tests indicate that I3M alone serves as a strong oviposition attractant (Fig. 4a). The addition of myrosinase to catalyze the breakdown of I3M significantly decreases this attractiveness when compared to intact I3M (Fig. 4b). This result is in agreement with results from the glucosinolate fractionation, thus implicating the importance of intact indole glucosinolates (Fig. 3). Furthermore, tests using six commercially available indole glucosinolate breakdown products indicate that none of these compounds serve as oviposition attractants (Table 1). In fact, indole-3-carbinol was found to have a deterrent effect on oviposition when compared against the solvent-only control. However, mixing indole-3-carbinol with an equivalent amount of the oviposition attractant 4-methoxy-indol-3-ylmethylglucosinolate (4M-I3M) had no effect on oviposition attractiveness compared to 4M-I3M (12.3±2.76 and 10.1± 1.97, respectively; $P = 0.618$; Wilcoxon signed rank test).

Expanding on the research on isolated indole glucosinolates, aqueous solutions of I3M, 4M-I3M, and 1-methoxy-indol-3-ylmethylglucosinolate (1M-I3M) were compared directly against each other in oviposition assays. Female *P. xylostella* moths significantly preferred depositing their eggs on 4M-I3M compared to either of the two other indole glucosinolates (Fig. 4c, d), which were found to be equally attractive (Fig. 4e). Taken together, these results suggest that *P. xylostella* can distinguish secondary modifications in indole glucosinolate chemistry, thus identifying suitable hosts for oviposition.

To investigate the role of 4M-I3M, we made use of a recently described biosynthetic mutant that is disrupted in a cytochrome P450 involved in 4M-I3M production (Bednarek et al. 2009; Clay et al. 2009; Pfalz et al. 2009). Whereas plant extracts from Col-0 received significantly more *P. xylostella* eggs than those from a mutant plant with significantly lower concentrations of 4M-I3M (*cyp81F2*; Fig. 5a), a comparison of wildtype and *cyp81F2* showed no preference for either genotype (Fig. 5b).

Discussion

Our findings demonstrate that intact nonvolatile indole glucosinolates are important *P. xylostella* oviposition

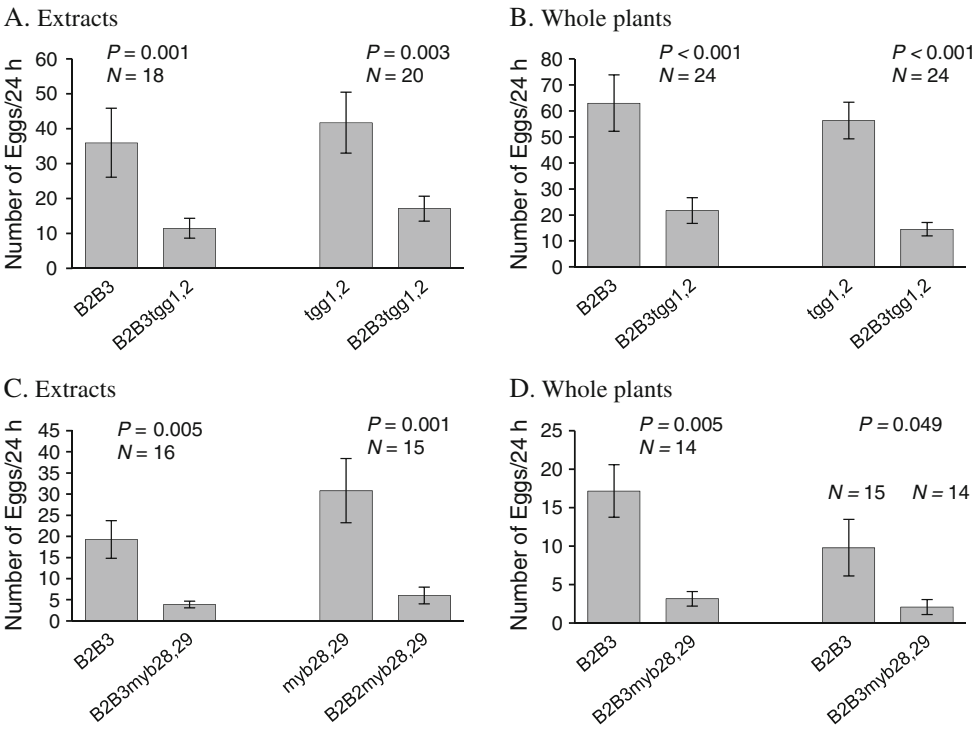

Fig. 2 *Plutella xylostella* 24 h oviposition choice tests comparing the number of eggs laid on previously described double and quadruple mutants with reduced production of either indole glucosinolates and myrosinase (c*yp79B2 cyp79B3 tgg1 tgg2*) or indole and aliphatic glucosinolates (c*yp79B2 cyp79B3 myb28 myb29*). **a**, **b** Oviposition on crude extracts or whole plants of c*yp79B2 cyp79B3 tgg1 tgg2* (B2B3tgg1,2) and its progenitor double mutants. **c**, **d** Oviposition on crude extracts or whole plants of c*yp79B2 cyp79B3 myb28 myb29* (B2B3myb28,29) and its progenitor double mutants. attractants, and that at least some *P. xylostella* oviposition decisions are made at the leaf surface. Previously implicated as oviposition attractants by Reed et al. (1989), indole glucosinolates now can be linked to *P. xylostella* host plant recognition *in vivo*. Mutant plants disrupted in the biosynthesis of indole glucosinolate exhibited a significant decrease in oviposition when compared to wildtype plants (Fig. 1a, b, c). Extract fractions of these mutant and wildtype plants indicate that intact indole glucosinolates rather than breakdown products serve as the oviposition cues (Fig. 3). Moreover, we demonstrated that myrosinase-catalyzed breakdown eliminates the attractiveness of I3M *in vitro* (Fig. 4b; Reed et al. 1989). This observation also is supported by the failure of several indole glucosinolate breakdown products to elicit any positive oviposition response (Table 1). Altogether, this indicates that *P. xylostella* do not use indole glucosinolate breakdown products for host recognition.

Interestingly, we found that, depending on their secondary modifications, indole glucosinolates have differential attractiveness for *P. xylostella* females. Purified 4M-I3M elicited a significantly higher amount of oviposition than either I3M or 1M-I3M (Fig. 4c, d). Hydrolysis of 4M-I3M by TGG1 and TGG2 myrosinases occurred significantly slower than that of the other indole glucosinolates or aliphatic glucosinolates (Barth and Jander 2006). It is tempting to speculate that *P. xylostella's* preference for this particular indole glucosinolate

may have arisen due to the increased stability of 4M-I3M, which therefore acts as a reliable host recognition cue. A beneficial role in protecting *A. thaliana* against generalist insect herbivores or pathogenic micro-organisms may explain why the conversion of I3M to 4M-I3M persists in *A. thaliana* and other crucifers. For instance, secondary modifications in indole glucosinolates play an important role in protection against phloem-feeding insects. Kim and Jander (2007) demonstrated that upon infestation with green peach aphids (*Myzus persicae*), *A. thaliana* plants specifically increase conversion of I3M to 4M-I3M, which reduces aphid reproduction *in vitro*. Moreover, mutant plants that lack 4M-I3M biosynthesis, through a mutation in a cytochrome P450 (CYP81F2; At5g57720), were independently shown to have increased *M. persicae* performance in comparison to Col-0 wildtype plants (De Vos and Jander 2009; Pfalz et al. 2009). Here, we showed that the same mutation (*cyp81F2*) leads to reduced oviposition of *P. xylostella* on plant extracts compared to those from wildtype plants (Fig. 5a). In contrast, we did not observe a difference in oviposition between Col-0 and *cyp81F2* in whole plant experiments (Fig. 5b). Perhaps the significant increases in intact I3M levels in *cyp81F2* plants (Bednarek et al. 2009; Clay et al. 2009) are sufficient to mask the lack of 4M-I3M. Alternatively, it has been demonstrated that indole glucosinolate distribution in leaves is not homogenous. In line with the anti-aphid properties of 4M-I3M, this indole glucosinolate could be phloem-specific and not located at outer lamina where other intact indole glucosinolates have been found (Shroff et al. 2008).

Aliphatic glucosinolate breakdown products, which previously have been demonstrated to attract *P. xylostella* oviposition through olfactory stimulation (Renwick et al. 2006), are most likely the factors that cause the differences in oviposition preference observed in our tests on both aliphatic glucosinolate and myrosinase-deficient mutants compared to the wildtype. The *myb28 myb29* and *tgg1 tgg2* double mutants produce very low amounts of aliphatic glucosinolate hydrolysis products, and tests on their crude extracts predictably showed that they receive decreased oviposition compared to Col-0 (Fig. 1a). In contrast, because the degradation of aliphatic glucosinolates is induced by physical foliage disruption, tests on intact plant

Table 1 Number of *Plutella xylostella* eggs laid in 24 h oviposition choice tests using commercially available indole glucosinolate breakdown products compared to solvent-only controls. Mean ± standard error, all comparisons for significance are Mann-Whitney *U*-tests

Breakdown Product	# of Eggs on Compound	# of Eggs on Solvent	*N*	*P*

tissue with little damage, i.e., whole rosettes and detached leaves, exhibited no such difference in oviposition between the mutants and wildtype (Fig. 1b, c) unless they were purposefully damaged (Fig. 1d). Alternatively, although less likely because of the above described results with the leaf extracts, the residual concentration of aliphatic glucosinolates (~6%), could be sufficient for *P. xylostella* attraction in whole plant experiments. The extremely low amount of isothiocyanates released in the headspace above undamaged crucifers (Finch 1978; Tollsten and Bergström 1988) does not appear to affect oviposition choices by *P. xylostella*, at least in the experiments described here.

Among the Lepidoptera, host plant selection by specialists through the detection of host-specific chemicals is well documented. In the monarch butterfly *Danaus plexippus*, a milkweed specialist, several tarsal and antennal contact chemorceptors detect non-volatile flavonoids found on the leaf surface of host plants, thus indentifying suitable oviposition targets (Haribal and Renwick 1996; Baur et al. 1998). Another lepidopteran crucifer specialist, *Pieris rapae,* also demonstrates a preference for ovipositing on *A. thaliana* containing intact indole glucosinolates and an aversion towards the indole glucosinolate breakdown product indole-3-acetonitrile (De Vos et al. 2008). Future experiments will determine the role of individual indole glucosinolates, including 4M-I3M, in *P. rapae* oviposition, thus allowing an interesting comparison with *P. xylostella*. For specialist insects, the identification of a suitable host plant confers a significant selective advantage by allowing them to take advantage of resources ill-suited for generalists. When reared on the mutant *A. thaliana* that lack components of the crucifer's defensive glucosinolate-myrosinase system, non-crucifer-specialist lepidopteran larvae experience a large increase in weight gain. This suggests that the glucosinolate content of wildtype plants has a significant negative effect on the fitness of these generalists (Barth and Jander 2006; Beekwilder et al. 2008; Schlaeppi et al. 2008).

Taking into the account the additive effect that intact indole glucosinolates and aliphatic glucosinolate breakdown products have in attracting oviposition by *P. xylostella,* as demonstrated with quadruple mutants that lack both indole and aliphatic glucosinolates (Fig. 2), these two types of compounds both appear to be important for *P. xylostella* attraction. Our experiments suggest that in the presence of indole glucosinolates, the effect of intact aliphatic glucosinolates is negligible (Fig 1b, c), but in the absence of indole glucosinolates, intact aliphatic or minute quantities of their breakdown products could account for attraction of *P. xylostella* females (Fig. 2b, d). Together, our data also suggest that intact indole glucosinolates are more reliable host recognition cues for ovipositing females on intact plants (Fig. 1c and d).

Perhaps, our experimental design, which used enclosed cages, directs *P. xylostella* host choice toward the use of tactile instead of olfactory cues. *Plutella xylostella* may recognize volatile isothiocyanates when in flight through olfaction by the antenna (Renwick et al. 2006), but nonvolatile intact indole glucosinolates are most likely detected at the leaf surface, possibly through leaf contact with tarsal chemoreceptors in a manner similar to that described for other Lepidoptera (Baur et al. 1998). We hypothesize that isothiocyanates and indole glucosinolates may function as long-range and short-range oviposition cues, respectively, for *P. xylostella*. The volatility of isothiocyanates allows for host recognition over a greater distance than molecules present at the leaf surface, but also decreases the reliability of detecting the molecule depending on plant and environmental conditions. Furthermore, because concentrations of isothiocyanates that affect *P. xylostella* oviposition are found only in extracts of *A. thaliana* plants (Fig. 1a), females that rely solely on this cue would risk decreased fitness of their offspring due to heightened plant defenses, increased presence of predators, and competition for nutrients by other insects on already damaged plants. The use of chemical host signals that results in the avoidance of the harmful effects that prior larval feeding would have on food availability, nutritional quality, and host defense responses has already been proposed for *P. rapae* (De Vos et al. 2008; Mumm et al. 2008) and *Pieris brassicae* (Rothschild and Schoonhoven 1977), and this concept may apply to *P. xylostella* as well. Interestingly, *P. xylostella* females preferred ovipositing on larvae-infested cabbage. Moreover, larval performance was

not impacted negatively by feeding conspecifics (Choh et al. 2008). These results might suggest that damage-induced aliphatic glucosinolate breakdown products function as host recognition cues without being associated with inherent negative effects on larval development. Future research aimed at understanding how the volatile and nonvolatile oviposition cues are recognized by specialist insects, such as *P. xylostella*, will lead to valuable insights to counteract these agriculturally important insect pests.

Acknowledgements We thank Adewale Martins Adio for the isolation of intact indole glucosinolates. This research was supported by NSF grant IOS-0718733 to GJ and funding from Faculty of Life Sciences, University of Copenhagen to IES.

mating by post-diapause winterforms begins in mid-February as ambient temperatures begin to increase (Krysan and Higbee 1990; Horton et al. 1998, 2007).

The role of chemical signals in psyllid mate location has only recently begun to be investigated. Behavioral evidence for a female-produced volatile sex attractant was reported for the pear psylla *C. bidens* by Soroker et al. (2004). More recently, similar results indicating male attraction to female-produced volatiles were obtained for both post-diapause winterform and summerform pear psylla, *C. pyricola* (Horton and Landolt 2007; Horton et al. 2007, 2008; Guédot et al. 2009), and for the citrus psyllid, *D. citri* (Wenninger et al. 2008).

Previous work with *C. pyricola* post-diapause winterforms showed that cuticular extracts of females were attractive to males (Guédot et al. 2009). These extracts were at least as attractive as a comparable number of live females, suggesting that cuticular extraction might be a suitable procedure for collecting the components of the attractant for analysis and identification (Guédot et al. 2009). Additionally, males were repelled by live males and extracts of males, further evidence that extracts contained sex-specific compounds or blends of compounds (Guédot et al. 2009). Thus, our first objective was to compare the chemical profiles of extracts from post-diapause winterform males and females, to look for differences between the sexes that might indicate putative pheromone components.

Olfactometer bioassays showed that field-collected winterform females did not become attractive to males until late February when ovarian maturation and mating begins in the field (Horton et al. 2007). Thus, our second objective was to compare the chemical profiles of extracts from post-diapause vs. diapausing winterforms. We were particularly interested in identifying chemicals that were exclusively or more abundantly present in post-diapause females than diapausing females, so as to pinpoint the chemicals that might be responsible for female attractiveness.

Several studies have suggested that, although psyllid males are attracted to female-produced pheromone, females are not attracted by volatiles from either sex. For example, females of the pear psylla *C. bidens* and the citrus psyllid *D. citri* did not exhibit attraction to either male or female conspecifics in bioassays (Soroker et al. 2004; Wenninger et al. 2008). With *C. pyricola*, field experiments that used live psylla indicated that females did not show a preference for either male- or female-baited traps compared to unbaited traps (Brown et al. 2009).

Our third objective was to determine if response by *C. pyricola* to a putative pheromone was sex-specific. To achieve this objective, we compared the behavioral responses of post-diapause males and females to an isolated chemical found to be more abundant in extracts of post-diapause females than post-diapause males. Because cuticular extracts of females were as attractive to males as live females (Guédot et al. 2009), we also compared attraction of males to the identified chemical vs. extracts of females, to determine whether this single chemical might be the major or even sole compound comprising the female-produced attractant.

For practical purposes, the development of a synthetic pheromone lure for pear psylla would provide a useful tool for monitoring and management strategies. Field experiments using live *C. pyricola* as attractants had shown that males exhibited a clear preference for female-baited traps vs. unbaited traps or traps baited with males (Brown et al. 2009). Thus, our final objective of this study was to field test the effectiveness of the chemical identified as a potential sex attractant for male pear psylla.

Methods and Materials

Source of Insects Winterform pear psylla were collected from a commercial pear orchard located near Yakima, Yakima Co., Washington, USA in December 2008 (diapausing winterform) and in February-March 2009 (post-diapause winterform) using a beat tray and aspirator. In December 2008, adults were separated by sex in the field, and placed in groups of ca. 350 insects on pear shoots (excised from branches in the field and placed in water vials) in 10-liter ventilated plastic containers. The containers and insects were stored at ~16°C under a L8:D16 photoperiod for 24 h before the insects were used for extractions. In February and March 2009, adults were separated by sex in the field and placed in groups of ca. 200 insects on pear shoots in 1-liter glass jars. The jars and insects were kept at ~24°C under a L16:D8 photoperiod for 72 h before the insects were extracted. Insects for olfactometer bioassays were held in glass jars under the same conditions for 3–7 d. On each collection date, a subsample of 10 post-diapause females collected in February-March 2009 was dissected to determine ovarian maturity (an indicator of diapause status), and the number of spermatophores (an indicator of the number of times a female had mated) (Krysan and Higbee 1990; Horton et al. 2007). Behavioral assays and extractions were not conducted until dissected females in the subsample had reached an average ovarian score of 5 or higher (Krysan and Higbee 1990), at which stage females are attractive to males in olfactometer assays (Horton et al. 2007). Although field collected psylla were mated, the mating status has no effect on female attractiveness in pear psylla (Horton et al. 2008).

Cuticular Extracts Extractions were performed between 12:00 and 15:00 h (P.S.T.). For each extraction, 50 psylla of one sex were transferred into an 11-ml glass vial containing 300 µl pentane for 5 min, during which the glass vial was agitated by hand. The solvent was then

transferred to a clean glass vial (extract). Simultaneously with each extraction, a control treatment was prepared using the same procedure with 300 µl pentane without psylla. Treatment and control extracts were stored for up to 5 d at 0°C until about 1 h before experiments were conducted. These samples were used in both chemical and behavioral assays. Samples used for chemical analyses were spiked with 10 µl of a 500-µg/ml solution of octadecane as an internal standard (Matheson Coleman & Bell, Cincinnati, OH, USA). In bioassays, each olfactometer consisted of paired 1-liter glass jars containing either the extract or a solvent control, applied with glass syringes (Hamilton Company®, Reno, NV, USA) to filter paper disks (55 mm diam; Whatman #1 Cat. No. 1001 055; Whatman®, Maidstone, UK), and allowed to evaporate in a fume hood for 1 min. Each filter paper disk was folded to prevent it from laying flat on the bottom of the jar. The disks were placed in the jars, and the jars were immediately attached to an olfactometer (described below).

Analysis of Extracts One-µl aliquots of extracts and associated solvent controls were analyzed by coupled gas chromatography-mass spectrometry (GC-MS) using an Agilent 6890 GC with a 5973 mass selective detector with electron impact ionization (70 eV). The GC was equipped with a DB-1MS fused silica capillary column, 0.25 mm ID×60 m, 0.25 µm film thickness (J&W Scientific, Folsom, CA, USA), programmed at 60°C for 1 min, increasing to 240°C at 30°C per min, then at 10°C per min to 340°C, and held for 13 min. Hydrocarbons were quantified using the integrated peak area data from the GC-MS response to increasing quantities (5–50 ng) of the authentic standards heptacosane, nonacosane, and hentriacontane (Sigma Aldrich®, St. Louis, MO, USA).

Quantitative GC-MS analyses were conducted to identify compounds present specifically or in greater abundance in females than males, comparing 1) diapausing winterform females with diapausing winterform males and 2) post-diapause winterform females with post-diapause winterform males. For each set, five extracts of females, five extracts of males, plus solvent controls, were analyzed. Because differences in chemical profiles between males and females of diapausing and post-diapause psylla appeared to be quantitative rather than qualitative, we calculated the female to male ratio for each identified chemical. Measurements of wing length and scutellum width of male and female pear psylla have shown that females are slightly larger than males, with a female to male ratio of less than 1.2 for both of these measurements (Wong and Madsen 1967). Thus, compounds that were at least twice as abundant in females compared to males were selected to be tested in the behavioral bioassays for attractiveness.

Compounds in extracts were identified by analysis on a Hewlett-Packard (HP) 6890 GC interfaced to a HP 5973 mass selective detector (electron impact ionization, 70 eV). The GC was fitted with a DB5-MS column (30 m× 0.25 mm i.d., 0.25 micron film thickness; J&W Scientific, Folsom, CA, USA), programmed from 100°C/1 min, 10°C/min to 280°C, and held for 20 min. One-µl aliquots were injected in splitless mode, with injector and transfer line temperatures at 280°C. Helium carrier gas was used in constant pressure mode.

Cuticular hydrocarbons were identified by a combination of retention time comparisons vs. straight-chain alkane standards (Carlson et al. 1998) and interpretation of their mass spectra. Where visible, the molecular ion indicated the total number of carbons in the molecule, methyl-branched hydrocarbons gave enhanced diagnostic ions at branch points that allowed the positions of the methyl branches to be determined, and the presence of methyl branches resulted in diagnostic shifts in retention times vs. straight-chain standards (Nelson 1993; Nelson and Blomquist 1995; Carlson et al. 1998). Long-chain aldehydes were identified tentatively by interpretation of their mass spectra and retention index comparisons with straight-chain alkanes, and identifications were confirmed where possible by comparisons of retention times and mass spectra with those of authentic standards.

Preparation of 13-Methylheptacosane Butyllithium (2.7 M in hexane, 1.1 ml, 3 mmol) was added to a slurry of tetradecyltriphenylphosphonium bromide (1.53 g, 2.8 mmol, Lancaster Research Chemicals, Windham, NH, USA) in 20 ml anhydrous ether under argon at room temperature. After stirring for 30 min, a solution of 2-tetradecanone (0.30 g, 1.4 mmol) in 5 ml ether was added, the resulting slurry was stirred 30 min, then poured into 1 M aqueous HCl. The mixture was extracted with hexane, and the hexane extract was washed with saturated aqueous $NaHCO_3$ and brine, then dried over anhydrous Na_2SO_4 and concentrated. The residue was taken up in ~10 ml hexane, and left overnight to precipitate the bulk of the triphenylphosphine oxide. The resulting solution was purified by vacuum flash chromatography on silica gel, eluting with hexane. The mixture of purified alkenes in hexane was then hydrogenated with 100 mg of 5% palladium on charcoal catalyst in a septum-sealed flask fitted with a balloon full of hydrogen for 3 h. After filtration, the crude product (0.43 g, ~95% pure by GC) was recrystallized from 12 ml acetone at −20°C, yielding 0.21 g 13-methylheptacosane as a low-melting white solid, mp 26°C. The ^{1}H NMR spectrum matched that previously reported (Marukawa et al. 2001). The mass spectrum showed *m/z* (abundance) 394 (trace, M^+), 379 (1), 365 (1), 225 (8), 224 (12), 197 (9), 196 (19), 168 (4), 155 (5),

141 (7), 127 (10), 113 (15), 99 (22), 85 (62), 71 (80), 57 (100), 43 (53).

Behavioral Bioassays A Y-tube olfactometer was used to assess the response of male and female post-diapause winterform psylla to olfactory signals. The olfactometer, fully described in Horton and Landolt (2007), consisted of a 27-cm long, 2.5 cm diam glass tube forming the stem of the Y, joined to two arms at 135° to one another, each 7 cm in length. The Y-tube was positioned horizontally with a ~15° incline. Commercial compressed air (Oxarc Inc., Spokane, WA, USA) was passed through a charcoal filter, an air humidifier, and 1-liter glass jars containing odor sources. A 25 cm × 2 mm diam polytetrafluoroethylene hose (PTFE) (Cole-Parmer Instrument Company, Vernon Hills, IL, USA) connected each jar to an arm of the Y-tube. Airflow through each arm of the olfactometer was maintained at 50 ml per min during the assays. Before each bioassay, air was passed through the whole system at 50 ml/min in each arm, including the jars containing the odor sources, for 15 min. For all assays, a replicate consisted of 10 psylla of the same sex assayed individually. For each replicate, after five psylla were assayed, the arms of the olfactometer were rotated 180° horizontally, and the other 5 males were assayed. Approximately 30 min preceding an assay, psylla to be assayed were placed in a 50 ml vial. During the assays, a single psylla was allowed to enter the olfactometer from the vial and was then given 10 min to enter an arm of the Y-tube. Psylla that did not enter an arm within 10 min were discarded. Choice was defined by a psylla contacting the upwind end of an arm, at the insertion point of the PTFE hose. After each replicate, the olfactometer was dismantled, soaked in hot soapy water, rinsed with water, acetone and hexane, and then baked in an oven at 150°C for at least 2 h. Two sets of assays were carried out, with comparisons within each set being randomized.

Bioassays were conducted using the Y-tube olfactometer to address response of post-diapause winterform male and female psylla to 13-methylheptacosane [hereafter, 13-MeC27], which was found in the chemical analyses to be substantially more abundant in extracts from post-diapause females than post-diapause males. In a first experiment, two comparisons were made in which either males or females were given a choice between 500 ng of 13-MeC27 and solvent controls. Each comparison consisted of 10 replicates. In a second experiment, three comparisons were conducted of post-diapause males to 13-MeC27 vs. cuticular extracts of post-diapause females: (a) 13-MeC27 vs. control; (b) cuticular extract of females vs. control; and (c) 13-MeC27 vs. cuticular extract of females. Each comparison consisted of 15 replicates. In the first and third comparisons, 250 ng of 13-MeC27 (equivalent to ~25 females) were applied to a filter paper. Each cuticular extract consisted of 25 females extracted in pentane for 5 min.

Field Trial A field assay was conducted 2–7 April 2009 in a pear psylla-infested pear orchard at the United States Department of Agriculture's Experimental Farm near Moxee, Yakima Co., WA, USA (46°30′ 18.60″ N 120°10′ 06.64″ W). The orchard is a mixture of Bartlett and Anjou pear trees approximately 3 m in height, with ~3 m spacing between tree trunks. Sticky traps were used to assess the attraction of male and female winterform pear psylla to 13-MeC27. Each trap was constructed of a 30×30 cm section of light brown Lumite® fabric (No. 5006304, Chicopee Mills Inc., New York, NY, USA) with 1 mm^2 sized mesh. Two opposite edges of a fabric section were each stapled to a 30 × 1.5 × 0.5 cm piece of hemlock. A ~30 cm section of twisty tie was stapled to the center of each hemlock piece, and traps were hung between two branches using the twisty ties. The fabric section was coated with a thin layer of Tanglefoot Tangle-Trap Sticky Coating (Grand Rapids, MI, USA). Gray halobutyl rubber septa (West Pharmaceutical Services, Lyonville, PA, USA) were used as dispensers. Septa were pre-extracted with methylene chloride, and then aired for 24 h at 24°C in a fume hood before use. Septa were loaded with 10, 100, or 1,000 μg of 13-MeC27 in 100 μl aliquots of pentane, followed by an additional 200 μl of pentane to adsorb the test compound into the rubber matrix. Control lures were treated with 100 μl of pentane, followed by 200 μl of pentane. Lures were aired at room temperature in a fume hood overnight, then stored in a freezer at 0°C overnight until use in field traps. Lures were attached to the center of traps using safety pins. Treatments were deployed in a randomized complete block design with eleven blocks. Each block consisted of four treatments: control, and 10, 100, and 1,000 μg doses of 13-MeC27 per septum. Traps were placed one per tree at ~1.5 m above ground; two trees separated adjacent traps. Traps were collected from the field on 7 April, and returned to the laboratory where captured male and female psylla on each trap were counted.

Statistical Analyses Statistical analyses were performed using SAS Version 9.1 for Windows (SAS Institute 2002). Behavioral bioassay data were analyzed with paired sample *t*-tests in PROC TTEST as described in Horton et al. (2007, 2008). The *t*-test assumes a normal distribution of the arithmetic differences between paired observations (Zar 1999). The normality assumption was tested using the Shapiro-Wilk statistic in PROC UNIVARIATE. When the normality assumption was not met, the paired differences were analyzed using a signed-ranks test in PROC UNIVARIATE (Zar 1999; Horton et al. 2007, 2008). Because the signed-ranks test yielded significant differences in all comparisons, possibly leading to the commission of a type I error, we opted for a more conservative approach and used results obtained with paired sample *t*-tests.

For the field assays, count data were square-root transformed to normalize the distributions for analysis. The data were analyzed as a randomized block, two-factor (sex × treatment) repeated measures analysis of variance using PROC MIXED, with sex being the repeated factor because both sexes were counted on each trap. The means of the three doses (10 μg, 100 μg, and 1,000 μg) were compared to the control mean to assess whether the compound led to an increase in trap catches vs. the unbaited controls. In the event of a significant treatment by sex interaction, the SLICE statement in PROC MIXED was used to examine treatment effects for each sex separately. Following a significant *F* value for the ANOVA, differences between means were separated by Tukey's test.

Results

Analysis of Extracts Analyses of cuticular extracts from male and female winterform *C. pyricola* revealed the presence of a number of long chain hydrocarbons and related compounds (Fig. 1; Tables 1 and 2). The identified cuticular hydrocarbons of winterform pear psylla comprised 36.4±1.8% (mean ± S.E.M.) C_{23}-C_{35} straight-chain alkanes, 28.8±0.5% C_{25}-C_{33} monomethyl-branched alkanes, 7.1± 0.6% C_{31} dimethyl-branched alkanes, and 15.0±0.4% C_{22}-C_{30} aldehydes. The most abundant compounds found in all extractions were heptacosane, 2-methylheptacosane, nonacosane, 2-methylnonacosane, hentriacontane, and a mixture of 11,15- and 13,17-dimethylhentriacontanes.

Comparisons of the chemical profiles of males and females of either diapausing or post-diapause psylla revealed quantitative rather than qualitative differences, with every chemical identified being present, although in different amounts, in every extract. Total amounts of identified hydrocarbons were significantly lower in diapausing vs. post-diapause winterforms (t=4.1; df=18; P<0.001), varying from 528.8±21.7 (mean ± S.E.M.) ng and 581.7±36.3 ng for diapausing males and females, respectively, to 690.6± 47.0 ng and 712.7±36.0 ng for post-diapause males and females, respectively. Diapausing winterforms had no chemicals that were at least twice as abundant in females as in males. By contrast, in post-diapause winterforms, 13-MeC27 was 3.2 times more abundant in females than males. The 13-MeC27 was also the most abundant compound in diapausing females compared to diapausing males, although it was only 1.5 times more abundant in females than males.

Three chemicals, 13-MeC27, tetracosanal, and hexacosanal, were at least two times more abundant in post-diapause females than diapausing females. Two of these chemicals (tetracosanal and hexacosanal) were also more abundant in post-diapause males compared to diapausing males.

Behavioral Bioassays In the first experiment on the response of post-diapause winterform males and females to 13-MeC27, all 100 males and 100 females assayed made a choice within the 10 min cutoff time. Males most often chose the filter paper that had been treated with the 13-MeC27 when paired with a solvent control filter paper; 62.0% of males choosing the 13-MeC27 (t=4.81; df=9; P=0.001; Fig. 2a). Females showed no preference when presented with the 13-MeC27 vs. the solvent control (t=1.18; df=9; P=0.27; Fig. 2a).

In the second experiment on the response of winterform males to 13-MeC27 vs. cuticular extract of winterform females, all 450 males assayed made a choice within 10 min. Males most often chose the filter paper treated with the 13-MeC27 when it was paired with a solvent control filter paper; 67.3% of males chose the 13-MeC27 (t=11.31; df=14; P<0.0001; Fig. 2b). Similar results were obtained when assaying males to filter papers treated with extracts of females vs. solvent controls; 63.3% of males chose the extract of females (t=5.74; df = 14; P<0.001; Fig. 2b). Males did not show a preference when exposed to the 13-MeC27 vs. the extracts of females, with 50.7% of males selecting the 13-MeC27 (t=0.27; df=14; P=0.79; Fig. 2b).

Field Trial A total of 6,974 male and 3,958 female psylla were caught over the 6 d of the study. A significant interaction between sex and treatment was observed (F=8.76; df=3, 70; P<0.001) (Fig. 3). The mean catch of females on traps baited with 13-MeC27 was not significantly different from catch on the control traps, regardless of the dose of 13-MeC27 (F=0.25; df=3, 70; P=0.86). In contrast, the mean trap capture of males was higher on traps baited with 13-MeC27 than control traps (F=20.31; df=3, 70; P<0.001) (Fig. 3). The control traps did not capture more males than females (F=1.49; df=1, 70; P=0.23). More males than females were caught on traps baited with the 10 μg dose (F= 21.58; df=1, 70; P<0.001), with the 100 μg dose (F=28.95; df=1, 70; P<0.001), and with the 1,000 μg dose (F=6.79; df=1, 70; P=0.01). Furthermore, more males were caught on traps baited with the 10 μg dose (t=-6.28; df=70; adjusted P<0.001), with the 100 μg dose (t=−7.15; df=70; adjusted P<0.001), and with the 1,000 μg dose (t=−4.69; df=70; adjusted P<0.001) than on the control traps.

Discussion

The role of chemical signals in mate location is well established for many species in numerous insect orders. Recently, studies have shown that males are attracted to female-produced volatiles in three species of Psyllidae: *C. bidens* (Soroker et al., 2004), *C. pyricola* (Horton and

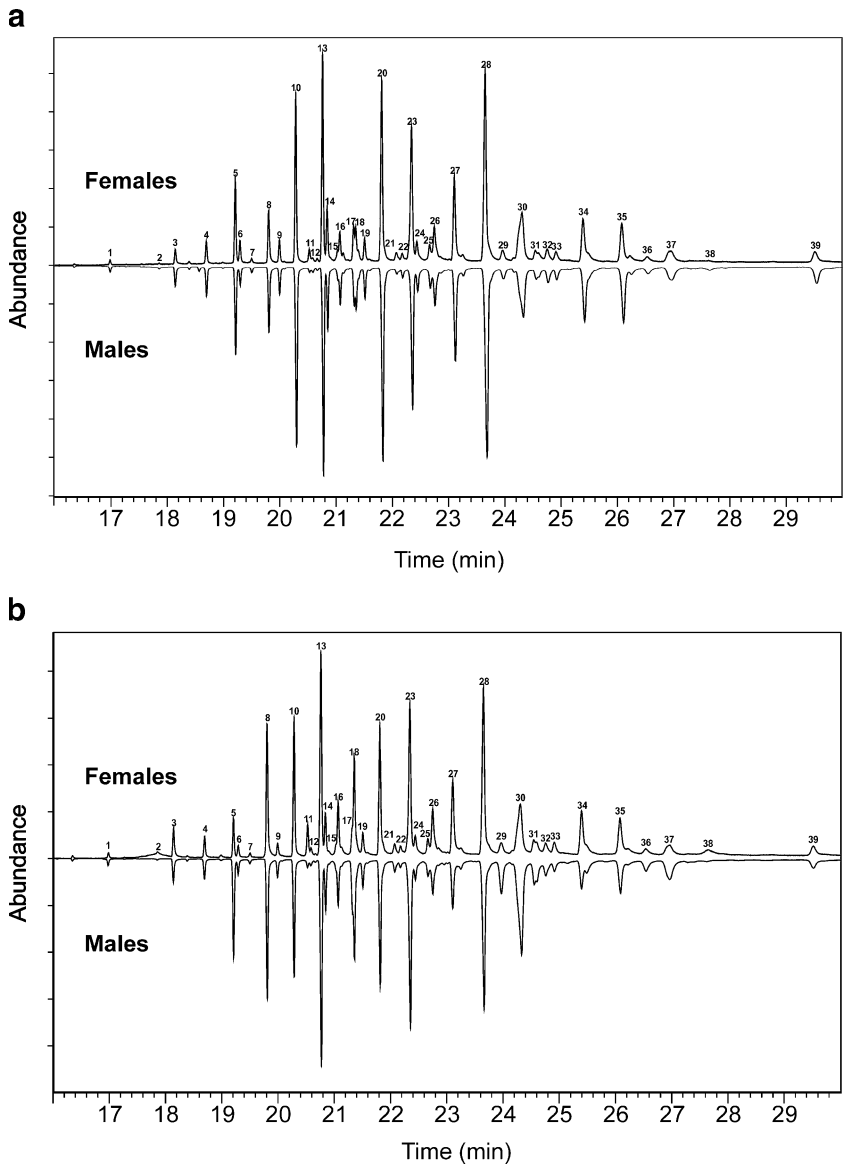

Fig. 1 Gas chromatography-mass spectrometry (GC-MSD) profiles of representative solvent extract of (**a**) diapausing winterform females (upper trace) and males (lower trace) and (**b**) post-diapause winterform females (upper trace) and males (lower trace), run on the DB5-MS column. Identifications of the numbered peaks are reported in Table 1

Landolt, 2007; Horton et al., 2007, 2008; Guédot et al. 2009), and *D. citri* (Wenninger et al., 2008). Despite the evidence and interest in the role of olfactory signals in mate location in the Psyllidae, the chemical(s) involved in the sex attractants had not been identified for any of these species.

The primary role of insect cuticular hydrocarbons is to provide a hydrophobic barrier that minimizes transpiration and that prevents desiccation (Nelson 1978; Lockey 1988; Howard 1993). However, components of the cuticular lipids often have important secondary roles as intraspecific recognition signals that communicate information such as sex, species, and physiological state (for review see Singer, 1998; Howard and Blomquist 1982, 2005). In the present study, the chemical analysis of cuticular extracts of male and female winterform *C. pyricola* revealed the presence of long chain (C22 to C35) *n*-alkanes, methyl- and dimethyl-branched alkanes, and aldehydes. To our knowledge, this is the first study that describes the cuticular lipid composition of any species in the Psyllidae.

The chemical profiles of extracts from diapausing and post-diapause winterforms were similar, with quantitative rather than qualitative differences. Post-diapause winterforms had greater amounts of cuticular hydrocarbons than diapausing winterforms. Similarly, hydrocarbon profiles of the adult face flies *Musca autumnalis* De Geer indicated a small increase in the total amount of hydrocarbons on the cuticle of reproductive females compared to diapausing females (Jurenka et al. 1998). In contrast, diapausing mosquitoes, *Culex pipiens* Linnaeus, produced more cuticular hydrocarbons than non-diapausing mosquitoes, purportedly as a mechanism to reduce water loss (Benoit and Denlinger 2007). Overall, the diapause syndrome is a

complex and often poorly understood process in which changes in cuticular lipids form but one small part of the overall changes in the physiological state of an insect.

The sexual dimorphism observed in the cuticular lipid profiles in both diapausing and post-diapause winterforms was quantitative rather than qualitative, with the same hydrocarbons being present in both sexes for both diapause states. Comparisons of the relative amounts of cuticular hydrocarbons in the post-diapause winterform revealed that only one chemical, 13-methylheptacosane (13-MeC27), was at least two times more abundant in females than males. Furthermore, comparisons of winterforms by sex revealed that post-diapause females produced relatively larger amounts of two other compounds, tetracosanal and

Table 2 Mean (± S.E.M.) amounts (ng) of cuticular hydrocarbons and related compounds per psylla for females and males of the diapause and post-diapause winterform of *Cacopsylla pyricola*, and female to male ratio (F:M) for each hydrocarbon. Peak in boldface type is 13-methylheptacosane. *N*=5 replicates

hexacosanal, compared to diapausing females, while post-diapause males produced relatively larger amounts of the two aldehydes than diapausing males. The two aldehydes were found in similar abundance in post-diapause females and males and are, therefore, probably not involved in mate attraction. Furthermore, in the Y-tube assays, 13-MeC27 alone was as attractive to males as the extract of females, which contained 13-MeC27 and a number of other hydrocarbons, including tetracosanal and hexacosanal. These results suggest that the relative and possibly absolute amount of 13-MeC27 produced by post-diapause females plays an important role in female attractiveness. Although 13-MeC27 is not specific to females, similar results have been obtained with other insects. For example, the contact sex pheromone produced by females of the locust borer, *Megacyllene robiniae* (Förster), also

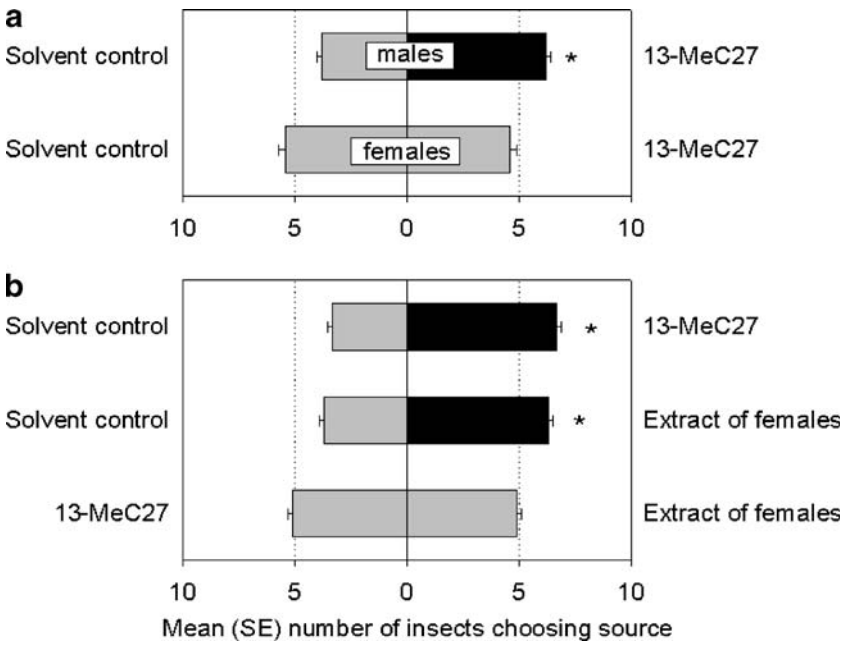

Fig. 2 Numbers of post-diapause winterform psylla (mean + S.E.M.) that chose paired odor sources. (**a**) Responses of males and females to 500 ng of 13-methylheptacosane (13-MeC27) vs. a solvent control (N=10). (**b**) Response of males to: 13-MeC27 (250 ng) vs. solvent control; extract of females (25 females) vs. solvent control; 13-MeC27 (250 ng) vs. extract of females (25 females) (N=15 per bar). * Choice is significant at P<0.05

was present, although in smaller quantities, on males (Ginzel et al. 2003).

The behavioral bioassays showed that responses to 13-MeC27 were sex-specific, with only males being attracted in both laboratory and field bioassays. In these assays, we tested the racemic blend of 13-MeC27, leaving male and female response to the individual stereoisomers unaddressed. The lack of responses by females to either female- or male-produced volatiles was also observed in the field with *C. pyricola* (Brown et al. 2009), and in the laboratory with *C. bidens* (Soroker et al. 2004) and *D. citri* (Wenninger et al. 2008). Males did not prefer the female extract over an equivalent amount of 13-MeC27, suggesting that 13-MeC27 may have been solely responsible for female attractiveness. These behavioral results are consistent with results described in the chemical analyses, and support the hypothesis that 13-MeC27 is a sex attractant pheromone for post-diapause males in *C. pyricola.* Further studies should address the attractiveness of the chiral forms of 13-MeC27.

13-Methylheptacosane is a relatively common constituent of insect lipids, and has been previously reported as a pheromone in insects. It is the major component of the contact recognition pheromone in males of the butterfly, *Colias eurytheme* (Boisduval) (Grula and Taylor 1979), and may be an aphrodisiac pheromone in that species (Grula et al. 1980). A mixture of three mono-methylheptacosanes, including 13-MeC27, was described as the major component of the post-pharyngeal gland secretions in the harvester ants *Pogonomyrmex salinus* Olsen and *Messor lobognathus* Andrews (Do Nascimento et al. 1993). As a cuticular hydrocarbon, 13-MeC27 occurs in the flesh fly, the pecan weevil, ants, grasshoppers, and crickets (reviewed in Nelson, 1978), and in termites (Haverty et al. 1996), wasps (Singer et

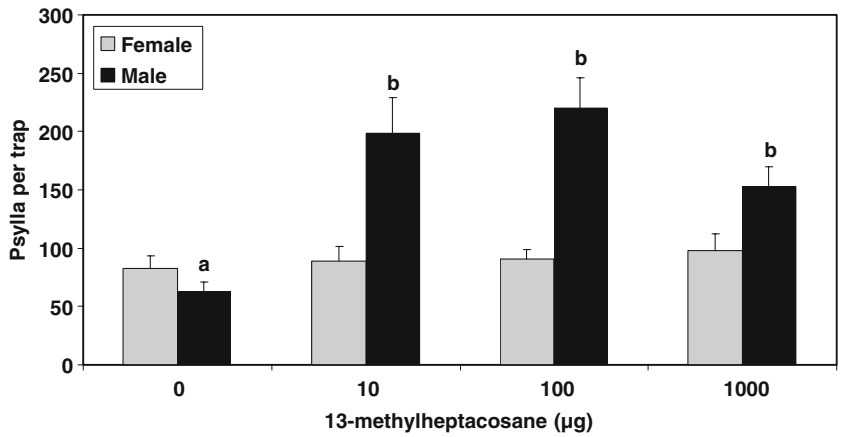

Fig. 3 Mean (+ S.E.M.) number of female and male winterform pear psylla captured on traps baited with 13-methylheptacosane dispensed from gray rubber septa at doses ranging from 0 to 1,000 µg (N=11 traps per dose). For male trap catches, treatments with different letters above them are significantly different (Tukey test, adjusted P≤0.05). Test conducted from 2 to 7 April 2009 near Moxee, WA

al. 1992; Liepert and Dettner 1996), and the moth *Scoliopteryx libatrix* (Linnaeus) (Subchev and Jurenka 2001).

Post-diapause winterform males of *C. pyricola*, but not females, were attracted to 13-MeC27 in the field. These results support field results with pear psylla indicating male attraction to females and no attraction between males, between females, and females to males (Brown et al. 2009), and support results of laboratory behavioral bioassays. This is also consistent with findings in two other psyllid species (Soroker et al. 2004; Wenninger et al. 2008). Our results indicate that males are attracted to a range of doses of 13-MeC27 covering two orders of magnitude, and that the doses tested were not critical for male attraction.

In summary, our results suggest that 13-MeC27 is a sex attractant pheromone for *C. pyricola* winterform males. Sex attractants are known to occur in non-psyllid Sternorrhyncha, including aphids, mealybugs, scale insects, and white flies (Yin and Maschwitz 1983; Lanier et al. 1989; Pickett et al. 1992; Hinkens et al. 2001; Rodriguez et al. 2005). This study provides the first identification of a sex pheromone in the Psylloidea. Further studies should address the optimization of this sex attractant for integrated pest management applications. Potential applications include a lure and trap useful to pear growers for monitoring pear psylla, lure and kill technologies, and mating disruption strategies for pear psylla management.

Acknowledgments We are grateful to Deb Broers and Merilee Bayer for conducting olfactometer and field assays and to Bonnie Ohler and J. Steven McElfresh for their assistance with the chemistry. We are also grateful to Erik Wenninger, David Hall, and two anonymous reviewers for their comments. ZAR, J. H. 1999. Biostatistical Analysis, 4th edn. Prentice Hall, New Jersey.

Prior to this research, laboratory studies that used a two choice olfactometer found that male *A. erythrocephala* exhibit a series of characteristic behaviors in response to female derived volatiles, as well as to decanal. The latter can be obtained from aerations and whole body extracts of both sexes (Staples 1999). Male behaviors included antennation, upwind flight, and courtship behavior that involved abdominal flexing accompanied by substrate vibration (Staples 1999). These responses were similar to laboratory and field data from another Pamphilliid sawfly, the web-spinning larch sawfly, *Cephalcia lariciphila*, in response to female derived odors and to a likely pheromone component, ortho-aminoacetophenone (Borden et al. 1978; Baker et al. 1983).

In this paper, we report that female *A. erythrocephala* produce an attractant pheromone, (*Z*)-6,14-pentadecadienal, to which only males respond. We demonstrate that the synthetic compound attracts male sawflies in the field, and provide preliminary evidence indicating that (*Z*)-6,14-pentadecadienal can be produced via abiotic oxidation of a long-chain unsaturated hydrocarbon found exclusively in females.

Methods and Materials

Life History In North America, adult *Acantholyda erythrocephala* emerge from underground in spring (March to May depending on latitude) to mate and oviposit (MiddleKauff 1958; Lyons 1994; Asaro and Allen 1999). Flight season lasts for approximately 3 wk, depending on local climate and weather conditions. Females oviposit on the previous year's needles. Larvae hatch approximately 10 d later and feed gregariously from within protective webs for 18–21 d (Middlekauff 1958). In May to July (depending on latitude), last-instars drop to the forest floor and burrow 1–15 cm into the soil (Jahn 1967; MiddleKauff 1938; Asaro and Allen 1999). Larvae overwinter in earthen cells as bright green pronymphs. Pupation occurs in the following spring (Jahn 1967), followed by adult emergence. Adult *A. erythrocephala* are strongly phototropic and readily bask in direct sunlight on cool days. As such, population densities usually are greater along sunny forest edges or in well-lit patches on the forest floor.

Collection and Rearing of Live Insects Most *A. erythrocephala* used in this research were collected as pronymphs in Sand Ridge State Forest (Mason County, IL, USA) during fall 2001, 2002, and 2003, by digging with a shovel under defoliated trees to a depth of approximately 15 cm. The bright green pronymphs were identified readily and collected by hand. Pronymphs were transported to the laboratory and placed in 31×8×6 cm plastic trays, 100–200 per tray, on moist, silica sand, 3 cm to 4 cm deep. Trays containing insects were then placed in growth chambers under total darkness at 4°C and ~70% RH for 2 mo. Pupation was initiated by raising the temperature to 12°C for 10–12 d.

Pupae and pre-emergent adults also were collected from the Sand Ridge site in mid March through early April and used for chemical analyses, behavioral studies, and field tests. Some adults were kept in 26×39×23 cm plastic boxes fitted with aluminum screen covers and maintained in the dark at 4°C and ~70% RH. Under these conditions, groups of healthy male or female sawflies (200 individuals per box) could be kept alive for up to 30 d.

Volatile Collection Volatiles were collected from aerations of individual and multiple male or female sawflies at the National Center for Agricultural Utility Research, Peoria, IL, as per Cossé and Bartelt (2000) and Cossé et al. (2001). Sawflies were aerated in 150 ml glass tubes (3×30 cm), and the resulting volatiles were collected on Super Q traps (80–100 mesh, Alltech Deerfield, IL, USA) (1×0.5 cm diam) plugged with silanized glass wool. These were placed at the inlet and outlet of each chamber. Airflow was held at 50 ml min^{-1} via valve-controlled vacuum. Sawflies were given access to water in 2 ml glass vials plugged with cotton and placed inside each chamber. Volatiles were collected from 1 d to 4 d under florescent light at 27°C and a 16 L:8D photoperiod. Outlet traps from each aeration were rinsed with 500 µl of HPLC grade hexane (Fisher Scientific) and concentrated to 50 µl under a steady stream of nitrogen and stored at −70°C.

Whole Body Extracts Whole body extracts were obtained from adult *A. erythrocephala* by soaking groups of six male or six female sawflies in 2 ml hexane for 2 min. The extracts then were concentrated to 200 µl under a stream of nitrogen. A series of fractions (1.5 ml of each) of increasing polarity were eluted on a silica gel column (0.6 cm ID× 2 cm height, gravity flow), beginning with, hexane, followed by 5%, 10%, and 25% diethyl ether (redistilled) in hexane, and finally 100% ether. Fractions were concentrated to 30 µl under a stream of nitrogen, and analyzed as described below for specific chemical constituents.

Chemical Analysis Volatile collections and chromatographic fractions of whole body washes were analyzed by using coupled gas chromatography-mass spectrometry (GC-MS). Equipment consisted of a Hewlett-Packard model 6890 gas chromatograph interfaced with a Hewlett-Packard model 5973 mass selective detector. Injections were made through a split/splitless inlet, operated in splitless mode. Columns used included DB-5 (30×0.25 mm ID with 0.25 µm film, J&W Scientific, Folsom, CA, USA), DB-1 (15×0.25 mm ID with 0.10 µm film, J&W Scientific), and a 30 m EC-5

(0.25 mm ID, 0.25 μm film thickness, Alltech Associates, Deerfield, IL, USA). A typical temperature program was 50°C for 1 min, increasing at 10°C min^{-1} to 300°C, and with a final hold time of 20 min. GC-MS settings were modified as necessary for specific analyses; however, the mass spectrometer scanning range was typically 40 amu to 550 amu (EI, 70 eV), except in analysis of dimethyl disulfide (DMDS) derivatives where the maximum mass was increased to 650 amu. The 1995 version of the Wiley mass spectral library was available on the data system (Wiley 1995).

Dimethyl disulfide (DMDS) derivatives of the unsaturated cuticular hydrocarbons were prepared and analyzed to determine double bond locations. The hexane fractions of the male and female whole body washes were prepared and analyzed according to the method in Carlson et al. (1989). Synthetic standards for (*Z,Z*)-1,9,15-pentacosotriene, (*Z*)-9,15-pentacosodiene, (*Z*)-9-pentacososene, and 6-14-pentadecadienal, were analyzed likewise to further verify chemical structures. GC-MS of DMDS derivatives was carried out on a thin film (0.1 μm) DB-1 column. GC inlet and transfer lines were set to 230°C and mass scan upper limit was set to 650 amu.

Electrophysiology Aerations and polar fractions of whole body extracts were analyzed by gas chromatography coupled with electroantennographic detection (GC-EAD) as per Cossé and Bartelt (2000). EAD recordings were made by severing the head of an adult sawfly at the cervix. The head was placed neck down into a vertical well (3× 3 mm) filled with physiological saline located 2 mm from the end of a Plexiglass stage. Antennae were extended horizontally along two shallow channels that ran from the well to the end of the stage. Antennae extended beyond the edge of the stage. A ring of dental clay (1 mm thickness) was placed around the well and covered with a Plexiglass plate to reduce evaporation. The plate was secured with a screw to ensure a water-tight seal. Distal ends of the antennae were severed at the inter-segmental membrane near the 20th antennal segment. EAD connections were made by inserting the distal ends of each antenna into glass capillary silver microelectrodes filled with physiological saline. The antenna with the recording electrode was positioned directly in the effluent stream coming from the GC, and the antennae with the grounding electrode was positioned out of the effluent stream. Compounds from either males or females that elicited antennal activity were identified subsequently based on comparisons to retention times and mass spectra of authentic standards, or to library spectra (as in the case of common well characterized compounds such as nonanal and decanal).

Synthesis 6,14-Pentadecadienal (**1**), 1,9,15-pentacosatriene (**2**), and 1,9-pentacosadiene (**3**) were synthesized as standards using Wittig condensations as the key step (Fig. 1). Reactions were monitored by GC-MS. Attempts were not made to optimize yields. The reagents were obtained from Aldrich Chemical Co., Milwaukee, WI, USA, and solvents were of HPLC grade.

Five Wittig salts were prepared by refluxing the corresponding alkyl halides with triphenylphosphine in acetonitrile (Sonnet 1974). Three of these (**4**, **5**, and **6**) had simple alkyl groups of 1, 10, and 16 carbons, respectively, and two had functionalized alkyl groups (**9** and **12**). To make **9**, 6-bromo-1-hexanol (**7**) was converted to the tetrahydropyranyl (THP) ether (**8**) (Miyashita et al. 1977), which was then converted to the salt. To make **12**, 1,6-dibromohexane (**10**) was first alkylated with allylmagnesium bromide under catalysis by dilithium tetrachlorocuprate as per Johnson et al. (1994); the Grignard reaction gave only monoalkylation. The resulting 9-bromo-1-nonene (**11**) was then converted to the phosphonium salt. Two aldehyde intermediates also were prepared: Octanedial (**14**) was made by oxidizing 1,8-octanediol (**13**) with pyridinium dichromate (PDC) (Corey and Schmidt 1979), and 6,6-dimethoxyhexanal (**16**) was made from cyclohexene (**15**) by ozonolysis, using the procedure of Claus and Schreiber (1986).

To prepare aldehyde **1**, a mixed Wittig reagent was made from salts **4** and **9** in tetrahydrofuran (THF) by treatment with butyllithium, and then dialdehyde **14** was added. The reaction was run essentially as per Sonnet (1974), but no dimethylsulfoxide (DMSO) was added (which Sonnet 1974, used to increase *Z* selectivity). Products with several chain lengths were created, but these differed widely in GC retention, and the THP ether of 6,14-pentadecadien-1-ol (**17**) was recognized readily from its mass spectrum [diagnostic ions, 308 (M), 222 (M-86), and 85 (intense in THP ethers)]. Both the 6*Z* and 6*E* isomers were formed, but 6*Z* isomer was more abundant and eluted earlier by GC. After purification on silica gel (elution with 5% ether in hexane), the THP ether **17** was converted to the free alcohol **18** (Miyashita et al. 1977), and the alcohol was then oxidized with PDC to aldehyde **1**.

When it became clear that **1** was identical to the key compound from female PFW, the synthesis was repeated by a more efficient route (Fig. 1, bottom). A Wittig reaction involving salt **12** and acetal aldehyde **16** (Sonnet 1974) gave just one product chain length, and predominantly the *Z* isomer (82%). After purification of acetal **19** on silica gel (elution with 10% ether in hexane) and by Kugelrohr distillation, **19** was readily hydrolyzed to aldehyde **1** (Ellison et al. 1975). The final product (140 mg, 70% of the theoretical yield) was diluted with hexane and stored at −20°C until needed for field tests.

Standard hydrocarbon triene **2** was prepared in one step by a Wittig reaction involving the decyl salt (**5**) and aldehyde **1**. Standard hydrocarbon diene **3** was made with a

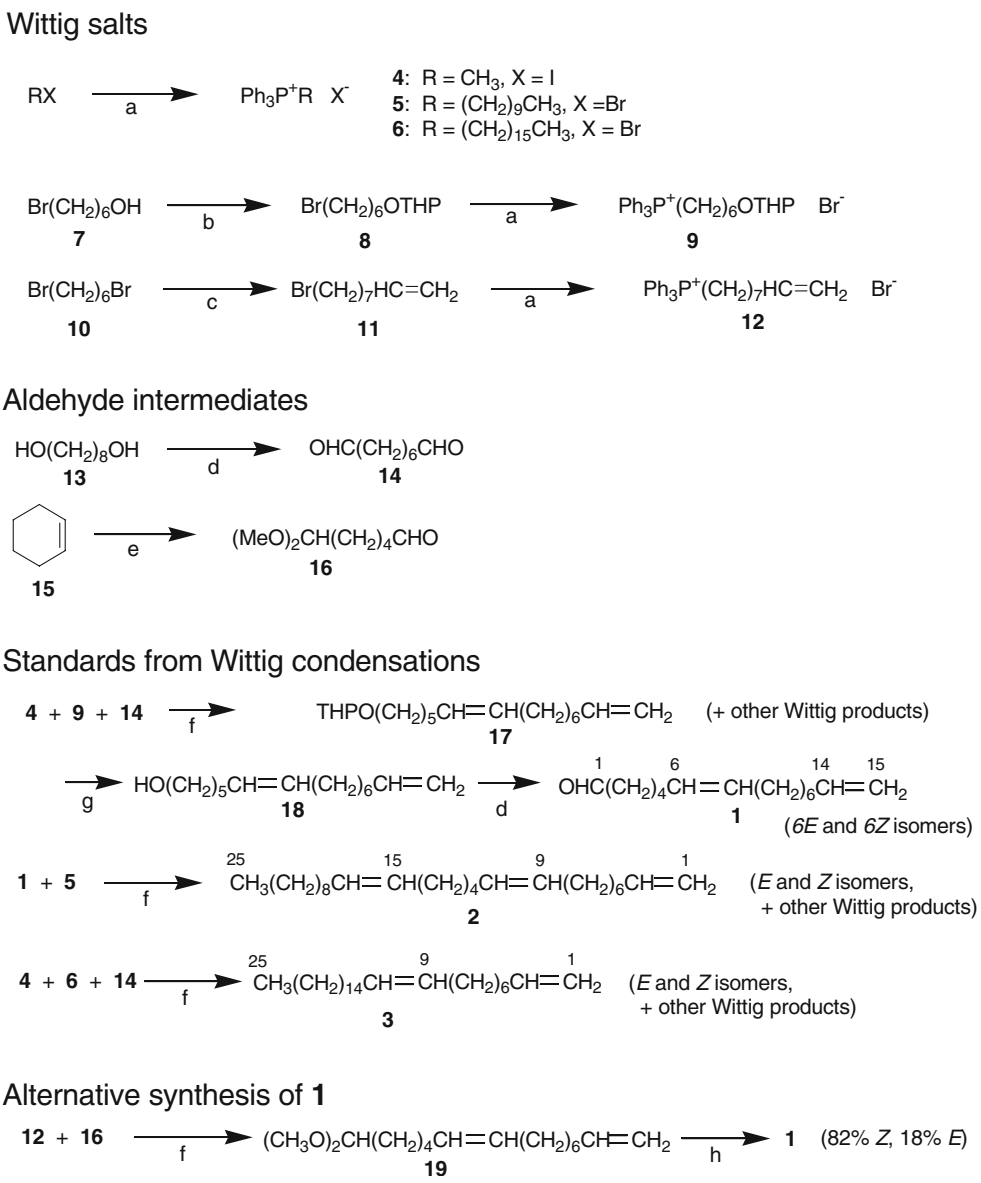

Fig. 1 Synthesis of 6,14-pentadecadienal (**1**), 1,9,15-pentacosatriene (**2**), and 1,9-pentacosadiene (**3**). Reaction conditions: **a** Ph_3P, CH_3CN, reflux, 10 h; **b** 2*H*-3,4-dihydropyran, pyridinium *p*-toluenesulfonate (PPTS), CH_2Cl_2, rt, 4 h; **c** allylmagnesium bromide, Li_2CuCl_4, ether, 0°C, 3 h; **d** pyridinium dichromate, CH_2Cl_2, rt, 4 h; (e) (*i*) O_3, MeOH, CH_2Cl_2, −78°C, until excess O_3 present, purge with N_2, (*ii*) TsOH, −78°C to rt, 1.5 h, (*iii*) $NaHCO_3$, rt, 15 min, (*iv*) Me_2S, rt, 12 h; (f) add BuLi to salt in THF, then add aldehyde, 0°C, 1 h; (g) PPTS, EtOH, 55°C, 2.5 h; (h) 1:2 50% aqueous CF_3COOH:$CHCl_3$, 0°C, 6.5 h

mixed Wittig reaction involving the methyl and hexadecyl salts (**4** and **6**) and dialdehyde **14**. In both reactions, the *Z* isomers predominated and eluted slightly earlier than the *E* isomers on the DB-1 GC column. The hydrocarbons were purified by silica gel chromatography (elution with hexane).

Weathering Experiment To determine if (*Z,Z*)-1-9,15-pentacosotriene could in fact oxidize to produce (*Z*)-6,14-pentadecadienal in the presence of air and ultraviolet light, a 5 μg sample of (*Z,Z*)-1,9,15-pentacosotriene in 100 μl of hexane was applied to the inside wall of a quartz cuvette (Beckman, CA, USA) and the solvent allowed to evaporate, leaving the hydrocarbon as a thin oily film. The cuvette was capped and placed inside a Suntest CPS solar simulator (Atlas, Gainesville, FL, USA), set up as described in McGuire et al. (2000), and exposed to simulated solar radiation for 4.5 h. The cuvette then was rinsed with 500 μl of hexane, and the solution was concentrated to 100 μl and analyzed by using GC-MS. Relative peak area of (*Z*)-6,14-pentadecadienal to (*Z,Z*)-1-9,15-pentacosotriene was determined.

Field Experiments Field testing for male *A. erythrocephala* response to synthetic and natural chemicals was carried out in the spring of 2002 and 2003 at two sites located in central Illinois and upstate New York. Both sites contain persistent outbreaks of *A. erythrocephala* and are remarkably similar in geology, topography, and host species composition, characterized by mixed and monoculture stands of white, red, and Scots pine.

The Illinois site is located in the Sand Ridge State Forest Reserve in Mason County, 50 km southwest of Peoria, Illinois. The reserve encompasses 2,913 ha, made up of

1,584 ha of mixed native oak (*Quercus* sp.) and hickory (*Carya* sp.) forests and 321 ha of fields and sand prairie. The remaining 1,008 ha consists of monoculture and mixed stands of white pine, red pine, and Scots pine. Although local conservation personnel noted feeding damage on pine species at this site for several years (personal communication), the specific defoliator responsible for the damage was not identified until the fall of 2001. This site continues to be infested as of this writing.

The New York field site is located 16 km southeast of Potsdam, New York, at High Flats in Saint Lawrence County. Species composition, geology, and topography of the area are described by Asaro and Allen (1999). An outbreak of *A. erythrocephala* has persisted at this site since the late 1980's and at its peak in the late 1990's covered more than 200,000 ha of mixed forest throughout St. Lawrence and Franklin Counties, New York (Asaro and Allen 1999, 2001). This area continues to be infested, though densities of *A. erythrocephala* appear to have declined in recent years.

Illinois Field Experiments 2002 The first field test of (*Z*)-6,14-pentadecadienal was carried out at the Illinois site from April 17 through April 20, 2002. Treatments included individual rubber septa infused with 50 μg of (*Z*)-6,14-pentadecadienal, 1 mg of nonanal, or 1 mg of decanal, whole body extracts of virgin male or female sawflies, and blank traps which served as controls.

Treatments containing nonanal and decanal were included in the 2002 field tests because these compounds elicit strong antennal activity in both sexes and are also found in aerations and extracts from both sexes. Furthermore, we have observed that decanal can elicit characteristic courtship behaviors in males that includes abdominal flexing and substrate vibration.

Chemical treatments were prepared 24 h prior to field testing by applying 50 μg of (*Z*)-6,14-pentadecadienal, 1 mg of nonanal, or 1 mg decanal each to individual rubber septa (Fisher Scientific, Pittsburgh, PA, USA). Treated septa were stored at −20°C and transported to the field site in Styrofoam coolers containing dry ice. At the field site, treated septa were attached to metal paperclips and hung inside wing traps (Trécé model-1C Great Lakes IPM, Inc., Vestaburg, MI, USA) in single-, double-, or four-compound combinations.

Whole-body extracts of unmated sawflies used in the Illinois field experiments were prepared by collecting pre-emergent adults from the field and extracting groups of either 400 male or 400 female sawflies in 300 ml of hexane for 20 min at room temperature. This method produced approximately 200 ml of extract. Twenty-ml aliquots of extract (roughly 40 insect equivalents) then were poured into plastic Petri dishes (35×10 mm) and allowed to evaporate at room temperature for 1 h, leaving behind an oily residue inside the dish. Petri dishes with residue were capped and sealed with Teflon tape and stored at −20°C before being transported to the field 12 h later in coolers containing dry ice. At the field site, dishes were uncapped and placed in the bottom center panel of individual wing traps.

Treatments used in all field experiments were set out following a randomized design with ten replicates per treatment. Treatments were placed inside wing-traps and secured to wooden stakes 30 cm above ground. At the end of each day, the bottom panel of each trap was removed, and sawflies were tallied per trap. Total trap data from the entire field season were transformed using sqrt (y+1) to meet assumptions of homoscedasticity (Bartlet's test, a=0.05) before performing one-way analysis of variance (ANOVA). *Post hoc* comparisons of the mean number of males caught among treatments were conducted with Tukey's honest significant difference test (Tukey HSD) (α=0.05) using Statistica version 6.0 (StatSoft Inc. Tulsa, OK, USA 2001).

New York Field Experiments 2002 A second field test was conducted at the New York site from May 21 through May 24, 2002. The goal of the second field test was to verify that the synthetic pheromone was indeed active in a different population of *A. erythrocephala*. Treatments at the New York field site included 500 μg and 50 μg doses of (*Z*)-6,14-pentadecadienal, whole body extracts, live virgin male and female sawflies, and blank traps. Because nonanal and decanal did not appear to influence male trap catches in the 2002 Illinois field experiment, they were excluded from the New York field experiments.

Whole-body extracts from virgin male or female sawflies (roughly 40 insect equivalents), were prepared in Illinois, as previously described, 72 h prior to conducting the New York field tests. Bulk extracts were transported to the New York site in sealed 500 liter Erlenmeyer flasks fitted with a rubber stopper sealed with Teflon tape and placed in individual Styrofoam coolers surround by dry ice. Petri dishes containing extracted residue were prepared indoors near the New York field site as described above for the Illinois experiments.

Live virgin male and female sawflies were obtained on site by digging in the ground for pre-emergent adults. Male and female adults also were collected on site and kept in individual translucent containers for 8–18 h prior to placing them in metal screen cylinders (3×5 cm), sealed with cork stoppers. Screen cylinders containing sawflies were hung in the center of each trap with a metal paperclip. Sawflies were replaced every morning. Because data did not adequately meet assumptions of normality or heteroscedasity, differences were analyzed via nonparametric Kruskal-Wallis analysis of variance. *Post-hoc* comparisons were

conducted via multiple comparisons of mean ranks for all pairs of groups (Siegel and Castellan 1988) via Statistica version 6.0 (StatSoft Inc., Tulsa, OK, USA 2001).

Illinois Field Experiments 2003 A third field test was carried out at the Illinois site in 2003 from April 24–27. Treatments included 1.5 μg, 5 μg, 15 μg, 50 μg, 150 μg, and 500 μg doses of synthetic (*Z*)-6,14-pentadecadienal, whole body extracts of virgin male or female sawflies, and live virgin male or female sawflies held in metal cylindrical cages as describe above. Blank wing traps served as controls.

Whole body extracts used in the 2003 Illinois field experiment were prepared as described above for the 2002 field experiments 6 h prior to placing them in the field. In 2003, Petri dishes containing whole body extracts were uncovered and placed in direct sunlight (~21°C air temperature) for 1 h prior to placing them in individual traps. The purpose of exposing whole body extracts to direct sunlight was to determine if exposure to sunlight would enhance the attractiveness of the extract relative to the previous year's results.

Adult male and female sawflies used in the 2003 field experiments were collected as eonymphs and reared at Illinois State University. Adults were kept in translucent 26×39×23 cm plastic containers with wire-screen covers. Containers with fresh sawflies were transported to the field every morning and placed in direct sunlight at approximately 20°C for 1 h prior to placing individual sawflies in screen cages hung centrally inside each trap. As with the whole body extracts, the purpose of exposing live extracts to direct sunlight was to assess whether exposing live female insects would enhance attractiveness. Cages were replaced with fresh sawflies every morning for the duration of the experiment. Total trap data from the entire field season were transformed using log (y+1) to meet assumptions of homoscedasticity (Bartlet's test, a=0.05) before performing one-way analysis of variance (ANOVA). *Post hoc* comparisons were conducted as described above.

Results

Chemical Analysis GC-MS analysis of aerations and whole body extracts obtained from both sexes of *Acantholyda erythrocephala* primarily contained saturated and unsaturated straight chain hydrocarbons, many with a double bond located at the Δ9 position. Qualitative and quantitative differences between sexes included a 25-carbon triene (MW 346), exclusive to females, and a 25-carbon diene (MW 348) that was abundant in females, but also occurred in trace amounts in aerations and extracts obtained from males. A 25-carbon alkene (MW 350) and pentacosane (MW 352) were present in both male and female aerations and extracts (Table 1).

The putative pentacosane was verified based on comparisons to library spectra, GC retention time, and mass spectra of authentic standard (Aldrich Chemical Co., Milwaukee, WI, USA). Preliminary identifications of the -ene, -dien, and -trien, were based on GC-MS analysis of their DMDS derivatives.

DMDS adducts of pentacosene (Fig. 2a) gave a molecular ion at *m/z* 444 (350+94), consistent with a 25-carbon chain containing two thiomethyl (CH_3S) groups. Diagnostic fragments A^+ (*m/z* 173) and B^+ (*m/z* 271) indicated a double bond at the 9 position (9-pentacosene).

DMDS adducts for pentacosadiene (Fig. 2b) produced a molecular ion at *m/z* 536 (348 + 188). This was consistent with a 25-carbon chain containing four CH_3S groups. Key diagnostic ions B^+ (*m/z* 265, 217,169) and D^+ (*m/z* 271) also suggested a double bond at the 9 position. Ion fragments A^+ (*m/z* 61) and C^+ (*m/z* 441, 393, 345) indicated the presence of a terminal double bond, resulting in 1,9-pentacosadiene.

DMDS adducts for pentacosatriene (Fig. 2c) produced a molecular ion at *m/z* 628 (346 + 282), consistent with a 25-carbon chain containing six CH_3S groups. Ion fragments A^+ (*m/z* 61) and D^+ (m/z 567, 519, 471), again indicated a terminal double bond. Fragments B^+ (*m/z* 265, 217, 169) and E^+ (383, 315, 267) indicated a double bond at the 9 position. Fragments C^+ (441, 393, 345) and F^+ (187) suggested a third double bond at the 15 position (1,9,15-pentacosatriene).

Synthetic hydrocarbons corroborated these identifications and helped clarify double bond configurations. Female-derived 1,9-pentacosadiene and 1,9,15-pentacosatriene showed GC retention times and mass spectra identical to the earliest-eluting (*Z*) synthetic isomers indicating that these hydrocarbons existed in the *Z* configuration (i.e., (*Z*)-1,9-pentacosadiene and (*Z,Z*)-1,9,15-pentacosatriene). DMDS derivatives of synthetic 1,9-pentacosadiene and 1,9,15-pentacosatriene produced mass spectra and GC retention times identical to DMDS derivatives of the natural 1,9-pentacosadiene and 1,9,15-pentacosatriene.

GC-MS analysis of natural and DMDS derivatized whole body extracts from ten male and ten female sawflies in hexane revealed that female sawflies contained a number of dienes with double bonds at the Δ1 and Δ9 positions. These dienes were either nonexistent in male extracts or present only in trace amounts (Table 1).

Electrophysiology Electrophysiological analysis of male and female aerations showed antennal sensitivity in both sexes to a series of aldehydes including nonanal, decanal, and possibly 2-undecanal. Male-specific antennal responses were also recorded for a single unknown compound (Fig. 3)

Table 1 Putative identification of major cuticular hydrocarbons collected from whole body extracts of ten male and ten female *Acantholyda erythrocephala* (4 hrs in hexane)

isolated exclusively from moderately polar fractions (10% ether) of female aerations and whole body extracts (Fig. 4). Key diagnostic ions obtained from GC-MS analysis of female aerations were *m/z* 222 (M), 204 (M-18), and were of low intensity (3.1% and 2.9%, respectively, of base peak) (Fig. 5). The apparent molecular weight of 222, likely loss of water (*m/z* 204), and the modest polarity on silica suggested a 15-carbon aldehyde with two double bonds. However, the amount of material obtained from the natural extracts was too small for double bond locations to be determined.

Based on previous reports from two other species of sawfly (Bartelt and Jones 1983; Bartelt et al. 1983, 2002; Cossé et al. 2002), and one Braconid species (Swedenborg and Jones 1992) suggesting that aldehyde pheromones could result from natural oxidation of unsaturated cuticular hydrocarbon precursors, we considered all potential oxidation products of (*Z,Z*)-1,9,15-pentacosatriene, a compound that was found exclusively in aerations and whole body washes of female *A. erythrocephala*, (see Frankel 1998 for a review of chemical mechanisms for natural oxidation of unsaturated lipids). We predicted that oxidation of (*Z,Z*)-1,9,15-pentacosatriene could yield a 15-carbon aldehyde containing two double bonds at the six and 14 positions. GC retention time, mass spectrum, and male-specific antennal activity of synthetic (*Z*)-6,14-pentadecadienal was found to be identical to the 15-carbon aldehyde also obtained exclusively from aerations and whole body washes of female *A. erythrocephala* (Figs. 4 and 6). Female sawflies showed no antennal sensitivity to natural or

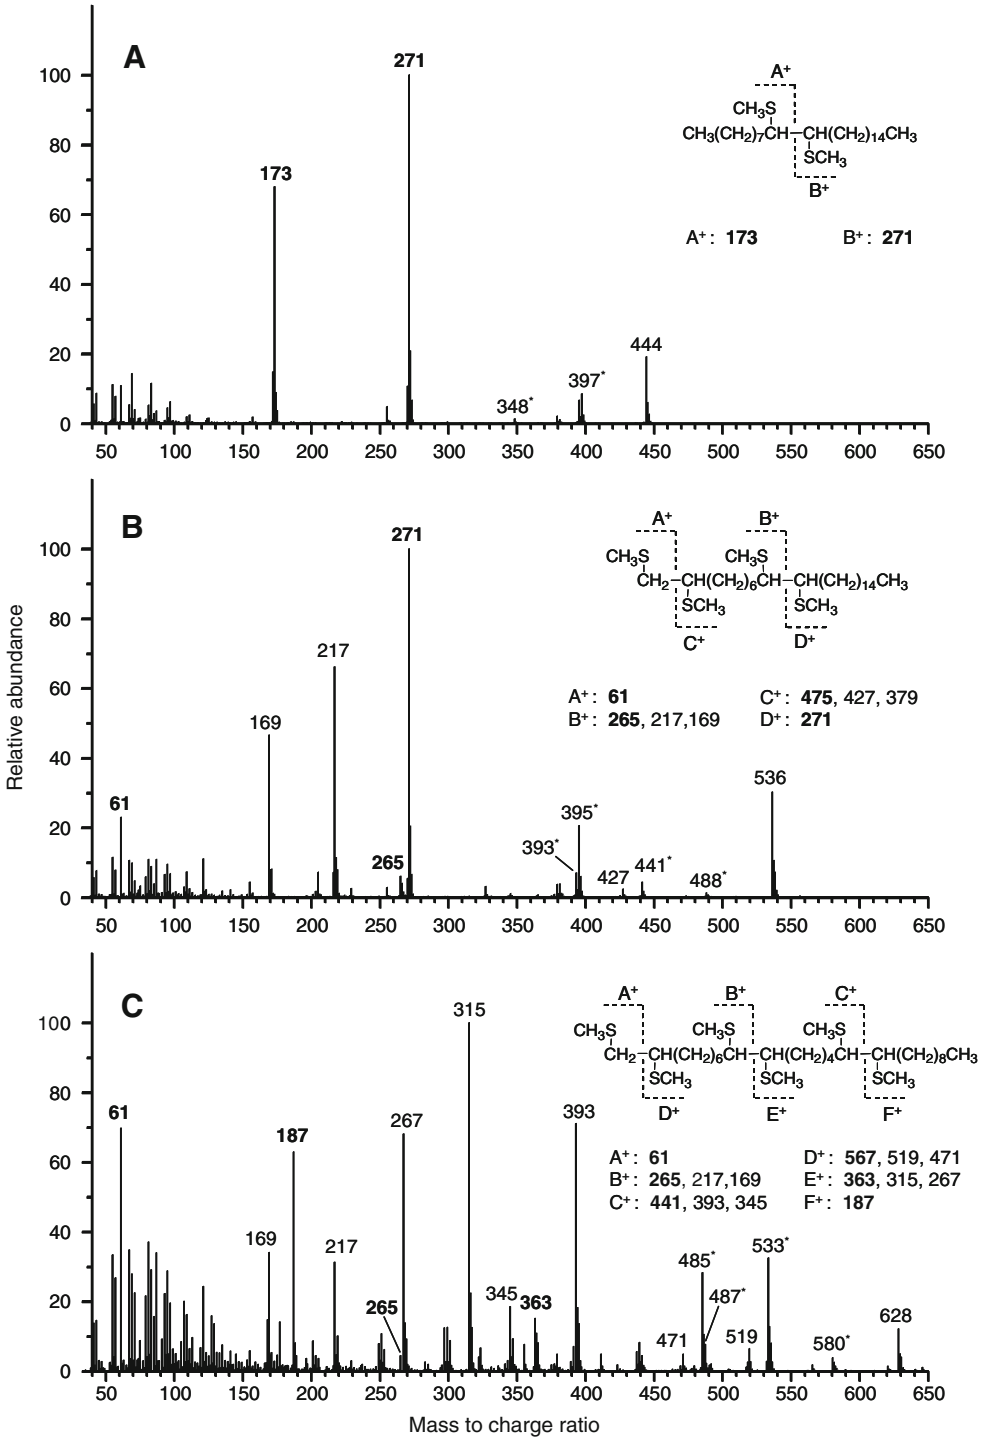

Fig. 2 Mass spectra of DMDS adducts from female-derived 9-pentacosene (Trace A), 1,9-pentacosadiene (Trace B), and 1,9,15-pentacosatriene (Trace C), and explanation of fragmentation patterns. Key one-bond cleavage fragments shown in bold type (some have very low intensity), followed by fragments representing elimination of one or two CH_3SH groups (48 mass units). synthetic (*Z*)-6,14-pentadecadienal (Fig. 6) suggesting that this compound had a sex-specific role in the mating system of *A. erythrocephala*.

Weathering Experiment After 4.5 h of exposure to simulated solar radiation, approximately 1% of (*Z,Z*)-1,9,15-pentacosatriene was oxidized to (*Z*)-6,14-pentadecadienal thereby providing a plausible mechanism for pheromone production in this insect.

Illinois Field Experiments, 2002 Data obtained from the 2002 Illinois Field Experiments showed that traps baited with (*Z*)-6,14-pentadecadienal, alone or in combination with nonanal and/or decanal, caught significantly greater numbers of males relative to all other treatments and blank controls (ANOVA, $F=10.83$; $df=9, 90$; $P<0.01$) (Fig. 7). There were no differences in the number of males caught in traps baited with nonanal or decanal, singly or in combination, relative to whole body washes from either

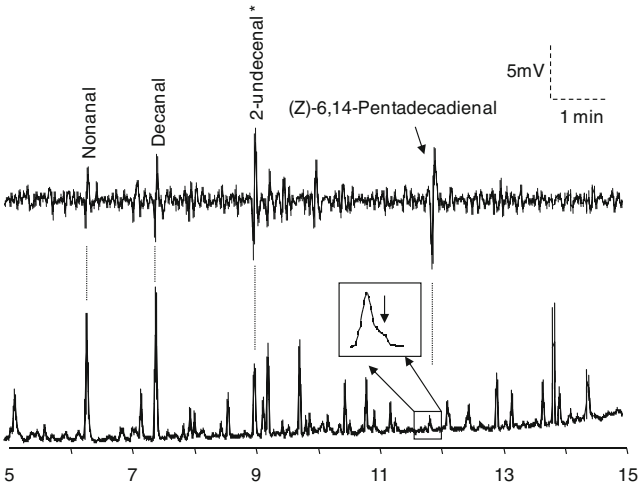

Fig. 3 Male antennal response (*top trace*) and GC detector response (*bottom trace*) to moderately polar silica fraction (10% either in hexane) obtained from female whole body extract of virgin females. Antennally active peaks, from *left* to *right*, correspond to nonanal, decanal, 2-undecenal (identification based on analysis of GC-retention time and mass spectra), and (*Z*)-6,14-pentadecadienal

sex (40 insect equivalents per trap) or blank controls (Tukey HSD, $P>0.05$). The addition of lures containing synthetic nonanal and/or decanal to traps baited with (*Z*)-6,14-pentdecadienal did not significantly improve field attraction relative to traps containing (*Z*)-6,14-pentdecadienal alone. Although there was a slightly greater number of males caught in traps baited with whole body extracts of virgin females relative to blank controls, these results were not significantly different from blank controls (Tukey HSD, $P>0.05$).

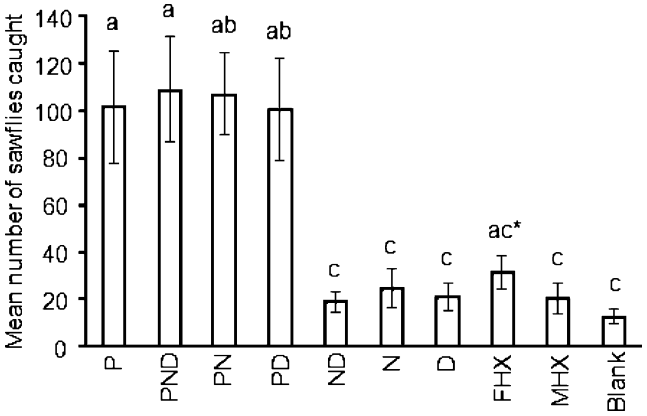

Fig. 7 Illinois field experiment 2002. Results showing the mean number of male *Acantholyda erythrocephala* collected per treatment from April 17 through April 20. Error bars = standard error of untransformed data. Different letters indicate significant differences. Treatments include *P*=(*Z*)-6,14-pentdecadienal (50 μg), *N*=nonanal (1 mg), D = decanal (1 mg), ND = nonanal and decanal (1 mg each), FHX = female whole body washes (in hexane), MHX = male whole body washes (in hexane), and blank traps

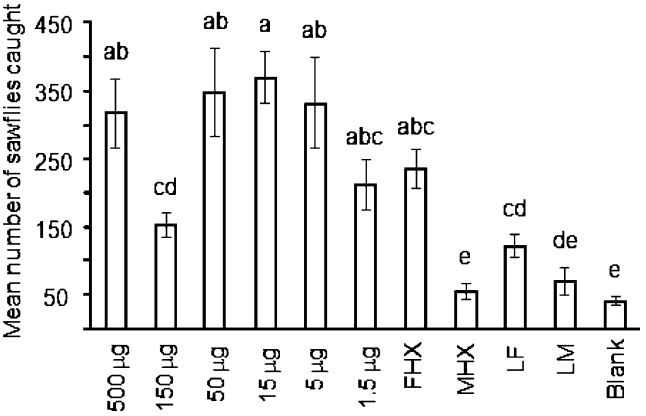

Fig. 9 *Illinois field experiment 2003*. Mean number of sawflies collected from April 24–27. Treatments include 500 μg; 150 μg; 50 μg; 15 μg; 5 μg; and 1.5 μg of (*Z*)-6,14-pentdecadienal. Error bars = SE. Other treatments include, FHX = female whole body washes (in hexane); LF = live females; MHX = male whole body washes (in hexane); LM = live males; and blank traps. Different letters designate significant differences

whole body washes relative to blank controls (multiple comparisons of *z* values for mean ranks $P>0.05$) (Fig. 8). Note that some treatments were lost due to animal damage.

Illinois Field Experiments, 2003 Significantly larger number of males were caught in traps baited with synthetic (*Z*)-6,14-pentadecadienal as well as female whole body washes compared with live males, male whole body washes, and blank controls (ANOVA $F=21.65$; $df=10, 99$; $P<0.01$) (Fig. 9). Traps containing whole body extracts of live virgin females attracted significantly more (Tukey HSD, $P<0.05$) males than those baited with male extracts or blank controls, but were not significantly different from traps baited with live virgin males (Tukey HSD, $P>0.05$).

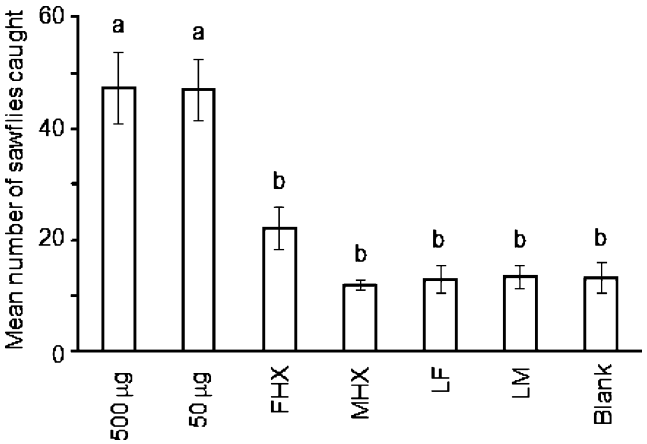

Fig. 8 New York field experiment 2002. Results showing the mean number of male *Acantholyda erythrocephala* collected per treatment from May 21 through May 24. Error bars = SE of untransformed data. Different letters indicate significant differences. Treatments include 500 μg [(*Z*)-6,14-pentdecadienal] (*N*=9); 50 μg [(*Z*)-6,14-pentdecadienal] (*N*=10); FHX = female whole body washes (in hexane) (*N*=9); LF=live females (*N*=8); MHX=male whole body washes (in hexane) (*N*=10); LM = live males (*N*=10); and blank traps (*N*=9)

Discussion

In this paper, we provide laboratory and field results demonstrating that (*Z*)-6,14-pentadecadienal, a compound derived exclusively from a female *A. erythrocephala*, functions as a attractant pheromone for male conspecifics. This is the first pheromone identified for the genus *Acantholyda* and the second to show pheromone-like properties in the family Pamphiliidae.

GC-MS analysis of aerations and whole-body extracts revealed that cuticular hydrocarbons from male and female sawflies were made-up primarily of unbranched straight chain hydrocarbons with little evidence of methyl branching. Major differences observed in cuticular hydrocarbons collected from male and female sawflies, included (*Z,Z*)-1,9,15-pentacosatriene, found exclusively in female aerations and whole body extracts, and a number of 1,9-dienes that were either more abundant or exclusive to female aerations and whole-body extracts (Table 1).

By considering potential oxidation products of (*Z,Z*)-1,9,15-pentacosatriene, we were able to gain valuable insight regarding the final chemical structure for (*Z*)-6,14-pentadecadienal. We also were able to demonstrate that production of (*Z*)-6,14-pentadecadienal can occur via abiotic oxidization of (*Z,Z*)-1,9,15-pentacosatriene. Although these results illustatrate a plausible mechanism for pheromone production in this species, they do not exclude the possibility that (*Z*)-6,14-pentadecadienal also may be produced through some dedicated biosynthetic pathway.

Field results from the Illinois and New York sites in 2002 and 2003 demonstrate that (*Z*)-6,14-pentadecadienal functions as an effective male lure. It is also interesting to note that in the 2003 Illinois field experiments, significantly more male sawflies were captured in traps baited with whole body extracts of virgin females relative to traps baited with extracts of virgin males after they were exposed to direct sunlight (Fig. 9). These observations fit well with laboratory experiments that demonstrate that (*Z*)-6,14-pentadecadienal can indeed arise via abiotic oxidation of female specific (*Z,Z*)-1,9,15-pentacosatriene.

Although we recorded antennal responses to nonanal and decanal in both male and female sawflies, neither of these compounds was found to significantly influence male attraction in the field. Similarly, neither compound exhibited synergistic or inhibitory influences on male response to (*Z*)-6,14-pentadecadienal. Nevertheless, these results do not rule out a bioactive role for these compounds. Indeed, it is interesting to note that *n*-decanal and 2-undecenal, respectively, not only stimulate courtship behavior and antennal responses in male *A. erythrocephala*, but both compounds also are likely oxidation products of (*Z*,*Z*)-1,9,15-pentacosatriene via either α-scission or β-scission of the C15 double bond. Future planned research will explore the role of 2-undecenal in the behavior of *A. erythrocephala*.

To date, approximately 22 pheromones have been identified among 14 families and 8,000 species (Smith 1993) of sawfly. Most of these pheromones have been reported in the Diprionidae and are made up of various methyl branched acetate or propionate products of diprionol (Jewett et al. 1976; Ahlgren et al. 1979; Anderbrant et al. 1992, 2000, 2005; Bergström et al. 1995, 1998; Chen et al. 1997; Tai et al. 1998, 2002; Wassgren et al. 2000; Ostrand et al. 2003; Hedenström et al. 2006). *Acantholyda erythrocephala* differs from diprionids in that its pheromone, (*Z*)-6,14-pentadecadienal, and likely pheromone precursor, (*Z,Z*)-1,9,15-pentacosatriene, are both simple unbranched straight chain hydrocarbons. Although this simple straight chain structure differs in comparison to active pheromones of diprionind species, it is not surprising in terms of a cuticular precursor or as a pheromone. Indeed, straight chain cuticular hydrocarbons, including those with a double bond in the Δ-9 position, are quite common among insect cuticular hydrocarbons (Blomquist et al. 1993; Howard 1993; Howard and Blomquist 2005; Steiner et al. 2007). Nevertheless, pheromone production by means of abiotic oxidation remains a relatively little explored area of study in insect chemical ecology. Other reports describing pheromone production by means of abiotic oxidation in insects include the yellow-headed spruce sawfly, *Pikonema alaskensis*, (P.) (Tenthredinidae) (Bartelt and Jones 1983), the parasitic wasp of the European corn borer *Ostrinia nubilalis* Hubner, *Macrocentrus grandii* Goidanich (Hymenoptera: Braconidae) (Swedenborg and Jones 1992), and the wheat stem sawfly, *Cephus cinctus* Norton (Hymenoptera: Cephidae) (Bartelt et al. 2002; Cossé et al. 2002). The results presented here, therefore, represent only the fourth report of pheromone production in an insect species that uses this mechanism.

With the development of a viable pheromone lure for *A. erythrocephala*, we now offer an additional management tool for monitoring and possibly controlling this forest pest.

Acknowledgments We thank Robert Behle of the USDA-ARS-NCAUR in Peoria, Illinois for use of the solar simulator, and the Illinois Department of Natural Resources for access to Sand Ridge State Forest.

aversion; and 4) flavor modification. Known repellent formulations employ these mechanisms singly or in combination.

At the most basic level, all repellents may deter herbivores by exploiting their fear of unfamiliar visual, olfactory, or taste cues (neophobia). However, repellents that rely on neophobia alone (there are no additional negative consequences associated with them) are subject to habituation and will not be avoided for extended periods (Nolte 1999). Visual and vapor repellents often rely on neophobia. Repellent stimuli disassociated from the food source (not applied directly to the food) can be referred to as "vapor repellents" as they are not ingested (thus, do not contribute to the flavor of the repellent stimuli) and are detectable at variable distances from the source.

Most contact repellents (applied directly to the plant) employ active ingredients that impart additional consequences beyond neophobia. One such mechanism is associated with activation of the trigeminal system. The consequence of peripheral (oral/nasal/ocular) contact with these repellents is pain. Among mammals, capsaicin is a well-known trigeminal irritant (Nolte and Wagner 2000). Another consequence of ingesting certain repellents is malaise. Repellent compounds that produce negative postingestive consequences (i.e., malaise or gastrointestinal distress) are avoided as a result of learning. This mechanism is often termed aversion learning or conditioned aversion (Burritt and Provenza 1989). The active ingredient required to produce the negative consequences is typically a toxin. Sensory cues of the repellent formulation (usually flavor) are associated with the negative consequences of toxin ingestion and are avoided at future encounters. In laboratory studies, lithium chloride often is used as the toxin to condition aversions (Riley and Tuck 1985). In formulated repellents, thiram (tetramethylthiuram disulfide) is a fungicide used to condition aversions (Nolte and Wagner 2000). Among other symptoms, chronic thiram exposure produces anemia and nausea (Maita et al. 1991).

Numerous compounds have been used to alter the flavor of treated plants without eliciting pain or malaise. One such strategy has been to employ compounds that impart bitter taste. In practice, repellents employing only bitter compounds are typically ineffective as deer repellents (Nolte and Wagner 2000) and there is some question about the reliability of bitter taste *per se* as a warning of toxicity (Glendinning 1994; Nolte et al. 1994b). Blood and egg are examples of ingredients that yield effective herbivore repellency when applied to plants without causing pain or malaise (Nolte and Wagner 2000). In recent years, hydrolyzed casein (HC) has been added to the list of stimuli that produce long-lived avoidance (Kimball and Nolte 2006). Repellent ingredients like blood, egg, and HC are non-toxic (i.e., unlikely to condition aversions) and typically are not subject to habituation in repeated tests (i.e., unlikely to cause avoidance merely via neophobia).

The relative effectiveness of repellents that rely on any of these mechanisms may depend on the individual herbivore's motivation to consume the protected resource. For example, when alternative foods are available, shiny ribbons (a visual repellent with no consequence) may provide significant protection in localized areas. However, when alternative foods are scarce, repellents with actual consequences to the consumer may be required to reduce browsing effectively. Previous studies of herbivore repellents failed to account for feeding motivation. In this study, the incentive to consume test diets was manipulated by allowing captive deer to learn about two test diets that differed in energy content. A series of experiments then were conducted to compare the different mechanisms of deer repellency and evaluate repellent effectiveness when incentive to consume the treated diet was varied.

Methods and Materials

Subjects Ten hand-reared white-tailed deer (*Odocoileus virginianus*) were group housed in a large (ca 2 ha) outdoor pen except during individual bioassays. Shelter, water, and mineral block were available *ad libitum*. Basal diet was provided at varying intervals: *ad libitum* on days with no scheduled bioassays and overnight from 1600 h to 0800 h daily in advance of individual bioassays. Thus, subjects were restricted from basal diet for 6 h. For individual bioassays, deer were led into individual pens (sheltered stalls measuring approximately 5×3 m). Water was provided in the rear of the stalls, and access doors located at the head of each stall allowed for placement and removal of plastic feed containers (ca 50 cm diam and 15 cm deep). This study was approved by the National Wildlife Research Center's Institutional Animal Care and Use Committee (QA-1642) and conducted during the period of 24 March to 25 April 2009.

Diets Three different pelleted diets were used during the study, including a basal diet familiar to the subjects (Antler Max®; Purina Mills, St. Louis, MO, USA). All test subjects had several years experience with Antler Max® as their primary food source. Two test diets were formulated to differ in net energy while containing similar protein (Table 1; X-Cel Feeds, Tacoma, WA, USA). High energy (HE) and low energy (LE) test diets were distinctly flavored with citrus-anise-vanilla or maple-anise flavors, respectively, to facilitate easy discrimination during bioassays (Table 1). Animals learn about foods they eat by integrating flavor with the postingestive consequences of consuming that food (Provenza 1995a). Preferences (or aversions)

Table 1 Composition and nutritional content of the high energy (HE) and low energy (LE) test diets

Ingredient	High energy (HE)	Low energy (LE)
Barley	22%	15%
Corn grain, ground	35%	7%
Corn, distillers	9%	6%
Wheat mill run	0	15%
Alfalfa meal	6%	19%
Soybean hulls	0	14%
Beet pulp	13%	14%
Soybean meal	11%	7%
Minerals and vitamins	3%	2%
Dry dairy krave® flavor[a]	0.1%	0
Anise-maple flavor	0	0.1%
Crude protein	15.3%	15.3%
Non-structural carbohydrates	47.3%	21.3%
Relative feed value	430	152
Net energy gain	1017 Mcal	803 Mcal

[a] Citrus-anise-vanilla and other natural flavors

based on flavor are formed such that these flavors are recognized readily at future encounters. Upon learning by the subjects, the distinct flavors were expected to be readily associated with the energy content of the food.

Repellents Test diets were treated with commercially-obtained repellents according to labeled use as specified by the manufacturers. Deerbusters® sachets (Trident Enterprises, Frederick, MD, USA) represented the neophobia mechanism. The irritation mechanism was represented by Miller's Hot Sauce® (Miller Chemical and Fertilizer Corp., Hanover, PA, USA). Chew-Nott® (Nott Products, Coram, NY, USA) that contained the fungicide thiram was the repellent chosen for conditioned aversion. The final mechanism, flavor modification, was represented by Plantskydd® (Tree World Plant Care Products Inc., St. Joseph, MO, USA), which contains blood meal.

Sachets similar to those marketed as Deerbusters® repellent, but containing only meat and bone meal were used as a vapor repellent (the repellent was not in contact with the diets). Unlike the usual commercial product, our experimental sachets did not contain capsaicin (irritant). As such, the sachets were suited perfectly for this study because their mode of action was limited to neophobia—largely owing to the fact that the meat and bone meal was not applied directly to the test diets. Sachets were attached to the inside of feed bowls by use of zip-ties passing through two holes drilled near the top edge of the bowl.

Two hundred and forty mL of Miller's Hot Sauce® (2.5% capsaicin) were mixed with 5 mL Tactic® (a latex-based sticker; Loveland Industries, Greeley, CO, USA) and 4.0 L tap water (resulting in a 0.14% capsaicin solution). A hand-held pump sprayer was used to treat test diets until the pellets were visibly coated, and were allowed to dry overnight. Approximately 40 ml were used to treat 2 Kg of diet. Two additional contact repellents were similarly prepared according to label directions and applied directly to the test diets. Chew-Nott® (20% thiram) was mixed 1:1 with tap water prior to application and Plantskydd® was employed as the ready-to-use formulation (Tree World Plant Care Products Inc., St. Joseph, MO, USA) consisting of 16.7% dried porcine and/or bovine blood.

Pre-trial Experience with Test Diets For 2 wk prior to individual bioassays, either HE or LE test diets were provided *ad libitum* in group housing according to a predetermined schedule (Table 2). Pre-trial exposure was designed to promote association of energy content of the diets with their specific flavors. During group feeding, the two test diets were offered in separate 100-L feed bins. For individual bioassays, HE diet always was presented in a blue-colored bowl, and LE diet was presented in a black-colored bowl—regardless of presence or absence of repellent treatment.

Experiment 1: Diet Preference Subjects were led/herded into individual stalls and untreated test diets (HE and LE) were offered in a two-choice test for two consecutive days (days 16 and 17; Table 2). The right/left position of the diets was predetermined and alternated on the 2nd day. The 30 min bioassays commenced at 1400 h daily following a 6 h period of basal-diet restriction. Intake of each diet was determined by difference (mass immediately prior to and after the 30 min bioassay).

Experiment 2: Repellency and Feeding Incentive Experiment 2 was initiated the following day and similarly employed two-choice tests with HE and LE in 30 min trials. The purpose of this experiment was to offer a choice

Table 2 Pelleted diets offered *Ad libitum* to test subjects in group housing before, during, and in between experiments 1, 2, and 3 (HE = High energy diet; LE = Low energy diet; BOTH = both HE and LE; MAX = Antler max®)

of treated diet and untreated alternative, while also varying the incentive to consume the treated diet. One diet was treated with a single repellent treatment, while the other remained unadulterated (Table 3). For example, one subject was offered a choice of HE diet treated with blood and untreated LE in a two-choice test, while another subject was offered a choice of LE diet treated with blood and untreated HE (i.e., the opposite diet-treatment pair). Each comparison was repeated on consecutive days with the right/left position determined in advance and alternated on the 2nd day. Each subject was tested with all four repellent treatments in four of the eight possible combinations of diet (HE or LE) and repellent in a balanced incomplete block design. As a result, all possible treatment and diet combinations were replicated five times over the 8 d experiment (Table 3). Intake of each diet was determined by difference (pre- and post-bioassay mass).

Experiment 3: Pair-wise Repellent Comparison Following a 2 d intermission, experiment 3 consisted of two-choice tests conducted with HE-treated diets (Table 4). Each diet was treated with a single repellent, and the four different treatments were compared pair-wise such that comparisons were repeated on consecutive days, and each subject was tested with three of the six possible comparisons (Table 5). As a result, all possible pair-wise comparisons were replicated five times over the 6 d experiment. Intake of each diet was determined by difference (pre- and post-bioassay mass).

Statistical Analyses Data from each experiment were analyzed separately. Preference scores (intake of one diet divided by the sum of both diets) from two-choice tests were analyzed by mixed model analyses of variance (ANOVA), and residual plots were generated to evaluate ANOVA assumptions. Outliers (defined as having studentized residuals greater than 3 or less than −3) were removed from the data set prior to all analyses. Subject was a random effect in all models. When necessary, the null hypothesis of indifference (defined as a preference score of 0.5) was tested by using the value 0.5 minus the preference score as the response in the model.

Day, position of the HE diet (right or left), and the interaction (day*position) were fixed effects in experiment 1. Diet preference was first evaluated by examining the distribution of mean HE preference scores (2 d averages for

Table 3 Low energy (LE) and high energy (HE) diets were offered in two-choice tests in experiment 2. One choice was treated with one of the repellent ingredients as indicated in parentheses (S = Sachet; T = Thiram; B = Blood; C = Capsaicin)

E	Sachet	Blood
F	Sachet	Capsaicin

each subject) using the Shapiro-Wilk test for normality (Proc Univariate; SAS 2002). The indifference response (0.5 minus HE preference score) was then subjected to *t*-test for the null hypotheis (mean=0) using the univariate procedure. Average total intake (sum of both diets) was determined for each subject, and the mean and standard error were calculated for later comparison with total intake during experiment 2.

Treatment preference scores were calculated for experiment 2 (treated diet intake divided by total intake). When total intake was zero (neither diet consumed), the preference score was considered a missing value. Fixed effects were: "protected" diet (either HE or LE receiving treatment); treatment (repellent); protect*treatment; position of the treated diet (right or left); protect*position; treatment*position; treatment*protect*position; and day. Separate ANOVA models also were produced for each level of protected diet (HE or LE) by using treatment, position, and treatment*position as fixed effects. Multiple comparisons of means were made by controlling the false discovery rate according to the procedures of Benjamini and Hochberg (1995). For HE diet protection, one *post-hoc* comparison of treatment*position was made for right and left positioning of the food container with sachet treatment. Total intake data also were subject to ANOVA with fixed effects: "protected" diet, treatment, protect*treatment, position, protect*position, treatment*position, treatment*protect*position, and day.

Four paired *t*-tests were conducted using data from experiment 1 and LE-protected diet data from experiment 2. Mean LE preference scores were calculated for each subject in experiment 1 (equal to 1—HE preference score as previously determined). Experiment 1 means were subtracted from experiment 2 preference scores according to subject. A *t*-test was conducted for each treatment using the univariate procedure in SAS. Each subject*day occurrence was considered a replicate for that treatment. False discovery rate for multiple comparisons was controlled by using the procedures of Benjamini and Hochberg (1995).

There were six pair-wise comparisons of repellents in experiment 3 (Table 3). Preference scores were calculated using one treatment as the reference (numerator) for all instances of that comparison. The indifference response (0.5 minus preference score) was calculated and subjected to ANOVA with comparison (Table 3), position of the reference treatment (right or left), comparison*position, and day the fixed effects. The null hypothesis (indifference response=0) was evaluated by *t*-test using the false discovery rate controlling procedure (Benjamini and Hochberg 1995).

Results

Experiment 1 Mean intake of the HE diet was 221±44 g and of the LE diet was 2.2±0.8 g. The resulting preference score (0.99) indicated a strong preference for HE diet ($P<0.001$). Preference scores were normally distributed ($P=0.625$) and not subject to day ($P=0.136$), position ($P=0.344$), or day*position ($P=0.852$) effects. Mean total intake for the ten subjects was 223±44 g.

Experiment 2 Preference scores were not subject to a day effect ($P=0.154$), but all other effects were highly significant ($P<0.001$). Inspection of treatment*protect*position means indicated that LE diet was avoided regardless of treatment or position, while avoidance of HE diets varied by treatment and position. Evaluation of protected LE diets alone confirmed that avoidance was not subject to treatment ($P=0.368$), position ($P=0.238$), or treatment*position ($P=0.587$). Treatment preference scores were less than 0.007 for all treatments (Fig. 1).

Paired *t*-tests indicated that two treatments reduced preference for LE diet in experiment 2 with respect to LE diet preference in experiment 1. Differences for capsaicin

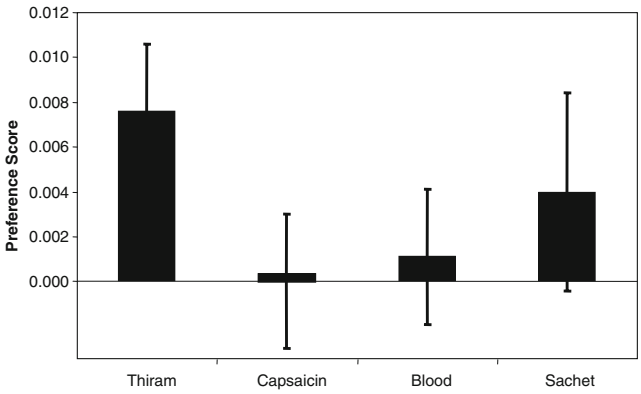

Fig. 1 LE diet preference scores (repellent-treated diet intake divided by total intake) did not differ significantly among repellent treatments (P=0.368). High energy (HE) diet was the alternative in 30 min two-choice tests. *Error bars* represent standard error

(−0.01; P=0.007) and blood (−0.009; P=0.022) reflected LE preference scores being reduced from approximately 0.01 in experiment 1 to nearly 0.0 in experiment 2 as a result of treating the LE diet with the test repellents (Fig. 2).

Conversely, avoidance of protected HE diets was subject to all fixed effects (P<0.001), including treatment*position. Thiram-treated HE diet was strongly preferred over the LE alternative, while both capsaicin and blood significantly reduced intake of the highly preferred HE diet regardless of position (Fig. 3). Interestingly, preference scores for HE diet presented on the left side with the sachet were higher than HE diet presented on the right side with the sachet (P< 0.001) while being consumed equally with the LE alternative.

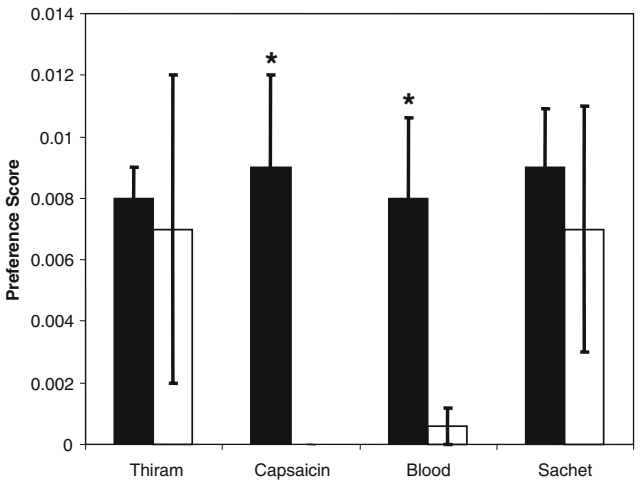

Fig. 2 Low energy (LE) preference scores (LE diet intake divided by total intake) from experiment 1 (pre-treatment intake in the absence of repellents) and experiment 2 (LE diets treated with repellent) in 30 min two-choice tests with high energy (HE) diet as the alternative. *Error bars* represent standard error. Paired *t*-tests indicated that preference scores differed significantly (*) between the experiments for capsaicin and blood (α=0.05). Legend: ■ Pretreatment (Experiment 1), □ Repellent (Experiment 2)

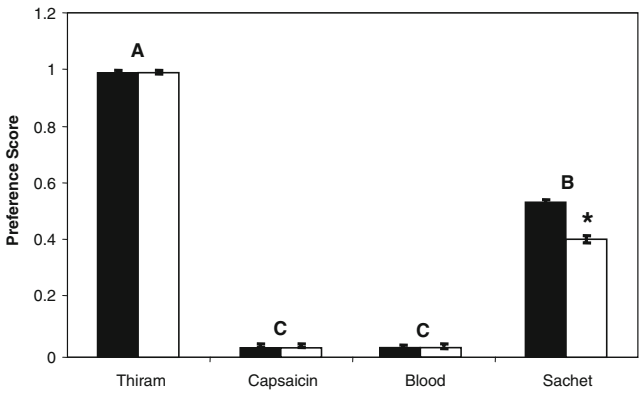

Fig. 3 Experiment 2 preference scores (repellent-treated diet intake divided by total intake) for high energy (HE) diets treated with the test repellents. Error bars represent standard error. Low energy (LE) diet was the alternative in 30 min two-choice tests. Letters indicate differences in preference scores due to repellent treatment (main effect). The asterisk indicates a position effect for one of the four treatments which led to the significant treatment*position interaction. Legend: ■ Treatment in left position, □ Treatment in right position

Total intake data was analyzed to determine if the odor of the test repellent influenced intake of both diets, not just the diet associated with the repellent. Total intake was impacted by diet protected (P=0.001), treatment (P= 0.003), and day (P=0.026). Total intake was 203±59.4 g when the LE diet was protected and 145±59.3 g when the HE was treated with repellent. This indicates that when HE diet was treated with effective repellents, subjects did not compensate for reduced HE intake with increased LE consumption. Treatment (P=0.003) and day (P=0.026) also were significant.

Among the treatments, total intake when one of the diets was treated with thiram (223±60.5 g) was not significantly different from capsaicin (189±60.5 g; Fig. 4). At the same time, total intake when blood (132±71 g), sachet (154± 60.5 g), or capsaicin treatments were applied to one of the

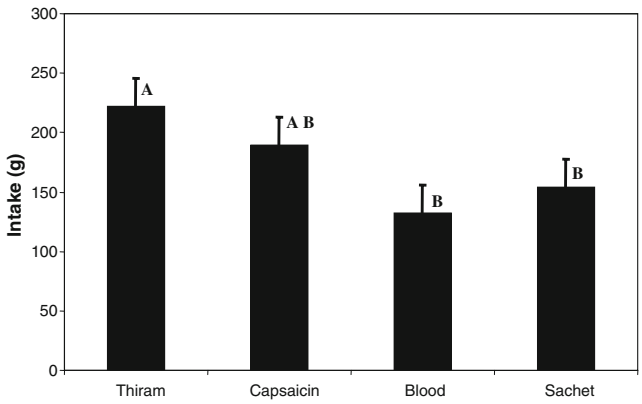

Fig. 4 Total intake data in experiment 2 of 30 min two-choice tests with either low energy (LE) or high energy (HE) diets treated with a repellent. Means marked with different letters are significantly different (α=0.05) and *error bars* represent standard error

diets were not statistically different. By comparison, total intake of HE and LE diet in the absence of a repellent (experiment 1) was 223±44 g.

Experiment 3 Treatment comparison was not subject to position (P=0.485), comparison*position (P=0.751), or day (P=0.745) effects. Further examination of the comparison effect (P<0.001) indicated that a preference for one of the repellents was evident for every two-choice comparisons except for capsaicin vs. blood (Fig. 5). Avoidance (repellency) of the treatments followed the order of greatest avoidance to least: blood = capsaicin > thiram > sachet.

Discussion

As intended, HE diet was significantly preferred by all subjects, by a factor of 99 to 1. By having a dramatic difference in preference for the two diets, subsequent experiments could be conducted in a manner that incorporated varying incentives to consume treated or alternative food items. Thus, experimental conditions modeled two extreme circumstances possible under field conditions: 1) the food source requiring protection from herbivory is highly desirable relative to the alternatives; and 2) alternative foods are more desirable than the food treated with repellents.

Deer strongly avoided repellent-treated LE diet when HE was available, regardless of repellent type (Fig. 1). Two repellent ingredients, capsaicin and blood, significantly reduced preference for the LE diet relative to untreated diets in experiment 1 (Fig. 2). Although statistically significant, the effect of capsaicin and blood avoidance was of no practical consequence, as LE preference scores were merely reduced from approximately 0.01 in the absence of repellents (experiment 1) to 0.0 when LE diets were treated with blood or capsaicin (experiment 2). When highly preferred alternatives are available, the less preferred food is easily protected.

A wider range of repellent activities were revealed when the highly desirable HE diet was treated with the repellents and the alternative was the less desirable (LE diet). In experiment 2, capsaicin and blood were extremely effective repellents when applied to the HE diet (Fig. 3). Previous studies have also shown that blood is an effective repellent (Nolte and Wagner 2000; Wagner and Nolte 2001; Kimball et al. 2008) and that avoidance of capsaicin is concentration dependent (Andelt et al. 1994). In the current study, subjects strongly avoided the HE diet treated with blood or 0.14% capsaicin despite being motivated to select the HE diet over the LE alternative.

Thiram was ineffective as a repellent. It was not unexpected for the deer to consume thiram-treated HE diet during the first two exposures to the treatment in experiment 2. In previous studies with mule deer (*Odocoileus hemionus*) and elk (*Cervus elaphus nelsoni*), Andelt et al. (1991, 1992) reported similar responses to thiram-treated foods. With both species, consumption of the thiram-treated food in cafeteria-type tests decreased daily in 4 day and 5 day experiments, as it took repeated exposures for subjects to develop an aversion to the familiar food. When familiar foods are treated with a toxin that promotes conditioned aversion, multiple exposures to the toxin-food pair are required to produce an avoidance response (Kimball and Nolte 2005). This is particularly true when the treatment does not impart a distinct cue (e.g., taste, visual, and/or odor). Unlike blood and capsaicin that discolored the diets, thiram treatment was not visually evident as the maximum absorbance of thiram

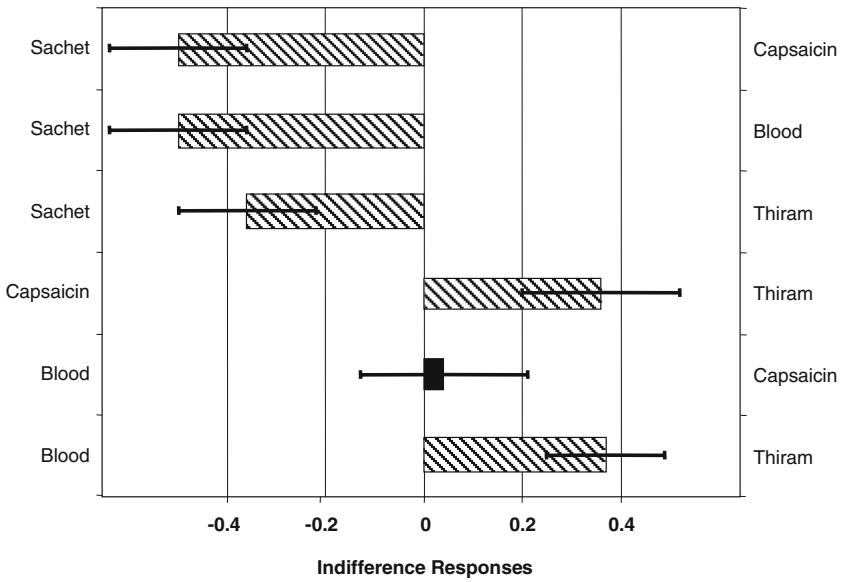

Fig. 5 Indifference responses from experiment 3 (with standard error bars). Indifference is indicated as a score of zero and determined by subtracting the preference score (intake of one choice divided by total intake) from the value of 0.5. Diagonal pattern indicates an indifference score significantly different from zero (α=0.05). The direction of the bar (positive or negative) indicates which of the two choices (right and left axes) was preferred in 30 min two-choice tests

(200–300 nm) is in the ultraviolet region (Talrose et al. 2009). Similar to many mammals, deer lack visual capability at ultraviolet wavelengths (Jacobs et al. 1994). Thiram is anecdotally reported to impart a bitter taste, but bitter taste is not a relevant cue to herbivores that forage in an environment replete with bitter plant stimuli (Nolte et al. 1994b).

The sachet was only moderately effective as a feeding deterrent in experiment 2 (Fig. 3). Several subjects were apprehensive about the sachet and limited consumption of diets placed in food bowls with attached sachets. However, there was tremendous variation among the subjects in response to the sachet treatment associated with HE diet. One subject ignored the sachet and readily consumed HE diet; one ate both diets; a few avoided the HE diet and consumed only LE diet; while others did not consume either diet. It was not evident why position (right or left presentation) of the sachet influenced repellency while position was not significant for the other repellents (Fig. 3). Odor may serve as a cue that can be associated with the palatability of foods via learning processes (Provenza 1995a). Learning about the odor of foods permits avoidance (or preference) at future encounters with that food on the basis of odor alone.

It is possible that the sachet was not the only treatment that served as a vapor repellent. Because volatiles were present throughout the test area (treatment odors were not confined to the treated diet), vapor repellents could be expected to influence intake of both diet choices. To test the effects of the treatments on intake of both choices, total intake data were analyzed for treatment and diet effects. Total intake data from experiment 2 suggests that non-volatile thiram had less influence on feeding from both food bowls than the more odiferous blood or sachet treatments (Fig. 4). Volatile components of blood treatment influenced not only intake of the treated diet, but also the alternative choice. Protein hydrolysis and lipid oxidation of animal-based stimuli (such as blood) produce volatile odors such as sulfides, aldehydes, and organic acids (Kamiya and Ose 1984). Sulfurous volatiles have been implicated in repellency of predator urine and egg (Nolte et al. 1994a; Lewison et al. 1995).

Volatile odors also may confer information regarding the surroundings. As such, certain odors such as blood, egg, meat, and bone meal have been thought to indicate danger from predators and have been called "fear" repellents (Nolte and Wagner 2000). However, behaviors such as approaches or head entries into feeders were unaffected by predator-based repellents (Pfister et al. 1990), and these repellents failed to exclude herbivores from treated locations as would be anticipated if predation were a consequence of foraging near the odor source (Belant et al. 1998; Nolte and Wagner 2000). Predator odors may provide cues regarding predator density and influence decisions about where and when to forage, but do not influence intake during a feeding bout once the decision to forage has been made (Chabot et al. 1996).

Extinction (cessation of avoidance behavior) among repellents that do not produce pain or malaise is likely to occur when the treated food is highly desirable. When the basal ration was restricted, deer and elk increased daily consumption of food treated with egg product (Andelt et al. 1991, 1992). In a winter field study conducted when alternative foods were scarce, plants treated with an egg-based repellent and netting were not protected (Milunas et al. 1994). At the same time, reappearance of alternative food sources can result in recurrence of the avoidance behavior. In a previous study, addition of casein to a ground diet reduced its intake relative to the unadulterated diet (Kimball et al. 2005). When the casein diet was offered subsequently to deer in a single-choice experiment, avoidance was not observed. Yet, after readily consuming the casein diet for 8 days, significant avoidance of casein-treated diet was evident when offered again in the presence of the unadulterated diet. Therefore, the mechanism by which repellency is achieved with animal-based products is not neophobia.

Avoidance of blood and other animal-derived substances may be the result of an "evolutionary memory" (Provenza 1995b) that conveys information about potential sources of pathogens. Just as a wide variety of toxins have been associated with bitter taste to humans (Bachmanov and Beauchamp 2007), compounds indicative of pathogenic activity (e.g., certain proteins or peptides) may be distinctly identified by herbivores. Importantly, the food item must be "contaminated" with these compounds in order to affect intake. Animal products employed as vapor repellents may alert foraging herbivores about the potential of contamination, and reduce their intake until habituation occurs (e.g., sachet). However, significant repellent efficacy is achieved when the animal product is in contact with the food and the herbivore avoids the treated food thus avoiding potential pathogens (e.g., blood).

In contrast to experiment 2, fewer subjects avoided the sachet in experiment 3; while avoidance of thiram treated HE diet was more evident (Fig. 5). Although not specifically tested in this study, experience with the sachet during experiment 2 may have contributed to habituation to the odors. Similarly, experience with thiram-treated diets also may have facilitated learning about the postingestive effects of thiram. Animals can learn that novel cues are associated with positive consequences (or have no associated consequences) as well as they can learn about negative consequences (Provenza 1995b). These data suggest that learning was not a necessary component of blood and capsaicin avoidance. When highly desirable diets were treated with blood or capsaicin (experiment 2), as well as

in head-to-head comparisons (experiment 3), the flavor modification (blood) and irritation (capsaicin) mechanisms continued to demonstrate significant repellency (Fig. 5).

In field applications, existence of alternative forage options is not always evident. It may not be feasible to compare nutritional quality of the agriculture resource in need of protection with forage alternatives. However, it is clear that when valuable resources are at risk, effective tools are needed to minimize losses due to herbivory. The results of our study suggest that repellents that rely only on neophobia as the mode of action may be effective in field applications only when foraging options are plentiful. Furthermore, repellents that rely on conditioned aversion may not be useful. The deer in this study did not reduce intake upon initial offering of thiram-treated diets. Thiram may be an impractical repellent if numerous exposures are required to condition an aversion. Conversely, repellents with immediate consequences to the consumer (i.e., irritation and flavor modification) can be effective repellents, even when the treated resource is highly desirable in comparison to other foraging options.

Acknowledgments Mention of specific products does not constitute endorsement by the United States Department of Agriculture. The authors are particularly grateful for the helpful review comments of two anonymous reviewers and Drs. Gary Beauchamp and Marci Pelchat on earlier versions of the manuscript.

Allelochemicals can induce a wave of ROS and a Ca^{2+} signaling cascade, with subsequent genome-wide changes in gene expression and root death in plants (Bais et al. 2003; Ding et al. 2007). Some factors involved in the signaling transduction pathway have been characterized (Baerson et al. 2005; Golisz et al. 2008). All physiological, biochemical, and transcriptional changes are implicated directly or indirectly in plant growth inhibition.

We are interested in phytotoxic phenomena in cucurbit plants, which exhibit great genetic variation in autotoxic potential (Yu et al. 2000). Similar to root exudates of asparagus and other plants, benzoic and cinnamic acids are found in root exudates of cucumber (Young 1984; Yu and Matsui 1994; Wu et al. 2000). They produce detrimental effects on ion uptake, and enhance the incidence of Fusarium wilt by causing oxidative stress in roots (Yu and Matsui 1994, 1997; Ye et al. 2004, 2006). Interestingly, root exudates of both cucumber and watermelon show high autotoxicity, but not toxicity to other species such as figleaf gourd (Yu et al. 2000, 2003). As *trans*-Cinnamic acid (CA) is a principal compound in root exudates and plant extracts of cucumber and other species, it often has been studied (Yu and Matsui 1994, 1997; Chon et al. 2003; Fujita and Kubo 2003; Ye et al. 2004, 2006; Blum 2005; Hiradate et al. 2005). *cis*-Cinnamic acid has been found in *Brassica parachinensis* and *Arabidopsis thaliana*, but the biosynthesis is not well understood (Yin et al. 2003; Wong et al. 2005). We have demonstrated that exposure to *trans*-CA significantly increases ROS generation and accumulation in cucumber roots but has minimal effect on ROS metabolism in figleaf gourd (Ding et al. 2007). Here, we investigated whether the different growth responses to *trans*-CA in cucumber and figleaf gourd are associated with a difference in uptake. We examined further whether Ca^{2+} signaling was involved in the interspecies recognition.

Methods and Materials

Plant Material and Growth Bioassay Cucumber (*Cucumis sativus* L. cv Jinyan No.4) and figleaf gourd (*Cucurbita ficifolia* Bouché) seeds were surface-sterilized in 1% (v/v) NaOCl for 5 min, rinsed thoroughly with deionized H_2O, and germinated on filter paper saturated with 0.5 mM $CaSO_4$ at 28°C for 6 d in the dark. Germinated seeds were exposed to light for 10 h and subsequently transferred to Enshi nutrient solution at pH 6.5 and electrical conductivity at 1.2 ms cm^{-1} (Yu and Matsui 1994). Then, they were maintained at a relative humidity of 95–100%, a photosynthetic photon flux density (PPFD) of 500 μmol m^{-2} s^{-1}, and a temperature of 25–30°C for 8 d.

Each of the 15-d-old seedlings then was incubated in 25 ml Enshi nutrient solutions in beakers containing 0 mM, 0.05 mM, 0.10 mM, or 0.25 mM *trans*-cinnamic acid (CA). The beakers were wrapped with aluminium foil to prevent the isomerization between *trans*- and *cis*-CA. *trans*-CA was dissolved in EtOH, and the final concentration of EtOH in each solution including the control was 0.1% (v/v), at which concentration EtOH has a negligible effect on cucumber plants (Yu and Matsui 1997).

Each treatment had eight plants and was done in triplicate. Five days later, plants were harvested, oven dried at 80°C for 3 d, and weighed. Relative growth inhibition (RGI) was calculated by $[(W_t-W_0)/W_0]/100$. W_t and W_0 were dry weights for seedlings after exposure to the *trans*-CA treatments and unexposed controls, respectively.

In Vivo trans-Cinnamic Acid Uptake by Roots Roots of 20-d-old seedlings of both species were excised and placed into an aerated medium consisting of 25 mM MES, 25 mM Tris, 0.5 mM KCl, 0.25 mM $CaSO_4$, and 0.1% sodium ascorbate with or without 0.25 mM *trans*-CA (Schulz et al. 1993). The uptake of *trans*-CA was determined indirectly by its decrease in the incubation solution. Free *trans*-CA in the incubation solution and in the roots were extracted as described by Schulz et al. (1993) and determined by HPLC (Shimadzu LC-10AT, Japan) using a C_{18} column with UV detection at 280 nm and a flow rate of 1.0 ml min^{-1}.

Gene Transcription and Metabolite Analysis To determine changes in the transcript of cinnamate 4-hydroxylase (C4H), a gene that encodes the enzyme that catalyzes the biosynthesis of *p*-coumaric acid from *trans*-CA, the roots of cucumber plants were sampled at 0 h, 4 h, 8 h, 12 h, and 24 h after inoculation. Total RNA was extracted with Trizol (Sangon, China) and reverse-transcribed with olig (dT) using reverse transcriptase (Invitrogen, Carlsbad, CA, USA). Specific primers for quantitative real time PCR (qRT-PCR) were designed in function of its conserved sequences: forward primer 5′-CTCACATGAACCTCCACGAC-3′ and reverse primer 5′-CCTCTTCCAAGAACCTCTCG-3′. qRT-PCR was performed using the iCycler iQTM Real-time PCR Detection System (Bio-Rad, Hercules, CA, USA). The PCR conditions consisted of denaturation at 95°C for 3 min, followed by 40 cycles of denaturation at 95°C for 30 s, annealing at 58°C for 30 s, and extension at 72°C for 30 s. A dissociation curve was generated at the end of each PCR cycle to verify that a single product was amplified by using software provided with the Real-time PCR Detection System. Identity of the PCR products was verified by single strand sequencing using MegaBACE 1000 DNA analysis system (Amersham Biosciences, USA).

Four glycosidases (all purchased from Sigma, USA) were tested for enzymatic cleavage of the metabolites. These glycosidases include a glucosidase (from *Aspergillus niger*), an α-glucosidase (from *Saccharomyces cerevisiae*),

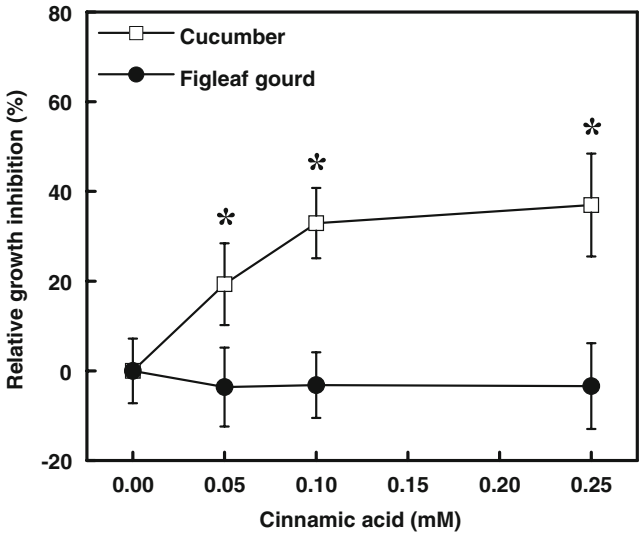

Fig. 1 Effects of *trans*-cinnamic acid (CA) (1) on root growth of cucumber (*open squares*) and figleaf gourd (*solid circles*) plants. Samples were taken 3 d after treatment. Each treatment involved eight plants and was done in triplicate. Data are represented as the means of three independent replicates with standard error bars. *Asterisks* indicate a significant difference between the untreated control and the *trans*-CA treatment within the species by Student *t*-test ($P \leq 0.05$)

a β-glucosidase (from almonds), and an esterase (from rabbit liver). The assays were carried out as described by Schulz et al. (1993). Reaction mixtures were analyzed for the decreases of the metabolite peaks and the presence of *trans*-CA, *p*-coumaric acid and ferulic acid by HPLC.

Fixation and Transmission Electron Microscopy of Roots After exposure to 0.25 mM *trans*-CA for 10 h, the 5-d-old seedling roots were fixed in 3% glutaraldehyde, 2% potassium pyroantimonate, and 75 mM potassium phosphate (pH 7.8) at 4°C for 4 h, and washed four to five times in 75 mM potassium phosphate and 2% potassium pyroantimonate (pH 7.8) every 30 min. Samples subsequently were fixed in 1% OsO_4 containing 2% potassium pyroantimonate and 75 mM potassium phosphate (pH 7.8) for 12–16 h at 4°C, rinsed in 60 mM potassium phosphate buffer four to five times (30 min each time), dehydrated in a graded EtOH series, and embedded in Epon 812 resin (Qin et al. 2005). Ultrathin sections were obtained using a Sorvall MT-6000 ultramicrotome (Wilmington, Germany), stained with 2% uranyl acetate for 15 min, and observed under a JEM-1200 EX transmission electron microscope (TEM Hitachi, Japan).

Loading of Fluo-3/acetoxymethyl Ester into Root Cells and Confocal Laser Scanning Microscopy A Zeiss Axioskop 2 epifluorescence LSM 510 confocal microscope (Carl Zeiss Mikroskopie, Jena, Germany) was used to determine $[Ca^{2+}]_{cyt}$ levels. Intact roots (1 cm to 2 cm long) of 7-d-old seedlings of both species were incubated in a solution containing 17 μM fluo-3/acetoxymethyl ester, 50 mM sorbitol, and 0.2 mM $CaCl_2$ at 4°C for 0.5 h in the dark. The dye-loaded roots were incubated in an aerated 0.2 mM $CaCl_2$ solution with or without 0.25 mM *trans*-CA at 25°C for 0.5 h in the dark (Zhang et al. 1998). Intact roots were mounted in a Plexiglas chamber (2 ml) with a clean cover slip attached to the bottom, and flushed with a control solution for about 10 min prior to confocal imaging with a Zeiss Axioskop 2 epifluorescence LSM 510 confocal microscope fitted with a Spot CCD camera (Diagnostic Instruments,

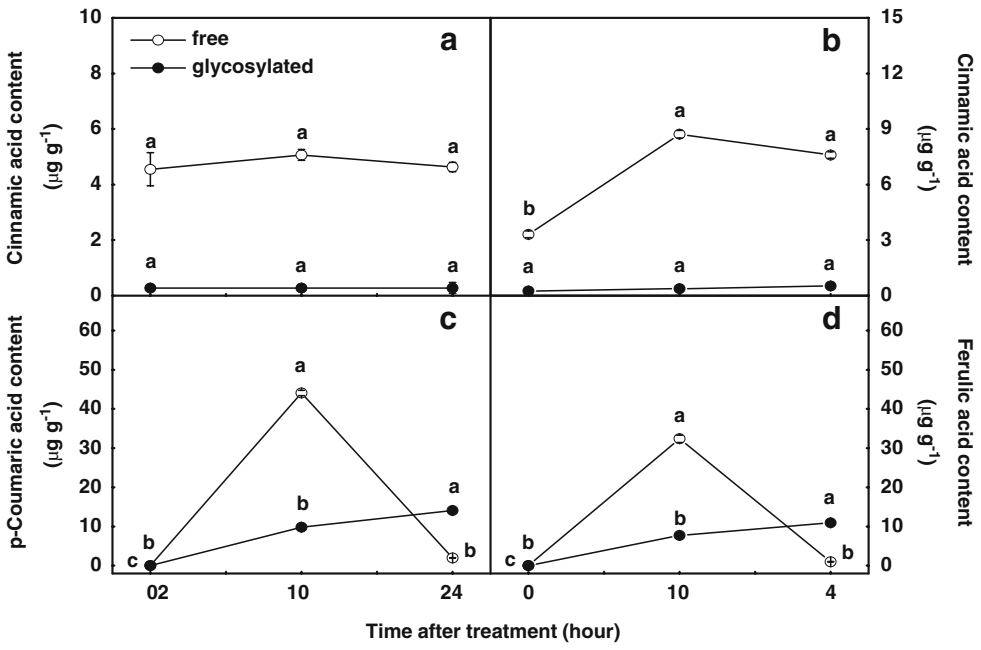

Fig. 2 Changes in free *trans*-cinnamic acids (*open circle*, CA) and glycosylated cinnamic acids (*solid circle*) concentrations in cucumber and figleaf gourd roots after exposure to 0.25 mM *trans*-CA. Sterling Heights, MI, USA) with 488 nm excitation and 515 nm emission. The same apical cells of six to eight roots of each treatment were scanned consecutively every 5 min for up to 30 min. The intensity of green fluorescence was analyzed by LSM 5 image software.

Observation of Cell Viability Viability of root tips was determined by staining with fluorescein diacetate (FDA), as described by Ishikawa and Wagatsuma (1998). In brief, roots were stained with FDA (12.5 μg ml^{-1}) for 10 min, then observed under a fluorescent microscope with light excitation (488 nm), and photographed (Leica DMLB). The same apical cells of six to eight roots of each treatment were scanned consecutively every 5 min for up to 30 min.

Results and Discussion

Selective Growth Inhibition The inhibitory effect of *trans*-cinnamic acid (CA) (Fig. 1) on plant growth was specific and concentration-dependent. Exposure to 0.05 mM *trans*-CA resulted in a significant inhibition of cucumber root growth. At a concentration of 0.25 mM, *trans*-CA inhibited root growth by 36.97%. In contrast, it had little effect on figleaf gourd growth, even at the highest concentration. This result supported earlier findings that *trans*-CA inhibited plant growth of cucumber but not figleaf gourd (Yu et al. 2000; Ding et al. 2007). Although the role of *trans*-CA under field conditions remains to be determined, it has been found in root exudates or root residues from several plants that exhibit high phytotoxicity to seed germination and seedling growth (Young 1984; Yu and Matsui 1994; Wu et al. 2000; Hiradate et al. 2005; Wong et al. 2005). *cis*-CA has been found in several plant species, and it exhibits much more phytotoxicity than *trans*-CA (Yin et al. 2003; Hiradate et al. 2005;Wong et al. 2005). Importantly, *trans*-CA is easily isomerized into *cis*-CA in the presence of sunlight or UV light (Wong et al. 2005). In this study, light was completely kept from the incubation solution, and isomerization between CA isomers could not occur in the incubation solution or the roots. Accordingly, the phytotoxicity to cucumber roots could be attributed to the direct effects of *trans*-CA.

Reasons for selective inhibition of plant growth remain elusive, although autointoxication has been suggested as a protective mechanism that prevents future conspecific competition for both annual and perennial plants (Singh et al. 1999; Canals et al. 2005). It seems probable that all known mechanisms of transport of substances through cell membranes participate in the translocation into root space, and from there, into the environment.

trans-Cinnamic Acid Uptake and Associated Metabolism To determine whether the different growth responses are associated with a difference in *trans*-CA uptake, changes

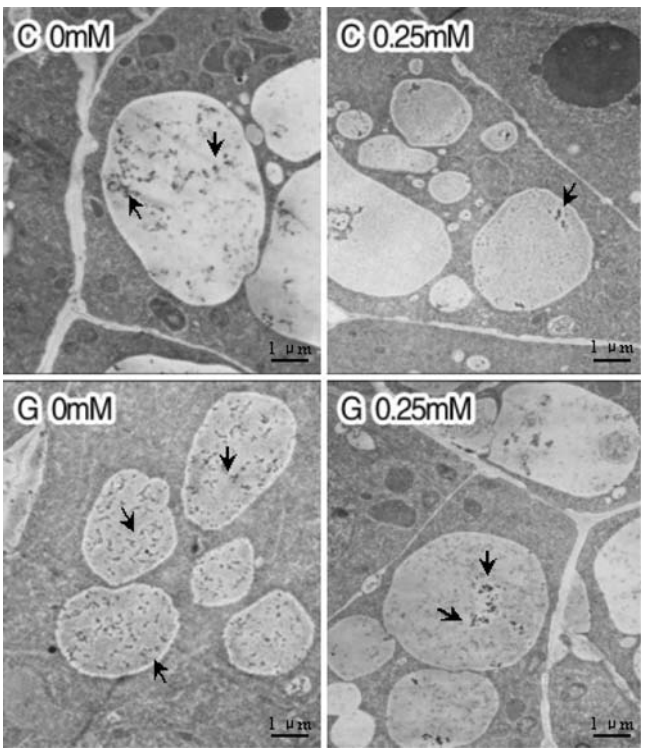

Fig. 4 Localization of calcium in root cells of cucumber and figleaf gourd exposed to 0.25 mM *trans*-cinnamic acid (CA). C 0 mM, cucumber control roots; C 0.25 mM, cucumber roots exposed to 0.25 mM *trans*-CA for 3 h; G 0 mM, figleaf gourd control roots; G 0.25 mM, figleaf gourd roots exposed to 0.25 mM *trans*-CA for 3 h. Photos were taken at ×6000 magnification. *Arrows* show calcium precipitates by dye

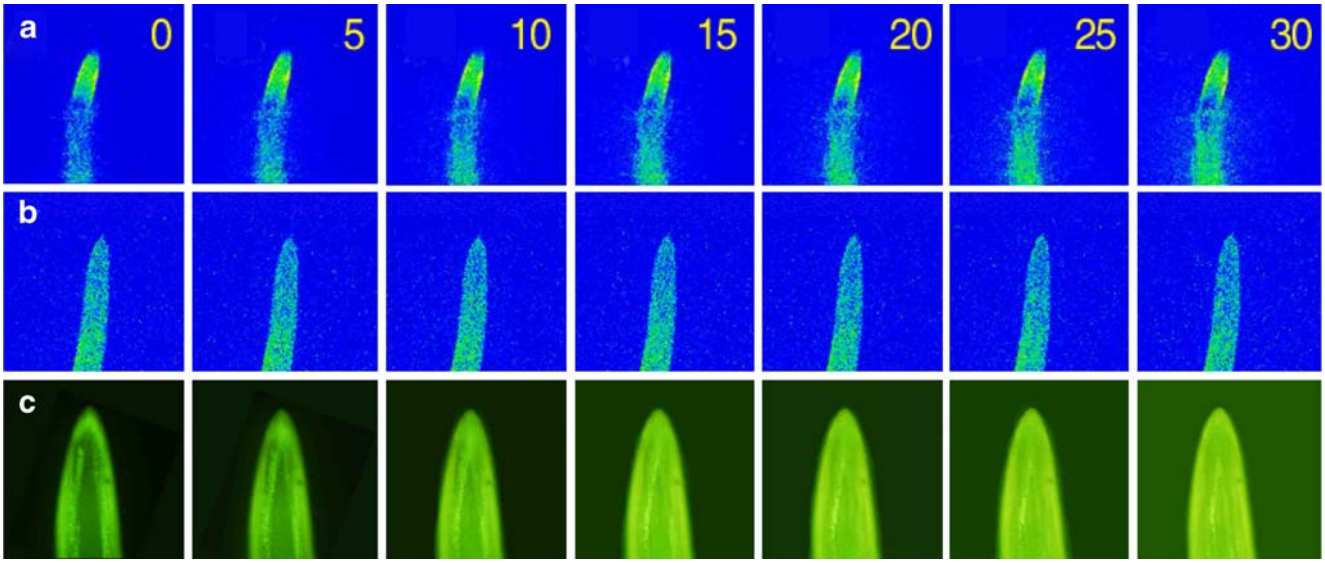

Fig. 5 Changes in $[Ca^{2+}]_{cyt}$ level and cell viability for roots of cucumber and figleaf gourd after exposure to 0.25 mM *trans*-cinnamic acid (CA). A), $[Ca^{2+}]_{cyt}$ level in cucumber roots; B), $[Ca^{2+}]_{cyt}$ level in figleaf gourd roots; C), cell viability of cucumber roots. Figures represent minutes after the *trans*-CA treatment. Photos were taken at ×5 magnification for Fig. 5a, b and ×10 magnification for 5c. Note: (1) Green fluorescence intensity increases indicate increased $[Ca^{2+}]_{cyt}$ level in Fig. 5a, b; (2) *Green color* indicates live cells while *yellow colour* indicates dying cells in Fig. 5c. High green fluorescence indicates high cell viability, while decreased fluorescence indicates leakage of dye from dead cells

in *trans*-CA concentrations in the incubation solution and in roots of these two species were determined. *trans*-CA concentrations remained 0.25 mM in the incubation solution with figleaf gourd roots, while it decreased from 0.25 mM to 0.05 mM in the cucumber root solution after 24 h incubation (data not shown). Thus, ca.73.2% of *trans*-CA in the solution was taken up by cucumber roots but little by figleaf gourd roots. Consistent with this, no significant change in free *trans*-CA concentration was found in roots of figleaf gourd (Fig. 2a). In comparison, free *trans*-CA in cucumber roots increased from 3.2 μg g^{-1} to 8.72 μg g^{-1} and to 7.59 μg g^{-1} at 10 h and 24 h after incubation, respectively (Fig. 2b). Similarly, significant increases in free *p*-coumaric and ferulic acid concentrations were observed at 10 h, but not at 24 h (Fig. 2c, d). In addition to free CAs, conjugated CAs also exist (Funk and Brodelius 1990). Of the four glucosidases and esterase tested, only β-glucosidase from almonds released the conjugated CAs, thus leading to increased amounts of free CAs, and suggesting that glycosylated CAs were present as metabolites after exposure to *trans*-CA, as found by Schulz et al. (1993). However, glycosylated *trans*-CA concentration was very low, and little increase was observed in *trans*-CA-incubated cucumber and figleaf gourd roots. In comparison, there were significant increases in the concentrations of glycosylated *p*-coumaric and ferulic acids in *trans*-CA-incubated cucumber roots (Fig. 2).

These findings are in agreement with results obtained in *Vanilla planifolia*, in which *trans*-CA glucosyltransferase preferentially accepts *p*-coumaric and ferulic acid as substrates, while *trans*-CA is a poorer substrate (Funk and Brodelius 1990). Modified phytochemicals such as glycosylated conjugates through the activity of glycosyltransferases are commonly deposited in vacuoles (Schulz and Friebe 1999). Furthermore, exposure of cucumber roots to *trans*-CA significantly increased transcripts of *C4H* (cinnamate 4-hydroxylase), a gene encoding the enzyme that

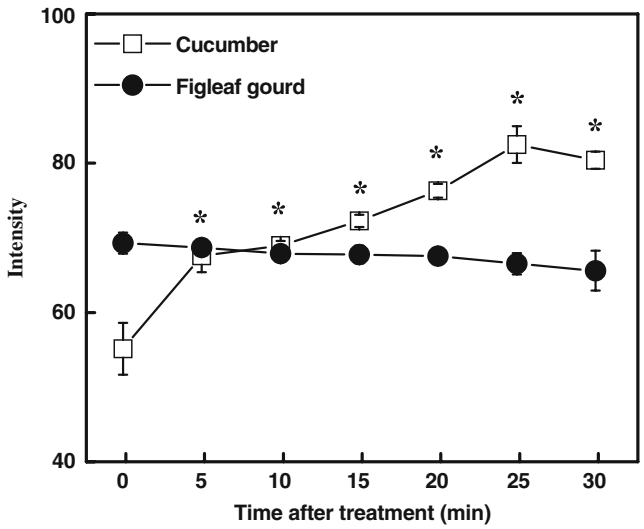

Fig. 6 Changes in $[Ca^{2+}]_{cyt}$ intensity in the cells of cucumber (*open square*) and figleaf gourd (*closed circle*) roots after exposure to 0.25 mM *trans*-cinnamic acid (CA) (photos shown in Fig. 5a and b). Data are the means of three experiments with standard error bars. *Asterisks* indicate a significant difference between the untreated control and the *trans*-CA treatment over time within the species by Student *t*-test ($P \leq 0.05$)

catalyzes the biosynthesis of *p*-coumaric acid from *trans*-CA (Fig. 3). Accordingly, selective *trans*-CA uptake appears to be the mechanism responsible for the differences in growth response of the two species, and the conversion to other CAs associated with glycosylation might be an important detoxification mechanism for *trans*-CA in cucumber.

Ca^{2+} Release and Cell Viability Calcium plays a crucial role in plant growth and development, e.g., acting as a second messenger in signal transduction (Hetherington and Brownlee 2004; Lecourieux et al. 2006). It is present in three forms: bound, free, or stored, and is distributed in the apoplasm, the cytoplasm, and intracellular organelles (endoplasmic reticulum and vacuoles). Transient spatial and temporal changes in calcium pools and cytoplasmic Ca^{2+} concentration ($[Ca^{2+}]_{cyt}$) are initial responses to external stimulation, which may trigger a physiological and developmental cascade (Knight 2000; Lecourieux et al. 2006). Transmission electron microscopy analysis demonstrated that calcium precipitates were distributed primarily in vacuoles of cucumber and figleaf gourd root cells (Fig. 4). These precipitates disappeared after treatment with EGTA (data not shown), suggesting that they were calcium antimonite deposits. Intriguingly, vacuole calcium precipitates were decreased greatly in cucumber root cells after *trans*-CA treatment, while almost no effect was observed in figleaf gourd root cells. This indicates that the vacuole-stored calcium was released in cucumber root cells upon exposure to *trans*-CA.

A pivotal role for cytosolic free Ca^{2+} ions revolves around its action as a second messenger in the transduction of hormonal and environmental signals (Lecourieux et al. 2006). Salinity, drought, oxidative stress, and osmotic shock all induce an increase in $[Ca^{2+}]_{cyt}$ resulting from both extracellular Ca^{2+} influx and intracellular Ca^{2+} release (Knight et al. 1997; Pandey et al. 2000). To determine whether Ca^{2+} fluctuation in the vacuole is associated with a difference in cytoplasmic Ca^{2+} concentration, the $[Ca^{2+}]_{cyt}$ was imaged after roots were loaded with fluo-3/acetoxymethyl aster, a fluorescent Ca^{2+}-sensitive probe (Fig. 5a and b). After *trans*-CA treatment for 30 min, the fluorescence intensity of $[Ca^{2+}]_{cyt}$ dye was increased by 45.84% in cucumber (Fig. 6). By contrast, the root $[Ca^{2+}]_{cyt}$ level was unchanged in figleaf gourd. A significant $[Ca^{2+}]_{cyt}$ change was found in the elongation zone at the cucumber root tip. Moreover, *trans*-CA treatment induced a gradual reduction of green fluorescence in cucumber root-top cells, suggesting that these cells were losing viability during exposure to *trans*-CA treatment (Fig. 5c).

The transient $[Ca^{2+}]_{cyt}$ elevation in cucumber suggested that Ca^{2+} signaling was involved in the phytotoxic response in susceptible species. Our data are consistent with an earlier observation in which an aluminium (Al)-induced $[Ca^{2+}]_{cyt}$ increase was greater in an Al-sensitive wheat line than in an Al-tolerant line, and increases in $[Ca^{2+}]_{cyt}$ were correlated with root growth inhibition (Zhang and Rengel 1999). Disturbance of cytoplasmic Ca^{2+} homeostasis and subsequent breakdown of Ca^{2+}-mediated signal transduction have been suggested as a primary mechanism for Al rhizotoxicity in plants (Zhang and Rengel 1999). There could be, however, various mechanisms that would come into play in post Ca^{2+} release in the cytosol. One likely probability would be a change in cytosolic pH (Bais et al. 2003). Accordingly, further work is necessary on the relationship between *trans*-CA-induced loss of Ca^{2+}-homeostasis and impaired root growth before we can conclude the role of Ca^{2+}-mediated signaling in phytotoxicity.

In summary, we demonstrated that selective *trans*-CA uptake in cucumber roots induced an intracellular release of Ca^{2+} from vacuoles to cytoplasm, leading to a $[Ca^{2+}]_{cyt}$ increase in cucumber roots. The $[Ca^{2+}]_{cyt}$ increases in root apical cells corresponded well with the inhibition of root growth. Taken together, our results suggest that disturbance of $[Ca^{2+}]_{cyt}$ homeostasis often might be involved in the signaling response to allelochmicals.

Acknowledgements We are grateful for the assistance of Dr. Hong J and Dr. Chen J in confocal and transmission electron microscopy. We also thank Dr. Margot P and Dr. Ye H for critical reading of the manuscript.
